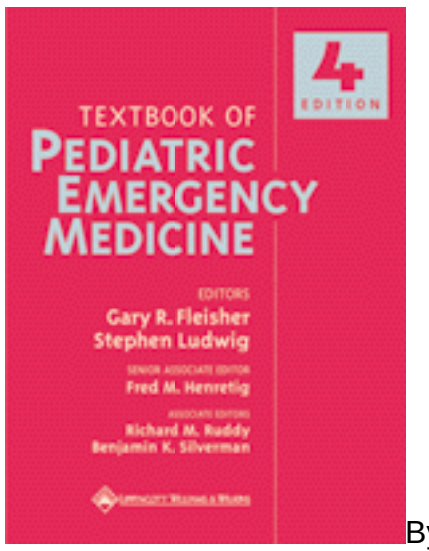
Textbook of Pediatric Emergency Medicine 4th edition (January 15, 2000): by Gary R. Fleisher (Editor), Stephen Ludwig (Editor), Silverman, Fred M. Henretig By Lippincott, Williams & Wilkins



By OkDoKeY

Textbook of Pediatric Emergency Medicine

Contents

Section III. Medical Emergencies
Gary R. Fleisher, MD, Section Editor

Section IV. Trauma
Gary R. Fleisher, MD, Section Editor

Section V. Surgical Emergencies
Stephen Ludwig, MD, Section Editor

Section VI. Psychosocial Emergencies
Stephen Ludwig, MD, Section Editor

Section VII. Procedures
Richard M. Ruddy, MD, Section Editor

Appendices

Benjamin K. Silverman, MD, Section Editor

Contributing Authors

Evaline A. Alessandrini, MD
Assistant Professor
Departments of Pediatrics, Emergency Medicine, and Epidemiology
The University of Pennsylvania School of Medicine;
Attending Physician
Division of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Elizabeth R. Alpern, MD
Assistant Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Attending Physician
Department of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Angela C. Anderson, MD
Assistant Professor
Department of Pediatrics
Brown University School of Medicine;
Attending Physician
Department of Pediatric Emergency Medicine
Rhode Island Hospital
Providence, Rhode Island

Amy M. Arnett, MD
Assistant Professor
Department of Pediatrics
Boston University School of Medicine;
Attending Physician
Department of Pediatric Emergency Medicine
Boston Medical Center
Boston, Massachusetts

Magdy Attia, MD
Clinical Assistant Professor
Department of Pediatrics
Jefferson Medical College
Philadelphia, Pennsylvania;
Director, PEM Fellowship Program
Division of Emergency Medicine
Alfred I. duPont Hospital for Children
Wilmington, Delaware

Jeffrey R. Avner, MD
Associate Professor
Department of Pediatrics
Albert Einstein College of Medicine; and
Director, Pediatric Emergency Service
Montefiore Medical Center
Bronx, New York

David Bachman, MD
Associate Professor
Department of Pediatrics
University of Vermont School of Medicine
Burlington, Vermont;
Director, Pediatric and Adult Emergency Services
Portland, Maine

Richard Bachur, MD
Instructor
Department of Medicine
Harvard Medical School;
Attending Physician
Division of Emergency Medicine
Children's Hospital

Boston, Massachusetts

M. Douglas Baker, MD
Professor
Department of Pediatrics
Yale University School of Medicine;
Chief
Department of Pediatric Emergency Medicine
Yale–New Haven Children's Hospital
New Haven, Connecticut

Jill M. Baren, MD
Assistant Professor
Departments of Emergency Medicine and Pediatrics
The University of Pennsylvania School of Medicine;
Attending Physician
Division of Emergency Medicine
Hospital of the University of Pennsylvania and The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Scott P. Bartlett, MD
Associate Professor
Department of Surgery (Plastic)
The University of Pennsylvania School of Medicine;
Attending Physician
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Marc N. Baskin, MD
Instructor
Department of Pediatrics
Harvard Medical School;
Attending Physician
Department of Pediatric Emergency Medicine;
Service Chief, Short Stay Unit
Children's Hospital
Boston, Massachusetts

Carl R. Baum, MD
Assistant Professor
Department of Pediatrics
Northwestern University Medical School;
Attending Physician
Division of Emergency Medicine/Toxicology Service
Children's Memorial Hospital;
Attending Physician
Division of Occupational and Environmental Medicine
Toxikon Consortium
Cook County Hospital
Chicago, Illinois

Louis M. Bell, MD
Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Attending Physician
Section of Infectious Diseases
Division of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Robert G. Bolte, MD
Professor
Department of Pediatrics
University of Utah School of Medicine;
Director, Emergency Services
Primary Children's Medical Center
Salt Lake City, Utah

Alison St. Germaine Brent, MD
Clinical Assistant Professor
Department of Pediatrics
University of South Florida College of Medicine;
Medical Director
Division of Emergency Medicine
All Children's Hospital

St. Petersburg, Florida

James M. Callahan, MD
Assistant Professor
Departments of Emergency Medicine and Pediatrics
SUNY Health Science Center at Syracuse;
Attending Physician
University Hospital
Syracuse, New York

Douglas W. Carlson, MD
Assistant Professor
Department of Pediatrics
Washington University School of Medicine;
Director, Pediatric Emergency Medicine
Missouri Baptist Medical Center
St. Louis, Missouri

Vincent W. Chiang, MD
Instructor
Department of Pediatrics
Harvard Medical School;
Attending Physician
Division of Emergency Medicine
Children's Hospital
Boston, Massachusetts

Lydia Ciarallo, MD
Assistant Professor
Department of Pediatrics
Brown University School of Medicine
Providence, Rhode Island

Theodore J. Cieslak, MD
Assistant Professor
Department of Pediatrics
Uniformed Services University of the Health Sciences
Bethesda;
Operational Medicine Division
US Army Medical Research Institute of Infectious Diseases
Fort Detrick, Maryland

Alan R. Cohen, MD
Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Chief, Division of Hematology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Howard M. Corneli, MD
Associate Professor
Department of Pediatrics
University of Utah School of Medicine;
Emergency Physician
Primary Children's Medical Center
Salt Lake City, Utah

Kate Cronan, MD
Clinical Assistant Professor
Department of Pediatrics
Thomas Jefferson University
Philadelphia, Pennsylvania;
Chief, Department of Pediatrics
A. I. duPont Hospital for Children
Wilmington, Delaware

Monica H. Darby, BS
Pharmacist
Department of Pharmacy
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Holly W. Davis, MD
Associate Professor

Department of Pediatrics
University of Pittsburgh School of Medicine;
Director
Division of Pediatric Emergency Medicine
Children's Hospital of Pittsburgh
Pittsburgh, Pennsylvania

Joanne M. Decker, MD
Clinical Assistant Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Attending Physician
Division of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Carlos A. Delgado, MD
Assistant Professor
Department of Pediatrics
Emory University School of Medicine;
Associate Fellowship Director and Attending Physician
Division of Pediatric Emergency Medicine
Egleston Children's Hospital
Atlanta, Georgia

Gregg A. DiGiulio, MD
Associate Professor
Department of Pediatrics
University of Cincinnati College of Medicine;
Associate Director
Division of Emergency Medicine
Children's Hospital Medical Center
Cincinnati, Ohio

David E. Drum, MD, PhD
Associate Professor
Department of Radiology
Harvard Medical School;
Staff Physician
Nuclear Medicine Service
West Roxbury Veterans Administration Medical Center
West Roxbury, Massachusetts

Dennis R. Durbin, MD, MSCE
Assistant Professor
Departments of Pediatrics and Epidemiology
Division of Emergency Medicine
The University of Pennsylvania School of Medicine;
Attending Physician
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Edward M. Eitzen Jr, MD, MPH
Associate Professor
Departments of Pediatrics and Emergency Medicine
Uniformed Services University of Health Sciences
Bethesda;
Chief, Operational Medicine Division
US Army Medical Research Institute of Infectious Diseases
Fort Detrick, Maryland

Karan McBride Emerick, MD
Clinical Instructor
Department of Pediatrics
Northwestern University Medical School;
Attending Physician
Divisions of Gastroenterology, Hepatology, and Nutrition
Children's Memorial Hospital
Chicago, Illinois

Mirna M. Farah, MD
Clinical Assistant Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Attending Physician
Division of Emergency Medicine

Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Joel A. Fein, MD
Assistant Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Attending Physician
Division of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Robert A. Felter, MD
Professor
Department of Pediatrics
Northeast Ohio University;
Chairman
Departments of Pediatrics and Adolescent Medicine;
Medical Director, Tod Children's Hospital;
Vice-Chairman, Pediatrics, NEOUCOM;
Chairman, EMS Board
State of Ohio Department of Public Safety
Youngstown, Ohio

Gary R. Fleisher, MD
Professor
Department of Pediatrics
Harvard Medical School;
Chief, Division of Emergency Medicine
Children's Hospital
Boston, Massachusetts

Janet H. Friday, MD
Assistant Professor
Department of Pediatrics
University of Connecticut School of Medicine;
Attending Physician
Division of Pediatric Emergency Medicine
Connecticut Children's Medical Center
Hartford, Connecticut

Ronald A. Furnival, MD
Associate Professor
Department of Pediatrics
University of Utah School of Medicine;
Attending Physician
Department of Pediatric Emergency Medicine
Primary Children's Medical Center
Salt Lake City, Utah

Carmen Teresa Garcia, MD
Attending Physician
Pediatric Emergency Department
Jackson Memorial Hospital
Miami, Florida

Michael H. Gewitz, MD
Professor and Vice Chairman
Department of Pediatrics
New York Medical College;
Director of Pediatrics and Chief, Pediatric Cardiology
Children's Hospital at Westchester Medical Center
Valhalla, New York

Timothy G. Givens, MD
Assistant Professor
Department of Pediatrics
University of Louisville;
Director, Pediatric Emergency Medicine Fellowship Program;
Associate Director, Emergency Department
Division of Pediatric Emergency Medicine
Kosair Children's Hospital
Louisville, Kentucky

Javier A. Gonzalez del Rey, MD

Associate Professor
Department of Pediatrics
University of Cincinnati College of Medicine;
Associate Director
Division of Emergency Medicine
Children's Hospital Medical Center
Cincinnati, Ohio

Marc H. Gorelick, MD, MSCE
Assistant Professor
Division of Pediatrics Emergency Medicine
A. I. duPont Hospital for Children
Wilmington, Delaware;
Department of Pediatrics
Jefferson Medical College
Philadelphia, Pennsylvania

David S. Greenes, MD
Instructor
Department of Pediatrics
Harvard Medical School;
Staff Physician
Division of Emergency Medicine
Children's Hospital
Boston, Massachusetts

Geeta Grover, MD
Assistant Clinical Professor
Department of Pediatrics
Harbor/UCLA Medical Center;
Attending Physician
Children's Hospital of Orange County
Orange, California

Karen Gruskin, MD
Instructor
Department of Pediatrics
Harvard Medical School;
Assistant in Medicine
Children's Hospital
Boston;
Director
Department of Pediatrics
Winchester Hospital
Winchester, Massachusetts

Daniel E. Hale, MD
Associate Professor
Department of Pediatrics
The University of Texas Health Science Center at San Antonio;
Senior Physician, Pediatric Endocrinology
Santa Rosa Children's Hospital
San Antonio, Texas

Steven D. Handler, MD
Professor
Department of Otorhinolaryngology: Head and Neck Surgery
The University of Pennsylvania School of Medicine;
Associate Director
Division of Pediatric Otolaryngology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Marvin B. Harper, MD
Instructor
Department of Pediatrics
Harvard Medical School;
Assistant in Medicine
Divisions of Emergency Medicine and Infectious Diseases
Children's Hospital
Boston, Massachusetts

Fred M. Henretig, MD
Professor
Departments of Pediatrics and Emergency Medicine
The University of Pennsylvania School of Medicine;

Director
Section of Clinical Toxicology
The Children's Hospital of Philadelphia;
Medical Director, The Poison Control Center
Philadelphia, Pennsylvania

Gordon R. Hodas, MD
Clinical Associate Professor
Department of Psychiatry
The University of Pennsylvania School of Medicine;
Statewide Child Psychiatric Consultant
Office of Mental Health and Substance Abuse Services
Pennsylvania Department of Public Welfare
Philadelphia, Pennsylvania

Dee Hodge III, MD
Associate Professor
Department of Pediatrics
Washington University School of Medicine;
Associate Director
Clinical Affairs, Emergency Services
St. Louis Children's Hospital
St. Louis, Missouri

Michael D. Hogarty, MD
Clinical Associate
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Division of Oncology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Paul J. Honig, MD
Professor
Departments of Pediatrics and Dermatology
The University of Pennsylvania School of Medicine;
Director
Department of Pediatric Dermatology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Daniel J. Isaacman, MD
Professor
Department of Pediatrics
Eastern Virginia Medical School;
Director, Division of Pediatric Emergency Medicine
Children's Hospital of The King's Daughters
Norfolk, Virginia

Kathy Jabs, MD
Assistant Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Medical Director, Renal Transplantation
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

David M. Jaffe, MD
Professor
Department of Pediatrics
Washington University School of Medicine;
Medical Director, Emergency Services
St. Louis Children's Hospital
St. Louis, Missouri

Mark D. Joffe, MD
Assistant Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Director, Community Pediatric Medicine;
Attending Physician
Pediatric Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Howard Kadish, MD
Associate Professor
Department of Pediatrics
The University of Utah School of Medicine;
Attending Physician, Emergency Department
Primary Children's Medical Center
Salt Lake City, Utah

Robert E. Kelly Jr, MD
Assistant Clinical Professor
Departments of Surgery and Pediatrics
Eastern Virginia Medical School;
Chief
Department of Surgery
Children's Hospital of The King's Daughters
Norfolk, Virginia

Sigmund J. Kharasch, MD
Assistant Professor
Department of Pediatrics
Boston University School of Medicine;
Director
Division of Pediatric Emergency Medicine
Boston Medical Center
Boston, Massachusetts

Brent R. King, MD
Associate Professor
Departments of Pediatrics and Emergency Medicine;
Chair, Department of Emergency Medicine
The University of Texas Houston Medical School;
Chief, Emergency Medicine
Herman Hospital
Houston, Texas

Christopher King, MD
Assistant Professor
Departments of Emergency Medicine and Pediatrics
University of Pittsburgh School of Medicine;
Attending Physician
Department of Emergency Medicine
University of Pittsburgh Medical Center (UPMC) Presbyterian Hospital
Children's Hospital of Pittsburgh
Pittsburgh, Pennsylvania

Bruce L. Klein, MD
Associate Professor
Departments of Pediatrics and Emergency Medicine
The George Washington University School of Medicine and Health Sciences;
Associate Medical Director
Department of Emergency Medicine
Children's National Medical Center
Washington, D.C.

Susanne Kost, MD
Clinical Assistant Professor
Jefferson Medical College
Philadelphia, Pennsylvania;
Attending Physician
A. I. duPont Hospital for Children
Wilmington, Delaware

Baruch S. Krauss, MD, EdM
Instructor
Department of Pediatrics
Harvard Medical School;
Attending Physician
Division of Emergency Medicine
Children's Hospital
Boston, Massachusetts

Roy M. Kulick, MD
Staff Physician
Division of Emergency Medicine

Children's Hospital Medical Center
Cincinnati, Ohio

Nanette C. Kunkel, MD
Assistant Professor
Department of Pediatrics
University of Utah School of Medicine;
Attending Physician, Emergency Department
Primary Children's Medical Center
Salt Lake City, Utah

Nathan Kuppermann, MD, MPH
Assistant Professor
Departments of Emergency Medicine and Pediatrics;
Director of Research
Emergency Medicine
University of California at Davis
School of Medicine
Sacramento, California

Beverly J. Lange, MD
Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Medical Director, Pediatric Oncology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Jane M. Lavelle, MD
Associate Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Attending Physician
Department of Pediatrics
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Chris A. Liacouras, MD
Assistant Professor
Division of Gastroenterology and Nutrition
The University of Pennsylvania School of Medicine;
Attending Physician
Department of Pediatrics
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Alex V. Levin, MD
Assistant Professor
Departments of Pediatrics, Genetics, and Ophthalmology
University of Toronto;
Staff Ophthalmologist
The Hospital for Sick Children
Toronto, Ontario
Canada

William J. Lewander, MD
Associate Professor
Department of Pediatrics
Brown University School of Medicine;
Director
Department of Pediatric Emergency Medicine
Hasbro Children's Hospital
Rhode Island Hospital
Providence, Rhode Island

Lisa L. Lewis, MD
Department of Pediatrics
University of Cincinnati College of Medicine;
Attending Physician
Department of Emergency Medicine
Children's Hospital Medical Center
Cincinnati, Ohio

Erica L. Liebelt, MD
Assistant Professor

Department of Pediatrics
Johns Hopkins School of Medicine;
Attending Physician, Pediatric Emergency Medicine
Johns Hopkins Hospital
Baltimore, Maryland

James G. Linakis, MD, PhD
Associate Professor
Department of Pediatrics
Brown University School of Medicine;
Associate Director, Pediatric Emergency Medicine
Hasbro Children's Hospital
Rhode Island Hospital
Providence, Rhode Island

John Loiselle, MD
Assistant Director
Emergency Services
A. I. duPont Institute
Wilmington, Delaware

Stephen Ludwig, MD
Professor
Departments of Pediatrics and Emergency Medicine
The University of Pennsylvania School of Medicine;
Associate Physician-in-Chief, John H. and Hortense Cassel Jensen Endowed Chair
Division of Pediatric Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Dennis P. Lund, MD
Assistant Professor
Department of Surgery
University of Wisconsin;
Chief
Pediatric Surgery
Children's Hospital of the University of Wisconsin
Madison, Wisconsin

Joseph R. Madsen, MD
Assistant Professor
Department of Surgery
Harvard Medical School;
Neurosurgeon
Department of Neurosurgery
Children's Hospital
Boston, Massachusetts

James M. Madsen, MD, MPH
Associate Professor
Department of Preventive Medicine and Biometrics
Deputy Director, Occupational and Environmental Medicine Residency
Uniformed Services University of the Health Sciences
Bethesda;
Formerly, Chief, Training Branch
Chemical Casualty Care Division
US Army Medical Research Institute of Chemical Defense
APG-EA, Maryland

Frank A. Maffei, MD
Clinical Instructor
Department of Pediatric Emergency Medicine;
Fellow
Department of Pediatric Critical Care
Strong Memorial Hospital
Rochester, New York

Soroosh Mahboubi, MD
Professor
Departments of Radiology and Pediatrics
The University of Pennsylvania School of Medicine;
Director, Body CT
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Eric S. Maller, MD
Assistant Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Attending Physician and Medical Director
The Liver Transplant Program
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Richard Malley, MD
Instructor
Department of Pediatrics
Harvard Medical School;
Assistant in Medicine
Divisions of Emergency Medicine and Infectious Diseases
Children's Hospital
Boston, Massachusetts

Kenneth D. Mandl, MD, MPH
Instructor
Department of Pediatrics
Harvard Medical School;
Director of Clinical Research
Division of Emergency Medicine
Children's Hospital
Boston, Massachusetts

Jonathan Markowitz, MD
Instructor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Fellow
Departments of Gastroenterology and Nutrition
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Constance M. McAneney, MD
Associate Professor
Department of Pediatrics
University of Cincinnati College of Medicine;
Associate Director
Division of Emergency Medicine
Children's Hospital Medical Center
Cincinnati, Ohio

Fred A. Mettler Jr., MD
Professor and Chairman
Department of Radiology
University of New Mexico Health Sciences Center
Albuquerque, New Mexico

Fran Nadel, MD
Assistant Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Attending Physician
Division of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Howard L. Needleman, DMD
Clinical Professor and Associate Chairman
Department of Pediatric Dentistry
Harvard School of Dental Medicine;
Associate Dentist-in-Chief
Children's Hospital
Boston, Massachusetts

Douglas S. Nelson, MD
Assistant Professor
Departments of Pediatrics and Emergency Medicine
University of Utah School of Medicine;
Attending Physician
Primary Children's Medical Center

Salt Lake City, Utah

Linda P. Nelson, DMD, MScD
Assistant Professor
Department of Pediatric Dentistry
Harvard School of Dental Medicine;
Associate in Pediatric Dentistry
Children's Hospital
Boston, Massachusetts

Michael E. Norman, MD
Clinical Professor
Department of Pediatrics
University of North Carolina School of Medicine
Chapel Hill;
Chairman and Residency Program Director
Department of Pediatrics
Carolinas Medical Center
Charlotte, North Carolina

Daniel W. Ochsenschlager, MD
Associate Professor
Department of Pediatrics
Department of Child Health and Development
George Washington University Medical Center;
Medical Director, Emergency Medical Trauma Center
Children's Hospital Medical Center
Washington, D.C.

Kevin C. Osterhoudt, MD
Assistant Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Attending Physician
Division of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Bonnie L. Padwa, DMD, MD
Assistant Professor
Oral and Maxillofacial Surgery
Harvard School of Dental Medicine;
Associate in Surgery
Division of Plastic and Oral Surgery
Children's Hospital
Boston, Massachusetts

Keith T. Paige, MD
Associate Staff Surgeon
Section of Plastic and Reconstructive Surgery
Virginia Mason Medical Center
Seattle, Washington

Jan E. Paradise, MD
Associate Professor
Department of Pediatrics
Boston University School of Medicine;
Director, Child Protection Program
Boston Medical Center
Boston, Massachusetts

Mary D. Patterson, MD
Assistant Professor
Department of Pediatrics
University of Cincinnati College of Medicine;
Attending Physician
Division of Emergency Medicine
Children's Hospital Medical Center
Cincinnati, Ohio

Ronald I. Paul, MD
Associate Professor and Chief
Division of Pediatric Emergency Medicine
Department of Pediatrics
University of Louisville School of Medicine;

Medical Director, Emergency Department
Kosair Children's Hospital
Louisville, Kentucky

Barbara B. Pawel, MD
Clinical Assistant Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Attending Physician
Division of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Catherine E. Perron, MD
Instructor
Department of Pediatrics
Harvard Medical School;
Attending Physician
Division of Emergency Medicine
Children's Hospital
Boston, Massachusetts

Holly Perry, MD
Assistant Professor
Department of Pediatrics
Division of Emergency Medicine
University of Connecticut School of Medicine
Farmington;
Attending Physician
Pediatric Emergency Department
Connecticut Children's Medical Center
Hartford, Connecticut

Jill C. Posner, MD
Instructor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Fellow
Division of Emergency Medicine
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

William P. Potsic, MD
Newlin Professor of Pediatric Otorhinolaryngology: Head and Neck Surgery
The University of Pennsylvania School of Medicine;
Director, Pediatric Otolaryngology and Human Communication
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Mark G. Roback, MD
Assistant Professor
Department of Pediatrics
University of Colorado Health Sciences Center;
Attending Physician
Department of Emergency Medicine
The Children's Hospital
Denver, Colorado

Bruce Rosenthal, MD
Division of Pediatric Emergency Medicine
Mercy Hospital
Pittsburgh, Pennsylvania

Henry D. Royal, MD
Professor
Department of Radiology
Washington University School of Medicine;
Associate Director
Division of Nuclear Medicine
Mallinckrodt Institute of Radiology
St. Louis, Missouri

Richard M. Ruddy, MD
Professor of Clinical Pediatrics
Department of Pediatrics

University of Cincinnati College of Medicine;
Director
Division of Emergency Medicine
Children's Hospital Medical Center
Cincinnati, Ohio

Richard A. Saladino, MD
Assistant Professor
Department of Pediatrics
Harvard Medical School;
Attending Physician
Emergency Department
Children's Hospital
Boston, Massachusetts

Stephen Santora, MD
Associate Clinical Professor
Department of Orthopedics
University of Utah School of Medicine;
Pediatric Orthopedist
Primary Children's Medical Center
Salt Lake City, Utah

John Sargent, MD
Professor and Dean
Department of Psychiatry
Karl Menninger School of Psychiatry and Mental Health Sciences;
Director, Education and Research
The Menninger Clinic
Topeka, Kansas

Thomas F. Scanlin, MD
Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Director, Cystic Fibrosis Center
The Children's Hospital of Philadelphia,
Philadelphia, Pennsylvania

Richard J. Scarfone, MD, MCP
Assistant Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Attending Physician
Department of Pediatric Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Deborah H. Schaible, PharmD
Clinical Associate Professor
Department of Pediatrics
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Louise Schnaufer, MD
Professor
Department of Pediatric Surgery
The University of Pennsylvania School of Medicine;
Senior Surgeon
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Jeff E. Schunk, MD
Associate Professor and Chief
Division of Pediatric Emergency Medicine
University of Utah School of Medicine;
Attending Physician
Emergency Department
Primary Children's Medical Center
Salt Lake City, Utah

Sara A. Schutzman, MD
Assistant Professor
Department of Pediatrics
Harvard Medical School;

Assistant in Medicine
Division of Emergency Medicine
Children's Hospital
Boston, Massachusetts

Steven M. Selbst, MD
Professor
Department of Pediatrics
Thomas Jefferson University;
Attending Physician
Division of Emergency Medicine
A. I. duPont Hospital for Children
Wilmington, Delaware

Michael Shannon, MD, MPH
Associate Professor
Department of Pediatrics
Harvard Medical School;
Associate Chief and Fellowship Director
Division of Emergency Medicine
Boston, Massachusetts

Kathy N. Shaw, MD
Associate Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Chief, Emergency Medical Services
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Stephen Shusterman, DMD
Associate Clinical Professor
Department of Pediatric Dentistry
Harvard School of Dental Medicine;
Dentist-in-Chief
Children's Hospital
Boston, Massachusetts

Benjamin K. Silverman, MD
Attending Physician
Emergency Services
Harbor/UCLA Medical Center
Children's Hospital of Orange County
Orange, California

Joseph E. Simon, MD
Medical Director, Care Delivery
Scottish Rite Children's Medical Center
Atlanta, Georgia

Jonathan I. Singer, MD
Professor
Departments of Emergency Medicine and Pediatrics;
Vice Chairman and Program Director
Department of Emergency Medicine
Wright State University School of Medicine
Dayton, Ohio

Howard M. Snyder III, MD
Professor
Department of Surgery in Urology
The University of Pennsylvania School of Medicine;
Associate Director/Academic Chief, Pediatric Urology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Anne M. Stack, MD
Instructor
Department of Pediatrics
Harvard Medical School;
Attending Physician
Division of Emergency Medicine
Children's Hospital
Boston, Massachusetts

Dale W. Steele, MD
Assistant Professor
Department of Pediatrics
Section of Emergency Medicine
Brown University;
Attending Physician
Emergency Department
Hasbro Children's Hospital
Providence, Rhode Island

Molly W. Stevens, MD
Assistant Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Attending Physician
Division of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Robert P. Sundel, MD
Assistant Professor
Department of Pediatrics
Harvard Medical School;
Director
Rheumatology Program
Children's Hospital
Boston, Massachusetts

Stephen J. Teach, MD, MPH
Assistant Professor
Department of Pediatrics
George Washington University School of Medicine;
Department of Emergency
Children's National Medical Center
Washington, D.C.

Frederick W. Tecklenburg, MD
Associate Professor
Department of Pediatrics
The Medical University of South Carolina;
Director
Division of Emergency/Critical Care
MUSC Children's Hospital
Charleston, South Carolina

Susan B. Torrey, MD
Instructor
Department of Pediatrics
Harvard Medical School;
Attending Physician
Division of Emergency Medicine
Children's Hospital
Boston, Massachusetts

Victoria L. Vetter, MD
Associate Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Chief
Division of Cardiology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Robert J. Vinci, MD
Associate Professor
Department of Pediatrics
Boston University School of Medicine;
Vice Chairman
Department of Pediatrics
Boston Medical Center
Boston, Massachusetts

Debra L. Weiner, MD, PhD
Instructor

Department of Pediatrics
Harvard Medical School;
Attending Physician
Department of Emergency Medicine
Children's Hospital
Boston, Massachusetts

Linton A. Whitaker, MD
Professor
Department of Surgery
The University of Pennsylvania School of Medicine;
Chief of Plastic Surgery
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

James F. Wiley II, MD
Associate Professor
Departments of Pediatrics and Emergency Medicine
The School of Medicine at the University of Connecticut Health Center;
Director, Emergency Medical Services
Connecticut Children's Medical Center
Hartford, Connecticut

George A. Woodward, MD
Assistant Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Medical Director, Emergency Transport Services
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Paul K. Woolf, MD
Associate Professor
Department of Pediatrics
New York Medical College;
Assistant Director, Pediatric Cardiology
Children's Hospital at Westchester Medical Center
Valhalla, New York

Loren G. Yamamoto, MD, MPH, MBA
Professor
Department of Pediatrics
University of Hawaii
John A. Burns School of Medicine;
Vice-Chief of Staff
Kapiolani Medical Center for Women and Children
Honolulu, Hawaii

Marc Yudkoff, MD
Grant Professor of Pediatrics
The University of Pennsylvania School of Medicine;
Chief, Child Development
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Moritz M. Ziegler, MD
Professor
Department of Surgery
Harvard Medical School;
Chairman
Department of Surgery
Children's Hospital
Boston, Massachusetts

Joseph J. Zorc, MD
Assistant Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Attending Staff
Division of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Preface

With age comes stability. Relatively profound structural changes occurred nationally during the years of development of the three prior editions of the *Textbook of Pediatric Emergency Medicine*, including burgeoning numbers of practitioners, the establishment of a specialty board, and most important, recognition and broadening of the mission for pediatric emergency medicine. This fourth edition arrives on the scene less than 20 years after the first, which essentially coincided with the birth and initial recognition of the subspecialty. Although growth and refinement of the art proceed at a gratifying pace, this edition appears at a time of consolidation of the gains of the prior two decades--from infancy to maturity.

Throughout the text, we have updated extensively but innovated selectively. We have continued to recruit authors who are fellowship-trained, board-certified and board-qualified pediatric emergency physicians. Fortunately, this task grows easier each time around. We believe you will agree that the chapters written by these new contributors reflect the skills that they acquired in the trenches, and emphasize the perspective of pediatric emergency medicine.

We have made some important additions. You will find six new chapters. The first, in the section on “Life-Threatening Emergencies,” is “Myocardial Infarction.” We have asked Baruch Krauss, MD, board-certified in family practice as well as pediatric emergency medicine, to discuss the immediate treatment of ischemic cardiac catastrophes, both to prepare us for the rare occurrence of this event during childhood and for the occasional parents and grandparents who show up in pediatric emergency departments, clutching their chests in pain. Then, under the section of “Signs and Symptoms” Anne Stack, MD and Mark Roback, MD provide an initial approach to two new problems, “Cyanosis” and “Oral Lesions,” the first quite serious, and the second less ominous but common, and at times confusing. Following, in the section on “Medical Emergencies,” you will find a chapter on “Neonatal Problems.” Our experience over the last five years, with the entrenchment of early discharge for newborns, is that parents are bringing their infants to the emergency department in many cases where they suddenly notice a color change, a rash, cranial swelling, jitteriness, or some other finding that represents an issue previously handled prior to discharge from the nursery on day 3 or day 4 of life. To address this topic, Benjamin K. Silverman, MD, shares his clinical acumen from 3 decades of pediatric practice and 15 years in pediatric emergency medicine. Also, we have identified an emerging area where parents call upon the pediatric emergency physician for unique expertise to manage the “Approach to the Care of the Technology-Dependent Child.” To address the diverse issues--many related to implanted hardware--that occur in these patients, Joel A Fein, MD, Kate Cronan, MD, and Jill Posner, MD, have written a new chapter for the section on “Surgical Emergencies.” Lastly, events around the world in the last five years have forced us to confront the medical consequences for children of chemical and biological terrorism. To address this, Chapter 132 reviews emergency department preparedness for such terrorism with an emphasis on pediatric issues.

Although the majority of the chapters are carried over from the third edition, you will find that they contain updated information and, not infrequently, address new diseases and treatments. For example, the chapter on “Infectious Diseases” discusses babesiosis and ehrlichiosis, two tick-borne infections that only recently have been well-described in children. In “Hematologic Emergencies,” a new option, using an anti-D antibody preparation instead of prednisone or intravenous gamma-globulin, is offered to simplify the treatment of the majority of cases of idiopathic thrombocytopenia, and 4-methylpyrazole is introduced in “Toxicologic Emergencies” for the management of poisoning with ethylene glycol. Thus, we believe you will encounter the newest and very latest information with each turn of a page in this fourth edition.

As a consequence of the aforementioned essential transition to authors trained in pediatric emergency medicine, some close friends and talented colleagues who served well as valued collaborators previously have not joined us in the current edition. We wish to thank each of these individuals for their immense contributions to the success and maturation of the prior editions. In many of the chapters that have changed hands, the new authors have followed our suggestions to retain those portions of the original framework, tables, and illustrations that have worked so well in the past and remain relevant. As editors, we wish to acknowledge our gratitude and debt to the former authors of these revised chapters.

Despite our protestations of constancy, you will encounter immediately one major change on the cover and title page. Jack Templeton, MD, who has labored with some of us since residency, and with the entire group throughout three editions, has relinquished his role as an editor. Several years ago Jack made the decision to retire from pediatric surgery at the peak of his illustrious career so that he could devote his full energy to the philanthropic efforts of the Templeton Foundation. Having chosen to work toward improving the health and well-being of humankind through a venue other than medicine, Jack asked us to reassign his responsibilities. Steve, Fred, Rich, Ben, and I cannot thank Jack enough for his tremendous assistance in sustaining the textbook throughout all these years.

Finally, we want to pay special recognition to two authors from the third edition, John Duckett, MD, and Edward B. Charney, MD, both now deceased. These two colleagues helped us to launch the textbook, and they would once again be among our contributors, were it not for their untimely deaths.

As editors, we rely on support from many sources to help us put forth a vital new edition of the textbook each time around. At home, our families tolerate our long absences during which we do our writing and fill us with the joy that motivates us in all our endeavors. At work, our colleagues, as well as our residents and fellows, allow us to spend some time in the “back office” and also offer up an endless flow of great ideas. Finally, at national meetings and through their correspondence, our readers have inspired us, by sharing their boundless enthusiasm for the textbook and their creative suggestions for future topics and alternative approaches. We have benefitted greatly from this feedback and hope that each of you will think about areas for expansion and/or revision whenever you consult the *Textbook of Pediatric Emergency Medicine*. You can rest assured that we have begun to plan the fifth edition and will look forward, once again, to receiving your input.

Acknowledgments

As we complete the final pages of the fourth edition of *Textbook of Pediatric Emergency Medicine*, it is more than appropriate to acknowledge and sincerely thank those around us who have made it all possible.

The writing and editing of this edition, like that of its predecessors, is a process that does not take place in the workplace. Most of the work was done during early morning hours, nights, and weekends. When deadlines drew close, it was done on vacations and on holidays. The precious commodity of time has been the very time that we have taken from our families. Their commitment to us and to our objectives and aspirations has been strong. Their donation of their own time has been magnanimous. Without their love and support our work would not have meaning. It is the treasure of our own families that drives us to help other children and families. To Jan and Zella, our love and gratitude. To Daniel, Carl, and Madeline Fleisher, and to Susannah, Elisa, and Aubrey Ludwig, our thanks for your sharing and understanding. Your only payback can come through the health and well-being of strangers of your generation and from those to come.

To our coeditors—our closest colleagues—we extend our greatest respect and thanks. You are the unsung heroes of this work. Fred Henretig's contributions have been so great that we have elevated his title to Senior Associate Editor. To Associate Editors Rich Ruddy and Ben Silverman, there are no appropriate accolades. We hope that your level of personal satisfaction fills the void of our inability to say enough about your skills and dedication to the project. May our careers continue to grow side by side.

During the years of the four editions there have been so many colleagues and coworkers, that it is impossible to name them all without forgetting some and thereby inadvertently offending them. They have worked by our side in the emergency department. They have taught with us in lectures, conferences, and workshops. They have served on committees, task forces, and boards. They have written chapters and rewritten them based on our whims and notions. They have covered some of our nights and weekends. They have taught us, questioned us, stimulated us, and always supported us. Many remain at our sides at Children's Hospital in Boston and the Children's Hospital of Philadelphia. But equally valuable are those who have moved to other centers of pediatric emergency care around the United States and around the world. Those who have moved beyond the "nests" are not forgotten. We continue to appreciate and acknowledge all.

We offer a special note of acknowledgment to our trainees. We appreciate all those we have encountered as medical students, residents, fellows, and continuing medical education students. We thank you all. It is you who have asked the questions. It is you who have longed for the information. You have held out the expectation that we provide the answers in an accurate and available form. We have also learned from our many thousands of our patients and their parents. They too have kept the bar of expectation high, forcing us to try to meet those expectations.

In each of our offices there has been a coworker of special patience and extraordinary skills. For this edition, Cindy Chow and Carolyn Trojan have gone above and beyond the call. We have not forgotten those who were there for other editions: Rose Beato, Pat Parkinson, and Carmen Christmas. Work without these devoted women would be unimaginable.

To our coworkers at Lippincott Williams & Wilkins, our thanks also. For this edition we appreciate your consistency and dedication to the project. In particular, we thank Tanya Lazar, Elizabeth Greenspan, Sonya Seigafuse, Lisa Franko, and Jeff Gruenglas.

A final note goes to our teachers, chairmen, and mentors. There are and have been many, and we thank you all. As Jean Cortner, MD, is about to retire, a special note of thanks goes out to him. He was there when it all began. He bet on two young faculty members. I hope he feels that his bet has had adequate pay out. And for each of us, there has been a special David in our careers. To the late David Cornfeld and the very active David Nathan, we often think about how you would have done it. It is the true sign of a mentor.

CHAPTER 1

Resuscitation—Pediatric Basic and Advanced Life Support

STEPHEN LUDWIG, MD

Departments of Pediatrics and Emergency Medicine, The University of Pennsylvania School of Medicine, and The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Cardiopulmonary resuscitation (CPR) is a series of interventions aimed at restoring and supporting vital function after apparent death. The urgent and immediate goal of resuscitation is to reestablish substrate delivery to meet the metabolic needs of the myocardium, brain, and other vital organs. The overall goal is to return the child to society without morbidity related either to the underlying disease process or to the resuscitation process.

Instruction in CPR techniques has come from two widely disseminated national courses: Pediatric Advanced Life Support (PALS) and Advanced Pediatric Life Support (APLS). Both of these courses have been successful in training health care providers in the appropriate resuscitative techniques. Both courses stress the early recognition of the child who is in need of resuscitative efforts. The outcome of resuscitation in situations in which there has been prolonged asystolic arrest is poor. As in many conditions we manage in pediatric patients, primary prevention, or at least early recognition, is the most successful strategy.

Pediatric CPR has been based largely on the adult model of resuscitation. There is an orderly progression through the assessment and management of the ABCs—airway, breathing, and circulation. Like its adult counterpart, pediatric CPR is best performed by a well-coordinated team of physicians, nurses, respiratory therapists, and other support personnel.

BACKGROUND

Incidence

There are no incidence data for pediatric resuscitations performed annually in the United States. We can estimate the incidence of potential resuscitations by examining the data on infant and childhood mortality. Table 1.1 shows the childhood mortality rates and the leading causes of death for children. Table 1.2 shows the leading causes of death in the United States in different age groups in 1996 and the relative rates per population. Note that there is a relatively higher mortality rate for young children. Note also that, of the causes of death listed in Table 1.1, most are potentially reversible. Trauma is the leading cause of death in childhood. Special techniques of trauma management are presented in Section IV. We believe that the techniques of basic and advanced life support, when readily available and skillfully applied, contribute to the significant reduction in childhood mortality.

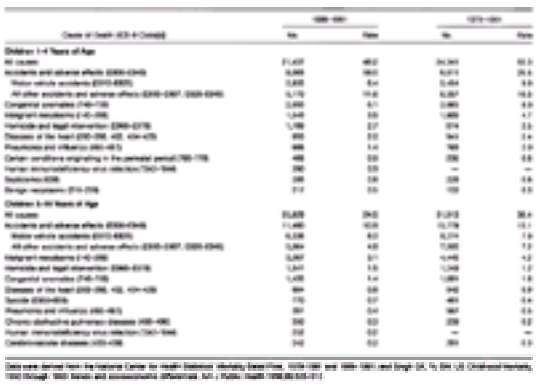

Table 1.1. U.S. Deaths and Death Rates per 100,000 Population for Children 1 to 4 and 5 to 14 Years of Age, for

the 10 Leading Causes of Death, 1979 through 1991

Birth–1 (70)*	1–4 (3)	5–9 (1.5)	10–14 (2.2)	15–19 (7)
Congenital anomalies	Injury	Injury	Injury	Injury
Prematurity	Congenital anomalies	Neoplasm	Neoplasm	Homicide
SIDS	Malignant neoplasm	Congenital anomalies	Homicide	Suicide
Respiratory distress syndrome	Homicide	Homicide	Suicide	Neoplasm
Newborn affected by maternal complications	Heart disease	Heart disease	Heart disease	Heart disease

*Rate per 100,000 population in specified group.

Table 1.2. Causes of Death: Five Leading Causes in United States, 1996

Patient Characteristics

Age

In many series of CPR cases, most children were at the younger end of the pediatric age range. In a series published from The Children's Hospital of Philadelphia, the mean age was 1.98 years and the median was 5 months. The age range was between 2 weeks and 16 years (Fig. 1.1). Although pediatric CPR education generally should be tailored to the anatomic and physiologic characteristics of the young child, emergency department staff must be prepared to cope with the full spectrum of age and size.

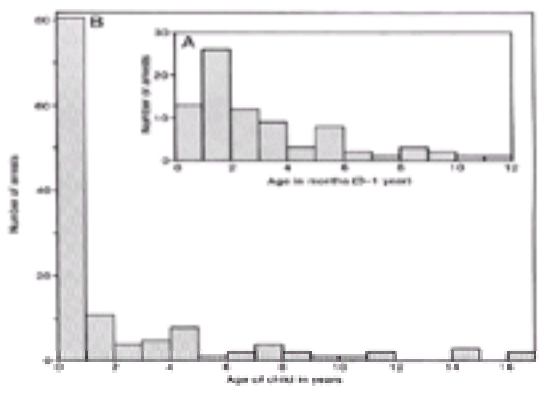

FIGURE 1.1. Histogram showing frequency of cardiac arrest as related to age in months **(A)** and years **(B)** from The Children's Hospital of Philadelphia survey.

Etiology

The most common primary diagnoses of hospitalized pediatric patients requiring resuscitation involve the respiratory system (Table 1.3). Conditions such as pneumonia, bronchiolitis, asthma, aspiration, and respiratory distress syndrome account for the largest group of diagnoses. Cardiac diagnoses and central nervous system (CNS) disorders occur in roughly equal frequency, but half as often as respiratory diagnoses. Common cardiovascular diagnoses include congenital heart disease, septic shock, and severe dehydration. CNS diagnoses include hydrocephalus (ventricular shunt failure), meningitis, seizure, and tumor.

Respiratory	*Central Nervous System*
Pneumonia	Acute hydrocephalus
Aspiration	Head trauma
Asthma	Seizure
Epiglottitis	Tumor
Laryngotracheobronchitis	Meningitis
Respiratory failure/chronic lung disease	Hemorrhage
Bronchiolitis	*Gastrointestinal*
Botulism	Trauma
Primary apnea	Enterocolitis
Bronchopulmonary dysplasia	Bowel perforation
Cardiovascular	Bowel obstruction
Congenital heart disease	Tracheoesophageal fistula
Septic shock	*Miscellaneous/Multisystem*
Dehydration	Sudden infant death syndrome
Pericarditis	Drug ingestion
Congestive heart failure	Tumors (non-CNS)
Myocarditis	Multiple trauma

From The Children's Hospital of Philadelphia 1979–1980.

Table 1.3. Diagnoses of Children Requiring Life Support by Body System

In the emergency department, the physician is more likely to encounter children whose cardiac arrest results from trauma, sudden infant death syndrome (SIDS), or unknown causes. Children with congenital anomalies, chronic sequelae of prematurity, and birth trauma, and those with chronic relapsing disease are also seen in the emergency department, as increasing numbers of children have survived the neonatal period, transplantation, complex surgery, and cancer therapy and have been discharged from the hospital. The broad range of diagnoses encountered in our review of resuscitation is noted in Table 1.3. This clearly differs from the adult circumstance of resuscitation, in which case most arrests are related to myocardial infarction secondary to coronary artery disease.

The PALS course teaches that the many etiologies of arrest follow one of two pathways: respiratory distress to respiratory failure to arrest or circulatory compromise to circulatory failure to arrest. In our experience, 80% of children who have arrested have followed the first pathway (Fig. 1.2). Twenty percent of patients follow the circulatory failure pathway to arrest. It is difficult in some cases to determine which mechanism was primary.

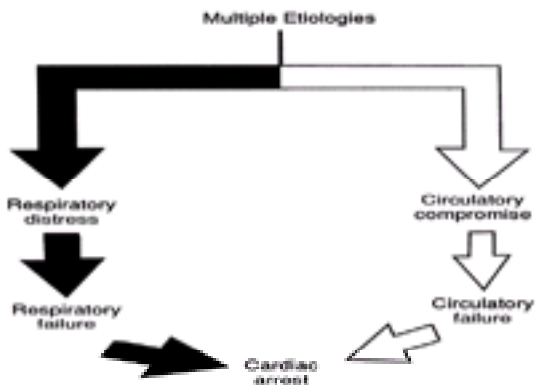

FIGURE 1.2. Pathophysiologic pathways from etiologies to cardiac arrest. (Adapted from P.A.L.S., American Heart Association.)

Demographics

There are no national demographic studies to identify socioeconomic, racial, familial, or community characteristics of the pediatric patient who requires life support intervention. Such studies would be important for developing profiles of the high-risk patient population for subsequent development of surveillance or prevention programs. It is most important to study such factors on a local level, where local solutions may be implemented. Some states have begun child death review efforts.

Treatment

Pediatric CPR presents the emergency physician with several complexities and frustrations. The first difficulty often encountered is that the patient has received only minimal prehospital care. Although this is changing with enhanced development of emergency medical services for children (EMS-C), pediatric patients are likely to be brought to the emergency department without the same field treatment that adult patients receive routinely. In many locales, paramedics are trained and equipped primarily to provide adult life support; however, they may be forced to initiate pediatric life support at the most basic level. In other areas, paramedics are limited by laws, regulations, or negative attitudes. Absent or inadequate prehospital care leads to longer periods of hypoxia and hypoperfusion, which directly affect prognosis and CNS morbidity (see Chapter 6). Seidel has documented the difference in survival rates between traumatized adults and children who require prehospital care as well as the lack of adequate pediatric equipment in prehospital care systems. Other investigators have documented the deficiencies in emergency care provided in free-standing emergency care centers and in primary care providers' offices.

The wide spectrum of age and diagnoses adds additional complexity. The resuscitation team must provide an array of technical skills, drugs, and equipment. Without delay, the team must have the flexibility to adjust to the correct sizes and drug dosages for children.

Our experience shows that careful management of airway and breathing is extremely important. Because the cause of the arrest is often related to respiratory failure and because the child's myocardium is relatively resilient to hypoxemia, the rapid correction of hypoxemia may be all that is necessary to effect resuscitation. In one-third of the resuscitations we reviewed, resuscitation was effected with only oxygen and positive-pressure ventilation.

For those patients who do not respond to airway and breathing management alone, life support will be significantly more difficult. In the emergency department, the lack of an immediate patient response usually predicts a need for multiple drug interventions. Our patients received a mean number of 4.5 drugs per patient.

One of the common frustrations when administering drugs is the establishment of an intravenous line. This technical skill continues to be the most common obstacle toward achieving successful CPR. However, the use of intraosseous technique and central line placement have been great advances in the solution of the access problem.

Arrhythmia management is generally not a problem in pediatric life support. The absence of atherosclerotic vascular disease makes the child's myocardium less susceptible to arrhythmia. As a result, antiarrhythmic medications and defibrillation are used infrequently. The most common cardiac rhythms to be recognized and managed are sinus bradycardia and asystole. The expectations to this are those children with congenital heart disease (preoperative and

postoperative) and those who have sustained direct myocardial trauma (see Chapter 82). These children may have unusual and difficult arrhythmias that require esoteric management to achieve a successful outcome.

Perhaps the greatest difficulty comes not with specific knowledge or technical skill, but with attitude. Many emergency departments are unaccustomed to resuscitating children and will become immobilized when faced with the task. There is a fear that the child is somehow more fragile. In other circumstances, there is overcompensation to the point that the resuscitation of a child is prolonged beyond an optimal point for either the child or the family.

On the other hand, many pediatric emergency physicians feel uncomfortable with the adult patient who may be a visitor at the pediatric hospital yet is brought to the emergency department with acute chest pain and possible myocardial infarction. Chapter 8 serves as a brief review of this important topic.

The emergency department team should review the effectiveness of each individual resuscitation effort as well as the emergency department's collective effort. This audit may be accomplished using one or more of the following approaches: 1) postresuscitation conference; 2) review of the videotape recording of resuscitation; 3) monthly morbidity mortality conferences; 4) chart audit; 5) review of resuscitation database (e.g., cross-referencing morbidity and mortality with various shifts, personnel teams, and prehospital treatment); and 6) performance on practice codes. When the team recognizes that its efficiency and effectiveness with children are less than ideal or less than they are with adults, specific remedial education should be undertaken.

Prognosis

The outlook for survival after CPR is very good for pediatric patients. In our experience, if the arrest is recognized rapidly and managed skillfully, immediate survival may be as high as 90% and the survival to discharge rate 60%. These figures are based on a hospitalized population of children who require resuscitation. For patients in the emergency department, the outcome is not as good. Children who arrive in the emergency department in asystolic arrest have a poor prognosis. In our small prospective series, patients who had no cardiovascular response to two standard doses of epinephrine were unable to be resuscitated. In the emergency department, the immediate survival may be as high as 60%, whereas the survival to discharge rate is 40%. The poorer prognosis for patients in the emergency department may be attributed to delayed recognition of the arrest and to limited prehospital care. Other series have documented an even more grim prognosis as shown in Table 1.4.

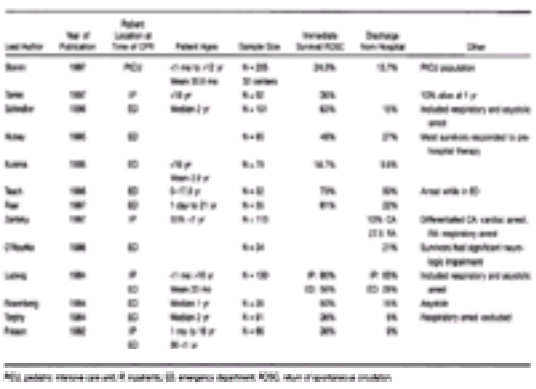

Table 1.4. Case Series and Outcomes of Pediatric Cardiopulmonary Resuscitation

Research

CPR research is extremely difficult to perform. Most of our information is based on retrospective studies like those reported in Table 1.4. Patient populations, characteristics, terminology, and methodology vary among studies, making it difficult to compare one investigator's work with another's. Performing a prospective study is challenged by legal and ethical considerations in enlisting patients at a time when “informed consent” is impossible. A recent conference was held and a Special Report issued to bring uniformity to the terminology of CPR research. This important report may bring more clarity to the CPR research of the future.

CLINICAL MANIFESTATIONS

Infants and children who have experienced disruption of oxygen or glucose delivery to the brain may benefit from the various elements of basic or advanced cardiac life support. The clinical manifestations of those requiring immediate life support are most often related to failure of oxygen delivery to the skin, brain, kidneys, and cardiovascular system. Cutaneous manifestations of oxygen deprivation include circumoral pallor, grayish hue, cyanosis, diaphoresis, mottling, and poor capillary refill. Manifestations of CNS hypoxia include irritability, confusion, delirium, seizures, and unresponsiveness. Cardiovascular manifestations include tachycardia, diaphoresis, bradycardia, and hypotension. Figure 1.3 shows the sequential development of signs and symptoms when there is failure of substrate delivery to different oxygen systems.

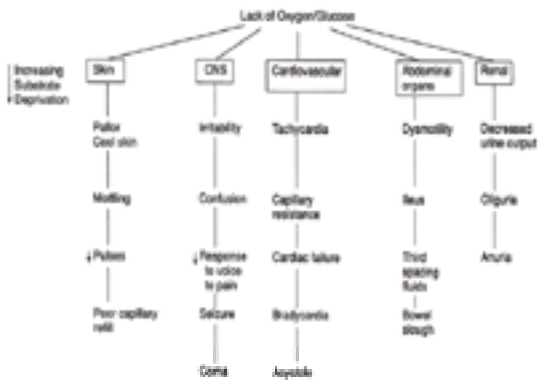

FIGURE 1.3. Signs and symptoms of lack of substrate delivery to vital organ systems.

Glucose is the second essential substrate necessary for maintenance of CNS integrity. Severe hypoglycemia may be just as devastating as severe hypoxemia. Clinical manifestations are often similar to hypoxemia because the primary effect on the CNS is coma. In addition, the effect of hypoglycemia on the cardiovascular system may lead to a secondary failure of oxygen delivery because of hypotension and related hypoperfusion.

A patient who has experienced a failure of substrate delivery to the central circulation must be resuscitated or supported until more specific diagnosis and management can be determined. It is also essential to identify patients who are *at risk* for failure of substrate delivery. This can be accomplished by a physical examination with emphasis on evaluation for airway patency, gas exchange, and cardiovascular integrity. In detecting those at risk, pulse oximetry, if available, may be useful in identifying mild degrees of hemoglobin desaturation. In addition, the laboratory may be helpful because patients with a low partial pressure of arterial oxygen (Pa_{O_2}), pH, glucose, hemoglobin, hemoglobin saturation, or high Pa_{O_2} are at risk. Also, recognition of certain disease entities allows early intervention, careful monitoring, and prevention of cardiovascular collapse. Examples include croup, airway foreign body, meningitis, and increased intracranial pressure (ICP).

MANAGEMENT

Management Sequence

Once a child has been identified as requiring life support, a sequence of evaluations and interventions should be accomplished (Fig. 1.4). Initially, CNS integrity must be evaluated: Is the patient alert? Does he or she respond to a shout or painful stimulus? If there is no response, the physician assumes that the brain is no longer receiving an adequate amount of oxygen, and the three basic sequences of evaluation and management are initiated.

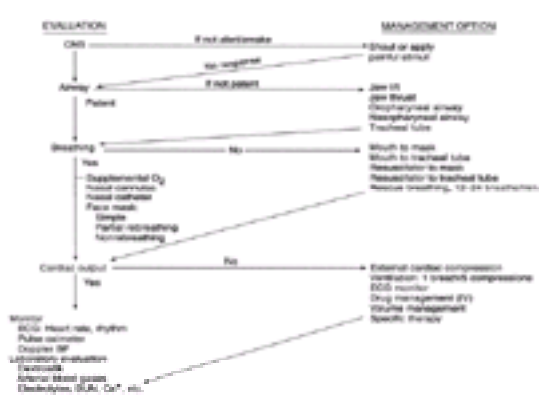

FIGURE 1.4. Management sequence for pediatric life support.

First, the airway is maneuvered to move the mandibular block of tissue up and off the posterior pharyngeal wall. The physician places his or her cheek next to the mouth and nose while listening and feeling for movement of air. At the same time, the physician is watching the chest for any evidence of chest wall movement. If the patient is moving air independently, the physician simply continues to support the airway and looks to provide a mechanism for delivering supplemental oxygen. If the patient is not breathing spontaneously, the physician must breathe for the victim, using an expired air technique when a manual resuscitator is not available. As soon as advanced life support breathing technology is available, it should be used. With the recognition that the airway is open and ventilation is occurring, the third phase of oxygen delivery is evaluated by feeling for arterial pulsations. The physician should palpate the brachial, carotid, or femoral arteries. If palpable pulses are not present after a 15-second evaluation, external cardiac compression (ECC) is initiated to provide a circulation. The adequacy of ECC is initially determined by feeling for pulses. In determining whether the oxygen delivery system has been reestablished, the physician should look for improvement in the level of consciousness or a return to spontaneous breathing or an inherent cardiac rhythm.

More specific management sequences are offered at the end of this chapter.

Airway

Evaluation

The first priority in the sequential evaluation and management paradigm of basic and advanced life support is evaluation and treatment of the airway. The physician should look, listen, and feel for evidence of gas exchange. The physician should *look* at the chest to see whether there is chest wall or abdominal movement suggestive of breathing effort. The physician should *listen* over the mouth and nose for the sound of air movement. With a stethoscope, the physician should listen over the trachea and the axilla for air entry. The physician should *feel* with his or her cheek for evidence of air movement. If there is evidence of spontaneous breathing and no evidence of gas movement through the central airway, the presumptive diagnosis is that of airway obstruction.

Management

If trauma is suspected, the head and cervical spine must be stabilized during evaluation and management of the airway. Someone must be assigned to hold the head in the midline position while applying gentle cephalad traction. The most effective noninvasive maneuver for clearing an obstructed airway involves tilting the head back slightly and lifting the chin forward by pulling or pushing the mandibular block of tissue forward (Fig. 1.5). The traditional mechanism of gentle flexion of the cervical spine on the thoracic spine may open the airway, but it provides less efficient ventilation and is hazardous if cervical spine trauma has occurred.

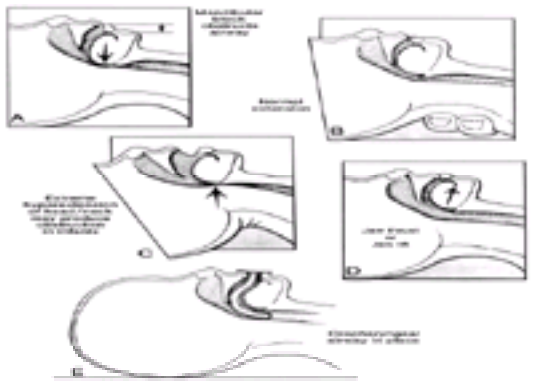

FIGURE 1.5. A. Upper airway obstruction related to hypotonia. **B.** Partial relief of airway obstruction by means of head extension (danger of cervical spine injury in cases of trauma). **C.** Extreme hyperextension causing upper airway obstruction. **D.** Fully open airway through use of jaw thrust or jaw lift. **E.** Oropharyngeal airway stenting mandibular block off of posterior pharyngeal wall.

Most airway obstruction is related to the mandibular block of tissue falling posteriorly and lying against the posterior wall of the hypopharynx. This can be relieved by physically grasping the mandibular block and pulling it forward so that the lower anterior central incisors are anterior to the maxillary central incisors. The same result can be obtained by pushing the mandibular block of tissue forward. The fingers should be placed behind the angle of the jaw and the jaw pushed forward so that the lower central incisors are in a plane anterior to the upper central incisors (Fig 1.5). These noninvasive maneuvers should be attempted before any of the more invasive airway adjuncts are tried. Table 1.5 lists airway equipment and respiratory monitoring equipment that should be available for pediatric life support. Table 1.6 lists rates of respiration to be achieved by providing CPR for pediatric life support.

Infant:	20-24 breaths/min
Child:	16-20 breaths/min
Adolescent:	12-16 breaths/min

Table 1.6. Rate of Respiration

Artificial Airways

Oropharyngeal Airways

Oropharyngeal airways are used when manual manipulation of the airway cannot maintain airway patency. The purpose of the oropharyngeal airway is to stent or support the mandibular block of tissue off of the posterior pharyngeal wall. There are three basic parts to this airway (Fig. 1.6). The flange is used to prevent the airway from falling back into the mouth. It also serves as a point of fixation for adhesive tape. The bite block portion is designed to prevent approximation of the central incisors. A forceful bite may produce obstruction of an oral tracheal tube. The stent of the oropharyngeal airway is designed specifically to hold the tongue away from the posterior pharyngeal wall. Secondarily, the stent may provide an air channel or suction conduit through the mouth. The proper size oropharyngeal airway can be estimated by placing the airway alongside the face so that the bite block portion is parallel to the palate. The tip of the airway should just approximate the angle of the mandible.

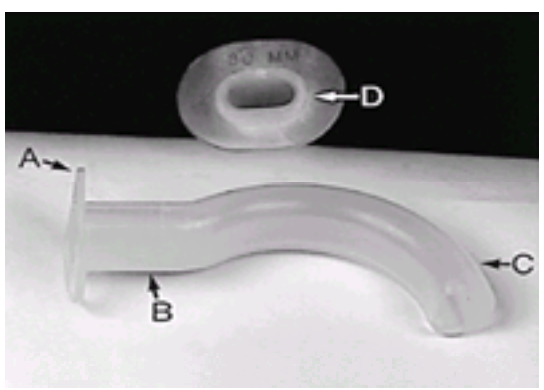

FIGURE 1.6. Oropharyngeal airway: flange *(A),* bite block *(B),* stent *(C),* and gas exchange or suction conduit *(D).*

The primary use of the airway is in the unconscious patient. The airway should be placed by using a wooden spatula or tongue depressor to press the tongue into the floor of the mouth. The airway is then passed so that the stent conforms to the contour of the tongue. If the oropharyngeal airway is not inserted properly, it may push the tongue backward into the posterior pharynx, aggravating or creating upper airway obstruction. If the airway is too long, it may touch the larynx and stimulate vomiting or laryngospasm.

Nasopharyngeal Airways

The purpose of nasopharyngeal airways is to stent the tongue from the posterior pharyngeal wall (Fig. 1.7). It may also be used to facilitate nasotracheal suctioning. The length of the nasopharyngeal airway is estimated by measuring the distance from the nares to the tragus of the ear. The outside diameter of the airway should not be so large that it produces sustained blanching of the skin of the ala nasae. The nasopharyngeal airway is inserted through the nares and passed along the floor of the nostril into the nasopharynx and oropharynx so that it rests between the tongue and the posterior pharyngeal wall. Nasopharyngeal airways may lacerate the vascular adenoidal tissue found in the nasopharynx of children. Therefore, adenoidal hypertrophy and bleeding diatheses are relative contraindications to the use of these airways.

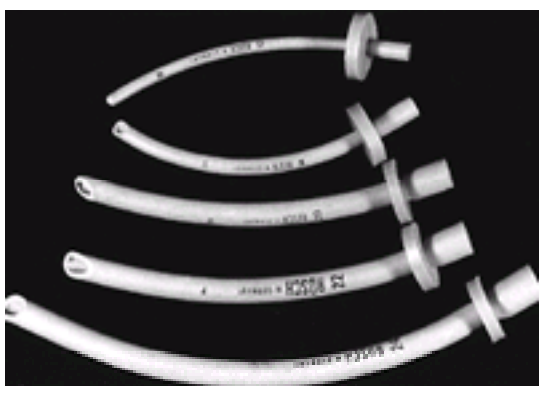

FIGURE 1.7. Nasopharyngeal airways in a variety of sizes.

Esophageal Obturator Airways

Esophageal obturator airways have not been designed or tested for use in children. Their use should be avoided.

Endotracheal Tubes

The purpose of the endotracheal (ET) tube (Fig. 1.8) is to supply a stable alternate airway. ET tubes are used to 1) overcome upper airway obstruction, 2) isolate the larynx from the pharynx, 3) allow mechanical aspiration of secretions from the tracheal bronchial tree, and 4) facilitate mechanical ventilation or end-expiratory pressure. The correct tube size can be approximated by using a simple formula based on the patient's age:

$$\text{Inside diameter (ID) in mm} = \frac{16 + \text{Age in years}}{4}$$

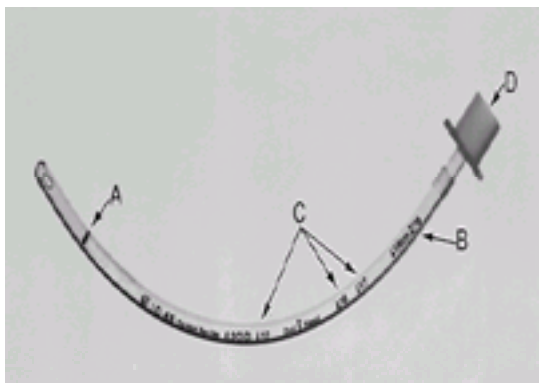

FIGURE 1.8. Oral tracheal tube: vocal card marker *(A),* manufacturer's indication that tube meets ANSI-Z79 subcommittee standards *(B),* distance in centimeters from tip of tube *(C),* and standard 15-mm connector *(D).*

Because this is an estimate, it is prudent to have the next smaller and larger size ET tube available. Estimation of tube size based on the size of the patient's fifth finger is not accurate. Tube size may also need to be modified based on the cause of the arrest (e.g., croup). In the pediatric patient, uncuffed tubes are used and are compatible with positive-pressure ventilation. This is because in children, there is a normal narrowing of the trachea at the level of the cricoid ring (Fig. 1.9). With proper tube selection, this narrowing serves as a functional seal. With patients 10 years of age and older, cuffed ET tubes should be used. By using a cuffed tube, one essentially adds 0.5 mm to the tube size.

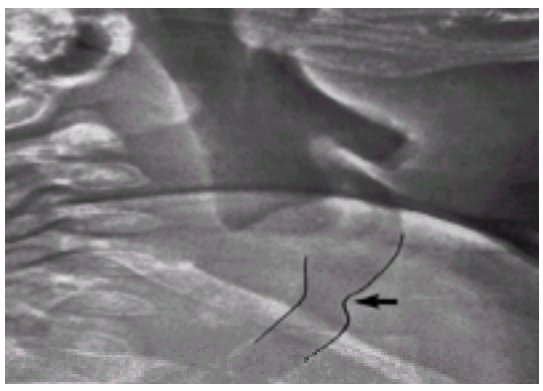

FIGURE 1.9. Lateral neck xeroradiograph showing narrowing at level of cricoid ring.

A variety of ET tubes are available. Tracheal tubes (Fig. 1.8) should be translucent to facilitate inspection of internal debris or occlusion, have a radiopaque tip marker, have the internal diameter noted proximally so that it is visible after intubation, have a distal vocal cord marker so that when the marker is placed at the level of the vocal cords the tip of the tube is in a midtracheal position, have centimeter markings along the course of the tube to be used as reference points for detecting tube movement, and meet the American National Standard Institute Z-79 guidelines for tracheal tubes and cuffs.

Other Techniques

Alternative airway management systems, including esophageal/tracheal tubes, laryngeal mask airways, and transtracheal ventilation systems, have all been used with adult patients with varying degrees of success. All of the methods have been approved by governmental agencies and professional societies, but their use in children has not been well tested or

researched. Thus, they remain as techniques worth consideration in a setting where standard methods have failed.

Laryngoscopy and Intubation (See Procedure in Section VII)

The purpose of laryngoscopy is to create a spatial plane through the mouth to the larynx through which an ET tube can be passed into the trachea. The laryngoscope consists of a blade and a handle. It is used to identify the glottis and to compress the intervening soft-tissue structures into the floor of the mouth. The three components of the laryngoscope blade are the spatula, the tip, and the flange (Fig. 1.10). The spatula may be curved or straight and is used to compress tissue. The tip of the blade is used for positioning the spatula so that an optimal compression of the mandibular block or soft tissue can be achieved. The purpose of the flange is to keep the tongue out of the way of the intubating channel. The laryngoscope is introduced into the mouth so that the tip of the blade slides down the right side of the tongue. As the tip of the blade follows the tongue posteriorly, it bumps into the anterior pillars of the tonsils. The tip is moved around the pillars of the tonsils until it bumps into the epiglottis. When using a curved spatula, the tip is placed in the vallecula, the space between the tongue and epiglottis. When using a straight spatula, the tip is placed under the epiglottis with the leading edge resting on the aryepiglottic folds. Once the tip is properly placed, the spatula is shifted from the right side of the mouth to the middle of the mouth. This left lateral movement of the spatula allows the flange to push the tongue ahead of it so that the tongue eventually occupies the middle third of the mouth. The right one-third of the mouth is then available as a channel through which the tracheal tube can pass. Once the tip of the blade is properly positioned and the flange has moved the tongue into the left corner of the mouth, the full surface of the spatula is used to compress the tongue into the floor of the mouth. With compression of the soft tissue of the mouth, the glottis should be exposed and the tracheal tube can be passed. The tracheal tube should be fitted with a stylet. The purpose of the stylet is to provide some degree of curvature to the tube for those circumstances where a totally straight channel cannot be achieved. The tracheal tube is passed through the glottis so that the ring marker near the tip of the tube is aligned with the vocal cords. If the tube selected is the proper size and the ring marker is placed directly at the vocal cords, the tip of the tube should be at a midtracheal position.

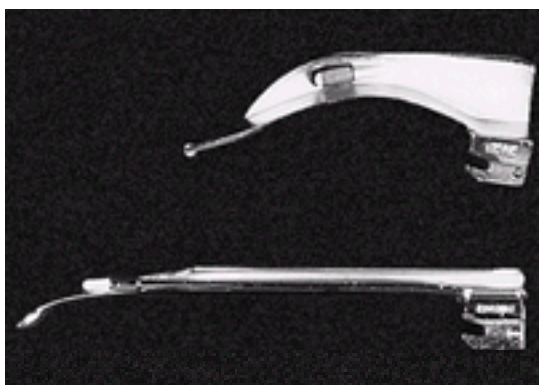

FIGURE 1.10. Laryngoscope blades—straight blade (Miller) and curved (MacIntosh).

Proper positioning of the tube is confirmed most accurately by end-tidal CO_2 monitoring (Fig. 1.11) and by auscultating for breath sounds and observing for symmetric chest movement. The child's small chest wall may transmit sounds widely and thus mislead the physician into thinking that positioning is correct. The physician should listen carefully. He or she should listen over the stomach and both axillas, and look for improved color of the patient. If breath sounds are not equal or end-tidal CO_2 monitoring is not available, the tube should be withdrawn slightly and the breath sounds and chest movement reevaluated. When circumstances allow, tube position should be confirmed with an anteroposterior (AP) chest roentgenogram. On the AP film, the tip of the tracheal tube should be at a T2 to T3 vertebral level or directly between the lower edges of the medial aspect of the clavicles (Fig. 1.12).

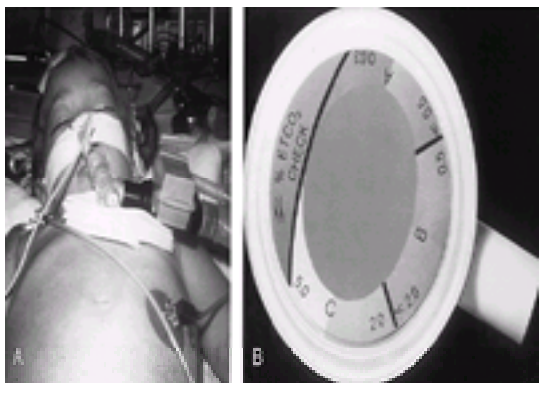

FIGURE 1.11. End-tidal CO_2 monitor. **A.** In-line on patient's endotracheal tube. **B.** Disposable-type monitor.

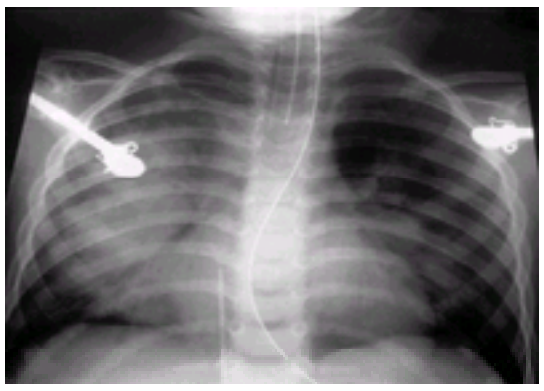

FIGURE 1.12. Chest radiograph showing proper endotracheal tube placement at T2 to T3 vertebral level.

Loss of an established airway is an unnecessary complication. The tracheal tube should be thoroughly secured with adhesive tape. The skin to which the adhesive tape is affixed should be cleansed, dried, and painted with tincture of benzoin (Fig. 1.11)

The management of airway obstruction is detailed in a separate section at the end of this chapter, and Chapter 5 covers other advanced aspects of airway management.

Breathing

Evaluation

When a clear and stable airway has been established, the patient should be reassessed. The physician should look, listen, and feel for evidence of gas exchange. In infants, adequacy of ventilation is assessed by observing free uniform expansion of the lower chest and upper abdomen. This is in contrast to older children and adolescents in whom one looks for uniform upper chest expansion as a sign of adequate ventilation. Gas exchanges should be confirmed by auscultation and by electronic monitoring of end-tidal CO_2 and pulse oximetry. First, the physician should listen over the trachea to establish quickly that gas exchange is occurring through the central airway. Then, he or she should listen to breath sounds bilaterally to assess for peripheral aeration and symmetric lung expansion.

Management

Spontaneous Ventilation

If the airway has been established and the patient is breathing spontaneously, supplemental oxygen should be administered. Although elimination of carbon dioxide is important, it is not nearly as important as delivery of oxygen. Children are quite resistant to the effects of severe hypercarbia and respiratory acidosis. They do not tolerate even short periods of oxygen deprivation.

Oxygen Delivery Devices

A variety of oxygen delivery devices are available for use in patients who have stable airways without ET tubes.

Nasal Cannulas. Nasal cannulas have two hollow plastic prongs that arise from a flexible hollow face piece. Humidified oxygen delivered through the hollow tubing is directed to the nostrils. One hundred percent oxygen is run through a bubbler into the cannula system at a flow of 4 to 6 L/minute. Because of oropharyngeal and nasopharyngeal entrainment of air, the final oxygen delivery is usually 30 to 40%. The advantages of cannulas are that they are easy to apply, lightweight, economical, and disposable. Inefficiency of the bubbler humidifier is compensated for by the fact that the normal humidification and warming systems of the upper airway are not bypassed. The use of this device presumes that the patient's oxygen needs can be met with substantially less than 100% oxygen. This method of oxygen delivery is best tolerated by the older child.

Oxygen Hoods. Oxygen hoods are clear plastic cylinders with removable lids (Fig. 1.13) or clear, soft, plastic tents just large enough to accommodate the infant's head. They are used for delivery of oxygen to infants and come in a variety of sizes. They usually have a gas inlet system for wide-bore tubing and a port for positioning the cylinder across the neck. Their purpose is to maintain a controlled environment for oxygen, humidity, and temperature. This can be done without producing a tight seal at the neck. Hoods are best used for newborns and infants. One can, without difficulty, deliver oxygen concentrations in the 80 to 90% range simply by increasing the oxygen flow to flood the canister. Another advantage is that the oxygen may be well humidified. Because of their potential for delivering concentrations of oxygen that may be toxic to the eyes or lungs of the infant, it is imperative to monitor both the fraction of inspired oxygen (FiO_2) and the PaO_2.

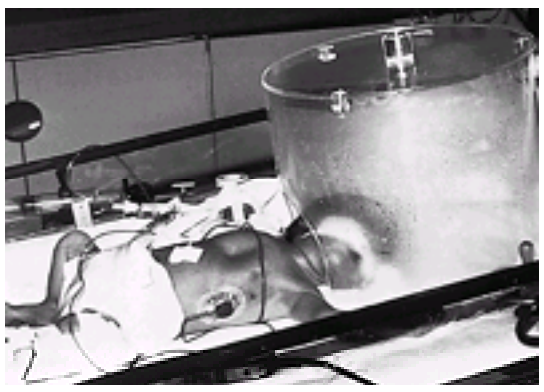

FIGURE 1.13. Infant oxygen hood. Oxygen hoods are clear plastic cylinders with removable lids or clear, soft, plastic tents just large enough to accommodate the infant's head.

Oxygen Tents. The basic purpose of the oxygen tent is to provide a controlled and stable environment for humidity, temperature, and oxygen. Tents are useful for delivery of oxygen between 21 and 50%. Oxygen concentration may be variable because of a poor seal and frequent entry. Therefore, a tight fit and only necessary entry should be allowed. Tents potentially impede access to the patient, and if mist is used, the patient may be hidden in a cloud which makes skin color difficult to evaluate.

Oxygen Masks. The most often used equipment for the spontaneously breathing patient is the oxygen mask. Several types of oxygen masks can be used to offer the patient a wide range of inspired oxygen concentrations. Masks seem to be better tolerated than nasal cannula by the young child, particularly when the mask is held by a calm parent or by emergency department personnel. There are several mask types from which to select. As with all equipment, even masks have associated hazards. In patients prone to vomit, the mask can block the flow of vomitus and increase the risk of aspiration. The obtunded patient wearing a mask must always be observed.

Simple Masks. The purpose of the simple face mask is to deliver a moderate concentration of oxygen. These masks are lightweight and inexpensive. They should be clear to allow observation of the child's color. They can be used in a loose-fitting fashion and are relatively comfortable. If the flow of oxygen is inadvertently disrupted, the child can breathe through side ports. A minimal flow of oxygen is necessary to flush potential dead space. This type of oxygen delivery device does not bypass the upper airway mechanisms for warming and humidification of inspired gas. The disadvantages of the simple mask lie in the fact that it is difficult to provide a known and stable Fi O_2. The FiO_2 will vary with the inspiratory flow rate of the patient and with the oxygen flow into the system. The actual pharyngeal Fi O_2 may be difficult to predict or measure.

Partial Rebreathing Masks. Partial rebreathing masks allow delivery of a higher oxygen concentration than simple masks do. They are also helpful in conserving oxygen. This system is a combined face mask and reservoir bag. When the flow rate into the bag is greater than the patient's minute ventilation and when the oxygen is adjusted so that the bag does not collapse during inhalation, there is negligible CO_2 rebreathing. Partial rebreathing masks are usually used for midrange oxygen delivery. We use one when we are trying to maintain an Fi O_2 between 35 and 60%.

Nonrebreathing Masks. Nonrebreathing masks are combined face mask and reservoir bag devices that have nonrebreathing valves incorporated into the face mask. They are useful for giving oxygen concentrations up to 100%.

Assisted Ventilation

If the airway has been established and the child is not breathing spontaneously or gas exchange is not adequate, artificial ventilation should be started. The recommended rates for rescue breathing in infants and children are shown in Table 1.5. Rates may need modification based on the etiology of the child's arrest (e.g., treatment of ICP may require a faster rate)

If adjuncts for mechanical ventilatory support are not available, an expired air technique may be used. Patient size, type of available airway, and trial will determine which type should be used. Because of risk of human immunodeficiency virus (HIV) transmission, mouth-to-mouth resuscitation is no longer recommended. Instead, rescue breathing should be done with a pocket mask that contains an appropriate millipore filter (Fig. 1.14). Placement of the mask over the mouth alone, over the mouth and nose, or over a tracheostomy site depends on the patient and the equipment available (Fig. 1.14). See Chapter 127 for care of the patient with tracheostomy.

Expired Air Techniques

Hand-Squeezed, Self-Inflating Resuscitators. Hand-squeezed, self-inflating resuscitators are the most commonly used resuscitators for infants and children. The elasticity of a self-inflating bag allows the bag to refill independently of gas flow. This feature makes the self-inflating bag easy to use for the inexperienced operator. Many of the self-inflating bags are equipped with a pressure-limiting pop-off valve that is usually preset at 30 to 35 cm H_2O to prevent delivery of high pressures. Self-inflating bags that are not pressure-limited should have a manometer in line. For gas to flow, the bag must be squeezed. Thus, for the patient who is breathing spontaneously, the operator must time the bag compressions to the patient's efforts. These resuscitators should be adapted to deliver high concentrations of oxygen. In most cases, this involves using an oxygen reservoir adaptation with the unit (Fig. 1.15). Recent research has shown that even with an attached reservoir, only oxygen concentrations of 60 to 90% were obtainable. Units without oxygen reservoir adaptations often deliver low concentrations of supplemental oxygen and therefore should be avoided.

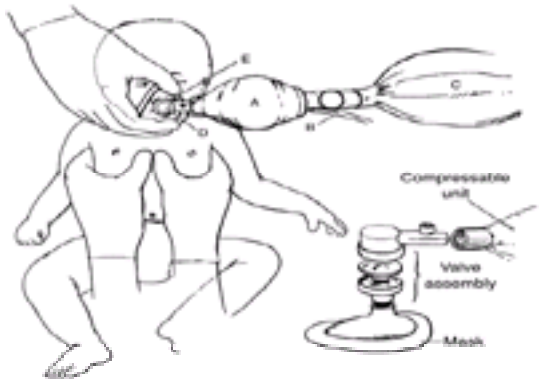

FIGURE 1.15. Self-inflating hand-powered resuscitator: compressible unit *(A),* oxygen source *(B),* oxygen reservoir *(C),* one-way valve assembly *(D),* and mask with transparent body *(E).*

The resuscitator may be used with a mask. When selecting a family of mask sizes, select a mask type that seals a variety of facial contours. Also, the body of the mask should be sufficiently transparent so that vomitus can be recognized easily through the mask. Masks with a pneumatic cuff design allow for easiest and most efficient fit to avoid air leaks around the mask. Resuscitators, masks, and ET tubes should be standardized so that any resuscitator can connect with any mask or ET tube.

Anesthesia Bags. Anesthesia bags depend on an adequate gas flow to maintain a compressible unit that propels gas toward the patient (Fig. 1.16). An exit port must also be present so that the bag does not become a carbon dioxide reservoir. When used with an oxygen blender, any desired concentration of oxygen may be provided for the patient because this system delivers directly the gas flowing into it. When used correctly, this device allows 100% oxygen to be delivered as well as maintaining end-expiratory pressure. However, the major disadvantage of this type of bag is that considerable experience is needed to use it effectively, which has prompted some to recommend the use of the self-inflating bag as the primary mode of ventilation. One must be able to judge accurately the rate of gas flow into the bag and the rate of gas escape from the exit port so that underfilling or overfilling does not occur. If the bag is removed from a leak-tight patient application, it promptly deflates and one must wait for the reservoir to refill. Overfilling the bag is dangerous because high pressures can be transmitted to the lung and stomach (Fig. 1.17).

FIGURE 1.16. Family of clear plastic, air-filled collar facial masks.

FIGURE 1.17. Anesthesia bag in use.

Mechanical Ventilators. The emergency department should be equipped with a mechanical ventilator as well. This is important in the event that the resuscitation is successful for maintenance of ventilation while the patient awaits transfer or transport to a critical care unit. A mechanical ventilator is also crucial in the event of multiple arrest victims in order to free personnel for other vital tasks.

Circulation

As with the other components of CPR, the circulation must be first assessed and then managed.

Evaluation

Once the airway has been opened and gas exchange ensured, the physician must evaluate the effectiveness of circulation by 1) observing skin and mucous membrane color and 2) palpating a peripheral pulse and checking capillary refill. If the patient's color is ashen or cyanotic, the circulation will need to be treated.

The palpation of a peripheral pulse and assessment of capillary refill is mandatory. Often, ineffective cardiac activity can be palpated over the child's thin chest wall. Thus, the presence of an apical pulse may not be meaningful. The palpation of a strong femoral or brachial pulse (Fig. 1.18) indicates presumptively that the cardiac output is adequate. Capillary refill should be assessed repeatedly (Fig. 1.19).

FIGURE 1.18. Palpation of brachial pulse on medial aspect of the upper arm in the subbicep groove.

FIGURE 1.19. Delayed capillary refill.

Most modern defibrillators have a “quick-look” paddle configuration that allows a rapid evaluation of cardiac rhythm to be made by placing the defibrillation paddles on the chest and using them as monitoring electrodes.

The resuscitation team will also find it helpful to have continuous blood pressure monitoring. Blood pressure measurements will help quantify the effectiveness of cardiac function. An ultrasound or portable Doppler device may be

necessary to detect systolic pressure at low levels in small infants (Fig. 1.20).

FIGURE 1.20. Portable Doppler device for determining blood pressure during resuscitation.

As soon as possible, the team will also require continuous electrocardiogram (ECG) monitoring to assess the development of arrhythmia as the resuscitation proceeds.

Management

Management may be divided into five phases: 1) cardiac compression, 2) establishment of an intravascular route, 3) use of primary drugs, 4) use of secondary drugs, and 5) defibrillation.

Cardiac Compression

Absence of a peripheral pulse requires immediate institution of cardiac compression (CC) to establish at least a minimum circulation to the brain. ECC has the advantage of immediate applicability. The technique of ECC is also widely known and can be applied in almost any setting. However, several recent reports have pointed to the potential advantages of open cardiac compression (OCC). This technique is obviously more difficult to apply. OCC may produce better coronary and cerebral perfusion pressures. Survival rates may also be higher in studies comparing OCC with ECC. The role of OCC may become more important as future studies evolve. For now, OCC is indicated primarily in the selected traumatized patient (see Chapter 104 and Chapter 107).

The mechanism by which blood moves during ECC has been the subject of ongoing investigation. The traditional view assumes that chest compressions move blood by direct CC. Therefore, it was believed to be important to compress directly over the ventricles that were believed to be located under the middle one-third of a child's sternum. However, another model suggests that the movement of blood is caused by an increased intrathoracic pressure and expulsion of blood from the lungs through the left heart, and simultaneous openings of both the mitral and aortic valves. This proposed thoracic pump mechanism quiets the controversy concerning the relative position of the child's heart within the thorax and its relation to the sternum. The intrathoracic pressure pump model for the production of blood flow has sparked the investigation of several alternative methods for achieving flow. Probably both models of ECC-produced blood flow play a part in the actual mechanism in children.

For now, we continue to recommend that compression be applied evenly over the midsternum of the child. This standard technique has proved effective. Compression over the lower one-third of the sternum should be avoided because of a potential risk of liver trauma.

The midsternal location for ECC can be found by spanning the sternum between the thumb and fifth finger and then measuring or judging the midpoint. Another method used in locating the midsternum is to find the point where the transnipple line intersects the sternum. Finger or hand position should be just caudal (toward the feet) to the transnipple line.

The depth and rate of compression are based on the child's age. Suggested rates and depths are shown in Table 1.7. Compression should be smooth, continuous, and uninterrupted. The compression phase should consume 60% of the time for the compression–release cycle. Jabby, jerky, brief compressions may produce pressure pulses of adequate amplitude on a monitor, but blood flow will be inadequate for cerebral perfusion.

	Infant	Child	Adult[a]
Compression (rate/min)	100	80	60
Depth of compression (inches)	0.5–1	1–1.5	1.5–2
Ventilation (rate/min)	20	16	12

[a]Two-person rescue.

Table 1.7. Ventilation/Compression Schedule for Pediatric Resuscitation

Because the child has a relatively large occiput, neck extension may elevate the shoulders and upper thorax off of the firm resuscitation surface. The resultant wedge-shaped dead space beneath the upper thorax may absorb the force of compression (Fig. 1.21A). The dead space must be filled with a firm substance so that the work of compression will not be lost. A firm towel or the rescuer's hand should be placed beneath the upper thoracic spine (Fig. 1.21B). Compressions may then be applied with one or two fingers in the infant or with one hand in the older child. When using the technique developed by Thaler, the rescuer links his or her fingers beneath the thoracic spine and compresses with the thumbs (Fig. 1.22). This method is comfortable when using external cardiac compression on a newborn patient. With older children, an effort should be made not to allow the encircling hands to limit the respiratory movements of the thorax.

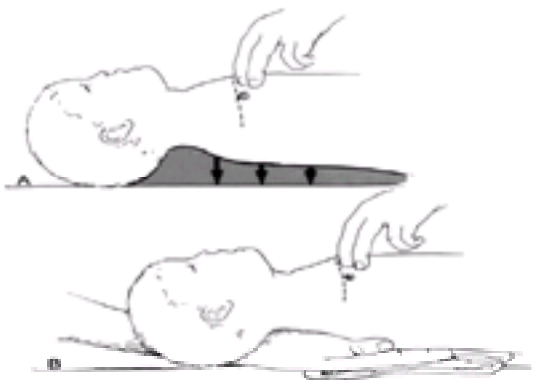

FIGURE 1.21. Thoracic cage support for external cardiac compression. **A.** Dead space created by prominent occiput. **B.** Hand providing thoracic support.

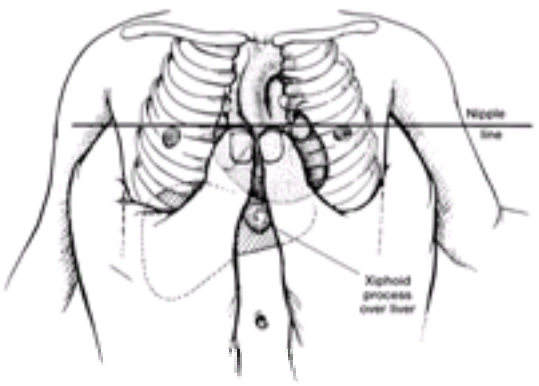

FIGURE 1.22. External cardiac compression—Thaler technique for infants.

Mechanical chest compressors should not be used for children. There is insufficient information about their effectiveness or safety for this patient population.

Intravenous Lines

The placement of an intravenous line is often the most difficult and time-consuming aspect of pediatric life support. The resuscitation team should have a set protocol for the attainment of intravenous access (an example is shown in Table 1.8). This protocol should outline which personnel should attempt which form of access for a finite period as well as when to move on to more advanced forms of access. When possible, a short, large-gauge intravenous line should be obtained. Peripheral sites are an acceptable choice and may be readily available. Central lines are useful for getting drugs and a large volume of fluids into the central circulation. Intraosseous (into the bone) infusion is an old technique that has been revived and widely promulgated (Fig. 1.23). The technique is explained in Appendix D, Section VII. Spivey et al. have shown it to be an excellent route for fluid and drug administration. While waiting for an intravenous line to be secured, some drugs may be given through the ET tube as they are absorbed at an alveolar level and circulated rapidly, the drugs should be administered through a small-gauge catheter which is inserted through the ET tube into the distal trachea or one of the mainstream bronchi and followed by several positive pressure ventilations. Table 1.9 lists the drugs that may be given through this route.

1. First 1.5 min Peripheral IV catheter, two sites 2. 1.5-5 min a. If intubated: Give drugs via endotracheal tube (including epinephrine/atropine/lidocaine) b. If not intubated: Intracsseous—one site Continued peripheral IV—one site 3. Longer than 5 min a. Femoral vein percutaneous b. External/internal jugular percutaneous c. Subclavian vein percutaneous d. Saphenous vein cutdown

Lidocaine

Table 1.9. Resuscitation Drugs That May Be Given Intratracheally

FIGURE 1.23. A and B. Intraosseous needle being placed in proximal tibia.

When using IV ET route, the physician should dilute the medications with normal saline to a volume of 3 to 5 mL lest they remain on the tube surface and fail to reach the lung.

Intravenous cutdown over the saphenous vein is another acceptable method but seems to be time-consuming in even experienced hands. Intracardiac administration of drugs is dangerous and should be avoided. In the circumstance of CPR, the cannulation of the subclavian vessel may also be difficult and associated with pneumothorax and hemothorax.

Three vessels that are easily cannulated and give access to the central circulation are the femoral, internal jugular, and external jugular veins. Our vein of first choice is the femoral because its cannulation does not interfere with ongoing CPR. The femoral vein is located by palpating the femoral artery pulsation and moving just medial to it. If good external cardiac compression is being accomplished, the pulsation should be present. When the pulse is not palpable, the physician should find the midpoint between the symphysis pubis and the anterior superior iliac spine on the plane of the inguinal ligament. The vein should be approached at a 45-degree angle to the skin 2 to 3 cm below the inguinal ligament at the defined midpoint. The needle must not pass cephalad to the inguinal ligament because it may enter the peritoneal cavity and pierce the bowel (see Appendix D, Section VII)

The internal jugular is best approached by finding the triangle created by the medial one-third of the clavicle and the two heads of the sternocleidomastoid muscle—the sternum and clavicular. The internal jugular vein courses within the triangle. The physician should puncture the skin at the apex of the triangle and direct the needle toward the ipsilateral nipple at a 45-degree angle to the frontal plane. The external jugular vein is located by placing the child in a 20-degree head-down position. With the patient at this angle, the vein will fill and be seen as it courses over the midportion of the sternocleidomastoid muscle (see Appendix D, Section VII)

In cannulating either the femoral or internal jugular vein, the Seldinger technique is recommended (see Appendix D, Section VII). This method uses a 20- to 22-gauge, short-beveled, thin-walled needle for the small child. Larger needles should be used for older children. The needle is attached to a syringe, and the vein is punctured and aspirated so that free blood flow into the syringe is seen. The syringe is then removed, and blood is sent for appropriate laboratory studies.

A braided wire is introduced through the needle and positioned in the lumen of the vein. The needle is withdrawn over the free end of the wire. Next, a flexible Teflon catheter is passed over the wire and into the vein. Finally, the wire is removed from the lumen of the catheter, and the catheter is secured with suture. Although this technique requires several steps, it represents a safe and effective way to secure an intravenous line. It allows a small initial puncture to result in the placement of a larger-bore catheter. It is particularly useful for the femoral and internal jugular veins.

If the Seldinger technique is unsuccessful, an acceptable alternative is to cut down over the lesser saphenous vein just above the anterior and the medial malleolus (see Appendix D, Section VII). In extreme circumstances, cut down over the femoral vein may be attempted. This technique is more difficult and fraught with more complications. Remember also that in newborns during the first 2 weeks, it may be easy to cannulate the umbilical vein (see Appendix D, Section VII).

Primary Drugs

The primary drugs for advanced life support are oxygen, epinephrine, sodium bicarbonate, atropine, and glucose (Table 1.10). Each agent has specific actions, indications, dosages, and untoward effects. The primary drugs are those that are used first in the resuscitation. Our recommended drug dosages are based on kilograms of body weight. The resuscitation team must be able to determine the weight of the child accurately. If estimates prove too difficult, a standardized growth curve should be posted in the resuscitation area so that the 50th percentile weight for the child's age may be used. Another method for establishing the correct dosage schedule has been proposed by Broselow in the invention of the Broselow Tape. This method bases dosage on the patient's length, which is determined by placing the tape along side the child in the supine position (Fig. 1.24A). An appropriate drug dosage schedule has been printed on the tape (Fig. 1.24B) at intervals. Using this method eliminates the estimation of patient weights and the need to cross-reference to a drug dosage chart or to memorize the dosage schedule. If the pediatric drug dosage schedule is not used often, it is advisable to prominently display the schedule on the emergency department wall.

Epinephrine	10–200 μg/kg IV or IT
Sodium bicarbonate	1 mEq/kg IV
Atropine	0.02 mg/kg IV or IT (min 0.2 mg)
Glucose	0.5–1.0 g/kg IV

Table 1.10. Primary Life Support Drugs and Dosages

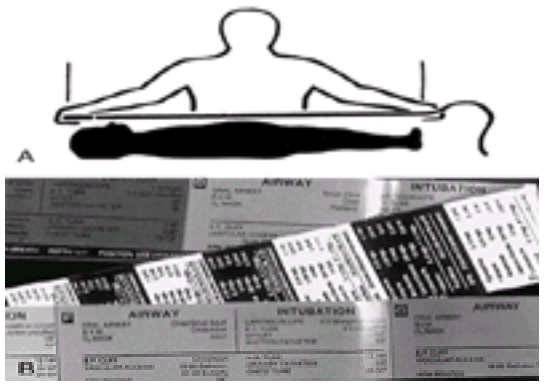

FIGURE 1.24. Broselow Tape for determining drug dosage schedule based on patient length. **A.** Placement of tape. **B.** Equipment size and drug dosage schedule printed on tape.

Oxygen. In the patient in cardiac arrest, there are many factors that contribute to the pathophysiologic disruption of oxygen delivery (i.e., hypoxemia). A fundamental goal of basic and advanced life support is to correct cerebral and myocardial hypoxia before irreversible injury occurs.

Oxygen is indicated for any patient who is having decreased oxygen delivery to the tissues, whether this is due to 1) pulmonary abnormality such as decreased air exchange, intrapulmonary shunting, or ventilation-perfusion abnormality; 2) cardiac dysfunction such as decreased stroke volume or arrhythmia; or 3) oxygen-carrying abnormalities such as low hemoglobin states, methemoglobinemia, or carbon monoxide poisoning. Any patient who is even suspected to be hypoxemic should be given oxygen.

During resuscitation, the initial dosage of oxygen for the patient needing oxygen is 100%. The potential negative effects of high oxygen concentration are not a consideration in the life-or-death setting of CPR.

The physician should be familiar with the different oxygen delivery systems mentioned in the sections on airway and breathing. Oxygen concentrations delivered by mouth-to-mask breathing vary from 17 to 21%. Bag-valve-mask devices deliver 21%. When an oxygen source is attached, bag-valve-mask devices may deliver 30 to 60%, and when a reservoir

is added, 70 to 90% may be achieved. An anesthesia bag may deliver 100%. Oxygen should be ordered like other drugs. The order should clearly specify the dose, mechanism, and duration of treatment.

Epinephrine. Despite the development of many new exogenous catecholamines, epinephrine remains the essential cardiac stimulant. Epinephrine actions include a- and b-adrenergic stimulation. The primary a effect is vasoconstriction and a resultant increase in systolic and diastolic blood pressure. The b-adrenergic action of the drug is also beneficial in producing an increased inotropic (contractile force) and chronotropic (cardiac rate) effect. In addition, the b effect produces vasodilation of the coronary and cerebral vasculature. All of these actions are beneficial to the resuscitative effort.

Indications for the use of epinephrine include asystole, symptomatic bradycardia, and hypotension not related to volume depletion. Epinephrine is also used to try to change a fine fibrillation pattern to a coarse one before a defibrillation attempt. There is belief that a coarse fibrillation pattern is more easily converted.

The recommended initial dose of epinephrine for asystole or electromechanical dissociation is 10 µg/kg intravenously (IV). Recently, several investigators have looked at the scientific basis for current epinephrine dose recommendations and have used doses 10 to 20 times greater (i.e., 0.1 to 0.2 mg/kg). Thus far, higher-dose therapy with epinephrine (HDE) has not been proved to be of greater efficacy. In the experimental situations in which it has been used, it has resulted in no adverse effects. We continue to support a dose-response method of epinephrine administration. We initiate therapy with the currently recommended dose (0.01 mg/kg). Subsequent doses are given by a dose-response method of titration. With this method, the second dose is increased tenfold to 0.1 mg/kg, and the physician observes the patient for the desired response. If an inadequate response occurs, the dose should be doubled to 0.2 mg/kg. In the absence of underlying cardiovascular disease, this is a safe and effective approach. The dose of epinephrine for hypotension is 1 µg/kg IV. An epinephrine infusion may be prepared by adding 6 mg of epinephrine to 100 mL of 5% dextrose in water (D5W). This creates a solution that has 60 µg/mL. When this solution is infused at 1 mL/kg per hour, the patient receives a dose of 1 µg/kg per minute. If an intravenous or intraosseous line has not been established, epinephrine can be given endotracheally. The dose and concentration of the drug (1:10,000) should be the same. The drug is instilled past the tracheal tube via a smaller-gauge catheter and is followed by several positive-pressure ventilations.

Epinephrine is a relatively safe drug, and few untoward effects are seen in pediatric patients. Ischemia of the myocardium rarely occurs and has not been reported even with high-dose epinephrine. There is the hazard of producing supraventricular or ventricular tachycardia, premature ventricular contractions, or ventricular fibrillation. When possible, the physician should avoid intracardiac injection of epinephrine because this route is associated with greater risk and complications. As previously noted, mixing bicarbonate with epinephrine inactivates the epinephrine.

Sodium Bicarbonate. With the onset of respiratory failure, the patient develops respiratory acidosis. Rising levels of carbon dioxide in the blood produce a fall in pH. The immediate treatment for this type of acidosis is adequate ventilation. As the patient's circulation begins to fail, there is production of lactic acid and a metabolic acidosis. Sodium bicarbonate corrects the metabolic acidosis by combining with hydrogen to form carbon dioxide and water. This additional production of carbon dioxide must also be eliminated through ventilation.

Metabolic acidosis is a harmful byproduct of the arrest because acidosis further impairs cardiac and circulatory function. Acidosis depresses spontaneous cardiac activity, decreases the contractile force of the ventricle, and predisposes the patient to ventricular fibrillation. In addition, catecholamines such as epinephrine will be less effective in a patient whose metabolic acidosis is uncorrected.

It is not necessary to prove a diagnosis of metabolic acidosis before beginning the first steps in treatment. Sodium bicarbonate is also indicated for the correction of suspected metabolic acidosis. This includes any patient who has arrested for more than a few minutes.

For the patient whose arrest was not witnessed, the initial dose of sodium bicarbonate is 1 mEq/kg IV. This should be given as full-strength bicarbonate (1.0 mEq/mL) for children more than 6 months of age. For infants less than 6 months of age, we recommend that the same dose be given, but in the form of half-strength bicarbonate (0.5 mEq/mL) to lessen the osmotic load of the drug.

After the initial dose of bicarbonate, subsequent doses are best determined by measuring arterial pH and calculating the dosage using the base deficit.

The factor of 0.4 represents the bicarbonate distribution space, which is 40% of the total body weight. The formula divides the dose by 2 to prevent overcorrection with bicarbonate and produce alkalemia. If blood gas analysis is impossible, doses of 0.5 mEq/kg may be administered every 10 to 15 minutes.

Untoward effects of bicarbonate include alkalosis, hypernatremia, and hyperosmolar states. Each of these effects are significant and can in themselves lessen survival. In the context of inadequate ventilation, bicarbonate administration may result in rapid increase in P_{CO_2} levels. Because carbon dioxide is readily permeable across cell membranes and sodium bicarbonate is not, rapid elevation in carbon dioxide can exacerbate intracellular acidosis. This intracellular acidosis depresses myocardial function in animal studies. Hypernatremia and hyperosmolar states are most easily produced in the young infant. Alkalosis is tolerated poorly by the body. Thus, it is important to determine the exact need for bicarbonate as quickly as possible. Bicarbonate administration must always be secondary to the establishment of an airway and ventilations that are important for correcting the acidosis of respiratory origin.

There are other potential untoward effects of bicarbonate: the precipitation of bicarbonate and calcium in the intravenous line and the inactivation of catecholamines. To avoid these two problems, we discourage the addition of bicarbonate to intravenous fluid reservoirs during the resuscitation. Bicarbonate should be given by direct intravenous administration

and followed with a saline flush solution before giving subsequent medication, such as calcium or epinephrine. ET administration of bicarbonate can be hazardous. Bicarbonate is irritating to the airways, destroys lung surfactant, and can produce massive atelectasis. Also, the large volume of bicarbonate usually required will virtually drown the patient.

Atropine. The actions of atropine are parasympatholytic. Atropine has both peripheral and central effects. The peripheral effect is vagolytic and thus increases heart rate by increasing the rate of discharge from the sinoatrial node, while increasing conduction through the atrioventricular node. The central effect of atropine is to stimulate the medullary vagal nucleus and is produced with low dosage of the drug. The actions are opposite to those desired for resuscitation therapy.

The indication for atropine is bradycardia associated with hypotension, premature ventricular ectopic beats, or symptoms of poor CNS or myocardial perfusion. Atropine may be used for second- or third-degree heart block, although its actions may be only temporary for these arrhythmias.

The dose of atropine is 0.02 mg/kg IV. There is a minimum dose of 0.10 mg repeated every 5 to 10 minutes to a maximum total dose of 1.0 mg in a child and in an adolescent. Atropine may be given intratracheally if an intravenous route is not available.

The untoward reactions associated with atropine include paradoxical bradycardia, atrial and ventricular tachyarrhythmias, and myocardial ischemia. Paradoxical bradycardia is caused by the central action of atropine. This side effect can be avoided by using at least 0.2 mg for any patient being treated with atropine. Tachyarrhythmias occur but are not usually hemodynamically significant in the pediatric patient. Myocardial ischemia is rare in the absence of existing cardiac disease.

Glucose. The action of glucose is to correct hypoglycemia. Glucose should be considered a primary drug. Infants have minimal glycogen stores for rapid conversion to glucose. Moreover, many infants may have had decreased caloric intake and excessive losses (diarrhea and vomiting) in the days before the arrest.

The dose of glucose is 0.5 to 1.0 g/kg IV. Either a 10% or a 25% solution may be used except in the neonatal period when 10% glucose is indicated. Doses of glucose should be based on a rapid serum glucose determination.

Untoward effects include hyperglycemia and hyperosmolality, but these should not occur if the initial dose of glucose is based on a documented need. Some studies have found a correlation between mortality and high serum glucose levels in pediatric head trauma patients.

Secondary Drugs

A number of useful second line drugs should be available in the emergency department for resuscitations. These secondary drugs are listed in Table 1.11.

Drug	Initial	Subsequent
Lidocaine	1 mg/kg IV or IT	10-20 µg/kg/min IV
Bretylium	5 mg/kg IV	10 mg/kg IV
Adenosine	0.1 mg/kg IV bolus	0.2 mg/kg IV
Dopamine	10 µg/kg/min IV	
Isoproterenol	0.1 µg/kg/min IV	
Calcium chloride	10-20 mg/kg/min IV	
Calcium gluconate	30 mg/kg IV	
Furosemide	1 mg/kg IV	2 mg/kg IV
Naloxone	1 mg child/2 mg adolescent	Repeat
Methylprednisolone	30 mg/kg IV	
Dexamethasone	1 mg/kg IV	
Difibrillation current	2 watt-sec/kg	4 watt-sec/kg

Table 1.11. Secondary Useful Life Support Drugs

Lidocaine. Lidocaine works by reducing the automaticity of ventricular pacemakers. Thus, it increases the fibrillation threshold. Ventricular fibrillation is a relatively uncommon event in pediatric resuscitations. However, when it occurs, lidocaine is the drug of choice. The initial dose is 1 mg/kg IV. This dose may be repeated three times at 5-minute intervals. Once the initial bolus has been given, an infusion of lidocaine 20 to 50 µg/kg per minute should be initiated (Table 1.12). If an intravenous line cannot be established, the initial dose of lidocaine may be administered by the tracheal route.

Drug	Add to D5W to Make 100 mL	Infuse	Dosage Delivers
Lidocaine	120 mg (3 mL)	1 mL/kg/hr	20 µg/kg/min
Dopamine	60 mg (1.5 mL)	1 mL/kg/hr	10 µg/kg/min
Epinephrine	6 mg (6 mL)	1 mL/kg/hr	1 µg/kg/min
Isoproterenol	0.6 mg (3 mL)	1 mL/kg/hr	0.1 µg/kg/min

Table 1.12. Drugs for Intravenous Infusion

The adverse reactions of lidocaine include nausea, vomiting, lethargy, paresthesias, tinnitus, disorientation, and seizures. CNS symptoms may be the first to appear. Later, symptoms of cardiac toxicity may appear, including depression of myocardial contractility and ventricular irritability. Heart block and eventual drug-induced asystole may occur. The metabolism of lidocaine depends on normal liver function. Thus, the dose must be modified for children with chronic congestive heart failure, hepatitis, or cirrhosis.

Bretylium. A second line drug for ventricular tachycardia or ventricular fibrillation is bretylium. The mechanism of action of bretylium has not been elucidated fully. It has been noted to have a positive inotropic effect in addition to its antiarrhythmic action.

The initial dose of bretylium is 5 mg/kg IV given rapidly. Then defibrillation is attempted. If defibrillation is not successful, repeat bretylium at 10 mg/kg IV and repeat the defibrillation attempt.

The most common untoward effect of bretylium is hypotension. The patient should be placed in a Trendelenburg position, and the physician should be prepared to support the blood pressure with the administration of fluids. Bretylium is contraindicated in patients with a digitalis-induced arrhythmia. The resuscitation team should be prepared to deal with the side effect of drug-induced vomiting.

Adenosine. Adenosine is an endogenous purine nucleoside. It was first noted to have an effect on cardiac condition in the early part of the 20th century. In the mid-1950s, it was first successfully used for treatment of supraventricular tachycardia (SVT). Adenosine seems to exert a strong but brief depressant effect on the sinus and atrioventricular (AV) nodes, resulting in slowed conduction and interruption of the reentry pathway. The indication for the use of adenosine is SVT with hemodynamic compromise. Other treatments for stable SVT are outlined in Chapter 82

The dose of adenosine is 0.1 to 0.2 mg/kg (maximum dose is 12 mg). The half-life of the drug is estimated to be less than 10 seconds. If an initial lower dose is chosen and is unsuccessful, the dose may be doubled and repeated. The agent must be given in an intravenous bolus.

The untoward effects of adenosine are flushing and dyspnea, but these are short lived. In patients with “sick sinus syndrome,” long sinus pauses may occur. Adenosine has been used successfully in infants and children of all ages.

Dopamine. Dopamine is a precursor of epinephrine. It acts on both a- and b-adrenergic receptors. Dopamine has a unique “dopaminergic” effect that increases blood flow to renal and mesenteric blood vessels. The dopaminergic effect occurs over the low-dose range, 2 to 10 µ/kg per minute. The cardiac actions of dopamine are similar to those of epinephrine and include a positive inotropic and chronotropic effect. There is also an increase in peripheral vascular resistance, which causes an increase in blood pressure at moderate dosages, 5 to 20 µ/kg per minute (Table 1.12). At high dosages, greater than 20 µ/kg per minute, there is a marked increase in peripheral vascular resistance and a decrease in the renal and mesenteric blood flow.

Dopamine is indicated for the patient with hypotension and inadequate renal perfusion. The dosage of dopamine is 10 µg/kg per minute, which is within the range for desired cardiac action. The standard infusion may be made by mixing 60 mg of dopamine in 100 mL of D5W. This solution is infused at 1 µ, 1/kg per hour. Thus, the rate in milliliters per hour is equal to the patient's body weight (e.g., in a 20-kg patient, the solution is infused at a rate of 20 mL/hour) (Table 1.12). This simple method is appropriate for emergency department use because minimal calculation is required. When the patient reaches an inpatient critical care unit, an infusion better suited for precision drug titration can be prepared. Dopamine may produce tachyarrhythmias as an untoward reaction. Ectopic cardiac beats, nausea, and vomiting may occur. Myocardial ischemia is a rare event in children. The drug must be used with careful monitoring. Rapid increases or decreases in the dosage must be avoided. At low dosages, the dopaminergic effect may result in hypotension that must be supported with intravascular volume expansion. Extravasation of the drug into subcutaneous tissue may cause tissue necrosis. Thus, it should be given through a central line when possible. As with other catecholamines, dopamine should not be mixed with bicarbonate because this will inactivate the drug.

Isoproterenol. Isoproterenol is a synthetic catecholamine. The action of this drug is almost entirely through b-adrenergic receptors. The effects on the cardiovascular system are due to an increase in heart rate, an increased contractile force, and an increase in venous return to the heart. Unlike epinephrine, isoproterenol produces peripheral arterial dilation. Despite the decrease in vascular resistance, the drug usually produces an increase in blood pressure due to increased cardiac output.

Isoproterenol can be used for bradyarrhythmias that are not responsive to atropine. Heart block, sinus bradycardia, or nodal bradycardia may be treated while the more definitive therapy of electrical pacing is arranged.

The dose of isoproterenol is variable. A simple infusion can be prepared by adding 0.6 mg of isoproterenol to 100 mL of D5W. Infusing the solution at 1 µg/kg per hour will deliver 0.1 µg/kg per minute (Table 1.12)

The adverse reactions of isoproterenol include tachyarrhythmias and myocardial ischemia. It should be used with extreme caution in children receiving digitalis. In dehydrated or hypovolemic patients, isoproterenol may produce or aggravate existing hypotension. Thus, the physician must be prepared to support a further drop in blood pressure with

intravascular volume repletion.

Calcium. The actions of calcium are to increase myocardial contractibility, increase ventricular excitability, and increase conduction velocity through the ventricular muscle. There is currently a trend against the use of calcium in CPR because of possible cytotoxic effects, but for pediatric patients, the positive cardiac stimulant effects require that it remain on the list of secondary drugs.

The indications for calcium include asystole and electromechanical dissociation, but there is no good scientific support for this. Further indications include documented hypocalcemia, hyperkalemia, hypermagnesemia, and calcium channel blocker overdose.

The dose of calcium depends on the form of calcium used. Calcium chloride should be given as 10 to 20 mg/kg IV (to deliver 3 to 5 mg/kg of elemental calcium). In the chloride form, calcium should be given only through a central venous line. Calcium gluconate has properties that make the calcium ion less available. Thus, the dose is 30 mg/kg IV. Calcium gluconate may be given through a peripheral vein. When giving either form of calcium, the physician should infuse it slowly while watching the cardiac monitor for the appearance of bradycardia. The initial dose of calcium may be repeated once. However, subsequent doses should be guided by a serum ionized calcium level.

The untoward effects of calcium are significant. The patient who is made hypercalcemic may experience an arrest in systole. This is an untreatable situation in which even ECC will not be beneficial. Calcium must always be given slowly, particularly to the patient receiving digitalis who is more prone to develop arrhythmias.

Dembo and others have questioned the use of calcium in the asystolic adult patient. The measured serum calcium levels 5 minutes after infusion of a standard adult dose ranged between 12.9 and 18.2 mg/dL. Other studies show that calcium antagonist drugs appear to be protective against ventricular fibrillation in the ischemic myocardium. However, in our experience, fibrillation is not a common arrhythmia.

Furosemide. Furosemide is fast-acting and thus is the agent of choice for treating acute pulmonary edema and congestive heart failure. Furosemide works by inhibiting reabsorption of sodium in the proximal and distal tubules and in the loop of Henle. In addition to its action as a diuretic, furosemide also acts to increase blood flow to renal vasculature.

The initial dose of furosemide is 1 mg/kg IV. If there is not adequate urine output within 20 to 30 minutes, a repeat dose may be given or the dose may be doubled. If the patient is hypovolemic, the administration of furosemide may result in worsening of hypotension. Other adverse reactions include hypokalemia and hyperosmolality. Hypokalemia in the patient receiving digitalis therapy may result in the development of life-threatening arrhythmias.

Naloxone. Naloxone is a narcotic antagonist. It works to block the action of both synthetic and natural narcotics. Naloxone reverses the actions of codeine, morphine, heroin, hydromorphone, and methadone. Children who have overdosed on these drugs may have signs and symptoms of respiratory or cardiorespiratory arrest. The details of management of these poisonings are discussed in Chapter 88.

If narcotic overdose is suspected as the cause of the arrest, naloxone should be administered at 2 mg in a child older than 5 years of age or an adolescent, or 0.1 mg/kg of body weight in a child less than 5 years of age or an infant. This drug has a rapid onset of action and a short half-life. If a positive reaction to the agent is noted, a repeat dose of 0.1 mg/kg should be given as often as every 3 to 5 minutes up to a total of 10 to 20 mg. After three to five doses, a sustained effect should be apparent. No significant adverse reactions are noted with naloxone.

Corticosteroids. There continues to be great controversy about the specific indications for the use of corticosteroids. There is a general belief that steroids exert a positive effect on the shock state by stabilizing lysosomal membranes and preventing the release of histamine interleukin, tumor necrosis factor, and bradykinin. The possible clinical indications for the use of steroids include adrenal insufficiency either primary or due to adrenal suppression secondary to prolonged steroid use, anaphylaxis, and asthma.

The dose of corticosteroids is also controversial. However, current recommendations include methylprednisolone 30 mg/kg IV, or dexamethasone 1 mg/kg IV. The adverse reactions with short-term administration of corticosteroids are minimal. There may be worsening of hyperglycemia and retention of sodium and water. The worsening of a bacterial infection is a theoretical risk that should not inhibit the short-term use of steroids in a life-threatening situation.

Defibrillation

Defibrillation is a relatively uncommon intervention in pediatric resuscitation. It is unusual for a child's heart to fibrillate, and thus there should be careful confirmation of the rhythm before attempted defibrillation. Unmonitored defibrillation of a child is discouraged. However, if the onset of fibrillation was monitored and the defibrillator is at the bedside, direct defibrillation should be attempted. Precordial thump is not recommended for use in children.

Defibrillation works by producing a mass polarization of myocardial cells with the intent that a spontaneous sinus rhythm returns.

Once the diagnosis of ventricular fibrillation has been made, the patient should be prepared for defibrillation. Acidosis and hypoxemia should be corrected. If the patient was unobserved or if a long interval of poor perfusion has elapsed, 100% oxygen and sodium bicarbonate (1 mEq/kg) should be administered. Coarse (high-amplitude) fibrillation is treated more easily than fine (low-amplitude) fibrillation. Fibrillation can be coarsened with the administration of epinephrine. Defibrillation doses are given two at a time. If the first dose is ineffective, a second dose at the same energy level is

given immediately. The first dose will lessen resistance; thus, the second may be more effective.

Standard adult paddles are 8 cm in diameter. Pediatric paddles that are 4.5 cm in diameter are also available for most defibrillators. The correct size paddle is that which makes complete uniform contact with the chest wall. If the large size paddle fits entirely on the chest wall, it is preferred because the larger the paddle the lower the intrathoracic impedance and the more effective the defibrillation current. The electrodes should be prepared with electrode paste or saline-soaked pads. Placement of the paste or pads must be meticulous. The small size of the child's chest wall predisposes to bridging of the electric current. Electrical bridging will result in ineffective defibrillation and possible burning of the skin surface.

Once the correct paddles are selected and the electrode skin interface carefully prepared, the electrodes are ready to be placed on the chest wall. Both electrodes may be placed on the anterior chest wall, one at the right of the sternum below the clavicle and the other at the level of the xiphoid along the left midclavicular line. An AP placement of the electrodes is also acceptable; however, this is cumbersome in the usual resuscitation situation. Using either method of electrode placement, the physician should apply firm pressure to the paddles to hold them in contact with the skin. Personnel should be cleared from contact with the patient and the bed.

A dose of current for the initial two shocks is 2 J/kg. If the first defibrillation couplet is unsuccessful, CPR is continued for 3 to 5 minutes and then the dose of current is doubled to 4 J/kg and repeated twice if needed. If a third defibrillation round is needed, the dose is again doubled to 8 J/kg. Defibrillation should not be confused with synchronous cardioversion, which is a treatment for ventricular tachycardia or resistant supraventricular tachycardia. With cardioversion, the synchronous switch of the defibrillator must be activated and a low dose of current used (see Chapter 82 for more details)

Adverse reactions from defibrillation include myocardial injury from excessive current or from multiple discharges delivered in rapid succession (less than 3-minute intervals). Another adverse reaction is the damage to skin and subcutaneous tissue that occurs when the electrode skin interfaces are inadequate. Alcohol pads should never be used as an electrode interface because they are flammable.

Specific Resuscitation Situations

Asystole

For the treatment of asystole, we suggest the algorithm presented in Figure 1.25. No algorithm can cover every clinical situation, thus those presented in this chapter represent guidelines for treatment and not absolute treatment regimens. The physician must keep in mind the possible etiology of the arrest in order to modify treatment in some cases. It should be noted that asystole can be diagnosed clinically or by monitor. The monitor tracing may be confused with ventricular fibrillation. If there is a doubt that it is asystole, the resuscitation leader may want to follow the protocol for ventricular fibrillation.

FIGURE 1.25. Management approach to asystole.

Bradycardia

The algorithm for bradycardia management is shown in Figure 1.26. As with other algorithms, this represents only a treatment guideline and not an absolute treatment. Remember that bradycardia may result from hypoxemia and that the patient should first have assessment of the airway and breathing. Other causes of bradycardia include intrinsic node disease, increased intracardiac pressure, hypoglycemia, hypercalcemia, drug effect (e.g., digitalis, propranolol), increased parasympathetic tone (e.g., distended abdomen), or hypothermia. An athletic adolescent may have a resting heart rate of 48 to 60 beats/minute. Treatment must be clinically indicated by signs of cardiovascular failure. There are many forms of bradycardia, including sinus bradycardia, the most common form, and bradycardia from second- and third-degree heart blocks. The differentiation of these forms of heart block is covered in Chapter 79.

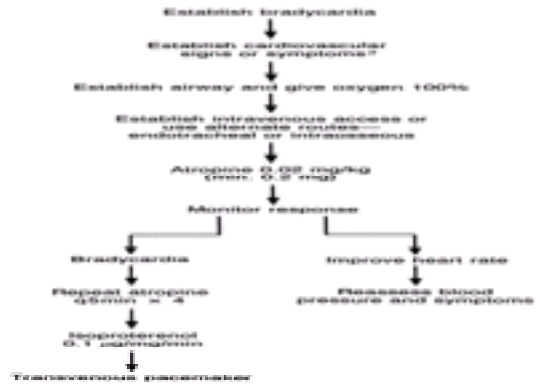

FIGURE 1.26. Management approach for bradycardia. [a]These include hypotension, altered mental status, poor peripheral perfusion, premature ventricular contractions, or chest pain.

Ventricular Fibrillation

Ventricular fibrillation initially may be mistaken for asystole. This depends on the sensitivity setting of the cardiac monitor and the coarseness (amplitudes) of the fibrillation. The treatment protocol for ventricular fibrillation is shown in Figure 1.27. It is essential that fibrillation be diagnosed correctly. Loose electrodes can readily simulate fibrillation; thus it is important to check the leads and correlate the monitor with the clinical appearance of the patient. It may be difficult to differentiate ventricular fibrillation from ventricular tachycardia with hypotension. This differentiation is moot because the same treatment protocol should be followed in either case.

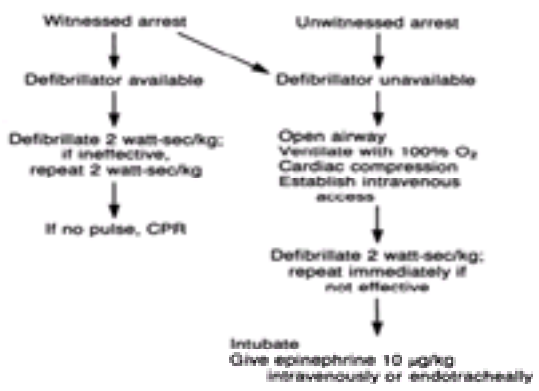

FIGURE 1.27. Management approach for ventricular fibrillation or ventricular tachycardia without pulse.

If the onset of fibrillation is witnessed, the immediate response is to attempt defibrillation. If the arrest was not witnessed, basic CPR must be initiated and the patient prepared before defibrillation is attempted. We do not recommend precordial thump for the pediatric patient.

Rarely is ventricular fibrillation an agonal rhythm in the pediatric patient. Its presence usually indicates some underlying cardiac pathology such as myocarditis, cardiomyopathy, prolonged Q-T syndrome, cardiac trauma, electrical shock, or intoxication with digitalis.

Electromechanical Dissociation

The term *electromechanical dissociation* (EMD), or pulseless electrical activity, refers to a state in which there is an observable cardiac rhythm on a monitor, yet no apparent effective circulation. A number of clinical conditions result in this form of arrest. Figure 1.28 shows the management scheme for EMD. The physician must keep in mind the potential causes of EMD and must assess the patient for each of these and treat specific causes when indicated.

FIGURE 1.28. Management approach to tachycardia with poor perfusion (for electromechanical dissociation.)

Tachycardia with Poor Perfusion

Tachycardia with poor perfusion is a condition that requires resuscitative effort. The underlying rhythm is usually SVT caused by aberrant reentry pathways due to defects in the normal cardiac conduction system. Most often, SVT is reasonably well tolerated by the infant or young child whose only manifestation may be increased restlessness, pallor, sweating, or poor feeding (see Chapter 82). Sometimes, however, SVT can result in cardiovascular collapse and circulatory failure requiring resuscitation. For the physician, the major point of caution is differentiation between SVT and sinus tachycardia. With SVT, heart rates are usually 230 beats/minute or higher. The P wave axis is usually abnormal (if P waves can be found) and there is little beat-to-beat variation. In sinus tachycardia, there is more rate variation, P waves have a normal axis, and the rate is usually less than 200 beats/minute. Also consider causes for sinus tachycardia such as dehydration, hypoxemia, fever, shock, pneumothorax, cardiac tamponade, or drug induced.

At times, it may also be difficult to differentiate SVT from ventricular tachycardia, particularly if the SVT is associated with aberrant conduction that widens the QRS waves of the ECG. Usually in SVT, the QRS is less than 0.08 seconds. Figure 1.28 outlines the treatment strategy for tachycardia with poor perfusion. If there is no pulse present, the physician should follow asystole management scheme.

Upper Airway Obstruction

If acute upper airway obstruction is not relieved properly and expeditiously, the child is likely to either die or sustain a hypoxemic CNS injury. The emergency department physician, pressured by time to move through a sequence of evaluation and management, knows that inefficiencies or mistakes place the child at increased risk. Unfortunately, this is a circumstance that often generates panic. Panic can be avoided and the child's life saved if calm prevails and an orderly sequence of evaluations and interventions occurs quickly and atraumatically.

Clinical Manifestations

If the clinical process predisposing to upper airway obstruction has not evolved to produce complete airway obstruction, the usual clinical manifestations are related to an increased work of breathing or compromised oxygen exchange. Intercostal retractions qualitatively reflect the increased work of breathing. If the negative intrapleural pressure required to produce gas exchange is increased, retractions will be evident in the intercostal spaces. As the work of breathing continues to increase, retractions will be transmitted beyond the thoracic cage and one may see subcostal or supraclavicular retractions. In the extreme situation, the sternocleidomastoid muscles are outlined by the negative intrapleural pressure transmitted into the neck. Another important clinical marker of airway obstruction is a decrease in breath sounds. Breath sounds should be auscultated both over the trachea and the peripheral lung fields. By following the pattern of inspiratory breath sounds, one can appreciate a gradual diminution during progression of the process of airway obstruction.

Upper airway noises, such as stridor, croupy cough, and “bark,” may be useful signs to identify those at risk for upper airway obstruction. The general appearance of air hunger or of gasping respirations may indicate airway obstruction. In addition, the symptoms of dysphagia, dysarthria, and dyspnea should trigger a thorough evaluation of the airway.

Management

A number of tasks must be accomplished as quickly as possible once the patient has been identified as being at high risk for total airway obstruction. The child should receive supplemental oxygen and have his heart rate and blood pressure monitored. Equipment for managing an obstructed airway should be immediately available (Table 1.5). The hospital's identified airway specialist should be notified of the child's condition and should move as quickly as possible to the emergency department. Beyond the emergency physician, if additional expertise is needed, specialty groups commonly identified as having airway expertise include anesthesiologists, otorhinolaryngologists, nurse anesthetists, general surgeons, respiratory therapists, and cardiothoracic surgeons. It is important to keep in mind that the two important elements for successful management are technical expertise and judgment. These attributes are not necessarily found in the same individual. What may be necessary is a cooperative effort between those with technical expertise and those with clinical experience and judgment.

If obstruction is not imminent, there is usually time to obtain a history and to perform an abbreviated physical examination. In addition, a chest radiograph and lateral neck radiographs may help to define more specifically the pathophysiologic process. These evaluations should occur only if there is no obvious evolution of the airway obstruction and if the natural history of the disease under consideration suggests further diagnostic studies.

If the patient is obtunded, the team must initiate the formal sequence of evaluation and management as described previously. The airway should be opened by flexing the cervical spine on the thoracic spine and tilting the head backward so that the skull is extended on the cervical spine. In addition to this maneuver, the jaw thrust or jaw pull may be used by pushing or pulling the mandibular block of tissue forward off of the posterior pharyngeal wall. At this time, the examiner evaluates the respiratory effort by looking, listening, and feeling for air flow. If the patient is breathing and there is gas exchange, the patient should receive supplemental oxygen and the sequence should progress toward an evaluation of the cardiovascular system. If the patient is not breathing, the oropharynx should be suctioned and an oropharyngeal or nasopharyngeal airway placed in an effort to open the airway. With the airway in place, the physician should reevaluate for gas exchange. If there is now gas exchange, supplemental oxygen should be administered. If there is no gas exchange, the physician should proceed immediately to laryngoscopy.

The purpose of laryngoscopy is twofold: the first priority is placement of an ET tube; second, the laryngoscopy may provide diagnostic information. If a foreign body is evident, the physician should try to intubate before attempting

removal.

If the tracheal tube can be placed, the child should be oxygenated and ventilated. Then the cause of the upper airway obstruction should be evaluated and treated. If the child cannot be intubated, a transcricothyroid membrane catheter should be inserted for delivery of supplemental oxygen (see Appendix D, Section VII). Jet ventilation may be accomplished through the catheter oxygenation system. Once the catheter is in place and oxygen is being administered, it is appropriate to reexamine the upper airway, to look for a cause of the obstruction, and to reattempt placement of an ET tube. If the airway cannot be secured at this time, a surgical team should be mobilized to perform a tracheostomy. Effective needle oxygenation and ventilation may permit transfer of the child to the operating room for tracheostomy. If circumstances do not allow oxygenation and ventilation, a formal tracheostomy may have to be performed in the emergency department.

STABILIZATION AND TRANSPORT

Once resuscitation efforts have achieved cardiorespiratory stability, the patient should be transported to an inpatient special care unit for the critically ill. This transport may be several hundred yards or several hundred miles to an appropriate pediatric hospital. In either circumstance, the patient should be transported with advanced life support technology in place, qualified personnel in attendance, and options for further treatment or intervention immediately available (see Chapter 6 and Chapter 7).

Waddel has reported on the direct and indirect effects of movement within the hospital. Direct effects include patient discomfort, pain, and the physical stimulation of movement. Indirect effects include lack of equipment and facilities and the limitations that occur by being in motion, for example, the ability to provide continuous ventilation while maneuvering the stretcher into a small elevator. All the equipment needed for a complete resuscitation should be available. Table 1.13 lists the equipment that is required. Transport should never be rushed because this may result in direct morbidity to the patient. Pediatric patients are particularly prone to hypothermia and should be warmed to avoid the adverse hemodynamic effects of cold stress. This is particularly important for any young infant who has not established temperature control or for the older child whose CNS pathology has resulted in loss of temperature regulation. Pediatric patients are likely to become physically active once CNS perfusion is adequate. Intravenous lines, ET tubes, and nasogastric tubes must be well secured. Extremities must be restrained. The transport team must include a sufficient number of individuals to fully resuscitation the patient. Responsibility for the patient still rests with the resuscitation team until discharge of that responsibility takes place at the inpatient critical care unit.

1. Airway box—items noted in Table 1.5.
2. Portable suction—compact, battery operated
3. Bag-valve-mask with O_2 reservoir or anesthesia bag
4. Oxygen tank with yoke and flow meter
5. Intravenous fluids
6. Primary and secondary medications
7. ECG monitor defibrillator
8. Infusion pump—battery operated
9. Blood pressure apparatus—battery operated, Doppler or ultrasound
10. Pulse oximeter (optional) and end-tidal CO_2 monitor

Table 1.13. Essential Equipment for Transport in Pediatric Resuscitation

DISCONTINUATION OF LIFE SUPPORT

Termination of life support in the emergency department is usually determined by whether the cardiovascular system can be supported with other than closed-chest massage. If the heart and supporting technology applied to it cannot sustain brain function, resuscitative effort should be discontinued. Obviously, time must be allowed to mobilize and implement for appropriate technology and therefore most unsuccessful resuscitations often go beyond 1 hour. There is growing evidence that if the cardiac muscle is not responsive to the first three doses of epinephrine in the state of adequate oxygenation and ventilation, there is no hope for a successful resuscitation. Additional research will be needed to confirm this as an absolute indicator of when to stop.

Respiratory functions are easily supported mechanically and therefore are not used as markers for continuation or discontinuation of effort.

Brain death is becoming widely accepted as the ultimate determinant of death. It is a clinical diagnosis that should be confirmed by observations over time or by studies documenting absence of cerebral blood flow or cerebral metabolic activity. We have seen infant botulism and postictal depression misdiagnosed as brain death and are therefore extremely cautious of making this diagnosis in the emergency department.

Ultimately, the diagnosis of death and subsequent discontinuation of resuscitative effort is a judgment that should be made by the senior physician who is directly attending the child. A decision not to begin resuscitation is generally not made in the emergency department unless there is a clear plan made with parents and written documentation of the plan transmitted by the child's primary attending physician.

CEREBRAL RESUSCITATION AND OTHER NEW APPROACHES

The term *cerebral resuscitation* refers to an important new focus of resuscitation research. The key concept is to monitor the effects of the hypoxic state on the cerebral nervous system and to discover what can be done to minimize or reverse these effects. Investigators have questioned the ethical appropriateness of “saving a heart” while the resultant brain injury renders the person vegetative. White and others have hypothesized that, in the brain, injury from cardiac arrest occurs during the reperfusion phase. The mechanism for this injury is through ion-dependent lipid peroxidation. White also noted an increase in iron released in the brain for 2 hours following a 15-minute arrest induced in laboratory animals. In the future, cerebral resuscitation may be aimed at reducing lipid peroxidation and iron release during the reperfusion phase following arrest.

Other new approaches have centered on methods of increasing blood flow, so-called new CPR. The techniques have been used to attempt simultaneous chest compression and ventilation to increase ventilatory flow rates and longer systolic compression times. Other efforts have been to use abdominal binding, chest binders, or cardiopulmonary bypass. Mateer et al. have studied the use of interposing abdominal compressions between chest compressions. To date, all these techniques are experimental and none has shown so clear an advantage that use in humans is indicated.

SUMMARY

In most circumstances, resuscitation of the pediatric patient can be approached with a sense of optimism for reversing the process that acutely threatens the child's life. Well-organized and well-qualified personnel can effect a high rate of successful resuscitation. However, organization and qualification require advanced planning, training, and preparation. Inherent in this preparation is the development of personnel disciplined to follow the sequence of evaluation and management for airway, breathing, and circulation. In addition, personnel must be familiar with the nuances of resuscitation peculiar to the age and size ranges of the pediatric population. A complete list of pediatric resuscitation equipment may be found in the Appendix A.

CHAPTER 2

Neonatal Resuscitation

EVALINE A. ALESSANDRINI, MD

Departments of Pediatrics, Emergency Medicine, and Epidemiology, The University of Pennsylvania School of Medicine, and Division of Emergency Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

EPIDEMIOLOGY

Approximately 4 million infants are born each year in the United States. Although medical personnel attend virtually all births, more than 85% of infants are born in hospitals without neonatal facilities. Despite the fact that more U.S. women are seeking prenatal care in the first trimester of their pregnancies and that there has been a decline in women who receive late or no prenatal care, the United States has one of the highest infant mortality rates of developed countries: 7.2 per 1000 live births in 1996. This rate is markedly affected by birth weight. The infant mortality rate in 1996 was 3.0 per 1000 for infants who weighed 2500 g or more and 65.5 per 1000 for infants who weighed less than 2500 g.

Resuscitative needs also vary greatly by birth weight. Approximately 6% of term newborns will require resuscitation at birth, compared with nearly 80% of infants weighing less than 1500 g. Improvements in prenatal care, infant care, and neonatal resuscitation, as well as the development of the specialty of neonatology and neonatal regional centers, have decreased infant deaths and mortality rates by nearly 45% between 1979 and 1996. The most notable decreases have occurred because of advances in the management of respiratory distress and intrauterine hypoxia and birth asphyxia. Resuscitation of the newborn in the emergency department (ED) is an uncommon yet critical event that can cause a ED team well versed in other resuscitative scenarios to panic. The key to a successful newborn resuscitation for the ED team includes preparedness of staff and equipment and anticipation of high-risk births.

EMERGENCY DEPARTMENT PREPAREDNESS

The best place for the birth of a newborn infant is in the delivery suite. However, because of varying circumstances, infants are born at home, in the prehospital setting, and in the ED. Most neonatal resuscitations in the ED occur without prior notice. Any knowledge that can be obtained before arrival of the laboring mother or recently born infant will aid in the success of the resuscitation. Education of staff, available and functioning equipment, and familiar policies and procedures are critical for preparedness.

Staff

The American Heart Association (AHA) and the American Academy of Pediatrics (AAP) have been leaders in developing guidelines for and offering training in neonatal resuscitation since 1979. Their Pediatric Advanced Life Support (PALS) course offers didactic and skills teaching for neonatal resuscitation that occurs outside of the delivery room. In addition,

resuscitation in the delivery room is addressed in depth in the Neonatal Resuscitation Program (NRP). In concert with the goals of the AHA and the AAP, all personnel responsible for care of newborns should complete courses and maintain their skills in the area of newborn resuscitation. At least one person skilled in newborn resuscitation should attend every delivery. Additional trained personnel must be available for high-risk deliveries, such as most of those occurring in the ED or other locations outside of the delivery room. Ideally, there should be three members on the team that are trained to work together. Identification and training of staff is the first step in preparation for neonatal resuscitation.

Equipment

In addition to a standard obstetric tray, every ED should have a newborn resuscitation kit that is readily accessible, maintained meticulously with other emergency equipment, and rapidly replenished after use. Necessary equipment and medications are listed in Table 2.1. A medication dosing chart by weight and a radiant warmer are invaluable to a neonatal resuscitation.

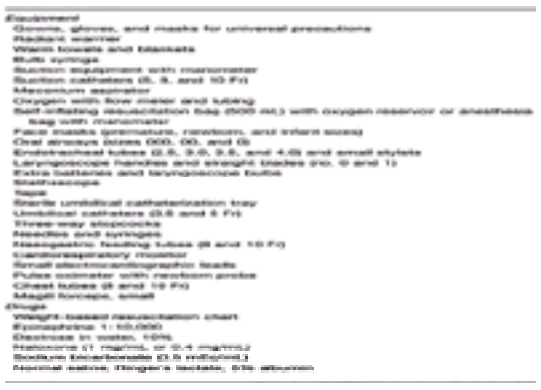

Table 2.1. Neonatal Resuscitation Equipment and Drugs

Policies and Procedures

As soon as the need for neonatal resuscitation becomes evident, a prearranged plan should be activated to organize personnel and assemble equipment. Readily available procedure logs for accessing pediatric and neonatal consultants, as well as neonatal transport teams for transfer to regional centers, are critical. Because neonatal resuscitations in the ED are uncommon, mock codes and scavenger hunts for newborn equipment on a routine basis allow staff to remain familiar with their neonatal resuscitation skills and supplies.

HIGH-RISK BIRTHS

Most births that occur outside of the delivery room have high-risk components such as trauma-induced labor and unexpected or teenage pregnancy. There is usually little time to obtain a complete obstetric history, but a brief period of questioning may reveal pertinent information that will affect a successful newborn resuscitation. Particularly important information includes prematurity, multiple gestation, meconium-stained amniotic fluid, and maternal drug use. The team can then anticipate the need for assisted ventilation, simultaneous resuscitations, tracheal suctioning, and potential naloxone administration, respectively. Table 2.2 lists other risk factors associated with the need for neonatal resuscitation.

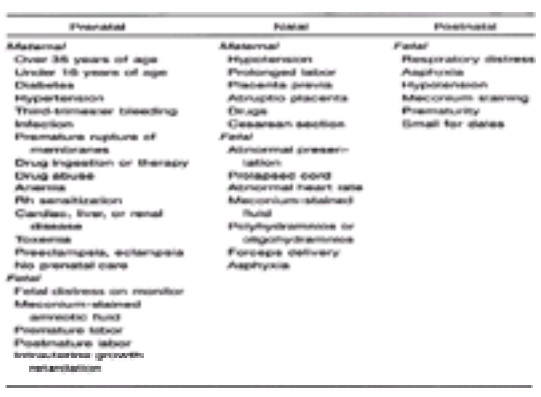

Table 2.2. Neonatal High-Risk Profile

PATHOPHYSIOLOGY

Physiology of Intrauterine Development

The lungs develop over the second and third trimester of pregnancy. Terminal airways develop by approximately 24 weeks' gestation, and the alveoli by 30 to 32 weeks. Surfactant is initially produced by about 23 to 24 weeks; however, sufficient amounts for opening the airways are not present until 34 weeks' gestation. In utero, the lung is filled with amniotic fluid, which is primarily removed by chest compression during vaginal birth. Preterm infants or those born by

cesarean section tend to have more fluid in their lungs. At birth, the key physiologic change is the initiation and maintenance of respiration. Factors such as cold, touch, hypoxia, and hypercarbia help stimulate respiration. However, severe acidosis, hypoxia, maternal drugs, and moderate hypothermia depress this effort.

The heart and circulatory system start developing during the third week of gestation. In utero, the circulation is more like a parallel circuit rather than a series circuit because of the foramen ovale and ductus arteriosus that serve as bypasses. After birth, these structures close physiologically. Severe acidosis, hypoxia, hypovolemia, and hypothermia can impair the closure. Anatomic closure of the bypasses may not occur for 2 to 4 weeks. The fetal heart is also sensitive to hypoglycemia because of the neonate's limited energy stores, and myocardial failure can occur if the infant becomes hypoglycemic.

Changes at Birth

The fetus has two large right-to-left shunts: one from the right atrium to the left atrium through the foramen ovale, and the second from the pulmonary artery to the aorta across the ductus arteriosus. The placenta is the gas-exchange organ, which provides a low-resistance shunt compared with the high resistance of the fetus' peripheral circulation. At birth, two major changes occur that eliminate these shunts: the umbilical cord is clamped and then, respirations are initiated. Expansion of the lungs increases the neonate's Pa_{O_2} and pH, which causes pulmonary vasodilation and a fall in pulmonary vascular resistance. The normal heart rate will vary between 100 and 200 beats/minute initially and then stabilize between 120 and 150 beats/minute.

The normal newborn will begin spontaneous respirations within seconds after birth. The normal rate will be between 35 and 60 breaths/minute. The initial breaths taken by the infant must inflate the lungs and effect a change in vascular pressures so that lung water is absorbed into the pulmonary arterial system and cleared from the lung. This inflation pressure is a powerful mechanism for the release of pulmonary surfactant, which increases compliance of the lung and establishes a functional residual capacity.

The neonate oxidizes free fatty acids released from the brown fat stores for heat production and increases oxygen consumption. The neonate experiences substantial heat loss by all four heat loss mechanisms, especially if he or she is not dried promptly and thoroughly.

Asphyxia

Asphyxia is defined as the failure to provide the cell with oxygen and remove carbon dioxide, resulting in metabolic acidemia. Both circulation and ventilation are essential to avoid asphyxia. There are multiple stimuli at birth to alter the prenatal circulation and initiate respirations. The actual stimuli for initiating respirations are thought to include a rise in $PaCO_2$, interruption of umbilical circulation, and tactile and temperature stimulation.

Neonatal asphyxia can result from multiple factors, as listed in Table 2.3. The initial response to asphyxia will be hyperpnea for 2 to 3 minutes and sinus tachycardia. If there is no significant increase in Pa_{O_2}, respirations will stop for 1 to 1½ minutes (primary apnea). The infant loses muscle tone and becomes mottled, pale, and then cyanotic. The infant may attempt gasping, nonrhythmic respiratory efforts of 6 to 10 times/minute for several minutes, while the heart rate falls below 100 beats/minute. Soon thereafter, the child ceases to gasp (secondary apnea). At this point, ventilatory and circulatory support must be aggressively provided for the newborn to survive. Brain and other organ damage progresses rapidly beyond this point.

Maternal	Fetal
Diabetes	Abnormal presentation
Hypertension	Meconium aspiration
Toxemia	Sepsis
Preeclampsia	Hypovolemia
Eclampsia	Prolapsed cord
Treatment with alcohol, magnesium, β-adrenergic agents, narcotics	Congenital anomalies
Isoimmunization	
Infection	
Abruptio placenta	
Placenta previa	

Table 2.3. Causes of Neonatal Asphyxia

It is important to realize that when one evaluates a neonate in distress or full arrest, the asphyxial event may have begun in utero. It is difficult to document the beginning of the hypoxic period. Indeed, the infant may have passed through both stages of apnea in utero. Thus, there must be aggressive intervention if the infant is to survive. The rule of thumb is that for every minute of secondary apnea, the infant will require 4 minutes of artificial ventilation before rhythmic breathing is reestablished. An apneic infant must be treated as if he or she is in a secondary apneic stage, and resuscitation must begin immediately. If hypoxemia is not treated, there may be further pulmonary vasoconstriction and increased right-to-left shunting through the ductus arteriosus and foramen ovale and a persistence of fetal circulation.

CLINICAL MANIFESTATIONS

Successful resuscitation of a depressed newborn requires accurate assessment of the infant's temperature, respiratory

effort, heart rate, color, and tone. Assessment of these critical parameters occurs simultaneously with management of any detected abnormality in a rapid and timely fashion. The evaluation of the clinical manifestations of a depressed newborn should take place along with resuscitative efforts within the first minute after birth. Complete assessment is performed after the infant is dried and placed in a warm environment, the airway is cleared, and stimulation has been provided.

Temperature

Particular attention must be paid to the thermoregulation of all infants, especially those born in a prehospital setting or in a cool ED. As the patient is dried and placed under a radiant warmer, the temperature should be monitored via the axillary route using electronic thermometers with a disposable tip. Normal axillary temperatures fall between 36.5 and 37.4°C. Rectal temperatures are reserved for infants whose core temperature may be in question. Recovery from acidosis is delayed by hypothermia. In addition, hypothermia increases metabolic needs and produces hypoxia, hypercarbia, metabolic acidosis, and hypoglycemia. Thus, efforts to maintain a normal body temperature are crucial to a successful resuscitation.

Respiratory Effort

Most newborns will begin to breathe effectively in response to mild stimulation. The infant should be assessed for respiratory rate (between 35 and 60 breaths/minute is normal). Adequacy of respirations is noted by evaluating chest rise, auscultating good air movement, and confirming a heart rate above 100 beats/minute with improving color of the infant. Observation of tachypnea, retractions, or grunting warrants close evaluation and management. A gasping, cyanotic, or unresponsive infant requires immediate respiratory support with oxygenation and ventilation (see Management section following).

Heart Rate

The newborn's heart rate is an excellent objective measurement of the success of the resuscitation and should be monitored closely after assessment of respiratory effort. The heart rate may be determined by one of many ways: 1) palpation of the pulse at the base of the umbilical cord, 2) auscultation of heart tones with a stethoscope, 3) palpation of the femoral or brachial pulse, or 4) placement of a cardiac monitor. Auscultation of the apical heart rate is often difficult in a noisy environment, and the electrodes of a cardiac monitor may be difficult to place while vernix covers the newborn's body. The normal infant's heart rate is greater than 100 beats/minute at birth. The average awake infant's heart rate is between 120 and 150 beats/minute shortly after birth. Variations in heart rate commonly occur with hypoxia, hypovolemia, hypothermia, and maternal drug use. Trends in heart rate are followed closely during resuscitation and postresuscitation stabilization.

The average mean arterial pressure of term infants in the first 12 hours of life is between 50 and 55 mm Hg.

Color

As respirations begin and pulmonary vascular pressures fall, the newborn rapidly becomes pink. Acrocyanosis, or persistent cyanosis of the distal extremities, may persist for several hours after birth. Acrocyanosis is not a reflection of inadequate oxygenation, but it may indicate hypothermia if persistent. Pallor may be a sign of decreased cardiac output, anemia, hypovolemia, hypothermia, or acidosis. Its cause should be investigated and corrected promptly. Central cyanosis that has not resolved with administration of oxygen and ventilation within the first minute of life must be emergently evaluated for heart disease, sepsis, diaphragmatic hernia, other congenital anomalies, or other causes.

Apgar Score

The Apgar score is a useful guide to evaluate the newborn at specific intervals after birth. Five objective signs—heart rate, respirations, muscle tone, grimace, and color—are assessed 1 minute and 5 minutes after birth. Each sign receives a score between 0 and 2, and the points are then totaled for the final score (Table 2.4). If the 5-minute Apgar score is less than 7, additional scores are obtained every 5 minutes until the infant is 20 minutes old. The Apgar score has been used as an indicator of responsiveness to resuscitative efforts. The score at 5 minutes and beyond is more predictive of survival and neurologic status. Although experienced physicians have developed these guidelines, they have not undergone rigorous clinical trials. Thus, if resuscitative efforts are needed for a newborn infant, they should be started immediately and not be delayed while the Apgar score is obtained.

	Score		
Sign	0	1	2
Heart rate	Absent	<100 beats/min	≥100 beats/min
Respirations	Absent	Slow, irregular	Good, crying
Muscle tone	Limp	Some flexion	Active motion
Reflex irritability	None	Grimace	Cough, sneeze, cry
Color	Blue or pale	Pink body, blue hands and feet	Completely pink

Table 2.4. Apgar Score

MANAGEMENT

The initial steps of neonatal resuscitation include prevention of heat loss, stimulation, clearing of the airway, initiation of respirations, and evaluation of circulation. When possible, all resuscitation equipment should be ready for use, the radiant warmer on, and a team with preassigned roles assembled. Figure 2.1 is a flow diagram of neonatal resuscitation.

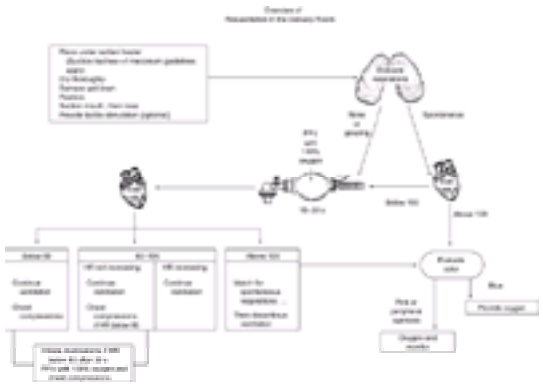

FIGURE 2.1. Overview of resuscitation in the delivery room.

When and if to begin resuscitative efforts on a newborn is fraught with emotion and difficult to objectively study. Studies have shown that between 40 and 50% of term newborns who were stillborn survived. Approximately two-thirds of these infants had a normal neurologic outcome. It thus seems obvious that resuscitative efforts should be performed on any term infant. A difficult decision is when to stop resuscitation. One predictor is the Apgar score. Survival is extremely unlikely if the 10-minute Apgar score remains zero. There are multiple ethical issues regarding initiation of resuscitation of the very low–birth weight infant. However, with surfactant therapy and improved management of these infants, outcomes have improved over time and the controversy of resuscitation remains. At the stressful time of an emergency delivery, if there is any question of viability, it is probably best to initiate resuscitative efforts.

Thermoregulation

The initial step of drying the infant to minimize heat loss is extremely important, and further resuscitation is continued after warming has begun. As previously stated, recovery from acidosis is delayed by hypothermia, and hypothermia is a special problem for the infant born outside of the hospital. Thus, simply resuscitating the baby in a warm environment, under a prewarmed radiant warmer (Fig. 2.2) while drying the amniotic fluid from the infant and removing wet linens from contact with the skin will markedly decrease heat loss. These maneuvers will maximize the infant's chance at recovery. Alternative methods of warming infants, particularly while awaiting a radiant warmer in the case of an unexpected delivery, include warm blankets and towels. Placing the infant naked against the mother's body and covering both mother and infant with blankets may also warm the stable infant.

FIGURE 2.2. Radiant warmer.

Suctioning

Many newborns have excessive secretions, including amniotic fluid, cervical mucus, and meconium, which may obstruct their airways. (Meconium is a special situation discussed in the following section.) These secretions can generally be removed by placing the infant on his or her side and gently suctioning the buccal pouch with a bulb syringe. Mechanical suction with an 8- or 10-Fr suction catheter may also be used. To avoid soft tissue injury, negative pressure from mechanical suctioning should not exceed –100 mm Hg. Deep suctioning of the oropharynx in a newborn is likely to cause vagally mediated bradycardia and/or apnea. Excessive suctioning may also contribute to atelectasis. Most clear fluid is resorbed by the lungs into the arterial system. Consequently, suctioning should be gentle and limited to 5 seconds per pass. Adequate time must be allowed between necessary suctioning attempts for spontaneous or assisted ventilation.

Stimulation

Most newborns will begin effective breathing during routine drying and suctioning. Other methods of safe stimulation include flicking the heels and rubbing the back of the newborn infant. More vigorous methods of stimulation are unnecessary. If after 10 to 15 seconds of stimulation, effective respirations have not been established, positive-pressure ventilation (PPV) is initiated.

Airway and Breathing

Oxygen Administration and Airway Positioning

Most infants require only warming, drying, stimulation, and suctioning after birth for a smooth transition to their extrauterine environment. If a newborn is exhibiting signs and symptoms of airway obstruction after routine suctioning, the airway should be repositioned. This maneuver is often accomplished by placing a towel or blanket beneath the shoulders and upper back of the supine infant. By elevating the shoulders and upper back approximately 1 inch, the airway is slightly extended into a neutral position, compensating for the infant's relatively large occiput. Avoid flexion or hyperextension of the newborn's neck, which is likely to exacerbate airway obstruction.

An infant who exhibits central cyanosis, yet is making adequate, spontaneous respirations and has a heart rate above 100 beats/minute, needs supplemental oxygen. Oxygen is delivered at 100% and a flow rate of at least 5 L/minute by blow-by through tubing, a face mask attached to an anesthesia bag, an appropriately sized simple mask, or an oxygen hood. Ideally, oxygen should be warmed and humidified. Although this may not always be possible initially in an emergency setting, efforts to warm and humidify oxygen delivered to a newborn should be made as soon as possible.

Bag-Valve-Mask Ventilation

Adequate expansion of the lung is often the only and most important measure needed for successful resuscitation of the newborn. The fluid-filled lungs must be inflated with air. Adequate inflation stimulates surfactant secretion and also allows some gas trapping during exhalation to create a functional residual capacity. Although this is best done by negative pressure generated by a vigorous term infant with a strong chest wall, some infants require PPV to initiate lung expansion. Indications for PPV are listed in Table 2.5.

Apnea or gasping respirations
Heart rate <100 beats/min
Persistent central cyanosis despite administration of 100% oxygen

Table 2.5. Indications for Positive-Pressure Ventilation

Lung expansion is best achieved with a well-fitted face mask, which covers the infant's nose and mouth but does not place pressure on the eyes. A cushioned rim on the face mask allows the best possible seal. A relatively high inflation pressure, between 25 and 40 cm H_2O, delivered slowly over several seconds is necessary for the infant's first breath. Subsequent ventilations typically require less pressure and are best judged by good chest wall rise and breath sounds. If effective ventilation does not result, the airway should be repositioned and suctioning of the oropharynx considered. An assisted ventilatory rate of 40 to 60 breaths/minute will provide effective oxygenation and ventilation. Typically 100% oxygen is delivered via PPV. However, some authors advocate resuscitation with room air because of concerns about the generation of free radicals from high concentrations of oxygen, which may exacerbate brain injury. Although current findings do not justify changes in guidelines for resuscitation, further work in this arena may have implications for neonatal resuscitation in the future.

PPV may be delivered by a self-inflating bag or an anesthesia bag. Although self-inflating bags do not require a gas source to operate, they must be used with an oxygen source and a reservoir to deliver high concentrations of oxygen. They are straightforward and easy to use, but several caveats must be kept in mind. First, relatively small volumes of air (approximately 6 to 8 mL/kg) are delivered to newborns during PPV. A 450-mL self-inflating bag rather than the larger bags should be used to avoid complications from barotrauma such as a pneumothorax. In addition, many self-inflating bags have a pressure-limiting pop-off valve set at 30 to 45 cm H_2O. In some circumstances, when an infant requires higher initial inflation pressures, the bag may not allow the resuscitator to deliver enough pressure to the newborn for an adequate first breath. Unless the valve is occluded, effective inflation may be prevented.

Anesthesia bags require air flow into them as well as a good mask seal to inflate. Consequently, the resuscitator must be facile at positioning the airway and mask, controlling the flow valves, and monitoring the manometer, which is needed to monitor peak ventilatory pressures delivered to the infant. Benefits of the anesthesia bag include the ability to deliver a wide range of peak inspiratory pressures, positive end-expiratory pressure, and high concentrations of oxygen compared with the self-inflating bag. Proper use requires training and practice.

Recently, investigators have successfully used a size 1 laryngeal mask airway to resuscitate 20 newborns who required PPV. This method of airway management warrants further investigation.

If bag-valve-mask ventilation is prolonged or results in gastric distension, an orogastric tube should be placed to decompress the stomach so that further effective ventilation is not inhibited. The infant should be reevaluated after 30 seconds of PPV for spontaneous respirations and heart rate. If the infant has begun breathing and the heart rate is above 100 beats/minute, PPV may be slowly discontinued. If respirations are inadequate or the heart rate remains less than 100 beats/minute, assisted ventilation must be continued and endotracheal (ET) intubation must be considered.

Endotracheal Intubation

Most resuscitative efforts succeed with bag-valve-mask ventilation alone. Indications for ET intubation are listed in Table 2.6. Once the decision to intubate the trachea has been made, supplies from the newborn resuscitation tray are organized. Sizes of airway equipment can be determined by birth weight (Table 2.7). ET tube size can also be estimated by gestational age:

$$\text{ET tube size in mm} = \frac{\text{Gestational age in weeks}}{10}$$

Ineffective bag-valve-mask ventilation
Prolonged need for positive-pressure ventilation
Suctioning of meconium
Administration of resuscitation medications

Table 2.6. Indications for Endotracheal Intubation

Weight (g)	Endotracheal Tube Size (mm)	Suction Catheter (Fr)	Oral Airway	Laryngoscope Straight Blade
<1000	2.5	5	000	0
1000-1250	2.5, 3.0	5, 6	000	0
1250-2500	3.0	6	00	0, 1
2500-3000	3.0, 3.5	6, 8	0	1
>3000	3.0, 3.5, 4.0	8	0	1

Table 2.7. Selection of Airway Equipment by Weight

Thus, a 35-week premature infant would require a 3.5-mm ET tube.

ET intubation is typically performed via the orotracheal route during direct laryngoscopy. Laryngoscopy in the newborn is challenging because of the infant's large tongue and secretions, which may obscure airway landmarks. Hancock et al. advocate finger intubation of the trachea in newborns. They successfully and quickly used this method to intubate 37 infants and had no complications. The technique requires some practice, as does laryngoscopic intubation.

Successful ET intubation also requires proper tube positioning. Most neonatal ET tubes have a black vocal cord line near the tip. When this guide is placed at the level of the vocal cords, the tip of the tube is likely to be positioned properly in the trachea. Another estimate for the insertion distance of the ET tube is:

$$\text{Total centimeters at gum line} = 6 + \text{Weight of the infant in kilograms}$$

Proper positioning of the ET tube must be confirmed by auscultation of equal breath sounds in both axillae; good, symmetric chest wall movement; improvement of the infant's cardiorespiratory status; and detection of exhaled carbon dioxide. Once positioning is clinically verified, the ET tube must be securely taped in place, and positioning may then be confirmed with a radiograph as indicated.

Circulation

Chest Compressions

Chest compressions are rarely needed during neonatal resuscitation. In 1993, Jain reported that 0.03% of newborns delivered required chest compressions (in 1995, Perlman demonstrated a need in 0.12%). Bradycardia and asystole in the newborn are virtually always a result of respiratory failure, hypoxemia, and tissue acidosis. Consequently, oxygenation and ventilation are critical to successful resuscitation even of the infant's circulation. Indications for chest compressions, which are always performed simultaneously with PPV with 100% oxygen, are listed in Table 2.8.

Heart rate <60 beats/min
Heart rate 60-80 beats/min and not rapidly increasing despite positive-pressure ventilation with 100% oxygen for 30 seconds

Table 2.8. Indications for Chest Compressions

Current recommendations state that 3 chest compressions are followed by a brief pause for 1 ventilation. Thus, in 1 minute, the newborn should receive 90 chest compressions and 30 ventilations. This technique, when compared with previous recommendations of 120 compressions and 40 to 60 simultaneous respirations per minute, allows for optimal lung expansion by not compressing the chest during PPV. The most important aspect of reversing neonatal asphyxia, good oxygenation, and ventilation is maximized.

Two techniques of performing chest compressions in the neonate or young infant are recommended. The preferred method involves placing the thumbs on the middle third of the sternum, encircling the chest and supporting the back with the fingers (Fig. 2.3). Ultimately, the thumbs should be placed side by side just below the nipple line. However, if the neonate is very small or if the resuscitator is large, the thumbs may need to be superimposed. Pressure must be placed on the sternum and not the adjacent ribs. In the event that the resuscitator's hands are too small to encircle the newborn's chest, or encircling the chest obstructs other resuscitative efforts such as umbilical line placement, then the two-finger technique may be used. This method entails placing the ring and middle fingers on the sternum just below the nipple line for chest compressions.

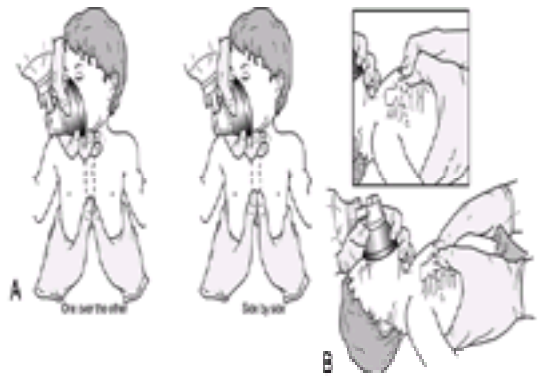

FIGURE 2.3. A. Thumb method of chest compressions. Infant receiving chest compressions with thumb 1 fingerbreadth below the nipple line and hands encircling chest. **B.** Hand position for chest encirclement technique for external chest compressions in neonates. Thumbs are side by side over the midsternum. In the small newborn, thumbs may need to be superimposed (inset). Gloves should be worn during resuscitation.

With either method of chest compression, the resuscitator should compress the chest approximately ½ to ¾ of an inch in a smooth fashion. The compression and relaxation phases should be equal in duration, and the fingers or thumbs should not be lifted off of the chest at any time. The spontaneous heart rate should be checked periodically during the resuscitation, and chest compressions discontinued when the heart rate exceeds 80 beats/minute.

Vascular Access

A newborn requires vascular access for administration of medications or volume expansion. Bradycardia or asystole unresponsive to effective oxygenation, ventilation, and chest compressions warrant pharmacologic therapy. Infants exhibiting signs of poor perfusion, particularly those with risk for hypovolemia such as fetal hemorrhage or maternal hypotension from placental abruption, require volume expansion.

Several methods of vascular access may be used in the newborn. The umbilical vein is often considered a preferred site for vascular access during neonatal resuscitation because it is easily located and cannulated. See Section VII, Umbilical

Vein Catheterization for methods. A skilled resuscitator may elect to cannulate the umbilical artery to obtain arterial blood gases as well as to monitor arterial pressures in a significantly ill infant. See Section VII, Umbilical Artery Catheterization. Vascular access may also be obtained by placing peripheral catheters in the extremities or scalp (see Section VII, Intraosseous Infusion). In a newborn resuscitation scenario, peripheral venous access may be difficult. In the event that fluids and medications are required and other methods of vascular access have failed, intraosseous lines may be used. Although experience with other infants is extensive in this arena, experience in the neonate is limited. A 20- or 22-gauge spinal needle may replace the 16- or 18-gauge larger intraosseous needles; however, the procedure for line placement in the proximal tibia is the same as for older children (see Appendix 3.8). Finally, the ET tube may be used for administration of epinephrine and naloxone hydrochloride when vascular access has not yet been established.

Medications and Volume Expanders

Epinephrine

Epinephrine is the most commonly needed medication for neonatal resuscitation. Because asystole and bradycardia are usually the result of respiratory failure and tissue acidosis, epinephrine therapy is indicated when the newborn's heart rate remains less than 80 beats/minute despite effective ventilation with 100% oxygen and chest compressions for approximately 30 seconds. Epinephrine works because of its a-adrenergic effects. Swine models have demonstrated that a-vasoconstriction in infants increases the diastolic and mean arterial pressures and thus increases the perfusion pressure to the coronary arteries, enhancing oxygen delivery to the heart. The b-adrenergic effects of increased myocardial contractility and stimulation of spontaneous contractions appear less important.

The dose of epinephrine therapy in neonates is 0.01 to 0.03 mg/kg of a 1:10,000 concentration, or 0.1 to 0.3 mL/kg (Table 2.9). It may be administered via an umbilical catheter, a peripheral IV, an intraosseous line, or the ET tube. The dose should be repeated every 3 to 5 minutes as needed throughout the resuscitation. The safety and efficacy of high-dose epinephrine (0.1 to 0.2 mg/kg) has not been studied in neonates. A concern that large doses of epinephrine may lead to prolonged hypertension and subsequent intracranial hemorrhage in neonates has precluded changing dosing recommendations. In addition, the AHA continues to recommend that the dose of endotracheally administered epinephrine remain at 0.01 to 0.03 mg/kg. This is because of the findings by Lindemann in 1984 that 10 infants unresponsive to PPV and chest compressions were successfully resuscitated using regularly recommended doses of epinephrine. If the neonate has no vascular access and fails to respond to PPV with 100% oxygen, and a standard dose of epinephrine by the ET route, administration of a larger epinephrine dose (0.1 mg/kg) by the ET route may be considered.

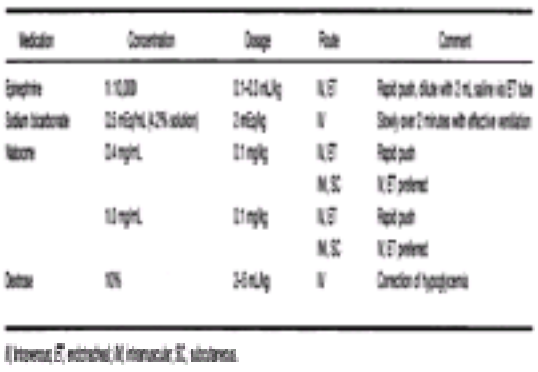

Table 2.9. Medications for Neonatal Resuscitation

Sodium Bicarbonate

Bicarbonate therapy is indicated in neonatal resuscitation, after establishment of adequate ventilation, for documented metabolic acidosis or presumed metabolic acidosis when other resuscitative measures have failed. The dose is 1 to 2 mEq/kg administered intravenously and slowly over 2 minutes to decrease adverse effects associated with its hypertonicity. For the same reason, only the 0.5 mEq/kg (4.2%) solution should be administered to neonates. If only the 1 mEq/kg solution is available, it should be diluted 1:1 with sterile water before intravenous delivery.

Recommendations for bicarbonate therapy have changed recently. In animal studies performed over the last 40 years, acidosis has been shown to reduce cardiac contractility, blood pressure, and heart rate responses to catecholamines. Subsequently, sodium bicarbonate therapy was recommended before administration of epinephrine. Correction of metabolic acidosis is very dependent on carbon dioxide removal by pulmonary gas exchange. This in turn is reliant on minute ventilation and pulmonary blood flow. Recently, investigators have discovered that in a resuscitation scenario, both minute ventilation and pulmonary blood flow are decreased. As a result, hypercarbia ensues and exacerbates intracellular acidosis. Therefore, bicarbonate should be administered only to the well-ventilated infant with a documented metabolic acidosis.

Naloxone Hydrochloride

Naloxone is a narcotic antagonist that reverses respiratory depression induced by narcotics. Naloxone is indicated for infants displaying signs of respiratory depression whose mothers have received narcotics within the 4 hours before delivery. Prompt and effective oxygenation and ventilation must be provided before administration of naloxone. The current dosing recommendation for naloxone is 0.1 mg/kg, which may be given as 0.1 mL/kg of the 1 mg/mL concentration or 0.25 mg/mL of the 0.4 mg/mL concentration (Table 2.9). This increased dosage from previously

published statements has been found more effective in opiate reversal. Naloxone is best administered via the intravenous, intraosseous, or ET routes. Sporadic and delayed absorption may occur if the medication is given intramuscularly or subcutaneously, particularly in an infant with poor perfusion. Furthermore, the resuscitator must remember that repetitive doses of naloxone may be required because the duration of action of narcotics may exceed that of naloxone.

Atropine

Atropine is a parasympatholytic drug that reduces vagal tone and accelerates sinus or atrial pacemakers and atrioventricular conduction. Because vagal stimulation does not cause bradycardia in neonatal resuscitation, atropine is not indicated. Furthermore, many investigators believe that the bradycardic vagally mediated response to hypoxia is a valuable reflex to guide resuscitative efforts and should not be pharmacologically abolished by atropine.

The usual dose of atropine is 0.02 mg/kg with a minimum dose of 0.1 mg and a maximum dose of 2 mg. Because most newborns weigh less than 5 kg, their dose would require the 0.1 mg minimum. If smaller doses are given, paradoxical bradycardia and slowed atrioventricular conduction will likely occur. In conclusion, the efficacy of atropine in newborn resuscitation is unproven and anecdotal and could have deleterious consequences.

Volume Expanders

Volume expanders are indicated for the treatment of hypovolemia. Both historical and physical examination findings suggest the need for volume expansion. Historical factors include fetal hemorrhage from an avulsed cord or trauma, or maternal hypotension from placenta previa, placental abruption, or trauma. Umbilical cord prolapse may cause hypovolemia in the newborn. Physical examination findings include pallor that persists despite oxygenation, weak peripheral pulses with a good heart rate, and a poor response to resuscitation, including effective ventilation.

Volume expanders (Table 2.10) are given intravenously in 10 mL/kg aliquots; after each infusion, the infant is reassessed for improvements in perfusion, blood pressure, and oxygenation. It is appropriate to begin with a bolus of normal saline or Ringer's lactate and proceed to albumin or packed red blood cells based on the infant's clinical response. Volume replacement should be given over 10 minutes to decrease the risk of intracranial hemorrhage from delicate vascular beds.

Fluid	Dosage	Route
5% albumin	10 mL/kg	IV
Normal saline	10 mL/kg	IV
Ringer's lactate	10 mL/kg	IV
Packed red blood cells	10 mL/kg	IV

IV, Intravenous.

Table 2.10. Volume Expanders for Neonatal Resuscitation

Post-resuscitation Stabilization

After appropriate resuscitative efforts, continuous monitoring and anticipation of complications must occur until the patient is safely transported to a neonatal facility. Priority must be given to thermoregulation by providing the infant with a warm environment and repetitively monitoring the temperature. Measures of effective oxygenation and ventilation are assessed. Pulse oximetry and arterial blood gases are performed. ET tubes are securely taped and a chest radiograph is ordered to confirm tube and venous access placement. Vascular access is secured, and correction of metabolic acidosis and hypovolemia is continued.

If mechanical ventilation is required while waiting transport to the neonatal facility, a pressure ventilator is used. Peak pressures are determined by clinical evaluation of adequate chest wall rise and blood gas analyses. A good starting point for peak pressure is that pressure needed for good chest wall rise and breath sounds during resuscitation as shown on the manometer. In general, this is between 15 and 30 cm H_2O. The physician should try to use the lowest pressure necessary for good clinical and laboratory response. Excessive positive pressure will decrease venous return to the heart, decrease cardiac output, and cause injury to lung tissue.

SPECIAL SITUATIONS

Meconium

Meconium staining of the amniotic fluid complicates between 10 and 20% of all pregnancies. The risk of meconium at delivery increases to nearly 30% in infant's born after 42 weeks' gestation. Approximately 2 to 5% of infants born with meconium in the amniotic fluid will experience some degree of aspiration syndrome, ranging from mild tachypnea to very severe pneumonitis with persistent pulmonary hypertension (Fig. 2.4). The management of an infant born through meconium differs from that previously discussed for other depressed infants. Efforts to remove meconium from the

oropharynx and trachea must precede other interventions because of the risk of its aspiration into the lungs with the infant's first breath.

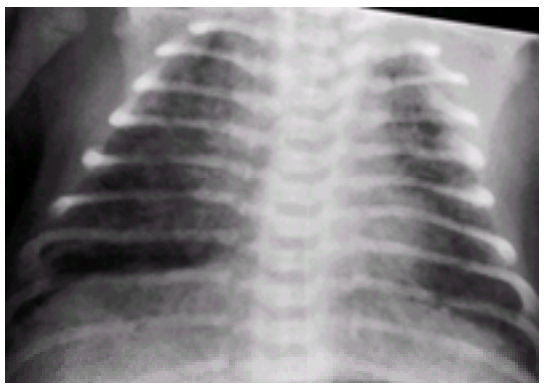

FIGURE 2.4. Meconium aspiration radiograph.

When meconium staining is detected during delivery, a sequence of events to prevent aspiration must occur (Fig. 2.5). As soon as the infant's head is delivered, suctioning of the mouth, nose, and posterior pharynx must occur with a 12- or 14-Fr suction catheter or bulb syringe at the perineum. Suctioning must be performed before delivery of the shoulders and thorax to decrease the risk of aspiration. After delivery, the infant is placed in a warm environment in a slight Trendelenburg position, and before other usual resuscitative efforts, meconium suctioning is completed. First, the oropharynx is visualized with a laryngoscope, and any remaining meconium is removed with a suction catheter. Next, the trachea is intubated, and suctioning of the lower airway occurs. Because the ET tube itself is the largest diameter item placed in the trachea, it is the most effective means of suctioning viscous meconium. Thus, a meconium aspirator directly attached between the ET tube and mechanical suction is the preferred method of removing meconium from the lower airway. Negative pressure is applied by occluding the opening on the side of the aspirator with a finger. Mechanical suctioning should not exceed –100 mm Hg. It may be necessary to repeat intubation and suctioning with another ET tube until the aspirated material is clear. Upon completion of tracheal suctioning, orogastric suctioning is performed to empty meconium from the newborn's stomach, which could potentially be aspirated later.

FIGURE 2.5. Diagram of management of infant born with meconium-stained amniotic fluid.

Several controversies exist regarding the management of meconium-stained amniotic fluid. Although all sources agree that thick, particulate meconium necessitates ET suctioning, management of thin meconium in a vigorous infant remains without consensus. Many authors, including the AHA and AAP, advocate ET suctioning for all infants with meconium-stained fluid. Their recommendations are supported by the finding that meconium aspiration syndrome necessitating prolonged periods of mechanical ventilation occur in infants with thin meconium as well as those vigorous infants with Apgar scores greater than 8. In addition, several studies have demonstrated no adverse sequelae of intubation. However, many authors contend that infants born through thin meconium warrant visualization of the cords with a laryngoscope and ET suctioning only if meconium is present in the larynx and the infant is depressed. As yet, no large prospective studies have investigated the benefits or complications of either a selective or nonselective approach to the management of the infant with thin meconium-stained amniotic fluid.

Prematurity

Prematurity greatly increases the likelihood of needing newborn resuscitation. Early involvement of neonatologists and neonatal centers adept in the management of low–birth weight infants is crucial to improve outcome. Only 15% of hospitals have specialized neonatal units. Hospitals without neonatal units need easily available guidelines and established relationships for accessing neonatal consultation and transport. Several factors have added importance in the resuscitation of the preterm infant. These include greater risk for heat loss, greater mechanical ventilation needs, and greater risk of intraventricular hemorrhage.

Premature infants are at greatest risk for heat loss because of their higher ratio of body surface area to body mass. Premature infants require strictest attention to maintenance of normal body temperature.

Premature infants are more likely to develop respiratory distress than term infants are. As a result, assisted ventilation

must be provided effectively but gently. ET intubation is usually necessary for surfactant administration and transport to a neonatal facility. Too much ventilatory pressure may result in barotrauma to the lungs and decreased cardiac output as a result of decreased venous return. Good clinical judgment should be used by watching for adequate chest wall rise and listening for good breath sounds. Then, the physician should use the lowest pressure necessary to achieve these clinical end points, which can be confirmed by blood gas analysis. Hyperoxia may lead to complications such as retinopathy of prematurity in low–birth weight infants. Once the infant is stabilized after initial resuscitative care, the fraction of inspired oxygen can be decreased while monitoring pulse oximetry.

The germinal matrix of the preterm infant's brain is vulnerable to bleeding. Factors contributing to subsequent intracranial hemorrhage include excessive pressure or osmolality delivered to an already maximally dilated vascular bed. Subsequently, in premature infants, hyperosmolar solutions such as 25% dextrose or 8.4% sodium bicarbonate should be avoided. Volume expanders, dextrose, and sodium bicarbonate solutions, when indicated, should be administered slowly to minimize injury to these vascular beds.

Pneumothorax

Pneumothorax is a potentially lethal problem in the neonate because it can rapidly progress to a tension pneumothorax and thereby decrease cardiac output. It is often the result of PPV, positive end-expiratory pressure, or resuscitation.

Pneumothorax is also more common in premature infants with surfactant deficiency and in infants with meconium aspiration. Signs and symptoms include grunting respirations; intercostal, sternal, and substernal retractions; elevated respiratory rate; and tachycardia followed by bradycardia and hypotension. The physical examination findings may include decreased breath sounds and distant heart tones. However, it often may not be possible to diagnose or localize a pneumothorax by auscultation. Transillumination by a high-intensity light in a dark room will reveal increased light transmission on the side of the pneumothorax.

If significant respiratory distress is present and pneumothorax is suspected, rapid decompression may be achieved with a large syringe, 20-gauge needle or catheter over needle, and three-way stopcock. The chest is cleansed with antiseptic solution, and the needle is advanced at the fourth intercostal space in the anterior axillary line or the second interspace in the midclavicular line. This will relieve the tension and decompress the pleural space. Subsequently, a chest tube (8 Fr) may be placed using a standard technique (see Section VII, Insertion of a Chest Tube). If the infant is stable, an expedient portable anteroposterior (AP) chest radiograph may be taken to confirm the diagnosis.

Diaphragmatic Hernia

Diaphragmatic hernia is a true neonatal emergency and may be suspected by tachypnea, asymmetric chest wall motion, and a scaphoid abdomen. The diagnosis is confirmed by a chest radiograph showing bowel gas within the thorax (Fig. 2.6). The patient should be given oxygen and a nasogastric tube placed to decompress the stomach. Intubation and PPV are often necessary. The infant must be rapidly evaluated by a pediatric surgeon after ventilation is stabilized and venous access is achieved.

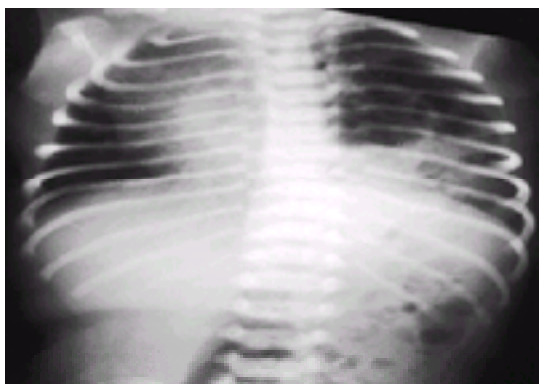

FIGURE 2.6. Left diaphragmatic hernia.

Omphalocele/Gastroschisis

Omphalocele and gastroschisis are defects of the umbilical ring that allow herniation of the abdominal contents outside of the abdominal wall. An omphalocele is covered by a thin layer of amnion that may be intact or broken. The abdominal contents are free-floating in the amniotic fluid in gastroschisis (Fig. 2.7). Cardiovascular malformations are commonly associated with omphalocele. The infant must be kept dry and warm, and the eviscerated bowel covered by warm saline-soaked gauze and placed in a plastic bag. If a sac covers the omphalocele and the sac is intact, it should be covered with saline-soaked gauze. A nasogastric tube must be placed and oxygen and IV fluids given. The infant may be hypovolemic from peritoneal fluid loss. The physician should maintain good peripheral perfusion and a urine output of 1 to 2 mL/kg per hour. The infant must be evaluated promptly by a pediatric surgeon who can repair these defects.

FIGURE 2.7. Gastroschisis.

Spina Bifida

Spina bifida (meningocele, meningomyelocele, and lipomeningocele) involves a wide array of defects. It can range from the least significant form (spina bifida occulta, nonfusion of vertebral laminar arches) to the severe form with meninges and neural tissue protruding, with poorly organized cord tissue exposed to the surface. Neurologic deficit ranges from none to severe impairment and associated hydrocephalus. The child should receive proper supportive care, oxygen and fluid (as needed), sterile moist dressings to the exposed sac or tissues, and prompt referral to a pediatric neurosurgeon.

CHAPTER 3

Shock

LOUIS M. BELL, MD

Department of Pediatrics, The University of Pennsylvania School of Medicine, and Section of Infectious Diseases, Division of Emergency Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

All physicians who care for ill children will be faced with managing the clinical syndrome of shock. Many common childhood illnesses, such as trauma, gastroenteritis, infection, and accidental drug ingestions, can lead to shock. Ultimately, without timely medical intervention, the child in shock will follow a common pathway to multiorgan system failure and death. Early recognition and appropriate therapy are vital if we hope to reduce the morbidity and mortality associated with this serious syndrome.

The first section of this chapter is devoted to early recognition, which demands a clear understanding of the definition, pathophysiology, and clinical manifestations of shock. Next, the etiologic types of shock, including hypovolemic, cardiogenic, distributive (septic), dissociative, and obstructive shock, are discussed.

Finally, the appropriate therapy and prevention of shock are discussed. Exciting developments are occurring within this area. Advances in molecular biology and immunology have led to a better understanding of the biochemical mediators involved in initiating and maintaining shock. Treatment modalities that antagonize or prevent the inflammatory cascade that lead to shock, multiorgan system failure, and death are now being studied. Combined with aggressive supportive and microbial therapies, these experimental immunotherapies may further reduce the morbidity and mortality associated with shock.

DETERMINANTS OF CARDIAC OUTPUT AND THE DEFINITION OF SHOCK

Circulation in the Child

Normal circulatory function is maintained by the complex interplay between the central pump (heart) and blood flow at the regional level, all done with the sole purpose of delivering oxygen and nutrients to the tissues.

The cardiac output is calculated by multiplying the stroke volume (volume of blood ejected by the left ventricle) by the heart rate (ejection cycles per minute). The stroke volume depends on the filling volume of the ventricle (preload), myocardial contractility (Starling's curve), and the resistance against which the heart is pumping blood into the systemic vasculature (afterload).

Heart rate is controlled through the vagus nerve and endogenous catecholamine release. Hypertension and severe hypoxemia can lead to increases in vagal tone and bradycardia. In times of “flight, fright, or stress,” endogenous catecholamine release increases adrenergic tone with an increased heart rate. In the infant, who has relatively less myocardial contractility, in times of metabolic need, increase in cardiac output depends on an increasing heart rate rather than on an increase in stroke volume. This is also the reason bradycardia is poorly tolerated in this age group; cardiac output falls quickly because there is little ability to compensate with an increase in stroke volume. Conversely, faster heart rates are best tolerated in infants, in whom ventricular filling time is less critical in contributing to stroke volume and, ultimately, to cardiac output.

Definition of Shock

An understanding of normal physiology allows us to define *shock* as an acute syndrome that occurs because of cardiovascular dysfunction and the inability of the circulatory system to provide adequate oxygen and nutrients to meet the metabolic demands of vital organs. Note that this definition recognizes that shock can and does exist without hypotension.

PATHOPHYSIOLOGY

Microcirculatory Dysfunction

The clinical manifestations of shock can be directly related to the abnormalities seen on the tissue, cellular, and biochemical levels. Microcirculatory dysfunction, common to all etiologic types of shock, is characterized by maldistribution of capillary blood flow. Local sympathetic, vasoconstrictor nerve activity and circulatory vasoactive substances (Table 3.1) cause smooth muscle contraction in the precapillary sphincters and arterioles. As shock continues, mechanical obstruction of capillary beds occurs by blockage with cellular debris. Normally, polymorphonuclear leukocytes undergo extensive deformation as they squeeze through the capillaries. Hydrostatic pressure within the capillary makes this possible. However, hydrostatic pressures fall by 30 to 40% during shock states. As a result, capillary beds are blocked and endothelial damage occurs. Subsequent complement activation causes still further aggregation of platelets and granulocytes. During septic shock, exposure to endotoxin directly damages vascular endothelium. Once damaged, endothelial cells can generate procoagulant activity, which may explain the mechanism by which fibrin is deposited in the microcirculation. Superoxide radicals, lysosomal metabolites, and cytokines produced by macrophages and neutrophils for bacterial killing can result in further tissue damage, especially to endothelium, adding to the vicious cycle of damage to the microcirculation.

Mediator	Stimulus	Major Source	Major Actions
Norepinephrine	Hypovolemia	Sympathetic nervous system	Vasoconstriction
	Head trauma	Adrenal medullae	β_1, β_2 stimulation
Epinephrine	Hypovolemia	Adrenal medullae	Vasoconstriction
	Hypercapnea		α_1, β_1 stimulation
Angiotensin II	Hypovolemia	Kidneys, brain, blood	Vasoconstriction
Arachidonic acid metabolites			
Leukotrienes	Tumor necrosis factor	Macrophages	Capillary permeability
	Bacterial antigens		Vasoconstriction, release of myocardial hydrolases
Thromboxane A_2	Hypoxia	Platelets	Vasoconstriction, platelet aggregation
Prostaglandins $F_{2\alpha}$	Hypoxia	Platelets	Vasoconstriction
		Vascular smooth muscle	
Prostaglandins I_2	Hypoxia	Healthy vascular endothelium	Vasodilator counterbalance thromboxane A_2
Myocardial depressant factor	Ischemia	Pancreas	Direct negative inotropic effects
	Tissue damage		
Opiates (β-endorphins)	Hypoxia	Pituitary	Decreased myocardial contractility
			Decreased sympathetic tone hypotension

Table 3.1. Endogenous (Host-Derived) Vasoactive Mediators in Shock

Tissue Ischemia

Tissue ischemia is also basic to all forms of shock. The consequences of poor tissue perfusion sustain the cascade of events that occur during shock. When there is a lack of oxygen, energy production at the cellular level becomes inefficient, producing only 2 moles of adenosine triphosphate (ATP) per mole of glucose, instead of the normal 38 moles of ATP produced by aerobic metabolism.

In addition, anaerobic metabolism depletes glycogen stores with an accumulation of lactate and associated acidosis. The decreasing energy and acidosis lead to an efflux of potassium and an influx of sodium and calcium with an obligate influx of water into the cell. Cellular swelling and further cellular dysfunction occur, which is seen clinically as edema.

Release of Biochemical Mediators

Biochemical mediators play an important role in the development and continuation of all types of shock. These vasoactive and inflammatory mediators are endogenous (host-derived) products primarily from cells of nervous system and hematopoietic origin. Although in septic shock these mediators are stimulated after exposure to microbial products (e.g., endotoxin) and play a primary role in initiating shock, in hypovolemic and cardiogenic shock, they are released secondarily in response to ischemic cellular injury as just described.

VASOACTIVE MEDIATORS

The vasoactive mediators exert their effect primarily by induction of severe vasoconstriction and vasospasm, induction of platelet aggregation and thrombus formation, increased capillary permeability, and redistribution of blood flow away from vital tissues (Table 3.1).

INFLAMMATORY MEDIATORS

In the past, it was believed that invasive microbial agents were directly responsible for the cellular damage and microcirculatory dysfunction seen in septic shock. However, within the last decade, it has become clear that endogenous inflammation mediators are the real culprits in the pathogenesis of septic shock and that lethal tissue injury occurs when

production of these mediators escalates out of control.

Septic shock starts with exposure to microbial products. Perhaps the most potent stimulator of the inflammatory cascade is the outer cell membrane of Gram-negative bacteria, a lipopolysaccharide coat (LPS), also called endotoxin. Once in the bloodstream, the LPS attaches to a plasma protein called LPS-binding protein, or LBP. This complex (LPS-LBP) binds to the CD14 receptor on the surface of the monocyte/macrophage, which leads to stimulation of tumor necrosis factor (TNF) and interleukin-1 (IL-1) and ultimately to the entire cascade of inflammatory mediators.

As a group, these newly described protein mediators are called cytokines (Table 3.2). TNF plays the pivotal role in triggering the production of not only other cytokines but also other inflammatory mediators. TNF is one known endogenous factor that is capable of inducing a broad range of vasoactive and inflammatory mediators. Because of this, treatment of shock with anti-TNF antibodies has been attempted with mixed results (see “ Initial Therapy ,” following). TNF in physiologic amounts has beneficial effects in tissues and promotes wound healing, tissue remodeling, and neovascularization. In pathogenic amounts, TNF and other inflammatory mediators (Table 3.2) cause severe septic shock in animal models and act primarily by inducing fever, increasing the white blood cell counts, inducing production of procoagulant and cell adhesion molecules by endothelial cells, causing aggregates of hematopoietic cells, and increasing vascular permeability.

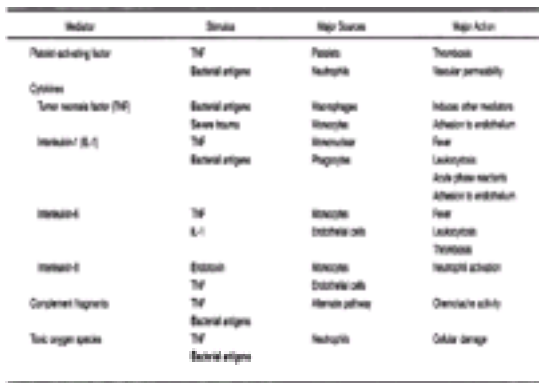

Table 3.2. Endogenous (Host-Derived) Inflammatory Mediators in Shock

NITRIC OXIDE

In 1990, several groups noted that circulatory shock appears to be intimately associated with an increased production of nitric oxide by a variety of different cells. After exposure to TNF-a and IL-1 a variety of cells, including, macrophages, vascular endothelium, vascular smooth muscle, hepatocytes, and cardiac myocytes, are induced to increase nitric oxide production. In pathologic amounts, nitric oxide causes vasodilation, vascular hyporesponsiveness, and hypotension. Although nitric oxide has beneficial effects that make it important in host defense against infection, in excessive amounts, nitric oxide leads to hypotension, worsening the shock state. Studies are ongoing to determine whether drugs that inhibit nitric oxide production may be useful in controlling shock.

COMPLEMENT ACTIVATION

The complement system is activated by circulating bacteria and bacterial products. The low-molecular-weight peptides that are released as a result induce both vasoactive and inflammatory effects. Vasoactive effects are seen with C3 and C5 fragments, which promote the release of histamine and other vasoactive mediators, which produces increased permeability and vasodilation. Complement fragments also stimulate an inflammatory response by promoting the activation and aggregation of platelets and granulocytes.

MYOCARDIAL DEPRESSANT FACTOR

Myocardial depression occurs in all types of shock. Recent investigation suggests that myocardial depression may occur as a result of mediators that act directly on myocardial tissue. Discovered in 1970, a small peptide called myocardial depressant factor is produced when the pancreas is ischemic and hypoperfused. Myocardial depressant factor has been shown to have negative inotropic effects in isolated heart muscle and causes constriction of the splanchnic vascular bed. In 1985, Parker, using isolated heart muscle preparation, found altered inotropic responsiveness within 1 to 2 hours of endotoxin treatment, demonstrating in vitro what is apparent in patients with shock syndrome.

Intrinsic myocardial depression either primarily as in septic shock or secondarily as in hypovolemic or cardiogenic shock adds to other circulatory derangements that have been discussed. Understanding this intrinsic or direct cardiac depression is important in designing treatment strategies.

CLINICAL MANIFESTATIONS

Early or Compensated Shock

Regardless of the etiology, shock begins when there is absolute or functional hypovolemia. Absolute hypovolemia exists in cases of severe emesis and diarrhea, trauma with blood loss, peritonitis, and “third-spacing” of fluids or increased capillary permeability, as in sepsis. Functional hypovolemia exists when vascular capacity increases, as in septic shock,

spinal cord injury, anaphylaxis, and barbiturate overdose.

The signs of early shock include tachycardia, mild tachypnea, slightly delayed capillary refill (more than 2 to 3 seconds), orthostatic changes in blood pressure or pulse, and mild irritability. These earliest symptoms result from an effort to compensate for shock and increase cardiac output and maintain perfusion of vital organs (brain, heart, kidneys). Unexplained tachycardia without other signs may be one of the earliest signs of shock. Tachycardia occurs to compensate for a diminished stroke volume (Fig. 3.1). Delayed capillary refill occurs as increases in sympathetic tone by endogenous catecholamines cause peripheral vasoconstriction. In some cases of early septic shock, the skin may be warm and dry without a decrease in capillary refill, reflecting cutaneous vasodilation in a state of increased cardiac output and increased venous capacitance—so-called warm distributive shock. As systemic vascular resistance falls, cardiac output must increase to maintain normal arterial pressure. Often, in this form of distributive (septic) shock, the pulse will be bounding and the pulse pressure widened.

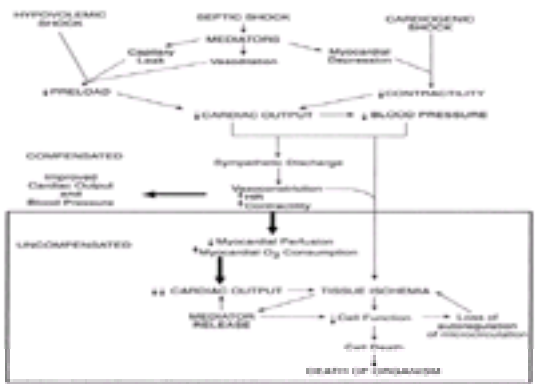

FIGURE 3.1. Sequence of pathophysiologic events in clinical shock states. (Reprinted with permission from Witte MK, Hill JH, Blumer JL: Shock in the pediatric patient. Adv Pediatr 34:139–174, 1987.)

Late or Uncompensated Shock

As shock continues, these early compensatory mechanisms are not enough to meet the metabolic demands of the tissue, and uncompensated shock follows (Fig. 3.1). In uncompensated shock, the effects of cellular ischemia with the associated release of vasoactive and inflammatory mediators begin to effect the microcirculation, and the child shows signs of brain, kidney, and cardiovascular compromise.

Tachycardia and tachypnea continue. Tachypnea becomes more severe because an increasing acidosis elicits a compensatory increase in the minute ventilation, resulting in a fall in Pa CO_2 and a compensatory respiratory alkalosis. The skin may be mottled or pale and extremities cool as vasoconstriction and diminished blood flow to the skin occur. Capillary refill becomes markedly delayed (more than 4 seconds). Hypotension is noted. Decreased cardiac output and vasoconstriction cause renal perfusion, and oliguria is noted. The gastrointestinal tract is also underperfused and may become ischemic. Under these conditions, decreased motility, distension, release of vasoactive and inflammatory mediators, and fluid accumulation may occur. In patients with septic shock, fever (greater than 38.3°C rectally) or hypothermia (less than 35.6°C rectally) may occur. As perfusion of the brain occurs, irritability progresses to agitation, confusion, hallucinations, alternating periods of agitation and stupor, and finally coma. The multiorgan dysfunction secondary to ongoing shock and exaggerated inflammatory responses has been termed systemic inflammatory response syndrome (SIRS).

The effects of a dysfunctional microcirculation, tissue ischemia, and release of vasoactive and inflammatory mediators obviously affect all tissues, including the pulmonary tissues and vasculature. Damage to the capillary endothelium in the lung allows fluid to fill the interstitium of the intra-alveolar septum. If the shock syndrome progresses, fluid accumulation will eventually lead to fluid leakage into the alveolar spaces, which prevents adequate gas exchange. As the damage to the lungs continues, the child demonstrates dyspnea, tachypnea, cyanosis refractory to oxygen therapy, decreased lung compliance, and diffuse alveolar infiltrates. These signs, when grouped together, have been termed the adult respiratory distress syndrome (ARDS), which, despite the name, has been seen in infants as early as 2 weeks after birth. For example, Carcillo found that 11 (32%) of 34 children with septic shock develop ARDS.

TYPES OF SHOCK

Hypovolemia

Hypovolemia (decreased circulating blood volume) is the most common cause of shock in children. The most common cause of hypovolemic shock occurs from water losses associated with diarrhea and vomiting (see Chapter 16). The World Health Organization estimates that in developing countries, 5 to 10 million diarrhea-associated infant deaths occur annually, primarily because of hypovolemic shock, secondary to the vomiting and diarrhea that occurs with a variety of infectious agents, such as rotaviruses. Other causes of hypovolemic shock include blood losses (trauma, gastrointestinal, intracranial hemorrhage), plasma losses (burns, hypoproteinemia, peritonitis), and water losses (glycosuric diuresis, sunstroke).

Distributive Shock

Distributive shock occurs primarily because of vasodilation and pooling of blood in the peripheral vasculature. Causes

include anaphylaxis, central nervous system (CNS) or spinal injuries, drug ingestions, and most commonly in children, sepsis. The primary derangements in septic shock results from exposure to microbial components (e.g., endotoxin, teichoic acid, viral proteins), which trigger the cascade of inflammatory and vascular mediators described. The bacterial etiology of septic shock (and meningitis) is listed in Table 3.3. *Haemophilus influenzae* type b used to be the most common bacteria associated with septic shock in infants and children but has been virtually eliminated through vaccination.

Organism
Streptococcus pneumoniae
Neisseria meningitidis
Group B *Streptococcus*
Listeria monocytogenes
Haemophilus influenzae type b
Gram-negative bacilli[b]
Staphylococcus aureus
Pseudomonas aeruginosa
Salmonella enteritidis

[a]Listed in order of most to least frequently isolated from blood or cerebrospinal fluid. Based on data from Schuchat A, et al. *N Engl J Med* 1997;337:970–976.
[b]Includes *Escherichia coli* and *Enterobacter* species.

Table 3.3. Bacterial Etiology of Invasive Disease in Infants and Children[a]

In 1990, Jacobs et al. retrospectively analyzed more than 2000 admissions to their pediatric intensive care unit over 3 years. They found that 27% (564 cases) of admissions met criteria of sepsis syndrome, which included 1) clinical manifestations of sepsis, 2) fever (greater than 38.3°C) or hypothermia (less than 35.6°C), 3) tachycardia, 4) tachypnea, and 5) signs of inadequate tissue perfusion (e.g., decreased capillary refill, hypoxemia, oliguria, acidosis, altered mental status). Inotropic support was required to maintain an adequate blood pressure in 268 of 564 patients that met this criteria. However, an etiology for septic shock was found in only 143 (25%) of cases. Meningitis was found in half of these children (71 of 143), and mortality was 10% (14 of 143). In some cases of septic shock, superantigenic bacterial toxins are responsible. Toxins such as staphylococcal toxic shock syndrome toxin-1 (TSS-1) and streptococcal exotoxin-A (SPEA) are suspected to cause profound hypotension, leading to inflammation and multiorgan failure. Both of these superantigens have been shown to stimulate monocyte/macrophage production of TNF-a, IL-1b, and IL-6.

Cardiogenic Shock

Cardiogenic shock can usually be distinguished from other forms of shock because of associated signs of congestive heart failure, including rales auscultated throughout the lungs, a gallop cardiac rhythm, enlarged liver, and jugular venous distension.

Regardless of the etiology, cardiogenic shock leads to decreased cardiac output, in most cases as a result of a decrease in myocardial contractility. As we have seen, direct myocardial damage occurs in all types of shock as a late manifestation. Other common etiologies of cardiogenic shock in children include viral myocarditis, arrhythmia, drug ingestions, postoperative complications of cardiac surgery, metabolic derangements (hypoglycemia), and congenital heart disease. Occasionally, congenital heart disease is diagnosed in an infant, usually within the first 3 months of life, when the infant presents to the emergency department in congestive heart failure and shock. These infants invariably have congenital heart abnormalities, such as truncus arteriosus, transposition of the great vessels, or left hypoplastic heart syndrome, that depend on flow through the ductus arteriosum to maintain adequate oxygen delivery. The closure of the ductus precipitates congestive heart failure and eventually cardiogenic shock.

The management of obstructive shock, which is caused by mechanical obstructions to ventricular outflow and occurs with pericardial tamponade or tension pneumothorax (see Chapter 100 and Section VII), and dissociative shock, which occurs secondary to carbon monoxide poisoning (see Chapter 86) or methemoglobinemia, are discussed elsewhere.

TREATMENT

Initial Therapy

To determine proper therapy, we should recall the definition and pathophysiology of shock. *Shock* is defined as an acute syndrome that occurs because of cardiovascular dysfunction and the inability of the circulatory system to provide adequate oxygen and nutrients to meet the metabolic demands of vital organs. Therefore, initial therapy in the emergency department can be applied universally, regardless of the etiology of shock, and is directed to reverse or halt further tissue injury. To underscore this, in 1989, Carcillo compared hemodynamic and oxygen use in children with either cardiogenic shock or septic shock. These data suggested that there was little difference physiologically, and therefore, initial treatment should be similar.

As noted previously, the basic defects are in shock hypovolemia, microcirculatory dysfunction, tissue ischemia, and cardiovascular dysfunction. Each of these defects becomes more severe the longer the shock state exists, so prompt and aggressive treatment is mandatory. The etiology of shock can be determined as therapy begins.

With this pathophysiology in mind, the first steps of therapy are to 1) establish an adequate airway; 2) determine whether breathing is adequate; 3) provide oxygen at 100% Fi O_2; 4) establish vascular access and obtain laboratory samples; and 5) provide aggressive fluid resuscitation, beginning with 20 mL/kg of crystalloid 0.9% sodium chloride or Ringer's lactate

given intravenously as rapidly as possible (minutes). Reassessment after each therapeutic maneuver is vital (Fig. 3.2). After the initial therapy, the following questions should be addressed: 1) Is tracheal intubation needed? 2) Should additional intravenous therapy be given? If so, blood, crystalloid, or colloid? 3) Are positive inotropic drugs needed? If so, which one initially? 4) What is the urine output? 5) What other drugs are needed (antibiotics)? 6) Should arrangements for admission to the intensive care unit be initiated?

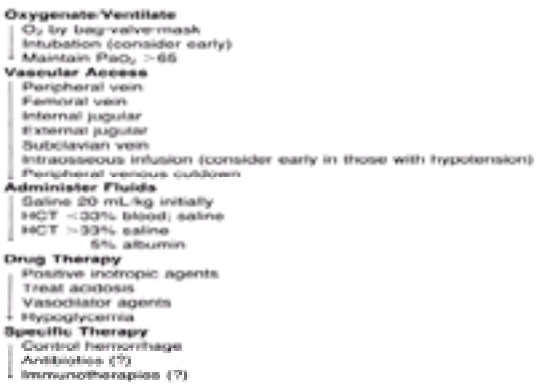

FIGURE 3.2. Management of shock—overview.

Simultaneously, a history should be obtained while the initial treatment is started. If possible, another physician can obtain a history from the caretakers. Questions pertaining to trauma, fever, diarrhea, vomiting, medication, allergies, heart disease, and seizures should be addressed.

Decision and Monitoring in the Emergency Department

Oxygenation

Oxygen delivery to the tissues remains our primary focus in children with shock. While the airway and ventilatory effort is assessed, 100% oxygen should be provided via a bag-valve-mask apparatus. Assisted bag-valve-mask may be indicated. If there is any question that the airway is obstructed or that ventilatory effort is inadequate, the insertion of an artificial airway is indicated. We suggest the orotracheal intubation route initially. Measurements of the Pa O_2 by an arterial blood sample or pulse oximetry should be done throughout the decision-making process. The goal is to maintain the arterial oxygen tension above 65 mm Hg; therefore, 100% oxygen should be continued until that is achieved.

Vascular Access

Vascular access is vital in treatment. If possible, a large-bore intravenous catheter should be inserted in a peripheral vein. However, in many instances, the peripheral extremities will be cool because of vasoconstriction and no vein is found. Central vein venous placement by the Seldinger technique (see Section VII, Procedure 3.2) is the next step. Use of the femoral vein is preferred in infants and younger children. In older children and adolescents, cannulation of the internal jugular, external jugular, and subclavian veins can also be considered. If there is any delay in accomplishing prompt placement of a central venous catheter, an intraosseous line should be placed.

In children less than 5 years old, needle placement into the marrow space of the medial portion of the proximal tibia, angulated away from the growth plate and 1 to 2 inches below the tibial tuberosity, is indicated (see Section VII, Procedure 3.8). In older children (more than 5 years old) and adults, needle placement 1 to 2 inches above the medial maleolus is indicated. If central line placement is delayed, intraosseous fluid replacement is an excellent interim step in infants and children who require fluid resuscitation. In 1991, Velasco et al. found this technique to be useful in resuscitation in a hemorrhagic shock model. Others have commented on the safety and ease of placement. Intravenous fluid, blood products, bicarbonate, and catecholamines are among the therapies successfully given using this technique and are comparable in effect to the central or peripheral intravenous routes.

The last resort in establishing venous access would be for a venous cutdown (see Section VII, Procedure 3.1). Simultaneous with attempts at vascular access, venous blood samples can be obtained for complete blood count, platelets, prothrombin and partial thromboplastin times, electrolytes, blood urea nitrogen, creatinine, glucose, and blood culture (if indicated). An arterial blood sample should also be obtained.

Fluid Administration

After venous access is established, 20 mL/kg of 0.9% normal saline or Ringer's lactate is infused as rapidly as possible. Then reassessment should occur. The decision to give additional intravenous fluids can be based on arterial pressures, heart rate, and oxygenation. If blood pressure is normal, additional fluids will depend on urine output, heart rate, capillary refill, and mental status. If the child remains hypotensive after the initial fluid challenge, an additional 20 mL/kg should be infused and, if possible, titrated against central venous or right atrial pressures because they correlate better with intravascular volume than does systemic arterial pressure. If there is a delay in transfer to the intensive care area, central venous pressure monitoring can be accomplished in the emergency department. Once in the intensive care setting, placement of a balloon-tipped, flow-directed pulmonary artery catheter may be needed to assess more accurately the filling pressures of the heart.

If there is delay in transfer to the intensive care area, fluid management may be directed by right heart filling pressures

(central venous pressures). This can be accomplished by using a modification of Weil's “4 and 2 rule” (Fig. 3.3). Central venous pressure (CVP) is observed for 10 minutes. If that pressure is less than 6 mm Hg, 4 mL/kg is infused over 10 minutes, discontinuing the infusion if CVP rises at any time more than 4 mm Hg. If, after the infusion, CVP has risen by less than 4 mm Hg but more than 2 mm Hg, the patient should be observed for 10 minutes. If CVP remains above 2 mm Hg of the starting value, the patient should be monitored without administering additional fluid. If CVP declines to within 2 mm Hg of the initial value, again 4 mL/kg should be infused over 10 minutes. We repeat these maneuvers until the systemic arterial pressure reaches a normal value, the patient manifests other signs of restored circulation integrity, or the “4 and 2 rule” is violated. If the initial CVP lies between 6 and 10 mm Hg, we administer 2 mL/kg over the 10-minute period and look for the same CVP changes. If the initial CVP exceeds 10 mm Hg, we infuse 1 mL/kg fluid over 10 minutes and again observe the CVP change.

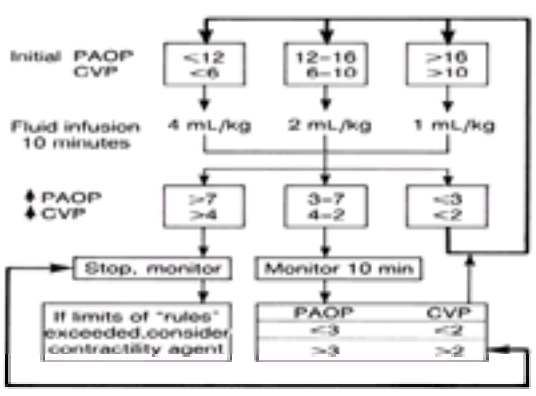

FIGURE 3.3. “7-3, 4-2 Rules” of Weil. *CVP,* central venous pressure; *PAOP,* pulmonary artery occluded pressure. (Adapted from Weil MH. J Am Med Assoc 1969;207:337–340.)

Two points should be emphasized. First, we examine the change in CVP measurement in response to the fluid infusion, rather than look for an absolute value. Second, because the veins are very distensible vessels and act as a reservoir for fluid, a threefold increase in the volume of fluid contained in the venous system may be necessary before we see changes in CVP. When the pulmonary artery occluded pressure (PAOP) is used, 7 and 3 mm Hg should be substituted for 4 and 2 mm Hg CVP measurements (Fig. 3.3).

If this type of management is not possible in the emergency department or if transfer to the intensive care is imminent, changes in vital signs and perfusion can be used to guide fluid management. Despite the fact that we do not base fluid management on an absolute amount and are guided by the child's clinical condition, we can give some ballpark figures for initial fluid resuscitation. In 1991, Carcillo et al. studied all children with septic shock who presented to the emergency department over a 6-year period and who had a pulmonary artery catheter inserted within 6 hours of presentation. Interestingly, fluid resuscitation in excess of 40 mL/kg in the first hour improved survival and was not associated with an increased risk of either cardiogenic pulmonary edema or ARDS, compared with children who received smaller amounts of fluid. Therefore, in severe shock, fluid resuscitation, if indicated, up to 60 mL/kg or approximately 50% of the circulation blood volume may be given within the initial phase of therapy. The important point to remember is that, in most cases of shock, not enough fluid is given and the child remains in relative hypovolemic shock. Monitoring such signs as heart rate, capillary refill, mental status, and urine output (at least 1 mL/kg/hour) is helpful in determining the amount of fluids needed in the initial phases of resuscitation. Monitoring of cardiac output is essential for children with cerebral damage of those in cardiogenic shock, in which case the need for adequate fluid resuscitation must be balanced with concerns over cerebral edema or cardiac disease, respectively.

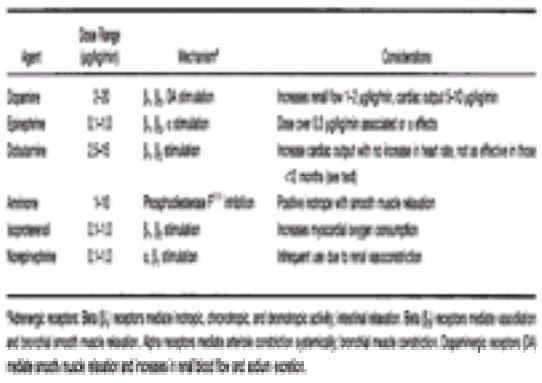
Choice of Fluids and Blood Products

The initial choice of fluid should be 0.9% saline or Ringer's lactate given as described earlier, beginning with 20 mL/kg over minutes. Packed red blood cells should be given at 10 mL/kg over 1 to 2 hours to maintain a hematocrit of 33%. Children with cyanotic heart disease, or neonates, may require higher hematocrit percentages to ensure adequate tissue delivery.

If the hematocrit is over 30% or if blood is not available, 5% albumin in 0.9% sodium chloride can be used in combination with crystalloid fluids. Initially, albumin can be given in 10 mL/kg doses. When colloids (albumin) are used, appropriate intravascular monitoring should be considered when possible to guard against circulatory overload.

Improving Myocardial Function

Catecholamines (adrenergic agents) are the drugs of choice for improving myocardial contractility in patients with shock because of their very short half-life (2 to 3 minutes) and potency (Table 3.4). A brief review of adrenergic receptor physiology is important if we are to have a rational approach to their use.



Agent	Dose Range (µg/kg/min)	Mechanism[a]	Considerations
Dopamine	2–20	β_1, β_2, DA stimulation	Increases renal flow 1–2 µg/kg/min; cardiac output 5–10 µg/kg/min
Epinephrine	0.1–1.0	β_1, β_2, α stimulation	Dose over 0.3 µg/kg/min associated w α effects
Dobutamine	2.5–10	β_1, β_2 stimulation	Increase cardiac output with no increase in heart rate, not as effective in those <12 months (see text)
Amrinone	1–10	Phosphodiesterase F^{111} inhibition	Positive inotrope with smooth muscle relaxation
Isoproterenol	0.1–1.0	β_1, β_2 stimulation	Increases myocardial oxygen consumption
Norepinephrine	0.1–1.0	α, β_1 stimulation	Infrequent use due to renal vasoconstriction

[a]Adrenergic receptors: Beta (β_1) receptors mediate inotropic, chronotropic, and dromotropic activity; intestinal relaxation. Beta (β_2) receptors mediate vasodilation and bronchial smooth muscle relaxation. Alpha receptors mediate arteriole constriction systemically; bronchial muscle constriction. Dopaminergic receptors (DA) mediate smooth muscle relaxation and increases in renal blood flow and sodium excretion.

Table 3.4. Positive Inotropic Agents

There are at least three broad populations of adrenergic receptors, termed alpha (a), beta (b), and dopaminergic (DA) receptors. Although all have been subdivided further, in general, b $_1$-receptors mediate inotropic (contractility), chronotropic (rate), and dromotropic (increased conduction velocity) activity. b $_2$-Receptors mediate vasodilation and bronchial smooth muscle relaxation. a-Receptors mediate arteriole constriction systemically and bronchial muscle constriction. Dopaminergic receptors, termed DA_1 and DA_2 mediate smooth muscle relaxation and increase renal blood flow and sodium excretion.

Catecholamines may stimulate some adrenergic receptors more strongly than others, providing some rationale for selection. In general, the mechanism of action for most positive inotropic agents seems to be an increased concentration of or sensitivity to intracellular calcium during systole. If the desired effect is not achieved with one agent, combinations of several agents together may be necessary. It is important to note that there may be decreased responsiveness to adrenergic stimulation in patients with congenital heart disease, after heart transplantation, or in those with bronchopulmonary dysplasia.

Currently, dopamine is the first choice to improve cardiac function and improve splanchnic and renal circulation if the patient is relatively stable but remains hypotensive after initial fluid resuscitation. At low dosages (2 µg/kg/minute), dopamine increases renal blood flow up to 50% and sodium excretion up to 100%. Cardiac output is increased with dosages of 5 to 10 µg/kg/minute. Improvement in perfusion as measured by increased urine output, blood pressure, and warming of the extremities can be seen early. More accurate measurements of cardiac index, arterial mixed venous difference, or left ventricular stroke work can be used to titrate the dosage in the intensive care unit.

In some cases of profound septic shock and hypotension, epinephrine should be considered initially. A low dosage (less than 0.2 µg/kg/minute) of epinephrine stimulates both b $_1$ cardiac effects and b $_2$ peripheral vascular effects, which results in an increase in skeletal muscle blood flow and a decrease in diastolic blood pressure. Dosages higher than 0.3 µg/kg/minute are associated with increased a-adrenergic effects and increases in blood pressure. If the child is unresponsive to dopamine, epinephrine may be useful in maintaining blood pressure and cardiac output.

When epinephrine is being used, one may need to consider vasodilator therapy. Nutrient flow may be improved, left ventricular stroke work enhanced, and myocardial oxygen consumption decreased by lowering impedance to left ventricular ejections. A short-acting vasodilating drug such as sodium nitroprusside, beginning with 0.1 µg/kg/minute, is preferred. The infusion can be increased until evidence of decreased peripheral vascular resistance exists or until the generally accepted safe dosage of between 8 and 10 µg/kg/minute is reached. Toxicity results from the accumulation of cyanide, which should be monitored. The use of this therapy in the emergency department is rarely needed, although in cases in which transfer to the intensive care unit is delayed, it may be indicated.

Dobutamine should be considered initially in patients with cardiogenic shock because it is a very selective stimulant of b 1 receptors. In patients with cardiogenic shock, it tends to increase cardiac output without increasing the heart rate. Starting dosages should be 2 to 5 µg/kg/minute. However, Perkins found that infants with cardiogenic or septic shock who were less than 12 months of age derived little benefit from dobutamine, demonstrating insignificant increases in cardiac index and stroke index. If dobutamine fails, epinephrine should be used.

Finally, amrinone represents a class of inotropic agents distinct from the catecholamines. Although the mechanism of action is not fully understood, data favor inhibition of phosphodiesterase F ^{111}. A direct relaxant effect on vascular and vasodilation that results in smooth muscle causes afterload, and preload reduction contributes to the improved hemodynamic state. Amrinone facilitates atrioventricular conduction, relaxes smooth muscle, and dilates coronary arteries. At this time, there is seldom an indication to start this agent in the emergency department.

Acid-Base Abnormalities

It is clear that unless perfusion and ventilation are adequate, infusion of sodium bicarbonate rarely maintains arterial pH. Therefore, bicarbonate should be considered as a temporary and immediate therapy to acutely alter arterial pH so that myocardial performance will be optimized. Ultimately, improved blood flow will result in a decrease in acid products of anaerobic metabolism and only then will pH concentration remain normal. We calculate the dose of sodium bicarbonate according to the following formula: bicarbonate administered in milliequivalents (mEq) equals the body weight (kg) times base excess (BE) times 0.6. In the presence of acute hypercapnea, one-half of the calculated dose is administered and pH remeasured. If correction is not achieved, the remainder is infused. The suggested rate of administration should not exceed 2 mEq/minute.

Steroids

Bone, in a prospective, randomized, double-blind, placebo-controlled study of adults, concluded that high-dose corticosteroids provided no benefit in the treatment of septic shock. Patients in this study who exhibited serum creatinine levels above 2 mg/dL and received steroids experienced a significantly higher mortality rate than the placebo group. Furthermore, patients who received methylprednisolone died as a result of secondary infection more often than their placebo-treated counterparts. Currently, there is no good evidence to support the use of steroids in shock syndrome.

Disseminated Intravascular Coagulation

As we have seen, microcirculatory dysfunction, tissue ischemia, and cardiovascular dysfunction, regardless of etiology, leads to shock and consumption of coagulation factors and platelets. This consumption is characterized by thrombocytopenia, an increase in fibrin split products, a decrease in fibrinogen, and abnormally prolonged prothrombin time and partial thromboplastin times (see Chapter 36). Management includes platelet transfusions (if indicated for bleeding or platelet counts less than 50,000/mm^3) with infusion 0.2 unit/kg. Fresh frozen plasma, 10 mL/kg intravenously, may be given for prolonged prothrombin and partial thromboplastin times.

Antibiotics

Antibiotics are given presumptively in most cases of severe shock when the etiology is unclear. Antibiotics are chosen based on age and suspected bacterial pathogens. If the child is less than 4 weeks of age and there is no suspicion or evidence of meningitis, ampicillin and gentamicin is one effective combination. From 4 to 12 weeks of age, ampicillin and cefotaxime are favored by many pediatric infectious diseases specialists when meningitis is ruled out.

In some cases, the infant or child is too unstable to tolerate a lumbar puncture. Presumptive antibiotics should not be delayed in these cases. After resuscitation, the lumbar puncture can safely be performed and the cerebrospinal fluid (CSF) profile will still indicate a bacterial etiology. Latex agglutination tests can be obtained on urine plus CSF if the CSF culture and blood culture are negative. Presumptive antibiotics in children with shock and meningitis or when meningitis cannot be ruled out would include Vancomycin and cefotaxime for the possibility of a strain of *Streptococcus pneumoniae* that is resistant to penicillin or cefalosporins.

Immunotherapies

Over the last several years, the identification of the mediators of septic shock has lead to a better understanding of how these mediators cause and contribute to the pathophysiology of shock. Coincidentally, the use of monoclonal antibody techniques has allowed for the production of large quantities of antibody that are free from human infection and are of known isotype and epitope specificity. This new knowledge has led to the development of a number of investigational therapies aimed at different components of the inflammatory cascade. These therapies can be divided into three broad categories (Table 3.5): agents aimed at blocking the effects of circulating microbial products, agents that block cytokines, and finally agents that reduce or prevent nitric oxide production.

Category	Product and Mechanism of Action
Antiendotoxin	
E5	Murine IgM monoclonal antibody; binds to lipid A of endotoxin
HA-1A	Human IgM monoclonal antibody; binds to lipid A of endotoxin
Soluble CD14	Blocks binding of endotoxin to macrophage
Anti-CD14 antibody	Blocks binding of endotoxin to macrophage
Anticytokine	
Anti-TNF antibody	Blocks inflammatory cascade
TNF soluble receptor	Binds TNF, inhibits inflammatory cascade
IL-1 receptor antagonist	Blocks IL-1 binding
Nitric Oxide (NO) Inhibitors	
L-NMA	L-arginine analog; inhibits NO synthase and decreases NO production
L-NAA	Same as above

*The safety and efficacy studies of these agents in humans and animals have been mixed. In some cases, use of the above products have resulted in an increased mortality as compared to controls. Further research is needed.
TNF, tumor necrosis factor; IL-1, interleukin-1.

Table 3.5. Experimental Therapies[a] for the Treatment of Septis Shock (Selected)

Although initially there was much optimism that these products would reduce mortality by blunting the detrimental effects of inflammatory mediators, subsequent animal and human studies have revealed mixed results. In fact, some of these studies have been associated with an increased mortality.

The use of these agents needs further study in both animals and humans to first establish safety then efficacy. If proven effective, we can almost certainly expect to use these agents in the emergency department. Therefore, emergency medicine physicians will need to understand the indications and risks of these agents as new data are made available for review.

Laboratory Indications of Improvement in Shock

The initial phase of treatment for shock are directed to improve oxygen delivery to the tissues by ensuring adequate ventilation, correcting hypovolemia, and improving cardiac function.

The success of the initial resuscitation is usually reflected in signs of improved perfusion (skin, kidneys, brain, heart rate)

and indications of normal CVP if invasive monitoring is required. However, other laboratory parameters may be useful, if monitored sequentially, in determining if the shock syndrome is persisting despite early clinical improvement. Sequential measurements of serum lactate levels, and expired CO_2 gas (end-tidal CO_2) may indicate that continued aggressive resuscitation is needed despite signs of improvement.

In 1983, Vincent et al. found that a 5% reduction in serum lactate in the first hour was a good prognostic sign for patients presenting in circulatory shock. Lactate should fall over time as perfusion and oxygen delivery to the tissue improves. High serum lactate levels (approximately 4 mm/L) or serum lactate levels that continue to rise despite therapy are indications of severe shock. Aggressive therapeutic maneuvers to reverse the shock should be redoubled in this setting.

In addition, end-tidal CO_2 is a noninvasive laboratory value that may indicate continued hypovolemia. In hypovolemia and poor perfusion of the peripheral tissues and pulmonary tissues, CO_2 is not excreted in the lungs. Subsequently, there is a reduction of expired CO_2 gas, which is measured as a decreased end-tidal CO_2. As perfusion improves, end-tidal CO_2 increases. Investigators hope to correlate whether sequential end-tidal CO_2 measurements can be used to titrate the amount of intravenous fluid needed during resuscitation of the patient in shock. These measurements are noninvasive and may be a valuable adjunct in accessing improvements in perfusion in children with severe hypovolemia in the emergency department.

CHAPTER 4

Sedation and Analgesia

STEVEN M. SELBST, MD

Department of Pediatrics, Thomas Jefferson University, and Division of Emergency Medicine, A. I. duPont Hospital for Children, Wilmington, Delaware

Pain is an unpleasant sensory and emotional experience usually defined in terms of tissue damage, which is signaled by some form of visible or audible behavior. Acute pain serves a useful function and is necessary for survival; it alerts us to avoid certain painful stimuli, and it warns us that some body tissues may be damaged. It often helps the emergency physician make a correct diagnosis. For example, a fracture might be diagnosed by localizing pain with palpation of an extremity. Appendicitis might be diagnosed by finding tenderness in the right lower abdominal quadrant. Chronic pain, however, serves no useful function; thus, a child's pain must be relieved as soon as possible.

One of the most common reasons for seeking care in an emergency department (ED) is to relieve pain and suffering. Injuries and painful medical conditions are common among children, and ED physicians are expected to manage this pain appropriately. Unfortunately, pain control is not often addressed satisfactorily. In 1990, Selbst and Clark found that in the ED setting, 60% of adult patients received adequate analgesia for painful conditions, but only 28% of pediatric patients received adequate analgesia for similar painful conditions. Emergency physicians and pediatricians were equally unlikely to give analgesics to children. There have been great advances in recognition, assessment, and management of pain in children since then. The care of infants and children who undergo painful procedures in the ED has improved considerably. However, two recent studies showed that children still often fail to receive analgesia for painful conditions. Inadequate dosing of medications for children upon discharge from the ED is a significant problem.

Many theories try to explain why pediatric pain is not successfully managed in the ED. Physicians expect babies to cry, so this nonspecific response to pain often is tolerated instead of controlled. Moreover, because young children and infants cannot describe or localize their pain, it is often ignored or presumed not to exist. Adult patients who clearly indicate that they are in pain generally get a direct response from a physician, whereas a young child who is crying or whimpering may not. In addition, some ED physicians avoid giving adequate analgesics to children because they fear it will lead to drug addiction. This is fear unfounded, however, because narcotic addiction is extremely rare when medications are used appropriately to manage acute pain. Hypotension and respiratory depression are other feared consequences of narcotic use with children, and although these fears may be legitimate, respiratory depression and hypotension are unlikely to occur if proper protocols are adhered to. These unlikely occurrences should be manageable in the ED, and they should not inhibit the attempt to control pain. Furthermore, it is likely that ED physicians often are forced to concentrate on other aspects of resuscitation and care before managing pain. Plans for pain control, therefore, may be forgotten because of other priorities. Also, in some cases, pain is ignored because it is inconvenient to wait for analgesics to take effect. Thus, some physicians may convince a young child that a painful procedure or repositioning of an extremity will hurt only for a minute. Brute force (instead of medication) is then used, and more pain is inflicted on an already uncomfortable child. Table 4.1 summarizes some reasons for inadequate pain control with children.

Inability of young children to talk
Misconception that infants cannot feel pain
Misconception that children will not remember pain
Misconception that children will get addicted to narcotics
Fear of respiratory depression and hypotension
Unfamiliarity with analgesics and dosages
Other conditions taking priority

Table 4.1. Possible Reasons for Inadequate Pain Control in the Emergency Department

Pain control may not be properly addressed with children because many physicians lack knowledge about the management of such pain. Some textbooks and residency programs do not emphasize the management of acute pain. Until recently, pain control has been poorly studied in children. Children are often unable to cooperate or provide good verbal descriptions of pain, so it may be difficult to assess or quantitate pain or to measure success in treating it. Great progress has been made lately in the assessment of pain in children. Self-report pain scales are the best indicators of pain and are the gold standard for assessing pain in children. Pain measured with visual analog scales and "thermometers" have been validated for children. A visual analog scale is used with children older than 4 years of age. This scale has some limitations but seems useful regardless of the child's education, background, or gender. It consists of a 10-cm horizontal line with endpoints marked as "no pain" (0 score) to "worst possible pain" (10 score). Children can indicate the level of their pain by marking the line.

There are modified visual analog scales, such as color scales for use with younger children. Children score their pain on these scales by interpreting the pain as red, black, or purple. Also, children as young as 3 or 4 years old can use a face scale (e.g., the Oucher Scale), which has six pictures of a young boy's face, each displaying a different expression of pain, placed along a thermometer scale of increasing pain levels from 0 to 100.

Behavioral pain scales and physiologic pain scales (measuring heart rate, blood pressure, respiration, palm sweating, and transcutaneous oxygen) provide information about general distress levels in infants and young children. The Children's Hospital of Eastern Ontario Pain Scale (CHEOPS) is a behavioral scale that measures the child's face and verbal behaviors, as well as crying and movement. The scale has been found to be valid for assessing pain in younger children and infants who cannot use self-report scales. Research in the area of pain management for children has increased dramatically in recent years, and this should allow us improve our abilities to control pediatric pain in the future.

Emergency physicians must understand that pain is an individual experience and that many factors contribute to the degree of pain that a child feels for any given condition. For example, the age and cognitive development of a child are important. Children of all ages can experience pain. It is believed that even newborns feel pain, and many react to a painful stimulus (e.g., circumcision) with wriggling motions and crying. Younger children have lower pain thresholds than older children, and they do not tolerate painful procedures as well. For example, they often exaggerate the size and power of needles. Older children may be better able to understand the need for a painful procedure; they are usually less anxious and better able to tolerate this pain. However, an older child may have a better understanding about the significance of an injury or an illness that could cause depression, anxiety, and more pain. Similarly, parental response (anxiety or reassuring calm) may affect a child's perception of pain. Other psychological factors such as the child's emotional state or personality traits may create more or less anxiety, and this also can alter the degree of pain.

Some children seem to have a hypersensitivity to pain, whereas others tolerate it well. The child's gender or cultural background is likely to influence the pain experience, but this is not well studied in children. A study of Israeli children on a kibbutz found they did not scream or cry when they received inoculations. This was in contrast to 26% of urban Israeli children who expressed their pain quite emphatically with inoculations. It was thought that the kibbutz philosophy that "doctors are friends" accounted for the different responses of the two groups.

The context of the situation also plays a role, because children who are punched in play may not complain of pain. Yet, the same impact could elicit a significant response if it was meant as an attack or as punishment. A child's past experience with painful stimuli also is meaningful. A recent study showed inadequate analgesia for one painful procedure may diminish the effect of adequate analgesia in subsequent procedures. Of course, the painful stimulus itself is important, and a stimulus that causes a great deal of tissue damage may hurt more than one that causes minor injury. Figure 4.1 summarizes the components of the pain experience.

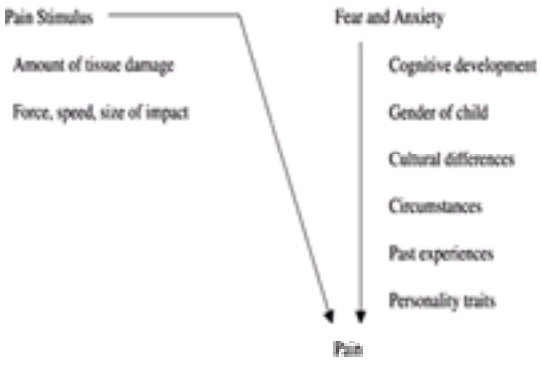

FIGURE 4.1. Components of pain. (Adapted from Schecter NL. Pain and pain control in children. Curr Prob Pediatr 1985;15:4–67.)

PAIN MANAGEMENT

Realistically, pain in the pediatric patient who presents to the ED is never eliminated completely. Efforts must be made, however, to relieve this pain as much as possible. Several means are available for managing pain in children, and various medications and techniques can be used, depending on the type of pain that requires treatment.

Minor Pain

Conditions such as headache, myalgia, chest pain, pharyngitis, otitis media, arthralgia, sunburn, strains, and sprains often produce minor pain in children. For treatment of this mild pain, aspirin, acetaminophen, ibuprofen (nonnarcotics), and codeine (narcotic) are excellent oral analgesic medications. *Aspirin* is one of the oldest analgesic medications, but its use has recently declined. It has the advantage of being inexpensive, and it has anti-inflammatory effects. Sustained high dosages are needed, however, for the anti-inflammatory effect. Thus, in most instances, aspirin is not much better than non–anti-inflammatory drugs. Aspirin may be given every 4 hours at a dosage of 10 to 15 mg/kg per dose. Higher dosages increase only the anti-inflammatory effect—not the analgesic effect. Buffered aspirin may be tolerated better and absorbed faster, but there is no evidence to show that it acts more rapidly or lasts longer than the nonbuffered variety. Likewise, enteric-coated aspirin is better tolerated but has variable absorption.

There are some definite disadvantages to using aspirin for pain management. It has many side effects, particularly gastrointestinal irritation in some patients, which can lead to nausea and vomiting. Aspirin also inhibits platelet function, which can lead to bleeding with overdosage, and it may cause reversible liver toxicity and central nervous system (CNS) problems (tinnitus, dizziness). Moreover, it may induce bronchospasm in asthmatic patients. Reye syndrome has been associated with the use of aspirin for varicella and flulike illness, but not for control of pain from trauma.

Acetaminophen acts centrally on nonopioid receptors in the brain to inhibit prostaglandin synthetase. Acetaminophen is more expensive than aspirin but is probably a better choice for pain associated with minor trauma or otitis media because it is tolerated better and it comes in liquid form, making it easier to give to young children. In some studies, acetaminophen has been shown to be a less potent analgesic than aspirin, but most claim it is equipotent. One study showed that 1000 mg of acetaminophen equals to 60 mg of codeine for postpartum pain. In addition, acetaminophen does not cause bleeding and is less likely than aspirin to cause bronchospasm in asthmatics. It is dosed at 15 mg/kg per dose every 4 hours and takes effect in 20 to 40 minutes, with a peak effect in 2 hours. High dosages are usually well tolerated, but therapy should not exceed 4 to 6 g/day. Acetaminophen has no anti-inflammatory effects, and therapeutic doses rarely are associated with side effects; overdose, however, can cause liver toxicity.

Nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., ibuprofen) are excellent choices for treating minor pain such as headache, dysmenorrhea, or musculoskeletal injuries. NSAIDs are thought to be more potent drugs than aspirin, and they have a longer half-life. Like aspirin, NSAIDs act on the peripheral nervous system to block formation of prostaglandins. The dosage is 8 to 10 mg/kg given every 6 hours. The recommended dosage for ibuprofen in older children is 400 mg every 4 to 6 hours for mild to moderate pain. Ibuprofen is available in liquid form, making it suitable for use in very young children. Ibuprofen is nonaddictive and does not cause respiratory or cardiac depression. They may cause gastrointestinal bleeding, but this risk is small. Like aspirin, these agents also cause renal and hepatic dysfunction and should be used with caution in children with renal or hepatic disease. Unlike aspirin, however, their effect on platelets (acetylation) is reversible. They can cause sodium retention, and they have cross-reactivity with aspirin, so they should not be used with patients who have aspirin sensitivity.

Finally, *codeine* is a narcotic analgesic that can be given orally (even to young children) to control minor pain. Codeine usually is given orally because it maintains two-thirds of its effectiveness in oral form compared with parenteral use. It is thought to be more potent than aspirin but less potent than meperidine; thus, it is valuable for moderate pain (dental abscess, severe otitis media, or stomatitis) and has a low addiction potential. The dosage is 0.8 to 1.5 mg/kg per dose every 4 to 6 hours. Codeine can be changed into a liquid form for use in young children, and it can be combined with acetaminophen or aspirin to produce an even greater analgesic effect than when either is used alone. Codeine can cause respiratory depression, but this occurs very rarely. It has no renal or hepatic toxicity and does not alter platelet function, but it can cause the same gastrointestinal side effects (e.g., nausea and vomiting) as noted for other narcotics.

The benefits of using codeine and the other analgesics described here for mild pain far outweigh the few side effects involved with their use in young children. Table 4.2 summarizes the advantages and disadvantages of these analgesics for treating minor pain in children.

Analgesic	Advantages	Disadvantages
Acetaminophen	Well tolerated, safe	Liver toxicity if overdosed
Aspirin	Inexpensive	Gastrointestinal irritation
Ibuprofen	Long duration of action	Gastrointestinal irritation
Codeine	Potent opioid analgesia	Nausea, constipation

Table 4.2. Analgesics for Mild Pain

Moderate and Severe Pain

Opioid medications are extremely important for treating patients in the ED with moderate to severe pain (burns, fractures, sickle cell vaso-occlusive crises). Most opioids can cause important adverse effects (respiratory depression and hypotension), but these often are dose related and may be reversed with naloxone, making opioids safe in the ED setting. Because of pharmacokinetic differences in young infants that may predispose them to respiratory depression, these drugs should be used with caution in infants less than 6 months of age who are not ventilated. Such infants should receive one-fourth to one-third of the initial calculated dosage recommended for older children, and they should be closely monitored. Opioid analgesics can be given by various routes. In general, the intramuscular route should be avoided because the injection itself is painful, it causes delayed drug absorption, and the dosage of drug given cannot be titrated. The intravenous route is more advantageous because titration is possible, although some pain is involved in starting the intravenous line. Some physicians choose to deliver the opioids with a patient-controlled analgesia (PCA) device that allows the patient to self-administer the drug at a safe dosage as it is needed. This allows patients to have some control over their own pain while relieving the ED nurse of time needed to administer the drugs.

For severe pain from a significant burn, sickle cell crisis, fracture, or other injury, *morphine* is an excellent choice. The usual dosage of morphine is 0.1 to 0.15 mg/kg per dose given intravenously over a few minutes. The maximum dose is 10 mg for opioid naive subjects, which is repeated every 3 or 4 hours. The higher dosage, and a dosing interval of every 1 to 2 hours, is suggested for those who get narcotics often (e.g., those with sickle cell disease or cancer) because they may have some tolerance to the drug. If needed, a subsequent dose is reduced to 0.05 mg/kg if the patient is moderately sedated. Morphine can also be given as a continuous infusion at 0.07 to 0.10 mg/kg per hour, and it can be titrated, if needed (increase 25% every 3 hours). When given intravenously, its effect is almost immediate, with the peak effect occurring in 20 minutes. Morphine can cause pooling of blood by decreasing peripheral vascular resistance, which may result in hypotension. However, this is a concern only in the patient with a severe injury who may be hypovolemic. Certainly, the fluid status of an injured child requires careful attention from the ED staff, but morphine should not be withheld after intravenous fluids have corrected volume depletion. If the child is awake, alert, and screaming in pain, morphine can be given safely as long as the patient is monitored carefully.

Meperidine is another opioid agent that can be used to treat moderate to severe pain. It can be given intravenously or intramuscularly at a dose of 0.5 to 1 mg/kg, given every 2 to 3 hours. The maximum recommended dose for opioid-naive patients is 125 mg. Meperidine is more effective than morphine when given orally, and it reaches peak effectiveness more quickly than morphine when given by the intramuscular route (about 90 minutes). Otherwise, it has no significant advantages over morphine, but there can be problems with it use. For example, it may cause nervousness, tremors, disorientation, and even seizures when used intravenously. Morphine therefore may be a better opioid for severe pain unless a patient indicates that meperidine works best.

Fentanyl is a synthetic opioid that should be given slowly at a dose of 2 to 3 µg/kg intravenously over 3 to 5 minutes. It has a rapid onset of action (a few minutes) and a short duration of action (30 to 40 minutes), which makes it useful in the ED. It is an excellent agent for severe pain from fractures. Fentanyl also has several other advantages. It is a relatively safe drug and rarely causes hypotension, making it an excellent choice for injured children in severe pain. A study of adult patients found that the drug caused hypotension in only 0.4% of patients, and alcohol intoxication may have been responsible for some cases of hypotension. It is thought that hypotension is unusual because histamine is not released when the drug is given. Respiratory depression can occur within minutes of fentanyl administration, but this is reported in only 0.7% of adult patients, some of whom were intoxicated with alcohol. There is a greater risk of respiratory depression when coadministered with other sedatives and in infants younger than 3 months of age. Apnea occurs even less often, and this may be related to the rate of infusion of fentanyl rather than the dosage. Although these adverse effects are serious, they can be reversed with naloxone and reduced if the dosage guidelines are followed and the drug is given slowly. Individualized dosing titrated to effect may reduce these side effects. Also, equipment and personnel who can manage an obstructed airway should be nearby when fentanyl is used.

An uncommon event caused by fentanyl is neuromuscular blockade, with severe thoracic and abdominal muscle rigidity. However, this is expected only when high dosages (greater than 15 µg/kg) are used and especially when fentanyl is administered rapidly. Most often, this side effect is reversible with naloxone, but succinylcholine may be required. Despite the problems already noted, fentanyl remains a valuable analgesic that should be used liberally in the ED when a child has severe pain.

Ketorolac tromethamine is a parenteral nonsteroidal anti-inflammatory drug that has been used to treat moderate to severe pain. This drug is relatively new, and few data are available regarding its use with children. However, studies with adult patients show intramuscular ketorolac is comparable to narcotic agents and oral ibuprofen for treatment of

musculoskeletal pain, headaches, sickle cell crises, and orthopedic injuries with less sedation and fewer side effects. It does not cause respiratory depression or nausea or vomiting. Intravenous ketorolac has been found to be as effective as morphine for postoperative pain in children with fewer side effects. It may have an opioid sparing effect, but this is not well proven. The drug is not yet approved by the Food and Drug Administration for intravenous use, although studies have demonstrated this route to be safe and efficacious in adults and children. Many pediatric centers use ketorolac with a loading dose of 1 mg/kg intravenously to a maximum of 60 mg followed by 0.5 mg/kg IV (maximum 30 mg) every 6 hours.

Other Agents

Another semisynthetic agent used occasionally with children in the ED is hydromorphone (Dilaudid), which can substitute for morphine and codeine. This is often given orally, rectally, or parenterally, and the analgesic effects last 4 to 5 hours. Also, hydrocodone (Hycodan) is an oral analgesic that is more potent than codeine with less associated nausea and vomiting. Likewise, oxycodone is 10 times more potent than codeine and about equal to the strength of morphine. Like codeine, it retains about 50% of its efficacy when given orally. It is often combined with aspirin (Percodan) or acetaminophen (Percocet, Tylox). The agents described next are not used in the ED for children. Propoxyphene (Darvon) has been shown to be inferior to aspirin, and in some studies, it was no better than placebo. It has significant addiction potential. Pentazocine (Talwin) is a narcotic agonist–antagonist that is better than placebo but not much better than aspirin. It is expensive and causes dizziness and hallucinations, as well as sedation and gastrointestinal discomfort. Methadone is an excellent analgesic with actions similar to those of morphine. It is well absorbed from the gastrointestinal tract and reaches peak concentration 4 hours after ingestion. This is a useful drug for treating chronic pain because it has few gastrointestinal side effects, less sedation, and less euphoria. Heroin is not available in the United States for pain control.

Table 4.3 summarizes the advantages and disadvantages of several analgesics used to treat moderate to severe pain.

Analgesic	Advantages	Disadvantages
Morphine	Rapic onset, potent analgesia	Respiratory depression, hypotension
Meperidine	Potent analgesia	Respiratory depression, seizure
Fentanyl	Potent analgesia, less hypctensicn	Respiratory depression, spnea
Ketorolac Tromethamine	Nonnarcotic	Not well studied in children

Table 4.3. Analgesics for Severe Pain

PROCEDURAL PAIN/CONSCIOUS SEDATION

Children often undergo painful procedures in the ED, including fracture reduction, laceration repair, incision and drainage, burn debridement, gynecologic examination, and foreign body removal. The pain involved with these procedures can be alleviated largely with the appropriate use of analgesics. Because a child's anxiety may further exacerbate the feeling of pain, it is often useful to give the child a combination of an anxiolytic with an analgesic medication before a painful procedure is performed.

The narcotics mentioned earlier commonly are given intravenously just before and during a painful procedure. For example, Fentanyl has been used for safe repair of complicated facial lacerations that might otherwise have required general anesthesia. It should be noted that fentanyl causes an unusual tendency for children to reach up and scratch their faces. If fentanyl is used for repair of lacerations, restraints may be needed to prevent a child from contaminating a sterile field. Fentanyl can also be given in the form of a lollipop. Oral transmucosal fentanyl citrate is a raspberry flavored fentanyl impregnated lozenge that allows oral transmucosal absorption, resulting in a narcotized child within 15 to 30 minutes. This is advantageous because it does not require a needle and is nonthreatening to young children. A disadvantage of delivering the drug in this form is that vomiting is a common side effect, occurring in up to 45% of children who received the agent before laceration repair. Oxygen desaturation is also common.

Some emergency physicians combine opioids with phenothiazines. Morphine and hydroxyzine, combined in an intramuscular injection, are used by some physicians. For years, the combination of meperidine 2 mg/kg, promethazine 1 mg/kg, and chlorpromazine 1 mg/kg has been used for sedation and analgesia (“lytic cocktail,” or “DPT”). Because this combination can produce deep and prolonged sedation with respiratory depression, its use is undesirable in the ED. It also requires a painful intramuscular injection and can result in dystonic reactions. Therefore, the use of the lytic cocktail, or DPT, is not recommended.

Sedatives

Sedatives should be used for painless procedures or in combination with analgesics when pain is anticipated.

Diazepam has been used as a sedative in doses of 0.1 to 0.2 mg/kg intravenously or orally. It can also be administered rectally, but the intramuscular route is discouraged because of pain and poor absorption. One retrospective study of

children undergoing orthopedic procedures found the combination of fentanyl and diazepam to be safe.

Midazolam has become more popular and may be given at a dose of 0.05 to 0.2 mg/kg slowly, intravenously every 15 minutes as needed. Intranasal midazolam (dose of 0.2 to 0.4 mg/kg) and oral midazolam (dose of 0.2 to 0.5 mg/kg) have also been used with narcotic analgesics before painful procedures are performed. The intranasal route is irritating to the nasal mucosa and may not be tolerated well by the pediatric patient. Midazolam may be preferable over diazepam because it has a shorter onset of action (about 5 minutes) and a more rapid recovery (about 1 to 4 hours). The combination of a benzodiazepine and a narcotic analgesic produces amnesia, sedation, and muscle relaxation, which is preferred for orthopedic procedures and laceration repair. The likelihood of respiratory depression increases when a sedative is added to a narcotic, so proper precautions must be taken to protect the airway.

Propofol is an intravenous anesthetic used for sedation during short procedures, gynecologic examinations, and cardioversion. Propofol does not have analgesic properties of its own. This agent has been used rarely in the ED, but one report found it to be effective when used in combination with fentanyl for fracture reduction, abscess drainage, and chest tube placement in 20 adult patients. There were few side effects in that study, and propofol is advantageous because it has a rapid onset of action, a rapid recovery phase, and amnesic properties. It is a potent sedative, associated with significant respiratory depression, so great caution should be exercised with its use.

Pentobarbital is another sedative that is useful for pediatric procedures. Pentobarbital has no analgesic properties of its own and may increase pain perception, so it is not ideal for painful procedures. It has greatest use for nonpainful procedures such as sedation of children for imaging studies. Narcotics can also be combined with pentobarbital 4 to 5 mg/kg, but this may result in prolonged sedation, making the combination less convenient to use in a busy ED. Sedation occurs rapidly after intravenous administration, and the effect dissipates in 15 to 20 minutes.

Chloral hydrate is a pure sedative hypnotic. It has no analgesic properties but may also be useful for painless procedures such as imaging studies. Unfortunately, the sedation effect is variable and sometimes long lasting, making it less desirable for use in the ED. The peak effect may take 40 to 60 minutes or longer to accomplish. It is usually given orally in a dose of 20 to 75 mg/kg. Vomiting and paradoxical hyperactivity may occur with its use, but it is a relatively safe drug. Cardiac arrhythmia is a rare event associated with large doses, and respiratory depression may be a risk if the patient has obstructive sleep apnea.

In one study of 95 children who received 25 to 30 mg of chloral hydrate orally, there were no adverse cardiovascular, respiratory, or gastrointestinal effects. All sedated children recovered promptly in less than 60 minutes.

Nitrous Oxide

Nitrous oxide gas has been used for analgesia in an emergency setting since 1969. A few studies on children have shown that it is an effective agent for reducing pain when performing painful procedures, and it can be delivered painlessly.

Nitrous oxide has a short duration of action and a sedative, dissociative effect on the patient. The patient may complain of pain but does not seem to experience it (dissociative effect) and does not remember it later (amnesic effect). Patients who receive this gas feel as if they are floating, drowsy, or euphoric. It takes about 4 minutes to induce these effects with a nitrous oxide–oxygen mixture and about 4 to 5 minutes for them to wear off. When used in a 50/50 mixture with oxygen, nitrous oxide provides analgesia, not anesthesia. That is, the patient remains awake during a procedure and is able to follow instructions. These properties make it useful in the emergency setting.

The nitrous oxide–oxygen mixture has been used on children as young as 16 months of age, but it is certainly more difficult to use in young, uncooperative children. It may be best for children 8 years and older. (Masks for administering the gas can be flavored to help gain acceptance with young patients.) It has been shown to be useful to treat lacerations, burns, or Colle's fractures or to reduce a dislocated radial head injury. It has been used in adults to drain abscesses and pilonidal cysts, for which local anesthesia is difficult to administer. It has been proved useful for managing a child whose penile foreskin got caught in his zipper.

When used properly in a mixture with more than 20% oxygen, nitrous oxide does not produce serious side effects. Nitrous oxide affects the cerebral cortex (not the brainstem), so circulatory and respiratory depression does not occur and there is little relaxation of skeletal muscle. The gas is nonallergenic and not flammable or explosive, but it must be used with oxygen, and it will support combustion if a fire develops. It must be used with a fail-safe system that shuts off the flow of nitrous oxide when oxygen flow stops. The child can hold the mask on his or her face so that it will fall off if the child becomes unresponsive. Nitrous oxide also can be given with a nasal mask, enabling the patient to breathe through the mouth during the procedure. These precautions will avoid possible anoxia, which could be catastrophic. Some patients have experienced vomiting with this mixture of nitrous oxide, but this usually is an inconvenience rather than a danger because the patients maintain their cough and gag reflexes. In one study, 7% of patients fell asleep with the gas, but they all could be easily aroused. Prolonged intermittent dizziness has been reported after nitrous oxide–oxygen administration, but bone marrow suppression, testicular dysfunction, and liver and CNS disorders are seen only with chronic exposure to the gas.

Still there are some limits to the use of nitrous oxide. Personnel demands are great because staff who can manage an obstructed airway in an unconscious patient should be present. Nitrous oxide is not recommended for children who are already sedated, unconscious, or intoxicated or who have head or chest injuries. In addition, the equipment required costs several thousand dollars and must be inspected daily to ensure safety. Also, a scavenger device is needed to eliminate nitrous oxide from the ED so that workers and other patients do not experience the effects of the gas. A simple device can be attached to the machine to accomplish this.

Finally, not all patients report complete pain relief with nitrous oxide. Some studies have shown it to be helpful in 80 to

95% of patients. There was marked pain relief in 29% of patients and partial pain relief in another 61%. Table 4.4 reviews the advantages and disadvantages of nitrous oxide–oxygen analgesia.

Advantages	Disadvantages
Has rapid onset, short duration of action	Fail-safe system required
Causes sedation, dissociation, and amnesia	Expensive equipment
Is useful when local anesthesia is impractical	Scavenger device needed
May be used for young children	Not all patients benefit
Is safe when mixed with oxygen	More personnel required

Table 4.4. Nitrous Oxide–Oxygen Analgesia

Ketamine

Ketamine hydrochloride is another anesthetic agent used when performing wound debridement, foreign body removal, laceration repair, and other painful procedures. It can provide intense analgesia at subanesthetic doses. It causes dissociative amnesia and a trancelike state in which the child can follow commands but cannot respond verbally. The drug can be given intramuscularly (at a dosage of 3 to 4 mg/kg), and it also can be given intravenously (at a dosage of 0.5 to 2 mg/kg). This can be followed by an infusion of 0.01 to 0.2 mg/kg per minute if anesthesia is needed for more than 20 minutes. Ketamine has the advantage of rapid onset of action (1 minute if given intravenously, 5 to 10 minutes if given intramuscularly). It does not cause prolonged sedation and a single intravenous dose has an effect for about 15 minutes. With repeated doses or continuous infusion, ketamine's effect depends on its elimination half-life and is considerably prolonged (1 to 2 hours). Ketamine can also be given orally (10 mg/kg), in which case sedation occurs in 30 to 45 minutes with duration of effect about 2 hours.

Ketamine does have disadvantages, however, in addition to the pain of injection. Rarely, ketamine causes unusual, unpleasant sensations and dreams with subsequent flashbacks, but benzodiazepines may decrease this reaction if given with ketamine. In a recent prospective study, no children experienced nightmares. Ketamine also can cause increased production of saliva in 11%, and vomiting upon awakening in about 6% of those who receive this medication. Excess salivation can be effectively prevented by prior administration of atropine (0.01 mg/kg) or glycopyrrolate (0.005 mg/kg). Ketamine does not generally impair pharyngeal or laryngeal function or protective airway reflexes such as cough or swallowing. Thus, the risk of airway compromise is less with ketamine than with some other agents. However, a rare adverse effect is laryngospasm, so precautions should be taken to manage the airway if this develops. Neonates and those with upper respiratory infection are more likely to have laryngospasm, and they should not receive ketamine. Ketamine also can elevate blood pressure, intracranial pressure, and pulmonary artery pressure, so patients with head trauma, CNS malformations, and cardiovascular or respiratory disease should not receive this drug.

Local Anesthetic Agents

Lidocaine

Lidocaine is an excellent local anesthetic that has been used frequently in the ED for wound repair, foreign body removal, insertion of intravenous infusion lines or lumbar puncture needles, drainage of abscesses, and arterial puncture. Lidocaine has been shown to reduce pain of lumbar puncture in neonates without decreasing the success of the procedure.

Lidocaine usually is administered as a 1% solution (10 mg/mL) at a dosage of 3 to 5 mg/kg. A 0.5% solution is used for infiltration when large volumes are needed or in smaller patients when it is desirable to limit the total number of milligrams per kilograms given. When vasoconstriction is desired for suturing, lidocaine can be used in combination with epinephrine, at a dosage of (lidocaine) 7 mg/kg. Lidocaine should not be combined with epinephrine for use in areas supplied by end arteries such as the digits, penis, or pinna of the ear. Lidocaine is advantageous because it provides excellent local anesthesia and takes effect quickly (within a few minutes). The effect lasts long enough to complete most procedures (about 1½ to 2 hours). It is a safe drug, as few people have a true allergy to it. Serious toxicity, such as seizures and cardiac arrest, can occur, but only when large amounts are injected inadvertently or when the drug is injected directly into a blood vessel.

The major disadvantage of using lidocaine as a local anesthetic is that a painful injection is required for administration. This pain can be reduced, however, if a long, small (27- or 30-gauge) needle is used to produce a “fanning” effect of the anesthetic. When injecting deep into tissue, a larger needle is needed to aspirate blood so that inadvertent injection into a vessel is avoided. Otherwise, the small needle is recommended, and only a small amount of lidocaine should be injected to avoid tissue distortion. Some physicians recommend using a syringe with a thumb ring during infiltration for better control. A recent study shows that warming the lidocaine, by storing the medication and syringes in fluid warmed to 98.6°F, seems to reduce the pain of infiltration. It may also hurt less to inject the lidocaine into the damaged tissue inside the wound instead of in the intact skin. The needle should be pulled out to the tip and the injection given again at 90-degree angles to minimize the number of punctures. Subsequent injections to extend the area of anesthesia should be given through anesthetized tissue when possible. It is helpful to rub the skin near the site of injection first because this reduces pain by stimulating other nerve endings according to the gate theory of pain. The skin should be pulled tightly,

and only the smallest amount of lidocaine needed should be injected to avoid wound distension.

It may also help to use buffered lidocaine, which is more alkaline and perhaps less painful when administered. Some physicians recommend mixing 10 parts lidocaine and 1 part sodium bicarbonate before injection to minimize burning when injecting the anesthetic. A recent study showed that rate of lidocaine injection has a greater impact on perceived pain of administration than does buffering. It is best to inject lidocaine slowly, perhaps over 30 seconds. This may cause less rapid distension of local tissue and activation of fewer nerve endings. In all cases, a few minutes should be allowed for the anesthesia to take effect. Table 4.5 summarizes some hints to reduce the pain of lidocaine infiltration.

1. Do not allow child to see needles involved in preparing lidocaine.
2. Warm and buffer lidocaine with sodium bicarbonate.
3. Use a long, small needle for infiltration.
4. Rub skin around injection site before infiltration.
5. Infiltrate through devitalized tissue or anesthetized areas.
6. Inject slowly, only what is needed.
7. Wait for anesthetic effect.

Table 4.5. Hints to Reduce Pain of Lidocaine Infiltration

Other Injectable Local Anesthetics

Bupivicaine 0.25% is similar to lidocaine but may have a longer duration of action and may help reduce pain for 6 hours after a wound is repaired. Diphenhydramine, 0.5% and 1%, has been used and studied as a local anesthetic in adult patients. However, it seems to cause more pain on infiltration than does lidocaine and may cause tissue necrosis. In addition, a recent study showed that saline with 0.9% benzyl alcohol additive (the bacteriostatic compound in multidose vials of physiologic saline solution) provides anesthesia when injected into the skin of children just before placement of an intravenous line. With injection of 1 mL, anesthesia lasts about 2 minutes and there is minimal pain of injection and no side effects.

Topical Anesthetic Agents

LET

Wound repair can often be done painlessly with the use of a topical anesthetic such as LET. LET is a solution of 4% lidocaine, 0.1% epinephrine, and 0.5% tetracaine. It can be made in gel form with hydroxyethyl cellulose. LET has been used successfully and safely for repair of uncomplicated facial and scalp lacerations in children. The major advantage to using LET for suturing is that the anesthetic can be applied painlessly, without the use of a needle. This should reduce the fear and anxiety involved in wound repair and may help the suturing go more smoothly. Even in the small number of children who have inadequate anesthesia from LET, the application of this topical anesthetic will reduce the pain of subsequent administration of lidocaine by injection. The gel can be applied directly to the wound for 15 to 20 minutes, or the solution can be “painted” on to the wound with a cotton-tipped swab, or a saturated cotton ball can be applied to the wound and held in place manually or with tape. Subsequently, the surrounding skin will be well blanched, indicating adequate local anesthesia. Like lidocaine, LET should not be applied to body parts where vasoconstriction is contraindicated.

Table 4.6 suggests a protocol for the use of LET for wound repair.

1. Apply LET gel directly to the wound.
2. Apply LET for 10–20 minutes.
3. Alternatively apply 3–5 mL of LET solution for 3-cm wound.
4. Use cotton-tipped swab to paint solution onto wound.
5. Drip some LET into wound directly.
6. Tape cotton saturated with LET onto wound.
7. Avoid eyes, digits, and mucous membranes.

Table 4.6. Suggested Protocol for Use of LET for Wound Repair

TAC

In many centers, LET has replaced tetracaine, adrenaline, cocaine compound (TAC) as the preferred topical anesthetic

for wound repair because it is much less costly and has reduced toxicity. TAC is a clear solution of 2% tetracaine 25 mL, 1:1000 epinephrine 50 mL, and cocaine 11.8 g. This is diluted with normal saline to make a volume of 240 mL, which is divided into 3 or 5 mL aliquots for a 3-cm wound. An additional 3 ml of TAC can be used for each additional 3 cm of laceration. TAC has been shown to be as effective as lidocaine for most facial and scalp wounds, but perhaps less effective for wounds on the trunk or extremities. The maximum safe dose of TAC has not been established, but some recommend using no more than 0.09 mL/kg. TAC should be applied directly to the wound just as described for LET. The major problem associated with TAC is the risk of cocaine toxicity. This can lead to seizures and death, so TAC should never be used near mucous membranes where rapid absorption can occur. Death of a child was reported after TAC was absorbed through nasal mucous membranes. The solution can also cause corneal abrasions, so TAC should not be used near the eye.

EMLA Cream

Some physicians have used topical EMLA cream, which is a eutectic mixture of lidocaine and prilocaine with an occlusive dressing to supply local anesthesia. EMLA has been found helpful in relieving pain associated with intravenous catheter placement, lumbar puncture, and venipuncture in children. This cream may also be useful for draining perirectal abscesses or paronychias, draining arthrocentesis, or accessing subcutaneous drug reservoirs. The EMLA cream must be applied directly to the skin for 60 minutes before it is effective, so it is not practical for many situations in the ED. (Lidocaine does not penetrate well through intact skin.) If preparing for intravenous line placement, one should prepare multiple sites in case the first attempt is unsuccessful. Also, young children may become agitated, perspire, and have difficulty keeping the anesthetic on the skin. This could then mandate additional nursing time for a procedure. The cream works best for procedures where the child is unlikely to view the procedure needle and become agitated (e.g., lumbar puncture, bone marrow aspiration).

Despite these disadvantages, EMLA cream has been gaining popularity in the ED setting when time permits. In one recent study, EMLA was compared with TAC in a controlled, blinded fashion during wound repair in children. It was found to be superior to TAC in that patients treated with EMLA required less supplemental anesthesia than those who received TAC.

Other Topical Anesthetics

Smith et al. studied new combinations of anesthetics, including bupivacaine with norepinephrine (bupivanor), Etidocaine with norepinephrine (etidonor), Prilocaine with norepinephrine (mepivanor), and prilocaine with norepinephrine (prilonor). Bupivanor proved as effective as TAC in relieving pain upon infiltration of lidocaine for laceration repair. This offers the advantage of not risking the toxicity of TAC; however, none of the combinations were compared with LET.

Nerve Block

Lidocaine can be used for peripheral nerve block if the physician has appropriate knowledge of anatomy and the nerve supply to the wound is superficial. The skin at the nerve site should be anesthetized, and then lidocaine (5 mg/kg) should be infiltrated more deeply into the nerve in the same manner as would be used for local anesthesia. During this infiltration, the physician should aspirate to ensure that a blood vessel has not been penetrated accidentally.

Some EDs use lidocaine for regional nerve block. The preferred technique for fracture reduction at some institutions is a “mini-Bier” block. With this technique, a double pneumatic tourniquet or two blood pressure cuffs are placed above the elbow and intravenous lines are started in the child's upper extremities. One of these lines is for administration of lidocaine, and one is for other medications, if needed. Diazepam, midazolam, and thiopental should be available in case seizures result from lidocaine infiltration, and the child should be attached to a cardiac monitor during the procedure. The affected limb is elevated for exsanguination as the upper cuff is inflated to occlude the arterial blood supply. Then lidocaine (without epinephrine) is infused into the affected extremity at a dosage of 1.5 mg/kg (maximum 100 mg). This should be given slowly, and tourniquet pressures must be maintained so that the drug does not escape under the tourniquet. Now that the injured extremity has local anesthetic in an isolated compartment, the lower cuff, which should be wrapped around an anesthetized area, can be inflated. The upper cuff can be deflated. This lower cuff can be deflated very slowly after the procedure but not less than 15 minutes after the lidocaine infusion was given. The child should be observed in the ED for at least 1 hour. There are risks to this procedure, including seizures, coma, confusion, and cardiac arrest if the child were to receive accidentally a massive amount of lidocaine. Some physicians, therefore, prefer to perform the mini-Bier block in the operating room, where circumstances can be better controlled.

NONPHARMACOLOGIC METHODS FOR PAIN CONTROL

Hypnosis

Hypnosis has been used to treat pain in children for several years, and it has been successful in children as young as 2 years of age. Some physicians believe that the technique better serves children than adults because children have vivid imaginations and can more easily intertwine fantasy and reality. Also, it is thought that patients who present to the ED are already in a hypersuggestible state and thus may be more receptive to hypnosis.

This technique involves creating visual images for the child in an effort to reduce pain. For example, one could ask the child to think of the funniest movie he or she has ever seen and to imagine the pain getting less intense with each laugh. Or, the child could be asked to imagine the pain as a color that is fading away and is painted over with the child's favorite color.

Hypnosis is of value for chronic pain syndromes such as migraine headaches or long-term illnesses. It has also been used to treat children with sickle cell disease and painful crises. Such children have been taught self-hypnosis to reduce

the frequency and intensity of painful crises, but some required a few outpatient sessions before it became effective.

Hypnosis has also been recommended for the acute management of burns, fractures, and other injuries. In fact, it is thought to be more useful for those entities than when emotional problems are triggers for pain. However, hypnosis may again be less practical than analgesics in this setting in the ED. It may have a role in conjunction with analgesics, but hypnosis cannot completely replace the need for medications in the acute situation. The use of hypnosis for many painful procedures in a busy emergency department has not been well studied.

Distraction and Relaxation Techniques

Distracting a child (e.g., with counting or squeezing a parent's hand) during a painful procedure may help reduce pain. One study showed that asking children to “blow out” air as if they were blowing bubbles was helpful in reducing pain from needle sticks for immunizations. Singing a song or telling a story to a child is also helpful. Children become very involved when listening to their favorite story, and parents can help with this. Paintings on the walls or ceiling of a procedure room may also distract a young child. However, distracting a child may have short-lived success because of a child's limited attention span, and it is less effective than involving the child in a detailed imaginary story. One study showed that allowing adult patients to listen to musical audio tapes during suture repair provided a safe, inexpensive, and effective adjunct for pain management. It is also possible that such tapes or television would provide helpful distractions to older children undergoing painful procedures.

Restraint and Reassurance

Properly restraining a child for a painful procedure can be useful in reducing pain. Although this does not reduce fear or anxiety (in fact, it may heighten them), it allows the physician to perform the task better. This indirectly reduces pain because fewer attempts may be necessary to accomplish the task. One should never attempt a painful procedure on a moving subject! The need for restraint should be explained to the parents (who should not be involved in the actual process). Instead, the child might be wrapped in hospital sheets or papoose boards with Velcro straps, with the parents attempting to calm the child afterward. There are only rare complications with this restraint, including minor bruising, edema, or transient vascular compromise. More important, children need gentle reassurance and carefully chosen words during a procedure to reduce fear and pain. One should keep in mind that young children understand more than they say. Casual teasing, condescension, or talking about the child while excluding him or her should be avoided. Choices should not be offered if they do not exist. The child should be warned honestly about the possible pain, but it is best to allow for the possibility that it may not hurt as much as he or she expects. Table 4.7 summarizes possible means of reducing pain from procedures. One should not allow long delays between the explanation and the actual procedure because the anticipation may be the most distressing part of the procedure. One study showed that an empathic (age-appropriate) explanation of an upcoming needle stick reduced crying among patients compared with a group of children who received impersonal instructions. Fassler showed that allowing a child to read about a procedure and then allowing role-playing and discussion was helpful in reducing pulse rates and other physiologic and behavioral responses to pain. Such explanations and role-playing are a time-consuming processes, and this is not always possible in a busy pediatric ED. The value of empathy and reassurance, however, cannot be emphasized enough. Well-prepared parents can assist their child and reduce anxiety and pain associated with painful procedures.

Agent	Advantages	Disadvantages
Narcotics	Easy administration, may be titrated	Respiratory depression
Nitrous oxide	Painless administration, rapid onset, short duration, dissociative state	Requires nurse personnel, not always effective
Ketamine	Rapid onset, dissociative state	Hypersalivation, bad dreams (rare), laryngospasm (rare)
IST	Painless administration, low toxicity	Delays procedure slightly
TAC	Painless administration	Seizures, death if ingested
Lidocaine	Rapid onset, long duration, safe drug	Painful injection
Hypnosis	No side effects	Time-consuming, not always effective
Restraint	Rarely dangerous, increases success of procedure	May increase child's fear

Table 4.7. Summary of Some Choices Useful for Painful Procedures

During discharge from the ED, it is helpful to reassure the patient, to be honest, and to listen to the child. Perhaps writing a prescription, even for an over-the-counter analgesic, will help give a message that you are concerned about the child's pain. It is important to encourage the family to contact the ED or a private physician if pain persists.

CONSCIOUS SEDATION PROTOCOLS

Because of the potential for respiratory depression with the sedative and analgesic agents discussed previously, it is imperative that EDs develop protocols for their use. Conscious sedation generally refers to the state where the patient has a minimally depressed level of consciousness and can maintain protective airway reflexes and follow commands while responding to physical stimuli. Deep sedation refers to the state where the patient has a more depressed level of consciousness, may not have protective airway reflexes, and is difficult to arouse. Several organizations have prepared guidelines for conscious sedation in children, but the specifics of the ED protocol should be modified at each individual institution. The American Academy of Pediatrics recommends that if children are to have conscious sedation, there should be “emergency equipment” available for children of all ages and sizes. This should include a suction device and a positive-pressure oxygen delivery system capable of delivering at least 90% Fi O_2. Personnel who are trained in pediatric life support should be available, and at least one additional support personnel should be on hand to monitor the patient.

Patients should have continuous monitoring of oxygen saturation and heart rate with (at least) intermittent monitoring of blood pressure and respiration during and after the procedure. Pulse oximetry is essential because of the proven difficulty in recognizing hypoxemia even by experienced personnel.

If a patient is expected to have deep sedation, the requirements just discussed remain. In addition, an intravenous line should be established before sedation. Furthermore, there should be frequent monitoring of the child's blood pressure, cardiac rhythm, and temperature. Additional equipment recommendations include a nearby defibrillator and medications that might be needed for resuscitation. Reversal agents such as naloxone and flumazenil are also useful. Finally, there should be a third person trained in pediatric resuscitation assisting the patient.

Continuous pulse oximetry and monitoring of heart rate should continue until the patient has met discharge criteria. Before discharge, any child who has received conscious sedation should be awake enough to sit and speak without assistance and preferably able to ambulate. Younger children should be able to perform age-appropriate functions. The child should also have adequate hydration status, documentation of stable cardiovascular function, and an adequate airway.

SUMMARY

It is common to encounter children in pain in the pediatric ED. It is often impossible to avoid inflicting pain on some children in this setting. Therefore, the proper management of this pain is essential. This management should be accomplished with various narcotic and nonnarcotic analgesics, as well as with local and topical anesthetics. Other agents, such as nitrous oxide, ketamine, and other techniques such as hypnosis and distraction, play a more limited role in pain management. Gentle restraint and reassurance are of paramount importance.

CHAPTER 5

Emergency Airway Management—Rapid Sequence Intubation

LOREN G. YAMAMOTO, MD, MPH, MBA

Department of Pediatrics, University of Hawaii, John A. Burns School of Medicine, and Kapiolani Medical Center for Women and Children, Honolulu, Hawaii

Management of the airway is a critical initial step in the stabilization of patients who present to the emergency department (ED) with a life-threatening emergency. Tracheal intubation often is the most reliable means of maintaining airway control. Indications for tracheal intubation include cardiopulmonary arrest, apnea, respiratory insufficiency, actual or potential airway obstruction, respiratory depression, severe burns, severe multiple trauma, severe head injury, increased intracranial pressure (ICP), a depressed sensorium, and a loss of the normal protective airway reflexes.

Airway management is most optimal when the ED staff is trained to recognize the need for intubation and to accomplish this while minimizing complications. The equipment necessary for tracheal intubation should be readily available at the bedside for immediate access and use during the management of any critically ill patient in the ED (Table 5.1).

Pulse oximeter
End-tidal CO_2 monitor or detector
Electrocardiogram monitor
Uncuffed endotracheal tubes, sizes 2.5 to 6.0
Cuffed endotracheal tubes, sizes 6.0 to 8.5
Endotracheal tube stylets
Laryngoscopes (straight blade sizes 0 to 3, curved blade sizes 2 to 4)
Oral airways
Oxygen masks, preferably a nonrebreather
Ventilation masks in all sizes for bag-valve-mask ventilation
Large and small self-inflating ventilation bag with oxygen reservoir tail and positive end-expiratory pressure (PEEP) valve attachment
Laryngeal mask airways (LMA) in all sizes
Oxygen source
Suctioning source
Large-bore stiff suction tips
Flexible suction catheters
Nasogastric tubes
Tracheostomy tubes
Tracheostomy surgical instrument set
12- and 14-gauge needle catheters for needle cricothyrotomy
Percutaneous transtracheal ventilation setup

Table 5.1. Equipment Needed for Rapid Sequence Intubation

Tracheal intubation can be difficult because of seizures, agitation, combativeness, and inadequate muscle relaxation, resulting in poor airway visualization. Laryngoscopy and intubation result in ICP elevation, pain, bradycardia, and a higher risk of gastric regurgitation and hypoxemia. Patients who arrive in the ED often have full stomachs.

Although intubation often can be accomplished under these circumstances, the conditions are optimized and the adverse effects are minimized when a patient is intubated using rapid sequence intubation (RSI)—a rapid induction of general anesthesia that induces unconsciousness and muscle relaxation. The purpose of RSI is to rapidly render a patient unconscious and paralyzed so that intubation can be facilitated. Emergency intubations done under a fully relaxed state are usually easier to perform and have fewer adverse effects, such as pain and ICP elevation.

Pharmacologic paralysis makes it impossible to perform a neurologic examination on the patient and eliminates all respiratory effort by the patient. Would it be preferable to sedate a patient without paralysis for intubation because of these considerations? Although this was a common practice in years past, intubation using sedation alone has a higher complication rate than RSI does, making RSI the preferred technique.

RSI is not necessarily indicated in cardiac arrest. In cardiac arrest, for example, intubation without RSI would generally be preferable unless cardiopulmonary resuscitation (CPR), brain perfusion, muscle tone, and/or some degree of consciousness were maintained, in which case RSI may be of benefit. Understanding the principles of RSI is the best

means of determining when it is indicated.

A typical RSI consists of providing atropine to block vagal stimulation, a sedative to induce unconsciousness, and a muscle relaxant to induce paralysis. This typical sequence can become rather complicated when more considerations are added. It should be noted that the drugs for pediatric RSI have been recommended in their most basic forms as 1) atropine, 2) sedative, and 3) muscle relaxant. This chapter addresses the following controversies surrounding RSI: sedative selection, muscle relaxant selection, priming or defasciculation, and adjunctive medications such as lidocaine and fentanyl.

RAPID SEQUENCE INTUBATION SEDATIVES

The most common sedatives used in RSI include thiopental, midazolam (and other benzodiazepines), ketamine, and etomidate. Narcotic analgesics such as fentanyl can also be used, but this is less common. The use of propofol has increased in frequency, but its use is mostly for brief sedation for procedures, rather than for RSI. Each of these drugs has beneficial and detrimental properties that must be understood to select the best sedative for RSI in the patient at hand. The advantages and disadvantages of each drug are summarized in Table 5.2.

Drug	Onset	Duration	Cerebrovascular Effect	Cardiovascular Effect	Bronchial Effect	Other Considerations
Thiopental	Rapid	Brief	Good	Significant depression	Bronchospasm	
Midazolam	Less rapid	Brief	Modest	Neutral	Neutral	Titration recommended; not available in PRC
Ketamine	Rapid	Brief	Adverse	Stimulatory	Bronchodilatory	Psychic reactions and excessive airway secretions
Etomidate	Rapid	Brief	Good	Neutral	Neutral	Myoclonus, cortisol suppression
Fentanyl	Less rapid	Brief	Modest	Neutral	Neutral	Succinylcholine activity and chest wall rigidity
Propofol	Rapid	Brief	Good	Significant depression	Neutral	Less experience with agent in ED PRS

Table 5.2. Significant Properties of Rapid Sequence Intubation Sedatives

Thiopental (an ultra-short-acting barbiturate) was initially one of the most commonly used sedatives for RSI. Its advantages are reliable and rapid onset (10 to 20 seconds), short duration, and a cerebral protective effect accomplished by reducing ICP, cerebral metabolism, and oxygen demand. Its main disadvantages are vasodilation and myocardial depression, which may result in hypotension. Thiopental should be avoided or used in lower dosages in hypotensive or hypovolemic patients. These effects can be minimized by slowing the rate of injection. Thiopental causes respiratory depression and may result in coughing, laryngospasm, and bronchospasm. Thiopental is contraindicated in porphyria and status asthmaticus.

Midazolam (and other benzodiazepines such as diazepam) has a slower onset than thiopental does. It is more commonly used for conscious sedation or as an adjunctive agent in general anesthesia. Midazolam is capable of anesthesia induction at higher dosages. Cardiovascular and respiratory depression occur less often than with barbiturates. Lack of recall or anterograde amnesia results from benzodiazepines used for anesthesia. Benzodiazepines should not be used in patients with glaucoma. Midazolam has many properties that suggest its use for RSI in the ED. Many reports in the literature have advocated its use despite the lack of data to document its efficacy and safety. The dosing range is suggested at 0.1 to 0.3 mg/kg. The lower dosage is probably insufficient to reliably induce unconsciousness. Because these drugs also result in amnesia, studies may never be able to retrospectively assess the degree of unconsciousness attained during RSI.

Although attractive, benzodiazepines have a slower onset than thiopental and have an excessively wide dosing range during which titration is recommended. In RSI, however, titration is undesirable because a rapid induction of unconsciousness and paralysis is the goal, and paralysis makes it impossible to assess consciousness. The use of midazolam in RSI has grown in popularity, largely because it can be used in nearly all clinical situations. Despite this, there appear to be drugs that have advantages over benzodiazepines in specific clinical situations.

Ketamine produces rapid sedation, amnesia, and analgesia. It is described as a dissociative agent that induces a trancelike state in which the patient is unaware, but not necessarily asleep. In combination with a paralyzing agent as in RSI, this difference is not noticeable. Ketamine results in sympathetic stimulation and an increase in systemic blood pressure (BP); however, reduced doses or no sedative are still recommended in potentially hypovolemic patients. Adverse effects, which include ICP elevation, intraocular pressure elevation, hallucinations, excessive airway secretions, and laryngospasm, limit its use to ED patients who have hypotension, hypovolemia, or status asthmaticus. Ketamine increases airway secretions, so routine atropine premedication is recommended. Ketamine has a bronchodilating effect in addition to its sympathetic effect, making it useful for RSI of patients with severe bronchospasm that requires intubation. Ketamine is contraindicated in patients with hypertension, head injury, psychiatric problems, glaucoma, or an open globe injury. The psychic actions of ketamine have severely limited its use. These reactions usually disappear upon awakening but can be recurrent. The frequency of psychic disturbances with ketamine (5 to 30%) are less common in children. Other reports have shown no significant adverse psychological effects compared with other sedatives. The use of lorazepam during ketamine anesthesia has been recommended to reduce the likelihood of adverse psychological effects.

Etomidate has more recently been advocated as an RSI sedative. Although most RSI sedatives have advantages in certain clinical situations and disadvantages in others, etomidate has advantages in a broader range of RSI patients. It

shares some advantages of thiopental—rapid and reliable onset of unconsciousness, ICP reduction, and reduction of cerebral metabolic demand. Etomidate has minimal cardiovascular depression compared with thiopental. Etomidate appears to have superior cerebroprotective properties because it lowers ICP and cerebral metabolism with better preservation of cerebral perfusion pressure compared with thiopental. Etomidate's major disadvantage is its association with myoclonus resembling seizures. The frequency of this ranges from 10 to 80% in various reports. The etiology of this is not well defined. Etomidate has some anticonvulsant properties, but it also appears to stimulate seizures in others. Etomidate suppresses glucocorticoid and mineralocorticoid levels. This effect is clinically significant in long-term administration of etomidate. Single use as in RSI results in measurable decreases in corticosteroid levels, but this is not clinically significant unless etomidate is used over a long period. Replacement corticosteroids may be considered to offset this problem. Although unclear, etomidate should not be used in patients with partial seizures and adrenal insufficiency. Despite its broad applicability for RSI, etomidate has not been used frequently for RSI. It has only recently been recommended for RSI in the ED; thus, many ED physicians are not familiar with it. There are some disadvantages of using etomidate, and its ultimate use pattern in the future has yet to be determined.

Fentanyl is a short-acting narcotic analgesic that results in rapid analgesia and unconsciousness at higher dosages. Adverse effects associated with fentanyl are less than those of morphine. The doses of narcotics required to produce complete anesthesia are much higher than the doses required for analgesia alone and may vary extensively. Chest wall rigidity may occur with rapid injection of fentanyl, but this is reversible with a muscle relaxant or with naloxone. Fentanyl use has been associated with seizurelike activity. Fentanyl is used most often in cardiovascular surgery in combination with other anesthetics. Although it has some properties useful for RSI done in the ED, literature sources to support fentanyl use for RSI in the ED are lacking. Fentanyl should not be used with monoamine oxidase (MAO) inhibitors.

Propofol use in the ED is in its infancy. Largely used by anesthesiologists for short-term sedation and general anesthesia, propofol is gaining wider acceptance as an agent for short-term sedation for procedures in the intensive care unit (ICU) and ED. It can be used as a sedative in RSI, but its degree of experience here is limited and it does not have substantial advantages over other sedatives. Propofol shares many features with thiopental. Propofol decreases ICP and cerebral metabolism. Propofol's onset is rapid and brief, but it has significant cardiovascular depression. Although propofol can be used in instances when thiopental could be used, there is more experience with thiopental.

Although myocardial depression is most pronounced with thiopental, all sedatives cause some degree of cardiovascular depression, especially in hypotensive or hypovolemic patients. Because no sedative is entirely free of cardiovascular depression in the hypovolemic or hypotensive patient, such patients should receive reduced dosages or no sedative at all, depending on their cardiovascular status.

SEDATIVE SELECTION

Sedative selection remains one of the most controversial aspects of RSI. The addition of etomidate as a sedative for RSI has extended the sedative selection options. Etomidate appears to have the broadest applicability, but each agent should be well understood so that individual practitioners can make the best decisions about which agent would be most optimal in each clinical situation. No sedative is universally superior. The clinical situation determines the optimal sedative selection. Table 5.3 summarizes sedative selections in different clinical categories.

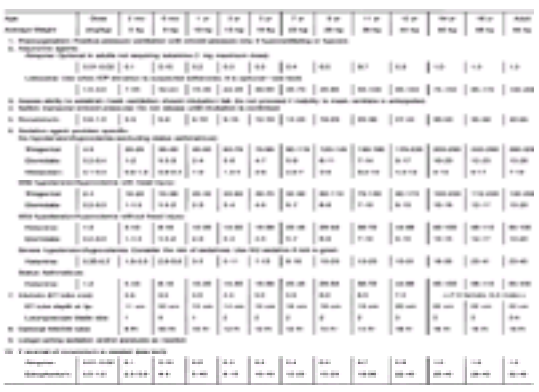

Table 5.3. Rapid Sequence Intubation Drugs and Doses (in milligrams)

Thiopental can be used for all patients except those with hypotension, hypovolemia, status asthmaticus, or porphyria. In potentially hypovolemic patients with suspected head injuries, midazolam or low-dose thiopental may be used in conjunction with volume resuscitation. Midazolam has the major disadvantage of ideally requiring titration, which is not feasible in RSI. Midazolam's dosing range is broad because its sedative effect is highly variable. Despite these major disadvantages, midazolam appears to be a popular choice in RSI; however, this popularity is difficult to justify because other agents appear to be superior.

Perhaps etomidate would be superior to thiopental in all these indications, but there is concern that patients with head injuries may be at risk for partial seizures. When thiopental can be used, propofol can be used as well, but its experience level does not approach that of thiopental.

In patients with suspected head injuries who have severe hypovolemia or hypotension, thiopental should be avoided. Any sedation agent may compromise cardiovascular function in such a state. There is not enough information in the literature to establish a clear consensus about which sedative would be the most optimal in this situation. A low-dose sedative or no sedative would be among the best options. Although etomidate appears to have many desirable characteristics, there

is concern that patients with head injuries may be at risk for partial seizures.

In a patient without head injuries who has hypotension/hypovolemia, ketamine or etomidate may produce the least adverse effects. Atropine should be used with ketamine. No sedative or a low dosage of sedative (ketamine, etomidate, or any acceptable sedative) is recommended in severe hypotension/hypovolemia to reduce the likelihood of cardiovascular collapse in patients with maximal endogenous sympathetic stimulation.

Ketamine or benzodiazepines have been recommended for sedating patients with status asthmaticus who require intubation; however, ketamine is associated with a bronchodilatory effect while diazepam is not. Etomidate can be used here, but ketamine has superior characteristics for severe status asthmaticus.

In patients with severe cardiovascular compromise or unconsciousness, a sedative may be considered optional to prevent further cardiovascular compromise.

MUSCLE RELAXANTS

Muscle relaxants result in total muscle paralysis, yet the patient may be fully conscious.

Succinylcholine is a depolarizing muscle relaxant with a rapid onset (30 to 60 seconds) and short duration (3 to 12 minutes). Even though it has been the most common muscle relaxant used in RSI, it has numerous disadvantages. Although not contraindicated in head injuries, it causes elevated ICP. Intraocular and intragastric pressure elevations may occur. Muscle fasciculations that may result in muscle pain, rhabdomyolysis, and myoglobinuria also may occur. These are more severe in muscular patients and can be prevented by a defasciculating dose of vecuronium before succinylcholine (this is not necessary in children under 5 years of age). Atropine premedication can prevent the bradycardia and excessive bronchial secretions associated with succinylcholine. Other less preventable adverse effects include negative inotropic and chronotropic effects, an association with malignant hyperthermia, hyperkalemia, hypertension, and arrhythmias. Succinylcholine is contraindicated in patients with glaucoma, penetrating eye injuries, significant neuromuscular disease, history or family history of malignant hyperthermia, and pseudocholinesterase deficiency. At 3 to 60 days after trauma or burns (in other words, day 3 or later following trauma or burns), succinylcholine results in an increased frequency of the risks described here and should not be used. Patients with severe burns or large crush injuries may already be acutely hyperkalemic; thus, the decision to use succinylcholine should consider this as well.

Of the nondepolarizing muscle relaxants, rocuronium currently has the fastest onset and shortest duration. Vecuronium is still commonly used because it was the most popular agent before rocuronium. Both agents have minimal cardiovascular effects. Onset times for rocuronium and vecuronium are 30 to 90 seconds and 90 to 120 seconds, respectively. Duration for both drugs is 25 to 60 minutes. Rocuronium comes in a premixed vial ready to use, whereas vecuronium comes in a powder that must be reconstituted. This factor gives rocuronium another advantage when the time to intubation may be prolonged because of medication preparation.

Other nondepolarizing muscle relaxants include pancuronium and atracurium. Pancuronium has a slower onset and more cardiovascular side effects. Atracurium has an onset time similar to that of vecuronium; however, it is associated with histamine release and cardiovascular side effects. Rocuronium is currently the nondepolarizing muscle relaxant of choice, but there is less experience with this drug compared to vecuronium. Other nondepolarizing agents should be eliminated from consideration.

MUSCLE RELAXANT SELECTION

In comparing rocuronium and succinylcholine, rocuronium has fewer adverse effects, whereas succinylcholine has a shorter duration. The onset times are similar. Some view rocuronium as preferable because it is safer. The contrary view is that because of its shorter duration (which allows restoration of spontaneous ventilation within 3 to 12 minutes compared with 25 to 60 minutes for rocuronium), succinylcholine is better if intubation fails. Rocuronium can be reversed pharmacologically with edrophonium and other similar agents; however, this is not clinically routinely useful because reversal cannot be achieved immediately. Reversal must wait for some degree of spontaneous recovery to occur, which happens later than the duration of succinylcholine.

In most patients, neuromuscular blockade facilitates both intubation and bag-valve-mask ventilation. For patients with risk factors that suggest a difficult intubation, succinylcholine may be preferable. For others, rocuronium may be preferable. Whether the shorter duration of succinylcholine justifies its greater risk of adverse effects is essentially a personal judgment that individual clinicians must make.

Defasciculation and Priming

Defasciculation refers only to the use of succinylcholine, which may cause fasciculations, muscle pain, rhabdomyolysis, and myoglobinuria. This effect is most pronounced in muscular individuals. Fasciculations may increase muscle tone and increase the risk of gastric regurgitation during RSI. To prevent fasciculations, “defasciculation” is recommended, where one-tenth the paralyzing dose of a nondepolarizing muscle relaxant (e.g., vecuronium 0.01 mg/kg) is administered 1 to 3 minutes before succinylcholine administration. This “defasciculating” dose of vecuronium will prevent fasciculations caused by succinylcholine. Defasciculation is most beneficial in muscular individuals. Defasciculation is not necessary in children 5 years of age or younger. Note that this defasciculating step delays the time to intubation and adds complexity to RSI.

Priming in RSI refers to nondepolarizing muscle relaxants only. Its purpose is to shorten the onset time of nondepolarizing muscle relaxants. A priming dose is one-tenth the paralyzing dose of a nondepolarizing muscle relaxant.

Using vecuronium as an example, a priming dose of 0.01 mg/kg is administered. Five minutes should elapse for the "priming" to take effect. The paralyzing dose of 0.1 mg/kg is now administered. The full paralyzing onset time of vecuronium is about 100 seconds without priming, 50 seconds with priming. Unfortunately, priming adds an additional 5-minute delay to intubation while saving 50 seconds in accelerating the onset of the full dose of vecuronium. Because the onset time of rocuronium is considerably faster, the advantage of priming is minimal. Although some experts still recommend priming, it appears to have little benefit in the ED when immediate intubation is required.

Defasciculation and priming are often confused because they both require one-tenth of the paralyzing dose of a nondepolarizing muscle relaxant. However, the two principles are different even though they have similar characteristics in that they both are optional and they both delay the time to intubation and they both add complexity to the drug administrations in RSI.

ADJUNCTIVE AGENTS

The RSI sequence shown in Table 5.3 considers the use of atropine and lidocaine. Atropine use is considered routine in children to prevent bradycardia, but it is optional in adults, unless ketamine is used as a sedative, in which case, atropine is recommended in adults as well.

Lidocaine is more controversial. It has been shown to reduce ICP and airway reactivity under certain conditions when given 2 minutes before intubation. If ICP elevation is suspected, a cerebroprotective sedative (thiopental or etomidate) is generally preferred in RSI. Lidocaine is cerebroprotective in isolation, but it is unclear whether lidocaine results in additional benefit when added to a cerebroprotective RSI regimen that includes thiopental or etomidate. Despite this controversy, most practicing academic centers and consensus reports recommend the use of intravenous lidocaine if ICP elevation is suspected. In addition to intravenous lidocaine, topical lidocaine has been recommended to blunt the adverse reaction to tracheal intubation. This adds considerable complexity to the laryngoscopy procedure, especially in patients in whom neck immobilization is critical and/or airway visualization may be less than optimal. The recommendation that lidocaine be used in intubating asthmatics stems from its beneficial effect in attenuating bronchospasm. If one truly believes that lidocaine has such a benefit, then if possible, it should be administered long before the patient requires intubation, as opposed to administering it during RSI.

Opiate analgesics such as fentanyl and morphine have been advocated as adjunctive agents in RSI to further reduce the adverse effects of intubation. Ketamine has analgesic properties; thus, coadministration of analgesics is unnecessary with ketamine. Sedatives such as benzodiazepines, etomidate, and thiopental have little or no analgesic properties. The coadministration of analgesics have been recommended to address this. When considering that the patient is fully unconscious when reliable sedatives such as etomidate and thiopental are used, the additional benefit of analgesics to reduce the amount of "pain" felt by an unconscious patient becomes small. Narcotic analgesics have adverse reactions and the additional risk that these pose may not justify their routine use. Benzodiazepines must ideally be titrated to assess the degree of sedation; thus, the degree of sedation with these agents is less reliable in RSI, in which case, coadministration of analgesics may be more beneficial.

If RSI is to accomplish its goal of rapid tracheal intubation, the addition of adjunctive agents should be critically considered because each additional agent adds time and complexity to RSI. This factor is often not considered when discussing the benefit of an individual adjunctive agent in isolation. Therefore, the RSI protocol described in Table 5.3 includes atropine for pediatric patients and intravenous lidocaine as an optional adjunctive agent for head trauma. Other adjunctive agents may be considered, but they have not been included in the table.

RAPID SEQUENCE INTUBATION PROTOCOL

After patient assessment, immediate stabilization, and intravenous access, patients should be assessed for any contraindications to RSI or its agents. The major contraindication to RSI is a likelihood that intubation or ventilation might not be possible, as in cases of limited cervical mobility, a receding mandible, limited jaw opening, major facial or laryngeal trauma, upper airway obstruction, or distorted facial or airway anatomy.

To simplify RSI, a table such as Table 5.3 should be adapted and modified to your preferences. This table should be taped to the wall in the critical care area of your ED. This table is not a substitute for thoroughly understanding the characteristics of each agent and the critical thinking necessary to select the agents. What follows explains the protocol given in Table 5.3:

1. Preoxygenation (by spontaneously inspiring or mask-ventilating 100% oxygen for 2 to 5 minutes) results in an oxygen reserve. Positive-pressure mask ventilation may inflate the stomach and increase the likelihood of gastric regurgitation; thus, positive pressure in conjunction with cricoid pressure (see step 4) should be done only if needed to oxygenate and ventilate the patient adequately. Hyperoxygenation is impossible in some patients. Pulse oximetry and an electrocardiogram monitor should be considered mandatory for patients undergoing RSI. If a self-inflating bag is used, oxygen is *not* delivered to the mask unless the bag is squeezed. Thus, if the patient is spontaneously breathing, a mask attached to a self-inflating bag should *not* be used; instead, a standard oxygen mask, such as a nonrebreather, should be used.
2. Atropine premedication is routinely administered in children. It prevents bradycardia and reduces oral secretions. This is considered optional for adults unless ketamine is used, in which case atropine is recommended. Lidocaine lowers ICP and suppresses the cough reflex. It may be beneficial to patients with ICP elevations. When used in conjunction with other ICP-lowering agents, however, its additional benefit is unclear. Lidocaine is generally recommended for patients with suspected ICP elevation.
3. Before proceeding, it should be ascertained that a good mask seal and an open airway can be maintained. In most instances, muscle relaxation facilitates mask ventilation and intubation. If an inability to intubate and/or mask ventilate is suspected, RSI should not proceed until additional assistance can be obtained.
4. The Sellick maneuver (application of pressure on the cricoid ring sufficient to occlude the esophageal lumen

without compressing the airway lumen or moving the cervical spine) reduces the likelihood of passive gastric regurgitation and aspiration. It should be maintained until tracheal intubation is confirmed. This also reduces the likelihood of gastric distension resulting from mask ventilation and therefore should be done before any positive-pressure mask ventilation unless this results in gagging.

5. After appropriate selection, a muscle relaxant and a sedative should be administered simultaneously or in rapid sequence. Administering the muscle relaxant first allows the sedative to be administered gradually while waiting for the full onset of the muscle relaxant. Some experts prefer the reverse sequence. For muscle relaxants, Table 5.3 lists only rocuronium. Succinylcholine or vecuronium may be substituted here. Optional priming (applies to nondepolarizing agents only) and defasciculation (applies to succinylcholine only) are not included in the sequence described in Table 5.3.
6. Intubation can take place when there is full relaxation of the airway muscles, usually 45 seconds after rocuronium administration (90 seconds after vecuronium).
7. Once intubation is completed, proper endotracheal (ET) tube placement should be confirmed by auscultation, end-tidal CO_2 detection, and the maintenance of oxygenation monitored by pulse oximetry.
8. Gastric evacuation can be done with a nasogastric or orogastric tube at this time.
9. Longer-acting sedatives and nondepolarizing muscle relaxants should be administered to maintain unconsciousness and paralysis as needed.
10. If reversal of rocuronium is necessary, edrophonium together with atropine can be administered to accelerate recovery; however, some degree of spontaneous recovery must be present for reversal to occur.

Nasal Intubation Compared with Oral Intubation in the Trauma Patient

Trauma victims who arrive in the ED have suspected cervical spine (C-spine) injuries in addition to other injuries. When it is not possible to rule out a C-spine injury before RSI, the head and neck should be immobilized during intubation.

Unless contraindicated, emergency intubation of pediatric patients should always be done orally. In spontaneously breathing patients, older literature sources have recommended blind nasal tracheal intubation, whereas newer recommendations prefer oral tracheal intubation using RSI. If the need for intubation is emergent, nasal tracheal intubation may not be as reliable as oral tracheal intubation. Nasal tracheal intubation is noxious, and it may cause the conscious patient to gag or become agitated, resulting in more neck movement, an increase in ICP, and possible vomiting. Nasal tracheal intubation is more difficult in children. Epistaxis, sinusitis, and cribriform fracture complications are other concerns with nasal tracheal intubation. Studies have not been able to show that nasal tracheal intubation results in less C-spine movement than oral tracheal intubation.

There is concern that laryngoscopy during oral tracheal intubation may displace a C-spine fracture. When using RSI, however, laryngoscopy manipulation and neck movement are minimized under these more ideal conditions. The concern that the loss of cervical muscle tone on an unstable C-spine will reduce its splinting effect and increase its instability has not been supported by evidence.

In a critical situation, intubation is best carried out by the means with which the clinician is most familiar for the given clinical condition. Oral tracheal intubation using RSI appears to be the best means of securing an airway for most clinicians.

Cervical Spine Immobilization During Tracheal Intubation

The terms that describe C-spine immobilization are ambiguous. Traction has been used synonymously with immobilization, although “traction” generally indicates a pulling action with an undefined degree of force. Manual cervical immobilization implies that hands are somehow used to immobilize the neck. Cervical immobilization implies the use of a stiff collar and other devices to immobilize the neck. Philadelphia collars used with manual stabilization do not provide any additional C-spine stability compared with manual stabilization alone. Axial (in-line) traction has been shown to worsen C-spine stability in patients. One preferred method is to remove the anterior portion of the cervical collar with an assistant immobilizing the head and neck once the patient is rendered unconscious and paralyzed. This enables the jaw to open wider, providing better visualization during laryngoscopy without sacrificing cervical immobilization.

ALTERNATIVE INTUBATION AND AIRWAY TECHNIQUES

Because the experience level of most ED physicians is greatest with oral tracheal intubation, it is unwise to deviate from this in managing a critically ill child who requires intubation. Alternative procedures should be reserved for instances in which conventional airway techniques prove unsuccessful.

Flexible fiberoptic scopes, lighted stylets to guide nasal tracheal intubation, retrograde intubations, and surgical airways all require high skill and experience levels to be done optimally. These procedures have a minimal degree of documented experience in children. Directly visualizing the airway through a fiberoptic scope is appealing; however, it requires extensive practice, and it may be especially difficult in critical intubations or in agitated patients. Intubation aided by bronchoscopy, lighted stylets, and the retrograde wire technique are not recommended in ED RSI because of the lack of spontaneous breathing during RSI and the time required for these procedures.

The Combitube (a registered trademark of Sheridan Catheter Corporation, Argyle, NY) is a double- lumen airway that is blindly inserted through the mouth. One lumen exits through the distal end of the Combitube. The other lumen exits through multiple side-holes proximal to the distal end. An inflatable (distal) balloon separates these two (the distal end-hole and the more proximal side-holes). Because the Combitube is inserted blindly, it will enter either the trachea or the esophagus. If it enters the trachea, the distal balloon is inflated and the distal end-hole lumen is used to ventilate the patient just as if this were a conventional ET tube. If the Combitube enters the esophagus, the inflation of the distal balloon occludes the esophagus and the lumen ending in the more proximal side-holes is used to ventilate the patient. The esophageal position of this tube is similar to an esophageal obturator airway. Use of the Combitube requires

familiarity with its function and method of insertion. It has been demonstrated to be effective in providing an airway during resuscitation, but failures occur as well. Widespread experience with the Combitube in pediatric patients is lacking.

The laryngeal mask airway (LMA) is a newer airway device. The LMA is not disposable and must be sterilized between uses. LMAs come in several different sizes, and their use in pediatric patients has been demonstrated. Experience with LMAs is growing. The correct insertion and placement position of the LMA is critical. The LMA is inserted blindly, taking about 15 to 20 seconds. LMA insertion methods are best taught using video or hands-on instruction. In-depth understanding of the LMA and previous hands-on experience are required to consider it as an airway management option. The LMA does not prevent aspiration.

Surgical airways may be considered. Complications, including incorrect tube placement, subcutaneous emphysema, pneumomediastinum, pneumothorax, bleeding, tracheal stenosis, subglottic stenosis, arterial injury, blood aspiration, and persistent tracheocutaneous fistulae, are more common when the procedure is performed on an emergency basis in children. Cricothyrotomy is faster and easier to perform than tracheostomy and also has a lower complication rate. However, in small children, the cricothyroid membrane is not readily palpable, and it may be too small for an airway. It is not recommended in children less than 10 years of age. Electrocautery devices should be avoided during these procedures because the presence of high-flow oxygen can result in spontaneous combustion.

Because surgical airways are difficult to perform in children, needle cricothyrotomy may be beneficial for children who cannot be ventilated by any other route, although the complications are similar to those of surgical airways and the experience level with this procedure in children is minimal as well. An over-the-needle 12- or 14-gauge intravenous catheter is directed inferiorly through the cricothyroid membrane, the needle is removed, and the catheter is left in place. It is vital to have a ventilation device preassembled and ready to use before such an emergency because ventilation through a transtracheal catheter requires a special setup. Many recommendations for transtracheal ventilation have appeared in the literature. Special transtracheal airway kits are available commercially. Two examples are shown in Figure 5.1. These use a wall outlet or tank oxygen pressure directly into the transtracheal catheter. It is the most optimal means to deliver an adequate tidal volume through the small catheter. By occluding the T-tube or the side-hole, oxygen is forced through the catheter at high pressure. Chest movement should be used as a visible indicator of adequate ventilation. Exhalation occurs passively through the larynx and not through the catheter. If exhalation is obstructed as well, transtracheal ventilation is contraindicated. The catheter must be held securely because a kink or movement of the catheter would compromise this fragile airway. Another common recommendation is to attach a ventilation bag to the transtracheal catheter through an ET tube connector (about size 3.0). Delivering an adequate tidal volume by squeezing the bag, however, is nearly impossible with this method.

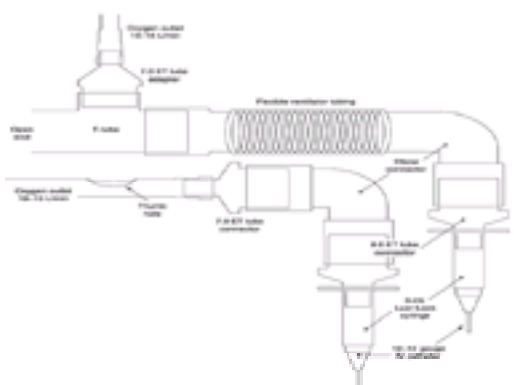

FIGURE 5.1. Transtracheal ventilation setup. (Adapted from Yamamoto LG. Rapid sequence anesthesia induction and advanced airway management in pediatric patients. Emerg Med Clin North Am 1991;9:611–638, copyright by WB Saunders, with permission from author and publisher.)

Transtracheal ventilation is only a temporizing measure, and a more definitive airway should be established as soon as possible. It is important to have ED staff members familiarize themselves with the transtracheal ventilation setup. By attaching a balloon or glove to the transtracheal catheter, air flow can be visualized during practice sessions.

AVOIDING PROBLEMS

Being prepared by becoming aware of the following problems commonly encountered during RSI can improve the success of the procedure greatly.

1. Oxygen delivery devices must be well-understood by the staff. New nurses and residents often do not know that oxygen is *not* delivered to the mask attached to a self-inflating bag unless the bag is squeezed. Thus, putting such a mask in front of a patient who is spontaneously breathing will deliver only 21% oxygen (room air), and the patient will fail to hyperoxygenate. For spontaneously breathing patients, oxygen should be delivered using a standard oxygen mask such as nonrebreather. A mask attached to a closed circuit bag (anesthesia-type bag, Rusch bag) with 100% oxygen can also be used. For patients who require positive-pressure mask ventilation, a self-inflating bag with an oxygen reservoir tail is satisfactory.
2. Drug preparation is time-consuming. Thiopental comes in kits that require familiarization before use. Other drugs are less troublesome.
3. Sedatives and muscle relaxants may precipitate if administered together. The line between the two medications should be cleared. When RSI begins, it is better to have the IV running at a high rate to more effectively clear the line to prevent precipitation. The IV rate should be turned back to baseline when RSI drug administration is completed. It may be more optimal to have two IVs running so that the drugs can be administered in rapid sequence

in two different lines.

4. Paralysis is not a substitute for sedation. Conscious patients remain conscious during paralysis (a frightening experience). It may be safer, however, to avoid sedatives in hemodynamically compromised or unconscious patients.
5. Intubation using a sedative without paralysis has a higher complication rate than RSI.
6. Incorrect weight estimates can result in underdosing or overdosing of drugs and can cause significant delays in the onset of RSI.
7. Avoiding unrecognized extubation and esophageal intubation is critical. Frequent clinical reevaluation, end-tidal CO_2 ($ETCO_2$) monitoring, and pulse oximetry are highly recommended because they often can prevent this serious complication. End-tidal CO_2 monitoring (capnometry) is preferable to $ETCO_2$ color detection because it permits quantitative PCO_2 monitoring, which is useful in patients who are difficult to ventilate or in those who have head injuries and require hyperventilation. $ETCO_2$ color detectors work only for a short period. After 15 minutes or so, moisture renders them nonfunctional; thus, these should not be used for long transports unless they are frequently replaced.
8. Bronchial mainstem intubation can occur easily in small children who have a small degree of ET tube movement.
9. RSI protocols should be reviewed with the ED staff at periodic in-services. A common problem occurs when the person who applies the Sellick maneuver releases it prematurely to tend to a seemingly more important task. This person should be dedicated to this maneuver alone and must not release it until intubation is confirmed.
10. Suction devices may malfunction; therefore, there always should be a back-up available. Standard Yankauer tips may be clogged by food particles, so newer stiff suction tips with larger openings may be more useful.
11. Be prepared for transtracheal ventilation. This may be lifesaving in a patient who cannot be intubated or mask ventilated.

MULTIPLE TRAUMA

A disciplined airway, breathing, circulation (ABC) approach should take priority in the management of multiple trauma victims. Deformities and open wounds must not distract team members from these priorities. The ABC assessment should be made quickly, followed by a brief neurologic assessment (*D* for disability) that specifically checks for signs of ICP elevation.

Airway management must include precautions for a possible C-spine injury. (C-spine immobilization and nasal versus oral tracheal intubation are discussed earlier in this chapter.) Available information suggests that, in most instances, children with multiple trauma who require intubation are best intubated orally using RSI. Succinylcholine may worsen hyperkalemia in patients with severe crush injuries or severe burns. In children with severe craniofacial or airway injuries, oral tracheal intubation may prove to be difficult. In such cases, a surgical airway may be indicated. This can be done emergently in the ED, or it may be done as a standby procedure if oral tracheal intubation fails. (The complications of this procedure are discussed earlier in this chapter.) The child's airway status may worsen during the procedure because of bleeding, agitation, or additional airway trauma. Needle cricothyrotomy with transtracheal ventilation should be available as a standby procedure if further airway difficulties occur.

Breathing is best assessed clinically by auscultation and by checking the patient's color. Arterial blood gas monitoring is useful to measure ventilation, oxygenation, and any occult metabolic acidosis objectively. Pulse oximetry is useful to monitor oxygenation continuously and noninvasively. It is also an indirect monitor of perfusion because it will show a shorter perfusion bar or waveform with pulsation in slightly marginal perfusion states and it will fail to register any signal in poor perfusion states. In patients who require intubation, colorimetric $ETCO_2$ detectors are an inexpensive way of confirming tracheal intubation; however, they are unable to measure $ETCO_2$ reliably. Continuous capnometry is preferable because it permits an ongoing estimate of $PaCO_2$ in most instances. As an exception, $ETCO_2$ measurements often are erroneous in extremely poor perfusion states (during cardiopulmonary resuscitation) because they depend on pulmonary perfusion as well. Maintaining PCO_2 in the 30–35 mm Hg range is beneficial for patients with head injuries because it lowers ICP. Capnometry prevents excessive hyperventilation and reduces the need for frequent blood gas analysis.

Oxygenation may be compromised by pulmonary injuries such as pneumothorax, hemothorax, chest wall injuries, pulmonary contusions, or aspiration. In addition to these, ventilation may be compromised by airway trauma and central nervous system (CNS) depression. Oxygen administration should be considered routine for all multiple trauma victims. Intubation is indicated in patients who have ventilatory compromise, a potential for airway compromise, a head injury that requires hyperventilation, moderate or severe shock, and hypoxemia despite supplemental oxygen. Positive-pressure ventilation may worsen a pneumothorax if a chest tube is not in place.

Circulation should be assessed by using multiple clinical parameters. Early mild shock should be treated aggressively to reverse any progression toward late shock and hypotension, which is associated with a poorer outcome. Acute symptoms and signs of early shock are subtle and often underestimated. These signs and symptoms include agitation, restlessness, lethargy, pallor, delayed capillary refill, coolness of the feet, metabolic acidosis, a short perfusion bar/wave on the pulse oximeter, and difficulty in picking up a pulse oximetry signal. Tachycardia and hypotension are indicators of late, severe shock. Paradoxical bradycardia has been noted in shock with hypotension; therefore, the absence of tachycardia cannot be used to rule out shock. Dismissing a low BP as “normal for a child” because of the absence of tachycardia is not valid.

Sedatives may have significant adverse effects on BP because of myocardial depression or vasodilation. In hypovolemic or hypotensive children, sedative doses should be reduced or avoided, depending on the clinical situation.

The initial treatment of shock related to hypovolemia consists of frequent clinical reassessment and fluid restoration with volume-expanding crystalloids such as normal saline or lactated Ringer's solution. The usual initial bolus should be 20 mL/kg. This is followed by reassessment of clinical shock parameters. This process should be repeated if evidence of shock persists until fluid volume is restored. Red blood cells should be transfused if excessive hemorrhage is sustained.

Large volume fluid resuscitation can result in complications because of hypothermia. When large fluid volumes are anticipated or the patient is very small, crystalloid solutions should be warmed gently and blood products should be infused through a blood warmer.

HEAD TRAUMA

The same priorities should be followed with head trauma as with multiple trauma. Children with head injuries who have depressed sensoriums may be hypoxic, hypovolemic, hypotensive, or acidotic. Although intracranial hemorrhage alone cannot account for significant hypovolemia that results in shock in an older child or adult, this is possible in an infant.

Unconscious patients should be intubated using RSI and should be hyperventilated. Patients responsive only to painful stimuli may need to be intubated as well. Some patients with lesser degrees of sensorium depression also may need intubation using RSI and hyperventilation, depending on the degree of head injury and the rate of deterioration. Patients at risk of ICP elevation should be given thiopental or etomidate in addition to lidocaine pretreatment as part of RSI unless hypovolemia or hypotension exist, in which case the dose should be reduced or eliminated, depending on the clinical circumstances. Thiopental and etomidate lower ICP and cerebral metabolic oxygen demand.

In patients with evidence of ICP elevation, cerebral dehydration may reduce ICP and prevent impending herniation. This can be done using diuretics (furosemide 1 mg/kg) or osmotic diuretics (mannitol 0.25 to 1.0 mg/kg).

Patients with head injuries may develop posttraumatic seizures related to cerebral contusions, cerebral edema, or intracranial hemorrhage. Under RSI, these seizures are not visible because of pharmacologic paralysis. It is prudent in most instances to give a loading dose of phenytoin (10 to 20 mg/kg) after intubation is confirmed to treat prophylactically any undiagnosed posttraumatic seizure focus.

BURNS

Children with severe burns represent a special form of multiple trauma. Burn patients may also sustain blunt trauma, and ABCs are still the priority. Early intubation using RSI is advocated for patients at risk of airway injury because airway edema is expected to worsen rapidly. These cases include children with evidence of soot in sputum or vomitus, burns of the face, singed nasal hairs, lip burns, wheezing, stridor, or severe burns. The possibility of carbon monoxide poisoning should be considered. It may be preferable to avoid succinylcholine in patients with severe burns for fear of worsening hyperkalemia.

Pulmonary compromise may result from smoke inhalation, burn injury, bronchial edema, bronchospasm, blunt trauma, or adult respiratory distress syndrome (ARDS). Initial chest radiographs may fail to show some of these injuries.

Children with severe burns have significant hypovolemia because of external fluid losses. Lactated Ringer's or normal saline boluses of 20 mL/kg should be used to immediately correct hypovolemia. Guidelines for fluid replacement based on body surface area (BSA) of the burns provide a means to estimate fluid requirements. The Parkland formula recommends 4 mL/kg (3 mL/kg if BSA is less than 30%) of lactated Ringer's solution for each BSA percent burn, required over the next 24 hours in addition to maintenance fluids. These guidelines require careful monitoring of urine output, gastric fluid output, and the subtle parameters that may identify early shock. Fluid boluses may be required to reverse any trend toward shock to restore circulatory volume immediately. Burns exude high-sodium and high-protein fluids, resulting in subsequent hyponatremia and hypoproteinemia. Syndrome of inappropriate secretion of ADH may develop in patients with cerebral injury, pulmonary injury, or prolonged bed rest. These factors should be considered when determining the initial fluid management.

Hypothermia caused by body exposure and fluid administration must be anticipated and prevented. The use of radiant warmers and the warming of IV solutions can prevent this complication.

Circumferential burns around an extremity may result in additional swelling and venous and arterial occlusion. Infarction of the extremity distal to this injury can be prevented by early recognition of this fact and surgical release of the constriction. Similarly, circumferential burns about the chest may result in chest wall constriction and respiratory difficulties.

STATUS EPILEPTICUS

In patients presenting to the ED with prolonged seizures, the standard approach of ABC support and immediate administration of benzodiazepines is generally initiated. Loading with IV phenytoin and/or phenobarbital may also be considered if seizures continue. This process of administering anticonvulsants and waiting to assess its effect occurs in 5- to 15-minute cycles. If seizures fail to respond to several doses of anticonvulsants, the child could be continuously seizing for an additional 30 to 60 minutes.

Prolonged seizures result in hypoxia and respiratory acidosis due to poor ventilation. The brain is simultaneously hypermetabolic with greater oxygen demand. RSI using thiopental effectively reverses this process. Skeletal muscle activity stops. Oxygenation and ventilation are restored. The brain may still be hypermetabolic because it may still be epileptogenic, but at least the patient is no longer hypoxic and acidotic. Thiopental has potent cerebroprotective and anticonvulsant activity. Simultaneous administration of high dosages of benzodiazepines, phenytoin, and phenobarbital can potently reduce the seizure potential of the brain while maintaining oxygenation and ventilation. The major adverse effect of most anticonvulsants is respiratory depression. Following RSI, this is no longer a concern and maximum doses of anticonvulsants can be administered to provide maximum anticonvulsant activity.

In refractory status epilepticus, the duration of seizures, hypoxia and acidosis is likely to contribute to cerebral injury. At

some point in the management of status epilepticus (e.g., 60 minutes), the failure of conventional anticonvulsants should be recognized and RSI followed by maximum anticonvulsant administration should be considered. Because potentially injurious seizure durations of 40 minutes or more can occur in the management of such patients, it has been my preference to initiate RSI earlier rather than later. The concern that seizures can no longer be visibly appreciated after RSI should be tempered by the clinical benefits of RSI as described. EEG monitoring in the ED is often recommended, but it is not feasible in most hospitals.

AGITATED PATIENTS WHO REQUIRE PROCEDURES OR TRANSPORT

Agitated or combative patients with head injuries or possible intracranial lesions that require computed tomography (CT) scanning cannot be scanned in such a condition. Sedation alone can be considered for such patients. In patients who fail to respond to standard sedation measures or in patients who may benefit from tracheal intubation, RSI provides an effective means of immediately securing airway control, breathing, and movement so that imaging can be completed with minimal trauma to the patient. Patients who require transport to another facility and who are agitated and hard to control may be difficult to manage during transport. After the clinical situation has been assessed, RSI may be indicated if its benefits outweigh its risks. Patients are more difficult to monitor during procedures and transports. The immediate detection of unrecognized extubation or hypoxemia is crucial. Portable pulse oximeters and $ETCO_2$ monitors can monitor oxygenation and confirm intubation continuously.

CHAPTER 6

Prehospital Care

***M. DOUGLAS BAKER, MD and †JEFFREY R. AVNER, MD**

**Department of Pediatrics, Yale University School of Medicine, and Department of Pediatric Emergency Medicine, Yale–New Haven Children's Hospital, New Haven, Connecticut;*
†Department of Pediatrics, Albert Einstein College of Medicine, Pediatric Emergency Service, Montefiore Medical Center, Bronx, New York

Fortunately, childhood is a period of life that generally is free of critical illnesses and injuries. In large populations, however, such cases are commonly seen. Injuries (both intentional and unintentional), acute medical diseases, and acute exacerbations of chronic disease afflict the pediatric population. Although prevention is the ultimate “treatment” for many of these disorders, it is inevitable that a substantial number of emergencies will continue to affect children in all geographic locations, emphasizing the need for appropriate pediatric prehospital care services.

In response to the need for such services, governmental efforts have been initiated to help states improve their emergency medical services for children (EMS-C). Eloquently summarized by Ludwig and Selbst, EMS-C is an all-encompassing, multidisciplinary system that includes parents, primary care providers, prehospital care providers and transport systems, community hospital and tertiary care referral center emergency departments, and pediatric inpatient units, including critical care facilities. Ideally, the elements of this system should be linked by effective communication and transportation systems and governed by well-established policies and procedures. The provision of prehospital emergency services, although a single link in this chain, is a critical component. This chapter familiarizes the reader with the structure of and services provided by these systems and their inherent limitations. There is great need for physician involvement in many aspects of prehospital care; we hope to stimulate involvement through better understanding of these services.

HISTORY OF EMERGENCY MEDICAL SERVICES AND PREHOSPITAL CARE

The concept of EMS was born centuries ago in the battlefield care of the sick and wounded. The roots of modern ambulance services reach back at least as far as the Napoleonic wars, when covered carts were used to carry casualties to rear dressing stations. Subsequent world conflicts have resulted in rapid advancements in medical care. The development of prehospital care as a specialty, however, is a more recent development. Arguably, this can be traced to the formation of formal EMS systems, which took place in the early 1970s.

In 1973, the critical components of EMS systems were outlined in the Emergency Medical Services Act (PL-93-154), which was designed to develop regional EMS systems. This act outlined 15 components that an EMS system had to address to receive federal funding. Notably absent from this list was the issue of medical control (i.e., physician involvement). Subsequently, Roush and McDowell have suggested that effective EMS systems should include the following elements: medical direction, prehospital transport agencies, interfacility transport agencies, dispatch, communications, protocols (for triage, treatment, transport, and transfer), receiving facilities, specialty care units, training, financing, auditing and quality assurance, public information and education, mutual aid, and disaster plans. Optimal function of this system requires uniformity of purpose and communication between all components, including prehospital care. The multiplicity of goals and functional independence of many of these components occasionally interferes with the service provided. Clearly, administrative streamlining and improved organization of EMS services are major challenges that lie ahead.

Although prehospital care and EMS systems have existed for more than 25 years, only recently has attention been focused on issues related to pediatrics. The development of pediatric emergency medicine as a specialty has highlighted the need for a greater emphasis on improvement of EMS systems for children. Pediatric emergency medicine specialists are increasing not only in numbers but also in sophistication, with the latter reflected by the improved level of medical care offered and the depth of research produced.

Many contributions have been made by pediatric researchers in terms of prehospital care issues that affect pediatric patients. These studies have helped elucidate the strengths and weaknesses of prehospital care systems' pediatric services. Studies by Seidel et al. have demonstrated the lack of readiness many prehospital care systems possess to manage childhood emergencies adequately. On the other hand, Scribano et al. have demonstrated overuse of both invasive and noninvasive interventions by prehospital personnel when transporting children. Research efforts such as these reveal the deficiencies in pediatric prehospital practice and the need for further evaluation of these issues.

Epidemiologic studies also have helped clarify the pediatric needs of EMS systems. Tsai et al. found those at the pediatric age extremes to be the principal users of prehospital services: teenagers for trauma and infants and preschoolers for illness (primarily seizures, ingestions, and respiratory diseases). Yamamoto et al. showed that the handicapped were also more likely to use an ambulance; however, ambulance personnel felt less prepared to handle those patients. In a survey of how pediatric practitioners used EMS services in Pennsylvania, Baker and Ludwig found that infants with serious illness were more likely to be transported by EMS services than were adolescents. The combination of these findings and the fact that most childhood medical arrests occur in children under four years of age highlights the need of EMS systems to provide age-appropriate equipment and personnel properly trained in pediatric emergency care. For the youngest children, these services often have been found to be lacking.

Even when appropriate EMS systems are available, they might be significantly underused. In the study by Baker and Ludwig, although 93% of practitioners surveyed had some form of professional transport services available, 54% most often chose to transport ill children to tertiary care centers in family automobiles, unaccompanied by advanced life support personnel or equipment. This was true even in the case of suspected epiglottitis. It is clear that further education is needed for EMS providers and EMS users alike regarding pediatric issues. However, education should be provided that has been properly studied and demonstrated to be effective. Although several studies have been conducted to evaluate the effectiveness of classroom training in increasing the knowledge and confidence of prehospital personnel in the management of acutely ill and injured children, few, if any, have included outcome measures of actual performance.

EMS-related research, although plentiful, suffers from general lack of rigor. Callaham has noted that of the 5842 publications on prehospital EMS that appeared in Medline from 1985 to 1997, only 54 were randomized controlled trials. Of the 54, only 7 randomized controlled trials showing a positive outcome of the intervention were uncontradicted. Only one of those examined a major outcome such as survival, and only one compared the intervention with a placebo and could therefore evaluate the efficacy of EMS itself. This paucity of scientific scrutiny of EMS highlights the need for future research focusing on EMS practice. In the meantime, we must resist the temptation to quickly add new technologies, procedures, and protocols to prehospital care without ensuring that these modalities have proven efficacy. There is a real concern that in an effort to aid one patient, many others will suffer from unnecessary intervention. Furthermore, additional interventions must be balanced against the need for rapid transport to the hospital described classically as scoop and swoop versus stay and play.

SERVICES AND GOVERNANCE OF PREHOSPITAL CARE SYSTEMS

The intentions of most prehospital care services are to provide immediate medical care to ill or injured persons who are outside of the hospital setting and to transport these patients to appropriate medical facilities for physician evaluation and management. Although prehospital care and other EMS components have improved significantly since the early 1970s, the capabilities of these components vary on a regional basis. In all 50 states, EMS legislation exists, providing a statutory basis for statewide systems. Under these laws, state agencies can set forth regulations that carry the weight of the law. Because EMS systems often are regionally based, however, municipal agencies ultimately govern the extent of services that can be provided by prehospital care personnel. Furthermore, many jurisdictions place restrictions on procedures that prehospital care providers may perform on children.

All states have identified lead agencies that provide coordination of EMS activities and purpose within the state. In most states, the lead agency is headed by an EMS director who reports to the state department of health. Often, state-level advisory councils exist to aid in the development of protocols and minimum standards of operation.

States often are divided into EMS regions, at which level prehospital care becomes operational and local government, hospitals, and ambulance services interact with each other. At this level, regional advisory councils exist as well. Physicians should be encouraged to become involved in these regional committees as advocates of the pediatric needs within their systems. The American Academy of Pediatrics (AAP) prehospital care committee of the section on emergency medicine has prepared an informative resource manual that addresses pediatric prehospital care issues. Agencies, educational programs, and other available avenues of physician involvement are outlined in this manual.

COMPONENTS OF PREHOSPITAL CARE SYSTEMS

Prehospital care is a multicomponent system that involves various personnel and equipment, both of which have undergone remarkable changes over the past 20 years. To understand the extent of the services provided by prehospital care systems, it is essential that physicians who interact with these systems understand the training and capabilities of prehospital personnel and the equipment available to them.

Prehospital Personnel

Prehospital personnel have not always been trained specially to provide the care that their patients require. It was not until 1964 that the first reports of attempts to train fire and police personnel in basic cardiopulmonary resuscitation (CPR) appeared in the literature. Since then, several classifications of prehospital care providers have emerged, each with different levels of training and varying degrees of capabilities. Three general categories of prehospital personnel exist (Table 6.1): first responders, basic life support (BLS) providers, and advanced life support (ALS) providers. Training standards and requirements for certification exist for all of these groups. Federal standards often are superseded by more precise state or local training prerequisites for practice. Many jurisdictions either offer to or require of the providers various supplemental training modules. As a result, many intermediate levels of providers have evolved, with variable capabilities.

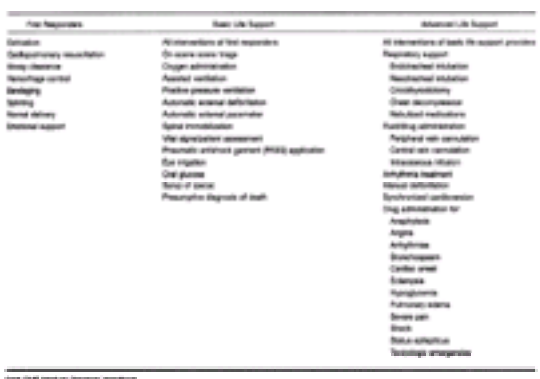

Table 6.1. Categories of Prehospital Care Providers and Their Capabilities

First Responders

The true definition of a first responder is the person who happens on the scene first to provide patient aid. In the context of classification of capabilities, however, *first responder* is a generic term that refers to a large group of persons who have limited but significant lifesaving capabilities. A national first responder course with a standardized 40-hour curriculum has been developed. Eisenberg et al. have demonstrated that properly trained community-based responders can shorten the time to CPR significantly and can enhance resuscitation outcome.

Although the exact capabilities of first responders might vary according to local standards, most are trained to help clear an obstructed airway, to provide lifesaving hemorrhage control and limb-preserving splinting, and to administer BLS while awaiting the arrival of ALS personnel. Spinal immobilization usually is beyond the capabilities of most first responders. First responders generally do not provide patient transport in ambulances; however, in some rural systems, first responders might replace emergency medical technicians (EMTs) as initial ambulance personnel.

Basic Life Support Providers

BLS providers are trained to give all the services of first responders, as well as to evaluate the severity of a patient's condition, provide other simple interventions, and transport patients. In different locations, alternative titles for BLS providers might exist; however, many refer to these personnel as EMTs.

The capabilities of EMTs exceed those of first responders. EMTs are capable of patient assessment, spinal immobilization, ventilatory assistance (exclusive of intubation), and application of pneumatic antishock garment (PASG). In addition to first responder recognition of pulselessness, apnea, upper airway obstruction, and extremity deformity, BLS providers are trained also to recognize respiratory distress, altered mental status, shock, mechanisms of injury, and obvious death. Initial patient triage and routing to receiving medical centers is another crucial responsibility of BLS providers.

For first responders, standardized EMT courses exist that provide 100 hours or more of didactic and clinical instruction. A basic curriculum, which often is expanded further, has been developed by the U.S. Department of Transportation. Occasionally, additional training modules are available to persons who have achieved such training. Satisfactory completion of this supplemental instruction might result in advancement and designation to an intermediate level of provider status. For example, many areas now offer EMT training in defibrillation. Once certified in this technique, the provider often is called an EMT-D.

Advanced Life Support Providers

More advanced than BLS providers are those who are trained to provide ALS. As previously stated, BLS providers often can advance their skills and levels of expertise in modular training formats. Certification exists for progressive skill levels in vascular access, respiratory support, and drug administration. Many intermediate levels have been created between BLS and ALS providers.

Just as BLS providers often are referred to as EMTs, so are ALS providers often called paramedics. The most intensively trained paramedics have more than 400 hours of training and are capable of administering advanced resuscitation in the field. Their capabilities include advanced general diagnostic skills, recognition of arrhythmias as well as drug and electrical conversion of arrhythmias, and advanced airway management (including endotracheal intubation). In many locations throughout the United States, field ALS providers have significantly decreased mortality following cardiac

arrest.

Intermediate Levels of Providers

Numerous intermediate levels of providers have been mentioned other than the basic three groups already described. Many such provider classifications developed in response to specific needs of local jurisdictions, regions, or states. For example, some localities might have found that patient outcome could improve by adding training in peripheral venous access to the basic EMT curricula. As a result, this and many other training permutations have been developed.

Many negative aspects of these hybrid programs have been realized. Intermediate-level designees often focus their efforts on learning interventions that (independently) are of little value or are easily forgotten because of infrequent use rather than concentrating on perfecting basic clinical skills. It is incumbent on the local and state medical directors to review existing and new interventions constantly and to make thoughtful decisions regarding additional training requirements of intermediate-level providers.

Equipment and Modes of Transport

Ground Transport

Napoleon's chief surgeons are credited with providing the concept from which modern ambulances developed. From these original covered carts to the most sophisticated mobile intensive care unit of the 1990s, many changes have occurred. Before the 1970s, most changes concerned the types of vehicles used as ambulances. Up until that time, ambulances were little more than taxis, sparsely equipped and staffed, at best, by first-aid-capable personnel. In 1969 and 1973, the National Academy of Science and the U.S. Department of Transportation published documents that generally defined the purpose of an ambulance and its contents. In 1974, the Department of Transportation and General Services Administration published another document (KKK Standards) that provided engineering specifications that incorporated the general recommendations of the ambulance design criteria. Although KKK standards have been amended, they remain the specifications by which federal agencies purchase ambulances. In 1983, the National Highway Transportation Safety Administration published minimum standards for ambulances not purchased by federal agencies but using federal highway safety funds. According to these guidelines, ambulances must comply with the essential equipment list established by the American College of Surgeons, have space for two litter patients, have 60 inches of head room for EMTs, be manned by two basic-level EMTs, and have adequate exterior lighting. No mention was made of capabilities for ALS or communication with medical command. As a result, many states have established more comprehensive standards.

Three types of ground transport vehicles generally are available today. Type I is a conventional truck cab chassis on which a modular transferable ambulance body is mounted. Type II is a standard van, the body of which is converted to conform with ambulance standards. Type III is a specialty van with a unitized cab and body or with a cab-over-engine chassis to which a modular transferable ambulance body is mounted.

Ambulances also are categorized according to their equipment and staffing capabilities. BLS units should be equipped to conform at least to the list of “Essential Equipment for Ambulances” published in 1983 by the American College of Surgeons (Table 6.2). Included in this list are ventilation and airway equipment, immobilization devices, bandages, pneumatic antishock garments, two-way communication equipment, obstetric kits, extrication equipment, and other miscellaneous items.

Table 6.2. Required Equipment and Supplies for Ambulances Providing Basic Life Support

In 1988, the American College of Emergency Physicians (ACEP) published a position paper that detailed staffing and equipment appropriate for ALS units (Table 6.3, Table 6.4 and Table 6.5). In addition to most of the equipment contained in the BLS list, these ALS units are recommended to carry intubation and vascular access equipment, a portable battery-operated monitor-defibrillator, and a variety of ALS medications.

Equipment	Burn pack—standard pack; towels or gel burn sheet acceptable
Oxygen tank with tubing, with humidified source for long transport times	Thermal absorbent blanket
Oral airways—sizes 0–5	Equipment sizing tape or equipment/age/weight chart
Nasopharyngeal airways with lubricant—12–30 Fr or equivalent sizes in mm	Heat source for ambulance
Self-inflating bags with oxygen reservoir—250-, 500-, 1000-mL bags	Supplies
Oxygen masks—infant, child, and adult	Adhesive tape
Nasal cannulae—infant, child, and adult	Alcohol sponges
Masks for bag-valve-mask—infant, child, and adult sizes 1–3	Arm boards—various sizes
Stethoscope	Povidone-iodine prep pads
Blood pressure cuffs—infant, child, and adult	Elastic bandages
Portable suction unit	Extra batteries and bulbs for equipment needs
Suction catheters (flexible and rigid)—6–14 Fr	Flashlight, bulb, and batteries
Backboard for spinal immobilization—short and long board neck immobilization	Gauze rolls
Towel rolls, blanket rolls, or equivalent	Gauze sponges
Rigid cervical collar (for children more than 2 years of age—infant, child, small, medium, and adult)	Protective eyewear, gloves, and masks
Femur splint—designed for pediatric patients	Scissors
	Tincture of benzoin
	Tongue blades

Table 6.3. Basic Life Support: Minimum Pediatric Equipment and Suppliers

Equipment	3-way stopcocks or adapter that allows administration of additional fluids or medications
BLS minimum equipment and supplies, plus	Syringes—various sizes
Monitoring	Blood sample tubes
Transport monitor—battery-operated with 3 or 4 lead wires	Intravenous tubing, Buretrol
Defibrillator with ECG and 8-cm paddles (or paddle adapter) and pads capable to dial down to appropriate watt-sec for pediatric patients (when replacing current equipment, new equipment should have settings below 20 watt-sec)	Tuberculin syringes
Monitoring electrodes	Intravenous Solutions
Equipment and drug dosage tape or age weight chart	Normal saline or lactated Ringer's
Glucose detection strips	D5W (diluent)
Airway	Sodium chloride—bacteriostatic, for injection
Laryngoscope handle with extra batteries and bulbs	Water—bacteriostatic, for injection
Laryngoscope blades—straight and/or curved, 0, 1, 2, 3	Medications/Concentrations
Stylettes—pediatric sizes	Atropine sulfate—0.1 mg/mL
Endotracheal tubes	Bicarbonate, sodium—4.2% (1.0 mEq/mL)
Uncuffed range 2.5–6.0	Diazepam or anxiolytic choice—5 mg/mL
Cuffed range 5.5–8.0	Epinephrine—1:1000 (1 mg/mL)
Magill forceps (Pediatric)	Epinephrine—1:10,000 (0.1 mg/mL)
Lubrication (water soluble)	Lidocaine hydrochloride (20—10 mg/mL)
Nasogastric tube—sizes 8–18 Fr	Naloxone hydrochloride (adult)—1.0 mg/mL
Vascular Access	Pain medication per medical control
Intravenous catheter of choice—16–22 gauge	D50 (dextrose 50 + water and diluent)
Intraosseous needles of choice	Inhaled β-adrenergic agent of choice
Tourniquet/rubber bands	Activated charcoal

Table 6.4. Advanced Life Support: Minimum Pediatric Equipment and Medications

Basic Life Support (BLS) for Newborn
Oxygen cylinder
Stethoscope
Bulb syringe
Portable suction
Suction catheters—5–10 Fr range
Resuscitation bag—(750 mL (250 or 500 mL)
Face mask (infant)—premature and newborn sizes
Gauze
Sterile scissors
Thermal absorbent blanket and head cover
Cord clamps
Appropriate heat source for ambulance compartment
Advanced Life Support (ALS) for Newborn
BLS equipment for newborn as listed above, plus:
Endotracheal tube uncuffed—3.0–4.0 mm
Endotracheal tube stylet—6 Fr
Laryngoscope—straight blades 0 and 1
Infusion set, microdrip unit

Table 6.5. Basic and Advanced Life Support: Minimum Resuscitation Equipment and Supplies for the Newborn

Pediatric Equipment

It has only been recently that the prehospital care needs of the pediatric patient have been addressed formally. When formulating equipment lists for pediatric prehospital emergencies, it is tempting to be all-inclusive. This desire should be tempered by the limitations of budget and carrying space. Because of the tremendous variability in pediatric-appropriate equipment carried by EMS agencies, an attempt was made to establish minimum standards for pediatric equipment (Table 6.6). The equipment listed centers mostly around airway, circulation, and immobilization needs. More technically sophisticated equipment can be added if patient needs and provider expertise warrant.

Equipment	Quantity
Airway[b]	
Suction catheter (for tracheostomy care)	
6.0 Fr	2
8.0 Fr	2
Ventilation	
Face mask	
Newborn	1
Infant	1
Child	1
Bag-valve-mask with pop-off valve	
500–750 mL	1
Oxygen delivery mask—partial rebreathing	
Infant	1
Child	1
Spinal immobilization	
Short board	1
Sand bag (5–10 lb)	4
Circulation[c]	
Cardiac monitor (with pediatric paddles approximately 20 cm²)	1
Blood pressure cuff	
Infant (6–8 cm)	1
Child (8–10 cm)	1
IV catheter (over the needle)	
22-gauge	[illegible]
24-gauge	[illegible]
Miscellaneous	
Short-arm board	2
Long-arm board	2
Bulb suction	1
Cord clamp	2
Sterile scissors	1

[a] Luten R, Foltin G, eds. Pediatric Resources for Prehospital Care. American Academy of Pediatrics, 1989:42–46.
[b] Consider oral/pharyngeal airways, equipment for endotracheal intubation.
[c] Consider intraosseous needle, infant and toddler [illegible]; IV catheter recommendations assume larger size catheters (20 gauge and greater) are available.

Table 6.6. Minimal Standard for Pediatric Equipment, 1989 (ALS Units)[a]

Ground Vehicle Staffing

Although vehicle staffing configurations vary by locality, the most common configuration consists of two persons trained at least to the level of EMT-ambulance. The ACEP position paper of 1988 outlines the minimum capabilities of providers who staff ALS units. Such personnel should have BLS as well as ALS skills and should be able to recognize, assess, and initially manage medical and trauma emergencies alike. In an ACEP (1989) publication that discussed the principles of EMS systems, Roush estimates that nine EMTs are needed to provide 24-hour staffing of one EMS vehicle and also suggests that five of them should be paramedic level if the service offers ALS.

In many geographic areas, the medical needs of the population served demand specialty transport services. Such services can be either ground-based or air-based. Examples of ground specialty transport units include mobile coronary care units, neonatal transport units, high-risk obstetrics units, and mobile intensive care units. For each of these, specialized equipment and staffing are incorporated.

Air Transport

Air medical transport had been envisioned by many immediately after the first successful flight of the Wright brothers in 1903. Again, however, the demands of war made air medical transportation a reality. The Korean and Vietnam wars provided tremendous experience with this prehospital service. Reduced mortality of battlefield casualties was attributable largely to the efficiency of air medical transport.

The gradual introduction of air medical transport into civilian prehospital care began in the 1960s. During that time, a National Academy of Sciences National Research Council document recommended the initiation of pilot programs to evaluate ground and air ambulance services in sparsely populated areas. During the 1970s and 1980s, air medical transport developed into a common part of EMS services.

Regardless of their degree of involvement, physicians should be aware of the air medical transport services in their region. Two basic types of air transport exist: helicopter and fixed-wing. Helicopters (rotor craft) are used more commonly in densely populated areas. Their unique capabilities of rapid, direct scene response give these craft a distinct advantage over fixed-wing craft. Helicopter services have allowed for the provision of ALS services to larger rural areas incapable of sustaining independent ALS units and have provided access to tertiary care centers for patients in regions without such centers. The second type of craft, fixed-wing, has the advantage of being smoother, quieter, faster, and more spacious. These craft are limited, however, by their need for runway facilities, and they are incapable of scene access.

Air medical transport is a specialized service and is an adjunct to and not a substitute for ground transport. Proper provision of air medical services requires specialized equipment and staffing, both on the ground and in the air. Physicians and transport personnel knowledgeable in flight physiology and experienced in working within the confines of cramped cabins are essential components of these systems. Air transport services carry higher safety risks and higher operational costs than their ground counterparts.

ACCESS TO EMERGENCY MEDICAL SERVICES FOR CHILDREN

For the EMS-C system to provide rapid prehospital care to an acutely ill child, the system must be accessed by a person who recognizes that the child needs emergency treatment. Children rarely access the system themselves; this decision usually is made by a parent, a bystander, or a primary care physician. Because it is a parent who is most often with the child when an emergency happens, it is imperative that the parent be able to recognize a child with an emergency illness or injury. Although most parents do recognize signs and symptoms of obvious life-threatening illness (e.g., seizures, respiratory distress), other emergencies with more subtle symptoms (e.g., dehydration, toxic ingestions) may be missed. However, parents may place undo emphasis on a relatively common symptom, such as fever, and activate the EMS-C system to transport a well-appearing child with fever rather than call the child's physician. If a child is involved in a severe accident when the parent is not present or when the parent is also involved in the accident, the responsibility of accessing the EMS-C system is with a bystander. Proper education directed toward recognizing emergencies and knowing how and when to access the system must be directed not just at parents and caretakers, then, but to all members of the community.

In the event that the parent calls or visits the primary care physician concerning the child's illness, the physician must then direct emergency care. The physician should be able to perform a rapid assessment of the child's condition and, if needed, initiate BLS. Depending on the nature of the illness or the injury, the physician may direct the transport of the child to an emergency facility (either by the parents or by activation of the EMS-C system). It is important that the physician take responsibility for the child's transport and, in some cases (e.g., acute epiglottitis), accompany the child by the safest, most expedient fashion.

MEDICAL COMMAND

Medical command is the entity primarily responsible for the overall medical supervision of the emergency medical system in a community. In general, medical command is composed of a group of base stations—facilities integrated into the paramedic program—with paramedics assigned to that facility as their operational base. Most base stations are hospitals or specialized fire department stations. A medical control facility is a hospital that provides direct medical control for advanced prehospital treatment and is responsible for designation of a medical director, a nurse liaison, and an administrative liaison officer to support a paramedic program. Medical control can be achieved by off-line direction of paramedics and other field personnel through training, provision and monitoring of protocols, and data collection and evaluation and by on-line medical consultation by base station physicians with emergency medical technicians and paramedics. This control is exercised on three distinct levels: 1) the EMS director, who has an off-line, systemwide

administrative role; 2) the base station hospital medical director, who has an off-line regional administrative role; and 3) the base station hospital emergency physician, who has an on-line physician supervisor role directing the care of individual cases in the field.

The EMS director can be an individual person or a group of representatives from areas hospitals, which comprise a Physician Advisory Board. This advisory board has the advantage of representing a consensus of opinion that may be more acceptable to system participants and local politicians. Furthermore, the supervisory work can be distributed among several physicians. However, the bureaucracy often associated with an advisory board may result in a delay in implementation of important policies.

Medical control systems for EMS in the United States are diverse, predominantly because of the various circumstances under which each system operates. Local geographic and medical constraints, financial restrictions, and experience of available personnel affect the extent of the regional system. Nevertheless, any system design for prehospital care should include the basic components described in the following sections.

Off-Line Medical Control

A fundamental requirement of an EMS system is that an off-line medical director be responsible for the planning, implementation, operation, and monitoring of the system. Essential components of the system include development of guidelines for prehospital care; establishment of protocols for patient treatment, triage, and transfer; development of minimum standards for participating facilities; and development of standards for certification of field personnel. In EMS systems with more than one base station, it also is necessary to have an off-line medical director of a regional base station who coordinates the prehospital care in the assigned region. This regional director is the medical liaison with other receiving hospitals in the region.

On-Line Medical Control

The management of individual cases by field personnel is the responsibility of the emergency physician on duty at the centralized medical control facility or at the regional base station. After patient assessment at the scene, field personnel follow operational protocols and then contact the on-line medical control physician for voice authorization of certain ALS procedures. This system allows immediate medical consultation and adjustment of treatment protocols for each case. To be most effective, the on-line physician must be experienced in efficient evaluation of the patient's emergent medical needs. Often, on-line medical command is associated with longer on-scene time and an infrequent physician-directed deviation from the written treatment protocols. Clearly, effective medical control rests on a close and trusting relationship between medical control physicians and field personnel.

An important component of on-line medical command is clear communication between the field personnel and the base station. Typical radio systems allow only one person to speak at a time, which may delay communication. Landline telephones allow both parties to speak at the same time and thereby, enhance the transfer of information. Furthermore, telephones have more clarity than radio communications. Clearer communication has been associated with shorter call duration. In the future, we can anticipate conversion of voice, data, and other communications to digital or other more modern technologies. These changes will make computerization universal and lead to more effective processing of information.

MECHANICS OF THE SYSTEM

The essence of an efficient EMS-C system depends on quick and reliable communication systems (Fig. 6.1). If the parent is unable to access the system, treatment will be delayed. Regardless of how good the receiving hospital services are, if the system cannot get the child to the hospital in a timely fashion, outcome is affected. Most regions with centralized emergency aid have a communications center that receives all calls and coordinates emergency response. This center may be located in a central city agency, such as the police or fire headquarters, or it may be located in a hospital facility. The goal of the communication center is to receive all distress calls, identify the type of emergency need, and route immediate BLS (and if necessary ALS) personnel to the scene. Although the mechanics of the EMS-C response vary from region to region, many components are common to the prehospital phase.

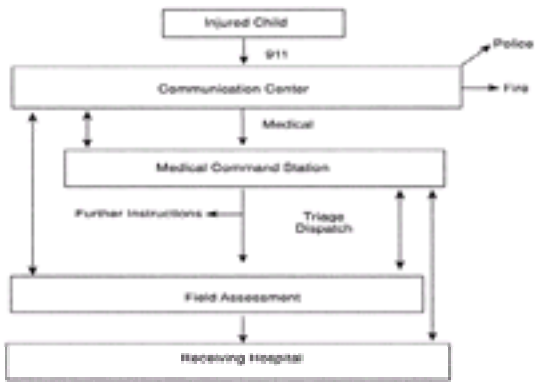

FIGURE 6.1. EMS-C communication system diagram.

Initiation of Emergency Medical Services for Children

Although the parent can use many methods to initiate an EMS response, the telephone is the easiest and most common. A major difficulty in accessing the system occurs when the parent is not sure who should be called—the primary care physician, the police, the fire department, or a nearby hospital. Faced with this dilemma, the parent often calls the operator at the telephone company, which delays the EMS response because the operator then must transfer the call into the regional emergency system. Furthermore, telephone operators are not trained in appropriate triage of calls, leaving room for errors in judgment that may affect patient outcome.

In an attempt to institute a single, coordinated telephone access system, most regions have adopted one easy-to-remember telephone number (911) to access a response for any emergency. In fact, some areas are using an enhanced 911 system that will automatically provide the dispatcher with the caller's name and telephone number. For this to be effective, residents in the region must be taught how to then access EMS. In addition, care must be taken to emphasize the fact that “911 must be saved for the real thing.” Depending on the local resources for accessing the health system, residents may become accustomed to using “911” for transport of nonemergent medical problems that may lead to unnecessary delays in response to other cases of life-threatening illness.

Receiving

In a developed, centralized EMS system, the distress call is made directly to a communication center. A trained operator at the communication center then routes the call to an operator at the police, fire, or medical center. These specialized operators then gather essential information concerning the nature of the emergency and relay the location of the child and the triage complaint to the EMS system for dispatch of a first responder. This first interaction of the parent and the communication system perhaps is the most crucial. In a matter of seconds, the medical operator must calm the caller, extract the complaint, make the triage decision, and obtain the address. While the EMS unit is being dispatched, the operator continues to talk with the caller. At this point, the operator usually uses computerized algorithms to provide the caller with additional basic lifesaving instructions.

Dispatch

When the distress call is received, a first responder is sent to the scene immediately. The first responder is the closest personnel (police, fire, EMT, or paramedic) with BLS training. Based on the severity of the complaint, additional responders (usually paramedics with ALS training) will be dispatched. In the event of a medical disaster, multiple response teams, including police, fire, and medical personnel, are activated.

Field Treatment

The first responder begins BLS techniques until the arrival of more experienced medical personnel. When the paramedics arrive, ALS is begun using established protocols and, if available, on-line medical command. The communication center and the medical command center then decide on the closest, most appropriate hospital for treatment. The hospital selected is based on various factors, including bed availability and critical care, trauma, or burn management capabilities. A severely injured child may be transported to a pediatric level 1 trauma center, a level 1 trauma center, or a community hospital, depending on the relative time available to transport the child and the extent of injuries.

Completion of Prehospital Service

Once the child is en route to the receiving hospital, medical command then notifies the receiving hospital of the transport. Based on the nature of the child's illness or injury, the receiving hospital then can begin to assemble personnel and equipment for prompt treatment. On arrival, essential information concerning the child's condition and the field treatment is transferred to the accepting physician.

TYPE OF TRANSPORT USED

The decision about whether to use ground or air transportation depends on the child's condition, the type and location of emergency facilities, and the resources in the community. In general, ground transportation is more readily available and safer if the appropriate emergency facility is within 20 to 30 minutes from the scene. Air transport is more valuable in rough terrain (helicopter) or when there is a long travel distance (fixed-wing). In the first instance, the first responder notifies the regional emergency air transport system (which may be hospital- or police-based) directly, and the helicopter then is dispatched to the scene. For long-distance transport, patients are taken to airports by ground transport vehicles and then are transferred to fixed-wing craft. In no other transport system is effective and efficient communications between prehospital providers and emergency department physicians more important than in air transport. It also must be emphasized that air transport is not without risk, especially in inclement weather, and should be used only when absolutely necessary. It is not intended for routine or nonemergent transport. When choosing between alternative forms of transport, safety factors should always be balanced against the urgency of transport and other special needs of the patient.

EMERGENCY MEDICAL SERVICE ORGANIZATIONS

Many organizations at the local, state, and national levels are available to a wide range of EMS personnel. These organizations serve as forums for discussing, teaching, and implementing policies used to promote the specific needs of EMS. A list of national organizations is shown in Table 6.7.

American College of Emergency Physicians (ACEP) Dallas, TX
American Trauma Society Upper Marlboro, MD
Association of Air Medical Services (AAMS) Columbia, MO
Emergency Medical Foundation Washington, DC
National Association of Emergency Medical Technicians Kansas City, MO
National Association of EMS Physicians Pittsburgh, PA
National Association of First Responders Orange Beach, AL
National Association of State EMS Directors Lexington, KY
National Emergency Number Association (NENA) Columbus, OH
National Registry of Emergency Medical Technicians Columbus, OH

Table 6.7. National EMS Organizations

MEDICAL-LEGAL ISSUES

Prehospital care providers are legally responsible for their actions or lack of actions. Malpractice suits increase annually, affecting all components of the health care system. More claims originate from urban areas than from rural areas. Because they act in an official capacity, for which they are paid, prehospital care providers generally are not protected by Good Samaritan laws.

Prehospital care providers practice in a precarious setting. They commonly attend to children in cramped, poorly lighted quarters, encounter large crowds or hostile family members, and lack equipment appropriate for pediatric patients. Despite these and other obstacles, prehospital care providers often must make important decisions about the management and transport of critically ill children with rapidly changing conditions. Because of inadequate pediatric training or experience, some prehospital care providers might not be prepared well enough to provide such management. Most lawsuits that involve prehospital care providers result from transport of patients to inappropriate facilities, deviation from standardized procedures, slow response, or failure to transport patients when indicated. Although prevention of all legal actions is unlikely, prehospital care providers can minimize their risks by attending to the three Ds: duties, details, and documentation. When there is doubt, prehospital care providers should consult with the on-line medical control physician.

Duties to Provide Care

All health care providers must understand their duties to provide care. Questions often arise concerning issues of consent. Most states allow for the treatment of minors without parental consent when an emergency exists. In general, any condition that threatens “life and health” or “life and limb” is considered an emergency and can and should be treated immediately. Patients with impaired cognitive function (i.e., irrational, unconscious, or retarded) also should be treated. It is best to err on the side of treatment.

If parents are present and refuse care for their children, they should be asked to sign a (witnessed) form releasing the prehospital care provider from responsibility. Regardless of religious beliefs or parental desires, the child must be treated, however, if there is a life-threatening emergency or possible child abuse. Treatment also should be rendered if the parents are incapable of understanding the risks of refusing care. Off-duty prehospital care providers in uniform still have some responsibility to provide emergency care.

Prehospital care providers are not required to provide care if they would be put at risk for personal injury. Some states also permit prehospital care providers not to administer CPR after being shown written physician orders directing such care.

Details of Standards of Care

Prehospital care providers must always provide care in accordance with local standards. Many municipalities have established written protocols that help streamline decision making. Communication with the command center is crucial; inquiries should be made when doubt exists.

Care should be taken to provide proper immobilization, when indicated. Lawsuits have resulted from improper immobilization. Furthermore, to protect themselves, prehospital care providers should insist that the receiving physician examine the traumatized patient before removal of immobilization equipment. Although treatment of the patient is the first priority, care should be given to preserve evidence if trauma resulted from a criminal act. Clothing and other items (e.g., poison containers) should be brought with the child.

Local regulations also must be obeyed. Laws that detail lines of authority among police, fire, and prehospital care units often exist. Likewise, local driving and speed laws govern ambulance road behavior.

Documentation

All actions by prehospital care providers should be documented. These documents become part of the child's record and may be used as evidence. Therefore, the person who provides documentation should strive for completeness. Each patient should have an individual report that contains vital signs, physical findings, medications and fluids given, procedures performed, position of the patient during transport, and communications (including failed) with medical command. Although these records are confidential, prehospital care providers are required to report suspected child

abuse, gunshot wounds, and illegal drug use.

SAMPLE PATIENT MANAGEMENT ALGORITHMS

Prehospital patient care often is required for seriously ill or injured children. For this reason and because pediatric skills often are suboptimal because of infrequent use, it is wise to develop standing protocols for various medical and surgical emergencies. Logically, such protocols should be developed regionally or locally so that they can incorporate the facilities and services available. Protocols always should reflect the principles of optimal medical and surgical management.

The chapter appendix (pp. 94–101) contains sample algorithms developed by the Philadelphia Emergency Medical Services Council, under the direction of Steven J. Davidson, MD. These protocols were created by the emergency medicine staff of The Children's Hospital of Philadelphia in 1990, and they are updated periodically.

APPENDIX
SAMPLE PATIENT MANAGEMENT ALGORITHMS

ASYSTOLE

Confirm presence of asystole in two lead positions.

[1] When given IV/IO, epinephrine should be repeated every 5 minutes. If IV/IO is unsuccessful, epinephrine 0.01 mg/kg may be administered via endotracheal tube.

[2] Intubation is preferable if it can be accomplished simultaneously with other techniques.

[3] Atropine administration may be repeated once in 5 minutes. If IV is unsuccessful, atropine 0.02 mg/kg (minimum dose = 0.1 mg) may be administered via endotracheal tube. **Maximum dose = 2 mg.**

[4] Sodium bicarbonate administered after 10 minutes of down/arrest time. For children less than 1 year of age, dilute this drug 1:1 with sterile water.

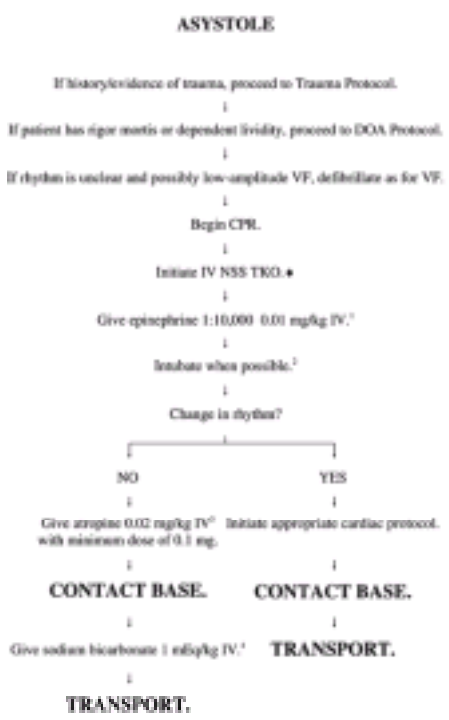
[u] Place an IO line if unable to obtain IV access. Once established, the IO line replaces the IV line as the primary route of administration for fluid and medications.

Time on scene for “cardiac code” generally should not exceed 30 minutes including contact with Medical Command physician.

Fiftieth Percentile Weights by Age

Age (yr)	Average Weight(kg) Boy	Girl
0.5	8	7
1	10	9.5
1.5	11	11
2	12	12
3	14	14
4	17	16
5	19	18
6	21	20
7	23	22
8	25	25
9	28	28
10	32	32
11	36	37
12	40	41
13	45	46
14	50	50
15	55	54
16	60	56

NOTE: If child's weight is **greater than** 50 kg, enter the Adult Protocol.



BRADYCARDIA

The rate at which a child is bradycardic depends on his or her age. The ECG is characterized by a slow rate, in addition to alteration of the P:QRS ratio and P-R interval.

[5] In a bradycardic child, therapy is reserved for the patient who is symptomatic as manifested by these symptoms that identify the presence of decreased blood flow to end organs.

[u] Place an IO line if unable to obtain IV access. Once established, the IO line replaces the IV line as the primary route of administration for fluid and medications.

Fiftieth Percentile Weights by Age Average Weight(kg)

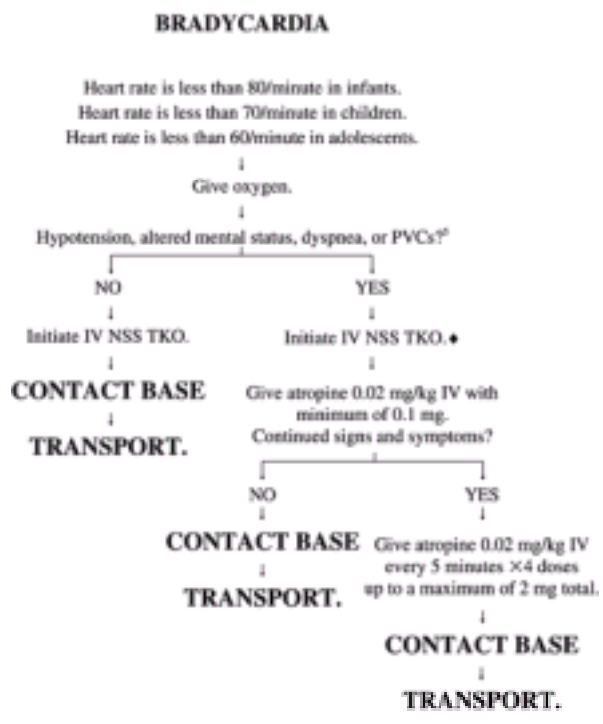
Age(yr)	Boy	Girl
0.5	8	7
1	10	9.5
1.5	11	11
2	12	12
3	14	14
4	17	16
5	19	18
6	21	20
7	23	22
8	25	25
9	28	28
10	32	32
11	36	37
12	40	41
13	45	46
14	50	50
15	55	54
16	60	56

NOTE: If child's weight is **greater than** 50 kg, enter the Adult Protocol.

AVERAGE PEDIATRIC VITAL SIGNS

Temperature	Pulse	Blood Pressure+	Respirations
36-37°C	Newborn: 140-160	80/50	Infant: 40
	1 year: 120	82/54	Preschool: 30
	2 year: 110	84/56	School-age: 20
	4-6 year: 100	90/60-110/76	
	8-10 year: 90	116/78	
	12 year: 80	120/80	

+ Hypotension implies a systolic blood pressure 10 mm Hg less than the average value for age; when in doubt; check with Medical Command physician.



APNEA/INADEQUATE RESPIRATIONS

Inadequate respirations are indicated by anxiety, restlessness, poor or unequal chest expansion, cyanosis, extremely shallow respirations, respiratory rate as listed below, and abnormal or absent breath sounds.

[6] Endotracheal (ET) intubation is the preferred method of airway maintenance. Refer to the table below for pediatric endotracheal tube size guidelines. EOA is contraindicated in children less than 16 years of age.

[7] Consider intubation of the right mainstem bronchus. If necessary, remove initial ET tube. Hyperventilate for 1 minute, then reattempt intubation.

[8] If ET intubation is unsuccessful after three attempts, use manual methods to maintain airway and ventilations. Immediately transport to closest appropriate hospital.

Rates of assisted ventilations for:

- Infants: 20–25 breaths/minute
- Children: 16–20 breaths/minute
- Adolescents: 12–15 breaths/minute

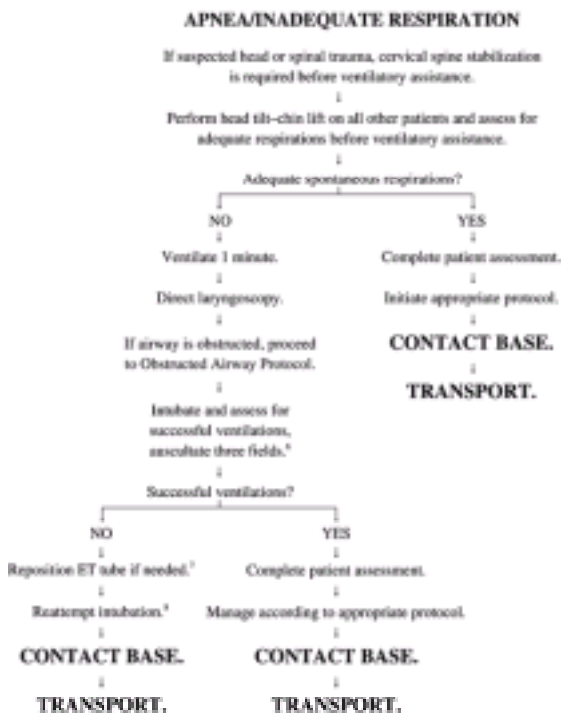
Pediatric ET Tube Size Guidelines

Age	ET Size(mm)
Newborn	3.0
6 months	3.5
1 year	4.0
2 years	4.5
4 years	5.0
6 years	5.5
8 years	6.0
10 years	6.5
12 years	7.0

$$\text{ET size} = \frac{16 + \text{age (yr)}}{4}$$

Laryngoscope Blade Size

Age	Laryngoscope Blade Size
Premature	0 Straight
Term-1 year	1 Straight
1-1½ year	1½ Straight
1½-12 years	2 Straight/curved
13+ years	3 Curved



OBSTRUCTED AIRWAY

If acute obstruction of the airway is due to systemic allergic reactions, proceed to Hypersensitivity Protocol. If maxillofacial trauma is present, proceed to Trauma Protocol.

[9] For children <1 year of age, put head down and use back blows/chest thrusts. For children >1 year of age, use Heimlich maneuver.

[10] ET intubation is the preferred method of airway maintenance after removal of a foreign body with Magill forceps. Refer to the table below for pediatric ET intubation tube size guidelines.

If ET intubation is unsuccessful, use manual methods to maintain airway and ventilate with immediate transport to closest hospital. EOA is **NOT** to be used in patients presenting with obstructed airway.

Successful ventilation is indicated by:

- Bilateral chest expansion
- Adequate tidal volume
- Adequate lung sounds

[11] Remove initial ET tube. Hyperventilate for 1 minute, then reattempt intubation.

Pediatric ET Tube Size Guidelines

Age	ET Size(mm)
Newborn	3.0
6 months	3.5
1 year	4.0
2 years	4.5
4 years	5.0
6 years	5.5
8 years	6.0
10 years	6.5
12 years	7.0

$$\text{ET size} = \frac{16 + \text{age (yr)}}{4}$$

Laryngoscope Blade Size

Age	Laryngoscope Blade Size
Premature	0 Straight
Term-1 year	1 Straight
1-1½ year	1½ Straight
1½-12 years	2 Straight/curved
13+ years	3 Curved

CHAPTER 7

Transport Medicine

***GEORGE A. WOODWARD, MD and †BRENT R. KING, MD**

**Department of Pediatrics, The University of Pennsylvania School of Medicine, and Emergency Transport Services, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania;*
†Departments of Pediatrics and Emergency Medicine, The University of Texas Houston Medical School, Herman Hospital, Houston, Texas

Pediatric interfacility transport involves patient transfer from one medical location to another. Patient status can vary from relatively stable to critically ill. The disease processes involved are detailed throughout this text and include inpatients with progressive or unresolved problems and the entire spectrum of neonatal illness. Although the ABC (airway, breathing, circulation) approach to care remains the integral focus during interfacility transport, it is essential to understand the disease process and expected progression of the disease during the transport period.

Interfacility transport can originate from or be directed to hospitals, emergency care centers, physician offices, clinics, or other medical care facilities. There may not be a clear distinction between interfacility and prehospital transport in terms of equipment, process, and in some instances, personnel. Many interfacility transport teams routinely transport patients from the prehospital care environment, and emergency medical services (EMS) may be involved in interfacility transport. The differences between prehospital and interfacility transport teams often revolve around extrication issues, personnel education, and experience (see Chapter 6).

Although transport teams care for patients with disease processes similar to those seen in emergency department (ED) and critical care units, the delivery of care can differ. The transport environment offers many opportunities for problems if care is not managed appropriately. Although issues of transport team organization can be found in other texts, we briefly review important concepts of interfacility transport here.

Interfacility transport begins with the recognition of a need or a desire for medical care not available at the patient's current location. Reasons for transport include the need for advanced levels of care or specialized care or services, a person's preference for a particular caretaker, the desire to obtain a second opinion, insurance issues, and parent or provider frustrations. However, as outlined in the Consolidated Omnibus Budget Reconciliation Act of 1985 (COBRA) and the federal Emergency Medical Treatment and Active Labor Act (EMTALA) regulations, interfacility transport cannot be used as a method to avoid initial assessment, stabilization, or intervention, especially with regard to a patient's ability to pay.

To prepare for interfacility transport, a transport system must have access to specialized equipment, trained personnel, and appropriate licenses (Table 7.1 A, Table 7.1 B, Table 7.1 C and Table 7.1 D). The transport system is responsible for ensuring the safety of the patient, team, and family members during the transport as well as guaranteeing that the patient is not cared for in a less medically sophisticated environment. The transport system should have an identifiable medical director who is responsible for ensuring adequate training and education as well as continuing assessment of the transport personnel and process. The medical director is the person ultimately responsible for ensuring a safe, reliable transport system.

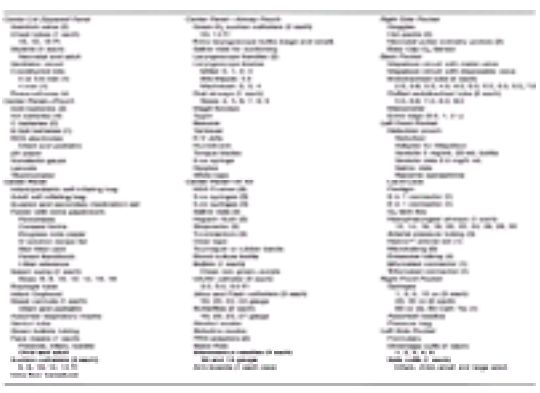

Table 7.1. ***An Example of Equipment and Pharmaceutical Supplies Useful for Pediatric Critical Care Transport. Because Transport Teams Must Be Self-Sufficient During the Transfer Process, Care Should Be Taken to Ensure Adequate and Appropriate Supplies. Specifics May Vary As Per Team Function and Intended Patient Population.***
A. Contents of a "Universal" Pediatric Critical Care Transport Equipment Bag

Cardiorespiratory Monitors	Infusion Pumps
Noninvasive	Single and/or multichannel
Invasive	Blood Sample Measuring Devices
Ventilators	Point of care testing
Pressure	Glucometer
Volume	Portable Suction
Capnography	Portable Oxygen
Pulse Oximeter	Cellular Phone(s)
Defibrillator with Pacing Capability	

Table 7.1.B. Additional Transport Equipment to Be Considered When Equipping a Pediatric Critical Care Transport Team

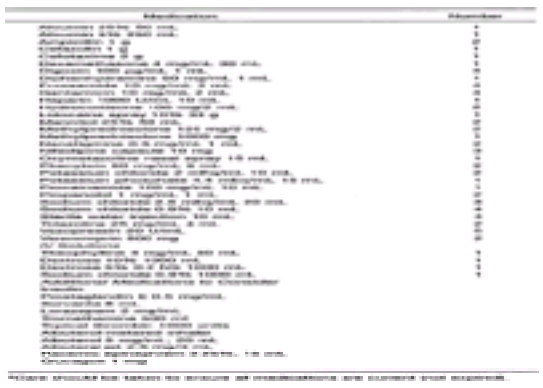

Table 7.1.C. A Standard Pediatric/Neonatal Critical Care Transport Medication Supply[a]

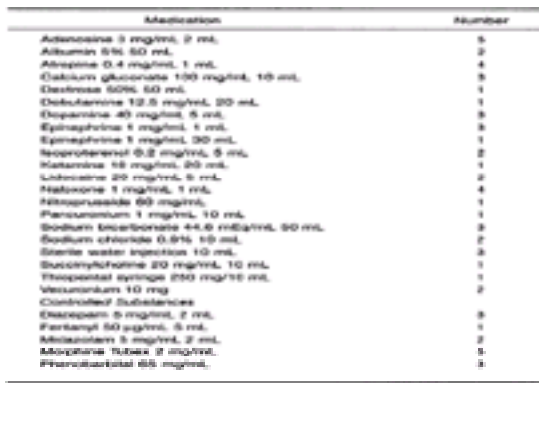

Table 7.1.D. A Rapidly Accessible "STAT" Medication Supply Should Be Included

Significant preparation is required to be an efficient user of transport services. The users of a transport system (the referral hospitals and physicians) must ensure that the transport services meet the standards required for the transfer of their patients. The referral physician must avoid the mind-set of getting the patient out of the ED as quickly as possible without first ensuring transport safety and medical integrity.

Transport medicine is a recognized section within the American Academy of Pediatrics (AAP). Many other groups, such as the Air Medical Physicians Association (AMPA), are dedicated to ensuring optimal care for transported patients. These organizations offer continuing education and are conduits for information regarding transport medicine. The AAP published the "Guidelines for Air and Ground Transport of Neonatal and Pediatric Patients" in 1993, and an updated revision is scheduled for publication in 1999.

TRANSPORT CONSIDERATIONS

Familiarity with the transport environment is necessary for optimal transport care, and the ability to understand the environment and troubleshoot as necessary is critical for the successful transport of a patient. Therefore, configuring a transport team in response to an acute request for patient transport, unless there has been adequate preparation and

training, should be avoided. Although the medical care of the transport patient is similar to that provided in an ED or an intensive care unit (ICU), the potential for errors during the transport process is significant. Issues to consider include ensuring proper equipment and medication supplies; intervening in a cramped, moving environment; safely securing the patient to the stretcher and the stretcher to the transport vehicle; and recognizing and managing the loss of inverter power. In addition, oxygen delivery and suction—as well as the issue of motion sickness—can be difficult for the non–transport-oriented participant. Noise, vibration, and temperature can also be formidable problems for the patient and provider if not anticipated and planned for.

In the transport process, one must be prepared for all types of patients and complications. When the transport team arrives, the patient's status may be significantly different than that initially described. This can be the result of a change in the patient's condition, incomplete assessment by the referring physician or transport team, or inadequate information flow. The ability to correctly assess severity of illness or injury before transport, from both the referring as well as receiving physician perspectives, helps facilitate appropriate triage, mode of transport, and personnel configuration decisions. The transport team may also be asked to transfer a different patient if a more critical patient has presented to the same referring institution. Inadequate numbers or types of personnel, equipment, or medications can render the transport team less effective in these situations.

The medical capabilities of the transport systems are important to assess. All transport teams do not have equivalent levels of pediatric skills. Transport services can vary from specialized pediatric teams, such as those supplied by tertiary care pediatric hospitals, to generalized transport services. A generalized transport service accepts all ages and types of patients; unfortunately, there are no universal standards or regulations regarding the level of experience or expertise in pediatrics required to transport pediatric patients. Although pediatric patients can be efficiently and safely transported by different types of transport systems, the referring physician is responsible for assessing each program for medical sophistication and safety. Pediatric diseases and processes are different from those in adults, and one should not assume that a general transport service has adequate experience in pediatrics to offer the appropriate level of care. Although patient transport by a general team may be quickly accomplished, the process may be classified as getting the patient to pediatric care quickly as opposed to rapidly bringing pediatric care to the patient. For many patients, this is an academic distinction. For example, the stable trauma patient, the child with a clearly defined medical process, or the patient needing referral for a nonprogressive, non–life-threatening issue may be adequately transported by a transport team without extensive pediatric experience. It is imperative, however, that general critical care skills be available for most of these transports. Consultation with a pediatric expert should also be included. When the differential diagnosis needs to be explored during the transport process or when the patient's condition is rapidly changing, an experienced pediatric team is usually preferred. In geographic locations where specialized pediatric transport is unavailable, involvement of a pediatrician on the referring and/or receiving end is important. When possible, a patient should not be referred from a nonpediatric provider to a pediatric institution via a transport team inexperienced in pediatric disease process and management. Ideally, advanced pediatric care should begin the moment the transport team is contacted. Pediatric medical or surgical advice, as well as adequate instruction before arrival of the transport team, can be lifesaving for that particular patient.

Technical skill capability in general transport teams does not necessarily translate into technical skill competence in the treatment of children. This is perhaps most evident in children needing advanced airway intervention. A child's anterior larynx and the recommendation to avoid nasal intubation in children can preclude successful airway intervention by personnel who are not sufficiently educated or experienced in managing the pediatric airway. This discussion is not meant to cause one to avoid nonpediatric transport services but only to ensure that skills necessary for adequate assessment and care of the patient during the transport process are optimal and that the cognitive components, if necessary, be augmented by an outside pediatric specialist.

When a decision is made to transport a pediatric patient, there is often a discussion of the appropriate mode of transport. Nonmedical transports include a parent's automobile or a taxicab. Problems with these choices include no assurance of direct transport to the receiving facility, inability to ensure patient safety, and the lack of available medical care during the transfer. Even the accompaniment of a physician or nurse does not markedly improve the ability for medical intervention in these nonmedical vehicles. A basic life support (BLS) ambulance offers direct transportation to the receiving institution but does not offer much in the way of pediatric expertise or intervention capability. Physician or nurse accompaniment in a BLS ambulance increases potential level of medical care; however, the BLS environment is limited with regard to basic personnel, pediatric equipment, and medications. Advanced life support (ALS) transport offers more sophisticated resuscitation abilities but often provides minimal pediatric expertise. Physician accompaniment may increase the level of available medical care within the ALS environment but may be limited by the particular service's use of protocols and off-line medical direction. Critical care transport services can increase the medical sophistication of ALS providers by ensuring the presence of a critical care transport nurse. Pediatric critical care transport systems include critical care participants (nurses and physicians) with significant pediatric experience and expertise.

When transport services are needed, the modes to be considered include ground ambulance, rotor-wing aircraft (helicopter), and fixed-wing aircraft (jet or prop plane) (Fig. 7.1, Fig. 7.2 and Fig. 7.3). Often, the decision is easy. For example, the available transport system may be ground only, or inclement weather may prevent air transport. Alternatively, the distance may be so great or traffic issues significant enough that ground ambulance transport is impractical. Several important issues should be considered when mode of transport is discussed. The first is personnel availability. If the transport modes require or offer different personnel configurations, the mode with the most appropriate personnel should be strongly considered. Ideally, a pediatric transport service with the capability for air and ground transport is available so that comparative personnel issues are not the major deciding factors. A choice between speed of transport and appropriate medical personnel can be difficult, although they are not necessarily mutually exclusive. Often, the referral hospitals or physicians want to have a patient taken to the receiving hospital as quickly as possible. They are sometimes willing to accept a transport team with little pediatric sophistication based solely on speed. Occasionally, this may be appropriate, but caution needs to be exercised to ensure that the transport system is capable of handling issues that can occur during the transport process. The referral physicians must be proactive in the mode of transport decision. This includes being aware of the transport systems that are available and evaluating those systems before using them. In areas without tertiary care pediatric transport options, local pediatric providers and the receiving pediatric physicians

should be available to provide expertise to the general transport services to help bridge the gap between the general (primarily adult) and pediatric provider.

FIGURE 7.3. Fixed-wing transport. Both jet and piston (propeller) aircraft are used.

The disease process must also be considered in mode of transport decisions. The patient with developing petechiae, fever, and hypotension should not be transported several hours by ground if a quicker method of transport is available. On the other hand, a short air transport for a stable patient may not be an appropriate use of resources or be in the patient's or team's best interest. One must be cognizant of the many issues surrounding the mode of transport choices. These choices should be individualized for each patient. Although appropriate medical care should not be withheld for financial reasons, a cost comparison of air and ground transports is often useful, especially if done before the acute transport. This may be an important factor in the decision process, however, if the referral or receiving physician or hospital is responsible for guaranteeing the cost of the transport. In general, rotor-wing (helicopter) transport costs two to three times as much as a ground transport for local transfers. However, the cost is often offset by the savings in time. A helicopter, which can travel directly to and land at the patient's location, is much quicker than an ambulance, which must take a more circuitous route. If the helicopter cannot land directly at the referring or receiving center, however, the time savings by air transport may be less significant. In that situation, in addition to the decreased time savings, the patient may be placed at greater risk with the multiple transfers from referral center to ambulance to helicopter to ambulance to receiving hospital. The riskiest time for the patient is often during transfer from stretcher to stretcher or vehicle to vehicle (Fig. 7.4). These transfers increase the opportunities for dislodgement of endotracheal tubes, central venous catheters, chest tubes, and other lifesaving equipment.

FIGURE 7.4. A–C. Transfer of patient during transport process. Patient transfer between vehicles or stretchers can be risky to the patient. Tube, line, oxygen, or medication disconnection or disruption, as well as shifts in immobilization, must be avoided. PERSONNEL ISSUES

Many types of providers can function effectively as part of a pediatric transport team. Nurses, respiratory therapists, emergency medical technicians, paramedics, and physicians serve on various transport teams. The choice of personnel depends on several factors, but the most important are the team's primary mission and the resources available for training and skill maintenance. In general, the personnel chosen for the transport team should have experience in the care of critically ill infants and/or children. The transport environment is not the appropriate place to learn basic pediatric critical care skills.

The primary mission of the team must be kept in mind when selecting personnel and planning training. For example, a team devoted to neonatal transport should consider team members with experience in the care of critically ill neonates, whereas teams that perform transports from nonhospital locations may want to employ personnel with prehospital care experience. These team members are likely to adapt more easily to the demands of their new roles. Teams that have multiple missions, such as those that transport both neonates and older children, should attempt to recruit team members from varied backgrounds. By necessity, such teams have to devote considerable time to the medical cross-training of staff members. However, having team members from varied backgrounds offers the potential for those members to assist in the training process. Regardless of the medical background of the transport participants, education and experience in the transport environment is imperative.

Transport team capabilities and types of personnel vary significantly depending on the transport system. However, pediatric critical care transport teams, the ideal interfacility transport configuration for children, often have several specific types of providers. At the heart of most pediatric critical care transport teams are highly trained pediatric nurses. These nurses usually have significant critical care or emergency medicine experience before becoming members of the transport service. They have often had their technical and cognitive skills enhanced by formal or informal specialized training as described in the following. Such training may allow them to be classified as advanced care practitioners. Depending on the sophistication of the transport system, training opportunities, skills and assessment, and medical licensure issues, transport nurses often provide advanced management for these children. This can include diagnosis and assessment skills as well as interventions (e.g., advanced airway management, central venous access, resuscitation). In addition to their cognitive and technical skills, transport nurses have become experts in the environment in which they practice. The transport nurse should be intimately aware of all operating systems within the transport environment as well as safety procedures for the patient and the transport team. The medical skills of pediatric transport nurses can often be complemented by the addition of an attending, fellow, or resident physician; respiratory therapist; nonpediatric transport nurse; or paramedic. Team compositions vary greatly in different systems, and no single team configuration is preferred. The ideal team composition is one that addresses the acute and projected needs of a particular patient and that has the flexibility to be amended when necessary.

In addition to the personnel already described, transport teams usually include drivers or pilots who may have no role in patient care or who may assist the other personnel. Communications specialists may be employed as part of the team's call receipt and dispatch process. Finally, all transport teams should have a clearly identified medical director or directors. The functions of the communications specialists and the medical directors are discussed elsewhere in this chapter.

Other important educational considerations are the resources of both time and money available to devote to training team members. If training time is limited, the transport team must consider hiring staff who are already well trained. For instance, a neonatal team could hire neonatal nurse practitioners. However, such well-trained staff usually demand higher wages, making them ultimately more expensive than a training program. Many teams do not have the luxury of hiring nurse practitioners or other highly skilled personnel; therefore, teams have to devote significant time and resources to training team members. The amount of time necessary varies with the team's mission and its customary personnel composition. A team with a well-defined scope of practice, like neonatal transport, should employ experienced neonatal nurses. In this circumstance, only those skills that are new to the team members are taught. Likewise, if a team usually includes a physician, the other team members may not need to learn advanced skills such as tracheal intubation. Teams that do not routinely include a physician must ensure that their members are competent in all procedural and management skills that may be required during transport. Such extensive training usually includes a didactic component, a skills segment, and rotations through various clinical care areas. If the group is large enough, the didactic component may be a series of lectures. However, this type of experience is difficult to arrange for one or two new team members.

Alternatives to formal lectures include videotaped or audiotaped lectures or a modular self-study curriculum.

Unfortunately, skill acquisition is only the beginning. Rarely used skills are quickly forgotten, so a process for skill maintenance must be established. Furthermore, as in all areas of medical practice, the knowledge base in transport medicine is constantly changing, making continuing education vital. Skill retention and continuing education are best accomplished using a three-part process. The first component is renewal of basic procedural and cognitive skills. Such retraining may include rotations through the operating room to practice airway techniques; dry or animal laboratory experiences for interosseous infusion, cricothyroidotomy, thoracostomy tube placement, and other important but rarely needed procedures; and mock codes to practice resuscitation.

The second component is formal continuing education through regularly scheduled programs, including lectures, journal clubs, and presentations of particularly unusual or difficult patients. In addition, such forums may be used to learn about new medical equipment, communication devices, and vehicle issues.

The final component of an effective education program is quality assurance. Routine, periodic case reviews should take place by the transport service in conjunction with other medical experts. A formal morbidity and mortality conference may be included as a part of such a program. In addition, topics such as response times and parent satisfaction may be discussed. The focus of these sessions should be on the process of patient transport. Determining and assigning blame for less-than-optimal outcomes is important only when the staff member involved was clearly negligent. It is far more important to focus on ways in which the team's practices may be changed to improve performance and minimize risk of similar events in the future.

COMMUNICATION

A key component of any transport team is effective communication. Referring physicians must be able to contact the transport team quickly and easily, and teams in the field must be able to communicate with the receiving facility. The ability to communicate with a command physician is particularly important for teams using resident physicians or nonphysician practitioners because they may need on-line medical direction. Ideally, a single point of contact (e.g., a dispatch center) should be established to help ensure that no calls are missed and that all communications are properly documented (Fig. 7.5).

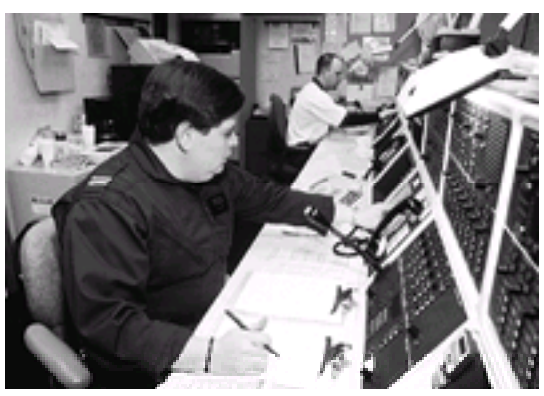

FIGURE 7.5. Transport communication center. A dedicated transport communication center and personnel are invaluable in coordinating all aspects of pediatric transport. The system need not be as elaborate as demonstrated, but should include dedicated phone lines, radio access, personnel notification capability systems, and personnel. (Used with permission, Hahnemann University Hospital, University MedEvac, Philadelphia, PA.)

Communication with the transport team begins with an initial call from the referring hospital. This initial contact is best managed by the use of a protocol or template, which helps ensure that all of the necessary patient and logistical information is properly received by the transport team (Fig. 7.6). During the initial call or soon thereafter, the referring provider may request advice regarding the medical management of the patient. Alternatively, such advice may be offered by the receiving physician. For critically ill infants and children, medical advice via telephone may be needed intermittently from the time of initial contact until the transport team arrives at the referring facility. For these reasons, it is preferable to have transport requests initiated and received by senior physicians who can ask for and offer advice directly. The more people between the source of the information and the final recipient, the greater potential for significant changes or omissions that may be vital to the patient. We also recommend that nurse-to-nurse conversation to evaluate the patient from the nursing perspective be an expected part of the transport process. Together, these two avenues of information flow offer the greatest potential for complete awareness of all aspects of the patient's disease process and current medical condition.

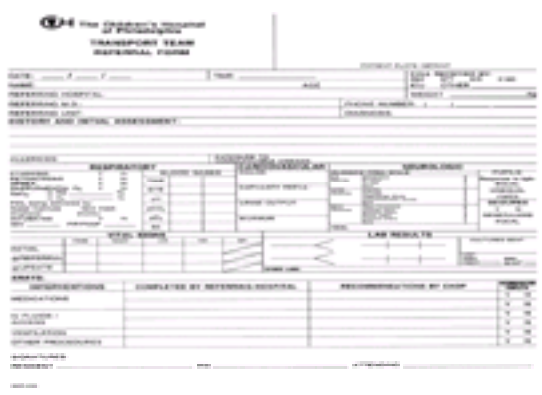

FIGURE 7.6. Transport referral form. A standardized form for recording transport referral information is important. This form should be readily accessible to those who receive the referral. Copies can also be distributed to referral centers to help streamline the process. The forms should, at least, be in duplicate to allow for an official medical record copy (which stays with the command physician during the transport process to document transport progress) and one to accompany the transport team which eventually resides in the patient's transport record.

After the transport team has arrived at the referring facility and performed a preliminary evaluation of the patient, they often need to communicate with one or more people at the receiving hospital. These calls can involve patient review and logistical issues such as patient disposition, scheduling of studies, and need for consultants. Such calls are best facilitated by a communication center.

En route to the receiving hospital, it may be necessary for the transport team to contact the medical command physician either for advice or because the patient's medical condition has changed. Reliable communications are especially important at this point in the transport. The team should be equipped with redundant systems to ensure that a reliable means of communication is always available. These should include cellular technology, long-range alpha beepers, and land radio communications systems. Newer technologies, including telemedicine and global positioning system (GPS), may improve communication and logistics capabilities. The transport command physician should be immediately accessible to the transport team by telephone or designated beeper.

After arrival at the receiving hospital, the transport team is responsible for ensuring an efficient and informative transition of care to the inpatient physician and nursing team. Adequate communication and information flow must take place to fully inform the inpatient team of the patient's disease process and care to date. Complete documentation, written in a clear, concise fashion, is mandatory (Fig. 7.7). Anything less than a complete transfer of information from referral physician to transport team to receiving physicians is a disservice to the patient and a source of potential liability.

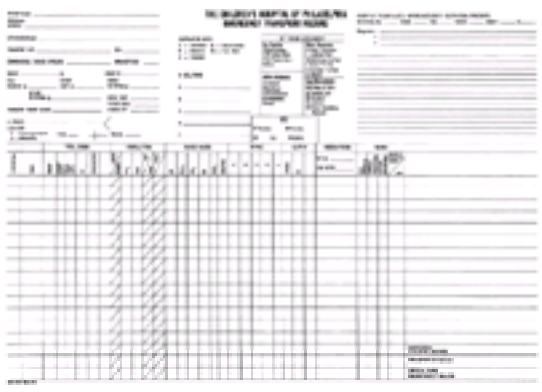

FIGURE 7.7. A. Transport record form (flow sheet). The intratransport period must be documented in an efficient fashion. It must document general medical information as well as progression and response to specific interventions in a timed, sequential fashion. This should also be at least in duplicate to allow for a medical record copy as well as one that remains with the transport system. (Figure **7.7 A**, Figure **7.7 B.1**, Figure **7.7 B.2**, Figure **7.7 C.1**, Figure **7.7 C.2**, Figure **7.7 D**, Figure **7.7 E** used with permission. © The Children's Hospital of Philadelphia, Philadelphia, PA.)

FIGURE 7.7. C.1. Written consent for transport is mandatory.

FIGURE 7.7. C.2.

FIGURE 7.7. D. A written release for medical records will help with transmission of information at time of discharge to referring physicians as well as the primary care physician.

FIGURE 7.7. E. A standardized form can be distributed to referral centers to allow demographic information to be collected prior to the arrival of the transport team. Identification of all principals involved in the patient's care can help future flow of information regarding the patient's diagnosis and outcome.

It is important to remember that transport communications have other medicolegal ramifications. The most important of these involve the giving of medical advice and the assumption of legal responsibility for patient management. When giving or receiving management advice by telephone, both parties should remember that the transport command physician is unable to see or examine the child in question. Therefore, his or her advice will often be somewhat general. The receiving physician must do his or her best to offer clear and complete information, especially when specific information is requested. Suggestions for care must be clearly and completely communicated. For example, if the transport command physician believes that a fluid bolus is needed, that advice should include type and amount of fluid and speed of infusion to avoid any misinterpretation of advice or an inadvertent mistake in one of those parameters. All advice should be documented in writing or by tape recording. The referring physician is under no obligation to accept the advice of the receiving physician, but he or she would be prudent to give it serious consideration. If the referring physician is unable or unwilling to perform suggested interventions because of personnel issues, equipment limitations, or other reasons, this should be discussed with the receiving physician. Likewise, results from interventions or marked changes in the patient's condition during the referral process should be communicated to the receiving physician and transport service. Clear, precise, efficient, and honest communication is imperative for the patient to receive the most appropriate care.

Communication with the patient and family is also important during the transport process. Straightforward communications about disease process and expectations can help prepare a family to accept the consequence of the illness or injury. Lack of communication or reluctance to give bad news can cause a family to expect different outcomes than they should and may pave the way for anger and resentment.

Written communication of all data regarding the patient's care is imperative. Patient summaries, copies of all medical paperwork, laboratory values, and radiographs should be available for the transport team on their arrival. A transport referral checklist may be useful to help streamline the process (Fig. 7.8). Adequate preparation of these documents before arrival of the transport team can greatly improve the efficiency of the transport process and the transition of care. Availability of the referring personnel at the time of transport can also make the process more efficient for all concerned. Telephone and fax numbers and the addresses of the referring and primary physicians should be available to the transport team so that follow-up information may be easily conveyed. Likewise, the referring and primary physicians should be given contact numbers for the transport team and its medical director.

FIGURE 7.8. Referral checklist. Transport referral checklists can decrease the transition time at the referring hospital by allowing the referral team to anticipate the logistics of the pre-transport process and accomplish many tasks prior to the arrival of the transport team. (Used with permission. © The Children's Hospital of Philadelphia, Philadelphia, PA.)

Finally, the family should receive preprinted directions to the receiving facility. Information about parking, mass transit, and the visiting policies of the receiving unit should also be provided. Allowing a family member to accompany the transport team may be useful for both the patient and family.

PATIENT AND TEAM SAFETY

Safety is a key consideration for the transport team. The team should do everything possible to provide for the safety of all involved in the transport process. This includes more than providing pediatric medical expertise for the patient during the transport. It starts with vehicle selection, driver or pilot capabilities, and ongoing licensure requirements. The transport medical director is responsible for continually assessing the capabilities of the particular modes of transport as well as the personnel involved with those functions. This goes beyond licensure issues. Active inspections and evaluations as well as continuous quality improvement (CQI) issues are important. Unsafe vehicles or personnel must be attended to or removed from service. Safety of the transport personnel must also be a priority. Avoiding the use of rotor-wing transport in bad weather is a good example of a safety decision in the transport environment. Fewer air medical transport accidents occur now than in the past. Part of this improvement results from pilots being isolated from patient care information. Instead of being informed that a critical child might die without their intervention, pilots now often make “go” or “no go” decisions based solely on weather and equipment issues. If an appropriate “no go” decision is made, this should not be countermanded by medical or administrative personnel. If a “no go” decision is made based on

weather considerations, another mode of transport or other patient care options must be considered. Competition between transport programs or aeromedical providers can be a safety hazard. In their desire to gain a competitive advantage, one or all of the programs (or specific personnel) may be willing to bend weather and safety rules. It is the policy of our systems that if one air service has denied a transport for weather-related issues, another air service is not contacted unless it is located in a separate environment that may change the weather issues. There is no excuse for risking or losing the lives of several caretakers for any one particular transport.

HOW TO EVALUATE A TRANSPORT TEAM

When assimilating information about pediatric transport options, the following recommendations are offered. First, an attempt to find the transport team with the most pediatric expertise available should be made. Ideally, this team should have the capabilities for both air and ground transport. An assessment of transport personnel should be made through discussions with the medical director or other representative of the transport system. Ideally, the transport team members are dedicated transport personnel who have significant experience in both pediatrics and the transport environment. In assessment of transport programs, one should look for a team that has the capability to vary personnel composition depending on the specific needs of the patient. One should not assume that a more sophisticated medical degree is synonymous with optimal care in the transport environment. The addition of a physician to a transport system does not necessarily suggest a better or more capable system. The system's capabilities depend on the skills of the transport team members as well as the skills and experience of the physician. The use of inexperienced physicians or junior residents who are not familiar with the transport environment may actually decrease the level of delivered care. The inexperienced transport physician may be an unequal partner in the transport process and one who may actually make the transport less effective. For example, the transport nurse may be required to perform most of the patient care and management functions as well as monitor the logistics of the environment. If the transport nurse also needs to tend to an inexperienced provider's personal medical needs during the transport (e.g., motion sickness), this detracts from direct patient care. The addition of a senior pediatric resident, fellow, or physician can be invaluable, however, if that person has transport experience and the patient requires the additional cognitive or technical skills the physician may offer.

The transport system should be easily contacted through an identifiable transport referral number that is answered by a transport communication specialist. One should be able to relay information efficiently and receive suggestions from a transport command physician regarding medical care. It is more efficient to directly contact the transport system regarding patient referral than to call a receiving unit or a particular physician. In an efficient system, a call to the transport communication center should allow the referring personnel to speak to the appropriate receiving physician in a timely fashion. This physician should be clearly identified as the single spokesman for the receiving institution. A single transport command physician allows the process to be streamlined for both the referring and receiving personnel. Transport direction will be from one source, with the use of consultants as necessary. The referring physician does not have to offer transfer information repeatedly, allowing him or her to direct attention to patient care issues. Calling a communication center should also enable the transport team to participate in the conversation as well as simultaneously prepare themselves for the transport. Pretransport preparations can be significant and time-consuming, and early notification can be invaluable. Calls to personnel, ambulances or helicopters, hospital admissions' office, other referral personnel (nurses), and arrangement of tests or procedures at the referral center can be undertaken while medical information is being relayed to the receiving physician. For the nonacute patient, insurance precertification can also be accomplished more efficiently by those who routinely address that issue. The simultaneous completion of these steps can lead to a quicker and more efficient transport. An estimated time of arrival should be given and updated as necessary, recognizing that transport resources may be limited and there may be a necessity to triage patients due to severity of illness.

In addition to initial medical advice, one should expect follow-up from the transport provider regarding the patient. The referring physicians and other caretakers should expect follow-up communication from the transport service regarding care of the patient during transport and within the receiving hospital, including location of the patient and his or her caretakers. There should be an easily identifiable path to the medical director or program manager for issues that develop during or around the transport process. One should expect concerns to be addressed in a timely and satisfactory fashion. In addition, the transport service should be willing to visit the referral physician and location to review specific transport issues. Because the referring physician should have a clearly defined path to the transport service regarding transport issues, the transport team should also have an opportunity to discuss problems with the referral physicians and facilities. These issues could involve timing of referral, preparation for transport, and diagnostic issues. Outreach education by the critical care transport service can be invaluable not only for the physicians but also for nurses and other personnel involved in patient transport preparation.

LEGAL ISSUES

Patient transport is governed by a variety of federal, state, and local statutes. Transport teams and their members may be sued for malpractice under traditional tort law. Therefore, it is important that all members of the transport team understand applicable regulations and avoid unnecessary medicolegal risk.

Of all regulations, the EMTALA has the greatest impact on the management of patient transport. This act places clear duties on both the referring and receiving hospitals. The referring clinicians must do everything possible to stabilize the patient's medical condition before transport and may not transfer a patient against his or her will unless the facility cannot provide the appropriate level of care. Furthermore, the referring physician must obtain informed consent for transfer and, as a part of this process, must advise the patient or the parents of a minor about the risks and benefits associated with transfer. Under EMTALA rules, these discussions should not include the financial ramifications of the decision. This aspect of the law is particularly important when the patient is being transferred solely because of a managed care contract. It seems only fair that parents know that a refusal of transfer may leave them responsible for a hospital bill. However, under EMTALA rules, such information, however well intentioned, may be construed as financial coercion to accept transfer. Instead, the patient should be told to contact the representatives of his or her insurer or the hospital financial personnel to discuss these issues. The referring hospital is also responsible for selecting an appropriate means

of transport. Obviously, the more critical the need for medical care and expertise, the more sophisticated the means of transport. This is an important point for the referral physician to remember. The desire to transfer a child to a more appropriate medical facility as soon as possible is understandable, but if the method chosen places the child in a medical environment that does not offer at least the level of care at the referral center, that center and physician will be liable for any untoward effects that can be construed as having occurred because of the choice of transport. Finally, the EMTALA requires the receiving hospital to accept the patient in transfer if the appropriate type and level of care are available. The ability of the patient to pay for medical care cannot be considered by either the referring or the receiving facility. In addition to the EMTALA, there are often local regulations that govern transport services. For example, some cities have laws designating certain agencies as official providers of prehospital services. Such laws must be considered when offering transport services.

Traditional tort law also applies to the transport team. Most of these issues are no different than those encountered in other health care venues. However, one potential source of medicolegal risk is unique to the transport team. As stated earlier, the transport team gradually becomes more and more involved in the care of the patient. At first, this involvement is limited to giving advice and management suggestions. It is the referring physician's responsibility to carry out these suggestions as he or she deems appropriate. At this stage in the transport process, transport personnel should try to gain the clearest possible picture of the patient's condition so that the most appropriate suggestions may be given. Furthermore, advice may be best prefaced with general phrases such as “Most patients with this condition” or “We often manage this problem by doing.” Finally, the transport team should clearly document any advice given in writing or by tape recording in case disagreements regarding what advice was given arise later.

The next stage of involvement occurs when the transport team arrives at the referral facility and begins to care for the patient, often along with one or more members of the referring hospital's staff. At this point, the greatest medicolegal risks are conflicts over management and difficulties in determining who gave or carried out medical orders. When management conflicts arise, the medical command physician should be contacted, and he or she should resolve these conflicts by speaking directly with the referring physician. The medical record should clearly reflect who gave and who carried out each order.

Finally, the transport team assumes total responsibility for the care of the patient when they leave the referral center. The team should be convinced that the patient is as stable as possible before leaving. If an unstable patient is transported, the team must document why it was in the patient's best interest to undertake transport at that time.

In some cases, transfer agreements exist between hospitals. Typically, such agreements stipulate that the receiving hospital will accept all transfers from the referring hospital. In the past, transfer agreements served to decrease the time needed to accept the patient by eliminating or shortening the approval process. More recently, transfer agreements have become less important for two reasons. First, the EMTALA places a duty on the receiving hospital to accept the patient as long as there is an appropriate bed location available. Second, for patients who are not critically ill, managed care organizations often stipulate certain facilities. In such cases, the transfer agreement exists between the managed care organization and the receiving hospital. However, the referring hospital must still meet obligations to the patient under the EMTALA.

Finally, if the transport team operates under specific guidelines or protocols, these may become the focus of legal action. Therefore, it is imperative that all guidelines represent the current standard of care. Furthermore, guidelines should be designed to ensure that providers do not exceed their scope of practice as defined by state and local regulations. Periodic review of existing protocols and guidelines is warranted. New guidelines should be developed in conjunction with recognized authorities and should be reviewed by risk management specialists before implementation.

STABILIZATION FOR TRANSPORT

The patient care philosophy of most interfacility transport teams stands in contrast to that of prehospital care systems. EMS providers are usually bringing a patient from an environment without medical care (e.g., home or accident scene) to a hospital. In many of these cases, the patient is better served to have the minimum stabilization necessary at the scene followed by rapid transport to an appropriate hospital, with further intervention being performed en route or on arrival. On the other hand, the transport team is most often taking a patient from a hospital, often an ED or another monitored setting, to a monitored bed within a more sophisticated care center. The transport team, therefore, is responsible for maintaining an appropriate level of care between the two centers. Ideally, the transport team should provide the level of care that the patient will have at the receiving facility. At a minimum, the transport team must maintain the patient's present level of care and must do this under difficult circumstances. Stabilization before transport is the key to this process.

Initial preparation for transport often begins when the referral caregivers recognize that the patient requires care beyond the capabilities of their center. Appropriate advice and suggestions from transport personnel or the receiving physician may allow much of the necessary preparation for transport to be accomplished before the team arrives.

When the transport team arrives, they should review the medical history, including all therapeutic maneuvers and interventions performed at the referring hospital. An immediate and thorough physical examination is mandatory. During the pretransport process, endotracheal tubes, chest tubes, intravenous and intra-arterial catheters, and other indwelling devices should be checked for proper placement and stability. When doubt exists, devices should be replaced or better secured.

After this initial assessment, the transport team, in concert with the medical command physician, should decide which, if any, further medical interventions are required before leaving the referring center. Such interventions are most appropriate when they may have a direct impact on patient outcome. For example, the child who may have meningitis should definitely receive antibiotics before transport, but a lumbar puncture may be deferred until he or she arrives at the receiving hospital. The appropriateness of interventions will, to some degree, be dictated by the distance to the receiving

hospital. For example, a child with a circumferential burn of an extremity may require a fasciotomy to prevent vascular compromise. If the receiving hospital is 15 minutes away, this procedure can be accomplished there. However, if the receiving hospital is 2 hours away, it may be better to have the procedure performed before departing from the referring center.

After the patient is optimally prepared for transport, he or she must then be moved from the referral facilities bed to the transport stretcher and then to the vehicle. Such movements represent great risk to the patient. If an intravenous (IV) catheter or an endotracheal tube is going to be displaced, it will likely be while the patient is being moved. This fact has several implications. First, patients should be subjected to the fewest transfers necessary to get them from the referring hospital to the bed they will occupy at the receiving hospital. Movement from the transport stretcher to a holding bed in the ED is often unnecessary and can be avoided with advanced planning. Second, extra vigilance should be used during patient transfer. Personnel should be assigned to secure lines and tubes, and the movement should be coordinated by a team leader. Precautions such as planned, temporary disconnection of the ventilator from the endotracheal tube may need to be considered during these moves. Finally, the patient should be reassessed immediately after each movement. The team must be ensured that the airway is stable and that potentially lifesaving tubes and lines have not become dislodged.

Monitoring is imperative during the transport process. Observation and palpation may be hindered by patient position relative to the caretaker within the vehicle. This may be especially evident in a small transport helicopter. Auscultation may also be impaired in a noisy transport environment. The air transport environment, especially in a rotor-wing or turbo prop aircraft, may be 50% louder than a comparable ground transport. Therefore, more reliance is placed on sophisticated monitoring tools, including cardiorespiratory, pulse oximetry, capnography, and gas delivery monitors with audible and visual alarms, as well as point-of-care laboratory testing. The transport team must ensure stability of the ABCs, and these monitoring tools help them accomplish this effectively.

ALTITUDE PHYSIOLOGY AND THE AIR MEDICAL ENVIRONMENT

When pediatric patients are transported by helicopter or fixed-wing aircraft, one must be cognitive of issues regarding altitude physiology. An increase in altitude brings with it a decrease in ambient oxygen as well as the potential for an increase in the size of air spaces. For most patients, however, these should be not major issues. For patients with severe hypoxia at sea level, diving injuries, or large, enclosed pockets of air, however, air transport can be dangerous.

Two gas laws are most important in the transport process. Boyle's law states that with a constant temperature, the volume of a gas varies inversely with the pressure ($P_1V_1 = P_2V_2$) (Fig. 7.9). As altitude increases, barometric pressure decreases; therefore, the volume of the gas increases. Dalton's law (the law of partial pressure) says that the partial pressure of a gas mixture is the sum of all the partial pressures of the gas within the mixture ($PT = P_1 + P_2 + P_3 . . .$) (Fig. 7.10). For example, the total pressure of air is 1. The partial pressure of nitrogen is 0.78, oxygen is 0.21, and other gases is 0.01. The partial pressure of oxygen will always be 21%. At higher altitudes, air becomes less dense and the partial pressure of oxygen, while still 21%, offers diminished oxygen availability.

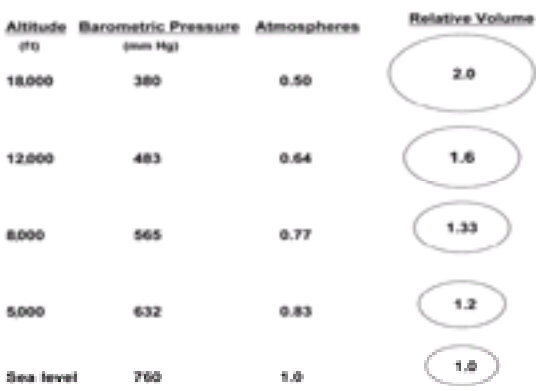

FIGURE 7.9. Boyle's Law ($P_1V_1 = P_2V_2$ or $P_1/P_2 = V_1V_2$). As altitude increases, barometric pressure decreases and volume of gas increases. The diagram illustrates enclosed gas expansion at specific altitudes. “Atmospheres” is comparison to the amount of pressure exerted by an overlying one square inch air column. At sea level, this equals 14.7 pounds per square inch (psi) and one-half that amount (7.35 psi) at 18,000 feet. (Used with permission. Woodward GA, Vernon DD. Pediatric and Neonatal Transport Medicine. Jaimovich DG and Vidyasagar D (eds). Philadelphia: Hanley & Belfus, Inc. page 40, 1995.)

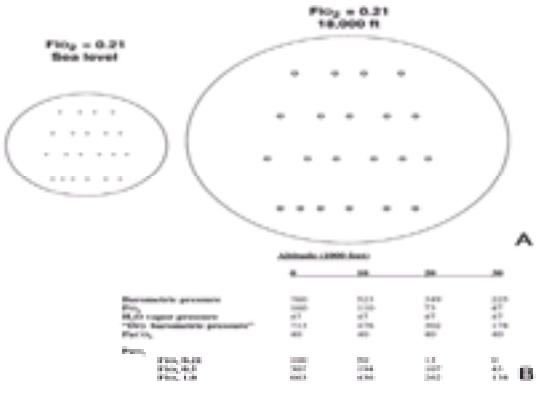

FIGURE 7.10. A. Dalton's Law (law of partial pressure): ($P_T = P_1 + P_2 + P_3...$). The total pressure of a gas is the sum of its component gases. The diagram illustrates that the percentages of air components (oxygen illustrated and represents

21% of air) at different altitudes does not change, although air is less dense at a higher altitude. **B.** The effects of altitude and decreased barometric pressure on oxygen availability. (Used with permission. Woodward GA, Vernon DD. Pediatric and Neonatal Transport Medicine. Jaimovich DG and Vidyasagar D (eds). Philadelphia: Hanley & Belfus, Inc. page 41, 1995.)

These issues can be important during the air medical transport. Entrapped air, if not vented, can be painful (middle ear sinus, teeth, bowel), annoying (flatus, belching), and dangerous (pneumothorax). Use of tight-fitting earplugs in flight can cause an artificial air pocket that may trigger the same problems. More significant air space issues include simple pneumothorax and pneumocephalus, which can become symptomatic at high altitudes. Patients with bowel obstructions may have increased gas volume leading to vomiting and potential aspiration. Air in military antishock trousers (MAST) may vary with altitude as will the air in pressure splints and blood pressure cuffs. Air in endotracheal tube cuffs and Foley catheters may also be affected and might need to be adjusted during flight. Patients with an air embolism from a diving injury or other cause are especially prone to gas volume–related issues during air transport. Hypoxia can be a major issue as well. This can usually be overcome with addition of 100% Fi O_2--unless the patient is already hypoxic at lower altitudes on 100% oxygen. Positive end-expiratory pressure is usually not effective in augmenting the hypoxemia that occurs secondary to an increase in altitude.

Most air transports, however, do not reach an altitude that will greatly influence the patient's care. Helicopter transport routinely occurs at 1000 feet or less above ground level, although this can be greatly altered in mountainous regions where traversing high-altitude peaks may be necessary. Fixed-wing transport aircraft are usually pressurized, meaning that they can simulate the atmospheric pressure of a lower environment. Air pressure in these aircraft is often set at a level of 5000 to 8000 feet, which can, however, still lead to a significant increase in gas volume. Opportunities for achieving higher ambient pressure (lower altitude pressure) may be available depending on the limitations of the particular aircraft. If an aircraft cannot be pressurized to a higher pressure, one can consider flying at a lower altitude. Tradeoffs include increased turbulence, speed restrictions, and fuel issues.

Other issues to be considered in air transport include vibration, turbulence, noise, humidity, temperature, air sickness, exhaust fumes, specific aircraft dangers, and gravitational forces. Helipad availability, landing zones, and other issues of aircraft accessibility must also be determined. Although these logistical issues are ultimately the responsibility of the air transport service and are usually predetermined for the interfacility transport, any additional information should be offered by the referral center personnel. One must be especially careful around running (hot) aircraft. The helicopter's tail rotor and plane's propellers are often invisible when turning but capable of inflicting severe damage upon those who venture too close. Loose clothing, medical equipment, and stretcher pads can become entangled in a helicopter's rotors, causing severe damage to the vehicle and to the passengers of the transport. In general, no one should approach an aircraft other than crew and specifically trained personnel.

SPECIFIC TRANSPORT ISSUES

Airway Management

Airway skills are of paramount importance for transport. There are several general principles of airway management for patients being transported that differ somewhat from those of patients in other clinical settings. First, when a patient being transported has the potential to have airway instability, elective intubation before transport should be considered. In an ED or ICU, similar patients might warrant observation; however, the potential difficulties with intubation in a transport vehicle make elective intubation before transport the more prudent option. This is not to say that the transport environment precludes successful airway intervention, only that the logistics and personnel available in a hospital setting may be more conducive to an efficient, successful procedure. This must be kept in mind when disagreements about airway management are encountered at the time of transfer. It is helpful for the transport personnel to recognize the referral physician's potential reluctance to perform an invasive procedure on a relatively stable patient, and the referral personnel should recognize the potential limitations of the transport environment. Inclusion of the medical command physician may be helpful if a stalemate regarding intervention is reached between the referring physician and the transport personnel. Addressing conflicting airway intervention issues by leaving the ED and “electively” intubating the patient in the ambulance is not an acceptable option. Second, transport teams must ensure that all artificial airways are well secured before transport. The team must be nearly fanatical about this issue. Loss of an airway is to be avoided at all costs. Third, as previously stated, the airway should be checked after each transfer of the patient from one stretcher or vehicle to another. Finally, intubated patients should have continuous end-tidal CO_2, as well as pulse oximetry and cardiorespiratory monitoring, during transport. These technologies allow rapid detection of displaced or ineffective tracheal tubes and are particularly important in aeromedical transport, where other methods of assessment, such as auscultation, are difficult to use.

Even under the best of circumstances, a tracheal tube may be lost during transport. When this occurs, the team members should first remember that their objective is to oxygenate and ventilate the patient. If this can be safely accomplished with a bag-valve-mask device, this type of ventilation should be used initially and perhaps continued for the remainder of the transport process. Reintubation, if necessary, should be performed by the most experienced team member. Each transport team should have at least one member skilled in airway management. Airway skills should not be limited to bag and mask ventilation and tracheal intubation. Transport team members should be prepared to perform needle or surgical cricothyroidotomy and/or retrograde intubation if necessary.

Status Epilepticus

The management of status epilepticus during transport differs little from its management in an ED. The initial approach is to address the ABCs. For most children, this involves provision of supplemental oxygen and appropriate positioning to

ensure a patent airway. Once these issues have been addressed, the team must treat the seizure itself. This activity is divided into two components that should be accomplished simultaneously. The team should attempt to identify immediately treatable causes for the seizures while concurrently preparing to administer anticonvulsant medications. Monitoring oxygen saturation and administering supplemental oxygen will identify and eliminate hypoxemia as a possible cause. Hypoglycemia may be identified by a simple finger-stick glucose. Newer modalities (e.g., handheld multichannel testing devices) can identify hyponatremia and other electrolyte disorders. If any of these causes are identified, appropriate treatment can be initiated.

In many cases, the patient will require anticonvulsant medications; the initial drug of choice is usually a benzodiazepine. In an ED, the usual agent chosen is lorazepam. However, lorazepam should be refrigerated, making it problematic for transport services. Alternatives to lorazepam include diazepam and midazolam. When possible, anticonvulsants should be given intravenously; however, if the patient does not have an IV line, he or she can be given rectal medication. Alternatively, midazolam and fosphenytoin may be given intramuscularly. Anticonvulsants may, of course, be given via the interosseous route. Finally, as a last resort, benzodiazepines may be given via a tracheal tube. If the initial dose of a benzodiazepine fails to stop the seizure within 10 minutes, the same dose may be repeated up to two more times. As more doses are given, the risk of respiratory depression increases, and the transport team should be prepared to support respiration.

If the patient continues to seize after a reasonable number of doses of a benzodiazepine, an alternative agent should be administered. Phenytoin, fosphenytoin, and phenobarbital are the second-line agents most often chosen. Phenytoin will not adversely affect the child's respiratory status and is an inexpensive and effective anticonvulsant. Unfortunately, phenytoin can be administered no faster than 1 mg/kg per minute without risk of bradycardia and is very toxic to tissues. If a child's IV line infiltrates while he or she is receiving phenytoin, a severe skin injury is likely to result. Like phenytoin, fosphenytoin will not contribute to respiratory depression. Fosphenytoin is not toxic to tissues and may be administered much faster than phenytoin. As noted, fosphenytoin may be safely given intramuscularly. It is, however, more expensive than phenytoin.

Phenobarbital will act synergistically with the benzodiazepines to cause severe respiratory depression. It also has cardiovascular depressant effects, making it a poor choice for children with hypovolemia, septic shock, and other forms of circulatory impairment. The use of phenobarbital will also likely depress the patient's mental status during the postictal period, making acute neurologic assessment more difficult. If this agent is chosen, the transport team should ensure that the patient has a large-bore IV line capable of supporting the circulation. Furthermore, elective intubation should be considered before initiating patient transport.

When both the first- and second-line agents have failed, the patient should undergo elective tracheal intubation and be placed on a continuous infusion of midazolam or pentobarbital. If these measures fail to control the seizures or cannot be initiated, the child should be given a nondepolarizing neuromuscular blocking agent and adequate sedation during transport. The purpose of neuromuscular blockade is protection of the patient and the team during transport. Neuromuscular blockade ensures adequate ventilation of the patient and prevents the patient from inadvertently harming himself or herself or a team member. It is particularly dangerous to attempt to transport a seizing patient by helicopter unless he or she is intubated, sedated, and paralyzed.

Active Cardiac Arrest

The reasons for transport should always be fully explored. Transport to avoid stopping a resuscitation when there is not an expected change in therapy is inappropriate. Transport teams may have different philosophies about response to calls for patients receiving active resuscitation. Many will not mobilize until the patient has been stabilized. Others will mobilize to offer assistance if needed or in anticipation of impending stabilization but will not transport the child unless he or she is stabilized. Still other teams may accept the patient for transport during resuscitation if there is a modality available at the receiving hospital that might make a difference, such as extracorporeal membrane oxygenation (ECMO). It is important to recognize that transfer of a patient with ongoing cardiopulmonary resuscitation (CPR) can be dangerous for the transport team because they must remain unsecured in the vehicle. It can also be difficult for families, who may expect that transfer suggests a positive resolution of the medical crisis, when it is clear to the medical personnel that the outcome will be poor. In general, transport of the patient with active CPR should be arranged—but not undertaken—until adequate stabilization has been achieved.

Shock

Transport of the hypotensive or hypovolemic patient must be anticipated. Care is similar to that performed in an ED, although the supplies and vascular access may be limited. Ensuring and securing initial and perhaps secondary IV access routes before transport is important. Almost all transported patients should have at least one patent IV line. Those with reliance on those lines should have backup lines in place.

Shock management is fundamentally the same in transport as it is in the hospital. Adequate volume status should be ensured and augmented with isotonic fluids, colloid, or blood products as indicated. Vasoactive drugs should available if required. Assessment should use all components of evaluation, including mental status, capillary refill, skin color, urine output, acid-base status, and vital signs. The transport team is responsible for assimilating and communicating all the care to date, so it is helpful to have a running total of all fluids and medications administered when the transport team arrives. This will help ensure adequate patient evaluation and continuation of appropriate care.

Trauma

Transport of the severely injured trauma patient is similar to the transport of the medical patients. If an urgent or potentially surgical lesion is present that cannot be adequately managed at the referral site, rapid transport is important. Adequate assessment and management of the patient during transport is imperative, and vigilance to the ABCs, including

cervical spine immobilization, is crucial. In general, clearing of the cervical spine should not be attempted by the transport team, but by the receiving service. Appropriate cervical immobilization of the patient should be maintained throughout the transfer process. Blood products should be available for the transport team if they might be needed during the transport. Inclusion of all patient radiographs and studies can help ensure a more efficient evaluation at the receiving center. Notification of the receiving hospital and service regarding transport of a trauma patient with a potential surgical lesion is important to allow for preparations to be made. A rapid transport with simultaneous preparation of an operating room can lead to improved outcomes for these patients.

Sedation

Many children will require sedation or analgesia during transport. These children can be can be divided into three general categories of patients. The first are the children who required analgesia or sedation at the referral hospital and most likely need to continue sedation medications during and after the transport. The postoperative patient, the child with sickle cell disease, and the patient with a femur fracture are examples. The second category involves children whose disease process and sedation requirements are evolving. This category might include the child who is intubated just before or during transport, the trauma patient who has deteriorated and requires insertion of a chest tube, or the patient whose mental status has improved enough to allow recognition of chest tube–related pain. The third category includes children for whom the transport process itself may sufficiently increase pain or anxiety enough to warrant additional analgesia or sedation. This group might include the child with a long-bone fracture or peritonitis who, while comfortable in a quiet, stationary hospital bed, experiences significant pain during the transport. Each time a patient is moved (e.g., hospital to ambulance, ambulance to helicopter, helicopter to plane) additional stress or pain can occur. In addition, the stress of a loud transport environment with accompanying vibration and temperature fluctuations can lead to reactive pathophysiologic changes. If necessary, the level of sedation and analgesia can be titrated in response to these environmental issues.

The stress of leaving family members and the concept of abandonment are potential issues for the child who needs interfacility transport. The transport team should be cognizant of nonpharmacologic pain and anxiety management options, including calming and distraction, positioning and immobilization, and play therapy. A parent, depending on his or her own level of anxiety, may be helpful in these situations. The parent may be of assistance with immobilization, calming, and distraction. The family should also be informed about transport and hospital expectations so that they can be of assistance in preparing the child for the ambulance journey as well as any procedures or diagnostic tests that will be performed at the receiving institution. Accompaniment of a family member during the transport can help the patient adjust to the new environment(s) and, perhaps, lessen the need for pharmacologic intervention.

Appropriate-sized airway equipment and resuscitation medications should be available for any patient receiving sedation or analgesia during transport. These medications should include reversal agents such as naloxone and flumazenil. Naloxone is a benign medication that has rapid and dramatic effects when administered to reverse the respiratory depressant actions of opiate overdose. The effects of naloxone, however, last only a short time, and the drug may need to be repeated during the transport. Titration of naloxone via infusion may be necessary for patients who are in severe pain yet experiencing respiratory compromise or loss of protective airway reflexes. This can be accomplished by placing 2 to 4 mg/kg of naloxone into 100 mL of saline and titrating to reverse the untoward effects while maintaining some pain relief. Naloxone can be useful for the patient who has received a large dose of fentanyl and is experiencing chest wall rigidity.

Flumazenil has been used to reverse adverse effects of therapeutic benzodiazepine administration. The recommended dose is 0.01 mg/kg, with a maximum initial dose of 0.2 mg. The drug may be repeated (0.005 mg/kg) every 1 minute to a total maximum dose of 1 mg. Because seizures are a potential side effect of flumazenil, it should not be used in patients who have ingested multiple medications or who have a propensity for seizures.

CHAPTER 8

Acute Myocardial Infarction

BARUCH S. KRAUSS, MD, EdM

Department of Pediatrics, Harvard Medical School, and Division of Emergency Medicine, Children's Hospital, Boston, Massachusetts

Although acute myocardial infarction (AMI) represents one of the most common diagnoses in adult emergency medicine, it is a rare event in the pediatric emergency department (ED). When it does occur, AMI is associated with a high morbidity and mortality if not recognized and treated. Five million patients with chest pain are seen in EDs in the United States each year. Of these patients, 1.5 million have an AMI, and approximately 450,000 die from the initial event. Almost half of these deaths occur in the prehospital setting. Early recognition and treatment are critical in lowering the morbidity and mortality associated with AMI. Pediatric EDs are not routinely set up to provide definitive treatment for patients with AMI. Therefore, pediatric emergency physicians must be prepared to recognize, acutely stabilize, and transfer the patient with an AMI. This chapter focuses on the recognition and initial stabilization of AMI in the pediatric ED.

HISTORICAL PERSPECTIVE

There have been two eras in the evolution of ED management of AMI: the prethrombolytic era (ending in the late 1970s) and the thrombolytic era (early 1980s to the present). In the prethrombolytic era, the mainstay of ED treatment of AMI was analgesics (morphine) and nitrates (nitroglycerin [NTG]). In the thrombolytic era, treatment focus shifted from antianginal treatment to clot lysis with an imperative to significantly reduce “door-to-drug” time.

The thrombolytic era has evolved in two phases: the intracoronary administration phase and the peripheral administration phase. In the early 1980s, multicenter clinical trials on the use of intracoronary thrombolytic agents demonstrated their ability to decrease morbidity and mortality associated with AMI by limiting infarct size through reperfusion of ischemic myocardium. During this period, patients with clinical criteria for AMI were taken to cardiac catheterization and given intracoronary streptokinase after demonstration of coronary occlusion by angiography. Once the benefits of thrombolytic therapy for AMI were clearly demonstrated, it was a relatively short time before large multicenter clinical trials showed that intravenous (IV) administration was as effective as intracoronary administration. In these studies, the patients who benefited most from thrombolytic therapy received treatment within 4 hours of onset of symptoms. Based on this data, a concerted effort was made to educate emergency physicians about the benefits of reducing door-to-needle time (time from presentation to the ED to the initiation of thrombolytic therapy). These studies lead to the current ED strategy for the management of AMI, which can be summarized as follows:

1. Early prehospital recognition of AMI (through sustained paramedic education and increasing availability of 12-lead electrocardiogram [ECG] in the prehospital setting)
2. National target to reduce door-to-needle time to 30 minutes or less
3. Peripheral thrombolytic administration in the ED
4. Enhanced cardiac specific serial markers for early detection of myocardial injury
5. ED 24-hour observation units and chest pain centers for management of patients with chest pain who are assessed to be at low risk for AMI (“soft rule-outs”)

PATHOPHYSIOLOGY

The pathophysiology of AMI evolves in three phases: progressive coronary artery narrowing from atherosclerotic plaque formation and deposition, acute reduction in coronary blood flow from platelet aggregation and subsequent thrombus

occlusion at the site of atherosclerotic narrowing, and myocardial injury.

The extent of damage to myocardial tissue from an acute reduction in coronary perfusion depends on multiple factors, including the extent of occlusion (partial or total), the location of the occlusion and the area of the myocardium supplied by the occluded vessel, the degree of existing collateral circulation around the occluded segment, and the myocardial oxygen demand at the time of occlusion (e.g., was the patient at rest or exercising at the time of occlusion).

CLINICAL MANIFESTATIONS

When the patient is suspected of having an AMI, a directed history and physical examination are essential in optimizing time to treatment and transfer. The key features of such an approach are discussed in the following sections and summarized in Table 8.1 and Table 8.2.

Presence of Pain Are you in pain right now?	
Time Frame When did the pain start?	
Activity Level What were you doing when the pain started? Did the pain occur at rest or with exertion?	
Pain Location Where is the pain?	
Pain Radiation Is the pain just in your chest or does it travel (to your shoulder, arm, neck, jaw, back)?	
Pain Characteristics What does the pain feel like (sharp, dull, heavy, crushing, squeezing, tight, crampy)?	
Associated Symptoms When the pain began, did you feel (sweaty, nauseous, short of breath, dizzy, weak)?	
Medical History Do you have any underlying medical problems? Have you ever had pain like this before? If yes, how many times and what was the frequency and pattern?	
Current Medications Do you take any medications regularly?	

Table 8.1. Acute Myocardial Infarction: Clinical History

Chest pain	Nausea/vomiting
Diaphoresis	Syncope or near-syncope
Pallor	Jaw pain or numbness
Anxiety	Neck pain
Confusion	Shoulder pain
Shortness of breath	Arm pain
Generalized weakness	Back pain

Table 8.2. Acute Myocardial Infarction: Initial Presentation

Presence of Acute Pain

Although acute chest pain is the most common presenting symptom in AMI, it may be atypical or absent. Classic chest pain associated with AMI is substernal or in the left side of the chest. Atypical chest pain may be in the right side of the chest, shoulder, upper arm, jaw, neck, or back. AMI without chest pain may occur in selected patient populations, including those who are elderly, diabetic, and hypertensive.

Time Frame

The time frame, from onset of pain to presentation in ED, in the patient with suspected AMI is a critical determinant of whether the patient is a thrombolytic candidate. A narrow window, of approximately 12 hours from onset of symptoms, exists during which patients have been shown to benefit from thrombolytic therapy. Furthermore, patients who receive thrombolysis within 4 hours of onset of symptoms have better outcomes in terms of myocardial salvage and reduced mortality than those patients who receive thrombolysis between 4 and 12 hours after onset of symptoms.

Activity Level

Pain may begin at rest or with exertion. Unlike angina pectoris, the exertional pain of AMI is usually not relieved by rest.

Location of the Pain

Substernal chest pain is the most common location of AMI pain. Atypical pain associated with AMI may occur only in the right side of the chest, one or both shoulders, one or both upper arms and/or elbows, the neck or jaw, the back (especially between the scapula), and even as a tight band around the upper abdomen. Periumbilical and lower abdominal pain are not usually associated with AMI.

Radiation of Pain

Radiation of the pain of AMI to the shoulder, neck, jaw, and back is common, and the patient should be specifically asked about pain radiating to any of these locations. Arm heaviness, weakness, or paresthesias are symptoms commonly associated with AMI.

Characteristics of the Pain

Numerous terms are used to describe and characterize the sensation of AMI pain (e.g., sharp, dull, heavy, crushing, squeezing, tight). It is important to find the appropriate metaphor or metaphors that fit with what the patient is experiencing. A patient may say that his or her chest or arm is sore, heavy, numb, or tight but deny having “pain.”

Associated Symptoms

Diaphoresis, nausea/vomiting, dizziness/light-headedness, dyspnea/shortness of breath, and fatigue/generalized weakness are all classically associated with AMI. Particularly worrisome symptoms include the following:

- Significant diaphoresis: This can range from the patient with cool and clammy skin to the patient literally drenched in sweat.
- Pallor: This is often described as an ashen appearance.
- Marked anxiety and restlessness: Some patients who are acutely infarcting may experience profound anxiety and even a premonition of doom.
- Dyspnea: This may herald the initial presentation AMI in the elderly as acute left ventricular failure. *Shortness of breath without chest pain may be the sole presentation of AMI in the elderly or diabetic patient.*
- Chest pain is preceded by syncope or near-syncope.
- Profound generalized weakness: Patients with AMI commonly report feeling as if all the energy had been suddenly drained from their body.
- Acute confusion or change in mental status: A spectrum from mild dizziness and light-headedness to confusion and disorientation is seen.
- Palpitations are present in the setting of chest pain.

Medical History

Establishing whether patients have had previous episodes of chest pain is useful in determining whether they are having a typical bout of angina (stable angina) or whether the pattern suggests a worsening from their baseline (unstable angina). Stable angina is characterized by a typical pattern of pain (e.g., one to two times per week with exertion, relieved by rest or a single dose of NTG). Unstable angina is defined as a worsening or escalating pattern from baseline (initially one to two times per week with exertion, relieved by rest or a single dose of NTG, now once a day with exertion relieved only by multiple doses of NTG or baseline chest pain with exertion now occurring at rest with increased frequency).

In addition, questions about smoking, family history of heart disease, other relevant medical history (Table 8.3), cholesterol level, diabetes, and hypertension, are helpful in assessing the patient's risk for coronary artery disease.

Congenital	Acquired
Antithrombin III deficiency	Patient's family history
Familial combined hyperlipidemia	Drug abuse (cocaine and amphet-amines)
Familial hypercholesterolemia	
Anomalies of the coronary arteries	Kawasaki disease
Homocystinuria	Transposition repair with coronary artery switch
Williams syndrome	

Table 8.3. Pediatric Populations at Risk for Acute Myocardial Infarction

Current Medications

Medications that may provide information about a patient's coronary risk include antihypertensive agents, cholesterol-lowering agents, and antianginal drugs (calcium channel blockers, nitrates, b-blockers).

Physical Examination

Because arrhythmias and heart failure are the most common complications of AMI, the physical examination should be focused on identifying the manifestations of these states (rhythm disturbances with or without hypotension, left ventricular failure with pulmonary edema or hypotension). Signs of hypoperfusion include diaphoresis, cool extremities, and confusion, and in the setting of persistent chest pain, these signs often herald the onset of cardiogenic shock. Rales, increased jugular venous distension (especially with right ventricular infarction and right-sided failure), hepatomegaly, and pitting ankle edema often indicate volume overload in the setting of singular or biventricular failure. An extra heart sound, either an S_4 (reflecting decreased left ventricular compliance) or an S_3 gallop (indicating heart failure), may be

heard.

In the uncomplicated AMI, tachycardia and elevated systolic blood pressure are usually present. A new murmur, particularly a new systolic murmur, is of special concern because it may signify acute mitral regurgitation and papillary muscle dysfunction or ventricular septal rupture.

The location of the ischemic myocardial segment often determines the presenting signs. Inferior infarction, affecting the right coronary and nodal arteries, may cause hypotension and bradycardia secondary to localized ischemia and enhanced parasympathetic discharge. Anterior infarction, affecting the left coronary artery and sympathetic system, may lead to the opposite signs (tachycardia and/or hypertension).

Vital Signs and ECG

The initial vital signs and ECG should be scrutinized carefully for rhythm disturbances (tachycardia and tachyarrhythmias, as well as bradycardia and bradyarrhythmias), conduction abnormalities (atrioventricular blocks and new bundle branch blocks), variations in blood pressure, changes in respiratory rate, and hypoxia.

Acute ischemic changes on the initial ECG are present in only 40 to 65% of patients with AMI. Therefore, repeat or serial ECGs should be considered in patients with symptoms suggestive of AMI with an initial normal ECG. The following information should be obtained from the ECG:

- *Rate*
  Sinus tachycardia without acute changes can indicate early ischemia before the presence of ST- or T-wave changes
- *Rhythm*
  Presence of arrhythmias
- *Intervals*
  Short P-R interval indicative of preexcitation syndromes
  Prolonged P-R interval indicative of atrioventricular block
  Widened QRS indicative of bundle branch block
- *Ischemic changes* (Table 8.4 and Fig. 8.1, Fig. 8.2, Fig. 8.3 and Fig. 8.4)
  Hyperacute T waves in the anterior and/or septal leads (early sign of anterior ischemia)
  Flipped or inverted T waves
  ST-segment elevation or depression
  Location of ischemic segment

Injury Location	ECG Leads	Coronary Artery	ECG
Anterior/ anteroseptal	V_1-V_4	LAD	Figs. 8.1, 8.2
Inferior	2, 3, and aVF	RCA	Fig. 8.3
Lateral	1, aVL, V_5, and V_6	LAD, circumflex artery	Fig. 8.4

LAD, left anterior descending; RCA, right coronary artery.

MANAGEMENT

The management of AMI in the pediatric ED consists of four sequential phases: early recognition of the clinical manifestations of AMI, acute stabilization, preparation for transfer, and transport.

Early Recognition

The strategy for managing patients with chest pain in the pediatric ED begins with the following steps: rapid recognition of the clinical manifestations of AMI, setting appropriate priorities, and mobilization of resources. The primary goal in managing AMI patients in the pediatric ED is acute stabilization followed by rapid transfer to the appropriate facility, whether intrahospital or interhospital, where definitive care can be provided. Management priorities should reflect this goal and time should not be wasted with unnecessary diagnostic tests or procedures that result in delay in transfer and delivery of definitive care. Resources (whether personnel, equipment, or information) from the treating facility, the receiving facility, and the prehospital system should be mobilized as soon as an AMI is recognized. Acute stabilization and treatment should be urgently initiated once the preliminary diagnosis of AMI has been made.

Acute Stabilization

The goals of acute stabilization are to decrease myocardial oxygen consumption, decrease preload, reduce afterload, and identify and treat complications.

During acute ischemia, oxygen supply to myocardial tissue is significantly compromised. Catecholamine activity increases secondary to pain and heightened anxiety. The catecholamine response further drives myocardial oxygen

consumption, which increases the rate of ischemia, creating a vicious circle. Decreasing myocardial oxygen consumption can reduce the extent of infarction. Initial treatment is therefore directed at relieving pain and anxiety and decreasing catecholamine response. Morphine sulfate (2 mg IV) and NTG (0.4 mg sublingual) are the first-line antianginal agents.

The main actions of NTG are venodilation (increased venous capacitance, leading to decreased venous return and a reduction in preload), coronary artery and collateral vessel dilation (with resultant increase in myocardial oxygen supply), and afterload reduction. A reflex tachycardia is commonly seen with NTG secondary to its potent vasodilatory properties. It is available in topical (ointment), oral, transmucosal (sublingual pills or spray), and IV formulations. In the ED treatment of AMI, the transmucosal and IV routes are the most useful. The transmucosal route provides rapid onset in 2 to 3 minutes. Expiration dates should always be checked because NTG has a relatively short shelf life. Patients usually experience a pounding sensation in the head or headache with the onset of NTG. If the patient reports no effects as described from NTG within 5 minutes, a different bottle of pills should be tried.

Topical NTG should never be used to treat acute chest pain. Its use should be restricted to maintenance therapy. Once the patient is pain free, 1 to 2 inches of NTG ointment can be applied for a sustained nitrate effect.

Morphine is an opioid that acts as a venous and arterial vasodilator, providing reduction in both preload and afterload as well as exerting a vagotonic effect resulting in a decrease in heart rate and myocardial oxygen consumption. Both NTG and morphine can cause significant vasodilation and hypotension, especially in patients with inferior wall or right ventricular infarctions, and must be used carefully. The simultaneous use of NTG and morphine should be avoided because severe hypotension may occur with a resultant increase in myocardial oxygen consumption and worsening ischemia.

Management of the uncomplicated AMI (Fig. 8.5) begins by placing the patient on a cardiac monitor, starting oxygen by nasal cannula at 2 to 4 L/minute, obtaining baseline vital signs including oxygen saturation, and securing peripheral IV access. A 12- to 15-lead ECG should then be obtained and a portable chest radiograph ordered (as long as the chest radiograph does not delay treatment). Treatment should then be initiated with chewable aspirin (160 mg) followed by NTG 0.4 mg (or $^{1}/_{150}$ grain) sublingual every 5 minutes times three or until symptoms subside. If the patient is symptom free after one to three doses of NTG, 1 to 2 inches of NTG ointment are applied and the ECG is repeated. This patient is now stabilized and ready for transfer.

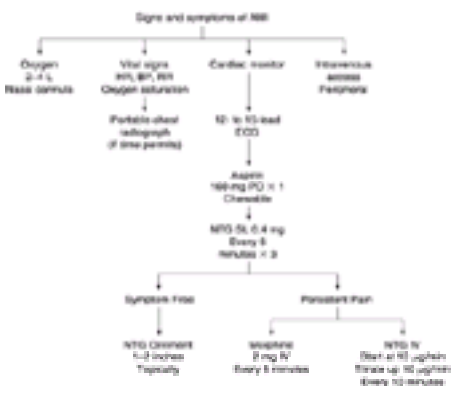

FIGURE 8.5. Treatment of uncomplicated AMI.

If the patient is not symptom free after the third NTG, two treatment options are available: morphine 2 mg IV every 5 minutes until pain subsides or NTG IV starting at 10 µg/minute and titrating upward in increments of 10 µg/minute every 10 minutes until symptoms subside. The patient whose pain or symptoms are not relieved with three sublingual NTG and who has been started on morphine or IV NTG is unstable but suitable for transfer as long as there are no active signs of heart failure or unstable cardiac rhythm or conduction disturbances (which if present, should be addressed before transfer).

Once the patient with an uncomplicated AMI is acutely stabilized, continued monitoring is essential to identify and rapidly treat emerging complications. Heart failure, cardiac arrhythmias, and conduction abnormalities can occur at any time during the course of an AMI. Patients with an uncomplicated initial course may go on to deteriorate into an unstable AMI. Figure 8.6, Figure 8.7, Figure 8.8, Figure 8.9 and Figure 8.10 illustrate the common complications of AMI and their treatment.

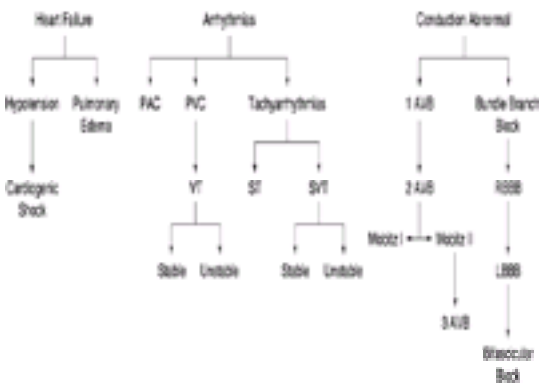

FIGURE 8.6. Complications of AMI. *1 AVB,* first-degree atrioventricular block; *2 AVB,* second-degree atrioventricular block; *3 AVB,* third-degree atrioventricular block; *PAC,* premature atrial contraction; *PVC,* premature ventricular

contraction; *ST,* sinus tachycardia; *SVT,* supraventricular tachycardia.

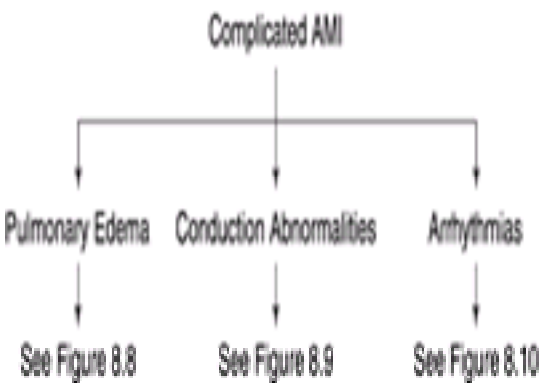

FIGURE 8.7. Treatment of complicated AMI.

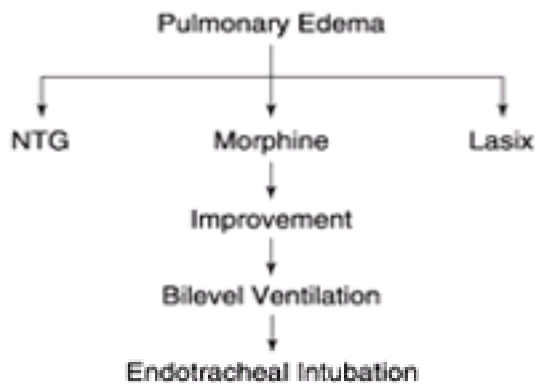

FIGURE 8.8. Pulmonary edema.

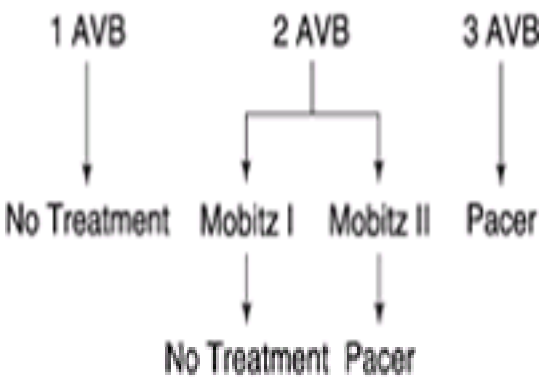

FIGURE 8.9. Conduction abnormalities. *1 AVB,* first-degree atrioventricular block; *2 AVB,* second-degree atrioventricular block; *3 AVB,* third-degree atrioventricular block.

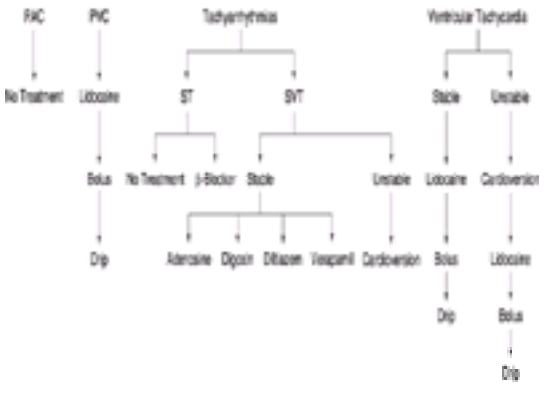

FIGURE 8.10. Arrhythmias. *PAC,* premature atrial contraction; *PVC,* premature ventricular contraction; *ST,* sinus tachycardia; *SVT,* supraventricular tachycardia.

A complicated AMI is defined, for our purposes, as AMI symptoms with heart failure and/or rhythm or conduction abnormalities. The initial management of these patients has a dual focus: global antianginal therapy and specific treatment of complications. The primary antianginal agents (NTG and morphine) can be used for global treatment of ischemia and for specific treatment of certain complications (e.g., pulmonary edema). In this case, the preload reduction

provided by NTG and/or morphine is useful to treat both ischemia and pulmonary edema.

Preparation for Transfer

While acute stabilization is under way, preparation for transfer should begin (Table 8.5). The nature and extent of the preparation depends on whether the transfer is interhospital (i.e., treating facility is not set up to provide definitive care) or intrahospital (intensive care unit, cardiac catheterization laboratory, angioplasty suite, operating room for bypass). If the transfer is interhospital, it is imperative that the treating physician alert the receiving facility that the patient is having an AMI so that the appropriate resources can be mobilized in advance of the patient's arrival. The patient's condition (stable or unstable) and whether he or she is a thrombolytic candidate (Table 8.6 and Table 8.7) must also be relayed to the receiving facility.

1. Begin arranging transfer as soon as AMI is recognized.
2. Determine mode of transport.
   - Intrahospital
   - Air
   - Ground
   - BLS with or without physician
   - ALS
3. Contact transport personnel.
4. Notify receiving facility

Table 8.5. Protocol for Transferring Patients with Acute Myocardial Infarction

1. Symptoms of AMI for at least 30 minutes and less than 12 hours
2. New ECG changes (any of the following):
   - ST elevations >1 mm in two of the anterior, inferior, or lateral leads
   - ST depressions in the anterior leads
   - New LBBB
3. No absolute contraindcations (see Table 8.7)

LBBB, left bundle branch block.

Table 8.6. Thrombolytic Therapy Candidates

Absolute	Relative
Active PUD	HTN (systolic >180 and/or diastolic >100)
Surgery or invasive procedure within 2 weeks	Brief CPR (<10 min)
Prolonged CPR (>10 min)	Chronic anticoagulation therapy
CVA within 1 year	Severe hepatic or renal disease
Suspected aortic dissection	
Gastrointestinal or genitourinary bleeding within 10 days	
Recent major trauma	

PUD, peptic ulcer disease; *CVA*, cerebrovascular accident; *CPR*, cardiopulmonary resuscitation; *BP*, blood pressure; *HTN*, hypertension.

Table 8.7. Contraindications to Thrombolytic Therapy

Transport

The treating physician in the pediatric ED must determine the appropriate mode of transport once the patient is acutely stabilized. The appropriate mode of transport will depend on the location and type of the treating facility (general or community ED, pediatric ED contiguous to adult ED, free-standing pediatric ED), the proximity of the treating facility to a facility with thrombolytic capability, and the length of transport. Transport options include ground versus air, advanced life support (ALS) transport with paramedics versus basic life support (BLS) transport with or without treating facility personnel accompanying the transport.

CHAPTER 9

Abdominal Distension

JOSEPH E. SIMON, MD

Care Delivery, Scottish Rite Children's Medical Center, Atlanta, Georgia

For this discussion, *abdominal distension* is defined as an increase in the volume of the abdominal cavity. Apparent abdominal distension secondary to poor posture, the natural lordosis of childhood, abdominal wall weakness, obesity, and pulmonary hyperinflation is easily mistaken for true abdominal distension. Examination of the patient in both the supine and upright positions assists the clinician in recognizing these factors before diagnoses that truly increase the volume of the abdominal cavity are considered.

Abdominal distension is a nonspecific sign. That is, the causes of abdominal distension are numerous (Table 9.1). Even when the discussion is limited to emergent and urgent causes of abdominal distension, as is the case for this chapter, the list is long. When confronted with a patient with abdominal distension, one approach is to divide the causes into the following generic categories: distended bowel, free air, extraluminal fluid, massive hepatomegaly, massive splenomegaly, and other causes. This categorization is more easily described on paper than discerned at the bedside. A large cystic mass is easily mistaken for ascitic fluid. A Wilms' tumor may examine much like splenomegaly. Another difficulty in the clinical application of this categorization is that many pathologic processes that lead to abdominal distension do so through several of the previously mentioned categories. For example, kwashiorkor causes abdominal distension secondary to hepatosplenomegaly and ascites. For these reasons, the reader is urged to regard this initial categorization, when used at the bedside, as tentative, pending confirmation from plain radiograph, ultrasound, computed tomography (CT), or other imaging studies.

Table 9.1. Differential Diagnosis of Abdominal Distension

DIFFERENTIAL DIAGNOSIS

Bowel distension occurs secondary to mechanical or functional intestinal obstruction, aerophagia, malabsorption, or obstipation (Table 9.2). Mechanical obstruction most commonly occurs in infants secondary to congenital malformations (atresias, volvulus, incarcerated hernia) and intussusception and in all ages secondary to previous abdominal surgery with resulting adhesions (see Chapter 118). The lack of air in the rectum and sigmoid colon on a prone cross-table lateral of the abdomen supports the diagnosis of mechanical obstruction. Functional obstruction, or ileus, is suggested by tympanitic distension in the absence of bowel sounds. It may occur secondary to numerous causes. Some of the more important causes are described briefly (Table 9.3). Peritoneal irritation secondary to infection, pancreatic enzymes, bile, or blood is suggested by signs such as involuntary guarding and pain with movement. Fever without peritoneal signs suggests intestinal inflammation, systemic infection, or anticholinergic poisoning (see Chapter 84 and Chapter 88). Various poisonings (atroponics), toxins (botulism), and electrolyte disturbances (hypokalemia) may result in an ileus. These will most likely occur in the patient who has no abdominal findings other than tympanitic distension. In particular, the abdomen will be nontender. Finally, posttraumatic gastric distension is an extremely important entity that may result in significant respiratory embarrassment secondary to upward pressure on the diaphragm. It probably is secondary to a combination of aerophagia and ileus.

Aerophagia (crying, feeding)	Pneumonia/sepsis
Gastroenteritis	Peritonitis
Obstipation	Intra-abdominal bleeding
Pregnancy	Hemolytic disease
Traumatic ileus	Congestive heart failure
Intestinal obstruction (mechanical)	Hepatitis
Obstructive uropathy (infants)	

[a] Listed in approximate order of frequency

Table 9.2. Common Causes of Abdominal Distension[a]

Infectious	*Other*
Peritonitis	Intestinal obstruction (mechanical)
Sepsis/pneumonia	Electrolyte abnormality
Botulism	Renal failure
Pancreatitis	Poisoning
Congenital syphilis	Necrotizing enterocolitis
Hepatitis	Intestinal perforation
Tuberculosis	Shock
Congenital	Budd-Chiari syndrome
Tyrosinemia	Congestive heart failure
Galactosemia	Pericarditis
Hemolytic disease	Portal hypertension
Traumatic	Acquired immunodeficiency
Intra-abdominal bleeding	syndrome
Neoplastic	
Leukemia and other malignancies	

Table 9.3. Life-Threatening Causes of Abdominal Distension

Bulky, foul-smelling, or diarrheal stools suggest malabsorption secondary to many causes: formula enteropathies, bacterial overgrowth, parasites, cystic fibrosis, and celiac disease (see Chapter 84 and Chapter 93). Obstipation is a common cause of abdominal distension. The patient usually has a history of irregular stooling or chronic constipation. This may represent a severe functional disturbance or reflect many pathologic processes, including Hirschsprung's disease and other defects in bowel enervation and hypothyroidism.

Free peritoneal air results from intestinal perforation secondary to trauma or inflammation. It is demonstrated with an upright or cross-table lateral radiograph of the abdomen. The child will be toxic, and peritoneal signs will be present. An ileus generally contributes to the abdominal distension.

Extraluminal fluid accumulates in the abdominal cavity because of a decreased serum albumin, inflammation, bleeding, intraperitoneal chyle, and/or increased venous and lymphatic resistance through the portal and hepatic veins. A low serum albumin level is suggested by peripheral edema and pleural effusion (see Chapter 22). It occurs as a result of protein loss secondary to nephrotic syndrome or protein-losing enteropathy, or decreased protein synthesis like that which occurs in cirrhosis and malnutrition. Obstruction of blood flow through the liver is suggested by distended abdominal wall veins, a history of hemoptysis, and an enlarged spleen. The obstruction may occur at the prehepatic level (portal venous thrombosis), within the liver parenchyma (end-stage cirrhosis), at the hepatic veins (Budd-Chiari syndrome), or at the intrathoracic level (congestive heart failure [CHF], pericarditis). Obstruction at the portahepatis usually is idiopathic, although a history of umbilical venous catheterization or omphalitis in the newborn period should suggest this possibility. Obstruction at this level generally does not cause marked ascites. Although cirrhosis evolves gradually, its clinical presentation may be abrupt. It results from Wilson's disease, a $_1$-antitrypsin disease, biliary atresia, and other congenital problems, or occasionally, from chronic active hepatitis. Decreased clotting factors would be among the many laboratory findings of cirrhosis. Obstruction of flow at the hepatic veins or above occurs as a result of Budd-Chiari syndrome, CHF, or constrictive pericarditis (see Chapter 82). The liver is engorged, resulting in hepatomegaly and right upper quadrant tenderness in each of these entities.

A history of recent trauma and signs of shock point to intraperitoneal bleeding, usually secondary to a splenic or hepatic laceration. An ileus secondary to both peritoneal inflammation and shock likely contributes to the abdominal distension. Trauma in the recent past suggests chylous ascites. Finally, a diffusely tender abdomen suggests infectious peritonitis, pancreatitis, or bile peritonitis.

Extreme hepatomegaly that develops acutely occurs secondary to inflammation, engorgement, or trauma (see Chapter 93). There will be marked right upper quadrant tenderness and generally systemic toxicity. Causes include hepatitis, CHF, constrictive pericarditis, and congenital enzyme deficiencies. Other causes of extreme hepatomegaly include neoplastic disease, storage diseases, and congenital hemolytic anemias. Generally, hepatomegaly develops gradually in these conditions and is accompanied by many other signs of chronic illness. If neoplastic disease is suspected because of suspicious lymphadenopathy or other masses or if trauma is a consideration, an abdominal tomographic scan should be considered.

Extreme splenomegaly without marked hepatomegaly in the toxic-appearing child suggests intraparenchymal bleeding with an intact capsule, sickle cell sequestration crisis, or malaria (see Chapter 84 and Chapter 87). In the nontoxic child, portal hypertension, neoplastic disease, and chronic hemolysis should be suspected. Neoplastic disease often results in

a spleen with an irregular surface. Abdominal CT scan again is useful in identifying this possibility. Chronic hemolysis secondary to sickle cell disease, b-thalassemia, and hereditary spherocytosis may result in a very large spleen. In the case of hemoglobin SS disease, but not hemoglobin SC disease or sickle-thalassemia, splenic enlargement is followed by splenic atrophy beyond 5 years of age. A peripheral blood smear generally identifies this group of causes of massive splenomegaly (see Chapter 87).

Other causes of abdominal distension include cysts, tumors, uterine enlargement, obstructive uropathy, bowel duplication, and inflammation. Cystic lesions include ovarian cysts; mesenteric, omental, or peritoneal cysts; choledochal cysts; and polycystic kidneys. These conditions generally present with a subacute history and physical examination. The exception is torsion of the large ovarian cyst, which produces vomiting and marked abdominal pain. Abdominal ultrasound generally identifies intra-abdominal cysts readily. Of course, an abdominal CT scan also is diagnostic. Obstructive uropathy is probably the most common cause of abdominal distension in early infancy. Although often normal, an abnormal urinalysis or blood urea nitrogen (BUN):creatinine ratio would add support to the diagnosis of obstructive uropathy. Tumors such as Wilms' tumor, an ovarian tumor, and a teratoma generally can be palpated easily as firm, discrete abdominal masses by the time they are causing frank abdominal distension (see Chapter 100). Bowel duplication can be a subtle diagnosis until a complication such as mechanical bowel obstruction or hematochezia develops. A contrast CT scan of the abdomen, however, generally confirms this diagnosis once suspected. Regional enteritis with sufficient inflammatory mass to cause abdominal distension is preceded by a long history of obstructive and malabsorptive symptoms. Acute phase reactants such as the sedimentation rate are likely to be abnormal in regional enteritis. Finally, a midline pelvic mass should suggest pregnancy or hematocolpos.

EVALUATION AND DECISION

History

The history should attempt first to differentiate acute from chronic symptomatology, focusing on rate of progression, recent trauma, weight loss, or weight gain. Next, systemic signs such as fever, anorexia, edema, and lethargy further define the acuteness of the problem and, to some degree, narrow the diagnostic possibilities. One must always be on the alert, however, for an acute complication superimposed on a more subtle chronic condition. Next, symptoms relative to specific organs, including the gastrointestinal (GI), renal, cardiac, and gynecologic systems, should be pursued. These symptoms include vomiting (bilious or nonbilious), abdominal pain, stool history, shortness of breath, cough, hemoptysis, urine output (including strength of stream and any abnormality of urinary color or foamy urine), and menstrual history. Finally, a family history of anemia, early infant death among relatives or metabolic disease, a travel history, and a careful newborn history may be revealing.

Physical Examination

After ruling out life-threatening respiratory embarrassment and shock, the physical examination should focus on determining whether the generic cause of the abdominal distension is bowel (air or stool) (Fig. 9.1), free fluid (Fig. 9.2), massive hepatomegaly (Fig. 9.3), massive splenomegaly (Fig. 9.4), inspissated stool, or a discrete mass (Fig. 9.5). A tympanitic abdomen with intestinal outlines on the anterior abdominal wall suggests bowel distension as the cause of the abdominal enlargement. Tympani in a toxic child without intestinal outlines suggest free air. A fluid wave and dullness suggest ascites. Palpable loops of bowel or a palpable descending colon suggests stool. Massive hepatomegaly and splenomegaly generally are defined easily by palpation. The examiner must be cautious, however, because other masses may mimic hepatomegaly and, in particular, splenomegaly. Other key physical findings include signs of CHF, abdominal tenderness, edema, signs of trauma or easy bruising, lymphadenopathy, pallor, and jaundice. A rectal examination for a mass, tenderness, and the presence or absence of stool is also helpful. More specific findings may be pursued once an initial hypothesis is made based on the algorithms in this chapter.

FIGURE 9.1. Bowel distension.

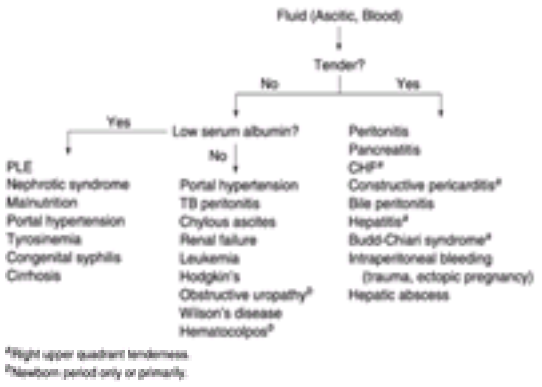

FIGURE 9.2. Fluid (ascitic, blood).

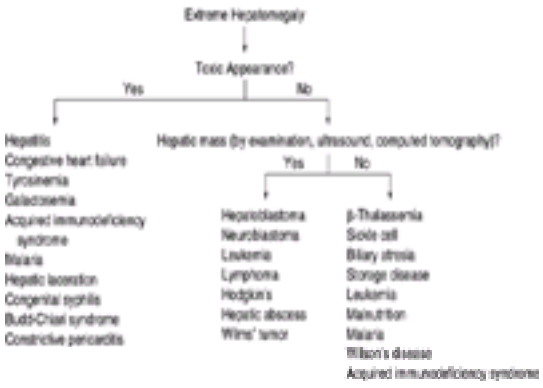

FIGURE 9.3. Extreme hepatomegaly.

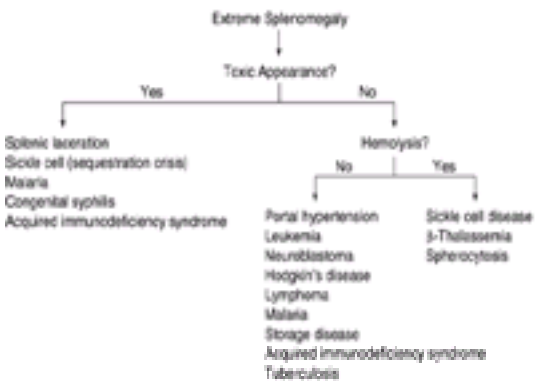

FIGURE 9.4. Extreme splenomegaly.

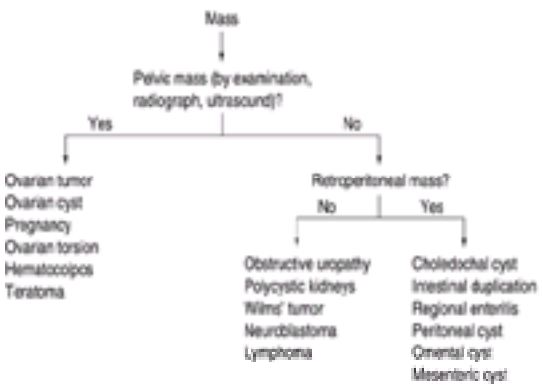

FIGURE 9.5. Mass.

Laboratory

The initial laboratory evaluation of abdominal distension is determined by the clinical findings and may include complete blood count with smear, erythrocyte sedimentation rate, reticulocyte count; liver function tests, including serum albumin and clotting studies; electrolytes with BUN, creatinine, and amylase; a urinalysis with reducing substances; and a chest radiograph and a two-view abdomen plain radiograph. If intestinal obstruction is suspected, one of the plain radiographs should be a prone cross-table lateral to determine the presence or absence of air in the rectum and sigmoid colon. It is preferable that this study be performed before a rectal examination is done.

Often, after the initial history, physical examination and laboratory evaluation imaging studies will be necessary. Ultrasound, if available, is an excellent first step because it does not involve radiation and often produces a definitive

answer. If intestinal obstruction is suspected, an upper GI series is the preferred study (or an air-contrast or barium enema if intussusception is suspected). An abdominal CT scan is the preferred study to evaluate abdominal distension thought to be secondary to trauma.

Management

Abdominal distension by itself may represent a medical emergency. First, this occurs when the distension is so severe that diaphragmatic excursion is compromised. For example, gastric and bowel distension secondary to aerophagia and ileus posttrauma may significantly impair a child's respiratory status. Massive ascites and free peritoneal air also may compromise respiration. Therefore, the first step in management is to assess and stabilize the child's respiratory status, including positive-pressure ventilation or emergent relief of distension or both. Passage of a nasogastric or orogastric tube may result in dramatic improvement in the child's respiratory status.

The second, far less common, situation in which abdominal distension may represent an emergent situation in itself is compression of the inferior vena cava (IVC), resulting in a compromised cardiovascular status. For example, occasionally, a child with severe obstipation may present with weak pulses and cool extremities. In this situation, a fluid bolus plus disimpaction will improve the patient's perfusion status rapidly. Managing the child in the lateral decubitus position may relieve pressure on the IVC. When the airway, breathing, and circulation have been stabilized, the diagnostic evaluation can proceed with laboratory and imagining studies as discussed previously.

CHAPTER 10

Apnea

SUSAN B. TORREY, MD

Department of Pediatrics, Harvard Medical School, and Division of Emergency Medicine, Children's Hospital, Boston, Massachusetts

Apnea is the final manifestation of many pathophysiologic processes seen among patients of all ages, but neonates and infants can experience apneic episodes in response to a variety of physiologic and pathophysiologic processes not seen in later life. Differences in maturity of the central nervous system (CNS), respiratory reserve, and susceptibility to infectious agents are among the factors that interact to make the very young patient unique. The causes of apnea in older children are similar to those in adults although the susceptibility and reserve of the child, again, are different. In this chapter, the neonate and young infant are emphasized, but for completeness, the older child also is considered.

Apnea is defined as a respiratory pause of greater than 15 seconds or of any duration if there is associated pallor or cyanosis and/or bradycardia. Apnea must be distinguished from periodic breathing, which is a common respiratory pattern in young infants and is characterized by cycles of short respiratory pause followed by an increase in respiratory rate. Normal newborn infants display respiratory patterns that vary by sex and by conceptual age as well as by sleep state. Premature infants have more apneic episodes, defined for research purposes as respiratory pauses of greater than 2 seconds, than term infants. Normal-term infants experience significantly more episodes of nonperiodic apnea during active sleep than during quiet sleep, although respiratory failure occurs more often during quiet sleep. Severe apnea may be accompanied by change in color, muscle tone, or mental status, or by choking. Such an episode is described as an acute life-threatening event (ALTE).

PATHOPHYSIOLOGY

Respiration is controlled through respiratory centers in the pons and medulla. The output from these centers to the upper airway and bellows apparatus through the vagus, phrenic, and intercostal nerves is modulated by peripheral and cortical factors. The response of the neonate and young infant to these influences differs from that of the older child, thus accounting, in part, for the vulnerability of these small patients. Specifically, the adult response to hypoxemia is to increase respiratory rate in proportion to the decrease in oxygen partial pressure (P_{O_2}). This tachypnea is maintained for the duration of the hypoxic stimulus. In contrast, the neonate demonstrates a brief increase in respiratory rate followed by depression of respiratory drive and, often, apnea. During sleep, infants who are mildly hypoxic tend to breathe periodically or develop apneic spells. Furthermore, hypoxemia during sleep may not cause arousal. Hypoxemia also results in less of a response to arterial carbon dioxide tension ($PaCO_2$) and further depression of respiratory drive with worsening hypoxemia.

Feeding affects ventilation in young infants. Poor coordination of sucking and breathing can result in hypoxemia, apnea, and bradycardia. Babies also become more vulnerable during sleep, when oxygen tension falls. In fact, it has been shown that regurgitation while hypoxemic, either from feeding or during sleep, produces profound apnea and bradycardia as a result of an accentuated laryngochemoreflex. Finally, some infants who have experienced an ALTE have increased levels of b endorphin in their cerebrospinal fluid (CSF), suggesting a relationship between the ALTE and respiratory depression from endogenous opioids.

A number of exogenous factors, including toxins and metabolic derangements, express their influence on respiratory control by causing medullary depression. Clinical experience demonstrates that newborn and very young infants are particularly sensitive to these factors; for example, hypoglycemia can be manifested as apnea in young infants, and anemia often is related to apnea in premature babies. The young infant is susceptible to bellows failure on a purely mechanical basis. The infant's thoracic cage is extremely pliable, and the diaphragmatic muscles tire easily, resulting in greater vulnerability to respiratory failure as a result of respiratory distress.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of apnea is extensive (Table 10.1), and several categories are unique to newborns and young infants. For example, apnea may be the only clinical manifestation of seizure activity. This may be particularly difficult for emergency physicians to identify, however, because they did not witness the episode, and neurologic examination may be normal in the postictal period. Several infectious processes can cause apnea. Meningitis, for example, even in the absence of fever, must be included in the differential diagnosis. Respiratory syncytial virus is the predominant cause of bronchiolitis, which may cause apnea in children who were premature or have preexisting lung disease or congenital

heart disease. Infant botulism is a diagnosis that will be made, it is hoped, before apnea occurs and must be suspected on the basis of age, symptoms, and clinical findings. Recent data suggest that gastroesophageal reflux often occurs in infants with an ALTE despite the absence of a history of vomiting. Several systemic disease processes, including metabolic abnormalities that result in hypoglycemia, and sepsis, will become evident because the child develops apnea. The presence of congenital abnormalities always must be considered in newborns and in young infants. Finally, there have been well-substantiated reports of life-threatening child abuse as the etiology of ALTE.

	Neonate, Infant	Older Child
Central nervous system	Infection (meningitis, encephalitis)	Infection
	Seizure	Toxin
	Prematurity	Tumor
	Intraventricular hemorrhage	Seizure
	Increased intracranial pressure (ICP)	Increased ICP (trauma, hydrocephalus)
	Congenital anomaly (e.g., Arnold-Chiari)	Idiopathic hypoventilation ("Ondine's curse")
	Breath-holding spell	
Upper airway	Laryngospasm (e.g., gastroesophageal reflux)	Obstructive sleep apnea
	Infection (e.g., croup)	Infection (epiglottitis, croup)
	Congenital anomaly (e.g., Down syndrome)	Foreign body
Lower airway	Infection (pneumonia, bronchiolitis)	Infection
	Congenital anomaly	Asthma
Other	Infant botulism	Guillain-Barré syndrome
	Hypocalcemia, hypoglycemia	Spinal cord injury
	Anemia	Fat cheat
	Sepsis	Arrhythmias
	Arrhythmia	
	Sudden infant death syndrome (SIDS)	

Table 10.1. Differential Diagnosis of Apnea

Of great concern to both parents and physician is the risk of sudden infant death syndrome (SIDS) for an infant who has an unexplained ALTE. Although any of the diagnoses previously described can result in an ALTE, no cause is identified in about half of patients. No clear relationship exists between an “idiopathic” ALTE and SIDS; however, such a possibility is of grave concern to all parties. SIDS is implicated in approximately 1.5 to 2 deaths per 1000 live births in the United States. This rate fluctuates, based on epidemiologic variables such as socioeconomic status, ethnic origin, maternal drug addiction, discharge from a neonatal intensive care unit (ICU), season of the year (higher in winter), and vigor with which other diagnoses are pursued. The relationship between positioning during sleep and SIDS has been extensively studied. As a result of this research, the American Academy of Pediatrics, since 1992, has recommended that infants be placed supine or on the side during sleep. A coincident decline in the incidence of SIDS has been observed since that time. There have also been reports of ALTEs occurring while sitting in the upright position in a car seat. These factors must be taken into account in considering the differential diagnosis and subsequent management of an infant who has had a significant apneic episode.

EVALUATION AND DECISION

Initial Stabilization

The first priority of the emergency physician, after immediate resuscitation of the patient, is to identify a life-threatening condition—persistent or recurrent apnea (Fig. 10.1), hypoxia, septic shock, and hypoglycemia among others. In addition to assessment of the vital signs, including a rectal temperature and blood pressure (BP), the general appearance and mental status should be noted. Regardless of the cause, apnea is life threatening; therefore, even in the absence of abnormal physical findings, appropriate diagnostic studies should be performed to evaluate the child for several common etiologies (Table 10.2). The next phase of evaluation addresses two key questions: Is this episode of clinical significance? and What is the risk of recurrence? Factors to consider include signs of another acute illness, the age of the child, and other possible risk factors for clinically significant or recurrent apnea (Table 10.3).

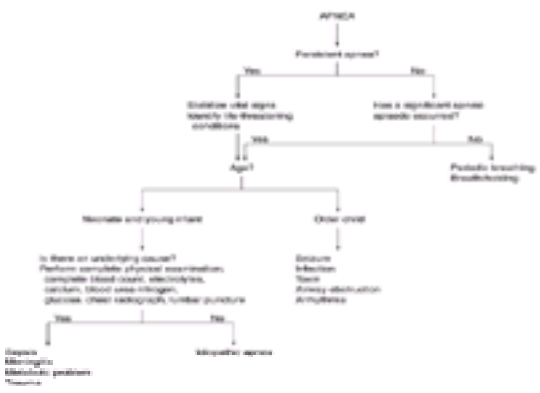

FIGURE 10.1. Approach to the diagnosis and management of apnea.

Pneumonia	Seizures
Sepsis/meningitis	Intracranial hypertension
Hypoglycemia	Shock

Table 10.2. Common Life-Threatening Conditions That Cause Apnea

History	Significant Apnea
Duration of event	Greater than 10 seconds
Was child asleep or awake?	Either, but apnea during sleep is more worrisome
Color change	Pallor or cyanosis
Associated movements, posture, or change in tone	Seizure activity Hypotonia "He looked dead"
Resuscitative efforts and response	Color change or hypotonia requiring cardiopulmonary resuscitation to improve
Interval since last feeding	If shortly after feeding, consider gastroesophageal reflux
Where event occured	Association with sleep, trauma

Table 10.3. Historical Features of Apnea

Has a Significant Apneic Episode Occurred?

The key to answering the questions previously outlined is invariably in the history (Table 10.3). Therefore, every effort should be made to obtain precise information from a firsthand observer. This may not be a simple task, considering the observer's recent stressful experience, but a clear initial history without the predictable influence of repeated questions is vital. The following details should be included: 1) where the event took place; 2) how long the event lasted; 3) whether the infant was awake or asleep; 4) whether there was an associated color change and, if so, to what colors and in what order; 5) description of associated movements, posture, or changes in tone; 6) what resuscitative efforts were made and the infant's response to them; and 7) when was the infant last fed? Attention to the response to these questions may provide the physician with a diagnosis. For example, if an 8-month-old infant was interrupted in a favorite activity, began to cry, turned red and blue, and finally had several seconds of tonic-clonic motor activity, the diagnosis of a breath-holding spell would be straightforward. In contrast, a story of 40 minutes of cyanosis and apnea in a now well-appearing child suggests that parts of the history are unreliable. Other recent events that should be documented are symptoms of other illnesses, including changes in behavior, activity, and appetite, as well as recent trauma and immunizations.

In many cases an absolute determination of significant apnea cannot be made in the emergency department (ED). Nevertheless, the description of the event may clearly suggest that significant apnea did occur, and hospitalization for further workup, as outlined next, is warranted. A typical case might be the previously well 2-month-old child who was noted by the parents to be apneic during a nap. The infant was described as limp and blue and “looked like he was dead.” There was no response to tactile or verbal stimulation for 5 to 10 seconds, but after 15 to 20 seconds of mouth-to-mouth breathing, the child coughed, gagged, and began to breathe. His color improved over the next 30 seconds, and the parents rushed him to the ED. Such a baby may look entirely normal on examination in the ED but be at grave risk for experiencing an ALTE.

The medical history also may provide important information regarding infants at risk for significant or recurrent apnea. The physician should ask specifically about previous similar episodes. Information about perinatal events, including gestational age (birth weight), labor and delivery, maternal health, and nursery course, is helpful. A family history with specific reference to seizures, infant deaths, and serious illnesses in young family members also should be included. Finally, information regarding poisons available in the household may be important in treating an older child.

Is There an Underlying Cause?

A careful physical examination identifies many treatable acute illnesses that can cause apnea; however, the likelihood of an underlying illness varies by age. One clue to serious systemic disease is fever or hypothermia. Tachypnea suggests either a respiratory or metabolic problem, and shock may be secondary to sepsis or hypovolemia from occult trauma. Evaluation of the nervous system should include notation of mental status, palpation of the fontanelles, and funduscopic examination. Dysmorphic features might suggest an underlying congenital abnormality; however, an entirely normal physical examination provides no reassurance that the described event was clinically insignificant and will not recur.

Laboratory evaluation should be guided by the history and physical examination. Tests to consider in the ED include a measurement of blood glucose and serum electrolytes. Any indication that the infant could have a serious infection should be pursued with cultures of blood and urine and by examination of CSF. Urine and blood for toxologic analysis

should be obtained on patients who may have been poisoned. In the child who has no pulmonary findings, an arterial blood gas serves primarily to indicate a persistent abnormality such as hypoxia or a metabolic derangement. For instance, in carbon monoxide poisoning, the Pa_{O_2} may be normal, but metabolic acidosis will be apparent. A significant apneic episode can occur, followed by recovery and a completely normal arterial blood gas determination. Therefore, the arterial or venous blood gas examination does not serve as a screening test for a serious event and should be obtained based on specific indications. Radiologic studies during the initial evaluation might include lateral neck, chest, abdomen, or skull films—again, as indicated by the history and physical examination.

The tasks of the emergency physician faced with a young patient who has had an apneic episode are to identify whether he or she should be hospitalized and to treat underlying conditions. If a careful history and physical examination suggest that a significant apneic episode has not occurred, the diagnosis of periodic breathing or breath-holding can be made, and the patient can be discharged after appropriate counseling of the parents and arrangements for follow-up. The evaluation of a young child with apnea, however, rarely will be so straightforward. If historical information indicates that significant apnea has occurred, the infant is at risk for a recurrence of this life-threatening event. An aggressive search for an underlying cause is necessary and often includes laboratory studies, lumbar puncture, chest radiograph, and electrocardiogram (ECG). Hospital admission should be arranged for observation and further diagnostic evaluation.

A significant apneic episode in the absence of systemic disease suggests a diagnosis of primary apnea. In a recent survey of pediatricians in varying types of practices, most reported that they would refer such children to a teaching hospital or to an established infant apnea study program for evaluation. There were considerable differences in opinion regarding the relationship between apnea and SIDS. This is not surprising considering that there is no single etiology for SIDS and little is known about how associated factors relate to the cause of death. This leaves the emergency physician in a quandary. There may not be an explanation for the event that satisfies the physician or the anxious parents. Thus, it is judicious to refer the family to an available specialist or center.

The standard evaluation that usually is pursued is designed to identify known causes of primary apnea. It generally includes in-hospital observation with monitoring as well as an evaluation of the CNS with an electroencephalogram, some type of sleep study, a chest radiograph, and an ECG. Respiratory function is evaluated with a pneumogram, and a barium swallow and esophageal pH study might identify gastroesophageal reflux. An ultrasound or computed tomogram (CT) of the head would be indicated if a central (CNS) cause for apnea is suspected. The decision to recommend home cardiorespiratory monitoring is beyond the scope of emergency practice because it necessitates a level of continuity of care and follow-up that cannot be provided by the emergency physician.

In many instances, a thorough history and careful physical examination with appropriate laboratory studies will suggest that a significant apneic event has not occurred and that there is no serious underlying illness. In this situation, the emergency physician should reassure and educate the family before discharging the patient. Good medical practice dictates that the parents also should be given specific instructions regarding indications for another ED visit and a follow-up visit to a primary care provider.

CHAPTER 11

Ataxia

JANET H. FRIDAY, MD

Department of Pediatrics, University of Connecticut School of Medicine, and Division of Pediatric Emergency Medicine, Connecticut Children's Medical Center, Hartford, Connecticut

Acute childhood ataxia is an uncommon presenting complaint in the emergency department. *Ataxia* is defined as a disturbance in coordination of movements and may be manifest as an unsteady gait. When it occurs, it is a distressing problem to both parent and clinician. It is important to establish the sign because true ataxia may be difficult to differentiate from clumsiness in toddlers. Parents are generally more sensitive to gait abnormalities in this age group. In older children, ataxia may be confused with weakness or vertigo. Life-threatening causes of pure ataxia are rare in children. After consideration of these, the problem may be approached in a cautious, step-wise fashion.

PATHOPHYSIOLOGY

The cerebellum coordinates complex activities such as walking, talking, and eye movements. Ataxia may be caused by a pathologic condition at either a focal or global level within the cerebellum or by disruptions in the afferent or efferent pathways. Anatomically, the cerebellum is located in the posterior cranial fossa, separated from the cerebrum by the tentorium. The ventral borders of the cerebellum form the roof of the fourth ventricle. Space-occupying lesions such as posterior fossa tumors and cerebellar hemorrhage may impede cerebrospinal fluid (CSF) flow, leading to hydrocephalus and increased intracranial pressure. Conversely, direct pressure on the cerebellar peduncles may cause ataxia to present.

The cerebellum links with other portions of the central nervous system (CNS) through the superior, middle, and inferior peduncles via the midbrain, pons, and medulla. Proprioceptive and sensory afferent impulses from muscles, joints, and tendons are carried via inferior peduncles to the cerebellar cortex. Labyrinthine afferent input is also conducted through the inferior peduncles. Connections from frontal motor cortex travel through the middle cerebellar peduncles. The superior peduncles carry efferent output to musculoskeletal tracts from the nuclei of the cerebellum.

The cerebellum is composed of two hemispheres. Because of the decussation patterns, a lesion that affects only one side of the cerebellum will result in movement abnormalities of the ipsilateral side, with distal movements more affected than proximal ones. Midline lesions lead to truncal ataxia, with swaying during standing, sitting, and walking, and/or with titubations of the head and neck. Finally, the intrinsic function of the cerebellum may be disrupted by autoimmune, metabolic, and toxic disorders.

DIFFERENTIAL DIAGNOSIS

Ataxia as a presenting sign invokes a broad differential diagnosis (Table 11.1). Distinguishing among acute, intermittent, and chronic progressive and chronic nonprogressive ataxia may be helpful, although some diagnoses have overlap in their time course at presentation.

Acute Ataxia	*Chronic, Progressive*
Acute cerebellar ataxia (postinfectious)	Hydrocephalus
Drug intoxication	Posterior fossa tumors
Labyrinthitis	Urea cycle defects
Vasculitis or Kawasaki disease	Multiple carboxylase deficiency
Meningitis	Vitamin E deficiency
Viral encephalitis	Abetalipoproteinemia
Intracranial hemorrhage	Refsum disease
Post-concussion syndrome	Hartnup disease
Benign paroxysmal vertigo	Familial periodic ataxia
Conversion reaction	Freidrich's ataxia
Intermittent	Ataxia telangiectasia
Migraine	Olivopontocerebellar atrophy
Epilepsy	*Chronic, Nonprogressive*
Transient ischemic attacks	Familial
Hartnup disease	Chiari I malformation
Wilson disease	Dandy-Walker malformation
Hereditary paroxysmal ataxia	Joubert syndrome
Maple syrup urine disease	Spastic cerebral palsy
Pyruvate decarboxylase deficiency	Cerebellar agenesis

Table 11.1. Differential Diagnosis

Fortunately, common causes of pure ataxia (Table 11.2) are not rapidly progressive. Acute cerebellar ataxia or postinfectious cerebellitis is truncal in nature and occurs 2 to 3 weeks after a viral illness (see Chapter 83). Children

ages 1 to 3 years are most commonly affected. Varicella is the classically identified culprit. This self-limiting illness is most severe at its onset, but complete recovery may not occur for several months. CSF may show mild lymphocytosis and increased protein. Imaging studies are normal. A small percentage of patients may show long-term sequelae such as learning disabilities or coordination problems.

Acute cerebellar ataxia
Drug ingestion
Guillain-Barré syndrome

Table 11.2. Common Causes of Acute Ataxia

Toxic ingestions of anticonvulsants, alcohol, and sedative-hypnotics generally cause ataxia and thus cause depressed mental status (see Chapter 88). However, for certain substances (phenytoin, carbamazepine, primidone), ataxia may be the most remarkable feature of intoxication.

When an ataxic patient presents with weakness and areflexia, Guillain-Barré syndrome may be present. If opthalmolplegia and areflexia are prominent, the Miller-Fisher variant can be suspected. Neuroimaging is normal, and the CSF may show a mild leukocytosis and elevated protein.

Ataxia may be an early prominent sign of posterior fossa tumors (especially medulloblastoma) and other conditions associated with increased intracranial pressure, including hydrocephalus and supratentorial tumors (see Chapter 100). Labyrinthitis and benign paroxysmal vertigo are rarely seen in young children but are occasionally encountered in adolescents. The sensation of loss of balance generally produces a classic wide-based gait. Conversion disorder should be suspected in a patient who walks with a narrow gait and has elaborate “near falls.”

Life-threatening causes of ataxia (Table 11.3) rarely present as ataxia alone. In a few cases, bacterial meningitis has been reported with ataxia as the first symptom. Viral cerebellitis may occur as a result of enteroviral disease. Neuroblastoma may present with titubations, myoclonic ataxia, and chaotic eye movements. The syndrome is immune-mediated. It should be suspected in patients with acute ataxia that waxes and wanes over several days. One should consider vertebrobasilar occlusion in a patient with neck trauma and ataxia, cerebellar hemorrhage with ataxia and headache, and vasculitis in a child with features of Kawasaki disease.

Meningitis	Neuroblastoma
Drug intoxication	CVA
Brain tumor	Intracranial hemorrhage

Table 11.3. Life-Threatening Causes of Ataxia

Migraine, seizure, transient ischemic attack, and metabolic disease are the most common causes for intermittent ataxia. Chronic progressive ataxias may have a basis in metabolic defects, some of which are treatable. When a progressive ataxia acutely worsens, this may signify severe hydrocephalus or hemorrhage into a posterior fossa tumor. A variety of familial, metabolic, and congenital causes exist for chronic nonprogressive ataxias.

EVALUATION AND DECISION

The approach to the problem should begin with a thorough history and physical examination. The duration and progression of the illness can be established and will help define the ataxia as acute, intermittent, or chronic. Chronic ataxia should be further divided into progressive or nonprogressive. Key historical points to cover include recent illnesses such as varicella or other viral diseases and access to medications or alcohol (Table 11.4). Family history may be helpful in recurrent or genetic causes.

Phenytoin	Dextromethorphan
Alcohol	Lead
Carbamazepine	5-Fluorouracil
Benzodiazepines	Ethylene glycol
Tricyclic antidepressants	Primidone
Antihistamines	Phenothiazines

Table 11.4. Drugs and Toxins That May Cause Ataxia

Physical examination should focus on signs of increased intracranial pressure (bulging fontanelle, papilledema, bradycardia, hypertension, abnormal respirations), meningeal irritation (nuchal rigidity, Kernig's or Brudzinski's sign), fever, rash, and evidence of middle ear disease. A detailed neurologic examination should document general level of consciousness, cranial nerve function, strength, tone, reflexes, sensation, and proprioception. Romberg's test will demonstrate a sensory deficit. Observation of the actual movements will help sharpen the diagnosis because particular syndromes have more truncal versus distal involvement, or unilateral versus bilateral involvement. Specific testing of cerebellar function is impossible in young children. However, a cooperative older child can be asked to perform a finger–nose–finger test, heel–shin test, and rapid alternating movements to further delineate neurologic dysfunction.

The decision to pursue specific laboratory testing is outlined in the algorithm shown in Figure 11.1. Patients with an acute presentation, focal neurologic deficits, recent head trauma, or signs of increased intracranial pressure warrant urgent evaluation via cranial computed tomography scan. Evidence of intracranial hemorrhage, hydrocephalus, or posterior fossa tumor provides an etiology for the ataxia. Neurosurgical involvement should be sought. If the imaging study is normal, the diagnosis may be postconcussion syndrome for patients with head trauma. Consultation with a neurologist may be indicated if physical examination findings other than ataxia persist.

FIGURE 11.1. The diagnostic approach to the child with ataxia.

If the patient appears “toxic” with fever or nuchal rigidity, an emergent imaging of the head is indicated because cerebellar tonsil herniation may cause neck stiffness. If imaging results are negative, a lumbar puncture can be performed safely. When bacterial meningitis is strongly suspected, appropriate antibiotics may be administered before the testing is done.

When other causes have been eliminated, it is prudent to suspect drug or alcohol ingestion (Table 11.4). With the exception of benzodiazepines and tricyclics, the routine toxicologic screen of urine will not detect these drugs. Thus, specific blood levels are indicated when intoxication is suspected.

Management of ataxia in children is directed at the underlying cause. Fortunately, the most common cause, acute cerebellar ataxia, is a self-limiting illness that resolves completely in most cases. During periods of significant ataxia, head protection may be warranted because of the risk of falling. Also, special caution with sedatives is necessary because their effect may be greatly heightened.

CHAPTER 12

Breast Lesion

JILL M. BAREN, MD

Departments of Emergency Medicine and Pediatrics, The University of Pennsylvania School of Medicine, and Division of Emergency Medicine, Hospital of the University of Pennsylvania and The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Complaints related to the breast usually involve pain, discharge, and discrete or diffuse enlargement. The evaluation of a breast lesion in a pediatric patient in the emergency setting is uncommon; however, pediatric emergency physicians must be able to distinguish problems that require immediate intervention from those that are most appropriately handled by referral to and close follow-up with either a general pediatrician or a subspecialist. Fortunately, most breast lesions that occur in children and adolescents are benign and self-limited. Many patients and their families, however, will benefit from the reassurance that neoplastic disease is extremely rare in any pediatric age group. This chapter covers the spectrum of disorders that pediatric emergency physicians are likely to encounter and focuses on an approach to the initial diagnosis and management of some of the more common causes.

DIFFERENTIAL DIAGNOSIS

Subsequent discussion of breast lesions in children is divided into the following categories: infections, benign cysts or masses, malignant masses, abnormal secretions, lesions associated with pregnancy and lactation, and miscellaneous causes, including both anatomic and physiologic entities (Table 12.1A and Table 12.1B). After completion of the history and physical examination, it is likely that the emergency physician will have a good idea into which category the lesion fits, and he or she can then decide how to proceed. With few exceptions, most lesions will be worked up as an outpatient procedure with referral to an appropriate subspecialist. The commonly encountered disorders (Table 12.2) are almost always benign, but consideration must be given to potentially life-threatening processes (Table 12.3).

Table 12.3. Life-Threatening Breast Lesions

Infections

Infection in the breast may take the form of a generalized cellulitis (mastitis) or an abscess. There is a bimodal age occurrence of breast infection with the first, less common peak seen in neonates and the second, in postpubertal females. Neonatal breast infection is most often seen in the first few weeks of life, when the breast bud is enlarged because of maternal estrogen stimulation. In some cases, excessive handling of the hypertrophied tissue by concerned parents or caretakers may lead to the introduction of bacteria. *Staphylococcus aureus* is the usual organism, but *Escherichia coli* has also been found. Neonatal mastitis generally requires a complete septic workup in the emergency department with initiation of broad-spectrum intravenous antibiotics for at least 48 hours because of the presence of fever in this age group. If an abscess develops, aspiration or, less commonly, incision and drainage is warranted, but care must be taken to avoid damaging the breast bud.

Mastitis in postpubertal females can be further classified as lactational and nonlactational. Lactational mastitis is discussed later. Nonlactational mastitis can develop in either the central or peripheral regions of the breast. It is often seen in women who are overweight, have large breasts, and possibly, practice poor hygiene. Peripheral mastitis can be associated with diabetes, rheumatoid arthritis, steroid treatment, granulomatous disease, and trauma. Other predisposing factors for mastitis include previous radiation therapy, sebaceous cysts, and hidradenitis suppurativa. Local signs and symptoms of infection in the breast include warmth, pain, tenderness, erythema, dimpling of the skin, and purulent nipple discharge. Fever may or may not be present. The organisms often isolated are *S. aureus*, enterococci, anaerobic streptococci, and bacteroides species.

Upon diagnosis of mastitis in the postpubertal female, the emergency physician should initiate oral antibiotics with an antistaphylococcal drug such as cephalexin or dicloxacillin. Patients should be instructed to keep the area as clean and dry as possible, to wear a clean cotton bra to avoid excessive sweating, and to avoid skin creams or talcum powders. Patients should have a follow-up appointment in 24 to 48 hours to ensure that the infection is clearing. Patients with systemic symptoms, those who appear toxic, or those who show no improvement should be admitted for intravenous antibiotics. If an abscess is suspected, it should be confirmed and treated with aspiration; incision and drainage are only occasionally necessary.

Benign Cysts and Masses

Enlargement of breast tissue may occur at any age beginning in the neonatal period. As previously discussed, the male and female neonatal breast bud is hypertrophied in the first few weeks of life because of maternal estrogen stimulation. No treatment is required because this condition abates over time; caretakers should avoid manual stimulation. In preschool-aged girls, there may be a temporary unilateral or bilateral enlargement of the breast bud. This is consistent with isolated premature thelarche as long as there are no other manifestations of developing secondary sexual characteristics. If premature thelarche is suspected, the girl can be referred for follow-up to her primary care physician;

the enlargement will most likely spontaneously resolve. If other secondary sexual characteristics are present (precocious puberty) or if this condition occurs in young boys (prepubertal gynecomastia), a specific cause should be aggressively pursued. The workup for this disorder generally includes a search for any adrenal, ovarian, or hypothalamic pathology, including tumors. Patients should be referred to an experienced pediatrician or endocrinologist if these conditions seem likely.

Fibroadenomas are the most common benign breast lesion in women less than 30 years of age. When present in adolescent girls, these lesions are sometimes called juvenile fibroadenomas. Fibroadenomas are usually discovered as solitary, mobile, and sometimes tender masses. Mammography is usually not indicated in adolescent girls unless there is a strong family history of breast malignancy or the contralateral breast needs to be evaluated. The treatment of choice for a fibroadenoma is excisional biopsy, so patients should be referred to a pediatric surgeon or breast surgeon. Reassurance may be given that the malignant potential of a fibroadenoma is very low. Hamartomas, benign breast tumors that can be mistaken for fibroadenomas, are also seen in pediatric patients and are also treated by excisional biopsy.

Fibrocystic disease is a benign, progressive process that is generally seen in women in their teens and twenties and may be encountered by emergency physicians. It usually presents as cyclically painful masses, sometimes bilateral and often most prominent in the upper outer quadrants of the breast. The masses often change in size or degree of nodularity during the course of the menstrual cycle, with the worst degree of pain occurring in the premenstrual phase. Nipple discharge may also be present and is nonbloody, green, or brown. Although not usually indicated, biopsy and histologic examination can provide a definitive diagnosis. These lesions are not considered precancerous. No specific treatment exists, but avoidance of caffeine and use of nonsteroidal anti-inflammatory drugs have been recommended for symptomatic relief.

Solitary or multiple breast cysts are also occasionally discovered on the breast examination of adolescent girls. These cysts are also benign lesions that can be confirmed easily by ultrasound. Referral of the patient to a primary care physician or surgeon should be done expediently so that aspiration can be performed with close follow-up.

Nipple masses represent another group of generally benign breast masses. Benign papillomatosis can be seen in prepubertal or pubertal boys and girls and often comes to attention because of bleeding. Occasionally, the lesion may obstruct the nipple and become more painful and possibly infected. In rare instances, a nipple mass can represent a carcinoma. Therefore, when detected, expedient referral to a breast surgeon or pediatric surgeon is indicated. Nipple masses may be observed for several weeks; if the mass or bleeding persist, they are usually excised.

Trauma to the breast can result in the formation of hematomas and fat necrosis, both of which can be palpated as firm, well-circumscribed breast masses. Initially, these lesions may be tender. If left untreated, they may develop into areas of scar tissue that are fixed to the skin. Breast trauma and fat necrosis are relatively common, but the differentiation from other more serious lesions may be difficult, requiring consultation with a surgeon in cases of uncertainty.

Malignant Masses

Cancers of the breast have been reported in young children; however, they are extremely rare. Often, these tumors are categorized as secretory carcinomas and behave more benignly than breast cancers in adults. Other histologic malignancies reported in children and adolescents are carcinomas, sarcomas, and the more common cystosarcoma phylloides, which can have both benign and malignant features. Characteristics that are suggestive of malignancy include a hard, nontender, solitary mass with ambiguous margins. There may be overlying skin changes (warmth, dimpling, or edema), bleeding from the nipple, and lymphadenopathy. The appropriate treatment is the same as that for a suspected benign mass—prompt referral to a pediatric surgeon or breast surgeon for definitive workup, which usually consists of excisional biopsy.

Abnormal Secretions (Nipple Discharge)

There are multiple causes for abnormal nipple secretions that can be divided according to whether they might require surgical treatment. Nonsurgical causes usually present as nonspontaneous discharges. The most common example is discharge fluid expressed during breast self-examination. The fluid may be milky, multicolored, and sticky. If infection is present, a purulent discharge may occur.

Galactorrhea is the most common spontaneous nipple discharge that usually occurs bilaterally. If it is not associated with pregnancy and lactation, increased prolactin secretion should be suspected. Both drugs and structural lesions of the hypothalamus and pituitary can cause high prolactin levels. Drugs that have been implicated include oral contraceptives, tricyclic antidepressants, phenothiazines, metoclopramide, reserpine, and a-methyldopa. Neonates may secrete a colostrum-like material that has been referred to as witch's milk. This discharge occurs temporarily, until maternal estrogen levels decline, and is not considered pathologic.

Other spontaneous nipple discharges have been described as multicolored, grossly bloody, serous, or clear and watery. Nonbloody discharges are usually not indicative of cancer. Mammary duct ectasia, traumatic nipple erosions (e.g., “jogger's nipple”), and eczema are some of the more common causes of nonbloody discharges. These disorders can be treated with nipple hygiene, warm compresses, and topical antibiotics if necessary. When nipple discharge is described as serosanguinous or frankly bloody or when it tests positive for occult blood, the association with cancer rises, particularly if a mass is palpable below the nipple. However, cancer is the cause of only 6% of bloody nipple discharges; more common causes include duct ectasia, papillomas, fibrocystic disease, and pregnancy. Any pediatric patient with spontaneous nipple discharge not explained by an obvious cause (e.g., jogger's nipples) should be referred to an appropriate specialist for close follow-up and further workup.

Lesions Associated with Pregnancy and Lactation

Significant changes occur in the female breast as a result of pregnancy, most prominently an increase in breast size and weight. Although pregnant patients may have any of the breast lesions seen in nonpregnant patients, they are prone to develop some unique conditions. The most common of these conditions occurs in lactating patients. Mastitis affects 2% of lactating women. If it occurs within several days of delivery, it is likely to be caused by *S. aureus*, which may be transmitted from infant to infant and then to the nursing mother through cracked skin in the nipple. Breast engorgement may exacerbate the symptoms. Therapy consists of warm compresses, continued breast-feeding, and an antistaphylococcal antibiotic. Mastitis that occurs 2 weeks or more after delivery is the result of either poor hygiene or inadequate emptying of the breast with subsequent milk stasis, engorgement, and colonization of bacteria within the milk. If an abscess develops, it usually requires both antibiotics and drainage, often by aspiration, for cure. Breast-feeding can usually proceed in the opposite breast, but not from the breast with an abscess because of the risk of the neonate acquiring infection. Pregnant patients may also have simple milk-filled cysts called galactoceles, which are often tender and located on the periphery of the breast. Ice packs, breast support, and aspiration may be needed to relieve the obstruction of the milk-filled ducts.

Nonlactating pregnant patients may have a bloody discharge from the nipple during the second or third trimester. This usually represents the benign condition of epithelial cell proliferation. If the discharge persists after delivery, a more thorough investigation should take place. Fibroadenomas often increase in size during pregnancy to the point of infarcting and causing significant pain. Excision is often advised for any solitary mass, and the patient should be expediently referred to a breast surgeon. The number of cases of breast malignancy diagnosed during pregnancy is small.

Miscellaneous Breast Lesions

Polymastia, Polythelia

Supernumerary breasts (polymastia) and supernumerary nipples (polythelia) are two congenital conditions that are unlikely to present as chief complaints in the emergency department but that may be discovered incidentally on examination. The incidence of polymastia is unknown, but it is more common in girls and results from failure of the embryonic mammary ridges to regress. Polymastia is present at birth, often resembling skin tags or nevi, and may not be noticed until the tissue is hormonally influenced during puberty, pregnancy, or lactation. Supernumerary breasts are most commonly found in the axillae but have been reported to occur in several locations. This ectopic tissue may become tender with menses and has been reported to develop the same range of pathology as normal breast tissue, necessitating excision under certain circumstances.

Polythelia is present in 0.6% of Caucasians and 1.5% of African-Americans. It is both sporadic and familial. Polythelia is most commonly found on the left, inferior to the normal nipple. In newborns, polythelia may appear as small, wrinkled lesions with or without pigmentation. The significance of polythelia is questionable. One series of patients with polythelia had a 23% incidence of associated unsuspected urologic anomalies. Other reported associations include pyloric stenosis, hypertension, congenital heart disease, and cardiac conduction defects. For this reason, patients with polythelia should be referred for at least a primary screening of underlying urologic disease. Otherwise, this disorder requires no treatment unless the diagnosis is uncertain (e.g., the lesion looks like a possible melanoma) or it is perceived as a cosmetic problem.

Juvenile Breast Hypertrophy

Juvenile breast hypertrophy is a rare disorder characterized by sudden, rapid, massive breast enlargement at a time of intense endocrine stimulation, usually around 8 to 16 years of age, just after menarche. It is thought to be caused by end-organ hypersensitivity to estrogen. The hypertrophy is usually bilateral and asymmetric and may progress at an alarming rate over 36 months. The differential diagnosis of this lesion includes cystosarcoma phylloides, juvenile fibroadenoma, and precocious puberty. Usually, no endocrine or neoplastic lesions are found. In some cases, the hypertrophy regresses in 1 to 3 years, but referral to a breast surgeon is always indicated because breast reduction or even total ablation may become necessary. This disorder is often associated with extreme emotional and psychosocial distress for patients and families.

Gynecomastia

Gynecomastia is a term commonly used to describe a broad spectrum of clinical breast lesions in boys, including excess breast tissue, breast enlargement, and a firm rubbery mass of tissue below the nipple that is discrete and nonadherent to the chest wall. Some texts assert that it is almost always unilateral; others assert that it is exclusively bilateral. Gynecomastia has been described as the male equivalent of fibrocystic changes in the female breast. Despite the confusion in the literature, histologically, there is a proliferation of dense periductal connective tissue with hyperplasia of ductal epithelial cells, which is the result of an increased effective estrogen:testosterone ratio in the serum or in the breast tissue. Causes of this relative hormone imbalance include physiologic changes (neonatal, puberty, aging); drug use; tumors of the testes, adrenal glands, and lungs; metabolic conditions (cirrhosis, hyperthyroidism, renal disease); and hypogonadism.

From a clinical perspective, gynecomastia occurs in about 50% of all boys between the ages of 11 to 18 years and lasts about 2 years. It can be associated with growth spurts and can also cause a significant degree of pain. More commonly, gynecomastia will come to a physician's attention because of the anxiety it causes in adolescent boys. If the patient with gynecomastia has normal-sized genitalia and none of the predisposing conditions listed earlier, reassurance is all that is needed. There is often particular concern about gynecomastia in obese boys because they may appear to have an overabundance of fatty tissue in the breast region. Surrounding fatty tissue may also give the illusion of small genitalia;

however, these patients have no higher incidence of gynecomastia than their nonobese counterparts. Gynecomastia is best dealt with by referral to the primary care physician for long-term follow-up.

Physiologic Mastalgia

During the first trimester of pregnancy, some teenage girls may complain of breast fullness. Occasional, nongravid patients may have breast pain for which no underlying cause is grossly apparent or suspected. These patients may have mastalgia that is likely related to the hormonal milieu of the breast throughout the menstrual cycle. Mastalgia is often described as a bilateral, poorly localized, heavy, dull, achy pain that radiates to the axillae. The pain is often worse with activity and relieved with the onset of menses. In general, there are no abnormal physical findings except tender, nodular breasts. The differential diagnosis includes costochondritis, Tietze's syndrome, cervical root syndromes, old breast trauma that has resulted in fat necrosis or hematoma, lung disease, and gallstones. Once these possibilities can be reasonably ruled out, mastalgia is the likely diagnosis. Most patients will improve with reassurance, analgesics such as nonsteroidal anti-inflammatory medications, warm compresses, and breast support. If the pain is refractory to these measures, other suggested therapies include caffeine avoidance, salt restriction, diuretics, and Danazol, a synthetic androgen, for severe, debilitating pain.

EVALUATION AND DECISION

History and Physical Examination

Initial evaluation of a breast lesion begins with a careful history and physical examination (Table 12.4). The two most common categories of breast lesions in children are infections and structural or mass lesions. When infection is suspected, especially in neonates or infants, particular attention should be given to the presence of systemic symptoms such as fever, chills, malaise, poor appetite, and lethargy. For the evaluation of mass lesions, it is imperative to obtain a detailed menstrual history and a chronology of the development of secondary sexual characteristics. Pregnant or lactating patients may also present to a pediatric emergency department. These patients should be asked about breast-feeding or breast-feeding attempts, as well as about general symptoms related to changes in the breast tissue. Medications may have an effect on the growth of certain breast lesions and may also affect hormonal pathways, leading to abnormal breast secretions. Therefore, a detailed drug history should be obtained. A few breast disorders may have a familial pattern, so a careful family history should also be taken.

History
Onset/duration of lesion
Presence/absence of pain
Presence/absence of nipple discharge
Change in lesion with menses
Complete menstrual and sexual development history including sexual activity and previous pregnancies
Family history of breast disease
Diet
Medications
Concomitant medical disorders
Systemic symptoms: fever, weight loss, sweating, headaches, visual changes
Physical Examination
Breasts: symmetry, skin appearance, temperature, areola, nipples, secretions, masses, chest wall, axillae
Lymph nodes
Hair distribution
Genitalia

Table 12.4. Important Historical and Physical Examination Components in the Evaluation of a Breast Lesion

A general physical examination should be performed on any pediatric patient who complains of a breast problem. Findings in other organ systems may be helpful in pinpointing the cause of the disorder. For example, premature secondary sexual characteristics, hirsutism, or abnormal skin coloring may indicate an endocrinopathy. A detailed evaluation of the breasts and adjacent structures is essential. The chest wall should be inspected for any gross deformities, asymmetry, or skin changes. The physician should have the patient lean forward with hands on hips and again observe for any asymmetry or skin retraction. With the patient supine with arms above the head, the physician should palpate each breast in a series of concentric circles radiating outward from the nipple, looking and feeling for nodules, cysts, masses, or inconsistencies in the breast tissue. Each areola should be gently compressed to assess for masses or nipple discharge. If present, the color, character, and odor of any discharge should be noted. The physician should feel for the presence of any masses or lymphadenopathy in both axillae.

Laboratory Testing

Very few laboratory tests will be helpful in the initial evaluation of pediatric patients with breast lesions. All postmenarchal girls should have a pregnancy test performed; breast tenderness and swelling may be some of the earliest signs of pregnancy. Chest radiographs are rarely helpful except in cases in which the examiner believes that signs and symptoms from the lungs or chest wall are referred to the breast. Mammography, cyst aspiration, and endocrinologic testing may be indicated for some breast lesions, although these generally take place outside the emergency setting.

Approach

The approach to the patient with complaints related to the breast depends first on whether the patient is prepubertal or pubertal/postpubertal. Among patients who are pubertal/postpubertal, the considerations vary greatly between boys and girls. Finally, unique considerations pertain to the pregnant or lactating girl, as discussed earlier.

Prepubertal Child (Fig. 12.1)

FIGURE 12.1. Approach to breast complaints in the prepubertal child.

Among prepubertal children, disorders of the breast occur commonly only in the immediate newborn period, usually because of physiologic hypertrophy. If erythema or tenderness is present, the physician should consider mastitis, a potentially serious bacterial infection. Among children, isolated lesions underneath the nipple are usually benign cysts. Diffuse enlargement calls for endocrinologic consultation.

Pubertal/Postpubertal Male (Fig. 12.2)

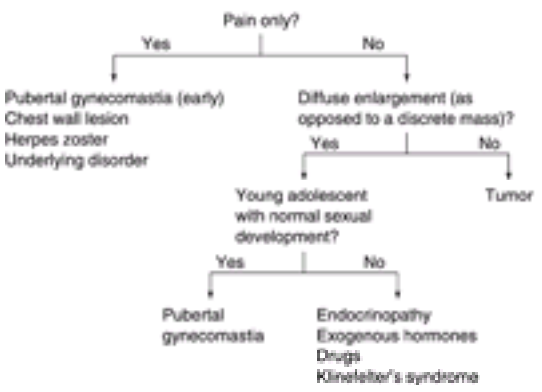

FIGURE 12.2. Approach to breast complaints in the pubertal/postpubertal boy.

The adolescent boy may complain of pain, yet have no clearly palpable breast enlargement. This sensation may be caused by minor chest trauma in a boy with early pubertal gynecomastia or may represent underlying chest pain (see Chapter 52). Most often, the complaint will be that there is bilateral (sometimes asymmetric) enlargement diffusely throughout the breast tissue, which represents (physiologic) pubertal gynecomastia in the boy who has normal sexual development. Either a unilateral, discrete mass or bilateral, diffuse enlargement with abnormal sexual development requires further evaluation.

Pubertal/Postpubertal Female (Fig. 12.3)

FIGURE 12.3. Approach to breast complaints in the pubertal/postpubertal girl.

The initial step in evaluating the adolescent girl is to obtain a pregnancy test, which when positive points specifically to a number of conditions that occur only in the gravid state (see earlier discussion). Both pregnant and nonpregnant girls may experience a myriad of disorders, related to the breast. The emergency physician's primary goal is to distinguish underlying disorders that are causing chest rather than breast pain (see Chapter 52) and to diagnose a few relatively

minor problems, including cellulitis, abscess, hematoma, and traumatic erosions. Other causes for breast enlargement, masses, and discharge require follow-up by an appropriate specialist.

CHAPTER 13

Coma and Altered Level of Consciousness

DOUGLAS S. NELSON, MD

Department of Pediatrics and Emergency Medicine, University of Utah School of Medicine, and Primary Children's Medical Center, Salt Lake City, Utah

Consciousness refers to the state of being awake and aware of oneself and one's surroundings. It is a basic cerebral function that is not easily compromised; impairment of this faculty may therefore signal the presence of a life-threatening condition. An altered level of consciousness (ALOC) is not in itself a disease. It is a state caused by an underlying disease process, which must be addressed quickly to maximize a patient's chance of recovery. *Coma* refers to a state of complete unawareness and unresponsiveness (e.g., unconsciousness) from which a patient cannot be roused; this represents the most extreme form of ALOC. The term coma is often modified with descriptors such as light or deep. Lesser levels of impairment are described using other terms whose meaning may overlap. Lethargy refers to depressed consciousness resembling a deep sleep from which a patient can be aroused but into which he or she immediately returns. A patient is said to be stuporous or obtunded when he or she is not totally asleep but demonstrates greatly diminished responses to external stimuli. Because neurologic status may vary dramatically over time, it may be difficult to describe such symptoms using a single descriptor. Recording the comatose patient's specific response (body movement, type of vocalization) to a defined stimulus (e.g., a sternal rub) is usually preferable (Table 13.1).

Eye Opening

No response	1

[a]Preverbal children should receive full verbal score for crying with stimulation.

Table 13.1. Glasgow Coma Scale

PATHOPHYSIOLOGY

The state of wakefulness is mediated by neurons of the ascending reticular activating system (ARAS) located in the brainstem and pons. Neural pathways from these locations project throughout the cortex, which is responsible for awareness. If the function of these neurons is compromised or if both cerebral hemispheres are sufficiently affected by disease, an ALOC will result.

Proper function of the ARAS and cerebral hemispheres depends on many factors, including the presence of substrates needed for energy production, adequate blood flow to deliver these substrates, absence of abnormal serum concentrations of metabolic waste products or extraneous toxins, maintenance of body temperature within normal ranges, and the absence of abnormal neuronal excitation or irritation from seizure activity or central nervous system (CNS)

infection.

Disorders that produce coma by raising intracranial pressure (ICP) increase the volume of an existing intracerebral component such as brain, blood, or cerebrospinal fluid (CSF). Alternatively, a new component such as a tumor may be introduced. The brain can initially compensate for this altered volume relationship by regulating blood flow and CSF production. When the limits of these compensatory mechanisms are reached, ICP will rise abruptly, decreasing cerebral perfusion pressure (defined as mean arterial pressure minus ICP) and placing the patient at risk for herniation.

Herniation, the displacement of a part of the brain from its usual position into an unfamiliar intracranial compartment, can occur in several locations within the cranium, as shown in Figure 13.1. Central herniation results from an increase in volume and pressure in both cerebral hemispheres, compressing and displacing the midbrain and upper brainstem downward through the tentorium. Cingulate gyrus herniation occurs as a result of unilateral cerebral hemisphere volume increase when the gyrus is displaced laterally underneath the falx, crossing the midline of the cranium. This unilateral volume increase may instead cause uncal herniation because the lower midline portion of a cerebral hemisphere and adjoining hippocampal gyrus are directed downward through the tentorium. Foramen magnum (or tonsillar) herniation is a consequence of increased pressure in the posterior fossa, forcing the cerebellar tonsils through the foramen magnum at the base of the skull.

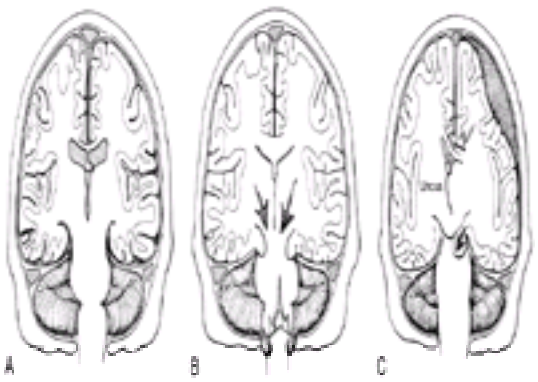

FIGURE 13.1. Intracranial contents. **A.** Normal relationships. **B.** Dark arrow, central herniation; light arrow, foramen magnum or tonsillar herniation. **C.** Dark arrow, uncal herniation; light arrow, cingulate gyrus herniation.

DIFFERENTIAL DIAGNOSIS

A differential diagnosis for children presenting in or near coma is shown in Table 13.2. Conditions arising from trauma or disease within the CNS are separated from those affecting the brain diffusely due to extracranial problems. The more commonly encountered causes of coma are listed in Table 13.3. These most likely causes of coma should be considered in every patient presenting in this condition. Life-threatening causes of ALOC are listed in Table 13.4 and must be considered in every patient. If present, these disorders require emergent treatment. More than one problem may be present simultaneously; for example, a drowning victim may incur a head injury when falling into a swimming pool, or a deeply postictal patient with known seizure disorder may have ingested a toxin.

Table 13.2. Etiology of Acute-Onset Coma/ALOC

Subdural hematoma	Posthypoxia
Epidural hematoma	Hypoglycemia

Cerebral edema	Toxic ingestions
Brain neoplasms	Hypotension
Cerebral infarctions	Hypoxia
Cerebrospinal fluid shunt malfunction	Sepsis

Table 13.4. Life-Threatening Causes of Coma/ALOC

Primary Central Nervous System Disorders

Trauma

Coma-producing brain lesions that result from trauma include subdural and epidural hematomas, intraparenchymal and subarachnoid hemorrhage, penetrating injuries, cerebral contusion, diffuse cerebral edema, and concussion (see Chapter 105). Penetrating injuries are rare and of obvious origin. Most cases of pediatric head injury are blunt in nature, involving rapid deceleration against an automobile interior or the ground. Inflicted injury is also common in young children. The site of hemorrhage may be located opposite external signs of trauma due to the rebounding of the brain within the skull after impact (contrecoup injury). Patients may present in a comatose state or may be alert for variable periods after impact. All traumatic lesions of the brain may increase ICP, which is the chief cause of the resulting vomiting, lethargy, and/or coma seen in these patients. Increased ICP reduces cerebral perfusion pressure initially and may eventually result in herniation.

Epidural hematomas are caused by bleeding from cerebral arteries or veins; 85% are associated with an overlying skull fracture. Epidural hematomas may occur after relatively minor trauma; in one series, 24 of 53 children with epidural hematoma had fallen less than 5 feet. The classic location of the injury is the temporal lobe, due to tearing of the middle meningeal artery. Such arterial bleeding produces a faster onset of symptoms such as headache, vomiting, and decreased LOC than venous hemorrhage. Approximately 40% of these patients may appear neurologically normal on presentation, during the classically described “lucid interval.” On computed tomography (CT) scan, epidural hematomas usually appear sharply localized and are unilateral with a lenticular (lenslike) shape.

Subdural hematomas, produced by tearing of cortical bridging veins between the dura and arachnoid, can occur bilaterally and are 5 to 10 times more common than epidural bleeding. They may occur on a chronic basis in young, abused children and are associated with skull fractures in 30% of cases. Retinal hemorrhages may be found in 75% of patients with subdural hematomas. On neuroimaging, these lesions may appear classically crescent-shaped.

Diffuse cerebral edema is more common than focal lesions after brain trauma and is unfortunately less amenable to neurosurgical intervention. Characteristic CT findings of loss of gray–white interface may not be visible for 12 to 24 hours after the trauma was sustained. When radiographic abnormalities appear, they may be similar to those produced by hypoxia. *Concussion* is an inexact term for a transient alteration in normal neurologic function, often involving temporary loss of consciousness, after experiencing head trauma. A postconcussion syndrome may last for hours to days and is characterized by nausea, vomiting, dizziness, headache, and lethargy. Neuroimaging studies are normal, yet patients may be ill enough to require admission for observation and intravenous hydration.

Seizures

LOC is greatly diminished both during and after periods of seizure activity. Although generalized seizure activity is readily recognizable by the rhythmic motor activity accompanying an ALOC, partial or absence seizure activity may present more subtlely with staring, tremors, eye blinking, rhythmic nodding, or other inappropriate repetitive motor activity. Seizures of all types except petit mal may be followed by a postictal period, during which obtunded patients gradually regain responsiveness to and awareness of their surroundings.

The diagnostic approach toward a patient with ALOC from seizure activity varies based on whether seizures have occurred in the past and the progression of resolution of his or her neurologic abnormalities (see Chapter 70). Posttraumatic or new focal seizures are assumed to reflect an intracranial lesion until proven otherwise. Children taking anticonvulsants for known seizure disorders benefit from drug level measurement during an observation period. Subtherapeutic anticonvulsant levels result in convulsions with postictal ALOC, whereas supratherapeutic levels produce ALOC of a different appearance based on the medication involved. The presence of fever may indicate that a febrile seizure has occurred or that the patient has contracted a CNS infection such as meningitis or encephalitis (see Chapter 83 and Chapter 84). The new onset of afebrile generalized seizures requires a more elaborate evaluation, as detailed in Chapter 70.

Infection

Coma-inducing infections of the CNS may involve large areas of the brain and surrounding structures, as in meningitis or encephalitis, or they may be confined to a smaller region, as in the case of cerebral abscess or empyema (see Chapter 84). Bacterial meningitis remains the most common infection severe enough to produce profoundly diminished LOC; despite the overall decrease in total number of cases since the introduction of vaccines effective against *Haemophilus influenzae, Streptococcus pneumoniae* and *Neisseria meningitidis* are now the most common etiologic agents after the neonatal period. Meningitis may be caused by viral (enteroviruses, herpes), fungal (Candida, cryptococcus), mycobacterial (tuberculosis), and parasitic (cysticercosis) organisms as well. These nonbacterial infections usually have a slower onset of symptoms. The incidence of viral meningitis peaks in late summer, when enterovirus infections are most common.

Encephalitis, or inflammation of brain parenchyma, may involve the meninges as well (see Chapter 84). It occurs most commonly as a result of viral infection or immunologic mechanisms. Mumps and measles viruses were common etiologic agents before immunizations against these diseases, and they still occur in unimmunized individuals. Varicella encephalitis occurs 2 to 9 days after the onset of rash. The incidence of arthropodborne encephalitides varies by geographic location but usually peaks in late summer and early fall. The herpes simplex virus remains the most common devastating cause of encephalitis, causing death or permanent neurologic sequelae in more than 70% of patients. It affects the temporal lobes most severely, leading to seizures and parenchymal swelling, which can cause uncal herniation.

Focal CNS infections include brain abscesses, subdural empyemas, and epidural abscesses (see Chapter 84). Brain abscesses occur most often in patients with chronic sinusitis, chronic ear infection, dental infection, endocarditis, or congenital heart disease. One-fourth of cases of brain abscess occur in children less than 15 years of age, with a peak incidence between 4 and 7 years of age. Subdural empyema occurs secondary to chronic ear or sinus infection as well, but it is most commonly seen as a sequela of bacterial meningitis. Cranial epidural abscess is rare, but most cases occur from extension of sinusitis, otitis, orbital cellulitis, or calvarial osteomyelitis.

Neoplasms

Alterations in consciousness as a result of intracranial neoplasms (see Chapter 100) may be caused by seizure, hemorrhage, increases in ICP caused by interruption of CSF flow, or direct invasion of the ARAS by the malignancy (which is unlikely to cause coma of rapid onset). The location of the tumor determines additional symptoms: ataxia and vomiting for infratentorial lesions versus seizures, hemiparesis, and speech or intellectual difficulties resulting from supratentorial neoplasms. Acute hydrocephalus secondary to tumor growth most commonly presents with headache, lethargy, and vomiting.

Vascular

Coma of cerebrovascular origin is caused by interruption of cerebral blood flow (stroke) as a result of hemorrhage, thrombosis, or embolism (see Chapter 125). Hemorrhage is often nontraumatic, stemming from an abnormal vascular structure such as an arteriovenous malformation (AVM), aneurysm, or cavernous hemangioma. Rupture of an AVM is the most common cause of spontaneous intracranial bleeding among pediatric patients. The hemorrhage is arterial in origin and located within the parenchyma, but it can rupture into a ventricle or the subarachnoid space. Aneurysm rupture is less common and is unusual in that repetitive episodes of bleeding may occur (“sentinel bleeds”), with rising morbidity and mortality from each subsequent episode of bleeding. Subarachnoid blood may be present in either case, although more commonly with aneurysm rupture. Cavernous and venous hemangiomas are lower-flow lesions that produce a less acute onset of symptoms.

Stroke may also occur from thrombosis or embolism of a normal vessel. Cerebral infarction caused by occlusion of the anterior, middle, or posterior cerebral artery usually produces focal neurologic deficit, not coma. Acute occlusion of the carotid artery, however, may produce sufficient unilateral hemispheric swelling that herniation and coma may ensue; infarction may lead to hemorrhage as well. Central venous thrombosis is most commonly seen as a sequela of infections of the ear or sinus or hypercoagulable states.

Swelling or hemorrhage from infarcted brain can cause increased ICP, leading to interruption of blood flow to the ARAS and resultant coma. Less severe, often focal symptoms vary based on the size and location of brain denied adequate blood supply. Vascular accidents in the cerebellum present with combinations of ataxia, vertigo, nausea, occipital headache, and resistance to neck flexion. Coma is an unusual early sign of infarction of cerebral structures but becomes more common as lower anatomic centers are affected. Occlusion of the basilar artery may result in upper brainstem infarction, resulting in rapid onset of coma, as does hemorrhage or infarction of the pons.

Cerebrospinal Fluid Shunt Problems

Children with congenital or acquired hydrocephalus as a result of prematurity, neoplasm, or trauma depend on the continued function of a neurosurgical shunt to drain CSF and prevent rises in ICP (see Chapter 83). The most common shunt type is ventriculoperitoneal (VP), draining CSF from a lateral cerebral ventricle, up through a small hole in the skull, through a valve with an attached reservoir located beneath the scalp, and into the peritoneum via tubing placed under the skin of the neck, chest, and abdomen. CSF shunts may malfunction for many reasons, including tubing rupture, valve malfunction, tubing blockage, tubing disconnection, and shunt infection. The risk of failure is greatest during the first 6 months after shunt placement or revision.

Systemic Abnormalities

The second major category of disorders causing coma listed in Table 13.2 arise in organs other than the CNS and affect the brain diffusely. These abnormalities alter neuronal activity by a variety of means, including decreasing metabolic substrates required for normal function (e.g., hypoxia, hypotension, hypoglycemia, other electrolyte abnormalities), altering the rate of intracellular chemical reactions (e.g., hypothermia, hyperthermia), and introducing extraneous toxins into the CNS.

Hypoxia

Oxygen delivery to the brain may be adversely affected by disorders that compromise a patient's airway, breathing, or circulation. Neurons are the cells most sensitive to oxygen deprivation, and they will cease to function within seconds after being deprived of adequate levels of oxygen. Hypoxic coma may result from airway obstruction, pulmonary disease, severe acute anemia, severe methemoglobinemia, carbon monoxide poisoning, or asphyxia (e.g., drowning). Permanent CNS dysfunction results from total anoxia lasting more than 4 to 5 minutes at normal body temperatures; lesser degrees of hypoxia may be tolerated for longer periods. Submersion in cold water may cool the brain sufficiently to exert a neuroprotective effect. It is usually unclear in the emergency department how much permanent neurologic damage has taken place as a result of hypoxia. Hypercarbia may accompany hypoxia and be responsible for neurologic depression and coma as well.

Cardiovascular Abnormalities

Hypotension may be the product of numerous causes, including hemorrhage, dehydration, sepsis, arrhythmia, and intoxication, but the result is poor cerebral perfusion, which produces diminished mental status (see Chapter 3). Hypertensive encephalopathy is distinguished by headache, nausea, vomiting, visual disturbance, altered mental status, or coma in the presence of a blood pressure above the 95th percentile for age and sex (see Chapter 35). The acute onset of severe hypertension may reflect ongoing renal (e.g., unilateral renal artery stenosis, acute glomerulonephritis), endocrine (e.g., pheochromocytoma), or cardiac (e.g., aortic coarctation) pathology, or it may be the result of a toxic ingestion (e.g., cocaine). Cerebral hemorrhage may result. Hypertension accompanied by bradycardia may indicate increased ICP.

Disorders of Thermoregulation

Hypothermia or hyperthermia in the pediatric patient is usually caused by prolonged environmental exposure to temperature extremes such as those found in cold water or in a closed car in sunlight (see Chapter 89). The child made comatose as a result of abnormal core temperature will have multiple organ system abnormalities in addition to CNS dysfunction. Mental impairment is progressive as body temperature is lowered because each fall of 1°C produces a 6% decline in cerebral blood flow. At 29° to 31°C, confusion or delirium is present, as is muscular rigidity. Patients with core temperatures of 25° to 29°C are comatose with absent deep tendon reflexes and fixed, dilated pupils. CNS findings in hyperthermia include headache, vomiting, and obtundation, leading to coma and/or seizures, especially above 41°C.

Toxic Ingestions

Pediatric toxic ingestions are often not witnessed, may involve a large dose on a milligram per kilogram basis, are rarely intentionally inflicted, and are usually complicated by the young patient's inability to provide information regarding the quantity or identity of the substance ingested (see Chapter 88). Table 13.2 lists many drug classes that cause coma when an overdose is taken. Exogenous toxins may impair neuronal function directly or by causing hypoxia, acidosis, enzyme inhibition, hypoglycemia, or seizures.

Metabolic Alterations

Abnormal serum concentrations of any substrate or product involved in neuronal metabolism can produce obtundation, leading to coma. Hypoglycemia is the most common disorder in this category, especially in infants and young children, whose capacity for hepatic gluconeogenesis is limited. Disorders known to produce hypoglycemia include serious bacterial infections, sepsis, dehydration, and toxic ingestions (especially ethanol and oral hypoglycemics). Diabetes mellitus, especially of new onset, may present with profoundly depressed consciousness from the combination of hyperosmolarity, dehydration, hypotension, and lactic acidosis and ketoacidosis. Patients under treatment for diabetic ketoacidosis may also develop cerebrae edema.

Metabolic acidosis or alkalosis of sufficient degree produces altered mental status. Severe dehydration that leads to significant metabolic acidosis is the most common disorder of this type seen in children. Abnormal concentrations of any serum cation, including sodium, calcium, magnesium, and phosphorus, can produce altered mental status as well. The degree of resulting neurologic compromise will be affected by the duration of the problem and concurrent disorders. Severe dehydration alone, from any cause without significant electrolyte abnormalities, may produce profound lethargy in infants and children as well.

Other causes of metabolic coma in the pediatric age group include kidney or hepatic failure, both of which may result in progressive apathy, confusion, and lethargy. Urea cycle defects may present with coma and hyperammonemia in young infants. Acute toxic encephalopathy (Reye syndrome) is a rare but devastating illness caused by mitochondrial injury of unknown origin that affects all organs of the body, particularly the brain and liver (see Chapter 83). An epidemiologic association exists between the disorder and an antecedent viral illness (including varicella) from which a patient is recovering. Patients with Reye syndrome typically develop severe vomiting, followed by combative delirium that progresses to coma. Cerebral edema, increased ICP, and central herniation may occur with typically poor outcome.

Miscellaneous Conditions

Other causes of coma or depressed LOC in children are less easily categorized. Children with intussusception, the most common cause of bowel obstruction in childhood, may have significant apathy and lethargy in addition to vomiting, intermittent abdominal pain, and bloody stools. As a result, they are often treated for dehydration, sepsis, or meningitis before the appropriate diagnosis is discovered. The presence of “currant jelly” stools or a palpable abdominal mass suggests this condition.

Psychiatric disorders may produce a true stuporous state. More commonly, neurologically intact patients attempt to feign unresponsiveness for reasons known only to them, and they may be remarkably successful at remaining immobile despite painful stimuli. The nature of their “impairment” may be discovered by a detailed neurologic examination. Conscious patients will usually avoid hitting their face with a dropped arm, may resist eyelid opening, will raise their heart rate to auditory or painful stimuli, and will have intact deep tendon, oculovestibular, and oculocephalic reflexes.

A useful acronym incorporating the common causes of coma in children has been proposed by Schunk and is listed in Table 13.5; the acronym is based on the names of childhood immunizations: DPT (for *d*ehydration, *p*oisoning, *t*rauma), OPV (*o*ccult trauma, *p*ostictal or *p*ostanoxia, *v*entriculoperitoneal shunt problem), HIB (*h*ypoxia or *h*yperthermia, *i*ntussusception, *b*rain masses), and MMR (*m*eningitis or encephalitis, *m*etabolic, *R*eye syndrome, other *r*arities).

DPT
*D*ehydration
*P*oisoning
*T*rauma
OPV
*O*ccult trauma
*P*ostictal or *p*ostanoxia
*V*entriculoperitoneal shunt problem
HIB
*H*ypoxia or *h*yperthermia
*I*ntussusception
*B*rain masses
MMR
*M*eningitis or encephalitis
*M*etabolic
*R*eye syndrome, other *r*arities

Modified from Schunk JE. The pediatric patient with altered level of consciousness: remember your “immunizations.” J Emerg Nurs 1992;18:419–421.

Table 13.5. Mnemonic for Causes of Coma

EVALUATION AND DECISION

An approach for the evaluation of pediatric patients presenting with coma is summarized in Figure 13.2. All patients need rapid assessment of their airway, breathing, and circulation, followed by a focused history, physical examination, and consideration of laboratory and imaging studies. This approach is based on the selective use of the following critical clinical and laboratory findings: 1) vital signs; 2) a history of recent head trauma, seizure activity, or ingestion; 3) signs of increased ICP or focal neurologic abnormality; 4) fever; 5) laboratory results; 6) brain CT scan results; and 7) CSF analysis. The evaluation of the comatose patient should follow an orderly series of steps, addressing the more life-threatening problems of hypoxia, hypotension, and increased ICP before progressing to the investigation of less urgent disorders. If one or more of the former are present, immediate resuscitative efforts are begun.

FIGURE 13.2. Evaluation of the comatose child.

History and Physical Examination

Although open-ended questions have merit in medicine, goal-directed questioning pertaining to suspected diagnoses are required in cases of coma of unknown origin. Specific queries regarding current medications, medications available to ingest, seizures, fever, headache, irritability, vomiting, changes in gait, and behavioral abnormalities should be made. The most important historical finding in a comatose patient is a history of recent head trauma. If no history of head trauma is present, it should be considered as a cause of ALOC if a pediatric patient was unsupervised at any time within 24 hours of presentation, if all caregivers are not available, or if the veracity of caregivers is questionable.

A patient's vital signs will reveal the presence of fever, hypotension, or hypertension. The LOC of a neurologically impaired patient may initially be evaluated using a simple AVPU scale, representing four major levels of alertness: *a*lert, responsive to *v*erbal stimuli, responsive to *p*ainful stimuli, and *u*nresponsive. Elements of a more detailed neurologic

evaluation are discussed in the following section.

The patient should be carefully examined for physical findings consistent with head trauma, including retinal hemorrhage, hemotympanum, CSF otorrhea or rhinorrhea, postauricular hematoma (Battle's sign), palpable or visual damage to scalp or skull, and periorbital hematoma (“raccoon eyes”). Child abuse should be suspected if unexplained bruising is present or the stated mechanism of injury is disproportionate to the degree of physical damage present. Other significant physical findings include anisocoria, no pupil reactivity, papilledema, and nuchal rigidity. Purpuric or varicelliform rashes may signify the presence of systemic infections with CNS involvement. Incontinence of urine or stool may indicate that an unwitnessed seizure has occurred.

Neurologic Examination and Scoring

The neurologic examination of the comatose patient should include standard tests of eye opening, responsiveness to verbal and tactile stimuli, and deep tendon reflexes, as well as the more specialized examinations described below. Any focal (unilateral) abnormal finding is always significant because it may indicate a structural CNS lesion. Abnormal findings on neurologic examination reflect the underlying pathologic condition causing coma and may allow localization of a lesion within the brain.

Patients with ALOC benefit from quantification of their impairment using standard measurements. This allows evaluation of patients' changing neurologic status over time and the recording of this information in the medical record. The effect of medical interventions may then be more easily assessed. The use of accepted scoring systems also facilitates communication with consultants such as neurologists and neurosurgeons. In addition, many outcome measures of neurologically injured patients rely upon scales used to assess neurologic function. A widely used measurement of consciousness is the Glasgow Coma Scale (GCS) shown in Table 13.1. Patients are graded on three areas of neurologic function: eye opening, motor responses, and verbal responsiveness. A GCS score of 3 is the minimum score possible and represents complete unresponsiveness; a GCS score of 15 is assigned to fully alert patients.

Pupillary responses provide the most direct window to the brain of a comatose patient. A unilaterally enlarging pupil (greater than 5 mm) that becomes progressively less reactive to light indicates either progressive displacement of the midbrain or medial temporal lobe, or downward displacement of the upper brainstem. Bilateral enlarged and unreactive (“blown”) pupils indicate massive CNS dysfunction and are most commonly seen with posttraumatic increases in ICP. Conditions affecting the brain diffusely usually spare pupillary responses. Exceptions include opiate intoxication, which may cause pinpoint pupils whose constriction is so subtle it may be detected only with an ophthalmoscope. Intoxication with substances having anticholinergic effects, such as scopolamine, is accompanied by widely dilated pupils that may not react to light.

Other ocular signs noted in patients with depressed LOC are the roving side-to-side conjugate eye movements seen in lighter stages of metabolic coma. Persistent conjugate deviation of the eyes to one side may be caused by focal seizure activity, its resultant postictal state, or focal lesions within the brain. Ongoing seizure activity is usually apparent because of the jerking ocular movements present. Most structural brainstem lesions abolish conjugate eye movements, but it is rare for a metabolic disorder to do so. Oculocephalic reflexes (doll's eye movements) consist of conjugate turning of the eyes in the direction opposite brisk head rotation. They should not be checked in any patient who has suffered a traumatic injury because the cervical spine injury may be exacerbated. In the comatose patient, the presence of this reflex implies an intact brainstem and cranial nerves. Deepening ALOC may also be measured by the reduction and loss of spontaneous blinking, then loss of blinking caused by touching the eyelashes, and finally loss of blink with corneal touch. Both eyes should always be tested to detect asymmetry. Neurologically normal patients with 30 degrees of head elevation exhibit an oculovestibular (caloric) response to irrigation of each ear with 10 mL of ice water, consisting of slow conjugate deviation of the eyes toward the irrigated ear with fast beats of nystagmus away from that side. Comatose patients with intact brainstem lose the nystagmic component and have eyes that remain deviated toward the irrigated side for several minutes.

Limb movement and postural changes seen in comatose patients include the bilateral restless movements of the limbs of patients in light coma. Unilateral jerking muscular movements may indicate focal seizure activity or generalized convulsions in a patient with hemiparesis. Decerebrate rigidity refers to stiff extension of limbs with internal rotation of the arms and plantar flexion of the feet. It is not a posture that is held constantly; it usually occurs intermittently in patients with midbrain compression, cerebellar lesions, or metabolic disorders. Decorticate rigidity, when arms are held in flexion and adduction and legs are extended, indicates CNS dysfunction at a higher anatomic level, usually in cerebral white matter or internal capsule and thalamus. Signs of meningeal irritation include Kernig's sign, resistance to bent knee extension with the hip in 90 degrees flexion, and Brudzinski's sign, involuntary knee and hip flexion with passive neck flexion.

The abnormal breathing pattern most commonly seen in comatose patients is Cheyne-Stokes respirations, where intervals of waxing and waning hyperpnea alternate with short periods of apnea. Other abnormal breathing patterns that occur with brainstem lesions include central neurogenic hyperventilation, which can produce a respiratory alkalosis, and apneustic breathing, in which a 2- to 3-second pause occurs during each full inspiration.

Laboratory and Radiologic Studies

Laboratory tests commonly obtained on comatose patients include electrolytes, blood urea nitrogen, creatinine, glucose, blood gases, hemoglobin, hematocrit, and anticonvulsant levels. Toxicologic screening of both blood and urine should be obtained in patients with ALOC of unknown origin. If bedside glucose determination is available, it should be performed on every patient with nontraumatic ALOC. Comatose patients need intravenous access, and laboratory tests may often be obtained at the time of intravenous catheter placement. A noncontrast CT scan of the brain can reveal many of the lesions associated with coma, such as cerebral edema, hydrocephalus, malignancy, hematomas, and abscesses. Infarction and thromboses may require the additions of contrast or the use of magnetic resonance imaging (MRI)

scanning to be fully defined.

Vital Sign Abnormalities

Evaluation and treatment of airway, breathing, and circulatory compromise always take precedence over neurologic problems in the child with ALOC. Airway patency and respiratory effort are both compromised by decreased mental status and may result in hypoxia and/or hypercarbia. The former may be readily measured using pulse oximetry, although values will be inaccurate if a toxic hemoglobinopathy, such as methemoglobinemia or carboxyhemoglobinemia, is present. Hypoxia is usually evident by cyanosis of the lips and nailbeds and pulse oximetry values below 90% (see Chapter 16). Arterial blood gas analysis is useful in some cases to quantify respiratory status and to identify altered hemoglobin states. The treatment of hypoxia, regardless of the cause, always begins with supplemental oxygen administered via an appropriate route.

The numerical definition of hypotension varies with age, but pallor and evidence of poor peripheral perfusion, with capillary refill time greater than 4 seconds, is recognizable even before placement of a sphygmomanometer cuff. Immediate administration of intravenous crystalloid therapy starting with 20 mL/kg of normal saline or lactated Ringer's solution is indicated, followed by additional boluses and pressors if needed (see Chapter 3). Efforts should be made during IV placement to draw blood for laboratory tests. Of the empiric antidotal therapies often used in adults, only glucose 0.25 to 0.5 g/kg is routinely administered to children; an empiric trial of naloxone (1 to 2 mg) is often justified, whereas flumazenil and thiamine are given only when specific indications for their use exist (see Chapter 88).

Severe hypertension is less easily discerned on physical examination. If confirmed in more than one extremity, antihypertensives should be administered via the intravenous or sublingual route (see Chapter 35 and Chapter 86). Mental status should improve after blood pressure is lowered to high normal levels. Patients in hypertensive crises are at risk for hemorrhagic stroke and should be evaluated with a head CT scan if they are neurologically abnormal after blood pressure lowering. Note that hypertension in the comatose patient with increased ICP may represent a physiologic response to maintain cerebral perfusion pressure (by raising mean arterial pressure) and in this context should not be treated with antihypertensives.

Hypothermia and hyperthermia are readily recognized once a core (rectal) temperature less than 35°C or greater than 41°C are obtained. The mental status of these patients should begin to improve as body temperature approaches the normal range. A significant percentage of patients with abnormal core temperatures have drowned, fallen through ice, or were engaged in sporting activities in extreme environments. Head trauma, hypoxia, and/or cervical spine injury may be present in these patients.

History of Head Trauma

The patient with deeply depressed consciousness (GCS score less than 9) after head trauma is presumed to have increased ICP until proven otherwise. Rapid sequence intubation with 1 mg/kg of lidocaine added to standard paralytics and sedatives to blunt rises in ICP caused by laryngeal manipulation is indicated. Cervical spine injury should be assumed and cervical immobilization maintained at all times. An emergent noncontrast brain CT scan should be obtained and neurosurgery consulted.

History of Seizures

The patient with ALOC in the absence of trauma should be evaluated for recent seizure activity with current postictal state (see Chapter 70 and Chapter 83). A history of previous seizures, witnessed convulsive activity, and ALOC consistent with previous postictal periods are valuable clues to this etiology of coma. Ongoing seizure activity may be revealed by the presence of muscular twitching, nystagmus, or fluttering of the eyelids. Subtle forms of status epilepticus may require an electroencephalogram (EEG), to diagnose usually performed somewhat later in the evaluation. The mental status examination of the postictal patient should gradually improve over several hours. Although temporary focal neurologic deficits may follow seizures of any cause, they must be presumed to indicate the presence of focal CNS lesions until proven otherwise or resolved.

The evaluation of neurologically depressed patients with seizures varies based on the patient's history, type of seizure, and presence or absence of fever. Patients with a history of seizures should have serum anticonvulsant concentrations measured and be observed until they approach their neurologic baseline. Children who have had a simple febrile seizure (see Chapter 70) should return to their baseline state soon, usually within 1 hour. Those who remain lethargic or irritable past this point (especially after antipyretics have been administered) should be suspected of having meningitis and are candidates for lumbar puncture. Patients with new-onset generalized seizures who do not meet criteria for simple febrile seizures (see Chapter 28, Chapter 70, and Chapter 83) require more extensive evaluation, which may include measurements of electrolytes (especially sodium, glucose, and calcium), toxicologic screening, examination of CSF, and neurology consultation.

The new onset of focal seizures, with or without the presence of fever, should be evaluated with a head CT scan (using contrast when indicated) to determine the presence of a focal lesion such as a tumor, abscess, or hemorrhage. Only after the results of this study are known should a lumbar puncture be performed. If neuroimaging is unavailable and meningitis or encephalitis is a concern, empiric treatment for bacterial meningitis or herpetic encephalitis may be administered and lumbar puncture deferred (see Chapter 84).

History of Toxic Ingestions

If no history or physical examination findings suggestive of head trauma or seizures are present, a toxic ingestion should be considered, especially in toddlers and adolescents. The availability in the home of any substances capable of depressing CNS function should be thoroughly explored. In general, coma from toxic ingestions is of slower onset than

that from trauma and may be preceded by delirium or other abnormal behaviors.

Chapter 88 lists major toxidromes that result from ingestions that produce CNS depression. The pupils of a poisoned comatose patient are a particularly valuable source of information. Miosis occurs with ingestions of narcotics, clonidine, organophosphates, phencyclidine, phenothiazines, and occasionally, barbiturates and ethanol. Mydriasis is produced by ingestions of anticholinergic agents (e.g., atropine, antihistamines, and tricyclic antidepressants) and sympathomimetic compounds (e.g., amphetamines, caffeine, cocaine, LSD, and nicotine). Nystagmus may indicate the ingestion of barbiturates, ketamine, phencyclidine, or phenytoin. Pupillary responses are more likely to be preserved in toxic or metabolic comas. Systemic toxins do not cause unequal pupils; anisocoria should be pursued with neuroimaging.

A toxicologic screen of blood and urine should be considered in all children with coma of unknown origin. Specific assays for other chemicals may be ordered as suspected. A serum acetaminophen level should be ordered in all children with significant ingestions. Table 13.6 lists compounds capable of causing coma that are not typically detected by drug screening; the compounds are grouped by pupillary effects.

Miosis Present
Clonidine
Chloral hydrate
Organophosphates
Tetrahydrozoline
Bromide
Mydriasis Present
Carbon monoxide
Cyanide
Methemoglobinemia
LSD

Table 13.6. Poisons Undetected by Drug Screening That Cause Coma

The poisoned patient with depressed consciousness should be intubated with a cuffed endotracheal tube for airway protection before decontamination efforts are made. Ipecac-induced emesis is never indicated in the patient with depressed consciousness. Naloxone may be administered as empiric antidotal therapy for coma-producing toxic ingestions involving unknown medications. Flumazenil should not be given to these patients because seizures may result. Its use is limited to pure benzodiazepine overdoses in patients with no history of seizures.

Increased Intracranial Pressure or Focal Neurologic Defect

Nontraumatic causes of increased ICP or focal neurologic deficits include neoplasms, CSF shunt malfunction, and hemorrhage secondary to cerebrovascular disease (see Chapter 83). These patients may present with a history of headache, vomiting, confusion, lethargy, meningismus, focal neurologic dysfunction, seizure activity, or deep coma. Initial physical signs of increased ICP include a bulging fontanelle in infants and sluggishly reactive pupils. More severe and prolonged increases in ICP produce a unilaterally enlarged pupil, other cranial nerve palsies (III, IV, VI), papilledema, and Cushing's triad of hypertension, bradycardia, and periodic breathing. All may signal impending or progressive herniation. From the standpoint of the emergency physician, which type of herniation is present is unimportant; all are life-threatening, and the initial treatment is identical for all. Endotracheal intubation using rapid sequence induction (with cervical immobilization) is performed to minimize increases in ICP while gaining airway control. Evaluation should parallel that of the patient with a traumatic head injury, with the only change being the increased desirability of using intravenous contrast during CT scan. Urgent neurosurgical consultation is recommended for all patients in this category regardless of the focality of findings on CT scan. Comatose patients with a CSF shunt may need their shunt reservoir or ventricle tapped to decrease ICP.

Fever

Coma accompanied by fever indicates that CNS infection may be present (see Chapter 28 and Chapter 84). Resistance to neck flexion is the most important physical finding in meningitis, the most common infection of this type, although children less than 2 years of age may lack this finding. Historical data may also include a steadily increasing headache, irritability, vomiting, and worsening oral intake. Kernig's and Brudzinski's signs may be present. Other useful physical clues to CNS infection are the rashes that accompany meningococcemia, varicella, and Rocky Mountain spotted fever. The historical and physical findings in encephalitis are similar to those in meningitis; meningismus may be absent, however. Seizures are particularly common if herpes simplex is the causative agent.

A history of localized CNS dysfunction or seizures before the onset of febrile coma or the presence of concomitant focal neurologic signs may indicate the presence of a focal cerebral infection such as an abscess, granuloma, or subdural empyema. In addition, either diffuse or focal infections may present with signs of increased ICP secondary to abscess formation, cerebral edema, or blockage of CSF flow. If this is the case, a head CT scan should be obtained before lumbar puncture is performed. A contrast-enhanced study is desirable if concern about focal infection is present. The ill-appearing patient should receive antibiotics before neuroimaging is performed.

CSF analysis remains the key to establishing the diagnosis of CNS infection. Abnormalities of CSF white blood cell count (pleocytosis), glucose, and protein occur in roughly predicable patterns with bacterial or viral meningitis, and pathogens may be visible using Gram and other stains (see Chapter 84). CSF pleocytosis in encephalitis is variable and, if present, is usually mild (less than 500 cells/mm^3), with normal levels of glucose and protein being common. CSF in herpes simplex

encephalitis contains red blood cells in 50% of cases. Bloody or xanthochromic CSF under increased pressure in the absence of signs of infection indicates subarachnoid hemorrhage.

Metabolic Abnormalities

The presence of a metabolic disorder leading to coma is usually apparent once the results of routine laboratory tests are available. These values for glucose, sodium, potassium, bicarbonate, calcium, magnesium, and phosphorus make any deficiency or excess of these serum components readily apparent and treatable. Blood gas analysis for evaluation of acidosis or alkalosis from metabolic or respiratory causes may be indicated as well. Decreased LOC caused by diabetic ketoacidosis may initially worsen because of a paradoxical temporary decrease in CSF pH and/or cerebral edema complicating therapy.

Renal and hepatic function should be quantified with analysis of blood urea nitrogen, creatinine, and ammonia. Markedly elevated serum blood urea nitrogen and creatinine, oliguria, hypertension, anemia, acidosis, and hypocalcemia indicate the presence of uremic coma as a result of renal failure. Hyperammonemia with decreased mental status is most commonly caused by hepatic failure, acetaminophen ingestion with resultant hepatotoxicity, and Reye syndrome. The hyperammonemia of Reye syndrome is accompanied by a history of antecedent viral illness (possibly varicella), resolving within the past week, and likely treated with aspirin (see Chapter 83). Encephalopathy begins soon after unremitting vomiting; jaundice, scleral icterus, focal neurologic signs, and meningeal irritation are absent. Hyperammonemia without accompanying liver failure in the young infant may indicate the presence of a congenital urea cycle defect.

Coma of Unknown Origin

Patients with coma of unknown origin not falling into any of the diagnostic categories discussed previously usually benefit from a noncontrast brain CT scan, CSF analysis, and neurologic consultation, in that order. If meningeal irritation is present without fever or other signs of infection, a subarachnoid hemorrhage may be the cause. Common avoidable errors in the evaluation and management of children with coma are listed in Table 13.7. Patients presenting in a comatose state usually need admission for continuing treatment, observation, and specialized care, except when there is an easily recognized and reversible cause, such as hypoglycemia in a known diabetic.

Assuming no head trauma has taken place if no such history is given
Neglecting to secure the airway before imaging studies are performed
Hyperventilating intubated patients to a Pco_2 well below 35 mm Hg
Not sedating patients once they are paralyzed
Believing that a toxic ingestion has not occurred because the "tox screen" is negative

CHAPTER 14

Constipation

[*]JONATHAN MARKOWITZ, MD and [†]STEPHEN LUDWIG, MD

[* †]*Department of Pediatrics and Emergency Medicine, The University of Pennsylvania School of Medicine, and* [*]*Departments of Gastroenterology and Nutrition, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania*

Constipation is an important problem in the pediatric emergency department for many reasons. It is one of the most common pediatric complaints, accounting for 3% of primary care visits. There are many causes for constipation (Table 14.1), some rare and some very common (Table 14.2). Occasionally, the presentation of constipation is atypical, with chief complaints that superficially seem unrelated to the gastrointestinal tract (Table 14.3). Although relatively rare, some causes of constipation are potentially life-threatening and need to be recognized promptly by the emergency physician (Table 14.4). In addition, constipation may produce symptoms that mimic other serious illnesses such as appendicitis.

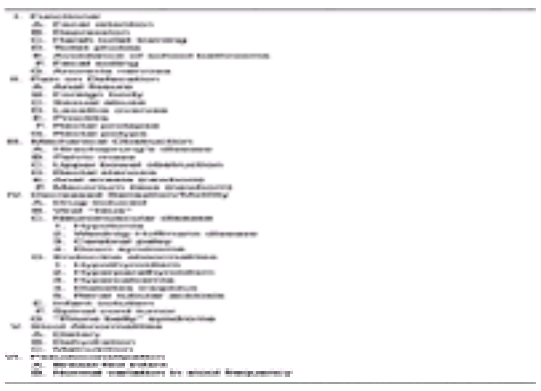

Table 14.1. Etiology of Constipation

Table 14.3. Some Atypical Presentations of Constipation

Acute Constipation	Chronic Constipation
Mechanical obstruction	Hirschsprung's disease
Dehydration	
Infantile botulism	

Table 14.4. Life-Threatening Causes of Constipation

DEFINITION

Although constipation most commonly is defined as decreased stool frequency, there is not one simple definition. The stooling pattern of children changes based on age, diet, and other factors. Average stooling frequency in infants is approximately 4 stools per day during the first week of life, decreasing to 1.7 stools per day by 2 years of age, and approaching the adult frequency of 1.2 stools per day by 4 years of age. Nevertheless, normal infants can range from 7 stools per day to 1 stool per week. Older children can defecate every 2 to 3 days and be normal.

It is easier to define constipation as a problem with defecation. This may encompass infrequent stooling, passage of large and/or hard stools associated with pain, incomplete evacuation of rectal contents, involuntary soiling (called encopresis), or inability to pass stool at all.

PHYSIOLOGY

The passage of food from mouth to anus is a complex process. The intestine relies on input from intrinsic nerves, extrinsic nerves, and hormones to function properly. Normal defecation involves voluntary and involuntary components. Disruption of any of these can result in constipation.

The colon is specialized to transport fecal material and balance water and electrolytes contained in the feces. When all is functioning well, the fecal bolus arrives in the rectum formed but soft enough for easy passage through the anus.

Normal defecation requires the coordination of the autonomic and somatic nervous systems and normal anatomy of the anorectal region. The internal anal sphincter is smooth muscle, which is innervated by the autonomic nervous system. It is tonically contracted at baseline. It relaxes in response to the arrival of a fecal bolus in the rectum, allowing stool to descend to the portion of the anus innervated by somatic nerves. At this point, the external anal sphincter, striated muscle under voluntary control, tightens until the appropriate time for fecal passage. Before defecation, squatting straightens the angle between the rectum and the anal canal, allowing easier passage. Voluntary relaxation of the external anal sphincter allows passage of the feces, and increasing intra-abdominal pressure via Valsalva aids the process.

EVALUATION AND DECISION

The evaluation of the child presumed to have constipation should begin with a thorough history and physical examination, with special attention paid to changes in frequency and consistency of stool for the individual patient in question. A complaint of constipation is not sufficient. A decrease in stool frequency or the appearance of straining is often interpreted as constipation. The physician should be aware of the grunting baby syndrome in which an infant grunts, turns red, strains, and may cry while passing a soft stool. This is the result of poor coordination between Valsalva and relaxation of the voluntary sphincter muscles. Examination reveals the absence of palpable stool in the rectum or abdomen. Complaints of constipation not supported by history or physical examination are called pseudoconstipation (Fig. 14.1).

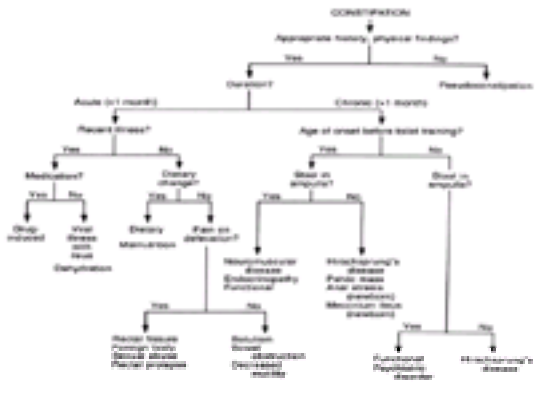

FIGURE 14.1. Approach to constipation.

Acute Constipation

Constipation is not a disease; it is a symptom of a problem. The patient's age and the duration of the constipation are important when determining the cause and significance of the problem. The infant less than 1 year of age with true constipation is particularly concerning.

Constipation of less than 1 month's duration is termed acute. In this case, history will identify many of the problems responsible. A recent viral illness is a common cause of short-lived constipation in the infant. Excessive water loss through vomiting, diarrhea, fever, and increased respiratory rate may cause hard stools. Adynamic ileus or decreased intake after gastroenteritis may cause slower transit time through the colon, and anal fissures after a bout of diarrhea may precipitate painful defecation, resulting in stool retention. The infant may be noted to assume a retentive posture consisting of extension of the body with contraction of the gluteal and anal muscles.

Excessive intake of cow's milk, inadequate fluid intake, and malnutrition should all be uncovered by a complete diet history. Recent courses of medication cannot be overlooked because many can cause constipation (Table 14.5). Ingestion of lead is also a potential and serious reason for constipation.

Aluminum	Iron
Amiodarone	Mesalamine
Amitriptyline	Omeprazole
Anticholinergic agents (benztropine, glycopyrrolate, promethazine)	Ondansetron
	Opioids
Antineoplastic agents (procarbazine, vincristine)	Phenobarbitol
	Phenothiazines and derivatives (prochlorperszine, promethazine, haloperidol)
Benzodiazepines	
β-Blockers	
Calcium salts	Phenytoin
Calcium-channel blockers	Ranitidine
Cholestyramine	Sucralfate
Diazoxide	Ursodiol

Table 14.5. Some Medications Associated with Constipation

Acute constipation can be caused by bowel obstruction, but it is normally a less prominent feature than other symptoms. Infantile botulism commonly presents with constipation, weak cry, poor feeding, and decreasing muscle tone.

Simple constipation in an infant should be treated initially with dietary changes (Table 14.6). Decreasing consumption of cow's milk and increasing fluid intake when appropriate may be enough to alleviate the symptoms. If not improved, constipation can be treated by supplementing the diet with barley malt (Maltsupex) or Karo syrup. Stool lubricants such as mineral oil can be administered orally when aspiration is not a concern. Good perianal care will eliminate stool retention from painful defecation. Follow-up is the most important aspect of treating simple constipation.

I. Dietary Change	IV. Lubricants
A. Increase fluids	A. Mineral oil (1-2 oz BID)
B. Increase carbohydrates (corn sugar syrup, Karo)	B. Kondremul
	C. Milkinol
C. Barley malt (Maltsupex)	V. Local Rectal Care
D. Bran and other fiber	A. Sitz baths
II. Bulk Stool Softeners	B. Vaseline ointment/A&D Ointment
A. Metamucil	
B. Hydrocil	VI. Other Important Treatments
C. Naturacil	A. Patient/parent education
III. Cleansing Enemas/Cathartics	B. Set bathroom time after meal
A. Hypertonic phosphate enema (Fleet) (1–3 only)	C. Proper size toilet with foot support
B. Polyethylene glycol—electrolyte solution (Golytely)	D. Vitamin supplementation
	E. Reward systems/positive reinforcement

Table 14.6. Treatment Steps for Functional Constipation

Acute constipation in the child older than 1 year of age occurs for many of the same reasons as in the infant. History may reveal recent viral illness or use of medication, as well as the presence of underlying illness, such as neuromuscular disease. Physical examination suffices to rule out anal malformations and other physical problems that could result in trouble defecating. Therapy for functional constipation should be the same as that for the infant, with dietary changes a mainstay; however, attention should also be paid to psychological factors such as recent stress that may be complicating the situation.

Chronic Constipation

Constipation of more than 1 month's duration in an infant is especially concerning. Spinal muscular atrophy, amyotonia, congenital absence of abdominal muscles, dystonic states, and spinal dysraphism, which cause problems with

defecation, can be readily diagnosed with history and physical examination.

Anorectal anomalies occur in approximately 1 in 2500 live births. Anal stenosis causes the passage of ribbonlike stools with intense effort. Diagnosis is made by anal examination, which demonstrates a tight, constricted canal. The condition is treated by repeated anal dilations, sometimes over several months. The anus can be covered by a flap of skin, leaving only a portion open for passage of stool. This “covered anus” may require anoplasty with dilation. Anterior displacement of the anus is thought to cause constipation by creating a pouch at the posterior portion of the distal rectum that catches the stool and allows only overflow to be expelled after great straining. The treatment may be medical or surgical.

Hirschsprung's disease, or congenital intestinal aganglionosis, is rare but must be considered in the constipated infant because it has the potential to cause life-threatening complications. The incidence is 1 in 5000 live births, with a male:female predominance of 4:1. As a result of failure of migration of ganglion cell precursors along the gastrointestinal tract, there is the absence of ganglion cells in the submucosal and myenteric plexuses of the affected segment. The absence of ganglion cells leaves the affected segment tonically contracted, blocking passage of stool. The segment proximal to the blockage dilates as the buildup of stool progresses. In most cases, the child never feels the urge to defecate because the blockage is proximal to the internal sphincter and anal canal.

In Hirschsprung's disease, abdominal examination often yields a suprapubic mass of stool that may extend throughout the abdomen. Rectal examination reveals a constricted anal canal with the absence of stool in the rectal vault, commonly followed by expulsion of stool when the finger is removed. The combination of palpable abdominal feces and an empty rectal vault is abnormal and must be further investigated.

Megacolon in Hirschsprung's disease can lead to enterocolitis characterized by abdominal distension; explosive stools, which are sometimes bloody; and fever progressing to sepsis and hypovolemic shock. Enterocolitis represents a major cause of mortality in this condition.

Of infants with Hirschsprung's disease, 80% are diagnosed within the first year of life. A history of late passage of meconium is often found (Table 14.7). However, if the involved segment is relatively short, the diagnosis may be delayed. If suspected, diagnosis is supported by unprepped barium enema, which typically demonstrates narrow bowel rapidly expanding to a dilated area. This transition zone represents the location where the aganglionic, tonically contracted bowel meets the dilated, innervated bowel. In disease where only a short segment of bowel is involved, barium enema may miss the transition zone and anal manometry aids in diagnosis. Confirmation is achieved by demonstration of aganglionosis on biopsy.

	Hirschsprung's	Functional
Onset in infancy	Common	Rare
Delayed passage of meconium	Common	Rare
Painful defecation	Rare	Common
Stool-withholding behavior	Rare	Common
Soiling	Rare	Common
Stool in rectal vault	Rare	Common
Failure to thrive	Common	Rare

Table 14.7. Findings in Hirschsprung's Disease and Functional Constipation

Hypothyroidism in the infant may present with constipation. Water-losing disorders such as diabetes insipidus and renal tubular acidosis may also contribute to this condition. Particularly among whites, cystic fibrosis merits consideration because it may lead to inspissated meconium or stool, presenting as constipation.

Chronic constipation in the older child is overwhelmingly likely to be functional constipation. Typically, a cycle of stool-withholding starts when the child disregards the signal to defecate and strikes a retentive posture—rising on the toes and stiffening the legs and buttocks. This maneuver forces the stool out of the anal canal and back into the rectum, which subjects the fecal bolus to further absorption of water. The longer the stool sits, the more likely defecation is to be painful and traumatic. This reinforces stool-withholding behavior, creating larger and harder stool in the rectum.

Over time in functional constipation, the rectum dilates and sensation diminishes. Eventually, the child loses the urge to defecate altogether. Watery stool from higher in the gastrointestinal tract can leak around the large fecal mass, causing involuntary soiling, or encopresis. This may be misconstrued as diarrhea or as regression in the toilet-trained child. Many parents consult a physician at this point. Other reasons parents seek medical attention for their children are abdominal pain, anorexia, vomiting, and irritability.

Peak times for constipation to develop are when routines change. Toilet training represents a major alteration in the toddler's routine. It also is a time when the child and caregiver battle for control. Another problematic time is after starting school, when a child may be uncomfortable using an unfamiliar bathroom or unable to adapt to a lack of privacy. Involvement with friends or games may distract a child from the signal to defecate. Painful defecation from streptococcal perianal disease or sexual abuse must be remembered as potential precipitants of stool-withholding.

A history supportive of functional constipation includes retentive posturing, infrequent passage of very large stools, and involuntary soiling during the peak ages. Physical examination normally reveals palpable stool in the abdomen. The back

should be inspected for skin changes over the sacral area that suggest spinal dysraphism. Normal deep tendon reflexes and strength in the lower extremities in conjunction with a normal anal-wink reflex virtually excludes neurologic impairment. The anus should be normal in placement and appearance. Rectal examination typically yields a dilated vault filled with stool. Abdominal flatplate can be helpful but is not necessary. Failure to thrive is not associated with functional constipation and, if present, should prompt further investigation.

The patient with functional constipation needs no further evaluation before induction of therapy. Treatment (Table 14.6) begins with evacuation of the stool remaining in the bowel. This is most readily accomplished with hypertonic phosphate (Fleet) enemas. A mineral oil enema administered the night before the first phosphate enema may soften existing stool, allowing less painful passage. The phosphate enemas should be given in doses of 3 mL/kg and administered as pairs 1 hour apart every 12 hours until clear. If there is no response after 2 days, more aggressive disimpaction under physician supervision is indicated. Phosphate enemas should be used with caution in patients with renal impairment. Tap water and soapsuds enemas should be avoided because of the possibility of water intoxication.

A lubricant such as mineral oil should be given orally in a dose adequate to overcome stool retention. Fat-soluble vitamins need to be supplemented during this phase of treatment. Reeducation of bowel habits is vital. Toilet training should be discontinued in the toddler. Regular toileting should be encouraged with positive reinforcement in the school-age child. Close follow-up is a mainstay of treatment. Successful therapy may take months to years to complete.

Although functional constipation encompasses most cases of chronic constipation in the child more than 1 year old, the less common causes must always be considered.

As in the infant, endocrine abnormalities can cause and present as constipation. Hypothyroidism is often associated with constipation, as well as with sluggishness, somnolence, hypothermia, weight gain, and peripheral edema. Increased serum calcium causes constipation through decreased peristalsis. Causes include hyperparathyroidism and hypervitaminosis D. Diabetes mellitus produces increased urinary water loss, possibly leading to harder stool.

Rarely, an abdominal or pelvic mass may present with chronic constipation. Careful abdominal examination will demonstrate the mass. Rectal masses may present similarly. Follow-up again is emphasized because a mass that does not resolve after clearance of impaction needs further evaluation. Hydrometrocolpos can present with constipation and urinary frequency; therefore, a genital examination is indicated in girls to document a perforated hymen. One must also remember that intrauterine pregnancy is a common cause of pelvic mass and constipation in adolescent girls.

Children with neuromuscular disorders often develop constipation. Myasthenia gravis, the muscular dystrophies, and other dystonic states can predispose children to constipation through a number of mechanisms. A detailed history and physical examination should recognize most neuromuscular problems, allowing symptomatic treatment to be provided.

Psychiatric problems must not be forgotten in the evaluation of constipation. Depression can be associated with constipation secondary to decreased intake, irregular diet, and decreased activity. Many psychotropic drugs can cause constipation. Anorexia nervosa may present with constipation because of decreased intake or metabolic abnormalities, and laxative abuse can cause paradoxical constipation.

CHAPTER 15

Cough

RICHARD BACHUR, MD

Department of Medicine, Harvard Medical School, and Division of Emergency Medicine, Children's Hospital, Boston, Massachusetts

Cough is a common pediatric complaint with a variety of causes. Although cough is usually a self-limited symptom associated with upper respiratory illnesses, it occasionally indicates a more serious process. Under most circumstances, history and physical examination can accurately determine the cause.

PATHOPHYSIOLOGY

Cough is a reflex designed to clear the airway. Although a cough can be initiated voluntarily, it is usually elicited by stimulation of receptors located throughout the respiratory tract, from the pharynx to bronchioles. The receptors are triggered by inflammatory, chemical, mechanical, and thermal stimuli. Direct (central) stimulation of a cough center in the brain occurs more rarely. The reflex consists of a forced expiration and sudden opening of the glottis, which rapidly forces air through the airway to expel any mucus or foreign material.

DIFFERENTIAL DIAGNOSIS

The causes of cough differ in the type of stimulus and the site of involvement in the respiratory tract (Table 15.1). The common causes of cough are listed in Table 15.2. Potentially life-threatening causes are listed in Table 15.3.

Infection	*Neoplasm*
Upper respiratory infection	Pharyngeal or nasal polyp
Sinusitis	Hemangioma
Tonsillitis	Papilloma
Laryngitis	Lymphoma
Laryngotracheitis (croup)	Mediastinal tumors
Tracheitis/tracheobronchitis	*Congenital Anomalies*
Bronchiolitis	Cleft palate
Acute bronchitis	Laryngotracheomalacia
Pneumonia	Laryngeal or tracheal webs
Pleuritis	Tracheoesophageal fistula
Bronchiectasis/pulmonary abscess	Vascular ring
Inflammation/Allergy	Pulmonary sequestration
Allergic rhinitis	*Miscellaneous*
Laryngeal edema	Gastroesophageal reflux
Reactive airway disease	Congestive heart failure
Chronic bronchitis	Swallowing dysfunction
Cystic fibrosis	Granulomatous diseases
Mechanical or Chemical Irritation	Psychogenic cough
Foreign body aspiration	Foreign body in otic canal
Neck/chest trauma	
Chemical fumes	
Inhaled particulates	
Smoking	

Table 15.1. Causes of Cough in Children

Upper respiratory infection	Acute bronchitis
Sinusitis	Pneumonia
Laryngotracheitis	Allergic rhinitis
Bronchiolitis	Reactive airway disease

Table 15.2. Common Causes of Cough

Reactive airway disease	Laryngeal edema
Croup	Pertussis
Bronchiolitis	Toxic inhalation
Foreign body	Congestive heart failure
Pneumonia	

Table 15.3. Life-Threatening Causes of Cough

EVALUATION AND DECISION

The history and physical examination are the keys to establishing a diagnosis for cough. The first priority is to recognize and treat any life-threatening conditions: patients with significant respiratory distress should receive supplemental oxygen and rapid assessment of their airway and breathing (Fig. 15.1).

FIGURE 15.1. Approach to the child with cough.

History

Cough can occur as an acute or chronic symptom, depending on the underlying process. Most common and serious causes of cough have an acute onset (Fig. 15.1). Certain conditions, such as asthma, may present with an acute or a chronic history of cough.

The relationship of the cough to other factors is helpful. Cough in the neonate must raise the possibility of congenital anomalies, gastroesophageal reflux, congestive heart failure, and atypical pneumonia (e.g., *Chlamydia*). If the cough began with other upper respiratory tract symptoms or fever, an infectious cause is likely. A cough that started with a choking episode, especially in an older infant or toddler, suggests a foreign body aspiration. Cough associated with exercise or cold exposure, even in the absence of wheezing, may be a sign of reactive airway disease. A primarily nocturnal cough often stems from allergy, sinusitis, or reactive airway disease. Systemic complaints should also be considered in patients with a cough: headache, fever, facial tenderness or pressure (sinusitis), acute dyspnea (asthma, pneumonia, cardiac disease), chest pain (asthma, pleuritis, pneumonia), dysphagia (esophageal foreign body), dysphonia (laryngeal edema or tracheal mass), or weight loss (malignancy or tuberculosis).

The quality of the cough may also be helpful in localizing the process. A barking, seal-like cough with or without stridor supports the diagnosis of laryngotracheitis. A paroxysmal cough associated with an inspiratory “whoop,” cyanosis, or apnea is characteristic of pertussis. Tracheitis gives a deep “brassy” cough, whereas conditions accompanied by wheezing (asthma or bronchiolitis) typically produce a high-pitched “tight” (often termed bronchospastic) cough. Determining whether a cough is productive can be difficult in young children who often swallow, rather than expectorate, their sputum. However, many parents can convey whether the cough is “dry” or “wet.” Although a productive-sounding cough may be seen with uncomplicated upper respiratory infections (URIs), sinusitis and lower respiratory tract infections are commonly accompanied by a productive cough.

Typically, the onset of cough with rhinorrhea suggests a viral URI. However, if a child with an apparent URI becomes more ill or has persistent symptoms, secondary bacterial infections should be considered.

Physical Examination

Patients with a cough require evaluation of the entire respiratory system. Older patients may be able to initiate a typical cough for assessing the quality, and with younger children, gentle gagging with a tongue depressor can trigger a cough. Usually, the cause of the cough can be localized to the upper or lower respiratory tract by the physical examination. Rhinorrhea, congestion, swollen turbinates, sinus tenderness, and pharyngitis are all signs of upper respiratory tract involvement. Allergic features include boggy nasal mucosa, an allergic nasal crease, and allergic “shiners.” An otoscopic exam may reveal a small foreign body (e.g. hair) in the otic canal which may cause chronic cough. Laryngitis and/or

stridor generally imply inflammation or obstruction at the level of the trachea or larynx. Unequal breath sounds, wheezes, rhonchi, and rales are signs of lower respiratory tract disease. A careful cardiac evaluation should be performed, and any clubbing should be noted. Young infants may have respiratory distress with localized upper airway congestion, but older infants and children usually have lower respiratory tract disease if significantly distressed (except in the obvious case of stridor).

Ancillary Studies

In most circumstances of children with a cough, the history and physical examination should be sufficient to make a diagnosis. In patients with unexplained cough or significant or persistent pulmonary signs, a chest radiograph is warranted. In children with an uncomplicated exacerbation of their asthma, a radiograph is unnecessary. If a radiolucent foreign body is suspected, inspiratory and expiratory films or decubitus films should be obtained to detect air trapping (see Chapter 29). Other studies that could be useful in selected patients include sinus films, lateral neck radiographs, barium swallow, and computed tomography of the sinuses, neck, or chest.

In addition, laboratory tests may be necessary for specific diagnoses. Such tests include a complete blood count and differential, blood culture, tuberculin test, nasopharyngeal swab for rapid assays or culture (commonly for pertussis and respiratory syncytial virus), Wright stain of nasal secretions (eosinophils with allergic rhinitis, neutrophils with sinusitis), and sputum culture and Gram stain (neutrophils and Gram-positive diplococci with pneumococcal pneumonia). Pulmonary function testing can be useful to diagnose or follow obstructive airway disease. In cases of airway masses, airway anomalies, foreign bodies, or atypical pneumonias, bronchoscopy may be necessary.

Approach

The major considerations in evaluating a child with cough include the quality of the cough, associated choking or emesis, and the findings of lower respiratory tract signs or fever (Fig. 15.1). Obviously, any child with respiratory distress needs immediate attention to oxygenation and ventilation.

Most patients with cough of acute onset will have a simple upper respiratory tract infection, asthma, bronchiolitis, or pneumonia. A sudden onset with choking or gagging, especially in the preverbal child, is suspicious for a foreign body aspiration (see Chapter 29). A barky cough, with or without stridor, in a child 3 months to 3 years of age suggests laryngotracheitis. Paroxysms of coughing associated with perioral cyanosis, posttussive emesis, or apnea points to pertussis. Visualizing the posterior pharynx with a tongue blade will elicit an episode of coughing.

Physical examination should include inspection of the nares and oropharynx and auscultation of the chest. Wheezing indicates bronchiolitis, asthma, or, rarely, foreign body aspiration. Patients with asthma may complain only of cough and deny any wheezing. Careful auscultation during forced exhalation may detect wheezing or a prolonged expiratory phase. In an older child, significant lower airway obstruction can be measured with a handheld peak flow meter. Asymmetric, or focal, wheezing is seen with lower airway masses and foreign bodies. Rales, rhonchi, and decreased breath sounds are characteristic of lower respiratory tract infection.

The remaining patients with a cough of acute onset will have pneumonia or an upper respiratory tract infection such as viral nasopharyngitis, sinusitis, pharyngitis, or tracheitis. Although rales, decreased breath sounds, or focal wheezing are signs associated with pneumonia, a small proportion of patients with pneumonia may not have any findings by auscultation. Therefore, in cases of significant cough, especially in very young children and those with high fever or elevated white blood cell counts, a chest radiograph is useful to exclude the diagnosis of pneumonia.

Children with chronic cough are likely to have reactive airway disease, allergic rhinitis, or sinusitis. In young children with failure to thrive or recurrent pulmonary infections, cystic fibrosis (see Chapter 96) should be considered. Chronic cough with a history of recurrent pneumonias or chronic bronchitis can also be suggestive of immunodeficiency or anatomic lesions (see Chapter 119). Choking with feeding or emesis followed by cough or wheezing in young infants is typical of gastroesophageal reflux. Newborns who exhibit a cough deserve special consideration for airway anomalies, atypical pneumonias, and congestive heart failure (see Chapter 82). Persistent cough during the day that stops with distraction or sleep is supportive of a psychogenic cause.

TREATMENT

The primary goal should be to treat the underlying process rather than to try to suppress the cough. Patients with any distress need supplemental oxygen and immediate assessment of the airway and breathing. Wheezing from asthma or bronchiolitis is primarily treated with inhaled bronchodilators. In children with suspected reactive airway disease based on history alone, a trial of bronchodilator therapy is warranted. Follow-up with their primary care physician is crucial for establishing a treatment plan. Children with suspected foreign bodies or airway masses (intrinsic or extrinsic to the airway) need appropriate intervention for their removal. Croup treatment consists of mist therapy in mild cases, and racemic epinephrine, steroids, and oxygen for more severe episodes. Treatment of pneumonia depends on the age and suspected pathogen. Patients with pertussis require antibiotics for eradication of the organism, and young infants or any child with significant paroxysms need hospitalization.

Antitussive medications have limited value and should not be used routinely in young infants. It is better to give specific therapy (bronchodilators in asthma, antibiotics with sinusitis) and avoid suppressing a cough in conditions with increased sputum production (e.g., asthma, pneumonia). In older children with a nonproductive cough that interrupts sleep, antitussives can be prescribed. Using cool mist humidifiers and elevating the head during sleep can be beneficial for coughs associated with viral URIs.

CHAPTER 16

Cyanosis

ANNE M. STACK, MD

Department of Pediatrics, Harvard Medical School, and Division of Emergency Medicine, Children's Hospital, Boston, Massachusetts

Cyanosis, a bluish-purple discoloration of the tissues, is a disturbing condition commonly confronted by the pediatric emergency physician. It is most easily appreciated in the lips, nailbeds, earlobes, mucous membranes, and locations where the skin is thin and may be enhanced or obscured by lighting conditions and skin pigmentation.

PATHOPHYSIOLOGY

Three factors that ultimately determine the occurrence of cyanosis are the total amount of hemoglobin (Hb) in the blood, the degree of Hb oxygen saturation or qualitative changes in the Hb, and the state of the circulation.

Oxygenated Hb is bright red, and deoxygenated Hb is purple. Cyanosis is evident when the reduced or deoxygenated Hb in the blood exceeds 5 g/100 mL or when oxygen saturation approaches 85%. When the total amount of Hb in the blood is increased, as in polycythemia, substantial contribution is evident in the overall appearance of the patient from the increased red blood cell mass, and the patient may appear ruddy. The relative increase in the amount of unsaturated Hb in the polycythemic patient will add a blue hue to the skin. Conversely, when the total amount of Hb is decreased, as in anemia, the patient appears pale, and even if Hb is desaturated, cyanosis may not appear.

The degree of Hb saturation is determined by several factors, including the partial pressure of oxygen (P_{O_2}) in the alveolus, the ability of oxygen (O_2) to diffuse across the alveolar epithelial cell wall into the capillary bed and subsequently into the red cell itself, and the Hb molecule. First, because the P_{O_2} in the alveolus is determined by a balance between the amount of O_2 added during alveolar ventilation and that removed by blood flow throughout the alveolar capillary bed, if the level of alveolar ventilation falls, so does the P_{O_2} of alveolar gas, causing a fall in arterial P_{O_2} and desaturation. Second, the ability of O_2 to diffuse across the alveolar wall into the red cell, or gas–blood barrier, is greatly affected by the circumstances of the barrier itself. According to *Fick's law,* the volume of gas per unit time moving across a tissue sheet is directly proportional to the area of the sheet and the difference in partial pressures between the two sides but inversely proportional to the thickness. Any condition that diminishes surface area or increases the thickness will decrease the amount of O_2 in the blood. Third, the Hb molecule itself has unique properties that affect the amount of oxygen it can carry. Although the complexities of Hb and its ability to carry O_2 are beyond the scope of this chapter, to understand cyanosis, it is critical to note that the color of whole blood is in part determined by the state of the Hb molecule. Oxygen binds reversibly to the iron molecule of the Hb subunit, changing its conformation, and oxygenated Hb is bright red. Consequently, factors that affect O_2 binding to Hb will affect the color of the blood. For example, carbon monoxide competitively binds to the ferrous portion of heme, but at an affinity 200 times more than that of oxygen. The change in conformation of Hb with carbon monoxide occupying all the iron in the heme tetramer gives carboxyhemoglobin a cherry red hue, despite the fact that little oxygen is bound to the Hb molecule. In addition, when heme iron is oxidized to the ferric state (it is normally in the ferrous state, even when bound to O_2), known as methemoglobin, it is also incapable of binding O_2. Therefore, Hb will remain deoxygenated, and methemoglobin itself is a brownish-purple color.

The state of the circulation plays an important role in the presence and degree of cyanosis. If a shunt is present, cyanosis can result. A *shunt* is defined as a mechanism by which blood that has not traveled through the ventilated alveolar capillary bed mixes with arterial blood. Deoxygenated blood mixing with oxygenated blood reduces the arterial P_{O_2}, and if the shunt is large, the reduction in P_{O_2} can be severe, leading to marked cyanosis. Another contribution from the state of the circulation on presence of cyanosis concerns blood as it travels through a capillary bed. Oxygen is unloaded to the tissues as blood travels through a capillary, with the relative concentration of unsaturated Hb increasing from one end of the capillary bed to the other. Factors that slow blood flow, such as poor perfusion states and cold temperature, favor the unloading of oxygen and thus increase the amount of unsaturated Hb in the tissue capillaries. A third contribution from the circulation concerns the ratio of blood flow to ventilation within the lung. Simply stated, in an upright lung, the apex is ventilated more than the base, and the base is perfused more than the apex. Because most of the blood flow in the lung then comes from the relatively less ventilated areas of the lung, depression of the blood P_{O_2} is inevitable. In normal healthy subjects, this depression is only a few millimeters of mercury; however, in patients with diseased lungs, the contribution of ventilation/perfusion inequality to lowering of blood P_{O_2} can be significant.

DIFFERENTIAL DIAGNOSIS

The most common causes of cyanosis are cardiac and respiratory diseases that lead to a decrease in the arterial P_{O_2}, but many other conditions can also cause a patient to appear blue (Table 16.1 and Table 16.2). Therefore, consideration of the pathophysiologic framework outlined previously allows an orderly approach to the differential diagnosis of cyanosis. Life-threatening causes of cyanosis are summarized in Table 16.3.

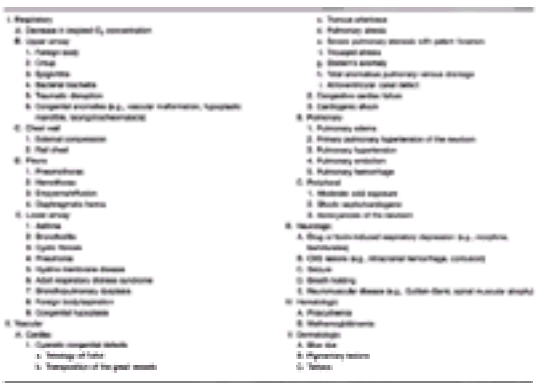

Table 16.1. Causes of Cyanosis

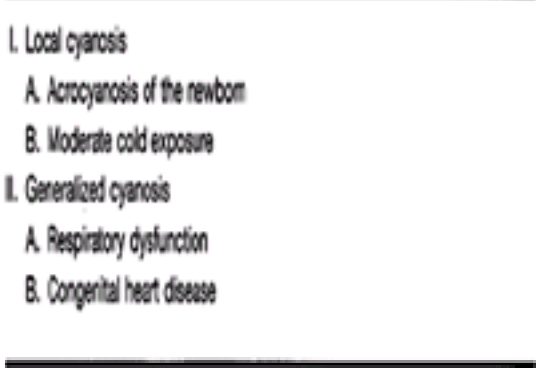

Table 16.2. Common Causes of Cyanosis

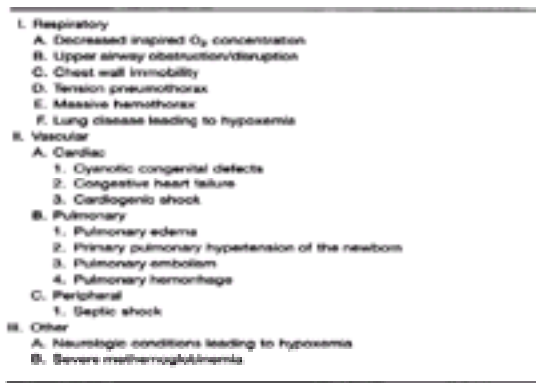

Table 16.3. Life-Threatening Causes of Cyanosis

With regard to the amount of Hb, polycythemia, as in newborns with twin–twin transfusion, infants of diabetic mothers, children with high erythropoietin states, or other conditions associated with increased red cell mass, may give the appearance of cyanosis because of the relative increase in the amount of unsaturated Hb.

The degree of Hb saturation is affected by many factors, which can be grouped conveniently by systems. First is the significant contribution from respiratory conditions. Any circumstance leading to a decrease in the concentration of inspired oxygen, such as a house fire where oxygen is consumed by combustion, confinement to a small unventilated space such as being locked inside a discarded refrigerator, or high altitude, can eventually lead to diminished P_{O_2} and cyanosis. Likewise, upper airway obstruction, as with a foreign body, croup, epiglottitis, bacterial tracheitis, tracheal/bronchial disruption, or congenital airway abnormalities, quickly leads to decreased alveolar ventilation and hypoxemia. Age, events leading to presentation, and examination features, such as barking cough, can help distinguish these. Cyanosis ensues rapidly when chest wall movement or lung inflation is impeded. This condition is often a result of trauma and includes external chest compression, flail chest, or hemothorax. Tension pneumothorax, whether traumatic or as a result of preexisting lung disease such as asthma or cystic fibrosis, is diagnosed by dyspnea, deviated trachea, and possibly distended neck veins with diminished breath sounds on the affected side. Empyema or pleural effusion caused by infection, malignancy, or large chylothorax may be associated with fever, respiratory distress, dullness to percussion, and an asymmetric examination on auscultation. Importantly, any lung dysfunction that directly affects pulmonary gas exchange can lead to cyanosis. The most common conditions in children are asthma, bronchiolitis, pneumonia, cystic fibrosis, pulmonary edema, and hyaline membrane disease. Other causes include bronchopulmonary dysplasia, foreign

body or substance aspiration, and congenital pulmonary lesions, to list a few.

Circulatory or vascular conditions leading to diminished arterial P_{O_2} are also associated with cyanosis. One of the most common causes of cyanosis in children is congenital heart disease. Although most newborns with cyanotic congenital heart disease are discovered while still in the newborn nursery, on occasion, such a newborn will initially present to the emergency department (ED) in the first few days or weeks of life with cyanosis. One condition particularly prone to such late presentation is tetralogy of Fallot, specifically in those infants with concomitant pulmonary atresia who have patent ductus arteriosis–dependent pulmonary blood flow. When the ductus closes, profound cyanosis ensues. Rarely, an infant with mild tetralogy of Fallot (or “pink tet”) may present with intermittent cyanosis during a “tet spell,” which is a 15- to 30-minute self-limited episode of cyanosis caused by increased right-to-left shunting and decrease in pulmonary blood flow. Diagnosis in the “pink tet” is facilitated by presence of a loud systolic murmur. The causes of cyanotic congenital heart disease are listed in Table 16.1, Section II, A. Although many mixing lesions are correctable, several congenital lesions remain with significant shunting of blood from right to left, and these cyanotic children will inevitably be seen in the ED over the course of their lives. Cyanosis may also be caused by pulmonary congestion from cardiac failure or left-to-right cardiac lesions leading to increased pulmonary blood flow and diminished diffusion of O_2 across the gas–blood barrier. (For a detailed discussion of cardiac disease, see Chapter 82.) Several pulmonary vascular abnormalities can lead to cyanosis as well. These include primary pulmonary hypertension of the newborn or pulmonary hypertension from other causes where, because of high pulmonary pressures, blood is shunted away from the lungs and the child becomes hypoxemic. Pulmonary embolism and pulmonary hemorrhage, although rare in children, also impair lung perfusion and must be considered.

Low perfusion states may lead to local cyanosis, particularly of the hands, feet, and lips. Moderate cold exposure slows transit time for red cells across capillary beds, leading to greater unloading of oxygen to the tissues and local blueness. Patients in septic or cardiogenic shock may have perfusion-related cyanosis with long capillary refill times as a result of vascular collapse of sepsis or pump failure. Acrocyanosis, or blueness of the hands and feet with preserved pinkness in the mucous membranes and elsewhere, is seen commonly in newborns and is related to variable perfusion in the extremities. It is seen in well-appearing babies and resolves within the first few days of life.

Neurologic conditions can lead to Hb desaturation and cyanosis as well. Patients who hypoventilate because of central nervous system (CNS) depression, whether from primary CNS lesions or drugs/toxins that depress the respiratory center, are often centrally cyanotic at presentation to the ED. Episodic blue spells in infants and young children who are otherwise well may be caused by breath holding, especially when associated with a sudden insult such as fright, pain, frustration, or anger. Vigorous crying is thought to cause cerebral ischemia via vasoconstriction from decreased P_{CO_2}, decreased cardiac output from Valsalva maneuver, and hypoxemia from apnea (see Chapter 131). Seizures are often associated with cyanosis from inadequate respiration during the convulsion. A variety of neuromuscular diseases that affect chest wall or diaphragmatic function may ultimately lead to hypoventilation.

With respect to the Hb molecule itself, methemoglobinemia is an unusual but not rare reason for admission to the pediatric ED. Methemoglobin can be either congenital or acquired. Congenital methemoglobinemia is caused by either Hb variants designated M hemoglobins or deficiency of NADH-dependent methemoglobin reductase. The more commonly acquired form occurs when red blood cells are exposed to oxidant chemicals and drugs. Young infants with gastroenteritis or oxidant toxin exposure are particularly susceptible to the development of methemoglobinemia as a result of immature enzyme systems required to reduce Hb. Symptoms, caused by decreased blood oxygen content and cellular hypoxia, include headache, dizziness, nausea, dyspnea, confusion, seizure, and coma. Even at low levels, skin discoloration is prominent, often with intense or “slate gray” cyanosis from the presence of methemoglobin as perceived through the skin. (For a more detailed discussion of methemoglobinemia, see Chapter 87.)

Other conditions leading to a blue appearance of the skin may be confused with cyanosis. A rare but perplexing presentation is that of the well-appearing child with unusually localized cyanosis, which after some head scratching, turns out to be related to blue dye of clothing. Certain pigmentary lesions such as mongolian spots can be confused with cyanosis, especially when uncharacteristically large or in unusual locations. Adolescents will occasionally “tattoo” areas of the body that may appear as local cyanosis.

EVALUATION AND DECISION

A careful yet rapid history and physical examination are critical to the approach to the cyanotic patient because timely correction may be lifesaving. Many historical features can help narrow the differential diagnosis and lead to prompt evaluation and treatment. The onset and pattern, location, quality, temporal nature, and presence of palliative or provocative features must be explored. Age of the patient with respect to onset of cyanosis, whether at birth, shortly after birth, or acquired later, is critical. In newborns, congenital cardiac and respiratory disease are the most common causes of cyanosis. Special attention must also be paid to known preexisting heart or lung disease that may predispose to the acute onset of cyanosis. History of exposure to environmental conditions or toxins, such as cold, trauma, clothing dye, smoke inhalation, confinement to an airtight space, drugs, or chemicals, is crucial. Known history or family history of M hemoglobin or deficiency of NADH-dependent methemoglobin reductase may lead directly to the cause of cyanosis. A history of sudden pain or fright with crying or seizure occurrence should be sought.

The physical examination must include a complete general examination, with special attention paid to the vital signs, oxygen saturation, and cardiovascular and pulmonary systems. An immediate and key physical examination feature is the presence or absence of respiratory distress. In general, children with respiratory distress are likely to have *respiratory* dysfunction, and careful examination of the airway, breathing, and circulation should be rapidly initiated. Presence of cough, “sniffing position,” stridor, retraction, or fever should be determined. Lung examination may reveal adventitious (e.g., wheezing or rales) or diminished breath sounds. Presence of a cardiac murmur suggests cardiac disease. Careful attention to the peripheral circulation, including pulses, capillary refill, and temperature, is helpful as well. A rapid neurologic examination should be done. Hypoventilation and subsequent hypoxemia can be the result of many conditions

affecting the CNS.

Location of cyanosis helps determine its cause. Central cyanosis is noted in the mucous membranes, tongue, trunk, and extremities. It is most often the result of decreased arterial P_{O_2} but can also result from severe methemoglobinemia or polycythemia. If the cyanosis is peripheral only (hands, feet, lips), moderate cold exposure, newborn acrocyanosis, shock states, or mild methemoglobinemia may be the cause. Local blue discoloration of a single extremity corresponds to compromise of distal circulation or autonomic tone as seen in traumatic vascular lesions or reflex sympathetic dystrophy. In addition, a local blue hue to the skin may also be a result of simple phenomena such as pigmentary lesions or blue clothing dye. If blue coloring appears on an alcohol swab wiped across the discolored area of skin, dye is responsible. Differential cyanosis of the lower body versus upper may indicate high pulmonary vascular resistance with right-to-left shunting via the ductus arteriosis Transposition of the great arteries with pulmonary-to-aortic shunt of oxygenated blood through the ductus arteriosis is represented in the rare instance that the upper body is blue and the lower body pink.

The path of the laboratory evaluation depends on the historical features and physical findings established on initial encounter (Fig. 16.1). All patients, except very well-appearing newborns and well-appearing cold-exposed patients with peripheral cyanosis only, require measurement of arterial P_{O_2}. (Oxygen saturation by pulse oximetry may be helpful in determining if hypoxemia is the cause of cyanosis, but it may also be misleading when forms of Hb are present other than oxyhemoglobin and deoxyhemoglobin.) If the P_{O_2} is normal, the laboratory evaluation is determined by the degree of ill appearance. Well-appearing oxygenated children with cyanosis usually have less urgent conditions, such as polycythemia, mild methemoglobinemia, cold exposure, newborn acrocyanosis, or dermatologic findings. In this case, laboratory evaluation might include a methemoglobin level and complete blood count or no further investigation may be warranted. Despite a normal P_{O_2}, an ill-appearing cyanotic patient may have a more emergent condition such as severe methemoglobinemia or septic or cardiogenic shock and may require aggressive laboratory investigation, including complete blood count, methemoglobin level, blood cultures, and blood chemistry. Blood with high methemoglobin content may appear very dark or “chocolate brown” and fails to turn red on exposure to air, such as in a drop on filter paper. Treatment is then directed at the underlying cause. Methemoglobinemia may improve with intravenous methylene blue. If the P_{O_2} is decreased, oxygen therapy should be instituted. In general, cyanosis caused by decreased alveolar ventilation or diffusional abnormalities often improves with delivery of 100% O_2. However, hypoxemia caused by decreased pulmonary perfusion responds little to oxygen therapy. Next, a chest radiograph should be obtained. Abnormalities of the lungs may confirm pulmonary disease as a major contributor to hypoxemia, and changes in the cardiac size or silhouette may suggest cardiac causes. If the chest radiograph is normal, other reasons for diminished arterial P_{O_2}, such as CNS or chest wall–related respiratory depression, upper airway obstruction, or pulmonary perfusion abnormalities, must be entertained. If a concomitant murmur or other concern for cardiac disease exists, an electrocardiogram (ECG) is essential. Abnormal ECGs suggest cardiac dysfunction, either congenital or acquired (see Table 16.1), and the addition of echocardiography will help establish the definitive diagnosis.

CHAPTER 17

Crying and Colic in Early Infancy

[*]BARBARA B. PAWEL, MD and [†]FRED M. HENRETIG, MD

[*]*Department of Pediatrics, The University of Pennsylvania School of Medicine, and Division of Emergency Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania;*
[†]*Departments of Pediatrics and Emergency Medicine, The University of Pennsylvania School of Medicine, Section of Clinical Toxicology, The Children's Hospital of Philadelphia, and The Poison Control Center, Philadelphia, Pennsylvania*

Crying is the means by which an infant may express discomfort, ranging from normal hunger and desire for company to severe, life-threatening illness. Many common minor irritations and illnesses are excluded by careful history and physical examination. Often, however, a normal, thriving baby will develop a chronic pattern of daily paroxysms of irritability and crying known as colic. The attacks usually have their onset in the second to third week of life and may last for several hours, more commonly in the late afternoon or evening. The typical episode is described as paroxysmal crying that develops into a piercing scream, as if the baby were in pain. The child may draw up the legs, the abdomen may appear distended, bowel sounds are increased, and flatus may be passed, leading parents to conclude that their child has abdominal distress. The emergency physician may be confronted with such a patient and the worried, occasionally hostile parents (usually no earlier than midnight). Colic cannot be cured in the emergency department (ED), and only when crying episodes are repeated and stereotypical and other causes of crying are excluded can the diagnosis of colic be considered. Establishing an orderly approach to the infant with unexplained crying is important to rule out the occasional physical illness and to provide preliminary guidance to the family.

PATHOPHYSIOLOGY

Any unpleasant sensation can cause an infant to cry. Pain or an altered threshold for discomfort (irritability) may be caused by diverse physical illnesses. Those most likely to present abruptly in a young infant are listed in Table 17.1. Numerous unproven theories abound about the etiology of colic. Cow's milk allergy, immaturity of the gastrointestinal tract or central nervous system, parental anxiety, poor feeding technique, and individual temperament characteristics all have been invoked. The search for a specific cause of colic continues. Recent publications suggest that a subgroup of infants who carry the diagnosis of colic may actually have “silent reflux” with resultant esophagitis causing irritability and crying paroxysms amenable to gastroesophageal reflux therapeutic modalities. Others have suggested that elevated serotonin levels found in colicky infants may contribute to the pathogenesis of colic. No single theory (or concomitant therapy) has gained uniform acceptance. Colic may be a syndrome that represents the manifestations of some or all of these factors in varying degrees in a normal population of babies whose tendency to cry varies along a normal distribution. Brazelton's original data on infant crying patterns has been supplemented by larger scale studies in Canada and England. All studies revealed crying levels to increase from birth to a peak of approximately 3 hours per day at 6 to 8 weeks, followed by a rapid decline.

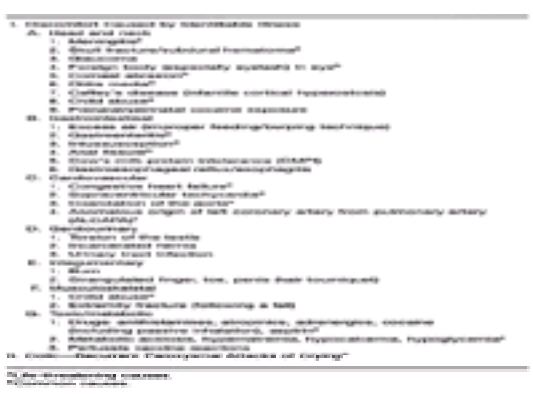

Table 17.1. Conditions Associated with Abrupt Onset of Inconsolable Crying in Young Infants

Early infant crying was also shown to cluster more commonly in afternoon and evening hours. These estimates of crying time over the first 12 weeks of life seem to reflect a certain degree of inconsolable crying behavior that normal infants are destined to exhibit in the first 3 months of life. An encounter with a health care provider is more likely if the infant is difficult to console or if the crying episode is thought to be associated with pain. The most persistent criers would be diagnosed by most pediatricians as having “colic.”

EVALUATION AND DECISION

A careful history and physical examination with emphasis on the head, eyes, ears, skin, abdomen, genitalia, and extremities, plus analysis and culture of a urine specimen, will usually enable the physician to diagnose identifiable illnesses or injuries causing severe paroxysms of crying (Table 17.1). Initially, this clinical evaluation must focus on those conditions that are potentially life-threatening: meningitis, child abuse, intussusception, incarcerated hernia, severe intoxication, and metabolic disturbance. Other less critical but more common conditions should be sought next; corneal abrasion or foreign body, otitis media, aerophagia, teething, gastroenteritis, and anal fissure are most commonly seen. As noted in Table 17.1, other diagnoses are encountered occasionally.

The history should include special attention to the onset of crying and any associated events—particularly recent immunization (“screaming spells” lasting up to 24 hours have been described after pertussis vaccine), trauma, fever, or use of medications. Physical examination must be thorough, with the baby completely undressed. Vital signs may reveal fever, suggesting infection (although not always present in young infants with serious infections), or hyperpnea, suggesting metabolic acidosis.

The head should be explored for evidence of trauma, and the fontanelle should be palpated. Eyes must be examined with fluorescein to look for corneal abrasion, even in infants with no symptoms referable to the eyes. In addition, eversion of the upper eyelids can exclude a foreign body. Funduscopy should be attempted (retinal hemorrhages are common signs of abuse, especially in shaken baby syndrome). Careful otoscopy is required to visualize the tympanic membranes. The heart should be evaluated for signs of congestive failure, arrhythmia, or rare ischemia-producing lesions (Table 17.1, Section I, C.). Abdominal and rectal examinations must be done to look for signs of anal fissure or intussusception. The diaper must be removed, and a careful search should be made for incarcerated hernia, testicular torsion, or strangulation of the penis or clitoris by an encircling hair. Crying may be the primary symptom of an occult urinary infection, so a suitable specimen of urine should be obtained for urinalysis and culture. Careful palpation of all long bones despite the absence of obvious signs of trauma can detect fracture sites that might otherwise have been overlooked. Each finger and toe should be inspected closely to rule out strangulation by hair or thread. Further consideration of laboratory evaluation is made in light of the clinical findings. A low threshold for urine toxicology screening is warranted in the persistently irritable baby, given the escalation in illicit drug use.

Many infants will have a completely negative examination, and the history (or subsequent follow-up) will be suggestive of colic. Over the time in which the crying attacks recur, the infant must demonstrate adequate weight gain (average 5 to 7 ounces/week in the first months of life) and absence of physical disorders on several examinations before underlying illnesses can be excluded and colic can be diagnosed confidently (Fig. 17.1). When it becomes clear that a given infant is experiencing colic, the practitioner faces a vexing problem. No dramatic cure is currently available, but the symptoms almost invariably resolve within 3 months of onset. Dicyclomine hydrochloride, an anticholinergic drug, is the only drug that has been shown to be effective in the treatment of colic; however, this drug has been associated with apnea, and its use is discouraged. Simethicone, although often prescribed, has been shown to be no more effective than placebos in most studies. In general, no safe and effective medical treatment for colic is available. Elimination of cow's milk protein through formula changes is only useful in the small subset of cases (4%) with cow's milk protein intolerance (CMPI). A study by Taubman found that parental counseling (to be more responsive to infant crying with immediate efforts at consoling) was far more effective than dietary manipulation. The safest and most effective course of treatment at this time seems to be counseling and empathy. The physician can reassure the parents that their baby is thriving and will outgrow the colic and develop normally.

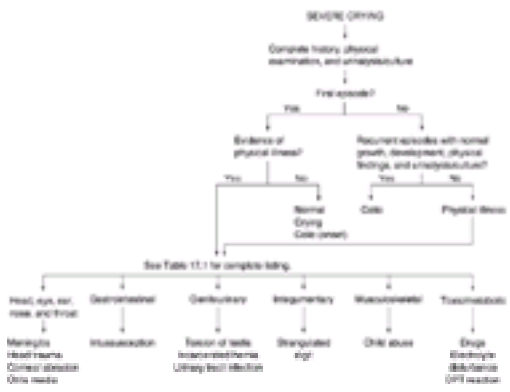

FIGURE 17.1. Approach to abrupt onset of severe crying in infancy. *DPT,* diphtheria-pertussis-tetanus (vaccine).

The emergency physician must be aware of colic as an entity to initiate the evaluation already described, to rule out acute treatable illness, and to refer the family to a pediatrician for follow-up. Colic is not serious and does not last forever, but it probably will be a nuisance for several weeks to come. The physician should stress to the family members their responsibility in the care of the baby so that the mother can get some periods of relief and rest from the child's care. The emergency physician is responsible for investigating the vulnerability of families and children who present with excessive crying. Assessment of the parents' emotional state and the status of available support systems is mandatory. Exhaustion of the parents may be dangerous for the infant, both psychologically and physically.

For immediate amelioration of crying at the time of the ED visit, no drug therapy or feeding change is recommended. Rather, most colicky babies derive some temporary relief from rhythmic motion, such as rocking, being carried, or riding in a car, and from continual monotonous sounds like those from a washing machine or electric fan. A purposefully chosen

circuitous route for the car ride home (one that combines motion and sound) should suffice as therapy for the first visit.

CHAPTER 18

Dehydration

KATHY N. SHAW, MD

Department of Pediatrics, The University of Pennsylvania School of Medicine, and Emergency Medical Services, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Dehydration is a physiologic disturbance caused by the reduction or translocation of body fluids and is a type of hypovolemic shock. Infants have higher morbidity and mortality and are more susceptible to dehydration because of their larger water content, higher metabolic turnover rate of water, renal immaturity, and inability to meet their own needs independently. Because dehydration is not a disease itself, children with various illnesses and circumstances will present to the emergency department (ED) with signs of dehydration (Table 18.1).

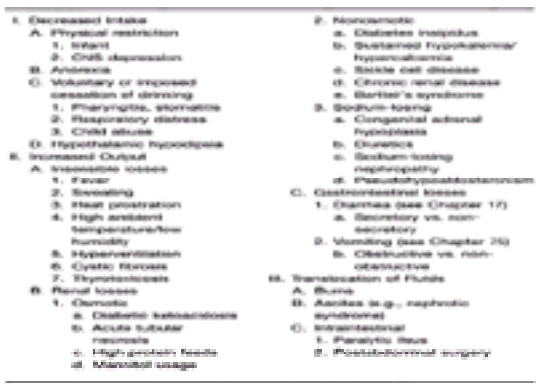

Table 18.1. Causes of Dehydration

Dehydration often is categorized by the patient's osmolarity (the disturbance of distribution of water among body spaces) and severity (degree of fluid deficit), which is helpful in determining fluid therapy. Based on the initial serum sodium, most children have isotonic dehydration (130 to 150 mEq/L), whereas others have hypertonic dehydration (greater than 150 mEq/L) or hypotonic dehydration (less than 130 mEq/L). The terms *isonatremia, hypernatremia,* and *hyponatremia* would be more appropriate. Severity is judged by the amount of body fluid lost or the percentage of weight loss, and the three categories include mild (less than 50 mL/kg, or less than 5%), moderate (50 to 100 mL/kg, or 5 to 10%), and severe (greater than 100 mL/kg, or greater than 10%).

DIFFERENTIAL DIAGNOSIS

Fluid losses in dehydration result from 1) decreased intake; 2) increased output secondary to insensible, renal, or gastrointestinal (GI) losses; or 3) translocation of fluid such as occurs with major burns or ascites (Table 18.1). Diarrhea (see Chapter 19) is the most common cause of dehydration in infants and children and is the leading cause of death worldwide in children less than 4 years of age. In the United States, an average of 300 children under 5 years of age die each year, and an additional 200,000 are hospitalized secondary to diarrheal illnesses with dehydration. Other common causes of dehydration in children include vomiting, stomatitis or pharyngitis with poor intake secondary to pain, febrile illnesses with increased insensible losses and decreased intake, and diabetic ketoacidosis (Table 18.2). More severe or life-threatening causes are listed in Table 18.3.

Table 18.2. Common Diagnoses

Gastroenteritis (especially infants)	Heat prostration
Diabetic ketoacidosis	Gastrointestinal obstruction
Burns over 25% of body surface area	Cystic fibrosis
Thyrotoxicosis	Diabetes insipidus
Congenital adrenal hyperplasia	Child abuse

Table 18.3. Life-Threatening Diagnoses

EVALUATION AND DECISION

The first step in evaluating a child with dehydration is to assess the severity or degree of dehydration, regardless of the cause (Table 18.4). Most children with clinically significant dehydration will have two of the following four clinical findings: 1) capillary refill greater than 2 seconds; 2) dry mucous membranes; 3) no tears; and 4) ill appearance. Dehydration is a type of hypovolemic shock. Mild, moderate, and severe dehydration correspond to impending, compensated, and uncompensated states of shock, respectively (see Chapter 3). If there is severe dehydration or uncompensated shock, the child must be treated immediately with isotonic fluids to restore intravascular volume, as detailed later in this chapter.

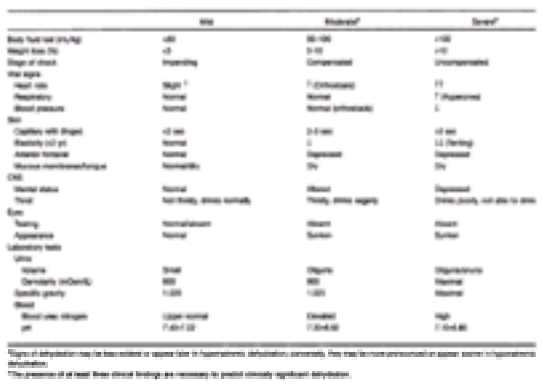

Table 18.4. Clinical Estimation of Degree of Dehydration[a]

History

A thorough history is needed to assess the child with dehydration to determine the cause and degree of dehydration (Fig. 18.1). Particular attention should be paid to the child's output and intake of fluids and minerals. Because overt GI losses from diarrhea and vomiting are the most common causes of dehydration in children, information about the amount and character of these losses is critical in determining a cause (see Chapter 19 and Chapter 78). The child may not be drinking because of physical restriction (e.g., dependence on a caregiver, pain, altered consciousness, anorexia). Fever, high ambient temperatures or bundling a baby, sweating, and hyperventilation may cause increased insensible losses. It is important to note whether there is any underlying disease that would contribute to dehydration (e.g., cystic fibrosis, diabetes, hyperthyroidism, renal disease).

FIGURE 18.1. Suspected dehydration.

Asking the parents about documented weight loss, amount of urine output, and the presence or absence of tears is helpful in determining the severity of the dehydration. All ingested fluids should be noted because diluted juices or water can be associated with hyponatremic dehydration, whereas excess salt intake or low liquid intake may indicate hypernatremic dehydration.

Physical Examination

Vital signs are important and objective parts of the evaluation of the child with dehydration (Table 18.4). The first sign of mild dehydration is tachycardia, whereas hypotension is a late sign of severe dehydration. In mild to moderate dehydration, the respiratory rate usually is normal. As a child becomes more acidotic and fluid depleted, the respiratory rate increases and the breathing pattern becomes hyperpneic. Unfortunately, vital signs alone are not always reliable. Tachycardia also may be caused by fever, agitation, or pain; respiratory illness affects respiratory rates; and orthostatic signs are difficult to obtain in babies and young children.

Age of the child, nutritional status, and type of dehydration also may affect clinical assessment, which is critical to effective management of the acutely dehydrated child. In general, older children show signs of dehydration sooner than babies do because of their lower levels of extracellular water. Fat babies may look less dehydrated than they really are, whereas severely malnourished babies may appear to be more dehydrated secondary to wasted supporting tissues. Signs of dehydration may be less evident or appear later in hypernatremic dehydration. Excessive irritability with increased muscle tone and doughy or smooth and velvety skin often are noted with this type of dehydration. Conversely, signs of dehydration may be more pronounced or appear sooner in hyponatremic dehydration. Keeping these caveats in mind, particular attention should be paid to the overall appearance, mental status, eyes, and skin on physical examination. The mildly dehydrated child usually appears well and may have decreased tearing and a slightly dry mouth. Dry mucous membranes are an early sign of dehydration, but this condition is affected by rapid breathing and ingestion of fluids. Conversely, the severely dehydrated baby classically appears quite ill with lethargy or irritability, a dry mouth, sunken fontanelle, and absent tears. More moderate states of dehydration, however, require more careful evaluation.

The skin is a reliable organ to assess for signs of peripheral perfusion because it is an indicator of the child's systemic vascular resistance and degree of shunting that is occurring to maintain blood pressure. Peripheral and central pulses and skin temperature should be compared. Cool peripheral extremities are an early sign of poor perfusion, whereas weak distal pulses are a very late sign. One of the more objective measures of dehydration is assessment of skin perfusion by measuring capillary refill time. Although the child's body temperature does not affect capillary refill time, it may be falsely prolonged when measured on the foot or in a cool room. Thus, the test should be performed on the fingertip or nailbed in a warm room. Light pressure is applied to blanch the fingernail bed, and the time is measured until color returns (Fig. 18.2). Delays of only 2 to 3 seconds indicate moderate dehydration, and a measurement of more than 3 seconds occurs with severe fluid losses. Skin elasticity can be assessed by determining whether there is a delay in return of skin to its original state after it is pinched into folds (tenting). This is a less reliable finding in older children and malnourished babies who have less subcutaneous tissue.

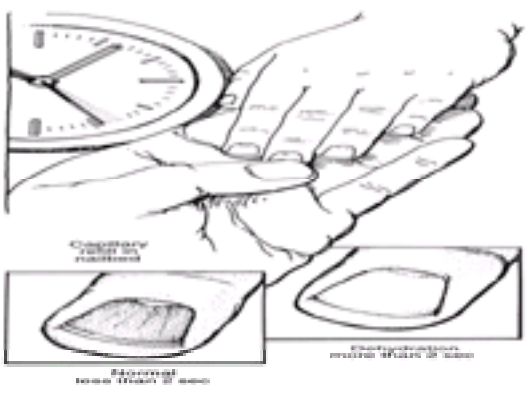

FIGURE 18.2. Assessing dehydration by capillary refill.

Laboratory

The quantity and quality of urine produced also are important indicators of the cause or degree of dehydration. Progressive decrease in urine output and increase in specific gravity and osmolarity are expected with increasing severity of dehydration. If the physical examination indicates significant dehydration and there is dilute or copious urine, a renal or adrenal origin is most likely. The presence of glucose or ketones may indicate diabetic ketoacidosis, and a history of disorders of the central nervous system (CNS) suggests diabetes insipidus.

In children who are judged to have moderate to severe dehydration that requires intravenous (IV) rehydration, laboratory tests of electrolytes, glucose, blood urea nitrogen, and creatinine usually are obtained to determine osmolarity and renal function. The acid-base status may be assessed further with an arterial or venous blood gas.

Diagnostic Approach

In approaching the patient with presumed dehydration, the initial assessment serves to determine whether shock is present. If the child appears to be in shock, resuscitation is called for immediately and a number of life-threatening disorders need to be considered, as listed in Table 18.3 and discussed in Chapter 3. Patients with obvious burns or

diseases that disrupt the integument in the same way (e.g., scalded skin syndrome) are presumed to have become dehydrated through transudation of fluids through the skin.

If the patient does not have an obvious cutaneous source for dehydration, GI losses provide the most likely explanation. A history of vomiting (see Chapter 78) or diarrhea (see Chapter 19) should be sought. Most children with vomiting or diarrhea have viral gastroenteritis, but many diseases (see Table 19.1 and Table 78.1) produce these symptoms. Additional history serves to establish the adequacy of oral intake. Several common minor infections, such as pharyngitis and stomatitis, as well as more serious disorders of the CNS, cause dehydration as a result of voluntary or involuntary limitation of fluids taken orally.

Next, the history should address the nature and quantity of the urine output. With dehydration, one expects to find oliguria or anuria, as seen with many renal diseases (see Chapter 86). The unexpected discovery of polyuria points to diabetes mellitus or insipidus.

By this point, the physician will have established a diagnosis in most patients. In hot weather or when there is prolonged fever, skin losses must be considered. Patients with cystic fibrosis (see Chapter 96) in particular are prone to dehydration under these conditions because of a high concentration of sodium in the sweat (the finding of hyponatremic dehydration seemingly unexplained by the estimated fluid loss should suggest this diagnosis). Additional considerations are listed in Table 18.1.

Initial Management

The dehydrated child must be examined immediately for the degree of dehydration or state of hypovolemic shock. If there is severe dehydration or uncompensated shock, the patient is treated acutely with isotonic fluids to restore intravascular volume regardless of serum osmolarity or cause of the dehydration. Normal saline or Ringer's lactate is given in 20-mL/kg aliquots over approximately 15 to 30 minutes or as quickly as possible if there is uncompensated shock. Reassessment is paramount after each fluid bolus. When blood pressure is restored, heart rate returns to normal, distal pulses strengthen, and skin perfusion improves, isotonic fluids may be safely discontinued. Urine output is the most important indicator of restored intravascular volume and should be a minimum of 1 mL/kg per hour. If dextrose is needed initially for low serum glucose, 0.5 g/kg is given in a single bolus of 10% or 25% dextrose and the serum level is rechecked.

Once the initial resuscitation phase is completed, an IV stock is determined (see Chapter 86). The initial stock often is D5¼NS or D5½NS with 20 mEq/L of potassium chloride. Notable exceptions include major burn patients who continue to require isotonic fluids (see Chapter 114), children with diabetic ketoacidosis who do not require dextrose initially (see Chapter 97), and children with severe electrolyte disturbances such as may occur with pyloric stenosis or severe hypernatremic dehydration (see Chapter 86).

The rate of the chosen stock is determined by the estimated fluid losses. If there are two documented recent weights on the same scale, each kilogram of acute weight lost is equivalent to 1 L of body fluid loss. If previous weights are unavailable, the current weight is assumed to be a certain percentage of the child's ideal or rehydrated weight. For example, if a 9-kg child is assessed to have moderate dehydration with an estimated 10% weight loss, the ideal or rehydrated weight would be 10 kg (9 kg is 90% of 10 kg). Therefore, the child has a 1-L or 1000-mL (100 mL/kg) deficit. Usually, 50% of the child's fluid deficit is given over the first 8 hours in addition to one-third of the maintenance fluid requirements. In the example given, the child would be given 500 mL of fluid replacement plus 333 mL of maintenance fluids over the first 8 hours. In hypertonic states, after initial stabilization with isotonic fluids, the replacement solution is given more slowly to allow equilibration across the blood–brain barrier (see Chapter 86 and Chapter 97).

Initially, oral rehydration should be considered strongly in children with mild or moderate dehydration who do not have uncompensated shock, severe vomiting, high stool output of more than 20 mL/kg per hour, or poor compliance. Oral rehydration also may be instituted after the initial resuscitation phase if the child is feeling well enough to take oral fluids. Initial rehydration solutions that contain 75 to 90 mEq/L of sodium and replacement or maintenance solutions that contain 40 to 60 mEq/L of sodium are available. Both solutions have approximately 20 mEq/L of potassium and a low glucose concentration of 2 to 2.5% to use the sodium–glucose cotransport system in the small intestine. The child is given a volume of rehydration solution equal to the estimated total fluid deficit to drink over approximately 4 to 6 hours. Then, the maintenance solution is begun or the initial rehydrating solution is alternated on a 1:1 basis with a no-sodium or low-sodium fluid such as water, low-carbohydrate juices, or breast milk. Disadvantages to oral rehydration therapy, including the need for prolonged, close observation and frequent feedings, often thwart this effective and safe approach when attempted in the busy EDs of developed countries.

In all types of dehydration and their methods of treatment, the patient must be reassessed continually, urine output monitored closely, ongoing losses quantified and replaced, and therapy individualized. Because dehydration has many causes, the origin of the problem needs to be determined and addressed.

CHAPTER 19

Diarrhea

GARY R. FLEISHER, MD

Department of Pediatrics, Harvard Medical School, and Division of Emergency Medicine, Children's Hospital, Boston, Massachusetts

Diarrhea refers to a softening in the consistency of the stool with or without an increase in the number of stools. Because of the variability in the frequency and type of stools among children, absolute limits of normalcy are difficult to define. Rather, any deviation from the child's usual pattern should arouse concern, regardless of the actual number of stools or their water content. Some infants, particularly those who are breast-fed, often have five or six loose stools daily as their normal routine; other healthy infants may produce only one formed stool every other day.

DIFFERENTIAL DIAGNOSIS

Diarrhea, with or without vomiting, often prompts a visit to the emergency department (ED). An estimated 15 to 20 million children less than 5 years of age have between 20 and 40 million episodes of diarrhea annually in the United States. Approximately 12% of all hospitalizations of children 1 month through 4 years of age include diarrhea among one of the top three positions on the list of discharge diagnoses. Although most bouts of diarrhea seen in the ED in developed countries result from self-limiting infections, diarrhea may be the initial manifestation of a wide spectrum of disorders, as outlined in Table 19.1.

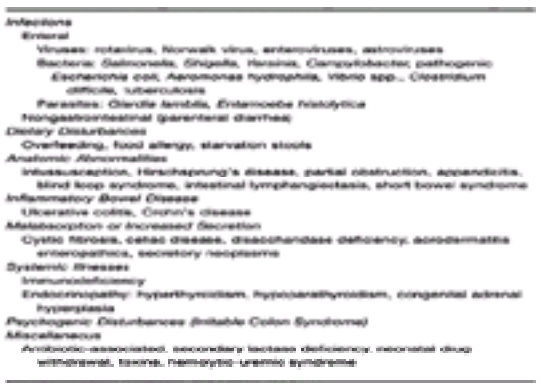

Table 19.1. Causes of Diarrhea

Of the many causes of diarrhea, a few are particularly common: infections with viruses and bacteria, parenteral diarrhea, and diarrhea associated with antibiotic administration (Table 19.2). The single most common disorder seen in the ED is viral gastroenteritis.

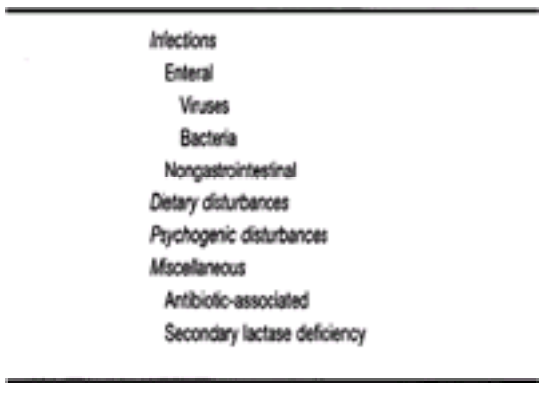

Table 19.2. Common Causes of Diarrhea

Any cause of diarrhea may produce a fatality secondary to dehydration. Approximately 400 young children die annually in the United States from gastroenteritis; however, most of the disorders, particularly viral gastroenteritis, are mild. The emergency physician must be vigilant in recognizing the few children who have diseases that are likely to be life-threatening from among the majority of children who have self-limiting infections. Particularly urgent are intussusception, pseudomembranous colitis, hemolytic uremic syndrome (HUS), and appendicitis (Table 19.3).

Intussusception
Hemolytic uremic syndrome
Pseudomembranous colitis
Appendicitis
Salmonella gastroenteritis (with bacteremia in the neonate or compromised host)
Hirschsprung's disease (with toxic megacolon)
Inflammatory bowel disease (with toxic megacolon)

Table 19.3. Life-Threatening Causes of Diarrhea

Intussusception is the most common of these serious disorders to have diarrhea as a predominant symptom. Although many children with intussusception primarily have rectal bleeding or severe abdominal pain, a significant number are brought to the hospital with the complaint of bloody diarrhea. Intussusception peaks in frequency between 5 and 10 months of age and tapers off rapidly after 2 years of age, unless there is a predisposing pathologic condition. Although the occasional child may be febrile, the temperature usually is within the normal range. Classically, intussusception causes colicky abdominal pain, vomiting, and an abdominal mass, in addition to a “currant jelly” stool. The finding of a mass in association with colicky abdominal pain, vomiting, and a currant jelly stool is pathognomonic for intussusception, but a mass actually is palpable in fewer than 50% of cases. Thus, the physician should consider this diagnosis even in the absence of a mass when a child in the first year or two of life has the combination of bloody diarrhea and severe, colicky abdominal pain. In addition, the child who is flaccid or lethargic out of proportion to the degree of dehydration should arouse the examiner's suspicions; intussusception can evoke “neurologic” signs. Plain films of the abdomen may be diagnostic (intussusception seen on the basis of air contrast), suggestive (mechanical obstruction), or nonspecific (normal or ileus); thus, a high index of suspicion mandates a contrast enema with air or barium.

HUS, although uncommon, merits consideration in the child with bloody diarrhea because it is a potentially fatal illness. Children are affected most often in the first 3 years of life. Over the course of several days, an initially mild gastroenteritis becomes complicated first by hematochezia and then by pallor (anemia), purpura (thrombocytopenia), hematuria (nephritis), and finally renal failure. When HUS is suspected, a complete blood count (CBC), urinalysis, and coagulation studies should be performed. The peripheral blood smear, in addition to reduced numbers of platelets, shows evidence of intravascular hemolysis, including helmet cells and red blood cell fragments. The urine tests positive for blood and may contain casts on microscopic examination.

Another serious disorder that may cause bloody diarrhea is pseudomembranous colitis. This disease results from an overgrowth of toxin-producing clostridial organisms in the bowel and must be considered after a course of antibiotic therapy, which can decimate the normal flora of the gut. It may occur at any age but is uncommon in early childhood. Although the incidence of pseudomembranous colitis is highest after treatment with clindamycin, an infrequently prescribed antibiotic, any of the antibacterial drugs may be the culprit. In fact, because of its frequent use, amoxicillin is responsible for most cases of pseudomembranous colitis in childhood, even though the incidence after therapy with this agent is low. Clinically, the patient with pseudomembranous colitis usually appears ill with prostration, abdominal distension, and significant amounts of blood in the stool. Microscopic examination of the feces, sigmoidoscopy, and stool toxin analysis are all useful tests.

Appendicitis manifests primarily with abdominal pain, followed by vomiting, often in association with constipation. Less commonly, appendicitis may cause diarrhea. The presumed mechanism for the diarrhea is irritation of the colon by the inflamed appendix. In most cases, careful questioning about the nature of the diarrhea will reveal a description of frequent, very low volume stools, with mucus. Particularly in very young children or among patients of any age who have a perforated appendix and a long duration of illness, the diagnosis of appendicitis as the cause of diarrhea may be delayed because the classic constellation of findings is often absent. However, the examiner will usually be able to elicit abdominal tenderness greater than that which would be expected with gastroenteritis.

EVALUATION AND DECISION

The initial evaluation of the child with diarrhea should serve the dual purpose of exploring the possible causes and assessing the degree of illness. Preexisting conditions in the child may account for the diarrhea or predispose him or her to unusual causes; in particular, the emergency physician should search for a history of gastrointestinal surgery or chronic illnesses, such as ulcerative colitis or regional enteritis. Immunodeficiency syndromes, neoplasms, and immunosuppressive therapy all lead to an increased susceptibility to infection. Institutionalized children and those recently returning from underdeveloped countries are more likely to harbor bacterial or parasitic pathogens.

A history of abdominal pain, particularly if severe, raises the index of suspicion for intussusception and appendicitis. Bloody diarrhea points particularly to bacterial enteritis but occasionally occurs with viral infections and may also herald

the onset of HUS or pseudomembranous colitis. The combination of episodic abdominal pain and blood in the stool characterizes intussusception. Vomiting in association with diarrhea is very suggestive of viral gastroenteritis, whereas vomiting in isolation (see Chapter 78) is more concerning.

With the initial interview, the physician should attempt to reconstruct historically the child's intake and output during the course of the illness. Detailed questions about the number and size of stools, the frequency of emesis, and the amount of liquid taken orally allow for an estimate of fluid balance. Decreases in the frequency or volume of urination (or the number of diaper changes in the infant) suggest an inadequate output, reflecting the development of dehydration.

The general physical examination can provide clues to an underlying illness in the child who appears malnourished or small for his or her age. The weight of the child always should be measured carefully and compared with weights previously recorded in the chart. If fever is present, infectious causes are most likely. The pulse and blood pressure, together with the turgor of the skin and mucous membranes, are useful in assessing the degree of dehydration (Table 19.4), except in the child who has hypernatremia. On abdominal examination, the finding of a mass (regional enteritis, intussusception) or evidence of obstruction is important. A rectal examination should be performed in the child who has chronic diarrhea. With overflow stools secondary to prolonged constipation, the rectal ampulla contains a large amount of hard stool, but it often is empty in the patient with Hirschsprung's disease. For selected children, laboratory measurements may assist in the evaluation of dehydration, but they often fall in the normal range despite marked loss of fluids.

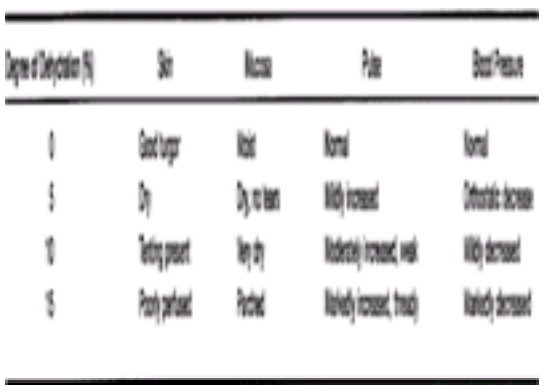

Table 19.4. Clinical Findings in Dehydration

A diagnostic approach to the pediatric patient with diarrhea is outlined in Figure 19.1. The physician should first determine whether the child appears seriously ill or has signs of a surgical abdominal process. Once it has been determined that immediate signs of a life-threatening process are absent, more than any other feature, the duration of diarrhea dictates the initial diagnostic considerations. Children with chronic diarrhea (more than 5 days) are likely to have irritable bowel syndrome, infections, inflammatory bowel disease, or various malabsorptive disorders. Such conditions, if uncomplicated, do not require a definitive diagnosis emergently but rather an extensive evaluation over time.

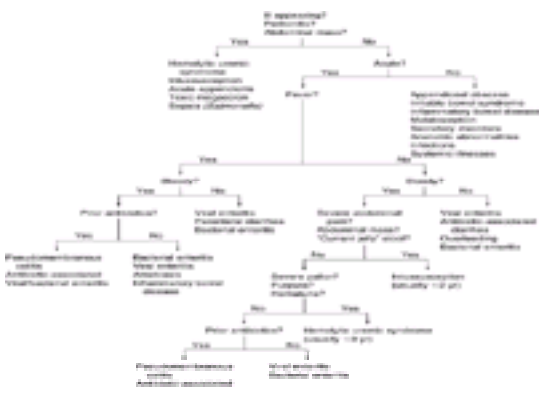

FIGURE 19.1. Diagnostic approach to the immunocompetent child with diarrhea.

Acute Diarrhea

With the acute onset of diarrhea, most children have an infectious cause for their disorder and will require evaluation in the ED. Fever, the hallmark of infection, serves as the first branch point in the approach to such patients. Although not all children with infectious enteritis have fevers, the finding of an elevated temperature points strongly in this direction. At the same time, the absence of fever, particularly in the presence of bloody stools, should alert the physician to the possibility of one of several serious noninfectious diseases, particularly intussusception and HUS.

The next question is whether hematochezia (bloody stool) is present. Blood is seen in the stool of approximately 10% of children with diarrhea. In most cases, the blood appears in small quantities as drops on the surface of the stool and should not be construed as ominous. A small percentage of children with diarrhea, however, have more profuse rectal bleeding. In these patients, one must exclude life-threatening disorders such as intussusception, HUS, and pseudomembranous colitis.

Febrile children with bloody diarrhea (Fig. 19.1) almost invariably have an infectious enteritis. Pseudomembranous colitis should be considered in patients who have received antibiotic therapy, but this diagnosis usually can be discarded on clinical grounds in the absence of systemic toxicity, abdominal distension, and gross blood in the stools. If pseudomembranous colitis is strongly suspected, admission to the hospital and a full diagnostic evaluation should be considered. Bacterial diarrhea should be sought by culture in febrile children with frankly bloody diarrhea but will be found only in 15 to 20% of cases; viral enteritis is much more common. In the first few months of life, in the infant for whom *Salmonella* gastroenteritis represents a more serious illness, a stool smear for polymorphonuclear leukocytes is useful because the finding of sheets of inflammatory cells strongly points to a bacterial origin. Amebiasis merits consideration only in endemic areas and among travelers. Finally, an occasional child with inflammatory bowel disease may present with an initial episode of acute, bloody diarrhea. With most of these children, the physician can elicit a preceding history of weight loss or recurrent abdominal pain; in the remainder, the diagnosis emerges when bloody diarrhea persists in the face of negative cultures.

Most febrile children with nonbloody diarrhea (Fig. 19.1) have viral enteritis. The physician must perform a thorough examination because nonenteric infections, particularly otitis media, may cause “parenteral” diarrhea. For similar reasons, a urine culture is indicated if any historical factors point to an infection of the urinary tract. Although a small percentage of these patients have a bacterial enteritis, routine cultures of stool are not recommended for nonbloody diarrhea of brief duration in otherwise healthy children. Immunocompromised patients, such as those with acquired immunodeficiency syndrome (AIDS) (see Chapter 85), require a more thorough evaluation, including bacterial cultures and examination for ova and parasites.

Afebrile children with bloody diarrhea (Fig. 19.1) represent the most worrisome category because most patients with intussusception, HUS, and pseudomembranous colitis have this symptom constellation. In particular, intussusception should be considered carefully in any child less than 1 year of age with bloody diarrhea that does not appear to have an infectious cause. Although the finding of a mass or a currant jelly stool is pathognomonic, a history of severe, colicky abdominal pain in a lethargic child warrants a contrast enema. Obvious pallor, purpura, and hematuria point to HUS, an unusual but potentially life-threatening disease. Once again, prior antibiotic therapy raises the possibility of pseudomembranous colitis. The most common diagnosis, infectious enteritis, should be assigned only after exclusion of the more serious disorders by history, physical examination, and occasionally, laboratory or radiographic studies.

Afebrile children with nonbloody diarrhea (Fig. 19.1) usually are judged to have viral enteritis. Those who receive antibiotic agents, such as amoxicillin, may be suffering from a drug-related gastrointestinal disturbance but not usually from pseudomembranous colitis. During the first 6 to 12 months of life, overfeeding may manifest as diarrhea. The tip-off to this diagnosis is the history of excessive intake in the overweight child. Bacterial enteritis, although a possibility, does not merit a stool culture in the usual clinical circumstances.

Chronic Diarrhea

Chronic diarrhea precipitates a child's visit to an ED less often than acute gastroenteritis does. An apparent worsening of a long-standing disease may be a final frustration on the part of the parents, however, particularly on a weekend when the family's usual physician may be unavailable. The evaluation of chronic diarrhea usually requires a period of observation and laboratory evaluation beyond the scope of the ED. In the management of these children, the role of the emergency physician is to select those few children who have urgent conditions and refer the remainder to their regular source of care. Particularly in the infant, consideration must be given to Hirschsprung's disease and to cystic fibrosis. A history of delayed passage of meconium, constipation since birth, and abdominal distension are compatible with Hirschsprung's disease. Malabsorptive stools and respiratory infections suggest cystic fibrosis. Failure to thrive, thrush, and pneumonia occur in association with human immunodeficiency virus (HIV) infection. A stool culture and examination for parasites serve to diagnose the serious infections of the gastrointestinal tract and provide a head start on the evaluation to the physician who subsequently sees the child.

The child who returns to the ED with the persistence of an acute diarrheal illness, presumed to be viral in origin and with no evidence of malnutrition or dehydration, often may be managed without an extensive evaluation. Three causes are common: 1) bacterial infections; 2) secondary lactase deficiency from mucosal sloughing; and 3) starvation stools in the child who inadvertently has been continued on a clear liquid diet for several days. A stool culture should be obtained, and testing for clostridial toxin is indicated in the presence of ongoing antibiotic therapy. If the child has remained on a clear liquid diet, gradual refeeding is recommended. Milk and all milk products should be proscribed temporarily when secondary lactase deficiency is suspected.

TREATMENT

The treatments for the myriad causes of diarrhea are covered in the medical and surgical sections of this book; however, the therapy for viral gastroenteritis or parenteral diarrhea merits a brief summary. Although all children with circulatory compromise and many children with moderate to severe dehydration need intravenous fluids, many patients with gastroenteritis can be managed with oral solutions. Most children, even those with vomiting, will tolerate frequent, small feedings, but occasionally delivery of fluids via a nasogastric tube may be helpful.

Optimal oral therapy emphasizes the use of appropriate glucose and electrolyte solutions as well as the early reintroduction of feeding. The ideal solutions, based on formulas carefully tested by the World Health Organization, have a carbohydrate:sodium ratio that approaches 1:1. Generally, initial rehydration is accomplished with a solution that contains 75 to 90 mEq/L of sodium (i.e., Rehydralyte®) and subsequent maintenance with a more hypotonic formulation (i.e., Pedialyte®). Older children with mild gastroenteritis tolerate juices and other household products, even though the carbohydrate:sodium ratio deviates from the standard. Recent studies have suggested that the use of glucose polymers (i.e., Ricelyte®) leads to a decrease in the amount and duration of diarrhea, compared with glucose alone; presumably,

these newer solutions will find more widespread use, particularly for patients with voluminous or prolonged diarrhea.

In general, antidiarrheal agents are ineffective and have no role in the treatment of infectious gastroenteritis during childhood; agents that decrease intestinal mobility (i.e., Lomotil ®) carry an additional risk of toxicity.

Preliminary studies that point to a decrease in stool output with bismuth subsalicylate (Pepto-Bismol) require confirmation of efficacy and safety before recommendations for use in children can be made. When selected pathogens are isolated or strongly suspected, antimicrobial agents should be prescribed.

CHAPTER 20

Disturbed Child

[*]JOHN SARGENT, MD and [†]GORDON R. HODAS, MD

[*]*Department of Psychiatry, Karl Menninger School of Psychiatry and Mental Health Sciences, and The Menninger Clinic, Topeka, Kansas;*
[†]*Department of Psychiatry, The University of Pennsylvania School of Medicine, and Office of Mental Health and Substance Abuse Services, Pennsylvania Department of Public Welfare, Philadelphia, Pennsylvania*

This chapter presents an approach for the diagnosis of the acutely disturbed child who manifests agitation and aggression or withdrawal. Additional details of management of the conditions discussed here are found in Chapter 129.

Human beings generally respond to stress or personal threats by developing a fight-or-flight response. They become aggressive in an attempt to confront the threat or they withdraw to maintain safety. Throughout their development, regardless of age or developmental stage, children respond to threats through fight (agitation and aggression) or flight (withdrawal). Although these behaviors differ in their manifestations at different ages, the underlying responses are similar throughout childhood.

At times, the child's ways of responding to external events and changes in the environment are inadequate. In other situations, a previously supportive environment no longer provides security and protection. As a result, the child may no longer be in control of his or her social and emotional responses. It is usually at this point of crisis that the emergency physician meets the child and his or her caretakers.

Although agitation and withdrawal are distinctly different behaviors, it is important to recognize that a child in crisis can fluctuate easily from one to the other. For example, a sullen, withdrawn, and uncooperative adolescent may become agitated, angry, and disruptive in the face of additional stress. Also, both agitation and withdrawal can result from the same underlying physical and psychologic causes. Thus, both agitation and withdrawal as presenting symptoms in children in crisis are signs of significant emotional stress that the emergency physician should recognize and be prepared to treat.

The agitated child is typically anxious, upset, and unresponsive to attempts at support. The child may pace back and forth and may threaten staff or family. Speech usually is loud and may be abusive. Some children also may be disoriented and out of contact with reality. When agitated, younger children may be out of control, running about the examining room and having severe temper tantrums. They may cry or strike out at the parent or physician. Older children or adolescents may be distraught, sullen, and angry as they meet the examiner. It is important for the emergency physician to be aware of his or her own responses to agitated children; feelings of anger and frustration in the physician often reflect the amount of stress that the child is experiencing. Some children or adolescents, however, may appear to be calm and under control when seen in the emergency department (ED). Information from the parents may reveal significant destructiveness at home before coming to the hospital. In many cases, the improvement in the child's behavior in the ED is a response to the structure provided and the sense that help will be forthcoming.

The withdrawn child primarily demonstrates significant unresponsiveness to the demands of the situation. He or she is inappropriately quiet and does not attempt to develop any relationship with the emergency physician. In younger children, this withdrawal may be demonstrated by clinging behavior, whining, and crying. The child may be unresponsive to parents as well as to the physician, instead responding to internal stimuli and demonstrating inappropriate affect. Older children may be sullen, unresponsive, or apathetic when asked about the precipitant of the current ED visit. It is important to distinguish emotional withdrawal from shyness, which is a temperamental quality within the range of normal behavior.

DIFFERENTIAL DIAGNOSIS

A wide variety of medical and psychiatric conditions can lead to a child's development of significant agitation and withdrawal. These disorders are listed in Table 20.1 and include severe psychiatric disturbances, life-threatening medical conditions, and minor aberrations in the child's ability to respond to stressful events. Regardless of the underlying cause, an emotional state develops that disrupts the child's daily routine and the family's usual ways of coping with stress. Resumption of normal growth and development for the child requires that the underlying cause of the presenting behavior

be appreciated and addressed.

I. Psychosis, caused by:
  A. Medical illness
  B. Ingestion of toxic substance
  C. Pervasive developmental disorder (i.e., autism)
  D. Adult type of schizophrenia
  E. Manic depressive illness
II. Depression
III. Conduct Disorder
IV. Adjustment Reaction of Childhood or Adolescence
V. Attention Deficit Disorder
VI. Medical Illness in the Absence of Psychosis (i.e., thyrotoxicosis, temporal lobe epilepsy)
VII. Sensory Deficit: blindness, deafness
VIII. Severe Communication Disorder (e.g., childhood aphasia)

Table 20.1. Differential Diagnosis of Agitation and Withdrawal in Childhood

Psychosis

An acutely psychotic child may present to the ED as anxious and agitated or as preoccupied and withdrawn. *Psychosis* refers to a mental state in which major disturbances in thinking, relating, and reality testing occur. Psychotic patients do not express themselves clearly and have difficulty answering direct questions. They also may be extremely suspicious and hostile. Psychosis may be the result of a psychiatric disorder or a physical cause. Psychiatric causes of psychosis include early childhood autism, childhood schizophrenia, adolescent-onset schizophrenia, and manic depressive disorder. Children who have been previously well adjusted or may have had mild to moderate emotional problems rarely develop an acute psychotic reaction after a severe, overwhelming trauma, such as severe abuse, or threatened or witnessed violence. Physical or organic causes of psychosis include an ongoing medical illness or an acute intoxication with an exogenous substance. The emergency physician must be able to determine the cause of psychosis in a child because treatment presupposes proper diagnosis. Certain aspects of the child's mental status help distinguish between psychiatric and organic psychosis. These differentiating features are outlined in Table 20.2.

Evaluation Feature	Organic Psychosis	Psychiatric Psychosis
Onset	Acute	Gradual
Pathologic autonomic signs[b]	May be present	Absent
Vital signs	May be abnormal	Normal
Orientation	Impaired	Intact
Recent memory	Impaired	Intact
Intellectual ability	May be impaired	Intact
Hallucinations	Visual	Auditory

[a]Children with both functional and organic psychoses will have impaired reality testing, inappropriate affect, thought disorder, poor behavior control, and disturbed relating ability.
[b]Increase or decrease in heart rate, respiratory rate, blood pressure and temperature, miosis or mydriasis, skin color changes.

Table 20.2. Differentiating Features of Organic and Psychiatric Psychosis[a]

The child or adolescent who has developed an organic psychosis is likely to be disoriented, particularly with regard to time and place. The child's recent memory also is typically impaired in organic psychoses, and the child may be unable to describe the onset of his or her problems coherently. In addition, hallucinations, when present, usually are visual or tactile rather than auditory (although the latter also may be present). In contrast, the child with a psychiatric psychosis is likely to be oriented to person, place, and time and should be able to report recent events accurately. Other intellectual and cognitive functions usually remain intact. Hallucinations, when present, tend to be auditory in nature, and a greater sense of suspiciousness is common. The rate of onset of psychosis is also revealing. Organic psychosis is more likely to be acute in onset or be the result of acute deterioration in an ongoing chronic condition. A psychiatric psychosis is more likely to be gradual in onset, following a prolonged period of progressive social and emotional withdrawal. Table 20.3 lists medical conditions in childhood that may induce, at some point in their course, acute psychosis with agitation or withdrawal. As can be noted from Table 20.3, many of these illnesses are chronic conditions that may have been present for some time and may have been already under treatment. Therefore, with all psychotic children, it is extremely important to obtain an accurate history of current and previous medical problems. Other medical conditions that may cause psychosis, such as head injury and Reye syndrome, can develop acutely and may progress rapidly to unconsciousness and death unless identified and treated.

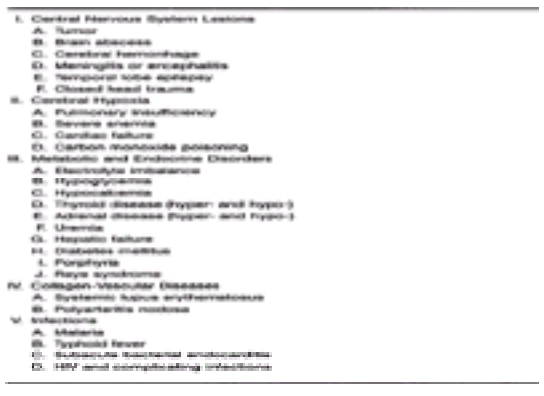

Table 20.3. Medical Conditions That May Lead to Psychosis

Table 20.4 lists drugs that may lead to psychosis characterized by agitation or withdrawal. Some of these drugs are used illicitly, and others are prescription drugs ingested either accidentally or on purpose. In obtaining a history, a frequent important clue in drug intoxication is the acute onset of disordered thinking in the presence of visual hallucinations. A history of drug abuse and the availability of toxic substances are other important historical clues to the diagnosis of acute drug intoxication. Intoxications with alcohol, sedatives, antidepressants, anticholinergic agents, and heavy metals all can be life-threatening if enough of the agent has been ingested and absorbed. Appropriate medical therapy must be instituted as rapidly as possible.

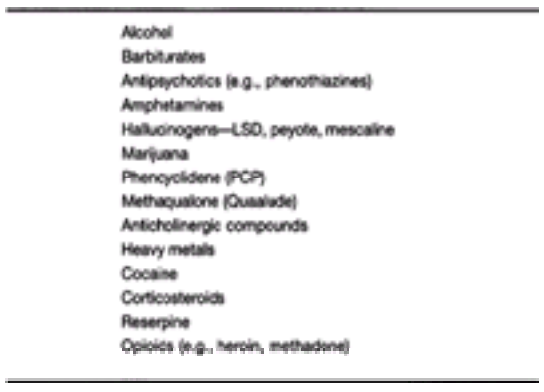

Table 20.4. Exogenous Substances Causing Psychosis after Ingestion of Significant Quantity

Psychiatric conditions that lead to psychosis in children and adolescents often are distressing and may also be life-threatening. This threat to life can occur when the child's hallucinations are so disturbing that suicide is sought for relief. Furthermore, as a part of psychosis, a child may develop a delusional system that leads him or her to attack another person who is seen as threatening. The psychotic child or adolescent may neglect his or her physical well-being through sleep deprivation and malnutrition. These deprivations themselves may intensify the child's vulnerability and exacerbate the psychosis. When dealing with the psychotic child or adolescent, it is imperative that the emergency physician evaluate the suicidal and homicidal potential of the patient as well as the overall physical condition and ability to maintain self-care.

Depression

Other children who may be brought to the ED for agitated or withdrawn behavior are those who are severely depressed. These children are more likely to be oriented, coherent in their thinking, and able to discern reality from fantasy. However, there may be a history of deterioration in social and intellectual performance over the preceding months and evidence of withdrawal from important activities and relationships. The child may be described by his or her parents as being apathetic and may be extremely sad. The child may present as withdrawn and hopeless and may make it difficult for the emergency physician to engage him or her in conversation. Other depressed children may present primarily as anxious and angry, with minor concerns that cause preoccupation and outbursts. Precipitants of depression and a sense of hopelessness may include parental divorce or separation, loss of a parent through death, a recent devaluation of personal abilities through poor academic performance, peer rejection, or the onset of significant physical illness. Once depression is identified as the cause of the child's agitation or withdrawal, it is extremely important for the emergency physician to inquire about the presence and nature of suicidal ideation. The physician also should ask about disturbances in appetite and sleep.

Other Conditions

Other psychiatric conditions—conduct disorders with severe behavioral disruption, adjustment reactions with interruption of normal coping mechanisms, and attention deficit disorder—also may lead a child to present in the ED with significant agitation or withdrawal. With each of these problems, the emergency physician's first task is to screen for suicidal or homicidal ideation and intent. Then, after evaluating the problem, the physician can consider and pursue alternatives for further treatment and referral. The child or adolescent who has a conduct disorder often will have a history of significant behavioral disruption, such as aggressiveness, stealing, fire-setting, truancy, and other forms of delinquency. The child presents as oriented and responsive but also may be angry and resentful about being brought to the ED. The child's

behavior may improve in the ED when it is made clear that misbehavior or temper tantrums will not be tolerated.

Children and adolescents who have been victims of past or ongoing physical or sexual abuse or other severe trauma may develop acute agitation or withdrawal brought on by posttraumatic stress disorder. The symptoms of this disorder include fluctuating behavior with episodes of excitement, fearfulness, or irritability; recurrent nightmares or flashbacks; and lack of involvement in usual friendships or activities. Children who experience posttraumatic reactions often avoid or refuse to talk about the trauma, and thus, parents may be confused about the reasons for the child's disturbed and disturbing behavior. If parents are aware of the traumatic event, they may be upset or feel guilty about its occurrence. In this situation, the parents' reaction may make it difficult for them to support and comfort the child and the emergency room physician may be faced with the need to calm the parents to evaluate the situation further.

A child who has an emotional disturbance from an adjustment reaction generally becomes calm as he or she recognizes the physician's concern and desire to understand the situation. An adjustment reaction is characterized by a deterioration of functioning from a previously higher level in the presence of some precipitating event or situation. The child with an adjustment reaction is oriented and usually can explain his or her problems well. At times, the precipitant may be a developmental event, such as enrollment in a new school, increased peer pressure, or the emergence of secondary sexual characteristics during puberty. The precipitant also may be an acute event such as the loss of a parent through death or divorce.

A child with an attention deficit disorder is likely to have a history of impulsivity with associated distractibility, as well as a history of learning difficulties at school. Acute agitation or withdrawal that requires an ED visit is likely to result from some consequence of the child's difficulties at school or at home.

Certain medical conditions, such as temporal lobe epilepsy and thyrotoxicosis, also can cause agitation and withdrawal without psychosis. The child with thyrotoxicosis will have tachycardia, appetite and sleep disturbances, weight loss, and possibly, exophthalmos in association with the disordered behavior. The child with temporal lobe epilepsy may be identified through the history of seizures and auras and the possible presence of abnormal neurologic findings on physical examination. Differentiation between temporal lobe epilepsy and psychiatric behavioral disturbances may, at times, be difficult and may require neurologic psychiatric consultation. Children with sensory deficits, such as blindness, deafness, or severe communication difficulties, including developmental aphasia, occasionally may present in the ED with concomitant agitation or withdrawal, and it is important for the physician to bear these possibilities in mind.

EVALUATION AND DECISION

The emergency assessment of the agitated or withdrawn child or adolescent involves three complementary areas. In actual practice, the physician gathers data from all three areas at the same time; however, for conceptual clarity, they are discussed separately here. The first area involves determination of whether the problematic behavior is caused by some medical condition or organic state and, if so, what diagnosis to make. To achieve this, the physician gathers information about the acute events that led to the ED visit, any possible drug ingestions or drug use, and the child's medical history. This is followed later by a complete physical examination. Potential life-threatening effects of the medical condition must be recognized and treated. Second, the psychiatric manifestations of the presenting condition, whether organic or psychiatric, are assessed. To do this, the physician performs a thorough mental status examination. Of particular concern is the determination of whether the patient is suicidal or homicidal. To complete the psychiatric evaluation of the child, the previous adjustment and the psychiatric history of the child are determined. These data should facilitate the diagnosis of psychiatric presenting problems. Third, the family system and social support for the child are assessed. This is done by observing the family's responses to the child during the ED visit and by assessing previous family functioning. Once these three areas have been evaluated, the physician can make an appropriate decision regarding disposition and further treatment.

Medical Conditions

First, to determine whether the child's agitation or withdrawal is organically based, the physician should bear in mind the differential diagnosis of these behaviors, which include psychiatric as well as organic origins (Table 20.1). A complete history of the acute events that led up to the ED visit, including any changes in behavior or functioning of the child, should be obtained. This information will help the psychiatric as well as medical assessment. The possibility of drug use or drug ingestions should be explored with the parents as well as with the child. The child's medical history should be documented carefully, and any previous episodes of the current behavior should be reviewed. In general, organically based problems are acute in onset and result from an ingestion, an injury, or the worsening of a medical condition. At times, the child's age may be helpful in suggesting certain diagnoses. For example, with children 12 years of age and older, drug abuse is common, whereas with younger children, acute ingestion of medications or other toxic substances is more common.

The differentiating features of organic psychoses and psychiatric psychoses already have been discussed and are listed in Table 20.2. Important information will come from the history (acuteness of onset of psychosis, presence of drug ingestion), the mental status examination (orientation, memory, intellectual function, nature of hallucinations), and the physical examination (presence of pathologic autonomic signs, abnormal vital signs, physical findings on medical and neurologic examinations). With an organic psychosis, the physician must consider the possible medical causes of psychosis (Table 20.3) as well as those that result from ingestion (Table 20.4).

The medical evaluation of agitation and withdrawal requires that every child who presents to the ED with these behaviors receive a complete physical examination, including full neurologic evaluation. This makes it possible to detect most significant ongoing organic illnesses and neurologic disease of traumatic, infectious, or structural origin. Pupillary abnormalities, when found in conjunction with abnormalities of pulse, temperature, and blood pressure, suggest an acute intoxication. Abnormal reflexes suggest central nervous system disease and may warrant further diagnostic study. Mild incoordination, abnormalities of rapid alternating movements, and impaired tandem gait may be present in children with

an attention deficit disorder. In situations in which an acute intoxication is being considered, blood and urine should be obtained and sent for specific drug determination or toxic screening, as appropriate. Additional laboratory studies should be pursued in accordance with the findings of the physical examination and may include a complete blood count, sedimentation rate, urinalysis, electrolytes, blood glucose, calcium, blood urea nitrogen, ammonia, and liver function tests. Thyroid studies are indicated when ongoing thyroid disease is suspected. With this information in hand, medical conditions, when present, can be diagnosed and appropriate treatment can be initiated. A computed tomographic (CT) scan or magnetic resonance imaging (MRI) examination may be helpful when trauma or a mass lesion is being considered.

Psychiatric Evaluation

The second major area in the ED approach to an agitated or withdrawn child involves assessment of psychiatric manifestations of the presenting condition. This is achieved through the mental status examination, in conjunction with an evaluation of the child's previous level of adjustment and the past psychiatric history. The ED mental status examination is the most important mechanism for determining the behavioral and emotional condition of the child, including the possible presence of suicidal or homicidal intent. The child's mental status can be determined through direct interaction with the child in the presence of the parents. The physician should approach the mental status examination systematically. With the various categories in mind, the physician can obtain much of the data during the history and physical examination. Other areas will require direct questioning of the child by the physician.

The categories of the mental status examination, as described in Chapter 129, also are summarized here. The child's appearance will have already been noted by the physician. Orientation to person, place, time, and situation should be determined. Short- and long-term memory should be tested, as should cognitive functions, which include intelligence, fund of knowledge, and the ability to reason and think (much of this information can be determined from the flow of the interview). The child's behavior should be assessed for activity level and age appropriateness. The child's capacity for relating to the physician can be determined by the physician's noting not only the child's behavior with him or her but also his or her own internal responses to the child's behavior. Particularly important in the emergency assessment of the child are affect and thinking. Affect refers to the predominant feelings displayed by the child. The examiner should observe the nature of the affect (e.g., happy, sad, angry, flat), its degree of appropriateness to the situation, and how it changes as various subjects are discussed. Thinking includes thought processes and thought content. The coherence and goal-directedness of verbal communication are assessed, and loose associations and speech that lacks internal consistency are noted.

Evaluation of thought content involves identifying the child's major themes and concerns. Preoccupations, such as hallucinations, delusions, and ideas of reference (present in psychosis), or sadness, hopelessness, and feelings of depression (present in depression), should also be sought. The child's strengths can be assessed from spontaneous statements as well as from forthrightness in answering specific questions. The child's insight into the current problem should be noted, and his or her capacity to suggest a plan to deal with the present crisis should be evaluated.

Determining the presence or absence of suicidal or homicidal ideation and intent is an essential part of the mental status examination and provides an opportunity to ask about past attempts. The circumstances and intent of any previous suicidal or homicidal attempts should be explored thoroughly. The most effective way of determining such intent is by asking the child directly. Such an approach opens the subject in a way that often is reassuring, thereby enabling the discussion to proceed.

As the mental status examination is carried out, the physician develops a picture of the child that leads to certain diagnostic possibilities. For example, the psychotic child will have bizarre or inappropriate affect, speech that is not goal-directed, and possibly, hallucinations or delusions. Such a child typically relates poorly to the physician, avoiding eye contact, failing to respond to the physician's attempts to empathize, and perhaps, engendering in the physician feelings of confusion and uneasiness. If the psychotic child is oriented with intact memory and cognitive functions, it is likely that the psychosis is psychiatric in origin. If the child's orientation, memory, and cognitive functions are significantly impaired, it is probable that the psychosis is organic in nature. When the child's thinking is coherent and the affect is not bizarre or inappropriate, it is likely that psychosis is not present. With depressed children, themes of sadness occur, and the physician may find himself or herself attracted to the child and feeling sorry for him or her. This same reaction by the physician also may occur with children who present with an adjustment reaction. Children who are upset about a previous trauma may be particularly difficult to evaluate. They will appear frightened, may be erratic in their behavior, and may be uncomfortable with relating and discussing previous traumatic events. These children may be helped to explain their thoughts and fears in a quiet environment, with gentle support from the physician. Younger children who are frightened and who do not easily separate from their parents should raise suspicion about past or current trauma. With a conduct disorder, the history usually is informative, and the child's manner of relating may be distant or manipulative. The physician may feel angry at such children. At times, the child with an attention deficit disorder may show distractibility and impulsivity in the ED, but often, these behaviors do not occur in one-to-one settings and will be revealed only by the history. The child who has some insight into his or her problem is more likely to have depression or an adjustment reaction than psychosis or a conduct disorder.

The child's previous level of adjustment offers important information for a complete profile. The physician can ask about the child's family relations, peer relations, and school performance before the onset of the crisis. The child's major areas of interest and special competences should be appreciated. A child in an age appropriate grade in a regular classroom who has had satisfactory involvement with friends and social activities has a good prognosis in general. The child from a chaotic family who is a loner and who attends school sporadically has a poorer prognosis. In all instances, however, it is important that the physician uncover some areas of strength in the child and family because this will serve as the basis for resolving the current crisis and for pursuing further treatment.

Previous psychiatric hospitalization or outpatient treatment should be determined, as well as any past incidents of suicidal or homicidal behavior. Knowledge of past and current medication also is crucial. Family history of psychiatric

disorder can be obtained at the same time that the child's history is taken.

Evaluation of Support Systems

Finally, emergency evaluation includes assessment of the family and social support system. To master a crisis, a child needs consistency and support within his or her environment. Information about who lives at home with the child, the nature of their relationships with each other, and any recent changes in family composition or in the child's living situation help in understanding the current problem and in determining treatment.

The physician can gain information about the family through observation and direct questioning. In so doing, information about family relationships, including the parents' level of concern and their ability to appreciate the child's current situation, is obtained. Family structure often is revealed by noting which family members accompany the child to the ED. Typically, the family members with the child are more involved. The parents' description of the child during the history taking offers insight into how the child is perceived in the family. The extent to which the parents try to engage a withdrawn child or to calm and set limits with an agitated child should be noted, as well as the child's response to these efforts.

As the child is asked a question by the physician, parents' responses are also informative. Do the parents answer for the child and interrupt when he or she tries to speak, or do they give their child an opportunity to form a relationship with the physician? The parental response suggests the degree to which the child's independent thinking and behavior are encouraged. If the child is not cooperative during the psychiatric or physical examinations, how effective are the parents in telling the child that he or she must cooperate? The parents' success in gaining the child's cooperation during the ED visit may offer a valuable clue about their ability to manage their child effectively at home.

The physician can assess the degree of coping by the family in part by the way in which the family members describe problems. Responses that suggest that the parents are overwhelmed and disorganized should lead the physician to consider psychiatric consultation and possible hospitalization. The openness of the family in discussing recent difficulties also is important. Some families are extremely guarded and deny problems, despite the presence of a major crisis that they are unable to manage. Other families offer a more balanced view of family functioning, instilling greater confidence in the physician. If the child's parents are divorced, assessing the relationship between the parents is important. Arguments and disagreements as well as the possibility of violence lead to a lack of safety and security for the child in crisis. The degree of support that a single parent receives from extended family and neighbors is also an important factor in evaluating family support and capacity.

The family should be asked about the adjustment of the child in the past and how earlier family difficulties were handled. Family history of emotional difficulties also should be obtained. The physician should be clear about who the major caretakers of the child have been through his or her life. In obtaining the family's perception of the crisis, it is best to begin by posing an open-ended question to each family member (e.g., “What do you think is going on with your child and in your family?”). After the family has responded, the physician can ask specific questions about recent significant events or changes that could be influencing the current situation. If the physician has any suspicion that previous or ongoing trauma or abuse underlies the child's acute difficulties, he or she should ask parents and child alike. (For further discussion of the management of child abuse, see Chapter 128). Before discharge, the physician should be confident that the child is safe; otherwise, social work or psychiatric consultation should be obtained. In all situations of posttraumatic stress reactions, outpatient psychiatric treatment generally is necessary.

In determining the disposition of a child with a psychiatric problem in the ED, the physician should be guided by the severity of the problem and by the ability of the family to manage the child on an outpatient basis. The physician should inquire about what social supports are available to the parents. If extended family or close friends are available and the parents believe that their participation would be helpful, the physician should encourage the parents to enlist such help. If other agencies are working with the family, their efforts should be coordinated with those of the hospital or mental health facility at which the child receives treatment. Many families express a clear preference about whether their child should be hospitalized. The physician should keep this preference in mind but should make the decision based on the data about the child's physical and emotional well-being and the assessment of the family support system.

Disposition

As depicted in Figure 20.1, agitation and withdrawal can occur in the presence or absence of psychosis. When psychosis is present, the first task is to establish whether an organic cause is present. Organic psychosis always requires a full medical evaluation, observation, and treatment of the underlying condition, all of which are best accomplished through medical hospitalization. Psychiatric consultation is indicated in all cases of psychiatric psychosis. Psychotic patients who are not suicidal or homicidal may be referred for ongoing outpatient treatment after a positive response to antipsychotic medication (see Chapter 129).

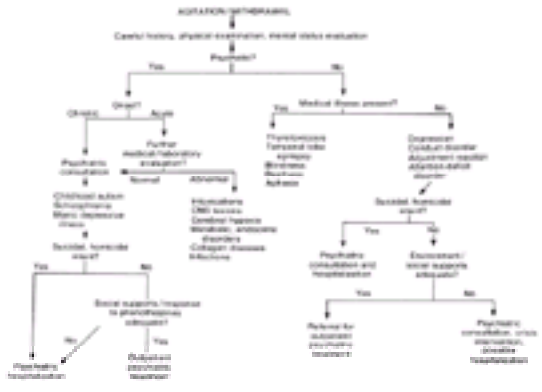

FIGURE 20.1. Approach to the diagnosis and initial disposition of the acutely disturbed child.

Psychotic patients who have suicidal or homicidal intent usually are hospitalized. Psychiatric consultation also is indicated in the presence of active suicidal or homicidal ideation in the absence of psychosis. Persistent suicidal or homicidal intent usually is an indication for psychiatric hospitalization. When suicidal or homicidal thoughts are absent, the ability of the family and social support system to control the child's behavior and prevent further emotional and physical harm should be assessed. If the support system is adequate, referral to outpatient psychiatric treatment may be appropriate. The physician who makes a referral for outpatient psychiatric treatment should help the family develop short-term measures to manage the child and relieve his or her distress until outpatient psychiatric treatment begins. When the support system is not adequate, psychiatric hospitalization may be necessary, especially with such behaviors as fire-setting, repeated running away, and persistent aggressiveness.

CHAPTER 21

Dizziness

STEPHEN J. TEACH, MD, MPH

Department of Pediatrics, George Washington University School of Medicine, and Children's National Medical Center, Washington, D.C.

“Dizziness” is a common complaint in the pediatric emergency department. True vertigo, the perception that the environment is rotating relative to the patient or that the patient is rotating relative to the environment, arises in the peripheral or central vestibular system. It can be immensely disturbing, even frightening, to patients and their families. Preverbal children, unable to articulate the sensation, may merely be irritable, vomit, and prefer to lie still.

Unfortunately, most patients who use the term *dizziness* are in fact describing one of numerous nonvertiginous disturbances (pseudovertigo), which may be difficult for the practitioner to distinguish from true vertigo. Light-headedness, presyncope, intoxication, ataxia, visual disturbances, unsteadiness, stress, anxiety, and fear from any of numerous causes can initially be described as dizziness.

Therefore, when evaluating a child complaining of dizziness, the practitioner must listen carefully to the details of the history that will allow him or her to distinguish true vertigo from pseudovertigo. The key element in the history that distinguishes true vertigo is the subjective sense of rotation. Often, the best response to a chief complaint of being dizzy is to say, “Tell me what you mean by ‘dizzy.’” Initially vague complaints often become increasingly concrete, and the underlying diagnosis becomes increasingly clear.

PATHOPHYSIOLOGY

True vertigo arises from a disturbance in either the peripheral or central components of the vestibular system. The two peripheral sensory organs of the system (together known as the labyrinth) are the semicircular canals (stimulated by rotary motion of the head) and the vestibule (stimulated by gravity). Both organs lie near the cochlea within the petrous portion of the temporal bone. The proximity of the vestibular and cochlear apparatus explain the frequent association of vertigo with hearing impairment.

Afferent impulses from these organs travel via the vestibular portion of the eighth cranial nerve to the vestibular nuclei in the brainstem and to the cerebellum. Cortical projections terminate in the superior temporal gyrus and the frontal lobe. Efferents from the cerebellum and vestibulospinal tract to the peripheral muscles complete the circuit by which the vestibular system helps maintain balance and position sense. Additional impulses from the vestibular nuclei ascend within the medial longitudinal fasciculus to cranial nerves III, IV, and VI, accounting for the oculovestibular reflexes. Almost all patients complaining of true vertigo should have nystagmus, at least when the vertiginous symptoms are peaking. If not, then a vestibular defect is much less likely.

DIFFERENTIAL DIAGNOSIS

As discussed earlier, dizziness is best divided into vertiginous conditions (true vertigo) and nonvertiginous conditions (pseudovertigo). Table 21.1 lists the differential diagnosis of true vertigo and highlights the life-threatening causes. Table 21.2 lists the most common causes of vertigo. Table 21.3 lists numerous nonvertiginous conditions that may initially be described as dizziness. Because the spectrum of nonvertiginous conditions is so broad, the following discussion will concentrate on true vertigo.

Peripheral Causes	Central Causes
Suppurative or serous labyrinthitis	Tumor*
External ear impaction	Meningitis*
Ramsay Hunt syndrome	Encephalitis*
Cholesteatoma	Increased intracranial pressure*
Perilymphatic fistula	Multiple sclerosis
Vestibular neuronitis	Trauma*
Benign paroxysmal vertigo	Seizure (usually complex partial)
Ingestions*	Migraine
Temporal bone fracture*	Stroke*
Posttraumatic vestibular concussion	Motion sickness
Ménière's disease	Paroxysmal torticollis of infancy

*Life-threatening causes of vertigo.

Table 21.1. Causes of Vertigo in Children

Suppurative or serous labyrinthitis	Ingestions
Benign paroxysmal vertigo	Seizure
Migraine	Motion sickness
Vestibular neuronitis	

Table 21.2. Common Causes of Vertigo

Depression	Cardiac disease
Anxiety	Anemia
Hyperventilation	Hypoglycemia
Orthostatic hypotension	Pregnancy
Hypertension	Ataxia
Heat stroke	Visual disturbances
Arrhythmia	

Table 21.3. Common Causes of Pseudovertigo

Vertigo follows a dysfunction of the vestibular system within the semicircular canals, vestibule, or vestibular nerve (peripheral vertigo), or within the brainstem, cerebellum, or cortex (central vertigo). It can also be divided into conditions in which hearing is impaired (usually peripheral causes) and conditions in which hearing is spared (usually central causes). Finally, vertigo can be divided into acute (usually infectious, postinfectious, traumatic, or toxic) and chronic-recurrent groups (usually caused by seizures, migraine, or benign paroxysmal vertigo of childhood).

Infections

Both acute and chronic bacterial and viral infections of the middle ear with or without associated mastoiditis may cause both vestibular and auditory impairment (see Chapter 32). Severe, untreated, acute suppurative otitis media with effusion may extend directly into the labyrinth. Even without direct invasion of the pathogens, inflammatory toxins can cause a serous labyrinthitis.

Chronic and recurrent otitis media can produce a cholesteatoma of the tympanic membrane, an abnormal collection of keratin caused by repeated cycles of perforation and healing. Cholesteatomas can erode the temporal bone and the labyrinth, producing a draining fistula from the labyrinth that presents as vertigo, nausea, and hearing impairment. Computed axial tomography (CAT) scans show destruction of the temporal bone.

Viral infections can directly affect the labyrinth or the vestibular nerve; together these conditions are known as vestibular neuronitis. Known pathogens include mumps, measles, and the Epstein-Barr virus. More commonly, a nonspecific upper respiratory tract infection may precede the illness. Onset is usually acute and can be severe. Nystagmus is usually present. Patients prefer to lie motionless with their eyes closed. Recovery is from 1 to 3 weeks. Early use of prednisone may shorten the course.

Migraine

Vertigo may be a prominent feature of classic migraine or migraine equivalent, in which there is no associated headache

(see Chapter 83). Up to 19% of children with migraine may have vertiginous symptoms during their aura. Basilar migraine presents as a throbbing occipital headache following signs and symptoms of brainstem dysfunction (including vertigo, ataxia, tinnitus, and dysarthria). Vertigo from migraine equivalent (without pain) is typically seen in patients with a family history of migraine headache and is associated with other transient neurologic complaints (e.g., weakness, dysarthria). Symptoms may suggest temporal lobe epilepsy. The latter is distinguished by altered consciousness.

The differential diagnosis of headache and vertigo includes a brainstem or cerebellar mass, hemorrhage, and infarction. These uncommon disorders are best assessed by magnetic resonance imaging (MRI).

Benign Paroxysmal Vertigo

Considered by many to be a form of migraine, benign paroxysmal vertigo is most common in children between the ages of 1 and 5 years. Patients have recurrent attacks, usually one to four per month, and occasionally in clusters. Onset is sudden—the child often cries out at the start of each episode—and is associated with emesis, pallor, sweating, and nystagmus. Episodes are brief, lasting up to a few minutes, and may be mistaken for seizures. Consciousness and hearing are preserved, and the neurologic examination is otherwise normal. The disorder spontaneously remits after 2 to 3 years.

Ototoxic Drugs

Most agents that disturb vestibular function will also disturb auditory function. Specific agents include aminoglycoside antibiotics, furosemide, ethacrynic acid, streptomycin, minocycline, salicylates, and ethanol. Toxic doses of certain anticonvulsants and neuroleptics can produce measurable disturbances of vestibular function, although associated complaints of vertigo are rare.

Posttraumatic Vertigo

Several mechanisms account for posttraumatic vertigo. The most obvious is fracture through the temporal bone with damage to the labyrinth. Presentation includes vertigo, hearing loss, and hemotympanum. Computed tomography (CT) scanning of the temporal bone should be obtained when there is hemotympanum or posttraumatic evidence of vestibular dysfunction.

More subtle causes of posttraumatic vertigo include trauma-induced seizures, migraine, or a postconcussion syndrome. The latter disorder (vestibular concussion) typically follows blows to parieto-occipital or temporoparietal regions and presents with headache, nausea, vertigo, and nystagmus. Hyperextension and flexion (“whiplash”) injuries can be associated with vestibular dysfunction, probably caused by basilar artery spasm with subsequent impairment of their labyrinth and cochlear connections. Symptoms may mimic basilar artery migraine.

Seizures

Two types of seizures are associated with vertigo: vestibular seizures (seizures causing vertigo) and vestibulogenic seizures (“reflex” seizures brought on by stimulating the semicircular canals or vestibules by sudden rotation or caloric testing). Vestibular seizures, the more common type, consist of sudden onset of vertigo with or without nausea, emesis, and headache and are invariably followed by loss or alteration of consciousness. The electroencephalogram (EEG) is abnormal. Anticonvulsants may be of benefit.

Motion Sickness

Motion sickness is precipitated by a mismatch in information provided to the brain by the visual and vestibular systems during unfamiliar rotations and accelerations. The most common situation occurs when a child travels in a car or airplane and is deprived of visual stimulus that confirms movement. Symptoms include vertigo, nausea, and nystagmus. Attacks can be prevented by allowing patients to watch the environment move in a direction opposite to the direction of body movement. In car travel, encouraging children to “look out the window” is helpful.

Ménière's Disease

Uncommon in children younger than 10 years, Ménière's disease is characterized by episodic attacks of vertigo, hearing loss, tinnitus, nystagmus, and autonomic symptoms of pallor, nausea, and emesis. Between episodes, patients may complain of impaired balance. The underlying cause is believed to be an overaccumulation of endolymph within the labyrinth, which causes a rupture (endolymphatic hydrops). Typical attacks last from 1 to 3 hours and usually begin with tinnitus, a sense of fullness within the ear, and increasing hearing impairment. Attacks are intermittent and unpredictable, often lasting for years and, at times, evolving to permanent hearing loss.

Miscellaneous Causes

Vertigo may occur at any point in the clinical course of multiple sclerosis when the central demyelination interferes with the vestibular nuclei in the brainstem or its efferents or afferents. Diagnosis is confirmed by MRI and lumbar puncture. Paroxysmal torticollis of infancy consists of spells of head tilt associated with nausea, emesis, pallor, agitation, and ataxia. Episodes are brief and self-limited and may recur for months or years. The cause is unclear, although some authors see it as a prelude to later benign paroxysmal vertigo (considered by some to be a migraine variant). Perilymphatic fistula is an abnormal communication between the labyrinth and the middle ear, with leakage of perilymphatic fluid through the defect. It may be congenital or acquired by trauma, infection, or surgery. Diagnosis is by middle ear exploration. Finally, vertigo may be associated with diabetes mellitus and chronic renal failure.

EVALUATION AND DECISION

Differentiation of True Vertigo and Pseudovertigo

Evaluation of children complaining of dizziness begins by separating those with true vertigo from those with pseudovertigo (Table 21.1 and Table 21.3). True vertigo is always associated with a subjective sense of rotation of the environment relative to the patient or of the patient relative to the environment. Acute attacks are usually accompanied by nystagmus. Pseudovertigo is suggested by complaints of light-headedness, flushing, weakness, ataxia, unsteadiness, weakness, fatigue, pallor, anxiety, stress, and fear.

True Vertigo (Fig. 21.1)

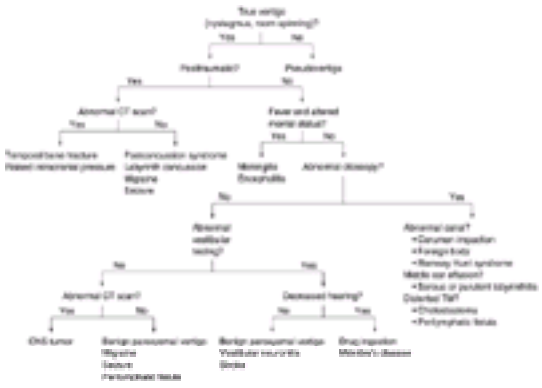

FIGURE 21.1. Approach to the child with true vertigo.

History and Physical Examination

Once true vertigo is identified, its severity, time course, and pattern must be established. In general, the most severe attacks of vertigo are due to peripheral causes, whereas central causes tend to be more recurrent, chronic, and progressive. Sudden onset of sustained vertigo suggests central or peripheral trauma, infection, central stroke, or ingestion. Chronic recurrent episodes suggest seizures, migraine, or benign paroxysmal vertigo. More persistent episodes suggest brainstem or cerebellar mass lesions. Recurrent, transient, altered mental status suggests seizure or basilar migraine. Episodes of prior head injury suggest concussion syndromes. Recent upper respiratory tract infections may suggest vestibular neuronitis. History of ototoxic drugs or intoxicants is important, as is a family history of migraine. Age of the patient is especially helpful—benign paroxysmal vertigo is unusual after age 5 years, whereas Ménière's disease is unusual before age 10 years.

The physical examination focuses on the middle ear and on neurologic and vestibular testing. Perforation or distortion of the tympanic membrane should be noted. A pneumatic bulb will enable the examiner to see whether abrupt changes in the middle ear pressure trigger an episode of vertigo, a suggestion that a perilymphatic fistula may be present (Hennebert's sign).

The neurologic examination must be complete, focusing closely on the auditory, vestibular, and cerebellar systems. Both vestibular and cerebellar disorders will present with an unsteady gait. In both situations, when there is a unilateral lesion, the child will fall toward the side of the lesion. The two can be distinguished by the presence or absence of nystagmus and, in the verbal child, by the presence or absence of a sense of rotation. In addition, if cerebellar dysfunction is present, there will be a breakdown of rapid alternating movements and finger-to-nose movements.

Nystagmus is a highly specific sign for both central and peripheral vertiginous disorders. A patient complaining of dizziness from vertigo may not have nystagmus at the time that he or she is examined. Tests to elicit positional vertigo and nystagmus can therefore be helpful in identifying and even distinguishing central and peripheral vestibular dysfunction, particularly if the tests elicit or increase the patient's complaint.

Initially, nystagmus should be sought in all positions of gaze and with changes in head position. Peripheral vestibular disorders are characterized by a “jerk” nystagmus with the slow component toward the affected side. Central lesions are characterized by nystagmus with the fast component toward the affected side and reversal of the fast component when changing from right to left lateral gaze. The Nylen-Barany test is performed by moving a child rapidly from a sitting to a supine position with the head 45 degrees below the edge of the examining table and turned 45 degrees to one side. Nystagmus and a vertiginous sensation may result as the vestibular system is stressed. Certain features of the nystagmus elicited may be helpful in distinguishing central from peripheral vestibular dysfunction. In central dysfunction, for example, onset of nystagmus is immediate; in peripheral vestibular disorders, it is delayed.

The cold caloric response tests for integrity of the peripheral vestibular system. Slow and careful irrigation of either 100 mL of tap water 7°C below body temperature or 10 mL of ice water into the external ear canal through a soft plastic tube, with the child lying about 60 degrees recumbent, should induce a slow movement of the eyes toward the stimulus and a fast movement away. Vestibular damage will suppress the response on the affected side. The test is contraindicated if the tympanic membrane is perforated.

Laboratory Data

Laboratory investigations have a limited role in the evaluation of vertigo. Useful initial tests include a complete blood count, a serum glucose, and an electrocardiogram. Together, these may help identify patients with pseudovertiginous conditions caused by anemia, hypoglycemia, and rhythm abnormalities. Further laboratory testing may reveal diabetes or renal failure, both of which have been associated with vertigo. Toxicologic testing including specific anticonvulsant levels and an ethanol level, if indicated, may be helpful. A lumbar puncture is indicated in cases of suspected meningitis or encephalitis.

Radiologic imaging of the central nervous system, preferably by MRI for adequate visualization of the posterior fossa and brainstem, is indicated in cases of chronic and recurrent vertigo to exclude mass lesions. Children with vertigo and an underlying bleeding diathesis or a predisposition toward ischemic stroke (i.e., sickle cell disease) may also need an emergent cranial CT or MRI. Posttraumatic vertigo, especially when accompanied by hearing loss or facial nerve paralysis, is best assessed by computed axial tomography including adequate images of the temporal bone.

Some children with true vertigo will require referral for more extensive testing. An EEG is indicated when vertigo accompanies loss of consciousness or other manifestations of a seizure. Audiometry is indicated when vertigo accompanies otalgia, hearing loss, or tinnitus. Specialized testing for nystagmus, including electronystagmography (ENG), which measures eye movements at rest and at extremes of gaze, can separate central from peripheral vestibular disorders.

Management

Specific disorders causing vertigo are treated directly. Suppurative or serous labyrinthitis, for example, is treated with antibiotics. An erosive cholesteatoma may require surgical removal. Anticonvulsants may diminish vestibular and vestibulogenic seizures. Motion sickness may respond to simple behavioral changes (e.g., encouraging children to look out the window). Other causes of vertigo spontaneously remit without therapy and merit only close monitoring. Vestibular neuronitis and benign paroxysmal vertigo are examples.

Subspecialist consultation is indicated in certain situations. Neurosurgical evaluation after trauma may be indicated in cases of suspected basilar skull fracture. Suspected perilymphatic fistula, cholesteatoma, or complicated otitis media may merit otorhinolaryngologic evaluation. Neurologists may be helpful in cases of suspected seizure or migraine.

Children with severe or recurrent attacks of vertigo may require treatment with specific antivertiginous medications. The antihistamines dimenhydrinate (5 mg/kg per day orally divided every 6 hours) and meclizine (25 mg orally every 12 hours in children over 12 years of age) may be helpful. Concomitant use of a benzodiazepine such as diazepam (0.1 to 0.3 mg/kg per day orally divided every 6 to 8 hours) as a sedative may be necessary in severe cases.

Pseudovertigo (Fig. 21.2)

FIGURE 21.2. Approach to the child with pseudovertigo.

Pseudovertigo refers to a broad array of diagnoses that present with symptoms such as light-headedness, presyncope, intoxication, ataxia, visual disturbances, unsteadiness, stress, anxiety, and fear. Uniformly absent are a sense of rotation and ocular nystagmus. Underlying causes are numerous; several of the most common causes are listed in Table 21.3. Careful consideration of the patient's age, sex, detailed history, and physical examination, together with a limited number of ancillary tests, may help establish the specific diagnosis.

CHAPTER 22

Edema

LYDIA CIARALLO, MD

Department of Pediatrics, Brown University School of Medicine, Providence, Rhode Island

Edema, the abnormal swelling of tissues from accumulation of fluid in the extravascular space, is a common emergency problem. This fluid characteristically appears either in the dependent portions of the extremities or lower back; in distensible tissues such as the eyelids, scrotum, or labia; or in organs or extremities at the site of tissue damage.

PATHOPHYSIOLOGY

The major mechanisms that lead to the formation of edema are decreased intravascular oncotic pressure (clinically indicated by a decreased serum albumin), increased venous or lymphatic pressure, and vasculitis from an allergic or hypersensitivity reaction. Hypoalbuminemia arises from decreased production of proteins caused by hepatic disease or increased renal or gastrointestinal (GI) losses. When the albumin level is less than 2.5 g/dL, the oncotic activity in the vascular space is reduced enough for fluid to move into the soft tissues and, eventually, the dependent extremities.

In the face of normal vascular permeability, edema formation without hypoalbuminemia requires an increased hydrostatic pressure that overcomes the oncotic pressure of intravascular protein and sodium, forcing fluid out of the vascular space. Hypervolemia from cardiac failure, salt retention, or estrogen–progesterone excess is the general mechanism responsible for the increased hydrostatic pressure that leads to edema. Renal tubular insensitivity to the natriuretic and diuretic actions of atrial natriuretic peptide is also a cofactor in the pathogenesis of edema.

In the hypersensitive or allergic state, the formation of edema may be rapid and localized. This may be life-threatening if the edema is formed near the airway or may be merely uncomfortable if restricted to the eyelids or ankles, as seen with insect bites. If the basis of edema is decreased oncotic pressure or elevated hydrostatic pressure, the onset of symptoms is sometimes gradual and may exist for weeks or months before edema is appreciated by the patient or physician. Usually, a 10 to 15% weight gain occurs before the patient comes to medical attention.

DIFFERENTIAL DIAGNOSIS

Numerous diseases may cause localized or generalized edema on the basis of the three major pathophysiologic mechanisms already discussed (Table 22.1). The most common origin for localized edema in children is an allergic reaction. Idiopathic nephrosis, although unusual (occurring in just 2 of every 100,000 children annually), is the most likely source for generalized edema (Table 22.2). Although most children who develop edema will have self-limiting disorders, potentially life-threatening conditions (Table 22.3) may be seen, including allergic reactions that involve the upper airway, bacteremic cases of cellulitis (see Chapter 84), thrombophlebitis, and dysfunction of the kidney, liver, or heart.

Table 22.1. Causes of Edema

Table 22.2. Common Causes of Edema

Table 22.3. Life-Threatening Causes of Edema

EVALUATION AND DECISION

When evaluating the child with edema, initially the physician must determine whether the patient has a localized or generalized process. Even if the complaint appears to be confined to one anatomic area, a thorough examination is necessary, checking in particular for edema around the eyes, the scrotum, and the feet. If there is any suspicion of generalized swelling, a urinalysis is indicated to rule out proteinuria (renal disease often leads to the formation of edema without other clinical findings). Acquired hypoproteinemia from hepatic or intestinal disease is unusual, and congestive heart failure (CHF) produces myriad findings.

LOCALIZED EDEMA

Children seek care in the emergency department (ED) more often with localized than generalized edema (Fig. 22.1). Rarely, an infant will have unexplained, localized swelling of an extremity since birth. In this situation, congenital lymphedema (Milroy's disease) should be considered; Turner's syndrome may be associated with bilateral leg edema and Noonan's syndrome with pedal edema. More commonly, the swelling arises over a few days. Most of these lesions result from minor trauma, infection of the subcutaneous tissues, or allergic (urticarial) reactions. Rapid onset of painful swelling typically follows pit viper envenomation (see Chapter 91). Tenderness to palpation points to trauma or infection, and fever with warmth over the lesion often occurs with the latter (Table 22.4). On the eyelids and over the ankles, insect bites are likely to produce a noticeable swelling, which can be difficult to distinguish from cellulitis. A therapeutic response to an antihistamine (diphenhydramine) or to a subcutaneous dose of epinephrine can aid in the diagnosis of an allergic reaction. When local edema occurs on the face, the physician should evaluate the child carefully for concurrent laryngeal involvement. When facial edema is severe or recurrent or when there is a family history of a similar problem, hereditary angioedema (see Chapter 92) is a consideration. Other causes of facial edema include acute sinusitis, dental abscess, orbital or buccal cellulitis, and cavernous sinus thrombosis. A history of environmental exposure can be helpful in the diagnosis of sunburn, frostbite, and plant-induced dermatitis. Sickle cell anemia may cause painful limb edema, as in the case of toddlers with dactylitis. Thrombophlebitis rarely occurs in the prepubertal child but may affect the adolescent; weightlifting and the use of oral contraceptive pills predispose teenagers to this condition. Finally, pregnant young women may develop edema in the lower extremities.

FIGURE 22.1. Edema in children.

Table 22.4. Differentiation among the Common Causes of Localized Edema

GENERALIZED EDEMA

Generalized edema, usually an indication of significant underlying disease, occasionally occurs with less serious conditions. Certain drugs (oral contraceptive pills, lithium, nonsteroidal anti-inflammatory agents) may cause some people to become edematous; cessation of the drug produces a resolution of the swelling. Just before menstruation, young women may complain of “bloating.” The cyclical nature of this problem usually provides a clue to the diagnosis.

The evaluation of the edematous child requires careful attention to the cardiovascular examination. The clinical manifestations of CHF or pericarditis are rarely subtle when these conditions are hemodynamically severe enough to produce edema. Tachycardia, tachypnea, adventitial pulmonary sounds, and hepatomegaly suggest CHF (see Chapter 82). In the child with a pericardial effusion, a pulsus paradoxus greater than 10 to 20 mm Hg, muffled heart tones, and jugular venous distension may occur. A chest radiograph often shows an enlarged cardiac silhouette with both conditions. An electrocardiogram with ST-segment elevation and generalized T-wave inversion on the tracing may suggest pericarditis with a pericardial effusion. Echocardiography is diagnostic.

Generalized edema that is not cardiovascular in origin most often arises secondary to diseases of the kidneys, particularly idiopathic nephrotic syndrome (see Chapter 86). Occasionally, other forms of the nephrotic syndrome, glomerulonephritis, hemolytic uremic syndrome, or Henoch-Schönlein purpura (HSP) are responsible. The detection of significant proteinuria (3+ or 4+) confirms the diagnosis of nephrotic syndrome or nephritis, and affected children require admission to the hospital for evaluation and treatment. In the child with HSP, the edema usually affects the lower extremities predominantly and often is accompanied by a purpuric eruption (despite normal platelet count and

coagulation studies).

In the absence of proteinuria or signs of CHF, occult diseases of the GI tract or liver remain considerations. An initial laboratory evaluation, including liver function tests, electrolyte levels, and measurement of total protein and albumin, should be performed. Abnormalities in these studies often suggest involvement of a specific organ system or severe vasculitis with protein leak.

By process of exclusion, the child with normal screening laboratory tests and no abnormal physical findings except generalized edema is likely to have some type of vasculitis. The finding of a normal albumin does not rule out vascular disease. In teenage girls, otherwise unexplained edema may occur in the premenstrual period and carries a benign prognosis.

CHAPTER 23

Epistaxis

[*]FRAN NADEL, MD and [†]FRED M. HENRETIG, MD

[*]*Department of Pediatrics,* [†]*Departments of Pediatrics and Emergency Medicine, The University of Pennsylvania School of Medicine,* [*]*Division of Emergency Medicine,* [†]*Section of Clinical Toxicology, The Children's Hospital of Philadelphia, and* [*]*The Poison Control Center, Philadelphia, Pennsylvania*

Epistaxis (nosebleeding) is a common symptom in young children and may be alarming to parents who often overestimate the amount of blood loss. It usually is noted first at about age 3 years and increases in frequency with age, until peaking before or in adolescence. An orderly approach to the history and physical examination is necessary to identify the small minority of patients who require emergent hemorrhage control, laboratory investigation, or referral to an otorhinolaryngologist (ORL) for special treatment.

PATHOPHYSIOLOGY

Minor trauma, nasal inflammation, desiccation, and congestion, as well as the rich vascular supply of the nose, contribute to the frequency of nosebleeds in otherwise normal children. The nose is a favored site for recurrent minor trauma, especially habitual, often absentminded, picking. The small vessels that supply the nasal mucous membrane have little structural support because the mucosa is closely applied to the perichondrium and periosteum of the nasal septum and lateral nasal walls. Furthermore, the nasal mucosa is richly supplied with vessels that form plexiform networks. One such anastomosis of common etiologic significance is Kiesselbach's plexus in Little's area of the anterior nasal septum, about 0.5 cm from the tip of the nose (see Fig. 121.4). Any factors that tend to cause congestion of the nasal vessels or drying of the mucosa will enhance the likelihood of epistaxis, resulting from a given degree of trauma.

DIFFERENTIAL DIAGNOSIS

Many types of local and systemic disorders may cause epistaxis (Table 23.1). Local factors predominate in etiologic importance (Table 23.2). In addition to minor accidental trauma and habitual picking, any cause of acute inflammation will predispose the nose to bleeding. Acute upper respiratory infections, whether localized as in colds or secondary to more generalized infections such as measles, infectious mononucleosis, and influenzal illnesses, contribute to the onset of epistaxis. Allergic rhinitis may also be a factor. Staphylococcal furuncles, foreign bodies, telangiectasias (Osler-Weber-Rendu disease), hemangiomas, or evidence of other uncommon tumors may be found on inspection. Juvenile nasopharyngeal angiofibroma usually is seen in adolescent boys with nasal obstruction, mucopurulent discharge, and severe epistaxis. These tumors may bulge into the nasal cavity but often require examination of the nasopharynx to be identified. Although benign, they can cause severe problems through local invasion of adjacent structures. A rare childhood malignant tumor, nasopharyngeal lymphoepithelioma, may cause a syndrome of epistaxis, torticollis, trismus, and unilateral cervical lymphadenopathy. *Rhinitis sicca* refers to a condition that is common in northern latitudes during the winter, in which low ambient humidity, exacerbated by dry hot-air heating systems, leads to desiccation of the nasal mucosa with concurrent tendency to frequent bleeding. Other rare local causes of epistaxis include nasal diphtheria and Wegener's granulomatosis.

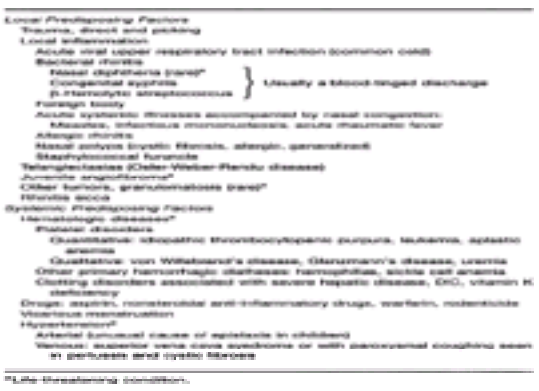

Table 23.1. Differential Diagnosis of Epistaxis

Trauma	Rhinitis sicca
Foreign body	Viral rhinitis
Allergic rhinitis	

Table 23.2. Common Causes of Epistaxis

Children rarely present with a nosebleed as their only manifestation of a more systemic disease. In children with severe or recurrent nosebleeds, a positive family history, or constitutional signs and symptoms, the physician should consider a systemic process. Von Willebrand's disease and platelet dysfunction are two of the more common systemic diseases that cause recurrent or severe nosebleeds. Other less common systemic factors include hematologic diseases such as sickle cell anemia, leukemia, hemophilia, and clotting disorders associated with severe hepatic dysfunction or uremia. Arterial hypertension rarely is a cause of epistaxis in children. Increased nasal venous pressure secondary to paroxysmal coughing, such as that which occurs in pertussis or cystic fibrosis, occasionally may cause nosebleeds. *Vicarious menstruation* refers to a condition occasionally found in adolescent girls in whom monthly epistaxis related to vascular congestion of the nasal mucosa occurs concordant with menses and is presumably related to cyclic changes in hormone levels.

EVALUATION AND DECISION

Rarely are nosebleeds in children life-threatening or do they require more than simple measures to gain control of hemorrhage. However, one's evaluation should begin with hemorrhage control and identification of children who are unstable by noting alterations in the patient's general appearance, vital signs, airway, color, and mental status.

Most childhood nosebleeds are anterior in origin. However, because posterior bleeds may require more extensive therapy, it is important to identify the site of bleeding. In general, posterior sites bleed more profusely, although parents may underestimate the volume because much of the blood is often swallowed. Blood seen in the oropharynx, blood in both nares, difficulty controlling bleeding despite adequate anterior pressure, and a normal anterior exam are more characteristic of a posterior nasal bleed but can be found with an anterior causative site.

After treating any emergent problems, the evaluation of the child with epistaxis begins with a thorough history. Specific features to be sought include frequency of occurrence, difficulty in control (and adequacy of simple at-home first aid), history of trauma, nose picking, frequent upper respiratory infection, allergic and chronic discharge, and obstructive symptoms. Often, asking children which finger they pick their noses with will elicit a more honest answer. Often, parents will note hematemesis or melena, prompting them to seek urgent medical attention. Specific questions regarding evidence for any systemic hemorrhagic disorder or family history of bleeding are asked. In adolescent girls, relation to menses is noted.

Physical examination must include a complete general examination with special attention paid to vital signs, including blood pressure, evidence of hematologic disease (enlarged nodes, organomegaly, petechiae, or pallor), and of course, inspection of the nasal cavity after reasonable efforts to stop the bleeding. When examining a child with a nosebleed, one will need a good light source, suction, and adequate body fluid precautions. Nasal inspection begins with clearing the passages by having the child blow his or her nose or by using gentle suction. On examination, one is looking for the site of bleeding, mucosal color, excoriations, discharge, a foreign body or other mass, and septal hematomas. Using one's thumb, the tip of the nose is pushed upward to allow examination of the vestibule, the anterior portion of the septum, and anterior portion of the inferior turbinate. If the mucosa is too boggy for adequate visualization, a topical vasoconstrictor or decongestant may be beneficial. A more thorough examination requires the use of a nasal speculum. Using one's nondominant hand, the speculum is passed vertically into the nares and opened, allowing examination of the septum, turbinates, and middle meatus. A topical anesthetic and restraints may be necessary for such an examination in young children.

Because most cases of bleeding in children are from the anterior nasal septum, the simplest way to stop the hemorrhage is to apply direct pressure on the bleeding site for 5 to 10 minutes by external compression of the nares between two fingers. In addition, a cotton (dental) roll may be placed under the upper lip to compress the labial artery. Occasionally, the addition of cotton pledgets moistened with a few drops of epinephrine (1:1000) or application of topical thrombin will help achieve hemostasis. The child should be sitting up, with his or her head tilted slightly forward during these procedures. If an anterior site of bleeding is identified and there is no evidence of a hemorrhagic diathesis—and particularly if bleeding has been recurrent—cautery with a silver nitrate stick may be warranted (see Section VII). For management of severe epistaxis not responsive to such measures, nasal packing or surgical ligation of vessels may be necessary (see Procedures 7.2). The recent advent of expandable nasal tampons has simplified the procedure of anterior nasal packing for the emergency physician, especially in patients who relapse after a successful cautery. However, nasal tampons pose the risk of toxic shock syndrome, necessitating careful patient instructions and follow-up. For children with nosebleeds from a hemorrhagic diathesis, one must also correct the underlying disorder. No laboratory workup is indicated in children without clinical evidence of severe blood loss in whom systemic factors are not suspected, and for whom an anterior site of bleeding is identified and stopped readily with local pressure. Reassurance and

education about appropriate at-home management needs to be provided.

Occasionally, recurrent epistaxis during an acute upper respiratory infection or flare-up of allergic rhinitis may be lessened with use of an antihistamine–decongestant preparation, although care must be taken not to dry the nose excessively, which can cause epistaxis related to dry mucosa. During the winter, especially in the context of forced hot-air heating systems, a cool mist vaporizer may lessen crusting and drying of nasal mucosa with its subsequent predisposition to recurrent bleeding. Petroleum jelly, placed in the nostrils twice daily, and saline nasal spray also are useful for maintaining normal moistness of the nasal mucosa. Keeping fingernails short may also be helpful.

All patients discharged from the emergency department (ED) after evaluation for significant epistaxis should be given specific instructions on nares compression and indications for repeat evaluation. For patients with specific local abnormalities, such as tumors, polyps, or telangiectasias, referral to an ORL is necessary. Such referral might also be considered, even with questionable findings on the ED nasal examination, if bleeding was severe, recurrent, or suspected to be posterior in origin.

Finally, evaluation for hemorrhagic diathesis should be done in any child with pertinent positive findings on history, family history, or physical examination. This usually would include prothrombin time, partial thromboplastin time, complete blood count, and bleeding time. Although the yield would be low in the absence of corroborative clinical features, some children with isolated epistaxis that seems particularly severe or frequently recurrent might also deserve such screening. Katsanis et al. found that 8 of 36 such children with isolated recurrent epistaxis had mild bleeding abnormalities; however, the diagnosis of these patients may be difficult, requiring more sophisticated laboratory evaluation (e.g., postaspirin bleeding time, factor VIII–related antigen, ristocetin aggregation study). These considerations are outlined in the epistaxis algorithm (Fig. 23.1).

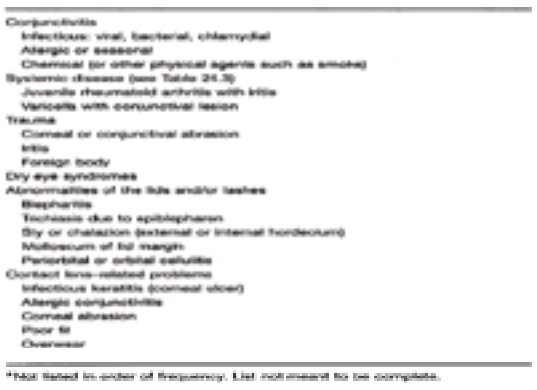
CHAPTER 24

Eye—Red

ALEX V. LEVIN, MD

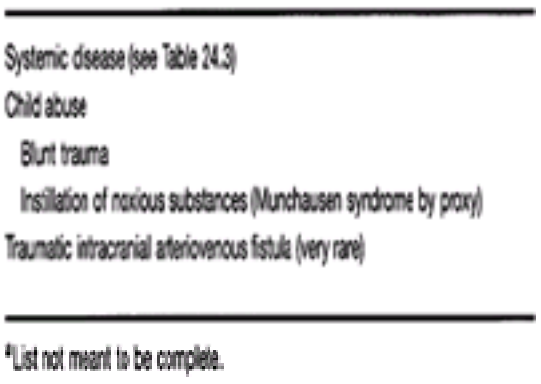
Departments of Pediatrics, Genetics, and Ophthalmology, University of Toronto, and The Hospital for Sick Children, Toronto, Ontario, Canada

When approaching the problem of “red eye,” it is important to determine which tissues are involved. This chapter is confined to disorders in which the conjunctiva, episclera, or sclera are inflamed, causing the “white of the eye” to appear red or pink. Red eyes may be caused by local factors, intraocular disease, or systemic problems. Table 24.1, Table 24.2, and Table 24.3 list common and life-threatening causes of red eye. Discussion of chemical conjunctivitis or irritation caused by agents such as smoke or trauma is limited because the history is almost always known in these situations, making the diagnosis clear. The management of these disorders is discussed in Chapter 111 and Chapter 120.



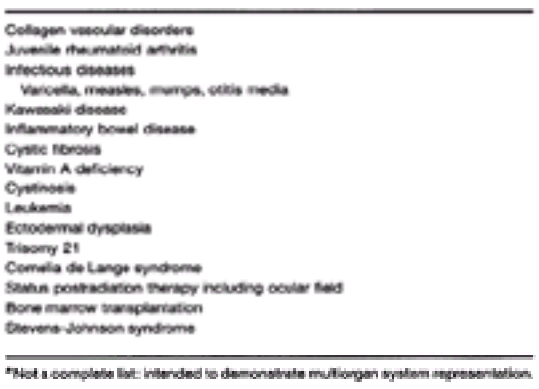
Conjunctivitis
Infectious: viral, bacterial, chlamydial
Allergic or seasonal
Chemical (or other physical agents such as smoke)
Systemic disease (see Table 24.3)
Juvenile rheumatoid arthritis with iritis
Varicella with conjunctival lesion
Trauma
Corneal or conjunctival abrasion
Iritis
Foreign body
Dry eye syndromes
Abnormalities of the lids and/or lashes
Blepharitis
Trichiasis due to epiblepharon
Stv or chalazion (external or internal hordeolum)
Molluscum of lid margin
Periorbital or orbital cellulitis
Contact lens–related problems
Infectious keratitis (corneal ulcer)
Allergic conjunctivitis
Corneal abrasion
Poor fit
Overwear
[illegible] listed in order of frequency. List not meant to be complete.

Table 24.1. Common Causes of Red Eye[a]



Systemic disease (see Table 24.3)
Child abuse
Blunt trauma
Instillation of noxious substances (Munchausen syndrome by proxy)
Traumatic intracranial arteriovenous fistula (very rare)
[a]List not meant to be complete.

Table 24.2. Life-Threatening Causes of Red Eye[a]



Collagen vascular disorders
Juvenile rheumatoid arthritis
Infectious diseases
Varicella, measles, mumps, otitis media
Kawasaki disease
Inflammatory bowel disease
Cystic fibrosis
Vitamin A deficiency
Cystinosis
Leukemia
Ectodermal dysplasia
Trisomy 21
Cornelia de Lange syndrome
Status postradiation therapy including ocular field
Bone marrow transplantation
Stevens-Johnson syndrome
[a]Not a complete list; intended to demonstrate multiorgan system representation.

Table 24.3. Systemic Conditions That May Be Associated with Red Eye[a]

Often, the cause of a red eye can be identified based on the history alone. Attention must be paid to documenting whether the inflammation is unilateral or bilateral, diffuse or sectorial, and acute or chronic. When bilateral, it is helpful to know whether both eyes were involved simultaneously or sequentially.

PATHOPHYSIOLOGY

With the exception of the cornea, the eye is covered by conjunctiva, a modified mucous membrane covered by nonkeratinized stratified squamous epithelium with goblet cells. The conjunctiva is contiguous with the corneal epithelium. The conjunctiva extends from the surface of the eyeball above and below onto the inner surface of the upper and lower eyelids, creating an upper and lower fornix as it reflects off the eyeball. These fornices may become repositories for foreign material or exudate. The conjunctiva overlying the eyeball (bulbar conjunctiva) may become inflamed without involvement of the conjunctiva lining the inner aspect of the eyelid (palpebral conjunctiva). The palpebral conjunctiva contains lymphoid follicular tissues that may become particularly prominent during ages when benign lymphoid hypertrophy (e.g., tonsils, adenopathy) is common. Benign lymphoid hyperplasia would appear as small bumps on the palpebral conjunctiva. A follicular reaction also may occur in some forms of red eye—in particular, viral conjunctivitis. The conjunctiva also covers the caruncle, a small lump of tissue containing glands located in the medial corner of the eye at the junction of the upper and lower eyelids.

The sclera (“the white of the eye”) is a largely avascular dense collagenous tissue that provides a tough fibrous outer wall for the eyeball. Four of the six extraocular muscles insert into the anterior sclera, 4 to 8 mm away from the cornea: superior, medial, inferior, and lateral recti (see Chapter 25). Although these insertions are not easily visible on the normal eye, inflammation of the muscles makes them apparent. Knowledge of this anatomy may be helpful in the diagnosis of myositis.

The sclera may become inflamed (scleritis). An intermediate layer, the episclera, lies beneath the conjunctiva, where it is firmly attached to the sclera. The episclera does not extend onto the eyelids. It is more vascularized than the sclera and may become inflamed either in a diffuse or localized fashion (diffuse, sectorial, or nodular episcleritis).

The term *conjunctivitis* should be reserved for disorders in which the conjunctiva is inflamed. Inflammation may be caused by direct irritation, infection, inflammation of underlying or contiguous structures, immune phenomena, or processes secondary to abnormalities of the lid and lashes. Disorders of the cornea may result in conjunctival inflammation. Inflammation within the anterior chamber between the cornea and iris (iritis) also may result in inflammation of the conjunctiva.

A tear film, which prevents desiccation, is constantly present over the surface of the eye. The tear film is made up of three components: an inner mucinous layer secreted by the goblet cells of the conjunctiva; a middle aqueous layer secreted by the lacrimal glands within the eyelid, orbit, and superior conjunctival fornix; and an outer layer secreted by glands in the body of the eyelids which empty at the eyelid margins. Each eyelid contains 20 to 30 glands. A disruption in the function of any three of these anatomic structures may result in an abnormal tear film with secondary desiccation of the ocular surface, resulting in irritation and inflammation (dry eye syndrome).

Innervation of the conjunctiva and cornea comes from the first division of the trigeminal nerve (V1). Abnormalities on the ocular surface may give rise to pain or a foreign body sensation. The efferent arm of a reflex arc that involves the trigeminal nerve (afferent limb) and the facial nerve results in a rapid blink, with contraction of the orbicularis oculi muscle, to protect the surface of the eye in response to noxious stimuli.

Two other reactions to noxious stimuli may occur: tearing and discharge. Tearing (epiphora) may accompany virtually any conjunctival inflammation or irritation. Tearing may even be a part of the dry eye syndrome, as the lacrimal gland attempts to compensate for ocular surface dessication due to disruption of the other layers of the tear film. Discharge results either from conjunctival exudation or precipitation of mucous out of the tear film. The latter occurs when the tear film is not flowing smoothly (e.g., nasolacrimal duct obstruction), causing misinterpretation as infection when the problem is actually mechanical. Although discharge may be a nonspecific finding, the nature of the discharge may be helpful in determining the cause of an infection. The presence of membranes or pseudomembranes (Fig. 24.1) on the palpebral conjunctiva is also helpful in establishing a cause. For example, these membranes are more common with adenovirus infection or Stevens-Johnson syndrome. These white or white-yellow plaques are caused by loosely or firmly adherent collections of inflammatory cells, cellular debris, and exudate.

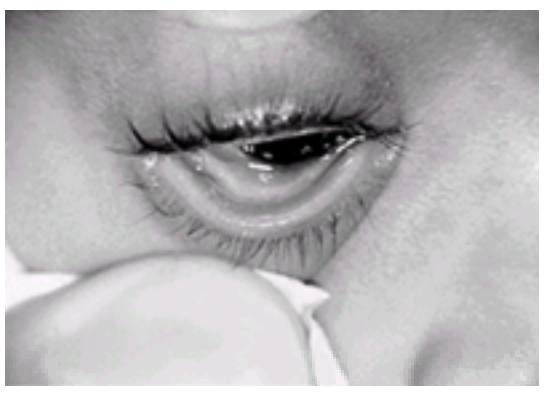


FIGURE 24.1. Pseudomembrane on lower lid palpebral conjunctiva and extending into inferior fornix in patient with epidemic keratoconjunctivitis. *Please see the color-tip insert (Color Plate 24.1).*

EVALUATION AND DECISION

The approach to the child who presents in the emergency department with a red eye is outlined in the flow chart shown in Figure 24.2. Any child who wears contact lens regularly, even if the lens is not in the eye at the time of the examination, should be referred to an ophthalmologist within 12 hours if he or she has red eye. Red, and often painful, eyes of a person who wears contact lens may represent potentially blinding corneal infection or the breakdown of the corneal epithelium, which subsequently would predispose the person to corneal infection. Other than removing the contact lens when possible (topical anesthesia may be helpful), further diagnostic or therapeutic interventions by the pediatric emergency physician are not indicated in these patients. It is recommended that empiric antibiotics not be started because the ophthalmologist may wish to culture the cornea.

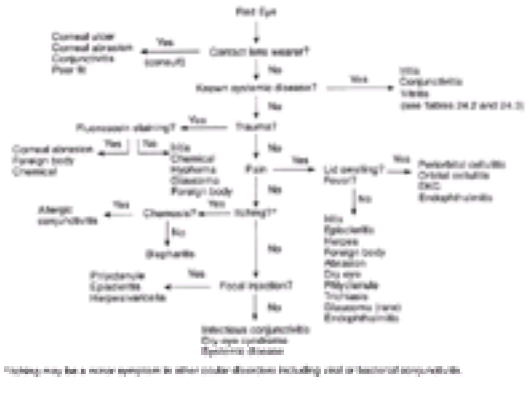

FIGURE 24.2. Approach to the child with red eye. *EKC,* epidemic keratoconjunctivitis (adenovirus).

Numerous systemic diseases may be associated with ocular inflammation. A representative sample can be found in Table 24.3. In some systemic diseases, the associated ocular abnormality involves intraocular inflammation (iritis, vitritis), which might cause secondary conjunctival infection. Patients with these diseases also may have coincidental ocular inflammation unrelated to their underlying conditions. Ophthalmologic consultation may be helpful in making this distinction.

Traumatic injury may result in a red eye because of corneal or conjunctival abrasion, hyphema, iritis, or rarely, traumatic glaucoma. (The diagnosis and treatment of these disorders are summarized in Chapter 111.) Very rarely, head injury may cause the development of an intracranial arteriovenous fistula that may present with proptosis, chemosis, red eye, corkscrew conjunctival blood vessels, and decreased vision. If there is no fluorescein staining of the conjunctiva or cornea and there is no obvious evidence of severe intraocular injury (e.g., hyphema, ruptured globe), the examiner may need to consider the possibility of noxious material coming in contact with the eyeball at the time of trauma. Both acidic and alkaline substances may cause a red eye. (The treatment of these disorders is summarized in Chapter 120.) Likewise, a foreign body may cause ocular pain and inflammation. Foreign bodies often can be difficult to see on brief, superficial examination. All the recesses and redundant folds of the conjunctiva must be inspected. The upper eyelid should be everted (see Chapter 111) and the lower eyelid should be pulled down from the globe as the patient looks upward so that the inferior fornix can be inspected. The patient should be asked to adduct the affected eye when the lateral canthus (junction of the upper and lower eyelid laterally) is stretched laterally to allow inspection of the lateral fornix. There is no analogous medial fornix.

It often is wise to inspect the position of the eyelashes before performing these manipulations. Eyelashes that turn against the ocular surface (trichiasis) may cause a red eye that is accompanied by pain or foreign body sensation. Although corneal fluorescein staining may reverse the irritation, the condition may be so mild that slitlamp biomicroscopy would be required despite significant symptoms. It is particularly common in patients who have had prior injury or surgery to the eyelid and in patients of Asian background. In the latter case, a prominent fold of skin (epiblepharon) may be found medially just below the eyelid margin, causing the eyelashes to rotate toward the eyeball (Fig. 24.3).

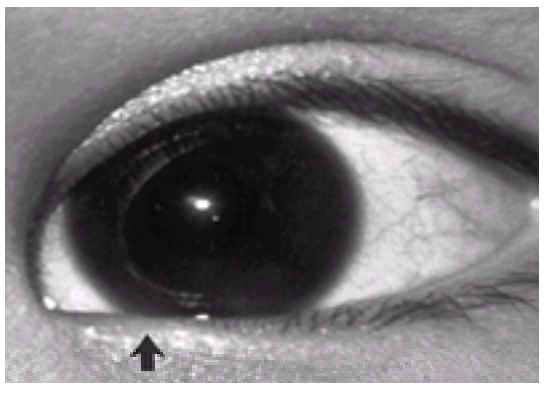

FIGURE 24.3. Epiblepharon. Extra skin fold medially on lower lid *(arrow)* rotates eyelashes back toward eyeball surface.

In the absence of cornea/conjunctiva abrasion, foreign body, and trichiasis, the painful red eye caused by trauma may have iritis. This may not present for up to 72 hours after the trauma was sustained. Photophobia and visual blurring also

may occur. The pupil may be smaller. Occasionally, one will see a cloudy inferior cornea caused by the deposition of inflammatory cells and debris on the inner surface. Iritis also may occur in association with systemic disease or as an isolated idiopathic ocular finding. Traumatic iritis and nontraumatic iritis often are indistinguishable except by history. All causes of iritis, regardless of the etiology, require ophthalmologic consultation and follow-up. The diagnosis of iritis requires slitlamp examination by a skilled observer. Topical steroids should not be prescribed by the primary care physician.

Episcleritis and scleritis also may cause a painful red eye. Although episcleritis usually is an isolated ocular abnormality, scleritis often is associated with an underlying systemic disease, particularly the collagen vascular disorders. Both entities may present with focal or diffuse inflammation. A nodular elevation may be seen involving the sclera. The eye may be tender, and the inflamed area may have a bluish hue. There also may be pain on attempted movement of the eye. Diagnosis and treatment require slitlamp examination and ophthalmologic consultation.

Another cause of painful ocular inflammation is herpetic corneal infection. This may be caused by the simplex or varicella-zoster viruses. Usually, there is no concomitant dermatologic manifestation except in association with chickenpox, when a unilateral or bilateral lesion may be seen on the conjunctiva (usually near but not on the cornea) with focal injection (Fig. 24.4) Usually, no treatment is required. However, herpetic corneal ulcers require urgent treatment to prevent corneal scarring and vision loss. Patients with herpetic corneal ulcers may have a history of prior recurrent painful red eye, although herpes occasionally can be painless because of induced corneal hypoesthesia. Herpes simplex is virtually always unilateral. Fluorescein staining of the cornea may reveal a linear branching pattern (see Fig. 120.10). If the infected area is located eccentrically on the corneal surface, the injection may be localized to the quadrant of conjunctiva adjacent to the lesion.

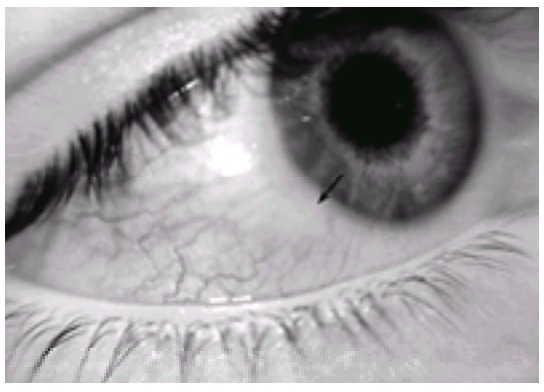

FIGURE 24.4. Red eye caused by chickenpox (varicella) involvement of conjunctiva. Note sectorial injection of conjunctiva. White area *(arrow)* at junction of conjunctiva and cornea is the pox lesion. *Please see the color-tip insert (Color Plate 24.4).*

If eye pain is relieved by a drop of topical anesthetic (see Chapter 111), the patient must have a surface problem (e.g., foreign body, abrasion). If the pain is not relieved and periorbital swelling and fever are present, the red eye may be caused by periorbital or orbital cellulitis. These are emergent conditions, the treatment and diagnosis of which are reviewed in Chapter 120. Eye pain and marked lid swelling also may be associated with epidemic keratoconjunctivitis (EKC) secondary to adenovirus (see Fig. 120.8). When questioned further, patients may reveal that they actually have a sandy foreign body sensation rather than true ocular pain. Pseudomembranes are a fairly diagnostic sign when present (Fig. 24.1). Low-grade fever and tender preauricular adenopathy also may occur, making it difficult to distinguish EKC from periorbital cellulitis. However, EKC usually affects the eyes consecutively and bilaterally. There also may be associated prominent photophobia and tearing, which is not usually seen in cellulitis.

Itching is another important diagnostic symptom. When it is associated with swelling of the conjunctiva, giving it the appearance of a blisterlike elevation (see Fig. 120.9), one should suspect allergic conjunctivitis. Often, there is no known causative agent, and there may be associated periocular swelling. The condition may be unilateral or bilateral and usually has an acute or hyperacute onset. Photophobia, tearing, and lid swelling also may occur. The emergency physician can prescribe topical antihistamines and/or vasoconstrictors as well as a cool compresses to relieve the symptoms.

Itching also may accompany blepharitis, an idiopathic disorder in which there is suboptimal flow of secretions from the glands normally present in the eyelids. Because these glands participate in the formation of the lubricating tear film that normally covers the eye, the deficiency of flow may result in an abnormal tear film and rapid corneal desiccation. Symptoms are aggravated by activities associated with prolonged staring and a decreased blink rate (reading, television viewing, and video games) or going outside on windy days. Patients may have photophobia and a sandy foreign body sensation. To compensate for the tear film deficiency, reflex excess tearing may occur from the lacrimal gland. The most characteristic sign is erythema of all four eyelid margins and flaking and crusting at the base of the eyelashes (Fig. 24.5). Slitlamp examination is helpful in making this diagnosis and is necessary to rule out the presence of corneal involvement.

FIGURE 24.5. Blepharitis. Note crusts and flakes at base of eyelashes.

Although itching and pain may be minor symptoms associated with several types of conjunctivitis, it is usually the absence of these symptoms that should lead one to suspect an infectious cause. Conjunctivitis usually causes diffuse inflammation of the conjunctiva, either unilaterally or bilaterally. The differentiation of bacterial, viral, chlamydial, and other types of conjunctivitis sometimes is difficult (see Chapter 120). Purulent discharge is particularly characteristic of bacterial infection. Diffuse injection may also be a sign of a previously unrecognized underlying systemic disease.

If the injection is localized, the examiner should consider a specific list of diagnostic possibilities. A phlyctenule appears as a small nodule on the conjunctiva at or near the corneal–conjunctival junction, usually with concomitant blepharitis. It usually represents an immune response to bacteria located on the surface of the eye or eyelid. Episcleritis and scleritis also may present with focal involvement, as previously discussed. Localized injection of the conjunctiva may be an indicator of an imbedded foreign body, herpes, chickenpox, or other focal processes that require the attention of an ophthalmologic consultant.

Although much feared, glaucoma in children is very rare. Congenital glaucoma usually is not associated with a red eye or pain. Small children who have glaucoma often have enlarged eyes (buphthalmos) with tearing, photophobia, and sometimes, heterochromia. Acute acquired glaucoma causes a painful red eye, perhaps associated with corneal clouding and decreased visual acuity. Acquired glaucoma, however, usually is associated with trauma, other anatomic abnormalities, or iritis that would be apparent on examination. Because it is difficult to determine intraocular pressure in children, ophthalmologic consultation is required in all cases.

CHAPTER 25

Eye—Strabismus

ALEX V. LEVIN, MD

Departments of Pediatrics, Genetics, and Ophthalmology, University of Toronto, and The Hospital for Sick Children, Toronto, Ontario, Canada

Strabismus refers to any ocular misalignment. *Esotropia* refers to eyes that are turned in (crossed eyes). *Exotropia* refers to eyes that are turned out (wall eyed). The terms *hypertropia* and *hypotropia* refer to a higher or lower eye, respectively. By convention, vertical misalignment of the eyes always is categorized by the higher eye (e.g., right hypertropia), unless it is known that a specific abnormal process is causing one eye to be held in a lower position (e.g., left hypotropia). Many children with strabismus require a formal evaluation by an ophthalmologist for definitive diagnosis and management, but the emergency physician should attempt to answer two questions: 1) Is the strabismus an emergency? and, if so, 2) What is the most likely cause?

PATHOPHYSIOLOGY

Six muscles surround each eyeball (Fig. 25.1). Although several of these muscles may individually move the eye in more than one direction, knowledge of the primary action of these muscles allows for the definition of diagnostic positions of gaze (Table 25.1). This can be helpful in pinpointing specific muscle dysfunction. For example, if a muscle that primarily governs abduction (lateral rectus) is impaired, the eye is unable to abduct and may lie in a position of adduction (esotropia). Likewise, if a muscle that is involved with downgaze (superior oblique muscle) is impaired, the eye will have a tendency to remain in relative upgaze (ipsilateral hypertropia).

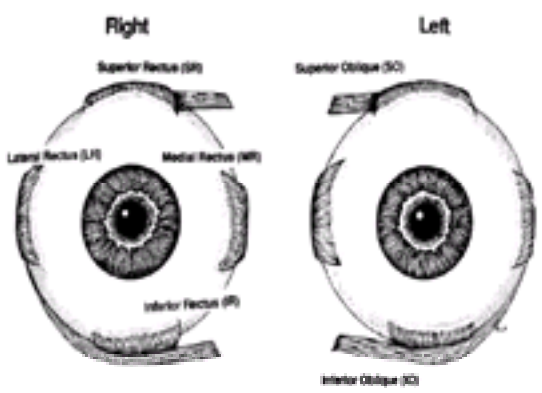

FIGURE 25.1. Normal extraocular muscle anatomy.

Muscle[a]	Cranial Nerve	Action[b]	Eye Position in Palsy
Medial rectus	III (inferior division)	Adduction	Exotropia
Inferior rectus	III (inferior division)	Downgaze	Hypertropia
Lateral rectus	VI	Abduction	Esotropia
Superior rectus	III (superior division)	Upgaze	Hypotropia
Superior oblique	IV	Downgaze	Hypertropia
Levator palpebrae[c]	III (superior division)	Eyelid	Ptosis (lid)

[a]Inferior oblique not included for simplicity. Isolated palsy of the inferior oblique is extremely rare.
[b]Action in the horizontal or vertical field only.
[c]By definition, not truly an extraocular muscle.

Table 25.1. Extraocular Muscles

Although the interactions of these muscles are complex, the eyeballs should always move symmetrically, both quantitatively and qualitatively, into each direction of gaze. On lateral gaze, the abducting and adducting eye should

move far enough that no sclera is visible laterally or medially, respectively (Fig. 25.2). On upgaze, the eyelids also should move up involuntarily. Likewise, on downgaze, the eyelids should move down symmetrically. In the primary position (straight ahead), no sclera should be visible superiorly. The upper eyelid margins should just cross over the iris without crossing over a significant portion of pupil. The lower eyelid margin usually crosses within 1 mm above or below the 6 o'clock position of the inferior iris.

FIGURE 25.2. Patient's head is being rotated passively to patient's left as he looks straight ahead. This causes displacement of eyes into right gaze. Left eye adducts fully, showing no visible sclera medially. Subtle right sixth nerve palsy demonstrated by failure of right eye to abduct fully: sclera is still visible laterally on right eye.

In general, there are two acute reasons why the function of a particular muscle might be impaired: neurogenic palsy or muscle restriction. Three cranial nerves are responsible for the innervation of the six extraocular muscles (Table 25.1). The sixth cranial nerve innervates the ipsilateral lateral rectus muscle. This nerve exits the ventral pons and then travels on the wall of the middle cranial fossa (clivus), reaching the sphenoid ridge, along which it travels until entering the cavernous sinus. The course of this nerve allows it to be injured by vascular or neoplastic changes in the midbrain, increased intracranial pressure (ICP), anterior midline craniofacial tumors (e.g., nasopharyngeal carcinoma), otitis media (OM), and any abnormality that involves the cavernous sinus.

The fourth cranial nerve innervates the superior oblique muscle. It is the only ocular cranial nerve that completely decussates and has a dorsal projection over the midbrain. This position renders the fourth cranial nerve particularly vulnerable to blunt head trauma, one of the most common causes of fourth nerve palsy. The fourth cranial nerve also has the longest intracranial course, which makes it particularly susceptible to increased ICP and parenchymal shifts caused by cerebral edema. It also runs through the cavernous sinus. Fourth cranial nerve palsy may be congenital, but asymptomatic for several years during childhood until the brain is no longer able to compensate. The eyes become misaligned vertically (ipsilateral hypertropia) in the same fashion that might result from a traumatic fourth nerve palsy. Ophthalmic consultation may allow differentiation of congenital and acquired palsy.

The third cranial nerve supplies the remaining four extraocular muscles. It is involved with downgaze, upgaze, and adduction. Parasympathetic innervation to the pupil (see Chapter 26) and innervation to the eyelid muscle (levator palpebrae) also are carried in the third cranial nerve. A complete third cranial nerve palsy results in an eye that is positioned down (from the remaining action of the unaffected superior oblique muscle) and out (from the remaining action of the unaffected lateral rectus muscle) with ipsilateral ptosis and ipsilateral pupillary dilation (Fig. 25.3). Because the third cranial nerve divides into a superior and an inferior division just as it enters the orbit from the cavernous sinus and because the fibers to individual muscles are segregated within the nerve throughout its course, partial third cranial nerve palsies may occur with or without ptosis and/or pupillary dilation. This may leave the patient with complex strabismus, which is best left to the ophthalmologic consultant. (The differential diagnosis of third cranial nerve palsies is summarized in Chapter 26.)

FIGURE 25.3. Right third cranial nerve palsy. When looking straight ahead with left eye, right eye rests in a hypotropic and exotropic position. Note right ptosis. Right pupil is involved (mydriatic), but both pupils were dilated pharmacologically by examiner just before this photograph was taken.

The action of a muscle also may be impaired by restriction. The muscle can become infiltrated with substances that might restrict its action or cause fibrosis. Children with hyperthyroid eye disease have large, tight eye muscles. An eyeball also may be restricted in its movements by tumors or infection in and around the globe. Orbital tumors, cellulitis, or abscesses

that cause restriction may be associated with proptosis or a displacement of the entire eyeball, either vertically or horizontally. Although it is beyond the scope of this chapter to discuss all the causes of restrictive strabismus, it is important to focus on the pathophysiology of strabismus that occurs after a blowout fracture. After blunt trauma to the eyeball, the globe may be translocated posteriorly, causing an increased intraorbital pressure that may result in fracture of the bony orbital wall. Limitations of movement caused by blowout fractures may not be noticeable until the eye attempts to move. In other words, the eyes may be parallel in the straight ahead position but may be misaligned when they attempt to look in a direction opposite the fracture site. When an orbital wall fracture occurs, the muscle that runs along that wall may become entrapped within that fracture, tethering the eyeball so that it cannot look in the direction opposite the fracture. For example, fractures of the orbital floor may entrap the inferior rectus muscle, tethering the eye downward so that upgaze is restricted (Fig. 25.4). Sometimes, the eye also may have a limitation of movement in the direction of the fracture.

FIGURE 25.4. Patient is looking upward. Right inferior orbital wall blowout fracture causes restriction of upgaze in right eye. Note light reflexes (Hirschberg test). Left reflex *(arrow)* is lower in reference to pupil than right reflex, indicating the presence of a right hypotropia.

Orbital wall fractures may be associated with enophthalmos, in which the eye appears to be sunken in the orbit, or proptosis caused by orbital hemorrhage. There usually is a history of trauma and, perhaps, other evidence of ocular injury. All patients with orbital fractures must receive a complete ophthalmic examination to rule out accompanying ocular injury. The most common fracture involves the inferior and/or medial walls of the orbit. The lateral wall is rarely fractured. Fracture of the superior wall (orbital roof) is particularly worrisome because it may allow communication between the intracranial space and orbit.

EVALUATION AND DECISION

The Hirschberg light reflex test can be helpful in determining whether strabismus is present. The physician should shine a penlight or direct ophthalmoscope light at the patient's eyes from 2 to 3 feet away while the patient is told to look at the other end of the room. In younger children, the patient may choose to look at the light itself. The examiner should observe the white dot light reflex that appears to be located on the cornea, overlying the iris or pupil of each eye. This reflex should be located in a nearly symmetric position in each eye (Fig. 25.5). In the normal state, the light reflex actually falls slightly off center in the nasal direction in both eyes (Fig. 25.5). If the eye were to be misaligned, this symmetry would not be preserved (Fig. 25.4 and Fig. 25.6).

FIGURE 25.5. Normal Hirschberg light reflex test. Light reflexes fall symmetrically in each eye. The reflex in the patient's left eye is a bit nasal to the center.

FIGURE 25.6. Left esotropia. Note lateral displacement of Hirschberg light reflex in the left eye. Photograph demonstrates right ptosis and orange-red reflex in the left eye with black reflex in the right eye. Pupils are pharmacologically dilated. Asymmetry of red reflex is caused by misalignment of the eyes. *Please see the color-tip insert. (Color Plate 25.6)*

Two findings are helpful in assessing whether strabismus is emergent: 1) the presence or absence of double vision and 2) the status of the eye movements. Although young children may not complain of diplopia, this symptom often indicates an acute or subacute onset of ocular misalignment. Nonemergent childhood strabismus usually is not associated with double vision because the brain becomes adept at suppressing the misaligned nonfixing eye. If a child complains of diplopia, ophthalmologic consultation is appropriate, even if no strabismus appears on examination by the pediatric emergency physician.

If the eye movements are completely full and symmetric, one can be virtually certain that the strabismus is not emergent. Problems that cause emergent strabismus do so by impairing the action of one or more muscles. A neurogenic palsy or restrictive phenomenon cannot be present if the eye movements are full. If there are any questions about subtle reductions in extraocular movement or if there is prominent nystagmus elicited in one particular field of gaze (more than the few beats of normal end point nystagmus), ophthalmologic consultation is most likely appropriate.

Because of fear and noncompliance, some children will not follow the examiner's target that is presented to assess eye movement. If they will not follow the target at all but look at the examiner only, the examiner should ask the parent to gently move the patient's head to each side and then up and down. The examiner also can do this by putting one hand on the child's head, although this may serve only to heighten the child's anxiety. As the patient continues to look straight ahead when the head is being turned, the eyes are moving passively in reference to the head and orbit. When the head is turned to the left, the eyes move into right gaze to maintain fixation straight ahead (Fig. 25.2). If the head is tilted up, the eyes are moved into relative downgaze. Essentially, this is the “doll's eye” maneuver used in the assessment of comatose patients. If the eyes move symmetrically and fully on passive movement of the head, this rules out the presence of a neurogenic or restrictive problem with the same accuracy as if the patient had voluntarily followed a target. Although the neuro-ophthalmologic contributions to the assessment of the comatose patient are beyond the scope of this chapter, the presence of a cranial nerve palsy can be ruled out even in the patient who is experiencing an altered mental status related to central nervous system disease if the eyes move fully on the doll's eye maneuver as the head is rotated by the examiner.

When an orbital blowout fracture is suspected, confirmation may be obtained by a computed tomography (CT) scan of the orbit. Some controversy exists about the need to perform this test emergently. Some ophthalmologists prefer to image only if the strabismus and diplopia do not spontaneously resolve over 1 to 2 weeks. To evaluate the extraocular muscles, it is essential that coronal views be obtained. Contrast enhancement is unnecessary. Plain skull radiographs play virtually no role in the diagnosis and management of orbital fractures. Should there be a concern about intracranial injury or orbital roof fracture as the cause of strabismus, a CT scan of the head also is important.

The causes of pediatric strabismus are summarized in Table 25.2, Table 25.3 and Table 25.4. If the physician has identified an impairment of the eye to look in a given direction, an emergent condition may be present. The first considerations (Fig. 25.7 and Fig. 25.8) are restrictive strabismus (e.g., trauma) and neurogenic palsies. Myasthenia gravis and thyroid ophthalmopathy (hyperthyroidism), however, can mimic virtually any strabismus with deficiency of extraocular movement and must always be considered in the differential diagnosis in any pattern of ocular misalignment. Myasthenia may cause ptosis, whereas thyroid disease causes retraction of the upper lid. The pupils are not involved in either condition.

Neurogenic Palsies
III cranial nerve palsy (partial or complete)
IV cranial nerve palsy
VI cranial nerve palsy
Traumatic extraocular muscle palsy
Myasthenia gravis
Internuclear ophthalmoplegia
Skew deviation
Restrictive Strabismus
Orbital wall fracture
Orbital hemorrhage, tumor, infection, or abscess
Thyroid eye disease
Nonthyroid extraocular muscle infiltration (e.g., metastasis)
Orbital cellulitis
Nonneurogenic Nonrestrictive Strabismus
Idiopathic childhood strabismus
Strabismus caused by refractive errors (e.g., accommodative esotropia)
Sensory strabismus (unilateral visual loss)

[a] Not listed in order of frequency.

Table 25.2. Differential Diagnosis of Strabismus [a]

Exotropia
Congenital or acquired (with or without farsightedness), nonparalytic, nonrestrictive
Medial orbital wall fracture
VI cranial nerve palsy
Orbital mass, hemorrhage, or infection
Long-standing unilateral visual loss
Esotropia
Nonparalytic nonrestrictive idiopathic childhood exotropia
III cranial nerve palsy
Orbital mass, hemorrhage, or infection
Long-standing unilateral visual loss
Hypertropia
Dissociated vertical deviation (a nonparalytic nonrestrictive childhood deviation)
Inferior or superior orbital wall fracture
IV cranial nerve palsy: congenital or acquired
Orbital mass, hemorrhage, or infection
Hypotropia
Inferior or superior orbital wall fracture
Orbital mass, hemorrhage, or infection

[a]Not listed in order of frequency.

Table 25.3. Common Causes of Strabismus[a]

Intracranial mass	Head trauma
Elevated intracranial pressure	Meningitis
Myasthenia gravis	Neoplastic infiltration of extraocular muscles
Orbital tumor	Superior orbital wall fracture
Orbital cellulitis	Retinoblastoma

[a]Not listed in order of frequency.

Table 25.4. Life-Threatening Causes of Strabismus[a]

FIGURE 25.7. Evaluation of horizontal strabismus. *EOM,* extraocular muscle movements; *MR,* medial rectus; *LR,* lateral rectus; *LW,* lateral orbital wall; *MW,* medial orbital wall; *fx,* fracture; *ICP,* increased intracranial pressure; *INO,* internuclear ophthalmoplegia; *boldface type,* most likely fracture.
[a] With head held in straight ahead position.

FIGURE 25.8. Vertical strabismus. *EOM,* extraocular muscle movements; *IR,* inferior rectus; *SR,* superior rectus; *SW,* superior orbital wall; *IW,* inferior orbital wall; *boldface type,* most likely fracture.
[a]With head held in straight ahead position.

Esotropia Emergencies

An eye that rests in the crossed position is esotropic. The Hirschberg light reflex will fall laterally in reference to the

central pupil, compared with the unaffected eye (Fig. 25.6). Figure 25.7 summarizes the approach to a patient with esotropia. Patients with a restrictive or neurogenic esotropia (deficiency of abduction) may adopt an abnormal head position to place the eyes in the position of best alignment to avoid double vision. By turning the face in the direction of the deficiency (e.g., right face turn for right sixth nerve palsy) when looking straight ahead, the eyes actually may be straight. The patient's head must be held in the straight ahead position to notice that the affected eye actually is crossed.

In the presence of proptosis or a history of eye trauma, one must be concerned that an orbital process is causing the esotropia. Fracture of the medial orbital wall may cause entrapment and restriction of the medial rectus. Fracture of the lateral wall—usually part of a tripod fracture that involves the zygoma and inferior lateral wall—may cause orbital hemorrhage that would displace the eye medially. Likewise, an orbital tumor or abscess can push the eye toward the nose or restrict abduction. Any infiltrative process that involves the eye muscles may also cause esotropia through restriction. Orbital cellulitis can cause any type of misalignment, including esotropia, with or without abscess formation. A CT scan of the orbit with coronal and axial views is the diagnostic procedure of choice in these situations.

Lateral rectus palsy (sixth cranial nerve palsy) occurs most commonly secondary to head trauma (see Chapter 105) or increased ICP. Other central nervous system signs, such as papilledema, may be present. Magnetic resonance imaging (MRI) of the brain is the procedure of choice. Sixth cranial nerve palsy also can occur rather precipitously after the placement of ventricular shunts designed to relieve increased ICP. Sixth cranial nerve palsy may be bilateral, in which case both eyes will be in the crossed position. OM also may be associated with sixth cranial nerve palsy (Gradenigo syndrome).

Exotropia Emergencies

Orbital cellulitis, thyroid eye disease, and orbital tumors also may cause exotropia. Trauma very rarely results in exotropia because lateral wall fractures rarely cause entrapment. Orbital hemorrhage (with or without medial wall fracture) can have a mass effect, causing the eye to be turned out.

Isolated paresis of the medial rectus muscle, resulting in a deficiency of adduction and a turned out eye, is quite unusual because other muscles also are innervated by the third cranial nerve. One should look for accompanying ptosis, pupillary dilation, or deficiencies of upgaze or downgaze to confirm third cranial nerve involvement, even if these findings are subtle.

Unilateral isolated deficiency of adduction may be the result of an intranuclear ophthalmoplegia secondary to a brainstem injury that involves the interconnecting pathways between the third and sixth cranial nerves. Bilateral isolated deficiency of adduction is virtually diagnostic of this condition. MRI of the brainstem should be ordered emergently. The observer also should look for prominent nystagmus on attempted abduction of the contralateral eye.

Hypertropia/Hypotropia Emergencies

Any vertical eye muscle imbalance must be referred to an ophthalmologist. Figure 25.8 summarizes the approach to the patient with vertical ocular misalignment. To determine whether it is the higher or lower eye that is abnormal, the examiner must have the patient look upward then downward. If one eye is unable to look downward fully, the patient has a hypertropia of that eye. If one eye is unable to look upward fully, that eye is hypotropic (Fig. 25.4). Patients may adopt abnormal head positions to compensate for this misalignment. By lifting the chin to look straight ahead, the eyes are placed in relative downgaze, thus indicating that the strabismus is worse when the patient looks up. Likewise, the patient may adopt a chin down position to look straight ahead, indicating that the strabismus is worse in downgaze.

An eye may become hypertropic for several reasons. Any mass underneath the eyeball—for example, an orbital tumor or a mucocele extending upward from the maxillary sinus—may push the eye upward. A tightened superior rectus is unusual but may be seen in thyroid eye disease or after trauma. An inferior orbital wall fracture could injure (weaken) the inferior rectus or cause hemorrhage that would push the eye up into a hypertropic position. A CT scan of the orbit would be the proper diagnostic modality.

Perhaps the most important cause of ipsilateral hypertropia is a lesion that involves the fourth cranial nerve. Although the eye may be able to look straight down fully, there may be a restriction of gaze in the down-and-in position relative to the other eye (which then would be looking down and out). Because of the torsional forces of the superior oblique muscle on the eyeball, the patient may adopt a head position with a face turn and a head tilt away from the affected eye. One must always consider the possibility that a new fourth nerve palsy actually represents a decompensated congenital abnormality. Old pictures that show a previous head tilt can be helpful. The head tilt is one of the mechanisms used by the patient unconsciously to help compensate for the muscle imbalance.

Although rare, neurogenic palsies of the inferior oblique or inferior rectus with resultant vertical misalignment may occur. These have been reported after viral illnesses, including varicella. As with exotropia of neurogenic origin, however, it would be more likely to have other branches of the third cranial nerve involved with other findings. Another type of vertical eye muscle imbalance, skew deviation, can be the presenting sign of a midbrain lesion. Ophthalmologic consultation can be helpful in deciding whether MRI is appropriate.

Hypotropia can be caused by an orbital roof fracture with superior hematoma that pushes the eye down. Alternatively, hypertropia from a deficiency of downgaze due to tethering of the superior rectus muscle also can occur. Orbital roof fracture is an emergent condition. Neuroradiologic evaluation must be obtained to rule out communication between the orbit and the intracranial cavity. Pulsating proptosis is a particularly ominous sign.

Traumatic hypotropia most commonly results from inferior wall blowout fractures (Fig. 25.8). The eye often is enophthalmic and there may be associated numbness in the distribution of the infraorbital nerve as it innervates the ipsilateral infraorbital and malar region. Orbital lesions, including those that may have extended from the intracranial

cavity, also may push the eyeball downward and prevent it from looking upward. Thyroid eye disease also can cause hypotropia due to tightening of the inferior rectus.

CHAPTER 26

Eye—Unequal Pupils

ALEX V. LEVIN, MD

Departments of Pediatrics, Genetics, and Ophthalmology, University of Toronto, and The Hospital for Sick Children, Toronto, Ontario, Canada

Abnormalities of the pupils can be helpful diagnostically when assessing central nervous system (CNS), autonomic nervous system (ANS), orbital, and ocular problems. The pupillary dilator muscle receives sympathetic innervation. The pupillary sphincter receives parasympathetic innervation that also supplies the ciliary muscle of the eyeball that governs focusing (accommodation) of the lens. Pupillary disorders can be divided into two categories: disorders in which the size of one or both pupils is abnormal and disorders in which the shape of one or both pupils are abnormal. When the size of both pupils is affected, the pupils usually are symmetrically abnormal. When the pupils are different in size, the term applied is *anisocoria.* An abnormally dilated pupil is called *mydriasis. Miosis* refers to an abnormally constricted pupil. Figure 26.1 represents a flowchart approach to anisocoria.

FIGURE 26.1. Unequal pupils. *CNS,* central nervous system; *DTR,* deep tendon reflex; *EOM,* extraocular muscle movement; *SLE,* slitlamp examination; *III,* third cranial nerve.

PATHOPHYSIOLOGY

The first-order sympathetic neurons extend from the hypothalamus through the midbrain, pons, and medulla into the spinal cord. There, they synapse with the second-order neurons at the ciliospinal center of Budge-Waller, just before exiting the cord at roots C8–T2. The thoracic sympathetic trunk then travels over the apex of the lungs to the superior cervical ganglion, where synapses are made with the third-order neurons. Sympathetic innervation to the face departs from the superior cervical ganglion or at the bifurcation of the common carotid artery. Therefore, complete unilateral anhidrosis in association with unilateral miosis suggests damage to the second-order neurons or superior cervical ganglion. The third-order neurons travel with the internal carotid artery into the cranial vault, where the fibers gain access to the orbit via the nasociliary branch of the first division of the trigeminal nerve. They then travel through the ciliary ganglion in the orbit without synapse. Fibers extend to the iris dilator via the ciliary nerves. Disruption of sympathetic innervation anywhere along the course results in ipsilateral miosis (Horner syndrome) and often is accompanied by ptosis, enophthalmos, and ipsilateral anhidrosis.

Parasympathetic neurons originate in the Edinger-Westphal nuclei, located on the dorsal aspect of the third cranial nerve nucleus in the anterior dorsal mesencephalon at the level of the superior colliculus, ventral to the sylvian aqueduct. These neurons travel with the third cranial nerve, exiting the midbrain on its ventral aspect and passing between the posterior cerebral artery and the superior cerebellar arteries as they arise from the posterior communicating artery in the circle of Willis. The nerve then runs anteriorly and enters the cavernous sinus superiorly and laterally. Just before entering the posterior orbit through the superior orbital fissure, the third cranial nerve splits into a superior and an inferior division. The latter contains the parasympathetic fibers that then pass into the ciliary ganglion, where they synapse. Short ciliary nerves then carry the postsynaptic fibers to the pupillary dilator muscle and the ciliary muscle (behind the iris). The

ciliary muscle governs accommodation of the lens. Unilateral mydriasis can be caused by damage to the parasympathetic fibers anywhere along their course. With the exceptions noted next, however, it is distinctly unusual for the parasympathetic fibers to be damaged without other evidence of third cranial nerve palsy (a deficit in the ability of the eye to adduct, look upward, or look downward).

Local factors also can cause physical changes in the iris or in the surrounding structures. This may result in unilateral miosis or mydriasis.

EVALUATION AND DECISION

When a child with unequal pupils arrives in the emergency department (ED), the initial concern is cerebral herniation leading to compression and stretching of the third cranial nerve. A rapid neurologic assessment usually is sufficient to diagnose herniation because most patients will have a decreased level of consciousness, focal findings in addition to a dilated pupil, and abnormal vital signs. Once the physician is certain that increased intracranial pressure (ICP) is not present, a more careful evaluation is appropriate.

When testing pupillary size, it is essential that the patient be instructed to look at a distant target that does not involve reading letters or numbers. This prevents the eyes from needing to accommodate. Because the innervation for accommodation is the same as that for the pupillary sphincter, the accommodating patient also has reflex contraction of the pupils. Likewise, focusing on the examiner's face, or on any other near object that would stimulate convergence of the eyes toward each other, also stimulates pupillary constriction. This method of examination is not pertinent for assessing the pupils of a comatose patient. Crying or forced eyelid closure also may induce miosis.

ANISOCORIA

When evaluating the patient with anisocoria, the examiner must answer two critical questions: 1) Which pupil is abnormal, the smaller or the larger? and 2) Is this abnormality acute or chronic?

To establish which pupil is abnormal, the relative difference in pupillary size should be noted under conditions of bright illumination and dim illumination. With the largest diameter circle used on the direct ophthalmoscope or a bright penlight, both pupils should be illuminated simultaneously in a room with the lights on. The room lights should then be turned off and the handheld light source held tangentially from below or from above so that the eyes are illuminated only enough that the examiner can note the pupillary size.

Normally, the pupils constrict in response to bright illumination and dilate in dim illumination. If the relative difference in pupillary size increases under bright illumination, the larger pupil is the abnormal pupil: the larger pupil is not constricting normally (Fig. 26.2). If the relative difference in pupillary size increases under dim illumination, the smaller pupil is the abnormal pupil: the smaller pupil is not dilating normally. If the relative difference in pupillary size is the same in both dim and bright illumination, the patient does not have an abnormal pupil (Fig. 26.3). Rather, the patient has physiologic anisocoria. Approximately 20% of people with normal pupils have a difference in the size of their pupils in excess of 0.4 mm.

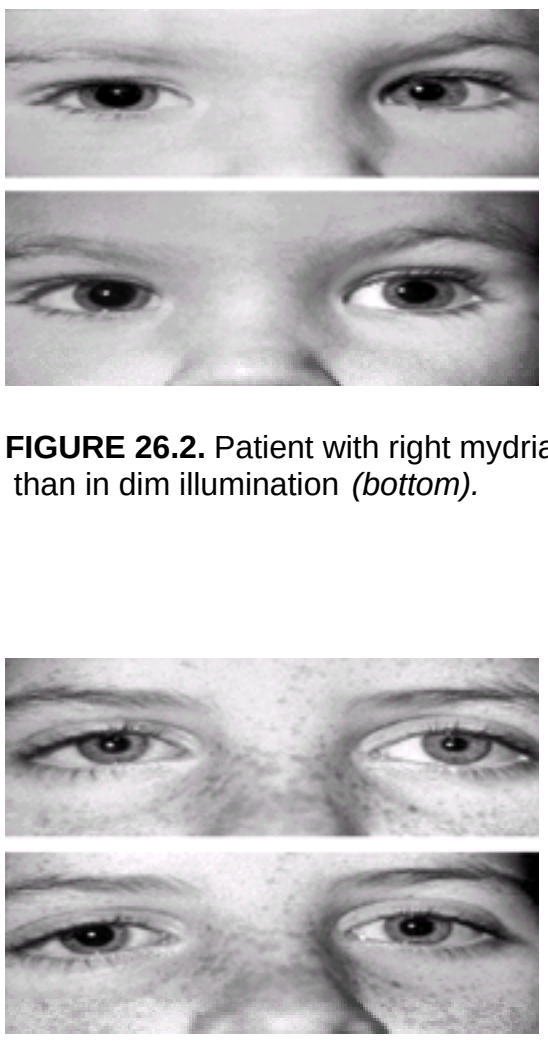

FIGURE 26.2. Patient with right mydriasis. Relative difference between the pupil size is greater in bright illumination *(top)* than in dim illumination *(bottom).*

FIGURE 26.3. Physiologic anisocoria. Relative difference in pupil size is the same in bright illumination *(top)* and dim illumination *(bottom).*

When trying to establish whether the anisocoria is of relatively recent or acute onset, as opposed to long-standing anisocoria, it is helpful to view old photographs. Sometimes, chronic physiologic anisocoria had not been noticed previously. The direct ophthalmoscope can be used to provide magnification of the photograph, as well as illumination. The focusing dial should be set on the highest black (or green) number and then the direct ophthalmoscope looked through at a distance that allows the photograph to be in focus. It also is important to note any other symptoms that accompanied the onset of anisocoria (headaches, eyeball pain, double vision, or blurred vision). The causes of anisocoria are summarized in Table 26.1, Table 26.2 and Table 26.3.

Physiologic anisocoria
Pharmacologic (miotics or mydriatics)
Local factors
Miosis: iritis, surgical trauma
Mydriasis: trauma
Abnormal pupil shape from scar formation following prior iritis or trauma
Neurologic causes
Miosis: Horner syndrome
Mydriasis: third cranial nerve palsy, Adie's pupil
Congenital abnormalities
Iris coloboma
Anterior chamber dysgenesis syndromes

[a]Not listed in order of frequency

Table 26.1. Differential Diagnosis of Unequal Pupils [a]

Physiologic anisocoria
Miosis
Iritis secondary to trauma, juvenile rheumatoid arthritis, or idiopathic
Abnormal pupil shape from scar formation following prior iritis or trauma
Horner syndrome (see Table 26.5)
Mydriasis
Trauma
Third cranial nerve palsy
Adie's pupil
Congenital abnormalities
Iris coloboma

Increased intracranial pressure
Intracranial mass lesion
Aneurysm
Cavernous sinus inflammation, thrombosis, or tumor
Orbital tumor

[a]Not listed in order of frequency.

Table 26.3. Life-Threatening Causes of Unequal Pupils [a]

MIOSIS

Local Factors

An irritated or inflamed iris sphincter muscle will result in miosis. Iritis, secondary to trauma or other factors, is a common cause. The eye usually is injected, and there are symptoms of eye pain, photophobia, tearing, and possibly, decreased vision. Injection may surround the cornea for 360 degrees, creating a ring of erythema (“ciliary blush”). More diffuse injection also may occur. Children with juvenile rheumatoid arthritis may not have these classic symptoms associated with their iritis; in fact, they may have no symptoms at all. Traumatic iritis is often not apparent for 12 to 72 hours after eye trauma. The diagnosis of iritis is confirmed by slitlamp biomicroscopy. This technique is described in Chapter 111. Ophthalmologic consultation is important for subsequent evaluation and treatment.

Other local factors include surgical irritation of the iris and pharmacologically induced unilateral miosis. Mechanical

contact with the iris during any intraocular surgical procedure may result in transient postoperative unilateral miosis.

Parasympathomimetic or sympatholytic drops also can result in transient miosis. A list of commonly used topical miotics is found in Table 26.4. These drops rarely are used in children, with the exception of their occasional bilateral use to treat crossed eyes or unilateral or bilateral use for glaucoma. Systemic drugs from the same categories may result in bilateral miosis. It is helpful to remember that most topical ophthalmic miotics are supplied in bottles that have green caps.

Generic Name	Trade Names
Cholinergics	
Pilocarpine	Adsorbocarpine, Akarpine, Almocarpine, Isopto Carpine, Miocarpine, Pilagan, Pilocar, Pilocel, Pilogel, Pilominin, Piloptic, Ocusert Pilo
Carbachol	Carbacel, Isopto Carbachol
Anticholinesterases	
Physostigmine	Eserine Sulfate, Isopto Eserine
Demecarium	Humorsol
Echothiopate iodide	Echodide, Phospholine Iodide
Isoflurophate (DFP)	Floropryl

Table 26.4. Topical Ophthalmic Miotics (Drops and Ointments)

Neurologic Factors

Miosis caused by damage to the sympathetic pathways (Horner syndrome) often is associated with ipsilateral mild ptosis, an upward displacement of the lower lid (“upside-down ptosis”), and the appearance of mild enophthalmos, with or without ipsilateral facial anhidrosis.

Congenital Horner syndrome may result from brachial plexus injury and often is associated with ipsilateral iris hypopigmentation. This sign is not helpful in the first few months of life.

More than 50% of children with congenital Horner syndrome have a history of difficult extraction at delivery. Congenital varicella infection may also be the cause. Knowledge of the sympathetic anatomy previously discussed can be exploited through the use of topically applied diagnostic agents to localize the site of the lesion. This testing is best performed by ophthalmologic or neurologic consultants. If the presence of Horner syndrome is questioned, one drop of topical 4% cocaine can be instilled into both eyes. Because cocaine prevents reuptake of norepinephrine at the terminal myoneural junction of the sphincter muscle, pupillary dilation will occur normally. Failure of the miotic pupil to dilate is diagnostic of Horner syndrome. Table 26.5 summarizes the causes of acquired Horner syndrome in children. All children who have Horner syndrome should receive a complete evaluation unless congenital Horner syndrome is present, based on history, old photographs, and examination.

First-order neuron
Brainstem glioma or other tumor
Brainstem vascular insult (aneurysm, infarct)
Spinal cord tumor
Syringomyelia
Poliomyelitis
Head or spinal trauma
Postsurgical
Second-order neuron
Intrathoracic tumor (neuroblastoma, ganglioneuroma, metastatic)
Intrathoracic aneurysm
Cervical tumor or adenitis
Trauma (especially brachial plexus trauma)
Postsurgical
Third-order neuron
Internal carotid thrombosis or aneurysm
Internal carotid or head trauma
Otitis media
Nasopharyngeal malignancy
Cavernous sinus thrombosis, tumor, or inflammation
Postsurgical

[a]Not listed in order of frequency

Table 26.5. Causes of Acquired Horner Syndrome in Children[a]

MYDRIASIS

Local Factors

Both trauma and topical agents can cause unilateral mydriasis. Blunt trauma (and, less commonly, intraocular surgery) can result in a fixed dilated pupil. Traumatic mydriasis usually occurs in a setting in which a clear history of trauma and other intraocular injuries, such as hyphema, is noted. The pupil may be somewhat irregular in shape if the sphincter is not damaged uniformly. Sometimes, pigment deposition can be seen on the anterior surface of the lens.

Topical parasympatholytics and sympathomimetics also can cause mydriasis. Systemic medications from the same classes can cause bilateral pupillary dilation. A list of topical agents is found in Table 26.6. Most topical mydriatics are supplied in bottles that have red caps. Pharmacologic mydriasis can be diagnosed by the instillation of pilocarpine 1% into both eyes. The pharmacologically dilated pupil will not constrict or will constrict only minimally.

Generic Name	Trade Names
Sympathomimetics	
Phenylephrine	Ak-Dilate, Ethicel, Mydfrin, Neo-Synephrine, Phenoptic
Cocaine (see text)[b]	
Parasympatholytics	
Atropine	Atropisol, Isopto Atropine, Ocu-Tropine
Cyclopentolate	Ak-Pentolate, Cyclogyl, Pentolair
Homatropine	Homatrocel, Isopto Homatropine
Scopolamine	Isopto Hyoscine, Mydramide
Tropicamide	Mydriacyl, Mydriafair, Tropicacyl

[a]Combination products may also be available.
[b]Diagnostic and anesthetic use only—not prescribed for outpatient use.

Table 26.6. Topical Ophthalmic Mydriatics[a] (Drops and Ointments)

Neurologic Factors

Unilateral mydriasis caused by disruption of parasympathetic innervation is often accompanied by other signs of third cranial nerve palsy: ptosis and/or abnormal eye muscle movements (see Chapter 25). Examination by an ophthalmologist often is indicated to help define patterns of extraocular muscle deficit and strabismus, as well as to assess for the possible presence of papilledema. Meningitis and increased ICP have been associated with mydriasis from third cranial nerve involvement without abnormalities of the extraocular muscles. In children, head trauma is the most common cause of acquired third cranial nerve palsy. Other causes are listed in Table 26.7. Neuroradiologic investigation is almost always indicated.

Head trauma
Congenital (isolated or with other cranial nerves involved)
Brain/meningeal tumor
Meningitis/encephalitis
Postviral syndromes
Hydrocephalus
Migraine
Cavernous sinus thrombosis
Aneurysm
Benign idiopathic ("cryptogenic")

[a]Not listed in order of frequency.

Table 26.7. Causes of Third Cranial Nerve Palsy in Children[a]

Other problems may mimic the eye muscle imbalance of third nerve palsy. For example, an inferior orbital wall blowout fracture (see Chapter 25) may cause a deficiency in the eye's ability to look up. Trauma also may result in unilateral mydriasis. Together, these findings may mimic a third cranial nerve palsy. This scenario underscores the need for ophthalmologic consultation when pathologic unilateral mydriasis and/or eye muscle deficits are present. Diagnostic clues to the presence of a long-standing third cranial nerve palsy include phenomena associated with aberrant regeneration of the oculomotor nerve. Examples include eyelid elevation when the patient looks down and pupillary constriction when the patient looks upward, downward, or into adduction.

Adie's pupil is most often unilateral. It is caused by parasympathetic denervation at the myoneural junction of the pupillary dilator muscle. It may be associated with deep tendon hyporeflexia. Also known as tonic pupil, an Adie's pupil constricts slowly to near convergence and then redilates deliberately. Slitlamp examination may reveal serpentine microundulations or asymmetries on constriction to light. Adie's pupil usually has an acute or subacute onset. It has been reported after trauma and viral illnesses, including varicella. The denervation is best demonstrated by instillation of weak pilocarpine (0.125 or 0.1%) into both eyes. This concentration is too weak to cause constriction of the normal pupil; however, the denervated Adie's pupil will become miotic. Acutely, this test may be falsely negative. Perhaps it is best that this test be left to the ophthalmologist so that complete ophthalmic examination can be conducted before pharmacologic alterations in pupil size are made.

A common misconception is that poorly seeing eyes have large pupils. Even an eye with very poor vision (light perception) or total blindness may have normal pupil size.

CORECTOPIA AND IRREGULAR PUPILS

Pupils can be unequal by virtue of irregularities in pupillary shape or position. Pupils that are located eccentrically (corectopia) rather than centrally usually are bilateral and represent congenital anomalies. When a unilateral pupil is located in a different position than its counterpart, however, this may indicate a progressive change in iris anatomy. Such changes may be associated with formation of other holes in the iris, abnormal iris strands that may become adherent to the cornea, or changes in iris color. These abnormalities also may be associated with glaucoma.

The direct ophthalmoscope can be helpful in identifying these rare anomalies. The focusing dial should be turned so that

the iris is in focus (less than 6 inches away from the patient). The dial will be turning in the direction of increasingly higher black (or green) numbers to provide increasing magnification with a shorter focal distance.

Pupils also may be irregular in shape despite having a central location. This often is caused by trauma or prior inflammation. After trauma, the presence of corectopia, or a teardrop-shaped pupil, is particularly ominous because this may indicate an underlying associated rupture of the eyeball (see Chapter 111). A history of iritis or undiagnosed recurrent ocular inflammation and pain may be associated with scar formation (posterior synechiae) between the edge of the pupil and the lens of the eye, which sits immediately behind the pupil. This can cause abnormal pupillary shapes.

Perhaps the most familiar disorder of pupillary shape and/or location is the congenital iris coloboma. This “keyhole” pupil (Fig. 26.4) represents a failure of proper embryologic development of the iris tissue. By itself, iris coloboma usually is asymptomatic and not associated with a functional deficit. However, associated colobomatous defects of the retina or optic nerve may exist, and these can result in serious visual compromise.

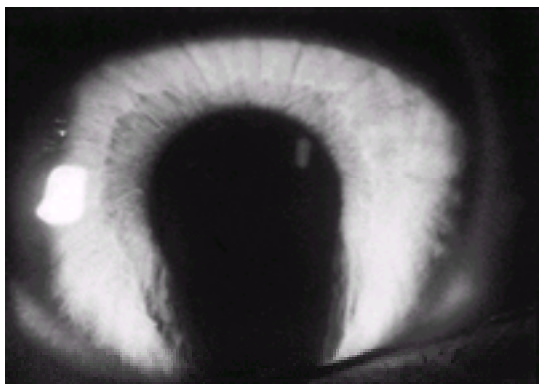

FIGURE 26.4. Iris coloboma creating a “keyhole” pupil.

It is wise to seek ophthalmologic consultation in all situations of unilateral corectopia or irregular pupillary shape. Occasionally, when dilating drops are instilled initially, the pupil may begin to dilate irregularly and asymmetrically. This is of no concern provided that the ultimate shape of the dilated pupil is round.

UNEQUAL PUPILLARY REACTIVITY

Both pupils should be equally brisk in their constricting reaction to a penlight (or direct ophthalmoscope light). When asymmetry in pupillary reactivity is found, it always is the more sluggish pupil that is abnormal. Often, the more sluggish pupil will be a unilaterally dilated pupil (for which the previous discussion applies). If both pupils are symmetric in their baseline positions, an abnormally sluggish pupil may indicate the presence of a serious retinal or optic nerve problem that is impairing the ability of the affected eye to perceive the light source equally. Testing visual acuity is essential under these circumstances.

The pupil should not be pharmacologically manipulated in the ED. Rather, direct referral to an ophthalmologist is appropriate so that the pupils may be observed unaltered.

CHAPTER 27

Eye—Visual Disturbances

ROBERT A. FELTER, MD

Department of Pediatrics, Northeast Ohio University, and Departments of Pediatrics and Adolescent Medicine, Tod Children's Hospital, State of Ohio Department of Public Safety, Youngstown, Ohio

Sudden loss or deterioration of vision (or diplopia) can be caused by numerous diseases and injuries (Table 27.1, Table 27.2 and Table 27.3). Although most cases are rare in the pediatric patient, a systematic approach is necessary to reach a correct diagnosis and to minimize permanent visual impairment. The patient's age, underlying disease conditions, visual history, and history of possible injury must be determined. It is important to remember that up to 5% of abused children present with ocular injuries and 40% of abused children will have ocular findings. The recent increase in survival of extremely low–birth weight infants has led to many children with varying degrees of visual disturbances that may not be readily noticed. The extent of the visual impairment and the rapidity of its onset also are vital pieces of information. A careful eye examination, including gross and ophthalmoscopic examination, determination of extraocular movement, and visual acuity, together with the history, leads to correct diagnosis and management of the patient (see Chapter 120).

	Traumatic	Nontraumatic
Periorbital	Eyelid hematoma, edema from trauma	Orbital or periorbital cellulitis, tumor, allergic edema
Cornea and conjunctiva	Chemical burns, thermal burns, ultraviolet or infrared burns, laceration of cornea	Conjunctivitis (bacterial, viral, fungal)
Anterior chamber	Traumatic iritis, hyphema, posttraumatic cataract, dislocation of lens, glaucoma	Acute iritis, glaucoma, uveitis
Posterior chamber	Vitreous hemorrhage	Endophthalmitis
Retina	Severed retinal artery, retinal tears or detachment, commotio retinae	Retinal vein or artery obstruction, spontaneous
Cortex	Head trauma	Optic neuritis, toxins, hysteria, hypoglycemia, melanoma, cerebrovascular accidents, migraine
Other	Carotid artery trauma	Poisoning Shunt malfunction Vitamin A deficiencies Measles

Table 27.1. Causes of Acute Visual Disturbances

Trauma	Rupture of globes
Chemical burns	Periorbital infection
Hyphema	Conjunctivitis

Table 27.2. Common Conditions That Cause Acute Visual Disturbances

Blowout fractures	Exercise
Poisoning	Arnold-Chiari malformation
Central nervous system pathology (tumor, bleed)	Myasthenia gravis
Shunt malfunction	Head trauma

Table 27.3. Causes of Acute Diplopla

Few ocular conditions in the pediatric population are truly emergent (Table 27.4), but many are urgent; most can be treated by the emergency physician or can be referred for appropriate follow-up with an ophthalmologist. Many conditions that a pediatric ophthalmologist sees are not discussed here because they rarely are seen in the emergency department (ED). Such conditions include congenital eye disorders and amblyopia. Sudden onset of diplopia may be secondary to many of the conditions listed, either as a direct effect of trauma, infection, central nervous system (CNS) pathology (tumor or shunt malfunction), or hysterical reaction. Likewise, head tilt may represent a visual disturbance and requires a complete ophthalmologic evaluation, although the condition also may be caused by musculoskeletal problems in the neck. Conditions that are more likely to be seen in the ED are emphasized in this chapter.

Alkali or acid burns
Central retinal artery occlusion

Table 27.4. Emergent Conditions That Cause Visual Disturbances

PATHOPHYSIOLOGY

Vision may be impaired through interference at any point in the visual pathway. Light must reach the eye, pass through the cornea and the anterior chamber, be focused by the lens, pass through the posterior chamber, and reach the retina. The retina must react to the visual stimuli, generate impulses, and pass these impulses along the optic nerve and eventually to the visual cortex for interpretation. In addition, for binocular vision, the movement of both eyes must be coordinated and smooth. If any step in this pathway is interrupted or damaged, visual impairment will occur. Loss of clarity of the visual media or damage to the conductive tissues leads to decreased vision.

DIFFERENTIAL DIAGNOSIS

Trauma and infections are the two most common causes of acute visual impairment in otherwise healthy children seen in the ED, and these two processes can interfere with any part or all of the visual pathway (Table 27.1 and Table 27.2). Children with shunts for hydrocephalus may have a variety of visual disturbances—from complete blindness to transient diplopia. Any child with an acute visual disturbance and a shunt must have the functioning of the shunt evaluated. The total spectrum of diseases that cause visual impairment can be understood best if the visual pathway is divided into its parts, and each part is considered sequentially (Table 27.1).

Vision may be limited by periorbital diseases such as orbital cellulitis, tumor, or infection or swelling of the eyelids. The history and physical examination usually make these diagnoses obvious.

Blunt trauma to the eye may cause a blowout fracture of the orbit. The weakest portion of the orbit, the floor, most commonly breaks, and this may entrap the extraocular muscles. Visual impairment may be limited to double vision when looking in a certain direction, particularly upward. Testing the extraocular movements reveals the limitation. Careful inspection of the globe also is necessary.

Diseases of the cornea that cause visual impairment are predominantly infectious or traumatic. Infections of the cornea and conjunctiva can be caused by bacteria, viruses, and fungi (see Chapter 24 and Chapter 120). All of these diseases may present as a unilateral or bilateral process, usually affecting only the conjunctiva and cornea. Onset is variable but usually occurs over 1 or 2 days, and vision is not greatly impaired. In the newborn period, gonococcal and chlamydial infections must be considered. With a recent eye injury or foreign body intrusion, fungal infections are possible. In the United States, the most common corneal infection that causes permanent visual impairment is herpes simplex, whereas trachoma is the most common cause worldwide. A careful ophthalmoscopic or slitlamp examination will reveal the

characteristic dendritic ulcers of herpes simplex infection after the eye has been stained with fluorescein. Unless this disease is excluded, steroid-containing medications should not be used. Herpes simplex infection may be recurrent, so if a child with a history of previous herpes simplex keratitis complains of a red eye on the previously infected side, recurrent herpes infection must be considered.

Traumatic injuries to the cornea include one of the true ophthalmologic emergencies: alkali burns. Alkali burns in general carry a worse prognosis than acid burns. Rapid treatment of this condition is imperative to prevent permanent visual impairment. The cause of the chemical injury usually is obvious from the history. Self-inflicted thermal injuries of the cornea from curling irons are increasing and should be sought in a child who has facial burns. Both ultraviolet and infrared light can cause damage to the cornea, resulting in severe pain and photophobia within 24 hours of exposure. Lacerations with perforation of the cornea usually affect other parts of the eye as well and can lead to significant visual impairment. Careful inspection of the globe with associated lid trauma is mandatory.

The anterior chamber of the eye consists of the aqueous humor, the iris, and the lens. Acute iritis is rare in children, and the cause often is uncertain. There is a sudden onset of pain, redness, and photophobia that usually affects one eye only. The degree of visual impairment varies with the severity of the inflammation. Certain diseases have associated iritis, such as juvenile rheumatoid arthritis, but these seldom are seen in the ED. Blunt trauma also can cause iritis, but vision is only slightly impaired unless other structures are involved. Trauma also can cause a hyphema or hemorrhage into the anterior chamber. This can result in little to severe visual impairment in the affected eye, depending on the extent of bleeding and associated trauma. Traumatic injuries can lead to cataract formation, usually within a few days of injury, but onset may be delayed for years. Dislocation of the lens after trauma causes significant visual impairment but can be recognized easily with a careful examination. Glaucoma and a retinal detachment may be late complications of blunt trauma. Congenital glaucoma is a major preventable cause of blindness in children; most cases manifest within the first 6 months of life and occasionally present to the ED. Corneal clouding, buphthalmos, or asymmetry in eye size may be the chief complaint. If any one of these is noted as a primary complaint or an incidental finding, immediate referral is required.

Injury or infection that involves the anterior chamber may lead to increased intraocular pressure. Glaucoma may become evident days to years after the initial trauma or infection. Pain around the eye, blurred vision, and occasionally, nausea and vomiting in a patient with glaucoma or with a recent eye injury may represent an acute attack of glaucoma. The diagnosis is made easily with tonometry.

The uvea consists of the iris, ciliary body, and choroid. One or all portions of the uvea may become inflamed, causing uveitis. Iritis and iridocyclitis may be called anterior uveitis, whereas inflammation of the choroid is often called posterior uveitis. The etiologies may be divided into infectious and noninfectious. Infectious uveitis may be caused by viruses, bacteria, fungi, or helminths. The most common cause of posterior uveitis in children is toxoplasmosis with *Toxocara canis* second. Noninfectious causes include sarcoidosis and sympathetic ophthalmia. Measles, mumps, and pertussis may be associated with uveitis that is not the result of invasion by the agent causing the infection. Vogt-Koyanagi-Harada syndrome is a panuveitis with meningeal and cutaneous findings. Prompt treatment of this syndrome is necessary for optimal visual outcome.

In addition to blurred vision in one or both eyes, anterior uveitis also is associated with pain in the affected eye, headache, photophobia, and conjunctival injection. Anterior uveitis may be confused with conjunctivitis or an acute attack of glaucoma. In posterior uveitis, the pain and photophobia may be less pronounced, but there may be a more pronounced visual impairment.

The posterior chamber is composed of the vitreous humor. The vitreous gel usually is clear, and any diseases that affect the clarity will impair vision. Certain chronic conditions such as uveitis can cause deposits in the vitreous humor, but the visual impairment is very gradual. Infections inside the eye (endophthalmitis) usually result from a penetrating injury, surgery, or an extension of a more superficial infection. Bacterial infections develop more rapidly than do fungal infections. The child will have severe pain in or around the eye and, with bacterial infections especially, may have fever and leukocytosis. The process usually is unilateral, and vision is severely compromised. Purulent exudate is formed in the vitreous humor, and ophthalmoscopic examination may reveal a greenish color with the details of the retina lost. A hypopyon—accumulation of pus in the anterior chamber—usually is present.

Either penetrating or blunt trauma (see Chapter 111) to the eye can lead to vitreous hemorrhage, but this is uncommon in children. Diabetes mellitus, hypertension, sickle cell disease, and leukemia may cause vitreous hemorrhage as well as retinal tears, central retinal vein occlusion, and tumor. There is a sudden loss or deterioration of vision in the affected eye. Findings on examination depend on the degree of hemorrhage. Blood clots may be visible with the ophthalmoscope, or the fundus reflex may be black, obscuring the retina in more severe cases.

Retinal vein and artery obstruction also are uncommon in pediatric patients. With central retinal artery occlusion, there is a sudden, painless, total loss of vision in one eye. If only a branch is occluded, a field loss will result. Ophthalmoscopic examination reveals the cherry-red spot of the fovea, the optic nerve appears pale white, and the arteries are narrowed significantly. A Marcus-Gunn pupil (relative afferent defect) may be present and may be diagnosed by shining a light in one eye, then in the other. When the light is shone in the normal eye, both pupils will constrict. When light is shone in the damaged eye, the pupil will dilate.

The retinal artery may be severed by trauma or obstructed by emboli, as in a patient with endocardial thrombi or arterial obstructions in systemic lupus erythematosus (SLE) and in diseases with hypercoagulability, such as sickle cell disease. The arterial spasm associated with migraine may lead to retinal artery obstruction.

As with retinal artery occlusion, retinal vein occlusion causes a painless loss of vision. Visual loss may be severe, with total occlusion of the central retinal vein, or less pronounced, with branch obstruction. Examination of the retina reveals multiple hemorrhages with a blurred, reddened optic disc. The arteries are narrowed, the veins engorged, and patchy

white exudates may be evident. These findings will be limited to one area in branch occlusion. Retinal vein obstruction, although rare, may occur with trauma or diseases such as leukemia, cystic fibrosis, or retinal phlebitis.

As mentioned, a tear in the retina may lead to vitreous hemorrhage, causing decreased vision in the affected eye. If the tear is in the macula, the visual loss will be severe. A tear in the retina may not cause immediate visual impairment. Retinal detachment from a retinal tear may be delayed for years. The visual impairment may go unnoticed if the detachment is peripheral. As the detachment progresses or when it involves more central areas, the patient will complain of cloudy vision with lightning flashes (photopsia). This may be followed by a shadow or curtain in the visual field. Visual acuity may remain normal if the macula is not involved. Examination of the eye will reveal a lighter appearing retina in the area of detachment, and it may have folds. Flashing lights or visual field defects, after trauma, should raise the suspicion of retinal detachment. Retinoschisis, splitting of the layers of the retina, may be seen in the shaken baby syndrome.

Commotio retinae, or Berlin's edema—that is, edema of the retina—may follow blunt ocular trauma by 24 hours. The visual loss is variable, and the retina will appear pale gray because of the edema, but the macula usually is spared.

The optic nerve transmits visual signals to the cortex. Optic neuritis is involvement of the optic nerve by inflammation or demyelinization. The process usually is acute and may be unilateral or bilateral. Loss of vision may take from hours to days, and visual impairment ranges from mild loss to complete blindness. Patients often complain of disturbance of color vision. Pain may be absent or present on movement of the eye or palpation of the globe. It rarely is an isolated event in children. Causes include meningitis, viral infections, immunizations, encephalomyelitis, Lyme disease, and demyelinating diseases. Exogenous toxins and drugs (e.g., lead poisoning, long-term chloramphenicol treatment) also may cause optic neuritis.

Various toxins are capable of causing impaired vision. The loss may be gradual or sudden, depending on the particular toxin. Toxins usually act on ganglion cells of the retina or on optic nerve fibers, causing contraction of the peripheral field, central visual defect, or a combination. Methyl alcohol, when ingested, may cause bilateral sudden blindness, which may be complete and permanent or may have a more gradual onset. With methyl alcohol ingestion, associated symptoms include nausea, vomiting, abdominal pain, headache, dizziness, delirium, and convulsions. Other toxins include halogenated hydrocarbons, sulfanilamide, quinine, and quinidine. Large doses of salicylates may cause amblyopia. Digitalis may cause transient amblyopia, visual blurring, or the perception of yellow halos around light (xanthopsia).

Visual impairment also may result from interference with the visual cortex of the brain. Cortical blindness has many causes (Table 27.5). Head trauma (see Chapter 38 and Chapter 105) may cause total loss of vision soon after the event. This has been called “footballer's migraine” because of its association with head trauma in soccer. Even trivial head trauma has been known to cause blindness. The apparent hysterical reaction that follows head trauma, especially in young children, may represent complete blindness in a child unable to express the problem or who is too frightened by the experience. The physical examination may be completely normal. There may be a delay of onset, but the entire course is usually brief, lasting minutes to hours. This form of blindness often is confused with hysterical blindness, the latter being a diagnosis of exclusion. Monocular blindness may be caused by trauma to the carotid artery on the affected side.

Cardiac arrest	Hydrocephalus
Status epilepticus	Shunt malfunction
Hypoxia	Head trauma
Perinatal asphyxia	Cardiac surgery
Cerebral infarction	Cerebral or vertebral angiography
Meningitis	Drugs (steroids)
Encephalitis	Carbon monoxide poisoning
Subacute sclerosing leukoencephalitis	Occipital epilepsy
Hypoglycemia	Postictal states
Uremia	

Table 27.5. Causes of Cortical Blindness

Migraine headaches are a common cause of bilateral field loss (hemianopsia) in adolescents. This field loss usually lasts less than 1 hour. It almost always is misidentified by the patient as loss of vision in only one eye. Headache and nausea after such an episode are the rule but occasionally may be absent.

EVALUATION AND DECISION

The absolute ophthalmologic emergencies are alkali burns, a ruptured globe, and retinal artery occlusion. The diagnosis of the first is by history, and therapy must be initiated promptly to minimize the damage to the eye. If there is any doubt about the actual substance to which the eyes have been exposed, treatment for an alkali burn is always prudent. A ruptured globe must be suspected with any possible penetrating injury to the eye. The injury may be subtle, and the vision may be normal. If a possibility of a ruptured globe exists, the eye should be protected and the patient should have immediate evaluation by an ophthalmologist. Retinal artery thrombosis is rare in children, but it should be suspected when there is sudden, unilateral painless loss of vision and a predisposing condition. Predisposing conditions include those associated with emboli, such as endocardial thrombi or amniotic fluid; conditions with arteritis leading to obstruction, as in SLE; disease states associated with hypercoagulability, such as sickling hemoglobinopathies; and conditions with arterial spasm, such as severe hypertension.

If alkali burns, a ruptured globe, and retinal artery occlusion can be excluded, the patient may be evaluated more carefully before instituting therapy. When visual acuity is being determined, the history may be obtained. Significant historical information includes episodes of recent trauma, unilateral or bilateral nature of the loss, and association of pain in or around the eye (Fig. 27.1). Child abuse may present with any of the variety of traumatic injuries. Retinal hemorrhages in a child are almost always caused by intentional trauma. Most children seen in the ED will have a traumatic or infectious process.

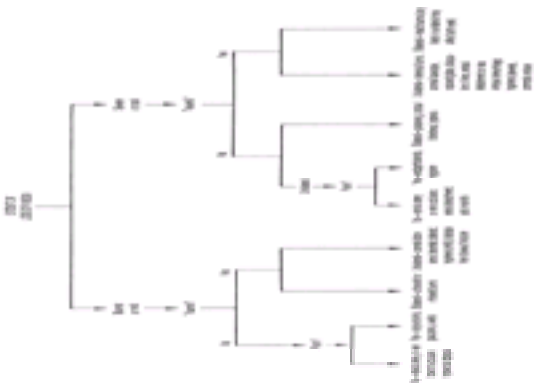

FIGURE 27.1. Diagnostic approach to visual disturbances.

Severe Visual Loss Associated with Trauma

Severe bilateral visual loss associated with trauma is the result of head trauma, causing cortical blindness. This condition usually is totally reversible in less than a few hours.

Any of the traumatic injuries that cause severe unilateral loss of vision may cause bilateral loss if both eyes are involved. The mechanism of injury should be elicited. If there is any possibility of a penetrating injury or rupture of the globe, the involved eye should be protected from further damage by shielding until careful examination can be performed by a skilled physician. If the globe is intact and no penetration by a foreign body occurred, an ophthalmoscopic or slitlamp examination usually leads to the correct diagnosis. These conditions include chemical burns of the cornea, hyphema, dislocation of the lens, vitreous hemorrhage, detachment or tear of the retina, and commotio retinae.

Severe Visual Loss Not Associated with Trauma

With severe bilateral visual loss not associated with trauma, the possibility of toxins must be explored. Also, cortical blindness may cause a similar picture, but this is rare and generally associated with another problem, such as hypoglycemia, leukemia, and cerebrovascular or anesthetic accidents. If severe visual loss is unilateral and painful, endophthalmitis must be suspected, but once again, such loss usually is the result of a previous penetrating injury or an extension of a local infectious process. If a headache is associated with the visual loss, migraine may be implicated. If the severe loss is unilateral and painless, retinal artery or vein occlusion or retinal detachment may be diagnosed by ophthalmoscopic examination. Optic neuritis will also present this way.

Mild Visual Loss with Trauma

If the visual loss is unilateral, not severe, and if trauma recently occurred, corneal abrasions, traumatic cataracts, and small hyphemas should be sought. A blowout fracture may cause diplopia, but if each eye is examined individually, the visual acuity should be normal. If the process is bilateral, exposure to ultraviolet or infrared light should be considered.

Mild Visual Loss without Trauma

When the visual loss is mild and nontraumatic, and if the process is unilateral and painful, conjunctivitis, uveitis, and acute attacks of glaucoma are possible. If the process is painless, retinal vein or artery branch occlusion may be suspected. Any of these processes may be bilateral as well.

CHAPTER 28

Fever

[*]ELIZABETH R. ALPERN, MD and [†]FRED M. HENRETIG, MD

[*]Department of Pediatrics, [†]Departments of Pediatrics and Emergency Medicine, The University of Pennsylvania School of Medicine; [*]Department of Emergency Medicine, [†]Section of Clinical Toxicology, The Children's Hospital of Philadelphia, [†]The Poison Control Center, Philadelphia, Pennsylvania

Fever, the abnormal elevation of body temperature, has been recognized for centuries by physicians as a sign of disease. Furthermore, the problem of the febrile child is one of the most commonly encountered in clinical pediatrics, accounting for as many as 20% of pediatric emergency department (ED) visits. Despite such considerable clinical experience, only recently has much progress been made in our understanding of the pathogenesis of fever. The problem of appropriate clinical and laboratory evaluation of febrile children, however, remains a major challenge to the pediatrician and emergency physician. The approach outlined in this chapter helps the physician treat a febrile child in the ED and proceed systematically with the appropriate diagnostic steps and the institution of therapy. The principal causes of fever in children are listed in Table 28.1.

Table 28.1. Principal Conditions in Children Associated with Fever

PATHOPHYSIOLOGY

Fever is a complex process, involving the highly coordinated interplay of autonomic, neuroendocrine, and behavioral responses to a variety of infectious and noninfectious inflammatory challenges. It is believed to represent an adaptive response to such threats and is manifested by nearly all vertebrate species. The febrile reaction is relatively stereotyped and independent of precise causation. Exogenous pyrogens (e.g., toxins, infectious agents, antigen–antibody complexes) from many sources produce fever in humans by inducing the production of proteins, collectively termed endogenous pyrogens, by phagocytic leukocytes. These are now identified as large proteins, with the average size being 15,000 to 30,000 daltons, and include interleukin-1, tumor necrosis factor-a, and several interferons. These proteins enter the circulation after their synthesis and interact with specialized receptor neurons in the organum vasculosum of the anterior hypothalamus, one of the “circumventricular organs” of the brain, which are now understood to have no blood–brain barrier and to function as neurohumoral receptors for blood borne hormones. Signaling at this site leads to the production of prostaglandins, particularly PGE_2, monoamines, and probably cyclic adenosine monophosphate. These mediators in turn initiate signals that reset the thermostatic set point in the hypothalamus and result in several responses. The principal effect is on the vasomotor center and results in peripheral vasoconstriction of cutaneous beds with redirection of blood flow to deeper tissues, thus minimizing skin heat loss. In addition, sweating is decreased; vasopressin secretion falls, which results in lowered extracellular fluid volume that requires heating; and behavioral adjustments such as shivering and seeking a warmer environment are stimulated. These effects all combine to elevate body temperature. There is some evidence that increased body temperature impairs replication of many microbes and may aid phagocytic bactericidal activity. The febrile response includes further adaptive neuroendocrine effects. Glucose metabolism is curtailed in favor of that based on lipolysis and proteolysis, thus depriving bacteria of their preferred substrate. Fever-induced anorexia further diminishes glucose availability to microbes. Hepatic production of acute-phase reactant proteins may result in binding of divalent cations, which are also growth factors for microorganisms. All of these effects combine to further enhance the host's response to microbial invasion. Very rarely, central nervous system (CNS) dysfunction (e.g., hypothalamic tumor, infarction) alters the thermostatic set point directly.

It is difficult to pinpoint the lowest temperature elevation considered to be definitely abnormal for all children under all circumstances. Some children normally have rectal temperatures as low as 36.2°C (97°F) or as high as 38°C (100.4°F).

Children, like adults, also have diurnal variations in temperature, with the peak usually occurring between 5 PM and 7 PM. This variation is less pronounced in infants. In the 2- to 6-year age range, the temperature may vary by 0.9°C (33.6°F), and in children over 6 years of age, diurnal variation may span 1.1°C (34°F). Factors such as excessive clothing, physical activity, hot weather, digestion of food, and ovulation can raise temperature in the absence of disease. For the appropriately dressed child who has been at rest 30 minutes, a rectal temperature of 38°C (100.4°F) is defined as fever for this discussion. Using the proper technique to record rectal temperature is important for optimal accuracy. Proper technique includes proper positioning and restraint in infants (prone, supine, or on the side with hips slightly flexed), depth of insertion (about 2 to 3 cm), and time for equilibration (2 to 3 minutes with glass thermometers, several seconds with electronic digital probes). The thermometer should not be placed directly into a fecal mass because the temperature may not have equilibrated with rapid fluctuations in core temperature and thus may be falsely low as temperature rises rapidly. Oral and axillary temperatures usually are about 0.6°C (33.1°F) and 1.1°C (34°F) lower than rectal temperatures, respectively. Recent attempts to measure temperature with a less invasive technique include temperature-sensitive pacifiers and forehead strips, both of which have been found to be unreliable in young children. However, one new technique that has been found to be acceptable to parents and reliable in most settings is that of infrared tympanic membrane thermometry. The tympanic membrane shares vascular supply with the hypothalamus, and it has been shown in adult intensive care settings that there is excellent correlation between core temperature (e.g., pulmonary artery catheter) and tympanic membrane readings. Several studies in children have tended to confirm the reliability of this technique compared with rectal temperature, although others have questioned the reliability of tympanic measurements in young infants, especially those less than 3 months of age. The presence of otitis media (OM) or cerumen does not seem to affect reliability adversely. Because even low-grade fever may be clinically significant in young infants and there is at least some doubt about the reliability of tympanic measurements in this age group, it would seem prudent to rely on rectal temperatures in this population.

EVALUATION AND DECISION

The importance of fever lies in its role as a sign of disease. The physicians caring for a febrile child should concentrate on discovering the cause of the fever and treating the underlying illness. Any fever may signify serious infection; however, severe hyperpyrexia, defined as a temperature of 41.1°C (106°F) or higher, is more often associated with diagnoses of pneumonia, bacteremia, or meningitis. The magnitude of reduction of a fever in response to antipyretics does not distinguish children with serious bacterial illnesses from those with viral diseases. If no specific treatment for the determined diagnosis is necessary, the physician's goal is then to provide appropriate supportive care and follow-up. Because many parents have “fever phobia,” instructions that explain the importance of fever as an indicator of disease, not as an inherently harmful entity, should be given.

A complete history and physical examination will provide most important clues in determining the diagnosis of children with febrile illnesses. The general impression obtained in the first few moments of an evaluation is extremely important in the recognition of potentially life-threatening causes of fever (Table 28.2). A great deal of information can be attained by visual assessment of the child while in the arms or lap of his or her parent. The severity of the illness may become apparent if the child is agitated or uninterested in the surroundings while in this comfortable, safe position. If the child appears nontoxic, observation of the child while the history of the present illness is being discussed with the parent may provide further insight into the diagnosis. Fever has different management implications for distinct subsets of children. Therefore, a clear understanding of the degree, mode of measurement, and duration of fever is especially important in the initial evaluation. The physician should ask questions concerning associated signs and symptoms, medications being given (including antipyretics and antibiotics), presence of ill contacts, travel history, and pet or insect exposures. The medical history should focus on recurrent febrile illnesses and the presence of any diseases or drug regimens that would compromise normal host defenses, such as sickle cell anemia, asplenia (functional, congenital, or surgical), malignancy (noting particularly chemotherapeutic or radiation treatments), human immunodeficiency virus (HIV), renal disease, prolonged steroid use, or indwelling catheters or ventriculoperitoneal shunts. Immunization status should also be determined. An understanding of prior evaluation and treatments during this illness may be helpful.

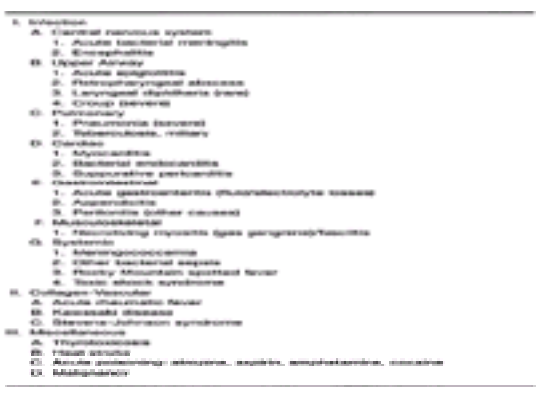

Table 28.2. Life-Threatening Acute Febrile Illnesses

As stated previously, the physical examination of the young febrile patient begins during the historical interview with the caregiver. The physician should note the child's alertness, responsiveness to persons and objects, work of breathing, color, feeding activity, and age-related appropriateness of social interaction and gross motor functions. If a child is noted to be playing with toys or smiling at his or her parent, the febrile illness is most likely not immediately life-threatening. However, the febrile infant who appears irritable and/or lethargic while being held by a parent before the examination has high probability of having a serious infection such as meningitis or sepsis. The complaint or observation that a child's crying increases with parental attempts to comfort is critical because “paradoxical irritability” is an important sign of

meningitis in infancy.

Other signs of severe or life-threatening infections heralded by fever should be sought early in the examination. CNS infections may be marked by fever with altered sensorium, convulsion, meningismus, or focal neurologic deficits. However, infants younger than 2 years of age with meningitis often do not have meningismus, but they may instead have irritability, anorexia, lethargy, vomiting, or bulging fontanelle. Severe upper airway infections may present with stridor, excessive drooling, and tripod positioning. A child with pneumonia, pericarditis, endocarditis, or sepsis syndrome may display dyspnea or tachypnea, cyanosis or pallor, tachycardia, and hypotension, as well as altered mental status. Hemorrhagic rashes may signal bacterial or rickettsial infections such as meningococcemia or Rocky Mountain spotted fever.

Although the index of suspicion for serious febrile illness must be high throughout the evaluation of each child, most childhood illnesses with fever are minor and self-limiting. Once the physician has ascertained that the child is not in immediate danger, the examination should focus on sites of common pediatric infections, including the ears, nose, and throat; cervical lymph nodes; respiratory, gastrointestinal, and genitourinary tracts; and skin, joints, and skeletal system (Table 28.3). Evaluation of each child is developed upon an understanding of the common infectious entities that affect that child's age group and the presenting signs and symptoms or lack thereof in each infectious entity (see Chapter 84 for a full discussion of infectious diseases).

Table 28.3. Common Causes of Fever

Many febrile exanthems are characteristic enough to be diagnostic (see Chapter 62, Chapter 63, Chapter 64, Chapter 65, Chapter 67, and Chapter 84). Varicella, rubeola, scarlet fever, and Coxsackie virus can all be identified by their pathognomonic rashes. However, if a child with chickenpox presents several days into the illness with a new fever, the possibility of group A b-hemolytic streptococcal coinfection needs to be fully evaluated. Children with fever and petechiae may have invasive meningococcal disease, disseminated streptococcal infection, or Rocky Mountain spotted fever. However, they may simply have a less serious viral infection or streptococcal pharyngitis. Differentiation of these entities is crucial and is based on clinical appearance of the patient and laboratory evaluation. A child with petechiae only above the nipple line, normal white blood cell (WBC) count, and well appearance is less likely to have invasive disease. However, any child who appears ill, has a laboratory abnormality, or has progressive petechial rash needs a full evaluation, including lumbar puncture and antibiotic administration.

On physical examination, acute OM is identified by changes in the tympanic membranes, such as redness, bulging, decreased mobility, loss of landmarks and light reflex, and purulent drainage from a perforation. Careful examination of the head and neck may reveal rhinorrhea and signs of inflammation, indicating a viral upper respiratory infection (URI). The oropharynx may reveal findings suggestive of acute pharyngitis or stomatitis (see Chapter 49 and Chapter 71). Children with a history of a recent respiratory infection may have tender swollen cervical lymph nodes characteristic of a subsequent adenitis. Croup is readily identified by a barky cough in young children, whereas a distinctive “hot potato voice” with unilateral tonsillar swelling in adolescents indicates a peritonsillar abscess. Wheezing, tachypnea, and fever in infants mark bronchiolitis. Pneumonia often presents with tachypnea, fever, and nasal flaring or retractions. Mild abdominal pain, tenderness, vomiting, and/or diarrhea may suggest viral gastroenteritis or early hepatitis or pancreatitis. More severe findings, particularly the occurrence of peritoneal signs, may indicate intra-abdominal abscess, peritonitis, or appendicitis (see Chapter 50 and Chapter 118). However, in children, fever with abdominal pain may also represent lower lobe pneumonia, streptococcal pharyngitis, or urinary tract infection (UTI). Additional findings in UTI may include suprapubic or costovertebral angle tenderness. Adolescent girls with pelvic or abdominal pain and fever should be evaluated for pyelonephritis and/or pelvic inflammatory disease (see Chapter 94). Differentiation of these diverse diagnoses depends on a thorough history, physical examination, and at times, well-directed laboratory evaluation (see Chapter 84).

Recent public health measures have changed the frequency and risk of certain febrile illness in children. In a recently published report from the Centers for Disease Control and Prevention, Schuchat et al. have revealed that the *Haemophilus influenzae* type B vaccine has drastically changed the risk and causative agents for meningitis in children. There has been a 94% reduction in the incidence of *H. influenzae* meningitis and a shift in the median age of those affected from 15 months to 25 years of age. The current rarity of epiglottitis in children is also due to this decline in *H. influenzae* infections. Recognition of this epidemiologic change is crucial in evaluating and treating the febrile child. Children between 2 and 18 years of age who have bacterial meningitis will most likely be infected with *Neisseria meningitidis*. Seventy percent of invasive *Streptococcus pneumoniae* infections in children less than 5 years of age present as bacteremia without a focus of infection. In this recent study and others, the risk of meningitis in the setting of invasive *S. pneumoniae* infections has been found to be between 2 and 6%. These findings obviously influence the evaluation and treatment of febrile children with signs of meningitis, as well as those young children without an identified

source of infection after thorough historical and physical examination.

Occult bacteremia is the presence of pathogenic bacteria in the blood of a well-appearing febrile child in the absence of an identifiable focus of infection (see also Chapter 84). Children most commonly suspected to be at risk for occult bacteremia are those between the ages of 3 and 36 months with a fever of 39°C (102°F) or higher. Infants less than 3 months of age are at increased risk for invasive disease and therefore necessitate different evaluation and treatment. The reported incidence of occult bacteremia among children 3 to 36 months of age with a temperature higher than 39°C before the initiation of the *H. influenzae* type B vaccine program was between 3 and 10%. However, Lee and Harper have recently shown that the prevalence of occult bacteremia in children 3 to 36 months of age is currently 1.6%, with *S. pneumoniae* accounting for 92% of infections. Preliminary work in children 3 to 24 months of age by Alpern et al. correlates with this study, showing a prevalence of occult bacteremia of 1.8%. Both studies failed to identify *H. influenzae* bacteremia in any of the children considered to be at risk for occult bacteremia.

Given these general considerations, an algorithmic approach to the child with an acute (less than 5 days) febrile illness can be formulated, using the following key features: overall degree of toxicity and presence of signs or symptoms of life-threatening disease, immunocompromised host status, patient's age, degree of fever, and presence of localizing features on history and physical examination (Fig. 28.1). Laboratory studies are indicated only for selected situations as defined by these clinical features. Most older febrile children seen in the ED need no laboratory testing.

FIGURE 28.1. Approach to the evaluation of the febrile child.

Infants less than 2 months of age are at increased risk of serious bacterial infections and bacteremia and are more difficult to assess clinically than older children. Thus, all children with fevers of 38°C (100.4°F) or higher who are less than 2 months of age should receive full laboratory investigation for serious infection (“sepsis workup”), including complete blood count (CBC), blood culture, urine analysis, urine culture, and lumbar puncture with cerebral spinal fluid (CSF) for cell count, glucose, protein, and culture. These infants less than 1 month old are usually admitted to the hospital for observation with presumptive antibiotic therapy. Herpes simplex virus polymerase chain reaction (PCR) or culture with presumptive antiviral treatment should be considered in neonates with historical concerns or physical findings of skin, eye, or mouth lesions; respiratory distress; seizures; or signs of sepsis. Stool for leukocytes and culture should be obtained if diarrhea is present. In a recent meta-analysis, Bramson et al. have shown that respiratory findings are good predictors of clinically significant positive chest radiographs in children less than 3 months old. Therefore, chest radiographs may be obtained only when there are clinically evident respiratory symptoms. Baker et al. showed that in children 1 to 2 months of age, a standardized observation scale (Yale Observation Scale) is not sensitive enough on its own to identify serious illness. Many recent studies (Baker et al., Baskin et al., Dagan et al., and Jaskiewicz et al.) have found that children between 1 and 2 months of age, not pretreated with any antibiotics, and who have a pristine physical examination and completely benign laboratory evaluation may be safely discharged home with careful observation and close follow-up. For such a disposition, parents should be able to watch the infant closely for changes in symptoms, should have ready access to health care, and should be willing to return for evaluation. These studies have also found that both empiric intramuscular ceftriaxone (e.g., Baskin et al.) and close observation without antibiotics (e.g., Baker et al.) are safe and effective management strategies in this age group.

An additional dilemma involves the young baby who presents to the ED with a description of either tactile fever alone or fever confirmed by rectal temperature at home but who is afebrile on arrival. This situation was studied by Bonadio et al., who found that the history of tactile fever in such infants did not correlate with subsequent fever, whereas an elevated rectal temperature at home correlated with subsequent fever in 20% of such patients. However, all infants who were found to have serious bacterial infections (including five who were afebrile on presentation) were observed to have had an abnormal initial clinical profile and/or laboratory workup. Although there is no consensus on the approach to this situation, it seems prudent to consider a careful clinical evaluation in all young infants with a history of fever, including one or more repeat temperatures over 1 to 2 hours in the ED after the baby is unbundled. If there is a reliable history of elevated rectal temperature, a sepsis workup should be considered seriously along with a subsequent disposition based on the evolution of temperature pattern, clinical findings, and laboratory results. The infant with only a history of tactile fever whose repeated temperatures are normal and who has an entirely normal clinical evaluation may be assessed as not requiring laboratory studies. All such infants discharged home warrant close follow-up and appropriate short-term monitoring of rectal temperature.

Children between 2 and 3 months of age are evaluated clinically for degree of fever and degree of irritability. Occasionally, an infant at this age may truly “look great,” despite significant fever, and be judged as requiring symptomatic treatment only without aggressive laboratory investigation or hospitalization. However, a sepsis workup should be done for infants with high fever and mild to moderate irritability and/or a full fontanelle. They should be hospitalized if signs of a serious bacterial infection (e.g., cellulitis, pneumonia, septic arthritis, osteomyelitis, UTI) are

present. If all laboratory results are normal, such a child may be discharged on symptomatic treatment and/or antibiotics, if a minor infectious focus (i.e., OM) is found. Even with normal laboratory parameters, however, these patients are at risk for bacteremia and subsequent focal infection, including meningitis. Therefore, it has been our tendency to admit infants who are aged 2 to 3 months with fever and marked irritability, even when CBC and CSF are initially normal.

The febrile child between 3 and 36 months of age with signs of focal infection (e.g., irritability, meningismus, tachypnea, flank tenderness) should be evaluated with the appropriate diagnostic tests and treated for the identified infection. However, if the child with a temperature of 39°C (102°F) or higher does not have localizing symptoms or laboratory/radiograph results indicative of definitive focal infection, he or she should be evaluated with a blood culture for occult bacteremia. Highly febrile children with OM on examination and those who have had a simple febrile seizure (discussed in the following) are also considered to be at risk for occult bacteremia. Teach et al. have analyzed data from a large multicenter trial and indicate that the Yale Observation Scale is not clinically useful in identifying patients with occult bacteremia. Therefore, all such children, despite "well" clinical appearance, are at risk for occult bacteremia.

There has been considerable controversy in the literature about the appropriate initial treatment of children at risk of such occult bacteremia (see Chapter 84). One large, prospective controlled study (Jaffe et al., 1987) found no benefit of oral amoxicillin versus placebo in preventing "serious bacterial infection" (SBI), although the number of randomized children with this outcome were few, and the power to detect a significant difference was small. In 1994, Fleisher et al. compared oral amoxicillin with intramuscular ceftriaxone in preventing SBI and found the latter to be protective. Several recent meta-analyses have attempted to further determine whether antibiotics decrease the risk of meningitis in children evaluated for occult bacteremia. Rothrock et al. determined the risk of SBI in children with occult *S. pneumonia* bacteremia to be decreased in those treated with oral antibiotics (3.3%) compared with those not receiving any antibiotic treatment (9.7%). They also found a reduction from 2.7% to 0.8% for meningitis in children treated with oral antibiotics compared with untreated children. Although Rothrock et al. reported that this difference in risk of meningitis was not statistically significant using their method of analysis, it should be noted that performance of a chi square test on their data yields a *P*-value of less than .05 and also that they eliminated children who underwent a lumbar puncture from the analysis. Bulloch et al. recently performed a meta-analysis that concluded that the use of antibiotics in children at risk for occult bacteremia did not statistically reduce serious sequelae (OR = 0.60; 95% CI 0.10 to 3.49), whereas ceftriaxone compared with oral antibiotics did significantly prevent SBI in children with proven bacteremia (OR = 0.25; 95% CI 0.07 to 0.89). The recent epidemiologic changes due to the *H. influenzae* type B vaccine are responsible for *S. pneumoniae* currently being the most common causative organism of occult bacteremia. *S. pneumoniae* bacteremia spontaneously resolves in most cases. Recent studies indicate that the current incidence of meningitis in children with occult bacteremia is much lower than reported when *H. influenzae* was a significant causative organism of occult bacteremia. Therefore, the role of treatment with empiric antibiotics has been further questioned.

Currently, several options are available to physicians facing this common but challenging situation in the ED (see Chapter 84). One approach is that of obtaining a blood culture and providing expectant therapy without antibiotics, including antipyretics, close observation for progression of symptoms, and reevaluation for any positive culture. Many authorities, including a panel of experts in pediatric emergency medicine and infectious diseases convened to recommend clinical practice guidelines, whose recommendations were published simultaneously in *Annals of Emergency Medicine* and *Pediatrics* (Baraff et al., 1993), suggest presumptive antibiotic treatment with intramuscular ceftriaxone for children at highest risk for occult bacteremia. Jaffe and Fleisher found the sensitivity of a WBC count of 10,000/mm ^{3} or more to be 92%, with a positive predictive value of 4.6% for occult bacteremia. Recently, Kuppermann et al. derived a multivariable model to predict occult pneumococcal bacteremia in children 3 to 36 months of age with temperatures of 39°C or higher and without focal infection. Age less than 24 months, high temperature, and absolute neutrophil count of 10,000/mm^3 or more (WBC 15,000/mm^3 or more) were identified as independent predictors of occult pneumococcal bacteremia and therefore may help delineate patients at highest risk. Others have differed with the published clinical practice guidelines regarding empiric antibiotic therapy, and even to the necessity of obtaining blood cultures in children who do not appear toxic (Kramer and Shapiro, 1997). The optimal management of children at risk for bacteremia may evolve as more emergent techniques to detect bacteremia at the time of the initial ED visit are developed. For example, currently available PCR assays for pneumococcal bacteria currently do not have the sensitivity or specificity needed to screen for occult bacteremia. However, further investigation may yield rapid, predictive tests for occult bacteremia in the form of pneumococcal PCR, plasma tumor necrosis factor, or interleukin 1b levels. Finally, it is likely that the introduction of a conjugated pneumococcal vaccine in the near future will almost completely eliminate the problem of occult bacteremia.

An additional consideration revolves around children with risk factors for bacteremia and whose initial presentation was notable for such irritability that a lumbar puncture was deemed necessary. Although clinical appearance may not predict occurrence of bacteremia per se, lumbar puncture itself has been reported to be associated with the occurrence of meningitis in bacteremic children. Thus, it might be particularly desirable to empirically treat infants with antibiotics who have undergone this procedure but whose cerebrospinal fluid was normal and were thus being considered for an ambulatory disposition.

Recent studies by Shaw et al. and Hoberman et al. have established the overall prevalence of occult UTI in young children without an identified source of infection to be between 3 and 5%. The risk is highest in febrile Caucasian girls less than 2 years of age and in uncircumcised boys less than 1 year of age. Laboratory testing is indicated for young febrile children without an identifiable focus of infection. One approach is to obtain a urinalysis and urine culture in febrile boys less than 6 months of age as well as in any age febrile boy who is uncircumcised and not yet toilet-trained. Febrile girls less than 2 years of age should have urine studies obtained if any two of the following characteristics are present: fever of 39°C (102.2°F) or higher, 1 year of age or younger; Caucasian, fever lasting 2 days or longer; or no identifiable source of infection. Aseptic urethral catheterization or suprapubic aspiration is an appropriate method to obtain urine for the diagnosis of urinary tract infections. Positive dipstick urinalysis with microscopic evidence of pyuria (5 WBC/HPF or greater) or any bacteria/HPF has a sensitivity between 65 and 83%; therefore, urinalysis alone is not adequate to diagnose UTI. Urine dipstick and culture should be performed for all children at significant risk for occult UTI (see Chapter 84).

Simple febrile seizures occur in 3 to 5% of all children (see Chapter 70). They are defined as generalized tonic-clonic seizures without focal neurologic findings, occurring only once per febrile illness (usually in the first 12 hours of onset of fever), in children 6 months to 5 years of age, lasting less than 15 to 20 minutes in duration. By definition, they are seizures accompanied by fever in children without CNS infection. The dilemma that faces the emergency physician is to decide whether a febrile seizure is truly such or if a child presenting with a fever and seizure requires a lumbar puncture to rule out meningitis. Green et al. reviewed 503 cases of meningitis in children 2 to 15 years of age and noted that no cases of bacterial meningitis presented solely as a seizure without any other neurologic signs or symptoms (nuchal rigidity, irritability, prolonged seizure activity, or multiple seizures). Nonetheless, each case of a child presenting with what appears to be a simple febrile seizure, even with a history of such episodes, needs to be evaluated individually. Whether a lumbar puncture is performed or not, the physician should evaluate each child for the underlying source of fever. The threshold to perform a lumbar puncture should be extremely low in children younger than 12 months of age (because of the difficulty in recognizing signs and symptoms of meningitis in very young infants) and in children pretreated with antibiotics (because symptoms of partially treated meningitis may be minimal or absent). Children with atypical febrile seizures should be closely evaluated for CNS infection and a lumbar puncture strongly considered.

Children older than 36 months of age usually can be managed on the basis of degree of irritability, evidence of meningeal signs, and/or other foci of infection found on history and physical examination. These children need not be screened routinely for occult bacteremia. After excluding meningitis, there are several important infections that may be present in ill-appearing, febrile children in this age group, without obvious initial focus. These include meningococcemia, Rocky Mountain spotted fever, salmonellosis or shigellosis, and pyelonephritis (see Chapter 84). Early institution of presumptive therapy may be lifesaving in some of these situations, so their possibility must be borne in mind with toxic, febrile children at any age. Obviously, if certain high-risk features are missed during the initial triage (or evolve after triage) and are encountered early during the physician's careful clinical assessment (e.g., a significant hemorrhagic rash), the child must be managed with extreme urgency (as befits the reclassification into the high-risk category).

Other causes of acute febrile episodes should be kept in mind, including intoxications, environmental exposure, and immunization reactions. Poisonous exposures to aspirin, atropinics, amphetamines, antihistamines, and cocaine present with hyperpyrexia (see Chapter 88). Additional uncommon febrile drug reactions include the serotonin syndrome occurring with the combined use of monoamine oxidase inhibitors and analgesic, antitussive, or psychotropic serotonergic medications (e.g., meperidine, dextromethorphan, fluoxetine), and the neuroleptic malignant syndrome (see Chapter 88). History of environmental exposure in the face of severe hyperpyrexia may represent heat stroke rather than an infectious cause for the increased temperature (see Chapter 89). The diphtheria–pertussis–tetanus immunization is associated with fever that occurs within 48 hours (occurring less often with DTaP vaccine administration). Fever, at times accompanied by a faint rash, may occur 7 to 10 days after immunization with the live-attenuated measles vaccine or the measles–mumps–rubella vaccine.

Fevers of unknown origin (FUO) are defined as daily temperatures of 38.5°C (101.3°F) or higher for at least 2 weeks without discernible cause. Infections commonly causing prolonged fever in children include Epstein-Barr virus infections, osteomyelitis, *Bartonella henselae* infections (cat-scratch disease), UTIs, Lyme disease, and HIV. Noninfectious causes of prolonged fever include neoplasms, collagen vascular diseases, and inflammatory disorders (ulcerative colitis or Crohn's disease).

Symptomatic Treatment

Over the years, there has been considerable debate about the theoretical benefits of fever in the mechanism of host defense, but few definite benefits have been demonstrated in humans. For example, the exanthem of varicella lasts about 1 day longer in children treated aggressively with antipyretics than in control patients. Nevertheless, most clinicians find that febrile children, especially those with high fevers (temperatures of 39.5°C [103°F] or higher), feel better if the temperature is brought down with antipyretic medication. Furthermore, antipyresis may allow the physician to see the child at his or her “best” and, in particular, can help in the decision to perform a lumbar puncture. However, antipyresis will not aid the clinician in discriminating bacteremic children from those with viral syndrome. Both groups typically respond with an equivalent pronounced drop in temperature.

In general, antipyretic therapy should parallel the pathophysiologic basis of the fever. When the fever is caused by altered hypothalamic set point, as in infection, antigen–antibody reactions, and malignancy, attempts to reset the “thermostat” with antipyretic medications are most likely to enhance patient comfort. Antipyretics in common use today work via the inhibition of hypothalamic prostaglandin synthesis. If fever is caused by imbalance of heat production and heat loss mechanisms, such as in heat stroke, urgent cooling by physical removal of heat is necessary, such as with ice water baths, and antipyretics will not help (see Chapter 89). Rarely, a patient with infection will have extreme hyperpyrexia (temperature of 41.1°C [106°F] or higher) and will require urgent temperature reduction with both antipyretics and external cooling. Patients with ongoing febrile seizures also warrant rapid treatment with antipyretics and external cooling, although tepid to cool water sponging usually is sufficient. On the other hand, children at risk for recurrent febrile seizures do not, unfortunately, tend to be protected by rapid use of “prophylactic” antipyresis at first sign of fever.

Most authorities consider acetaminophen to be the pediatric antipyretic of choice. The current dosage recommendation for acetaminophen is 10 to 15 mg/kg given every 4 to 6 hours, with a maximum of five doses per day, resulting in 50 to 75 mg/kg per day. Several recent reports have stressed that, although very rare, repetitive dosing of acetaminophen at the upper limit of, or just slightly above, recommended dosages may result in severe or fatal fulminant hepatic failure. This is particularly the case for children who were fasting (e.g., because of vomiting, diarrhea with febrile illness), under age 2 years, treated for several days, or treated with adult-intended preparations (see Kearns et al., 1998, and Heubi et al., 1998). Ibuprofen is now available in pediatric formulations and is typically dosed at 5 to 10 mg/kg per dose, given every 6 to 8 hours, with a maximum of four doses per day (e.g., 30 to 40 mg/kg per day). There has been concern that ibuprofen might manifest increased incidence of serious gastrointestinal bleeding, renal failure, or allergic reactions relative to acetaminophen, but this has not been borne out in large, prospective studies (see Lesko and Mitchell, 1995).

Nevertheless, in our view, ibuprofen does not confer any significant advantage over acetaminophen. Its proponents note greater antipyretic efficacy, faster onset of action, and longer duration than acetaminophen on a milligram-for-milligram basis, but this is hardly clinically significant, especially at safe, equi-antipyretic doses of both medications (e.g., 10 mg/kg of ibuprofen and 12 to 15 mg/kg of acetaminophen). Recently, some concern has been raised over undesirable effects of ibuprofen's anti-inflammatory activity in the treatment of routine febrile illnesses, particularly varicella, with a potential for exacerbating invasive streptococcal disease. Although not proven to be causally related, it might be prudent to particularly avoid ibuprofen in such cases of suspected or at-risk streptococcal disease (see Curtis, 1996). Aspirin is no longer recommended for routine antipyretic use in children because of its potential to cause gastrointestinal bleeding and its implication as a possible risk factor for Reye syndrome (see Chapter 83 and Chapter 93). The practice of combining or alternating ibuprofen and acetaminophen for “really bad fevers” is bound to confuse parents, result in increased risk of drug toxicity, and add to unreasonable “fever phobia.” It is important to remember that many parents greatly fear even moderately high fever in their children and require reassurance that the fever itself, in its usual range of severity, does not cause damage. They need education about appropriate indications for antipyretic treatment, particularly seeking to reduce fever-associated discomfort, rather than a modestly elevated temperature itself. They need further education about appropriate, safe antipyretic dosing regimens, the lack of urgency in treating fever (unless temperature goes above 41.1°C [106°F] or there are prolonged febrile seizures), and most important, the concept that the overall well-being of the child, in context with age, usually is far more important than the temperature per se.

CHAPTER 29

Foreign Body—Ingestion/Aspiration

JEFF E. SCHUNK, MD

Division of Pediatric Emergency Medicine, University of Utah School of Medicine, and Emergency Department, Primary Children's Medical Center, Salt Lake City, Utah

Through play, experimentation, and normal daily activities, children are likely to place foreign bodies just about anywhere. Once an object or foodstuff is in a child's mouth, it can lodge in the respiratory tree or be ingested. Young age (6 months to 4 years), a tendency to hold objects in the mouth, easy distractibility, inappropriate-for-age foods, and inappropriate playthings place the child at risk for foreign body aspiration or ingestion. Often, the “choking episode” completely clears the foreign body; however, the sequelae of an aspirated object can range from an immediate life-threatening event to a slowly evolving pneumonia. The seriousness of the foreign body ingestion is determined by the nature of the object (e.g., round, long, sharp, corrosive) and the potential level of lodgment in the gastrointestinal (GI) tract. Fortunately, children typically swallow round rather than sharp objects. Generally, most ingested foreign material is well tolerated, and many ingestions go unnoticed by the family as well as by the child.

PATHOPHYSIOLOGY

There are three main pathophysiologic considerations for aspirated and ingested foreign bodies: the anatomic determinants of lodgment site, the physical properties of the foreign body (size, shape, and composition), and the local tissue reaction to the foreign body.

The respiratory tract, once distal to the larynx, gradually narrows with each airway generation, whereas the GI tract has several sites of anatomic or functional narrowing that occur throughout. An ingested foreign body may lodge in three distinct esophageal sites—thoracic inlet, level of the aortic arch, or gastroesophageal junction—may be unable to pass through the pylorus, or may become impacted in the duodenum, cecum, appendix, rectum, or any other location of congenital or acquired narrowing.

The nature of the foreign body (size, shape, and composition) determines the site of lodgment and the potential for local tissue interaction. The widest diameter of the aspirated or ingested foreign body and the distensibility of the tissue determines, in part, where it lodges within the respiratory or GI tract. A sharp or long object may become impacted even where there is no anatomic narrowing. The aspirated object may affect air movement minimally, until the “fit” with the airway is sufficient to completely or intermittently impede air flow.

The composition of the foreign body also determines the local tissue reaction and the evolution of complications. A disc battery may erode through the esophageal wall much more rapidly than a coin. In the bronchial tree, the fatty oils in some aspirated foods (e.g., peanuts) create a more severe pneumonitis than a similarly sized plastic or metal object. Less commonly, the patient may absorb compounds from the foreign body that cause systemic toxicity.

DIFFERENTIAL DIAGNOSIS

Gastrointestinal Foreign Body

Esophagus

Impaction in the esophagus is the most common and most serious consequence of a foreign body ingestion. Most childhood esophageal foreign bodies are round or cuboidal objects. Coins account for 50 to 75% of childhood esophageal foreign bodies, with pennies predominating (Fig. 29.1). This contrasts with adults, whose impacted esophageal foreign bodies tend to be foodstuffs (meat) and sharp objects (bones). Esophageal foreign bodies in adults are often associated with underlying conditions that affect the esophagus (e.g., intrinsic strictures, neuromuscular conditions, extrinsic pressure), whereas most children with esophageal impactions have a structurally and functionally normal esophagus. Naturally, children with esophageal strictures either acquired (e.g., secondary to caustic ingestions) or from congenital conditions and their repair (e.g., esophageal atresia, tracheoesophageal fistula) are at increased risk for recurrent esophageal impactions, even with foodstuffs (e.g., hot dogs, chicken).

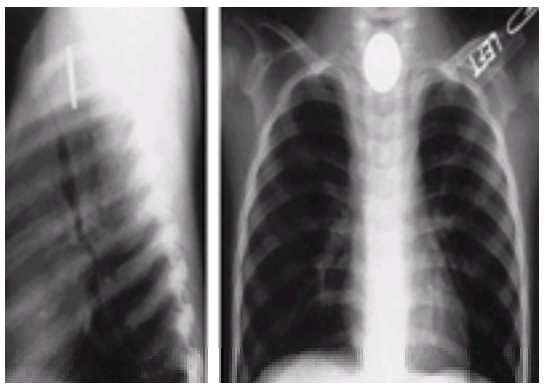

FIGURE 29.1. Two-view chest radiograph demonstrating impacted esophageal coin located at the thoracic inlet.

Foreign bodies of the esophagus tend to lodge at three sites. The most proximal location, at the thoracic inlet (Fig. 29.1), accounts for 60 to 80% of esophageal foreign bodies. The next most common level of lodgment is at the gastroesophageal junction, accounting for 10 to 20%, and last, at the level of the aortic arch, accounting for 5 to 20%. The level of lodgment in children with underlying esophageal conditions or strictures depends on the nature and location of the constricting lesion.

Foreign bodies that remain lodged in the esophagus may lead to potentially serious complications. For example, coins can cause respiratory distress with upper airway compromise, esophageal perforation, mediastinitis, and aortic and tracheal fistula formation. Therefore, it is imperative that the physician be alert to the possibility of esophageal foreign bodies, especially in the susceptible 6-month-old to 4-year-old age group.

Stomach and Lower Gastrointestinal Tract

Objects that can pass safely into the stomach generally traverse the remainder of the GI tract without complication. Safe passage has been documented in hundreds of cases involving various foreign objects (Fig. 29.2). This may not be true of some long (greater than 5 cm) objects that are unable to negotiate the turns of the duodenum and some other tight bends in the lower GI tract. This also may not be true of some very sharp objects (sewing needles are particularly high risk), which may perforate the hollow viscera. Bowel perforation from sharp objects has resulted in peritonitis, abscess formation, inflammatory tumors, hemorrhage, and death.

FIGURE 29.2. Abdominal radiograph demonstrating gastric radiopaque foreign body—a screw—that passed without complications.

Respiratory Foreign Body

Upper Airway

Foreign bodies that lodge in the upper airway can be immediately life-threatening. Such occurrences are responsible for more than 300 childhood deaths in the United States annually. Of fatalities caused by food aspiration, 65% occur in children who are less than 2 years old. The most common foods responsible include hot dogs, candy, nuts, and grapes. Childhood fatalities from man-made objects tend to be conforming objects, with balloons accounting for nearly one-third; children less than 3 years of age account for 65% of these fatalities. Children with foreign bodies in their upper airways present with acute respiratory distress, stridor, increased respiratory effort, or complete obstruction of their upper airway. In patients with complete airway obstruction, emergency treatment depends on proper application of basic life support (BLS) skills. Back blows and chest compressions are used in infants, and the Heimlich maneuver is used in toddlers, children, and adolescents. If these methods fail to dislodge the foreign body, rapid progression to direct visualization and manual extraction is necessary (see Chapter 1 and Chapter 5).

Lower Respiratory Tract

Because of the ubiquitous nature of the presenting symptoms, the frequency of the asymptomatic presentation, and the potential for false-negative and false-positive screening radiographs, childhood foreign bodies of the lower

tracheobronchial tree present a diagnostic challenge to all who treat children.

Foreign bodies of the lower respiratory tract are seen more commonly in the younger pediatric age groups. Approximately 60 to 80% of pediatric tracheobronchial foreign bodies occur in children less than 3 years old. In children, aspirated foreign bodies show only a slight propensity to lodge in the right lung. The nature of the aspirated objects is fairly consistent throughout studies in several countries. Organic matter accounts for most aspirations, with nuts (mainly peanuts) and seeds (sunflower and watermelon) accounting for 30 to 70% of cases, followed by other food products, including apples, carrots, and plants and grasses (Table 29.1). Plastics and metals make up a minority of aspirated objects (Fig. 29.3), and coin aspiration has been reported only rarely.

Foreign Body	Percent
Peanuts	38
Other nuts	10
Other organic (food) material	16
Seeds, weeds, or twigs	7
Plastics	6
Popcorn	6
Pins, screws, tacks, or nails	6
Crayons	2
Rocks or stones	1
Miscellaneous[b]	8

[a]Included a total of 440 foreign bodies removed. (Adapted from Black RE, Johnson DG, Mattak ME. Bronchoscopic removal of aspirated foreign bodies in children. J Pediatr Surg 1994;29:662–664.)
[b]Included cotton/lint, earrings, bullet shell casings, tooth, staple, shirt label, pellet, spring, aluminum foil, seashell, pencil lead, screw/silver, chalk, chain, coin, chicken bone, plaster, Styrofoam cup fragment, and others.

Table 29.1. Aspirated Foreign Bodies in Children Recovered at Bronchoscopy[a]

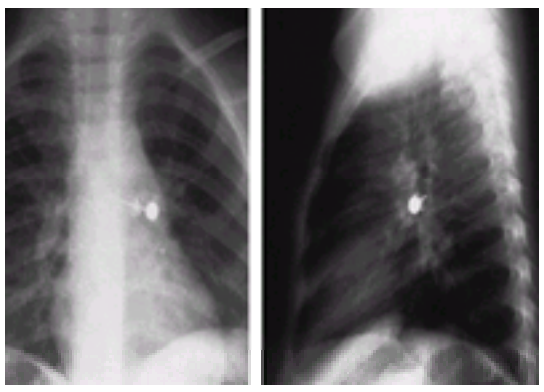

FIGURE 29.3. Two-view chest radiograph demonstrating aspirated radiopaque foreign body—an earring—located in the left bronchus.

The diagnosis of foreign body aspiration is often delayed. Previously, diagnosis on the day of aspiration occurred in fewer than half the cases, and the diagnosis was made a week or more after the aspiration in 20 to 30% of cases. A more recent report suggests diagnosis within a day in 70% of patients. Symptoms at diagnosis include cough in 75 to 90%, wheezing in 50 to 75%, and respiratory distress in 25 to 60%. The classic clinical triad of an aspirated foreign body (wheeze, cough, and decreased breath sounds) is present in only about one-third of all cases of pediatric foreign body aspiration. It has been demonstrated that this triad is more likely to occur the more delayed the evaluation from the aspiration event. Approximately 20% of patients with aspirated foreign bodies are asymptomatic. It should be noted, however, that in most surveys of pediatric foreign body aspiration, a history of aspiration, if sought, is present in more than 75% of patients.

EVALUATION AND DECISION

Unknown Location

Generally, the symptom complex and history that surround the event provide the clues necessary to decide whether to evaluate the respiratory tract or GI tract. Symptoms of cough, respiratory distress with tachypnea or retractions, stridor, wheezing, or asymmetric aeration suggest a foreign body in the airway. Symptoms of gagging, vomiting, drooling, dysphagia, pain, or localization suggest esophageal impaction. However, impacted esophageal foreign bodies may induce secondary airway symptoms, either location may induce coughing, vomiting, or gagging initially, and both types may be asymptomatic. If the history and physical examination do not provide the necessary clues, initial evaluation with a chest radiograph (to include the upper abdomen and oropharynx) will suffice as the first screen for a radiopaque esophageal or gastric foreign body. Coupling this with an expiratory chest radiograph (as outlined later) screens for an aspirated foreign body (Fig. 29.4). Alternatively, the combination of a soft-tissue lateral neck and a “wide” chest radiograph that includes oropharynx and abdomen is also used as an initial foreign body search.

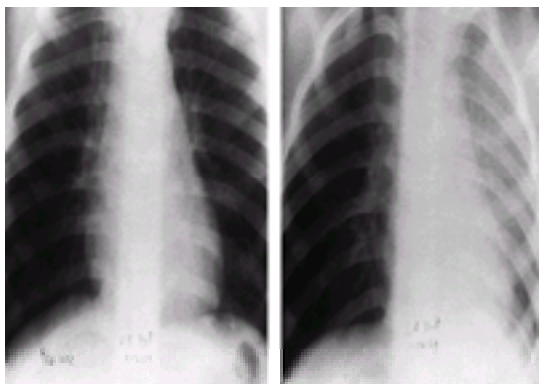

FIGURE 29.4. Inspiratory and expiratory chest radiographs demonstrating air trapping in the right lung during expiration, indicating likely right-sided foreign body. A peanut was removed at bronchoscopy.

Gastrointestinal Foreign Body

Esophageal Foreign Body: Diagnosis

Children with esophageal foreign bodies often have a history of having swallowed the foreign body. Symptoms associated with esophageal impaction include pain with swallowing, refusal to eat, foreign body sensation or localization, drooling, and vomiting. When these symptoms are associated with a history of foreign body ingestion, the diagnosis is straightforward. In the absence of an ingestion history, the diagnosis may be more subtle because these same symptoms occur with such common childhood ailments as acute gastroenteritis, pharyngitis, and gingivostomatitis. Any patient with swallowing difficulty requires a thorough examination, including mouth, oropharynx, neck, chest, and abdomen, as well as a radiologic evaluation in some cases (see Chapter 53).

The approach to a child with a foreign body ingestion is outlined in Figure 29.5. Children may be asymptomatic with an esophageal foreign body. Studies have demonstrated that 30 to 40% of children who showed coins in the esophagus were asymptomatic in the emergency department (ED). Therefore, it is suggested that all children with a history of ingested foreign bodies undergo radiographic evaluation, with the exception of the asymptomatic patient who has ingested a small (less than 1 cm in maximum diameter), nonsharp object (see Fig. 29.5). If the foreign body is not radiopaque (yet is large enough to become impacted) and the patient's symptoms suggest esophageal impaction, it is necessary to use contrast esophagrams to rule out an esophageal foreign body. Fortunately, childhood esophageal foreign bodies tend to be radiopaque (e.g., coins), so diagnosis with plain radiographs is not difficult (Fig. 29.1). Children with a predisposing condition (tracheoesophageal fistula repair, esophageal stricture) who have symptoms of an esophageal foreign body after eating should have contrast esophagrams; plain radiographs are not necessary. Similarly, with nonradiopaque ingestions and symptoms suggestive of impaction in children without underlying conditions, contrast esophagrams or esophagoscopy should be performed initially.

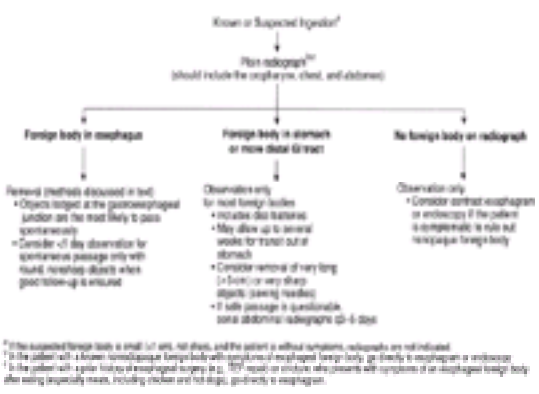

FIGURE 29.5. Management of ingested foreign body.

Handheld metal detectors may provide an alternative to conventional radiography as an initial screen when a coin ingestion is suspected. In study situations, these devices compare favorably with radiography in determining presence or absence of a coin and determining coin location (esophagus, or more distal GI tract). Users should gain some metal detector experience using x-ray confirmation before abandoning radiography, and patient follow-up is suggested because esophageal coins may be missed (this may be especially true in obese children).

Esophageal Foreign Body: Removal

In general, once an esophageal foreign body is detected, it should be removed promptly. This is especially true of sharp esophageal foreign bodies and disc batteries. It has been noted that some impacted esophageal foreign bodies pass spontaneously, regardless of location. Spontaneous passage is most likely to occur when the object is lodged at the gastroesophageal junction. It may be prudent to allow a period of less than 1 day for spontaneous passage of round, noncorrosive objects in the asymptomatic patient. This should be done only if good follow-up can be ensured and in consultation with the physician who will be involved in the removal. Handheld metal detectors may have a role in following such patients with coin ingestions. Serious complications have not resulted from an esophageal coin that was impacted for less than a few days; however, the esophageal mucosa may grow around a coin after several days, which

could hinder removal attempts.

Removal techniques for impacted esophageal foreign bodies vary regionally and may depend on the duration of impaction and the nature of the foreign body. Removal methods currently used include rigid esophagoscopy under general anesthesia, flexible endoscopy (with or without conscious sedation), and for round objects, a balloon-tipped catheter under fluoroscopic guidance or bougienage to advance the object into the stomach. All of these methods have a high success rate; provincial opinion and local referral patterns will dictate which method is used. Esophagoscopy under general anesthesia has been the method of choice for many years. This technique has proved to be safe and efficacious. The balloon-tipped catheter technique has been criticized because of lack of airway control, poor control of the foreign body during extraction, and inadequate visualization of the esophagus. Bougie dilators may be used to push the coin into the stomach, where spontaneous passage should occur. Both Foley catheter and Bougie dilator methods have been used successfully with low complication rates at several institutions and are less expensive than esophagoscopy with general anesthesia. These methods should be attempted only by clinicians familiar with the techniques and are generally reserved for rounded esophageal foreign bodies that have been impacted for less than a few days. Use of medications (e.g., glucagon, diazepam) to reduce muscular tone, to enhance esophageal motility, or to relax the lower esophageal sphincter has been suggested to facilitate passage from the esophagus. This has not been investigated thoroughly enough to offer guidelines for routine clinical application and dosing.

Stomach and Lower Gastrointestinal Tract

As mentioned, most foreign bodies of the stomach and lower GI tract can be managed expectantly (Fig. 29.2). Management recommendations for sharp objects are varied but conservative—watchful waiting usually is safe. Sewing needles seem to have increased propensity for perforation, however, and should probably be removed. Long objects (greater than 5 cm) should also be removed from the stomach. If the long or very sharp object has passed out of the stomach at the time of evaluation or, in any instance, to a place where a safe journey through the remainder of the GI tract is questionable, serial abdominal radiographs every 3 to 5 days and serial examinations may be necessary to document continued passage. Most round objects (e.g., coins) will traverse the GI tract in 3 to 8 days without any complication. Some physicians advocate parental examination of the stool for the foreign body, although in practice, this may not be very useful. It is an unpleasant task that is commonly, and understandably, abandoned. Furthermore, inability to retrieve the foreign body after 1 week or more of stool examination often heightens parental concern that some untoward complication has developed. Occasionally, some objects remain in the stomach for a long duration. A prolonged time, up to weeks, should be allowed for passage of inert objects out of the stomach before surgical or endoscopic removal is attempted.

Disc Battery Ingestion

Disc batteries are used as a power source for many household items, ranging from watches, cameras, and calculators to hearing aids. Therefore, these intriguing, bite-sized, “slippery when wet” batteries are often within reach of children. Most of these batteries fall into one of three varieties—a manganese dioxide system, a silver oxide system, or a mercuric oxide system. These systems may cause corrosive injury to the hollow viscera. Early reports of disc battery ingestions emphasize serious hemorrhagic sequelae, so disc battery ingestion often raises the level of concern for the physician caring for the child. Subsequent studies of large series of ingested disc batteries have emphasized the benign nature of most ingestions. A disc battery that reaches the stomach safely is likely to pass through the remainder of the GI tract without complication, and no operative or endoscopic intervention is indicated unless symptoms suggest serious sequelae. Only sporadic cases of systemic absorption of battery contents have been suggested in the literature, and no serious toxicities have been reported. Disc batteries that lodge in the esophagus should be removed promptly because of the potential to erode rapidly through the esophagus.

Respiratory Foreign Body

Lower Respiratory Tract: Diagnosis

A high clinical index of suspicion is necessary to diagnose foreign body aspiration accurately and promptly. Symptoms seen in pediatric foreign body ingestions also are present in other common diseases such as upper respiratory tract infection, bronchiolitis, pneumonia, and asthma. A few radiographic techniques serve as the most important diagnostic aids. Yet, when the clinical suspicion of foreign body aspiration is high (good history for aspiration, new onset of symptoms with focal physical findings), the lack of confirmatory radiographic studies should not dissuade the clinician from pursuing bronchoscopy for diagnosis and treatment. In patients diagnosed early, as many as one-third have normal chest radiographs. The abnormal findings seen on a chest radiograph include air trapping, atelectasis, and consolidation. The more time that has elapsed since the aspiration event, the more likely the chest radiograph will be abnormal and the greater the percentage of patients who exhibit consolidation and atelectasis. Inspiratory and expiratory films comparing the relative deflation of the two lungs may demonstrate unilateral air trapping indicative of a foreign body (see Fig. 29.4). In some series, up to 80% of the foreign bodies demonstrated abnormalities using inspiratory and expiratory chest radiographs. In the young or uncooperative child, in whom obtaining an adequate expiratory film may be difficult, lateral decubitus chest radiographs (both obtained during inspiration) that compare the relative deflation of the dependent lung may be a useful adjunct. In equivocal cases, chest fluoroscopy may show mediastinal shift during respiration; unfortunately, even this technique does not have 100% sensitivity.

The approach to diagnosing foreign body aspiration is outlined in Figure 29.6. In instances in which a respiratory foreign body is being considered, the patient should be kept on a nil per os (NPO) basis until the diagnosis is confirmed or the decision for bronchoscopy is made. The first step in the patient suspected of foreign body aspiration is inspiratory and expiratory chest radiographs. If these studies are normal, the aspiration history is poor, the material uncommonly aspirated, and the patient has mild or no symptoms without focal findings on physical examination, then discharge with follow-up in a few days usually is adequate. If diagnosis is still unclear after plain films and there is a historical or clinical suspicion of aspiration, fluoroscopy may be obtained, looking for air trapping and evidence of mediastinal shift away from

the foreign body. In some instances in which there are focal physical findings (unilateral wheeze, decreased aeration) and a good aspiration history, the patient might go directly to bronchoscopy. Similarly, in some cases, despite normal radiographic evaluation (including fluoroscopy), when there is a high clinical index of suspicion, bronchoscopy is necessary to confirm the presence of a pulmonary foreign object.

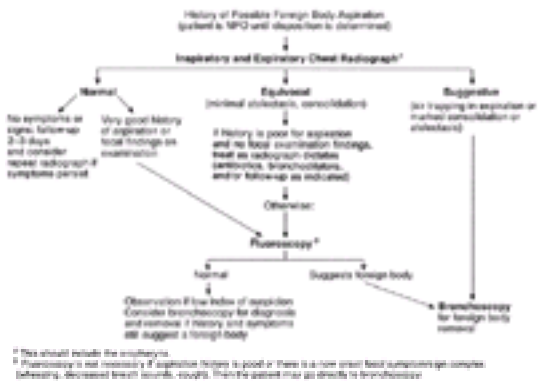

FIGURE 29.6. Guidelines for management of the child with suspected foreign body aspiration.

A history of aspirated foreign body should be sought in all cases of new-onset respiratory distress, wheezing, or cough, with special consideration to the high-risk children from 6 months to 4 years of age. History taking should include questions about recent choking episodes, especially when eating nuts (peanuts), seeds, apples, and carrots. The differential diagnosis of foreign body aspiration includes many common childhood diseases, including upper respiratory infection (URI), bronchiolitis, viral and bacterial pneumonitis, and reactive airway disease; specific questioning concerning aspiration events should be explored.

Lower Respiratory Tract: Removal

Once a foreign body of the lower respiratory tract has been identified, bronchoscopic removal is performed under general anesthesia. This technique is successful in more than 98% of cases and only rarely is a thoracotomy required. The procedure often can be done on an outpatient surgery basis, although any preoperative or postoperative concerns about the patient's respiratory status mandate in-hospital observation. Potential postoperative complications after removal of an aspirated foreign body include atelectasis, pneumonia, stridor, bronchospasm or laryngospasm, and retained foreign body.

Textbook of Pediatric Emergency Medicine

CHAPTER 30

Gastrointestinal Bleeding

SIGMUND J. KHARASCH, MD

Department of Pediatrics, Boston University School of Medicine, and Division of Pediatric Emergency Medicine, Boston Medical Center, Boston, Massachusetts

Gastrointestinal (GI) bleeding is a relatively common problem in pediatrics. Most infants and children who arrive in the emergency department (ED) with what appears to be GI bleeding have an acute, self-limited GI hemorrhage and are hemodynamically stable. In such patients, three important questions must be asked: 1) Is the patient really bleeding? 2) Is the blood coming from the GI tract? and 3) Is there more than a trivial amount of blood? Children with only a few drops or flecks of blood in the vomit or stool should not be considered “GI bleeders” if their history and physical examinations are otherwise unremarkable. Likewise, many substances ingested by children may simulate fresh or chemically altered blood. Red food coloring (as in some cereals, antibiotic and cough syrups, Jell-O, and Kool-Aid), as well as fruit juices and beets, may resemble blood if vomited. Melena may be confused with dark or black stools due to iron supplementation, dark chocolate, bismuth, spinach, cranberries, blueberries, grapes, or licorice. In these cases, confirmation of the absence of blood with Gastroccult (vomitus) and Hematest or Hemoccult (stool) tests will allay parental anxiety and prevent unnecessary concern and workup. Gastroccult is a specific and sensitive assay, stable in an acid environment, which can detect as little as 300 µg/dL of hemoglobin. A careful search for other causes of presumed GI bleeding, such as recent epistaxis, dental work, and sore throat, should be sought.

In most cases of upper and lower GI bleeding, the source of the bleeding is inflamed mucosa (infection, allergy, drug-induced, stress-related, or idiopathic). The emergency physician must be vigilant in differentiating inflammatory conditions that are often self-limited from causes that may require emergent surgical or endoscopic intervention, such as ischemic bowel (intussusception, volvulus), structural abnormalities (Meckel's diverticulum, angiodysplasia), and portal hypertension (esophageal varices).

INITIAL ASSESSMENT

The differential diagnosis of GI bleeding is broad. A systematic approach to all patients includes the following:

1. Assessment of the severity of the bleeding and institution of appropriate resuscitative measures
2. Establishing the level of bleeding within the GI tract
3. Pertinent history, physical examination, and laboratory tests based on knowledge of age-related causes
4. Emergency treatment based on general categories of causes

Estimation of blood loss (a few drops, a spoonful, a cupful, or more) should be obtained initially. Vomiting of coffee ground material does not necessarily signify a specific quantity of blood, nor does the vomiting of bright red blood mean that major bleeding is taking place. Hemoglobin and hematocrit are unreliable estimates of acute blood loss because of the time required for hemodilution to occur. The estimated volume of blood loss should be correlated with the patient's clinical status. The presence of resting tachycardia, pallor, prolonged capillary refill time, and metabolic acidosis points to significant blood loss. An orthostatic decrease in systolic blood pressure of 10 mm Hg or more or an increase of 20 beats/minute in pulse suggests a 10 to 20% loss of intravascular volume. Hypotension is a late finding in young children and demands immediate resuscitative measures.

ESTABLISHING THE LEVEL OF BLEEDING

There are two general categories of GI bleeding: upper and lower. *Upper GI bleeding* refers to bleeding proximal to the ligament of Treitz. *Lower GI bleeding* is distal to the ligament. In most cases, the clinical findings along with nasogastric lavage will delineate the cause of bleeding within the GI tract. *Hematemesis* is defined as vomiting of blood, which is either fresh and bright red or old with the appearance of coffee grounds. Melena, the passage of stool that is shiny, black, and sticky as a result of enzymatic or bacterial action on intraluminal blood, reflects bleeding from either the upper GI tract or the proximal small bowel. In general, the darker the blood in the stool, the higher it originates in the GI tract. Hematochezia, or the passage of bright red blood per rectum, is usually a manifestation of lower GI bleeding. Currant jellylike stools indicate vascular congestion and hyperemia as seen with intussusception. Maroon-colored stools occur

with a voluminous bleed anywhere proximal to the rectosigmoid area, such as seen with a Meckel's diverticulum.

All patients with a significant bleeding episode should have a nasogastric tube placed for diagnostic purposes (Fig. 30.1). In patients with hematemesis or melena, a positive examination of a nasogastric aspirate confirms an upper source of GI bleeding, whereas a negative result almost always excludes an active upper GI bleed. Occasionally, a postpyloric upper GI lesion, such as a duodenal ulcer, bleeds massively without reflux into the stomach, resulting in a negative examination of stomach aspirate. An upper GI endoscopic study is the best method to detect such a lesion. Patients with hematochezia and massive rectal bleeding should likewise have a nasogastric tube placed. Because blood exerts a cathartic action, brisk bleeding from an upper GI lesion may induce rapid transit through the gut, thus preventing blood from becoming melanotic. In patients with hematochezia manifested as bloody diarrhea or minimally blood-streaked stools, a lower GI source should be investigated.

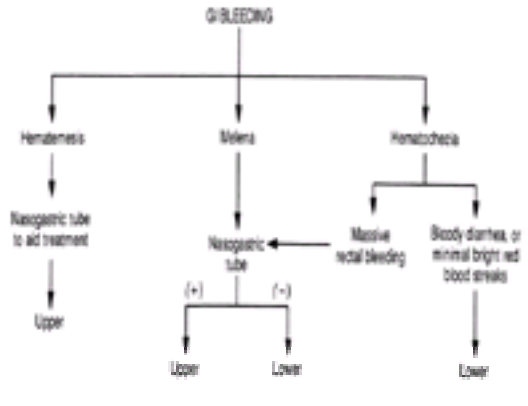

FIGURE 30.1. Establishing level of GI bleeding.

UPPER GASTROINTESTINAL BLEEDING

Differential Diagnosis

As seen in Table 30.1, Table 30.2 and Table 30.3, there is considerable overlap between age groups and causes of upper GI bleeding. Mucosal lesions, including esophagitis, gastritis, stress ulcers, peptic ulceration, and Mallory-Weiss tears, are the most common sources of GI bleeding in all age groups (see Chapter 93). Of all cases of upper GI bleeding in children, 95% are related to mucosal lesions and esophageal varices.

Neonatal Period (<1 mo)	Infancy (1-2 yr)	Preschool Age (2-5 yr)	School Age (5-18 yr)
Swallowed maternal blood	Gastritis	Epistaxis	Gastritis
Hemorrhagic gastritis	Esophagitis	Gastritis	Mallory-Weiss tear
Stress ulcer	Mallory-Weiss tear	Esophagitis	Peptic ulcer
Idiopathic	Stress ulcer	Mallory-Weiss tear	Stress ulcer
Bleeding diathesis	Pyloric stenosis	Toxic ingestion	Toxic ingestion
Esophagitis	Vascular malformation	Stress ulcer	Esophagitis
Duplication	Toxic ingestion	Foreign body	Inflammatory bowel disease
Vascular malformations	Duplication	Vascular malformation	Esophageal varices
		Esophageal varices	Vascular malformation
		Hemobilia	Hemobilia

Table 30.1. Etiology of Upper Gastrointestinal Bleeding Based on Age (in order of frequency of occurrence)

Neonatal Period	Gastritis
Swallowed maternal blood	Mallory-Weiss tear
Infancy	*School Age*

Mallory-Weiss tear	Peptic ulcer
Preschool Age	
Epistaxis	

Table 30.2. Common Causes of Upper Gastrointestinal Bleeding Based on Age

Ulcer	Duplication
Vascular malformation	Esophageal varices

Table 30.3. Life-Threatening Causes of Upper Gastrointestinal Bleeding

Hematemesis in a healthy newborn most likely results from swallowed maternal blood either at delivery or during breast-feeding (i.e., cracked nipples). The Apt test can differentiate neonatal from maternal hemoglobin based on the conversion of oxyhemoglobin to hematin when mixed with alkali. To perform the Apt test, the physician should mix one part bloody stool or vomitus with five parts water, centrifuge at 2000 rpm for 2 minutes, and mix the supernatant with 1 mL of 0.1 N sodium hydroxide. Fetal hemoglobin is more resistant to denaturing than adult hemoglobin and remains pink, whereas maternal hemoglobin becomes brown.

Although rare, hemorrhagic disease of the newborn should be considered with prolongation of the prothrombin time, if vitamin K has not been administered.

Significant and sometimes massive upper GI hemorrhage in a newborn infant may occur with no demonstrative anatomic lesion or only “hemorrhagic gastritis” at endoscopy. This is usually a single, self-limited event that is benign if treated with appropriate blood replacement and supportive measures.

Critically ill children of any age are at risk for developing stress-related peptic ulcer disease. Such ulcers occur with life-threatening illnesses, including shock, respiratory failure, hypoglycemia, dehydration, burns (Curling ulcer), intracranial lesions or trauma (Cushing ulcer), renal failure, and vasculitis. These ulcers may develop within minutes to hours after the initial insult and primarily result from ischemia. Hematemesis, melena, and perforation of a viscus may accompany stress-associated ulcers. Hematemesis secondary to gastroesophageal reflux and esophagitis is uncommon but should be considered in patients who are severely symptomatic with vomiting or aspiration. Hematemesis following the acute onset of vigorous vomiting or retching at any age suggests a Mallory-Weiss tear.

Idiopathic peptic ulcer disease is a common cause of GI bleeding in preschool and older children. Most preschool children with idiopathic ulcers develop GI bleeding (hematemesis or melena). Complications, including obstruction and perforation, may occur. Younger children have less characteristic symptoms, often localize abdominal pain poorly, and may have vomiting as a predominant symptom. Older children and adolescents describe epigastric pain in a pattern typical of adults. *Helicobacter pylori* has emerged as a leading cause of secondary gastritis, particularly in older children. Similar to adults, pediatric patients with evidence of *H. pylori* infection are often treated with antibiotics, bismuth preparations, and H_2 antagonists or omeprazole (Prilosec).

In older children, the possibility of bleeding esophageal varices must be considered in the differential diagnosis of upper GI bleeding. Although variceal bleeding is rare in infancy, esophageal and gastric varices associated with portal hypertension are the most common cause of severe upper GI hemorrhage in older children. One-half to two-thirds of these children have an extrahepatic presinusoidal obstruction, often resulting from portal vein thrombosis, as the cause of portal hypertension. Omphalitis with or without a history of umbilical vein cannulation, dehydration, and a number of other factors may contribute. Other children with portal hypertension have hepatic parenchymal disorders such as neonatal hepatitis, congenital hepatic fibrosis, cystic fibrosis, or biliary cirrhosis associated with biliary atresia. Two-thirds of patients with portal hypertension develop bleeding before 5 years of age, and 85% do so by 10 years of age.

Evaluation and Decision

History and Physical Examination

Pertinent historical elements to be sought include a history of umbilical catheterization or sepsis in the neonatal period, previous episodes of bleeding from the GI tract or other sites, and past hematologic disorders and liver disease. A family history of peptic ulcer disease can be found in up to 30% of patients with idiopathic ulcers. Ingestions should be sought as a possible cause. These include theophylline, aspirin, iron, nonsteroidal anti-inflammatory drugs (NSAIDs), alcohol, and steroids. Massive hemorrhage associated with right upper quadrant pain and jaundice in the posttrauma patient indicates bleeding into the biliary tract (hemobilia).

The physical examination should include visualization of the posterior nose and pharynx to eliminate epistaxis as a source of bleeding. Signs of liver disease or portal hypertension may be subtle in children. Icterus, abdominal distension, prominent abdominal venous pattern, hepatosplenomegaly, cutaneous spider nevi, and ascites suggest liver disease and/or portal hypertension with esophageal varices.

Laboratory Evaluation

Laboratory tests are not useful for identifying a precise cause of upper GI bleeding. Mucosal lesions are more likely than

esophageal varices to be associated with prior occult bleeding. A low mean corpuscular volume (MCV) and hypochromic, microcytic anemia suggest chronic mucosal bleeding. Initial low white blood cell and platelet counts may be seen in either hypersplenism from portal hypertension or sepsis with associated stress mucosal ulceration. Abnormal hepatic studies, including an elevation of serum bilirubin, transaminase, prothrombin time, and a low serum albumin, are suggestive of esophageal varices as a cause of bleeding. A blood urea nitrogen (BUN):creatinine ratio greater than 30 may indicate blood resorption and an upper GI source of bleeding.

Diagnostic Approach

Once it has been determined that a significant upper GI bleed has occurred and hemodynamic stability is restored, identification of the specific disorder is the next step (Fig. 30.2). If the bleeding is mild and self-limited or the gastric aspirate negative, a minor mucosal lesion is likely. Although mucosal lesions such as esophagitis, gastritis, or peptic ulcer disease can present with severe bleeding, most often bleeding from mucosal lesions is self-limiting and will respond to conservative medical management. In patients with persistent or recurrent hemorrhage, emergent endoscopy may be necessary if the bleeding is considered life-threatening (continued transfusion requirement, hemodynamic instability). In a small percentage of patients in whom bleeding is massive, making endoscopic visualization impossible, angiography or radionuclide studies (Technetium-sulfur colloid/Tc-labeled red blood cells) may be indicated. Treatment of specific mucosal conditions and esophageal varices is discussed in Chapter 93.

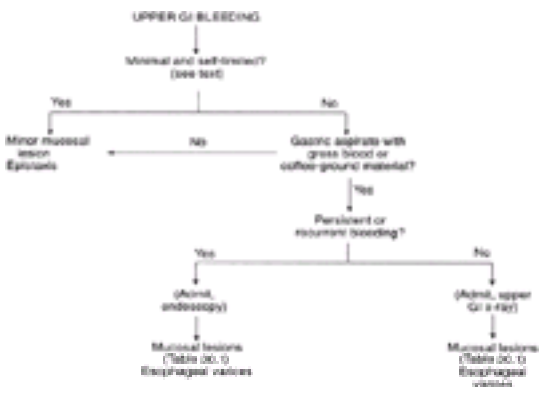

FIGURE 30.2. Diagnostic approach to upper GI bleeding.

Eighty to eighty-five percent of upper GI bleeding stops spontaneously, regardless of the source, before or early in the hospital course. In stable patients who have stopped bleeding, double-contrast barium examination of the upper GI tract and endoscopy provide valuable and often complementary information. In this group of patients, endoscopy need not be performed on an emergent basis and may be done electively in the first 12 to 24 hours after admission. Elective endoscopy should be performed in patients who stop bleeding spontaneously but who have required transfusion and/or have a history of previously unexplained upper GI bleeding episodes.

LOWER GASTROINTESTINAL BLEEDING

Differential Diagnosis

Neonatal Period (0 to 1 Month)

As is true for upper GI bleeding, a common cause of blood in the stool in well infants is the passage of maternal blood swallowed either at delivery or during breast-feeding from a fissured maternal breast. Although hemorrhagic disease of the newborn is uncommon after prophylactic administration of vitamin K at delivery, maternal drugs that cross the placenta, including aspirin, phenytoin, cephalothin, and phenobarbital, may interfere with clotting factors and cause hemorrhage. Infectious diarrhea can occur in very young infants, and stools may contain blood or mucus. Common bacterial pathogens in this age group include *Campylobacter jejuni* and *Salmonella*.

In ill-appearing infants with lower GI bleeding, midgut volvulus, necrotizing enterocolitis, and Hirschsprung's disease should be considered (Table 30.4). Malrotation with midgut volvulus is most common during this period. Initially, bilious vomiting, abdominal distension, and pain are present. Melena is seen in 10 to 20% of patients and signifies vascular compromise. Of all cases of necrotizing enterocolitis, 10% occur in term infants. These patients can present with nonspecific signs of sepsis (temperature instability or apnea and bradycardia) as well as with specific GI tract findings, such as abdominal distension, pain, and abdominal wall erythema. GI bleeding can be in the form of guaiac-positive or grossly bloody stools. Hirschsprung's disease with enterocolitis may present with GI bleeding in the newborn period. Enterocolitis has recently been shown to occur in up to 25% of children with Hirschsprung's disease. The risk of enterocolitis remains high until about 6 months of age. The diagnosis should be considered in any newborn who does not pass meconium in the first 24 to 48 hours of life.

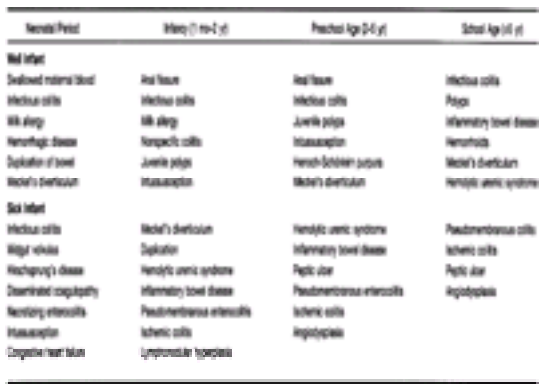

Table 30.4. Etiology of Lower Gastrointestinal Bleeding Based on Age (in order of frequency of occurrence)

Other common causes of lower GI bleeding are listed in Table 30.5. Life-threatening causes are listed in Table 30.6.

Neonatal Period	*Preschool Age*
Swallowed maternal blood	Anal fissure
Infectious colitis	Infectious colitis
Milk allergy	*School Age*
Infancy	Infectious colitis
Anal fissure	
Infectious colitis

Table 30.5. Common Causes of Lower Gastrointestinal Bleeding Based on Age

Midgut volvulus	Pseudomembranous colitis
Intussusception	Ischemic colitis
Meckel's diverticulum	Peptic ulcer
Hemolytic uremic syndrome	

Table 30.6. Life-Threatening Causes of Gastrointestinal Bleeding

Infancy (1 Month to 2 Years)

In the first 2 years of life, anal fissures are the most common cause of rectal bleeding and are usually associated with hard stools or constipation. Treatment with stool softeners and sitz baths will often resolve the problem spontaneously in most patients. Milk or soy enterocolitis usually occurs during the first month of life or shortly thereafter. These infants can present with chronic diarrhea, stools containing blood or mucus, or less commonly, fulminant colitis and shock. Milk-protein allergy responds to a change in formula from cow's milk or soy protein to a casein hydrolysate (Nutramigen, Alimentum, Pregestimil). Breast-fed infants whose mothers drink cow's milk may develop an allergic colitis that responds to removal of cow's milk from the mother's diet. Infectious enterocolitis as a cause of bloody diarrhea is common in all age groups. Bacterial causes (*Salmonella, Shigella, Campylobacter*, pathogenic *Escherichia coli,* and *Yersinia enterocolitica*) should be identified with stool cultures. In symptomatic infants and children, the presence of leukocytes in a stool smear for white cells may aid in preliminary diagnosis. Pseudomembranous colitis should be considered in any infant or child with bloody stools and a history of recent antibiotic therapy. “Nonspecific colitis” has been demonstrated to be a common cause of hematochezia in infants less than 6 months of age. Although the cause of nonspecific colitis is unknown, it may represent a variation in the colonic response to viral invasion.

Meckel's diverticulum should be suspected in infants or young children who pass bright or dark red blood per rectum. Intermittent painless bleeding or massive GI hemorrhage can occur. Sixty percent of complications from Meckel's diverticulum (hemorrhage and intestinal obstruction) occur in patients less than 2 years of age.

Idiopathic intussusception may occur in children 3 months to 1 year of age, with 80% occurring before 2 years of age. In children older than 3 years, a lead point (polyp, Meckel's diverticulum, or hypertrophied lymphoid patch) is often found. Paroxysmal pain may be associated with guaiac-positive stools or hematochezia. Lethargy alone (without pain) has been increasingly recognized as a presenting symptom of intussusception in young children. Lymphonodular hyperplasia is a

common cause of rectal bleeding in this age group and may cause mild, painless hematochezia. The nodular lymphoid response is self-limited and does not require any specific therapy. Intestinal duplications are an uncommon cause of lower GI bleeding and, when diagnosed, are usually found in children less than 2 years of age. Duplications can be found anywhere in the GI tract but are most common in the distal ileum. These usually present with obstruction and lower GI bleeding.

Preschool (2 to 5 Years)

The two conditions most likely to cause bleeding in children 2 to 5 years of age are juvenile polyps and infectious enterocolitis. Most polyps in childhood are inflammatory without significant malignant potential and are often multiple. Thirty to forty percent are palpable on rectal examination. Polyps may cause painless rectal bleeding in this age group. Significant bleeding is unusual. Infectious causes of colitis are similar to those discussed in younger age groups. Hematochezia is often a manifestation of systemic disease in infancy and throughout childhood. Hemolytic uremic syndrome is the most prevalent of these conditions reported in infants and children up to 3 years of age. Bloody diarrhea may precede the development of renal and hematologic abnormalities. GI manifestations of Henoch-Schönlein purpura (HSP) occur in 50% of patients and include colicky abdominal pain, melena, and bloody diarrhea. These symptoms precede the characteristic rash in 20% of patients. GI complications of HSP include hemorrhage (5%), intussusception (3%), and rarely, intestinal perforation.

Angiodysplasia is a rare cause of GI bleeding but can be associated with massive hemorrhage. Vascular lesions of the GI tract probably have a congenital basis. Several recognized syndromes, including Rendu-Osler-Weber syndrome, blue rubber bleb syndrome, and Turner's syndrome may be associated with intestinal telangiectasia.

School Age (5 Years through Adolescence)

For the most part, the diagnostic considerations relevant to the preschool child apply to school-age and adolescent children with the addition of inflammatory bowel disease. Although inflammatory bowel disease occurs in younger children, it is rare before the age of 10 years. Rectal bleeding is a common presentation of both ulcerative colitis and Crohn's disease. Massive lower GI bleeding occurs in 2 to 5% of children with Crohn's disease. Toxic megacolon is a life-threatening presentation of both ulcerative colitis and Crohn's disease.

Evaluation and Decision

History and Physical Examination

Symptoms of an acute abdominal process, including abdominal pain, distension, and vomiting, should be elicited. A history of bloody diarrhea may indicate infectious colitis, intussusception, or hemolytic uremic syndrome. Extraintestinal manifestations of inflammatory bowel disease, including weight loss, anorexia, and arthralgias, may be predominant symptoms in school-aged children. The dietary history may suggest features of a protein intolerance (cow's milk). Firm stool streaked with red blood characterizes anal fissures. A detailed family history (bleeding diathesis, familial polyposis) and drug history (NSAIDs, salicylates, iron) or antibiotics (pseudomembranous colitis) is important in patients with lower GI bleeding. Long-standing constipation with acute onset of bloody diarrhea suggests enterocolitis associated with Hirschsprung's disease.

Physical examination to detect abdominal obstruction (abdominal tenderness, distension, palpable mass, peritoneal signs, hyperactive bowel sounds) is the most urgent task of the evaluating physician. Careful separation of the buttocks with eversion of the anal mucosa may reveal a fissure. Prominent or multiple perianal skin tags may raise suspicion of Crohn's disease. Rectal polyps may be palpable. Cutaneous lesions may provide important diagnostic clues in patients with GI bleeding. Eczema may be associated with milk allergy, whereas erythema nodosum is the most common skin manifestation of inflammatory bowel disease. Mucocutaneous pigmentation (Peutz-Jegher syndrome) and cutaneous or subcutaneous tumors (Gardner's syndrome) indicate intestinal polyposis.

Diagnostic Approach

Rectal bleeding is a common complaint in the pediatric age group (Fig. 30.3). The causes of lower GI bleeding vary significantly with age and often are transient and benign. Occasionally, lower GI bleeding reflects a life-threatening pathologic condition, and establishment of a specific diagnosis becomes urgent.

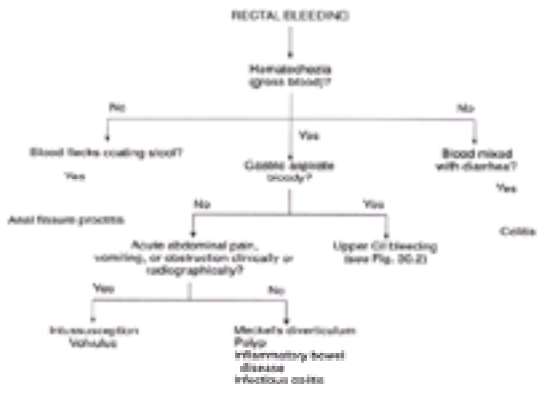

FIGURE 30.3. Diagnostic approach to lower GI bleeding.

The priority of the emergency physician in evaluating the patient with lower GI bleeding is to identify lower tract bleeding associated with intestinal obstruction. Intussusception and a late presentation of midgut volvulus secondary to malrotation are the major types of intestinal obstruction associated with lower GI hemorrhage. All causes of abdominal obstruction (e.g., adhesions, incarcerated hernia, appendicitis) eventually cause bleeding, however, if diagnosis is delayed and vascular compromise occurs.

Severe lower GI bleeding leading to hemodynamic instability or requiring transfusion is rare in pediatrics, and gastric lavage is essential in these cases to rule out a possible source in upper GI tract. Meckel's diverticulum is the most common cause of severe lower GI bleeding in all age groups. Following Meckel's diverticulum, Crohn's disease and arteriovenous malformation are prominent causes of massive lower GI bleeding in adolescents.

The urgency and extent of evaluation of patients with lower GI bleeding will depend on the amount of bleeding, the patient's age, and associated physical findings. In a healthy infant with a few streaks of blood in the stool and a normal examination, stool culture and observation are reasonable. If hematochezia is found and nasogastric aspirate is negative, significant pathology must be sought. Flat and upright abdominal radiographs should be performed if an obstructive process (e.g., intussusception, volvulus) is suspected by history or physical examination. The absence of radiographic findings should not, however, deter the physician from pursuing further diagnostic evaluation. A barium or air enema examination is diagnostic and often therapeutic in children with intussusception. If obstruction is not considered likely, the decision to perform contrast enema examination or colonoscopy will depend on the diagnosis suspected. Air-contrast barium enema is extremely valuable in the detection of polyps or inflammatory bowel disease. Indications for colonoscopy include severe bleeding, moderate but persistent bleeding with a negative double-contrast barium enema, or a lesion of unknown nature seen on barium enema. If undefined bleeding persists, radionuclide studies or angiography should be considered. A technetium scan may detect ectopic gastric mucosa as seen in Meckel's diverticulum, whereas angiography will help identify bleeding vascular malformations in the GI tract. Ongoing, undiagnosed GI hemorrhage accounts for fewer than 10% of cases in infants and children. Exploratory laparotomy may be necessary and lifesaving in these circumstances.

SUMMARY

Management of acute GI bleeding often requires a team approach, including the emergency physician, surgeon, and gastroenterologist. The foremost goals of ED evaluation of patients with GI bleeding are establishment of hemodynamic stability and determination of level of bleeding. All patients with nontrivial upper GI bleeding should be admitted for observation and further evaluation. If an acute abdominal process is suspected, surgical consultation and diagnostic workup should be instituted. If rectal bleeding is mild and self-limited and the history and physical are unremarkable, further investigation with a gastroenterologist is recommended.

CHAPTER 31

Groin Masses

***BRUCE L. KLEIN, MD and † DANIEL W. OCHSENSCHLAGER, MD**

**Departments of Pediatrics and Emergency Medicine, The George Washington University School of Medicine and Health Sciences, and Department of Emergency Medicine, Children's National Medical Center, Washington, D.C.; †Department of Child Health and Development, George Washington University Medical Center, and Emergency Medical Trauma Center, Children's Hospital Medical Center, Washington, D.C.*

Children occasionally present to the emergency department (ED) with an inguinal mass. It may be noticed during a diaper change, or the older child may bring it to the parent's attention; sometimes an adolescent arrives alone seeking help. There are many different causes, ranging from inconsequential to serious (Table 31.1). One generally can ascertain the correct diagnosis based on the age and sex of the child, the location of the mass, how painful it is, how rapidly it has evolved, and whether there are any associated symptoms or signs (Fig. 31.1). Admittedly, such categorization is imperfect; however, we believe it is useful nonetheless. Lymph node enlargement and retractile, undescended, and traumatically dislocated testes are discussed in this section. Hernia and hydrocele (as well as scrotal masses) are addressed in Chapter 58 and Chapter 118.

Painful
Torsion of an undescended testicle[a]
Trauma (e.g., dislocated testicle)[a]
Incarceration or strangulation of an indirect inguinal hernia[a]
Lymphadenitis
Usually or Comparatively Painless
Hernia
Hydrocele
Lymphadenopathy
Retractile or undescended testicle

[a]Urgent or emergent condition.

Table 31.1. Causes of Inguinal Masses

FIGURE 31.1. A. Groin masses in boys. **B.** Groin masses in girls.

DIFFERENTIAL DIAGNOSIS

Lymphadenopathy and Lymphadenitis

There are two groups of inguinal nodes: superficial and deep. The superficial ones can be subdivided into a horizontal group that runs parallel to the inguinal ligament and a vertical group located lateral to it. The horizontal group drains lymph from 1) the skin of the lower abdominal wall, perineum, and gluteal region; 2) the skin of the penis and scrotum; 3) the mucosa of the vagina; and 4) the lower anal canal. The vertical group drains lymph from 1) the gluteal region; 2) the

penis and deep structures of the scrotum; 3) the anterior and lateral areas of the thigh and leg; and 4) the middle and medial portions of the foot. The deep inguinal nodes, which lie beneath the fascia lata medial to the femoral vein, drain 1) all of the superficial nodes; 2) the clitoris or glans of the penis; 3) the medial areas of the thigh and leg; and 4) the lateral portion of the foot.

A healthy child can have a few small nodes normally. These tend to be less than half a centimeter long, and they are oval, firm, slightly moveable, and nontender. If the nodes are enlarged (especially unilaterally) or tender, erythematous, or suppurating, further evaluation is necessary (see Chapter 44).

Inguinal adenopathy—nodes that are enlarged but nontender—often is part of a more generalized lymphadenopathy. The list of causes of generalized lymphadenopathy is extensive and includes collagen vascular diseases (e.g., juvenile rheumatoid arthritis, serum sickness), immunologic disorders (e.g., chronic granulomatous disease), metabolic diseases (e.g., Gaucher's disease, Niemann-Pick disease), and certain anemias (e.g., sickle cell disease, thalassemia). Inguinal nodes may be enlarged because of malignancy (e.g., acute lymphocytic leukemia), but this is rarely the sole presentation of a malignant tumor. Of note, some local tumors, such as testicular tumors, metastasize to the inguinal nodes. Although many infections, particularly viral ones (e.g., human immunodeficiency virus, Epstein-Barr virus), produce inguinal adenopathy, these usually cause generalized lymphadenopathy as well as hepatosplenomegaly and other abnormalities.

Inflammation or infection of the gluteal region, perineum, genitalia, or ipsilateral lower extremity is the most common cause of isolated inguinal adenopathy or adenitis. These areas must be examined carefully. Chronic eczema, tinea cruris, or an innocuous inflammation (an insect bite or diaper rash) may produce lymphadenopathy. In such cases, treatment of the underlying condition suffices. If lymphadenitis—enlargement with tenderness, erythema, or suppuration—is detected, the node itself is probably infected. Group A b-hemolytic streptococcus, *Staphylococcus aureus,* or an enteric organism is the usual pathogen, depending on the site of the primary infection. A culture from the primary site or node aspirate helps identify the organism. Most children can be treated as outpatients with oral antibiotics (e.g., cephalexin or amoxicillin–clavulanate), but children with severe symptoms should be admitted and treated with intravenous antibiotics (e.g., oxacillin, cefazolin). Abscesses caused by these pathogens should be incised and drained (see Chapter 84).

Venereal diseases can result in inguinal adenopathy or adenitis in adolescents (see Chapter 84). Herpes is a common cause of genital ulcerations and bilaterally enlarged, painful lymph nodes. Enlarged lymph glands may precede the appearance of vesicles occasionally. Oral acyclovir shortens the duration of symptoms and viral shedding in primary disease but is less effective in recurrences.

The chancre of primary syphilis is painless and indurated and has raised, firm borders, a shallow, smooth base, and no exudate. Bilateral (70%) and unilateral, nontender inguinal adenopathy is common. A positive rapid plasma reagin (RPR) confirms the diagnosis, but this test is nonreactive in up to 30% of patients with primary syphilis. Recommended treatment for primary syphilis is benzathine penicillin G 2.4 million units intramuscularly.

Chancroid is more common in developing countries than in the United States. It is caused by *Haemophilus ducreyi,* which is hard to isolate and requires selective media. Unlike syphilis, the chancroid ulcer is painful and soft and has ragged edges and a deep, friable base covered with a dirty yellow exudate. About half of patients develop painful adenitis, usually unilaterally. The node or nodes often suppurate and drain spontaneously. The preferred treatment is azithromycin 1 g orally or ceftriaxone 250 mg intramuscularly.

Lymphogranuloma venereum, which occurs mostly in tropical and subtropical countries, is caused by *Chlamydia trachomatis.* The genital papule, vesicle, or ulcer often is missed because it is painless, inconspicuous, and transitory. One or more unilaterally enlarged, moderately tender, fluctuant nodes are characteristic. If left untreated, these nodes drain and form fistulae. Three weeks of treatment with doxycycline, erythromycin, or a sulfonamide is necessary.

Granuloma inguinale is caused by the Gram-negative bacillus *Calymmatobacterium granulomatis.* Granuloma inguinale is rare in the United States but if untreated results in extensive subcutaneous granulomas (pseudobuboes), which mimic suppurative lymph glands. The initial small, relatively painful, red nodule or vesicle progresses to a red mass of granulomatous tissue, which ulcerates and coalesces. Both tetracycline and trimethoprim–sulfamethoxazole are somewhat effective.

An enlarged, tender inguinal node can be caused by plague, brucellosis, tularemia, or cat-scratch disease if the portal of entry for the infective organism is the lower extremity. *Yersinia pestis,* which causes plague, is extremely rare in the United States and is commonly transmitted by flea bites. The buboes are firm and nonfluctuant but extremely tender. The overlying skin is often warm and edematous. Mortality can be as high as 80%. Streptomycin and gentamycin are the drugs of choice for children.

Inguinal lymphadenopathy can be seen in tularemia when it is caused by an infected tick bite. Enlarged tender lymph nodes precede the appearance of a small papule that later ulcerates. Streptomycin and gentamycin are the preferred treatments in children.

Infection with *Bartonella henselae* (cat-scratch disease) results in regional lymphadenopathy that is usually red, indurated, and warm. Usually, the lymphadenopathy resolves spontaneously within 2 to 4 months. Antibiotic treatment is of questionable value.

Filariasis, which is found in the tropics, can produce adenopathy or adenitis associated with lower extremity lymphedema and scrotal pathology.

Retractile, Undescended, or Traumatically Dislocated Testes

If the inguinal mass is firm, oval, and nontender and is associated with an empty scrotum, it probably is a retractile or undescended testis. A retractile testis, in contrast to a truly undescended one, is pulled into its abnormally high position by a hyperactive cremasteric reflex and can be milked back into the scrotum by the examiner. The scrotum appears fully developed when the testicle is retractile. Although it may retract again, it will ultimately assume a normal position; therefore, no treatment is needed.

An undescended testicle is found in 2 to 4% of term boys. As expected, cryptorchidism is about 10 times more common in premature boys. Its incidence correlates inversely with gestational age; for example, practically all babies who weigh less than 900 g are cryptorchid. The incidence falls to 0.7% by 1 year of age. Because this is similar to the incidence in adult men, it seems that spontaneous descent occurs rarely after 1 year of age. The testis can lodge anywhere along its natural line of descent—for example, intra-abdominally, in the inguinal canal, or just outside the external inguinal ring. It also may be discovered in an ectopic location—for example, in a superficial pouch near the external ring or, less commonly, in the abdominal, suprapubic, perineal, or femoral areas. Cryptorchidism is right-sided in 50% of patients, left-sided in 25%, and bilateral in 25%. There is a right-sided predominance because the right testicle descends later than the left one during embryologic development. Bilaterally undescended testicles occur more often in premature boys and in conjunction with some anatomic, enzymatic, and chromosomal disorders that are encountered in the delivery suite or shortly thereafter. There is an increased occurrence of cryptorchidism among family members.

If left untreated, various complications, including testicular atrophy, infertility, malignancy, torsion, injury related to trauma, and development of a hernia, can ensue. Germ cell depletion may be visible by as early as the first birthday; other degenerative changes, such as Leydig cell atrophy, smaller seminiferous tubules, and peritubular fibrosis, follow. These manifestations are worse in testicles located more proximally. Interestingly, these histologic abnormalities also develop in the normally descended testicle, although later and less severely. Adults with untreated bilateral cryptorchidism generally are sterile, but those with untreated unilateral cryptorchidism are somewhat infertile as well. Compared with men who have normally descended testicles, the incidence of malignancy is increased 22-fold. The malignancy usually is a seminoma, presenting in the third decade of life. Although intra-abdominal testes are most at risk, cancer also occurs more often in the contralateral descended testis. An undescended testicle is particularly prone to torsion and more likely to be injured from trauma. In such cases, if it is located in the inguinal region, it presents as a painful groin mass. Finally, 90% of undescended testicles are associated with a patent processus vaginalis, increasing the chance that a hernia will develop.

Early referral to a urologist is warranted. Currently, most urologists recommend orchiopexy between 1 and 2 years of age. At surgery, the testis, spermatic cord, and vascular structures are mobilized and brought down into the scrotum, where the testis is either pexed or placed in a dartos pouch; in addition, the processus vaginalis is ligated if it is patent. Although it is hoped that earlier surgery will lessen the incidences of infertility and malignancy, this has not yet been proved conclusively. Orchiopexy facilitates diagnosis of a malignancy because the testis can be palpated more easily in the scrotal sac. Hormonal therapy (e.g., human chorionic gonadotropin [HCG]) may be beneficial in a few select cases; however, studies from the United States have demonstrated that it is not particularly effective, especially when retractile testes are excluded. Some clinicians report that it does not work as well in younger boys, and it also is ineffective if the testis is located ectopically. Many pediatric endocrinologists and urologists use it mainly to differentiate retractile from undescended testes.

Finally, a traumatically dislocated testicle may be discovered in the groin. Testicular dislocation occurs primarily in the older adolescent and young adult but is uncommon even then. It usually follows major trauma—in particular, a motor vehicle accident. An associated injury, such as a pelvis or femur fracture, often is found. Despite swelling, ecchymosis, and tenderness, the scrotum feels empty. As mentioned, sometimes the testis is palpated in an abnormal location, most often in the groin in the superficial pouch anterior to the external oblique aponeurosis. At surgery, the testis is reduced into the scrotum and pexed to the wall.

EVALUATION AND DECISION

In evaluating groin masses, one should consider the sex of the child, presence or absence of pain, status of the testes (in boys), response to attempted reduction, history of trauma, and findings of local infection.

Boys (Fig. 31.1A)

Focusing first on boys, pain often heralds a potentially emergent condition, including torsion of an undescended testis, an incarcerated or strangulated hernia, or a significant injury. One begins the evaluation by carefully palpating the scrotum. An empty scrotum points to a dislocated testis after trauma or spontaneous torsion of an undescended testis. In a boy with bilaterally descended testes, an isolated, painful groin mass may represent an incarcerated or strangulated inguinal hernia. The finding of penile lesions, such as those of herpes or syphilis, or obvious signs of inflammation (erythema, fluctuance) suggest inguinal lymphadenitis.

Painless groin masses in boys are usually not urgent. If the mass is reducible, it is an inguinal hernia, which calls for elective surgical repair. The absence of a testis in the scrotum on the side of the mass suggests a retractile or undescended testis. A retractile testis is more likely in the boy presenting with new-onset swelling; the diagnosis can be confirmed in most cases by “milking” the testis into the scrotum. When both testes are descended, a painless mass is likely to be either a hydrocele or an enlarged lymph node. One must keep in mind that a recently incarcerated hernia may be painless and is easily confused with a solitary, enlarged lymph node.

Girls (Fig. 31.1B)

As for girls, one can approach the diagnosis of groin masses by first ascertaining the presence or absence of pain. The highest priority in girls with painful masses is to identify an incarcerated or strangulated hernia. Local lesions or signs of

inflammation point to lymphadenitis.

Although hernias occur less often in girls than in boys, they are still relatively common. The ability to reduce a mass with gentle pressure confirms this diagnosis. When a painless mass is irreducible, a recently incarcerated hernia (particularly involving an ovary) or an enlarged lymph node represent the most likely causes.

CHAPTER 32

Hearing Loss

ROBERT J. VINCI, MD

Department of Pediatrics, Boston University School of Medicine, and Department of Pediatrics, Boston Medical Center, Boston, Massachusetts

Normal hearing plays a critical role in the proper development of speech and language. Any persistent hearing loss will distort a child's perception of expressive speech and language and will compromise the ability to attain normal language. Failure to recognize hearing impairment can negatively impact school performance, socialization, and emotional development. Acute hearing loss is of two main types: conductive and sensorineural. Several serious—even life-threatening—disorders can accompany acute hearing loss. Therefore, prompt clinical evaluation is mandated when hearing loss is suspected.

Hearing loss can occur as an isolated symptom or in association with auditory or central nervous system (CNS) dysfunction. The differential diagnosis of hearing loss includes congenital and acquired causes. It may be produced by the abnormal transmission of sound waves to the inner ear (conductive hearing loss) or by the defective processing of sound waves (sensorineural hearing loss) in the inner ear (Table 32.1). In young children, the possibility of acute hearing loss may be suspected by parents when the child does not respond to noise or to simple commands. Abnormal or delayed language development may be a sign of a more chronic process. Older children and adolescents may complain directly of hearing difficulty.

Table 32.1. Differential Diagnosis of Hearing Loss

PATHOPHYSIOLOGY

An intricate series of properly aligned anatomic and physiologic connections is responsible for the precise functioning of the auditory system. When sound reaches the tympanic membrane, vibrations of the membrane are transmitted to the ossicles within the middle ear and from there to the cochlea, which is located in the inner ear. Within the cochlea, specialized receptors in the form of hair cells in the spiral organ of Corti convert this mechanical energy to nerve impulses that are transmitted to the CNS by way of the cochlear (acoustic) nerve, the auditory portion of the eighth cranial nerve. Anatomically, the acoustic apparatus is closely related to the vestibular system, which is concerned with the proprioceptive senses of posture and equilibrium. The three semicircular canals of the vestibular system are connected to the cochlear system; therefore, abnormalities in the inner ear may cause auditory and vestibular symptoms.

DIFFERENTIAL DIAGNOSIS

Conductive Hearing Loss

In children, conductive hearing loss occurs when there is a decrease in the transmission of sound waves to the cochlea from an external source. Commonly, middle ear effusion (acute or chronic), impacted cerumen, foreign body in the external ear canal, and ossification of the middle ear ossicles produce conductive hearing loss (Table 32.1). In children with chronic recurrent otitis media (OM), a cholesteatoma—an epidermal inclusion cyst of the middle ear—may develop and cause a slowly progressive conductive hearing loss. Acute head injury, especially in association with a basilar skull

fracture, may produce a conductive hearing loss secondary to hemotympanum, rupture of the tympanic membrane, or disruption of the inner ear ossicles. Rarely, the conductive hearing loss may be secondary to malformations of the external or middle ears, such as absence of the external ear canal.

Congenital Sensorineural Hearing Loss

Approximately 1 of every 750 infants is born with congenital hearing loss. Diagnostic possibilities include genetic disorders, chromosomal abnormalities, metabolic and storage diseases, and abnormal development of the auditory apparatus (Table 32.1). Congenital hearing loss secondary to aplasia of the inner ear (Michel's aplasia) and abnormal cochlear development (Mondini's aplasia) or absence of parts of the cochlear apparatus (Scheibe's aplasia, Alexander's aplasia) are reported in children. Sensorineural hearing loss has been described in more than 70 syndromes, including Waardenburg syndrome (facial dysmorphism, white forelock), Jervell and Lange-Nielsen syndrome (prolonged Q-T syndrome), Usher's syndrome (retinitis pigmentosa and sensorineural hearing loss), and Alport's syndrome (nephritis, optic abnormalities, and hearing loss). The chromosomal disorders caused by trisomies (especially trisomies 13, 14, 15, 18, and 21) are associated with defects in hearing. Many of these patients are diagnosed because of anatomic features associated with each of these disorders, although the hearing loss that occurs may be present at birth or develop over time. Individual patients with presumed idiopathic sensorineural hearing loss have a recurrence rate in siblings of 10%, much closer to the 25 to 50% rate of an inherited disorder than the overall risk of 1 in 750 for the general population. These data support the theory that the etiology of presumed isolated causes of sensorineural hearing loss may be genetic in origin.

Acquired Sensorineural Hearing Loss

Although acquired sensorineural hearing loss occurs less commonly than congenital hearing loss, the absence of associated symptoms may make it a more difficult diagnosis. An array of clinical problems can produce sensorineural hearing loss during childhood.

Acute Infection

Hearing loss secondary to bacterial meningitis is the most common cause of acquired sensorineural hearing loss. Reported in 15 to 20% of patients with meningitis, the hearing loss is usually profound and often bilateral. It is most commonly associated with infections caused by *Haemophilus influenzae*, *Streptococcus pneumoniae*, or *Neisseria meningitidis* and can develop despite appropriate antimicrobial therapy. Vaccine programs that have led to a decrease in the incidence of *H. influenzae* infections have been instrumental in decreasing the occurrence of this complication. Hearing loss from meningitis is thought to result from direct toxicity of the cochlear hair cells, and recent studies suggest adjunctive therapy with dexamethasone may decrease the incidence of this complication.

Untreated congenital syphilis is another infection associated with acquired sensorineural hearing loss. Hearing loss has also been described with congenital infections caused by rubella, toxoplasmosis, cytomegalovirus (CMV), and perinatally acquired herpes simplex infections.

Viral infection of the labyrinth (also called viral cochleitis) secondary to mumps, parainfluenzae, adenovirus, herpes simplex, CMV, and rubeola have been described and confirmed by serologic studies. Labyrinthitis usually has symptoms related to inflammation of the inner ear and involvement of the vestibular apparatus, and patients may complain of vomiting, tinnitus, and vertigo.

Vascular Insufficiency

Sudden hearing loss secondary to vascular insufficiency has been described in the pediatric patient. Vascular insufficiency may compromise blood flow to the cochlea, producing a hypoxic insult to the sensitive nerve cells in the organ of Corti. Once injured, these nerve cells may not regenerate and profound sensorineural hearing loss can develop. In children, sickle cell disease, long-standing diabetes mellitus, and hyperviscosity states associated with polycythemia can compromise cochlear blood flow and produce sudden hearing loss.

Perilymphatic Fistula

Anatomic defects in the bony or membranous enclosure that normally surrounds the perilymphatic space can produce a perilymphatic fistula. These defects may produce an anomalous communication between the middle and inner ear compartment and should be considered in the differential diagnosis of the pediatric patient with acute sensorineural hearing loss. A perilymphatic fistula can occur at any age. The sudden ingress of air into the inner ear is thought to produce the symptom complex of hearing loss, tinnitus, vertigo, dizziness, and nystagmus. Trauma usually underlies the development of a fistula. This is especially true in any patient who has a recent history of vigorous exercise or changes in barometric pressure associated with airplane travel or scuba diving. Although unilateral hearing loss is most common, bilateral hearing deficits have been described. Occasionally, a perilymphatic fistula will develop in a child with previously abnormal hearing. Therefore, this diagnosis needs to be considered in any patient who has sudden onset of hearing loss, fluctuation in hearing, or complaints of progressive hearing loss, regardless of baseline hearing function. Patients with a perilymphatic fistula generally have a normal otoscopic examination. If a tympanogram is performed, middle ear effusion usually is absent. Emergent referral to an otolaryngologist is warranted because surgery may be required for closure of the anatomic defect.

Head Trauma

Both the vestibular and cochlear nerves can be injured with fractures of the temporal bone. Assessment of audiologic function should be considered in any child with major head trauma; computed tomography (CT) scan may be required to

diagnose these injuries.

Acoustic Trauma

Immediate, severe, and permanent hearing loss can follow even a short period of exposure to sounds greater than 140 dB. Exposure to sounds in the 80- to 100-dB range can produce hearing loss with chronic exposure and is most commonly diagnosed in adolescents. Rock concerts, stereo headphones, machinery, and explosive devices are capable of producing sound at the intensity required to produce this condition.

Chronic/Recurrent Otitis Media

A history of chronic/recurrent OM may predispose patients to the development of sensorineural hearing loss. This hearing loss is thought to be related to inflammatory changes in the inner ear that are produced by the diapedesis of toxins through the round window membrane. Such involvement of the inner ear has been confirmed pathologically by the presence of labyrinthitis in patients with acute OM. Because middle ear effusions produce a conductive hearing loss, the clinician must be aware of the possibility of OM producing a mixed picture.

Miscellaneous

Acoustic neuroma, CNS tumors, and leukemic infiltrates also are associated with sensorineural hearing loss. Other considerations in pediatric patients include Kawasaki disease, hypothyroidism, lightning injury, hyperlipidemia, and the use of ototoxic drugs in the neonatal period. Finally, some children will have no demonstrable cause for their hearing loss.

EVALUATION AND DECISION

Any complaint of hearing loss requires prompt evaluation. Common causes of acute hearing loss are listed in Table 32.2. Life-threatening causes of acute hearing loss are rare in pediatric patients (Table 32.3). The initial step in evaluation is to confirm the presence of acute hearing loss (Fig. 32.1). Although sophisticated hearing tests are best performed by an audiologist, the emergency physician should attempt bedside testing of gross hearing function. In young children, behavioral responses to loud stimuli can be assessed. Without attracting visual attention, an auditory stimulus (e.g., vigorous hand clapping or ringing a bell) can be presented to the child. Eye blinking or turning toward the stimulus represents a positive response and suggests some degree of intact hearing. In older children or adolescents, hearing can be assessed by asking the patients whether they hear a low-intensity sound such as a watch ticking or fingers rubbing together. Because hearing dysfunction can be subtle and can occur over the entire range of auditory frequencies, these bedside tests may underestimate the degree of hearing impairment. Therefore, an abnormal test should be considered a confirmation of hearing impairment; a negative test needs to be interpreted in the context of the chief complaint of the patient. If the history remains strongly suggestive of hearing loss, the physician should assume some degree of hearing loss despite the results of bedside testing.

FIGURE 32.1. Evaluation of hearing loss.

Conductive Hearing Loss	Sensorineural Hearing Loss
Middle ear effusion	TORCH infections
Impacted cerumen	Birth asphyxia
Foreign body of external ear canal	Acute otitis media

	Perilymphatic fistula
	Trauma
	Acoustic neuroma

Table 32.2. Common Causes of Acute Hearing Loss

Acute head injury	Leukemic infiltrate
Brain tumor	Vascular insufficiency

Table 32.3. Life-Threatening Causes of Acute Hearing Loss

Critical elements of the medical history should include the onset of the hearing loss and the duration of symptoms. Family history of hearing loss may suggest the diagnosis of a genetic disorder with delayed presentation of hearing loss. A history of birth asphyxia, hyperbilirubinemia, or maternal infection points to a neonatal cause. A recent history of head trauma or barotrauma (e.g., scuba diving) may suggest the diagnosis of perilymphatic fistula. Fever and otalgia suggest a diagnosis of acute OM. Associated neurologic symptoms such as tinnitus, vertigo, and dizziness suggest inner ear disease or CNS involvement. Headache can be a marker for tumor of the CNS or extension of middle ear infection (Fig. 32.1).

On physical examination, the presence of fever may suggest an infection such as OM or viral labyrinthitis. A detailed otoscopic examination to detect the presence of a middle ear effusion, impacted cerumen, perforated tympanic membrane, foreign body, or other abnormality of the tympanic membrane is a priority. Tympanometry can be used to supplement the physical examination, especially if the otoscopic examination suggests the presence of middle ear disease. Because of the intricate relationship between the cranial nerves, a careful neurologic examination is required. Within the petrous bone, the cochlear nerve is closely related to the seventh cranial nerve and the vestibular branch of the eighth cranial nerve. An ipsilateral facial nerve palsy in a patient with hearing impairment suggests an intracranial process. Vestibular function should be tested looking for the presence of nystagmus at rest as well as with directed gaze. Patients with vestibular dysfunction often fall to one side with Romberg testing or have difficulty with rapid alternating movements or finger-to-nose testing.

Once hearing loss is established, the next step in the emergency department (ED) is to differentiate conductive from sensorineural hearing loss with the use of tuning fork tests (Fig. 32.1). Conductive hearing loss can be confirmed by the Weber test. In the Weber test, a vibrating, 512-Hz tuning fork is placed in the midline of the patient's forehead. The patient will describe the sound as being more prominent on the side of the conductive hearing loss or the side opposite the sensorineural hearing loss. For the Rinne test, the vibrating tuning fork is placed against the mastoid process. When the patient signals that the vibration has ceased, the tuning fork is placed adjacent to that ear to determine whether the patient can hear the sound of the still-vibrating tuning fork. Patients with conductive hearing loss will not be able to hear the tuning fork. This is a negative Rinne test (bone conduction greater than air conduction). Sensorineural hearing loss shows up as a positive Rinne test (air conduction greater than bone conduction). Finally a test by confrontation is done by placing a tuning fork at a point equidistant from both ears. Regardless of the type of hearing loss, the patient will report the sound to be higher on the side with normal hearing.

Laboratory evaluation is seldom necessary in the ED; when needed, it should focus on diagnosis that may be contemplated after obtaining a detailed history and physical examination. Complete blood count (CBC) and peripheral blood smear, renal function tests, serologic tests for syphilis, TORCH titers, and bacteriologic cultures should be performed only if the history and physical suggest an associated diagnosis. Thyroid function tests, lipid profile, and serum calcium levels should be individualized in the context of clinical findings.

In children with the clinical suspicion of intracranial pathology, a radiologic evaluation assists in the diagnosis. Patients with known or suspected congenital malformation of the middle and inner ears should be evaluated with a CT scan because bony detail is essential for diagnosis. Inner ear abnormalities have been demonstrated in 8 to 20% of patients with sensorineural hearing loss. A CT scan also should be performed in patients with suspected fracture of the temporal bone. Magnetic resonance imaging (MRI) is replacing the CT scan for the diagnosis of acoustic neuroma. With the addition of paramagnetic contrast, high-resolution scanning, and thin-section techniques, excellent detail of the internal auditory canal can be achieved.

Most children with decreased hearing in the ED have a conductive hearing loss. If impacted cerumen is seen on examination, it must be removed because it may be the cause of the decreased hearing and it prevents further evaluation. Children whose hearing improves after disimpaction and who have a normal otoscopic examination need no further treatment. Patients without impacted cerumen and those who fail to improve after removal of cerumen may have a foreign body in the ear canal. Only large objects that completely obstruct the external auditory canal should impair hearing; thus, this diagnosis is easily established during otoscopic examination.

The next step in the evaluation is a careful examination of the tympanic membrane, including pneumatic otoscopy. Many patients will show evidence of a middle ear effusion, the most common cause of hearing loss seen in the ED. Rarely, a cholesteatoma may been seen through the translucent tympanic membrane. Sensorineural hearing loss is seen less often in the ED. Most children with sensorineural hearing loss have congenital problems that are diagnosed during the course of routine care, although occasional cases will be brought to the attention of the emergency physician. Among the acquired causes, those that must be diagnosed urgently include CNS tumors, vascular accidents, and perilymphatic fistula. In cases of acquired sensorineural hearing loss, a history of trauma should be sought. Direct blows to the head

may cause temporal bone fractures or a perilymphatic fistula, and sudden changes in pressure may injure the cochlea. If there is no preceding trauma, a careful neurologic examination should be performed, looking for evidence of CNS tumors. A CT scan is indicated if these lesions are suspected. The most common cause of acquired sensorineural hearing loss seen in children in the ED without a history of trauma is viral labyrinthitis. These patients usually have associated tinnitus, vertigo, and vomiting but no focal neurologic abnormalities. Most of the remaining causes of hearing loss are idiopathic. Vascular insufficiency merits consideration in children with sickle cell anemia, diabetes mellitus, and collagen vascular disease. If the cause of the hearing loss remains uncertain, otolaryngologic consult and evaluation should be considered.

CHAPTER 33

Patients with Heart Murmurs

BENJAMIN K. SILVERMAN, MD

Emergency Services, Harbor/UCLA Medical Center, Children's Hospital of Orange County, Orange, California

In a “first encounter” examination of a child, the emergency physician will often hear a cardiac murmur—one previously 33 known to the family or one freshly discovered—and then he or she must determine how to fit this finding into the sometimes complicated evaluation of the patient's current illness. Is the murmur an incidental finding of no relevance? Is it suggestive of heart disease? If so, are there cardiac-related symptoms? Is it related to life-threatening illness, not necessarily of cardiac origin?

Certain priorities prevail that should precede the further definition of the murmur per se. It is not important to pinpoint a primary cardiac diagnosis immediately, but it is essential to determine whether the patient is in cardiac decompensation, whether life is at risk, and whether there is incipient need for evaluation by a cardiologist or cardiac surgeon.

A murmur is a noise created by the turbulence of blood flow, under varying pressures, through chambers and vessels and across valves that are of unequal sizes and shapes. The murmur itself is not abnormal. Most murmurs, in fact, are sounds created by normal turbulence and, therefore, are best referred to as “normal” rather than the less appropriate adjectives, “innocent” or “functional.” Some loud murmurs are created by clinically inconsequential defects (e.g., small ventricular septal defects), whereas other, barely discernible, murmurs may be associated with far more serious defects or illnesses, such as acute myocarditis or transposition of the great vessels.

The ultimate goal of the chapter is to provide criteria for determining whether a patient's murmur is irrelevant or associated with life-threatening illness of cardiac or extracardiac origin, and whether the patient needs cardiac consultation now, eventually, or not at all.

DIFFERENTIAL DIAGNOSIS

History

Unless the patient is in extremis, a careful, focused history is always the starting place. For the patient in whom a murmur is heard, in addition to usual history related to the present complaint, relevant questions might include the following:

- Is the murmur known to have been present? Since the neonatal period? If not, since when? Has it been evaluated at any previous examination? If so, what were the findings and conclusion? Has there been cardiac surgery?
- Was there an antecedent illness before discovery of the murmur? Sore throat? Viral infection?
- Are there or have there been associated signs or symptoms? Edema? Cyanosis? Difficult breathing? Hypertension? Chest pain? Joint symptoms? Feeding problems? Weight gain or loss? Congenital defects?
- Does the child tire easily? How far can he or she walk? Does the child squat after walking? Climb stairs? Have cyanotic “spells”?

Examination

The examination should consist of as complete a physical as possible under the prevailing circumstances.

Murmur Characteristics

Murmur characteristics can be defined in print only qualitatively or, at best, in a crude quantitative manner. Most physicians are not put in the position often enough of having to dissect a murmur in intricate detail to achieve the precision of the cardiologist. Therefore, although the characteristics are briefly defined here, the subsequent course of this chapter makes only minimal use of them. More detailed descriptions of murmur characteristics are given in the references at the end of this chapter.

- *Timing and duration:* Systolic (between the first and second heart sounds) or diastolic (between the second and first sounds)? Early, mid, late, or throughout systole (holosystolic)? Beginning in systole and persisting into diastole

(continuous)?

- *Intensity (loudness):* Usually graded from barely discernible (grade I) through accompanied by a palpable thrill (grade IV) to audible without making contact with the chest (grade VI).
- *Shape:* Terms such as *diamond-shaped, plateau, crescendo,* and *decrescendo* are easily understood when learned in conjunction with a phonocardiogram; interpreting them by ear requires much practice and training.
- *Quality: Musical, blowing, rumbling, wood-sawing, harsh, vibratory, twang, soft, rough, grating,* and *click* are among the subjective terms uses. One's own interpretation of “quality” is useful mostly in distinguishing the possibility that there are two separate murmurs.
- *Frequency (pitch):* Described qualitatively as low, medium, or high.
- *Location and transmission:* Location is the point of maximum intensity of the murmur (upper, lower, or mid left or right sternal margin; apex; midclavicular or axillary line; at which rib interspace?). Transmission refers to the areas of maximal spread of the sound (to the back; to the neck).

Precordial Examination

The remainder of the precordial examination should be completed; the physician should inspect for chest bulge, palpate for thrills and clicks and points of maximal impulse, and listen carefully for the heart sounds and adventitial sounds. The physician must interpret the first and second sound for intensity and splitting. The third and fourth sounds, opening snaps, clicks, rubs, and some unusual rhythms may be confused for murmurs at times and should be kept in mind as possible confounding factors.

Associated Signs and Symptoms

Vital Signs

Normal vital signs for age are listed in Appendix D.

- *Heart rate and rhythm:* Check the heart rate and listen and palpate for rhythm disturbances (see Chapter 74 and Chapter 82). The normally rapid rate of the infant makes evaluation of the murmur even more difficult. Palpate the femoral artery pulsations.
- *Blood pressure:* Lower extremity pressures are normally measured 10 to 40 mm Hg higher than upper pressures.
- *Respirations:* Count the rate and observe for retraction.
- *Body temperature:* Infective endocarditis must be thought of in any child with heart disease and fever.

Color

Central cyanosis (see Chapter 16) is diffuse and is best differentiated from peripheral cyanosis by involvement of the tongue. It may be subtle and sometimes difficult for the unpracticed eye to appreciate. If accompanied by clubbing of the distal fingers in the older child, cyanosis is probably persistent and chronic. Severe pallor related to marked anemia may be associated with high-output cardiac failure.

Other Signs Associated with Cardiac Failure (see Chapter 82)

- *Edema:* More likely to be dependent and pitting in cardiac disease. In the preambulant child, dependent edema may be appreciated best along the back, rather than the lower extremities, and also may be prominent in the periorbital area.
- *Neck veins:* Look for distended jugular veins in the neck of the patient when lying or propped at a 45-degree angle.
- *Respiratory effort:* Look for tachypnea, grunting, difficult breathing (particularly subcostal retractions), or a preferred upright position. Listen to the lung fields for crackles and wheeze.
- *Organ enlargement:* Palpate for a soft, engorged liver, mostly involving the left lower lobe. Check for splenomegaly.

Remaining Examination

- *Skin:* Look for petechiae on the surface of the skin, in the conjunctivae, and under the fingernails. Also search for erythema marginatum and subcutaneous nodules. Look for thoracotomy scars.
- *Joints:* Check for tenderness, redness, heat, and swelling (see Chapter 57).
- *Neurologic:* Cranial nerve deficiencies? Paresis? Papilledema?
- *Nutritional evaluation:* Are the child's height and weight within a reasonable percentile compatible with the parents'? Is the weight percentile significantly lesser or greater than that for height?

Ancillary Diagnostic Aids

None of the following need be used routinely, but most should be obtainable and interpretable for the emergency department (ED) setting. They should be ordered selectively if clinical assessment of the child does not allow a satisfactory conclusion regarding the significance of the murmur.

Electrocardiography

A lead II rhythm strip can be used for monitoring the patient in distress. A full 14-lead electrocardiogram (ECG), using age- and size-appropriate electrodes, should be readily obtainable for screening and evaluation purposes. The emergency physician should have a working knowledge of the criteria for determining normality, which may vary with the age group of the child (see Chapter 82 and Appendix D).

Echocardiography

Echocardiography allows definitive diagnosis for many congenital cardiac lesions, determination of the severity of cardiac failure, and differentiation of myocarditis from pericardial effusion. In evaluation of many lesions, echocardiography has replaced cardiac catheterization for preoperative diagnosis. Because it is expensive and the techniques vary significantly, the procedure is best reserved for patients for whom cardiologic consultation is to be obtained. The cardiologist will be in the best position to guide the technician as to optimal methodology.

Procedures such as angiocardiography, electrophysiologic mapping, and cardiac flow determinations, although they may prove essential for eventual diagnosis, require cardiac consultation and should not be part of the ED evaluation.

Chest Radiograph

Films should be taken in both posteroanterior (PA) and lateral views. The physician should look for gross cardiac enlargement in the PA views, which may be determined in older children by a transverse diameter greater than 50% of the width of the thoracic cage. In infants, the diameter normally may be considerably wider than that ratio. Thymic shadows and less than full inspiration may be confounding factors. The lung fields should be evaluated for increased or diminished pulmonary flow.

Pulse Oximetry

Pulse oximetry is used to evaluate the presence and degree of oxygen desaturation.

Blood Studies

Tests that might be of ancillary value under specific circumstances include a complete blood count, sedimentation rate, arterial blood gas measurements, blood culture, antistreptolysin titer, sickle cell screening, and antinuclear antibody.

EVALUATION AND DECISION

Neonates and older infants usually have different clinical presentations than older children. Therefore, in our first encounter evaluation, we divide murmur patients by two age groupings: from birth to 3 years of age (Fig. 33.1 A and Fig. 33.1 B) and over 3 years of age (Fig. 33.2A,Fig. 33.2B and Fig. 33.2C). Table 33.1 lists conditions that may be associated with murmurs.

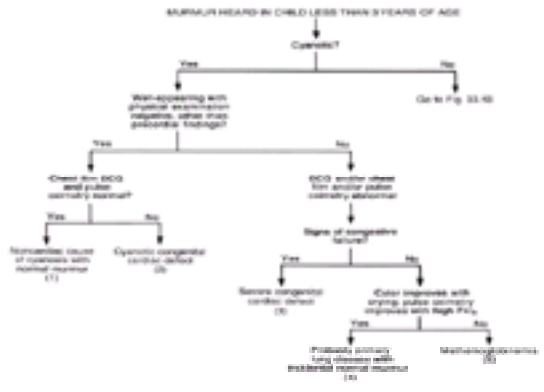

FIGURE 33.1A. Assessment of a noncyanotic child less than 3 years of age in whom a murmur is heard. (Numbers in parentheses refer to specific citations in text.)

FIGURE 33.1B. Assessment of a noncyanotic child less than 3 years of age in whom a murmur is heard. (Numbers in parentheses refer to specific citations in text.) *VH,* ventricular hypertrophy.

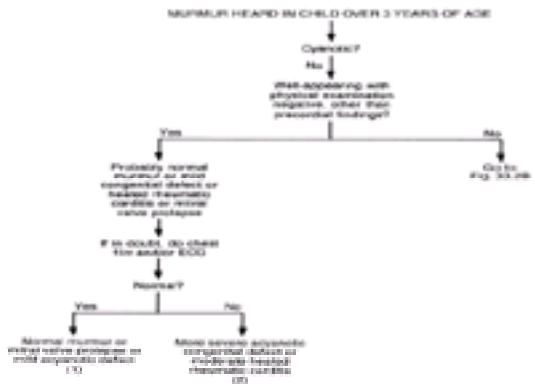

FIGURE 33.2A. Assessment of a noncyanotic, well-appearing child 3 years of age and over in whom a murmur is heard. (Numbers in parentheses refer to specific citations in text.)

FIGURE 33.2B. Assessment of a noncyanotic, sick child 3 years or over in whom a murmur is heard. (Numbers in parentheses refer to specific citations in text.)

FIGURE 33.2C. Assessment of a cyanotic child 3 years of age or over. (Numbers in parentheses refer to specific citations in text.)

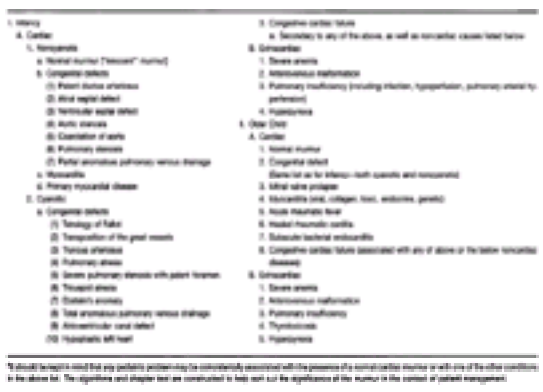

Table 33.1. Conditions That May Be Associated with Presence of a Cardiac Murmur[a]

Infants Less Than 3 Years of Age

Neonates or children less than 3 years of age in whom a murmur is heard require extremely careful assessment but are not necessarily in serious difficulty. The lead point in the evaluation is the presence or absence of cyanosis, preferably confirmed by pulse oximetry.

Infants Less Than 3 Years of Age Who Are Cyanotic (Fig. 33.1A)

Any baby who has a murmur and appears cyanotic should have a thorough physical examination and also should have an ECG, chest film, pulse oximetry, and possibly arterial gases.

If the physical examination is normal, except for the cyanosis and the murmur, and the ECG, film, and pulse oximetry are normal, the infant probably has a normal murmur and a noncardiac cause of only apparent cyanosis (peripheral acrocyanosis, polycythemia) (Fig. 33.1 A [1]).

A cyanotic infant who appears well but has an abnormal ECG and chest film and has diminished arterial saturation by oximetry or blood gas evaluation probably has cyanotic heart disease of a type not likely to get into early trouble (Fig. 33.1A[2]). This could include tetralogy of Fallot, transposition of the great vessels with single ventricle, truncus arteriosus, Ebstein's anomaly, tricuspid atresia, anomalous pulmonary venous drainage, or moderately severe pulmonary stenosis with shunting through an atrial or ventricular septal defect. These babies should be discussed with a cardiologist and referred for evaluation and echocardiogram. Neonates should be admitted for observation in the hospital, but children more than 4 weeks old do not necessarily need to be admitted.

If the cyanotic infant appears acutely ill, the likelihood is that the chest film and/or the ECG and pulse oximetry will be abnormal. If the findings on physical examination suggest congestive heart failure (CHF), the baby probably has severe cyanotic congenital heart disease or an extremely severe acyanotic defect with the cyanosis related to poor perfusion and failure (Fig. 33.1A [3]). Defects in the neonate could include extreme aortic or pulmonary stenosis, pulmonary atresia with intact ventricular septum, and hypoplastic left heart. In the somewhat older infant, considerations include tricuspid atresia, Ebstein's anomaly, large arteriovenous malformation, atrioventricular canal defect, large ventricular septal defect, and total anomalous pulmonary venous drainage. These babies should be admitted to the hospital or transferred immediately to a center for diagnostic cardiac workup and therapy.

If the evaluation of the sick cyanotic baby does not suggest CHF and the saturation improves somewhat with crying and in oxygen, the baby probably has primary lung disease caused by infection, hypoperfusion, or pulmonary arteriolar hypertension (Fig. 33.1A [4]). These babies should be admitted for further evaluation and therapy and the murmur followed closely during therapy, although it is most likely a normal murmur. If the saturation by oximetry of an infant not in failure does not improve with oxygen, the patient may have methemoglobinemia (Fig. 33.1A [5]), either on a congenital basis or secondary to toxin. Co-oximetry studies of blood gases should be done (see Chapter 88).

Infants Less Than 3 Years of Age Who Are Not Cyanotic (Fig. 33.1B)

Infants younger than 3 years old who are not cyanotic should be evaluated carefully, looking for the abnormalities as outlined previously under “Examination.”

If the baby has a negative physical examination and appears well, except for the murmur (Fig. 33.1B [1]), the murmur may represent a congenital cardiac defect that is physiologically insignificant at the time (small patent ductus, atrial or ventricular septal defect, mild aortic or pulmonary stenosis, partial anomalous pulmonary venous drainage) or a normal murmur. These children can be followed by the primary care physician. If doubt exists about the infant's status because of the intensity or transmission of the murmur, an ECG and chest film should be ordered; if normal, they confirm the above impression. Peripheral pulmonary stenosis, related to angulation of the distal pulmonary arteries, is a common cause of normal murmurs in neonates; this murmur transmits well to the back, may be quite loud, and in time, will not be discernible.

If the ECG shows abnormal atrial or ventricular hypertrophy and the chest film shows cardiac enlargement or abnormal pulmonary vasculature, a more serious degree of the same acyanotic defects, or possibly an acyanotic Tetralogy of Fallot, is likely, and nonemergent referral to a cardiologist is warranted (Fig. 33.1B [2]).

If the acyanotic baby with a murmur appears ill, an ECG and chest film are obtained. If these are normal, the murmur is most likely inconsequential, and the baby should be evaluated for an underlying medical or surgical illness related to the presenting complaints at this visit (Fig. 33.1B [3]). It is important to think of noncardiac conditions, such as severe anemia or hyperpyrexia, as causes of the murmur.

If the infant has signs suggesting cardiac failure, ECG findings of marked ventricular hypertrophy or tall, pointed P waves might be indicative of a severe acyanotic congenital cardiac defect (large ventricular septal defect, large patent ductus, severe aortic or pulmonary stenosis) (Fig. 33.1B [4]).

A baby in failure with only T-wave or ST-segment changes on ECG may have viral myocarditis, primary myocardial disease, or an extracardiac problem that causes high cardiac output (severe anemia, large arteriovenous malformation). Some of these babies, although not cyanotic on the basis of their underlying lesion, may show a degree of cyanosis with diminished saturation on pulse oximetry because of the hypoperfusion related to cardiac failure. All such babies need admission or transfer to a tertiary pediatric center for emergency evaluation and treatment (Fig. 33.1B[5]).

If the chest film or ECG is not normal and the baby appears ill but does not have signs that suggest CHF, a primary pulmonary disease should be considered, with the murmur being either a normal one or representing a milder acyanotic defect (Fig.33.1B[6]). Admission for therapy and further evaluation is appropriate.

Children 3 Years and Older

The assessment and disposition of an older child in whom a murmur is discovered is somewhat less of a challenge to the emergency physician. The child is more cooperative and generally more interactive than the infant, and as a result, the sometimes subtle evaluation of the child's state of well-being is less uncertain. The heart rate normally is slower, allowing

easier dissection of the murmur.

By the time children who live in geographic areas in which modern medical care is available reach 3 years of age, most congenital lesions have been discovered and many have been surgically repaired. Acquired cardiac and noncardiac illnesses, therefore, play a more prominent role in assessment. Still, some congenital lesions go unrecognized, some do not require surgery, and others that require surgery have not had access because of economic or social reasons.

Normal murmurs are by far the most common ones discovered at a first encounter with an older child. Table 33.2 describes the characteristics generally associated with a normal murmur. If the examining physician is satisfied that the murmur is a normal one and the child has no other symptoms referable to the cardiovascular system, cardiac consultation is neither necessary nor advisable. Still, it often is difficult to distinguish a normal murmur from the murmur of such intracardiac lesions as small atrial or ventricular defects or mild aortic or pulmonic stenosis; the management guidelines outlined in this chapter obviate the need for the emergency physician to be concerned about such a differential. For the purposes of the ED evaluation, it is important to determine only whether the patient is in difficulty or needs further evaluation. Again, the presence or absence of cyanosis is the lead finding.

Timing: midsystole
Intensity: grades I through IV
Location of maximal intensity: midsternal border
Radiation: possibly to the precordium and neck, but not the back
Quality: "twangy" or "vibratory"
Heart Sounds: readily definable, including splitting of S_2

Table 33.2. Characteristics Usually Associated with a “Normal” Murmur

Children 3 Years of Age and Over Who Are Not Cyanotic (Fig. 33.2A and Fig. 33.2B)

The acyanotic child with a murmur who seems essentially well (Fig. 33.2A [1]) and has a negative physical examination other than the precordial finding most likely has a normal murmur but may have a mild acyanotic congenital defect, a healed rheumatic carditis, or a mitral valve prolapse. The femoral artery pulsations should always be palpated for the possibility of coarctation of the distal aorta. In mitral valve prolapse, a midsystolic “click” is a more constant finding than the murmur, which follows the click and is quite variable. These children should be followed by the primary care physician. If in doubt because of the intensity or transmission of the murmur, an ECG and chest film should be ordered. If these are normal, one has further assurance that primary care follow-up is all that is necessary. If these are abnormal, there is concern about the possibility of a more severe acyanotic defect or moderately severe healed rheumatic carditis (Fig. 33.2A [2]). Referral should be made to a cardiologist on a nonemergency basis for further differentiation.

In evaluating the acyanotic child who appears acutely ill and has a murmur (Fig. 33.2B [1]), a careful history should be taken regarding prior or recent antecedent illness, including a significant sore throat or “viral” illness. If there is such a history, the possibility of swollen, red, and tender joints should be sought. If these are present, the child is febrile, and an ECG is abnormal, the child should be hospitalized to be evaluated for the possibility of acute rheumatic fever (see Chapter 82). On the other hand, the acyanotic ill child with objective joint findings but a normal ECG is more likely to have a normal murmur with a concurrent arthriticlike illness, such as Henoch-Schönlein purpura (HSP), juvenile rheumatoid arthritis, or septic arthritis (Fig. 33.2B [2]). These children need diagnostic evaluation of their acute illness and follow-up of the murmur.

The ill-appearing acyanotic child who has a murmur and a history of known chronic or recent antecedent illness but has no objective joint findings should have an ECG and a chest film taken. If the ECG shows ST-segment and T-wave abnormality and if the heart is enlarged, the patient probably has myocarditis, with the murmur resulting from turbulence created by ventricular dilation and atrioventricular valve insufficiency (Fig.33.2B [3]). The cause could be viral, collagen vascular, toxic, or endocrine (see Chapter 82, Chapter 97 and Chapter 101). These children must be admitted for evaluation and therapy.

The ill-appearing acyanotic child who has a murmur but no chronic or recent antecedent illness and who shows signs of CHF may have severe acyanotic heart disease, myocarditis, or high-output failure secondary to severe anemia, large arteriovenous malformation, or thyrotoxicosis (Fig. 33.2B [4]).

Whether in congestive failure or not, the ill-appearing child with a murmur and fever should be examined carefully for splenomegaly and petechiae on the skin surface, on the conjunctivae, and under the nailbeds. If these are found, although the murmur could represent the entire list of cardiac diseases, the important immediate concern is that of infectious endocarditis (Fig. 33.2B [5]). The child should be admitted for evaluation, cardiac consultation, and echocardiography (see Chapter 82).

If the patient with a murmur and petechiae is not showing signs of failure, the murmur may be normal or represent a mild acyanotic defect. In addition to infectious endocarditis, consideration must be given to other conditions manifested with petechiae, such as meningococcemia, idiopathic thrombocytopenic purpura (ITP), HSP, and rickettsial infection (Fig. 33.2B [6]). Blood cultures should be drawn, appropriate emergency treatment initiated, and the child admitted for further

evaluation and treatment.

If the acyanotic ill-appearing child with a murmur is not in failure, has no splenomegaly or petechiae, and had a normal ECG, the murmur is most likely normal or associated with the high cardiac output of hyperpyrexia or anemia (Fig. 33.2B [7]). These children should be evaluated for their underlying condition.

Children 3 Years and Older Who Are Cyanotic (Fig. 33.2C)

As with infants, cyanotic older children with murmurs should have an ECG, chest film, pulse oximetry, and possibly, arterial gases after a careful history and complete physical examination. If a patient is tested with these and the results are normal, except for the cyanosis and murmur, the child probably has a noncardiac cause of the cyanosis (polycythemia) (Fig. 33.2C [1]). The murmur may be normal or associated with a coincidental acyanotic congenital defect. The primary condition should be investigated.

The cyanotic child who is not acutely ill but has an abnormal ECG, chest film, and pulse oximetry has cyanotic heart disease that possibly could be improved surgically (Fig.33.2C [2]). The child should be referred to a cardiologist on an nonemergent basis for further evaluation, including echocardiography.

If the cyanotic child appears acutely ill and has signs of CHF, severe cardiac disease is present (Fig. 33.2C [3]). The causes could include a decompensating congenital cyanotic cardiac defect, in which case the cyanosis would be intense (Table 33.1), or failure secondary to acquired disease, in which the cyanosis is related to hypoperfusion and usually less intense. These children need to be admitted for therapy and evaluation.

Whether or not there are signs of congestive failure in the cyanotic child with a murmur, if there is fever, splenomegaly, and/or petechiae on the skin, on the conjunctivae, or under the nailbeds, blood cultures should be drawn for the likelihood of infective endocarditis (Fig. 33.2C [4]). If the child is not in failure and petechiae are found, infective endocarditis is still a possibility but other noncardiac causes of petechial presentations must be considered (meningococcemia, Valsalva maneuvers, ITP, HSP). Blood cultures should be drawn and the child admitted.

A careful neurologic examination should be part of the evaluation of every ill child with cyanotic heart disease. If findings are abnormal, consideration has to be given to the complications of hypoxemic “spells,” cerebrovascular accident, or if febrile, brain abscess (Fig. 33.2C [5]).

If the ill cyanotic child with a murmur and abnormal chest film shows significant improvement of oxygen saturation with supplemental oxygen, the child most likely has primary pulmonary disease. The ECG abnormality, if there is one, would most likely consist of tall, pointed P waves and evidence of right ventricular hypertrophy (Fig. 33.2C [6]). These children need admission for evaluation and therapy.

In the cyanotic child with a murmur who has a normal ECG and chest film, abnormal pulse oximetry, but normal arterial PO_2, the possibility must be considered of acute toxin-induced methemoglobinemia, with the murmur being normal or representing a mild acyanotic defect (Fig. 33.2C [1,7]).

SUMMARY

This chapter has provided clinical guidelines for the initial assessment and disposition of infants and children in whom a murmur is discovered during the first visit. Although diagnoses have been listed and suggested for most of the legs of the decision paths, it has also been shown that definitive diagnosis of the underlying lesion is not the primary aim of ED evaluation; careful assessment of the patient and safe disposition are required at first encounter. Particularly in older children, many readers probably can do considerably more dissection of the characteristics of the murmur and heart sounds and can arrive at more specific cardiac diagnoses than have been used in the evaluation approach described in this chapter. This process can be augmented, if desired, by supervised practice, by careful use of the references, and by judicious cardiac consultation.

CHAPTER 34

Hematuria

ERICA L. LIEBELT, MD

Department of Pediatrics, Johns Hopkins School of Medicine, and Pediatric Emergency Medicine, Johns Hopkins Hospital, Baltimore, Maryland

Hematuria, the presence of red blood cells (RBCs) in the urine, is a common presenting complaint in the emergency department (ED). Disease processes manifested by gross hematuria or other symptoms such as acute onset of edema, headache, and hypertension are the context in which hematuria requires urgent/emergent evaluation in the ED. Microscopic hematuria may be accompanied by other signs and symptoms or may be completely asymptomatic; it can usually be evaluated in the outpatient setting. Red or brown urine does not always indicate hematuria. Several foods, substances, and drugs may color the urine; therefore, it is important to document the presence of blood in the urine. Reagent strips (based on the peroxidase reaction with hemoglobin) can be used as the initial screening test for hematuria. Heme-positive reagent strips must be confirmed by microscopic examination for the presence of RBCs because both hemoglobinuria and myoglobinuria can cause a positive reaction in the absence of RBCs. The presence of 5 to 10 or more RBCs per high-power field (RBC/HPF) is abnormal and warrants further workup. The evaluation of a child with hematuria must take into consideration the clinical presentation, patient and family histories, physical examination, and complete urinalysis so that a logical, orderly, and cost-effective approach can be undertaken.

PATHOPHYSIOLOGY

Red cells can be added to the urine at any point along the urinary tract—from the glomerulus, through the tubule, or through the collecting system, the ureter, the bladder, or the urethra. The pathophysiology of hematuria can be explained by categorizing it as either glomerular or nonglomerular. Immune-mediated inflammatory damage to the glomerular filtration surface, as seen in postinfectious nephritis, causes disruption of the glomerular basement membrane with subsequent leakage of red cells and protein. Glomerular bleeding that results in gross hematuria may be brown, smoky, or cola- or tea-colored as a result of the acidic urine changing the hemoglobin to hematin. Red cells may become enmeshed in the protein matrix to form RBC casts, a sensitive indicator of glomerular hematuria. The renal papillae are sites of nonglomerular bleeding that are susceptible to microthrombi and anoxia in patients with sickle cell disease or trait. Inflammation of the tubules and interstitium caused by antibiotics can result in hematuria, proteinuria, and eosinophiluria. Nonsteroidal agents can produce hematuria from both tubulointerstitial nephritis and inhibition of prostaglandin synthesis. Grossly bloody urine that is bright red or pink with or without clots is more likely to be originating from the lower urinary tract, usually the bladder or urethra. Hematuria from trauma to the kidney or bladder is caused by contusions, hematomas, or lacerations anywhere along the tract. Increased vascularity from infection or chemical irritation can lead to leakage of RBCs into the urine. Exercise-related hematuria results from ischemic injury as well as direct trauma. Benign familial hematuria, a principal cause of asymptomatic hematuria, is caused by leakage of RBCs through a thin glomerular basement membrane and rarely comes to the attention of the emergency physician except as an incidental finding.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of hematuria is vast and can be categorized based on whether the site of bleeding is within the urinary system (glomerular, extraglomerular) or secondary to a systemic process (Table 34.1). The most common causes of hematuria (Table 34.2) are urinary tract infection (either cystitis or pyelonephritis), acute poststreptococcal glomerulonephritis, and trauma, the latter two also being the most common of the potentially life-threatening causes. Other potentially serious causes of hematuria (Table 34.3) include hematologic disorders, renal stones with obstruction, tumors, and hemolytic uremic syndrome (HUS). Other glomerular causes of hematuria that are primary renal diseases include nonstreptococcal postinfectious glomerulonephritides, membranous glomerulonephritis, immunoglobulin A (IgA) nephropathy, and Alport's syndrome (hereditary nephritis). Hematuria as a manifestation of a systemic condition is most commonly seen in children with vasculitides such as Henoch-Schöonlein purpura, systemic lupus erythematosus (SLE), and polyarteritis nodosa.

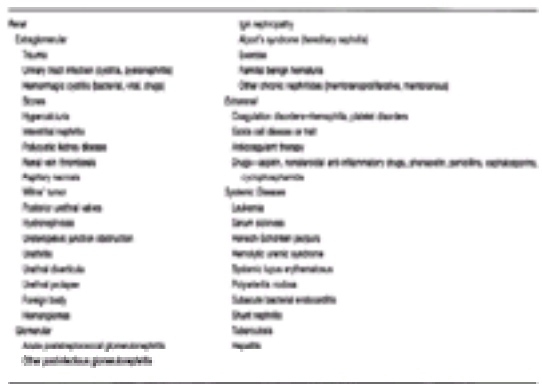

Table 34.1. Principal Causes of Hematuria in Children

Urinary tract infection—cystitis, pyelonephritis	Interstitial nephritis
Trauma (kidney, bladder, urethra)	Benign hematuria
Acute poststreptococcal glomerulonephritis	Urethritis
Sickle cell disease or trait	

Table 34.2. Common Causes of Hematuria

Trauma (kidney, bladder)	Tumor
Acute glomerulonephritis	Hematologic disorders
Hemolytic uremic syndrome	Toxins
Renal stones with obstruction	

Table 34.3. Life-Threatening Causes of Hematuria

Extraglomerular causes of hematuria include congenital anomalies such as diverticula of the urethra and bladder; hemangiomas in the bladder; cysts of the kidneys, as in polycystic or multicystic kidney; and obstruction of the ureteropelvic junction. In addition to congenital anomalies, renal vein thrombosis secondary to a coagulation disorder or to placement of an umbilical catheter is a cause of hematuria in the neonate. Wilms' tumor is a common childhood solid tumor associated with hematuria in 12 to 25% of the cases. Nephrolithiasis should be considered if there is a family history or a predisposing condition such as recurrent infection, bladder dysfunction (seen in myelomeningocele), or chronic diuretic therapy (as seen in infants with bronchopulmonary dysplasia). Hypercalciuria and cystinuria are metabolic diseases that also predispose patients to renal stones and hematuria. Finally, urethral prolapse, seen most commonly in girls 2 to 4 years of age, may present with vaginal bleeding that can contaminate a collected urine specimen and be misinterpreted as hematuria.

EVALUATION AND DECISION

The initial evaluation of hematuria must begin with confirmation of blood in the urine. Further investigation of the cause and treatment includes detailed patient and family histories, careful physical examination, and microscopic urinalysis (which lends information to probable causes and helps determine the site of bleeding within the urinary tract system). A specific diagnosis may or may not be made in the ED, and the patient may require further diagnostic testing. The most important role for the emergency physician in evaluating a child with hematuria is to identify serious, treatable, and progressive conditions such as trauma, nephritis associated with hypertension, bleeding disorders, and infection.

Blood in the urine may come from sources outside the urinary tract. Vaginal hemorrhage in the female secondary to infection, foreign body, or trauma (sometimes secondary to abuse) may contaminate the urine. In addition, parents may report finding blood in the urine when, in fact, a rectal fissure has caused a small hemorrhage, producing a mixture of blood and urine in the diaper or underwear. In prepubertal girls, urethral prolapse may present with vaginal bleeding, which may be confused with hematuria.

Urine dipsticks positive for blood require microscopic examination of the urine. Hemoglobinuria from hemolysis and

myoglobinuria from rhabdomyolysis will cause a positive dipstick reaction for blood and an absence of RBCs on urine microscopy. Many dyes, drugs, and pigments will change the urine color to pink, red, brown, or black but will not result in a positive dipstick test for blood. A partial list includes beets, blackberries, urates, aniline dyes, bile pigments, porphyrin, diphenylhydantoin, phenazopyridine (Pyridium), rifampin, deferoxamine, phenolphthalein, ibuprofen, methyldopa, chloroquine, homogentisic acid, and *Serratia marcescens* infection.

The history taking for infants and neonates with hematuria should include questions about umbilical vessel catheters (renal venous or arterial thrombosis), passage of clots on voiding (hemorrhagic disorders), abdominal swelling or palpable mass (tumor, polycystic disease, ureteropelvic junction obstruction, posterior urethral valves), and significant birth asphyxia (corticomedullary necrosis). Dysuria or frequency in children and adolescents suggests cystitis, whereas flank, abdominal, or back pain suggests trauma, genitourinary infection, or stones as the cause. Sore throat, upper respiratory infection, or pyoderma (preceding or appearing concurrently with the onset of hematuria) points to acute postinfectious glomerulonephritis, streptococcus being the most common bacterial cause. A history of gross hematuria with a concomitant viral upper respiratory or gastrointestinal infection may also suggest IgA nephropathy. Hematuria associated with systemic disorders may be uncovered by eliciting a history of skin rashes and arthralgia or arthritis as seen in Henoch-Schönlein purpura and SLE. Both sickle cell anemia and sickle cell trait are associated with chronic, asymptomatic gross hematuria. Finally, a history of drug use, especially use of the penicillins and cephalosporins, may point to interstitial nephritis as the cause. Antibiotic-associated tubulointerstitial nephritis is associated with high-dose, long-term antibiotic therapy and is characterized clinically by fever, rash, eosinophilia with pyuria, eosinophiluria, hematuria, proteinuria, and nonoliguric renal failure. Family history of renal stones, deafness, nephritis, renal anomalies, or hematologic disease may suggest a diagnosis in the child such as Alport's syndrome (hereditary nephritis), sickle cell anemia, or hemophilia.

Physical examination of a child with hematuria should always include a blood pressure measurement. Hypertension may accompany glomerulonephritis, obstructive uropathy, Wilms' tumor, polycystic kidney, or vascular disease. Periorbital edema and facial swelling may be the first physical sign of nephritis. Urethral prolapse presents as a doughnut-shaped mass at the site of the urethral meatus, which is usually hyperemic and friable with scant bloody drainage.

Bruising of the abdomen, flank, or back should raise suspicion of trauma, including child abuse, as a cause of hematuria. Tenderness of the flank or lower abdomen may signal pyelonephritis, obstructed kidney, or lower urinary tract infection. Flank or abdominal masses suggest Wilms' tumor or hydronephrosis, hydroureter, or polycystic kidney. Petechial or purpuric lesions on the skin and arthritis may accompany hematuria seen in vasculitic syndromes such as Henoch-Schönlein purpura, HUS, and SLE. Pallor may be a sign of anemia from chronic renal insufficiency, HUS, hemoglobinopathy, leukemia, or tumors.

A careful, detailed urinalysis plays an essential role in the evaluation of the child with hematuria. Several clues in the urinalysis can help localize the site of hematuria. RBC casts, cellular casts, tubular cells, tea-colored or smoky-brown urine, and proteinuria 2+ or greater by dipstick all point to glomerular bleeding. In addition, the presence of dysmorphic RBCs and/or acanthocytes (ring-formed RBCs with one or more protrusions of different shapes and sizes) as well as measurement of the mean volume of urine erythrocytes using a Coulter counter have been used as markers of glomerular bleeding (erythrocyte volume less than 50 μm^3). In contrast, nonglomerular bleeding is suggested by red or pink urine, blood clots, no proteinuria (or less than 2+ in the absence of gross hematuria), and normal morphology of erythrocytes. Calcium oxalate crystals may be seen in the urine of patients with renal stones.

Other blood studies may be useful in selected cases and include a complete blood count (CBC), prothrombin time (PT), partial thromboplastin time (PTT), erythrocyte sedimentation rate (ESR), blood urea nitrogen (BUN), serum creatinine, complement levels (C3 and C4), and streptococcal serologies (antistreptolysin O, anti-DNase-B, and antihyaluronidase titers). The history and physical examination should direct the emergency physician to those additional tests that are needed, if any. Most patients, other than those with isolated microscopic hematuria or lower urinary tract infection, will require at least a CBC as part of their evaluation.

A clinical algorithm for evaluating hematuria in the ED is shown in Figure 34.1. The first step is to confirm the presence of true hematuria. If a traumatic cause for the hematuria is suspected based on history or physical findings, emergent evaluation for serious anatomic lesions must be initiated. Parenchymal contusions, lacerations, renal transections, and pedicle disruptions are possible injuries. Hematuria is the cardinal marker of renal injury, with the severity paralleling the magnitude of the injury (except for renal pedicle injuries, which may have no associated hematuria). Microscopic hematuria greater than 20 to 50 RBC/HPF, gross hematuria, or history of significant mechanism of injury to the flank or abdomen necessitates emergent imaging. Hematuria disproportionate to the injury may indicate a congenital renal anomaly or tumor.

FIGURE 34.1. Approach to hematuria in the emergency department.

If there is no history of trauma, coagulopathies should be considered as a cause. However, the medical history alone usually will point to this cause because the sudden occurrence of isolated hematuria in a previously healthy child is unlikely with either a congenital or acquired bleeding disorder. Hematuria in a child known to have hemophilia or a related disorder often requires minimal investigation and is managed in accordance with standard protocols. If an acquired coagulopathy is suspected, a CBC with platelet count, PT, and PTT is warranted.

If trauma and coagulopathies are considered unlikely, identifying the site of bleeding as either glomerular or nonglomerular (based on urinalysis and other signs or symptoms) can direct further evaluation and diagnosis. Acute glomerulonephritis characterized by hypertension, edema, RBC casts, proteinuria, and tea-colored urine most often follows a streptococcal infection and merits serious consideration in the ED because it may cause significant hypertension and pulmonary edema requiring immediate intervention. HUS is a serious disorder that may present with glomerular-induced hematuria and proteinuria as well as a characteristic microangiopathic hemolytic anemia, thrombocytopenia, and renal failure. Laboratory studies useful in children suspected of having nephritis include a CBC, ESR, BUN, serum creatinine, complement levels, and antistreptococcal antibodies. Other nephritides may be associated with vasculitis (Henoch-Schönlein purpura, SLE, periarteritis nodosa, Wegener's granulomatosis) and may require further diagnostic evaluation before a specific diagnosis is made.

Most children without a history of trauma who are evaluated for gross and/or microscopic hematuria in the ED have a urinary tract infection (UTI). The infection may either be in the upper tract (e.g., pyelonephritis, characterized by fever, chills, flank pain, vomiting, and dysuria) or lower tract (e.g., cystitis, characterized by dysuria, frequency, and occasionally, abdominal pain and fever). The cause of UTI is either bacterial or viral. Acute hemorrhagic cystitis is often associated with adenovirus. The findings of pyuria and bacteriuria on urinalysis suggest an infectious cause, although their absence does not exclude either pyelonephritis or cystitis; thus, a urine culture is essential if no other cause has been uncovered. If the clinical suspicion is high for a bacterial UTI, presumptive antimicrobial treatment should be initiated.

Severe flank pain radiating to the groin is characteristic of renal colic from calculi, which may present with either gross or microscopic hematuria. Stones may occur in children with metabolic abnormalities or stasis secondary to obstruction and in premature infants taking furosemide, especially those with bronchopulmonary dysplasia. Crystals may be seen on urinalysis; further investigation with intravenous pyelography, renal ultrasound, or spiral computed tomography (CT) usually confirms stones if a plain abdominal radiograph does not reveal the presence of radiopaque material. Hypercalciuria is an important cause of hematuria in children and may be idiopathic or secondary to another disease and can lead to nephrocalcinosis.

Hematuria that persists after the previously mentioned causes have been ruled out or deemed unlikely based on history and physical examination usually does not require further evaluation in the ED and should be pursued by the primary health care provider, possibly in collaboration with a pediatric nephrologist. These additional causes are listed in Figure 34.1 and Table 34.1 and may require more extensive imaging, intervention such as renal biopsy, metabolic studies, or serial urinalyses (benign hematuria, exercise-induced hematuria).

CHAPTER 35

Hypertension

JAMES G. LINAKIS, MD, PhD

Department of Pediatrics, Brown University School of Medicine, and Pediatric Emergency Medicine, Hasbro Children's Hospital, Rhode Island Hospital, Providence, Rhode Island

Until recently, hypertension was considered predominantly a disorder of adulthood. Although there are currently no universally accepted standards for determining whether a child should be classified as hypertensive, the most commonly used definition of hypertension is a systolic, diastolic, or mean arterial pressure that is above the 95th percentile for age. Children with excessive height or lean body mass for age may not be included in this definition. Beyond this specific definition of hypertension, however, the nomenclature is often confusing because several other terms have been used with varying meanings, including *hypertensive crisis, malignant hypertension,* and *accelerated hypertension.* The Second Task Force on Blood Pressure Control in Children divided hypertension into two distinct classes: *significant (moderate) hypertension* was defined as blood pressure measurements persistently between the 95th and 99th percentiles for age and sex, and *severe hypertension* was defined as blood pressure measurements persistently at or above the 99th percentile for age and sex (Table 35.1). For the sake of the present discussion, the classification system of The Second Task Force can be expanded to include two additional terms. *Hypertensive urgency* is a severely elevated blood pressure that may be potentially harmful but is without evidence of end-organ damage or dysfunction. For the purposes of evaluation and treatment, blood pressure measurements at or above “severe” levels should be considered a hypertensive urgency even in the absence of symptoms. *Hypertensive emergency* describes a situation in which elevated blood pressure is associated with evidence of secondary organ damage such as hypertensive encephalopathy or acute left ventricular failure. It is important to note that these definitions do not rely solely on a particular level of blood pressure, but they also rely on the effect of an elevated blood pressure (usually markedly elevated) on end organs. Hypertensive urgencies ordinarily develop over days to weeks, whereas hypertensive emergencies generally develop within hours. Hypertensive emergencies are more commonly seen in individuals with poorly controlled chronic hypertension. In previously normotensive individuals, however, a hypertensive emergency may be the result of such factors as head trauma, drug ingestion, acute glomerulonephritis, toxemia, or pheochromocytoma.

Age Group	Significant Hypertension (mm Hg)*	Severe Hypertension (mm Hg)*
Newborn–7 days	Systolic BP ≥96	Systolic BP ≥106
8–30 days	Systolic BP ≥104	Systolic BP ≥110
Infant (<2 yr)	Systolic BP ≥110 Diastolic BP ≥63	Systolic BP ≥118 Diastolic BP ≥82
Children (2–5 yr)	Systolic BP ≥116 Diastolic BP ≥74	Systolic BP ≥124 Diastolic BP ≥84
Children (6–9 yr)	Systolic BP ≥121 Diastolic BP ≥81	Systolic BP ≥130 Diastolic BP ≥86
Children (10–12 yr)	Systolic BP ≥127 Diastolic BP ≥83	Systolic BP ≥134 Diastolic BP ≥90
Adolescents (13–15 yr)	Systolic BP ≥135 Diastolic BP ≥86	Systolic BP ≥144 Diastolic BP ≥92
Adolescents (16–18 yr)	Systolic BP ≥142 Diastolic BP ≥92	Systolic BP ≥150 Diastolic BP ≥98

Adapted with permission from the Task Force on Blood Pressure Control in Children. Report of the second task force on blood pressure control in children—1987. Pediatrics 1987;79:1–25.
BP, blood pressure.

Table 35.1. Classification of Hypertension by Age Group

Appropriate blood pressure cuff size is essential for accurate measurement of blood pressure. The inflatable rubber bladder should be long enough to completely encircle the circumference of the arm (overlap is acceptable). Bladder width should be approximately 40% of arm circumference at a point halfway between the acromion and the olecranon. A narrow cuff can produce falsely elevated readings. Sphygmomanometer measurements are difficult to perform in neonates, and blood pressure determinations are more reliably performed with oscillometric or Doppler devices. In older children, however, abnormal oscillometric readings should be verified manually with a sphygmomanometer. Current guidelines recommend that the fifth Korotkoff sound be used to define diastolic blood pressure in children, adolescents, and adults.

Ideally, repeated measures should be recorded over a series of visits before a diagnosis of hypertension is made. However, in the emergency department (ED) setting, the child with an initial moderate or severe hypertensive reading should have blood pressure measurements redone after a brief period of quiet rest. If the second reading remains mildly or moderately elevated and the child is asymptomatic with no evidence of end-organ compromise, outpatient follow-up is required. The child with evidence of hypertensive urgency or emergency, on the other hand, demands immediate attention.

PATHOPHYSIOLOGY/DIFFERENTIAL DIAGNOSIS

Hypertension is not a disease itself but rather the result of one or more pathologic processes. In many instances, the nature of the pathologic processes can be determined. Often, however, a specific cause for childhood hypertension cannot be identified, even after a comprehensive workup. In that case, the elevated blood pressure is called essential or primary hypertension. In fact, it has been suggested that for the general pediatric population, the incidence of essential hypertension is similar to that of the adult population. Although most cases of hypertension are considered essential, a number of other causes largely depend on age (Table 35.2). In newborn infants, for example, the most common causes of hypertension are renal artery thrombosis or stenosis, coarctation of the aorta, congenital renal malformations, and bronchopulmonary dysplasia. In children under the age of 6 years, coarctation of the aorta, renal parenchymal diseases, and renal artery stenosis remain the most common causes. Children between 6 and 10 years of age may have renal artery stenosis and renal parenchymal disease as the source of severe hypertension, although essential hypertension is the leading cause of moderate hypertension in this age group. In older children, although essential hypertension is the more common diagnosis, hypertension may be the result of renal parenchymal disease (Table 35.3). In adolescent girls, oral contraceptive pills may be a cause of hypertension, and in all age groups, drug- or toxin-induced hypertension should be considered. Life-threatening causes of hypertension (Table 35.4) are relatively uncommon in the pediatric age group and most often represent a severe presentation of the common causes.

Table 35.2. Complete Differential Diagnosis of Hypertension

Age Group	Cause
Newborn infants	Renal artery thrombosis, renal artery stenosis, congenital renal malformations, coarctation of the aorta, bronchopulmonary dysplasia
Infancy–6 yr	Renal parenchymal diseases,* coarctation of the aorta, renal artery stenosis
6–10 yr	Essential hypertension (including obesity), renal artery stenosis, renal parenchymal diseases
Adolescence	Essential hypertension (including obesity), renal parenchymal diseases

Adapted with permission from the Task Force on Blood Pressure Control in Children. Report of the second task force on blood pressure control in children—1987. Pediatrics 1987;79:1–25.
*Includes renal structural and inflammatory lesions, as well as tumors.

Table 35.3. Common Causes of Hypertension

Age Group	Cause
Infancy	Coarctation of the aorta, valvular insufficiency, congenital adrenal hyperplasia, renal vascular disease, renal parenchymal disease
Childhood	Renal parenchymal disease, renal vascular disease, coarctation of the aorta, pheochromocytoma, increased intracranial pressure, bacterial endocarditis, drug-induced/toxicologic
Adolescence	Renal parenchymal disease, pheochromocytoma, toxemia of pregnancy, drug-induced/toxicologic

*Any increase in blood pressure that is sufficiently acute or elevated to cause systemic symptoms should be considered life-threatening.

Table 35.4. Selected Life-Threatening Causes of Hypertension [a]

EVALUATION AND DECISION

The extent of ED assessment of the child with hypertension depends on the level of blood pressure and the clinical signs and symptoms of the child at presentation. The asymptomatic child with incidental, newly diagnosed mild or moderate hypertension (“significant” in Table 35.1) generally requires a brief but thorough history and physical examination with emphasis on detecting pathophysiologic risk factors for hypertension and signs and symptoms of the complications of chronic hypertension. Barring the discovery of any of these, the child should be referred for follow-up and further

evaluation with his or her primary care physician. The emergency physician in this circumstance should not institute outpatient treatment. In fact, although it is appropriate to initiate the process of patient education in the ED regarding such factors as weight loss, salt reduction, and exercise, a definitive diagnosis of hypertension should not be offered until the child has had repeated measurements of his or her blood pressure on several occasions.

The workup of a child with severe hypertension requires careful evaluation for the presence of clinical findings that may represent either the primary cause of the elevated blood pressure or the secondary, systemic effects. Relevant history includes frequent urinary tract infections, unexplained fevers, hematuria, dysuria, frequency, and edema—all suggestive of possible renal disease. A history of umbilical artery catheterization as a neonate may indicate risk of renal artery stenosis. Ingestion of prescription, over-the-counter, or illicit drugs may support the diagnosis of drug-induced hypertension. Alternatively, a history of sweating, flushing, palpitations, fever, and weight loss may indicate a pheochromocytoma.

Physical examination should concentrate on identifying involved organ systems. Thus, the cardiac examination should inspect for evidence of congestive heart failure (CHF) and pulmonary edema. Femoral pulses should be palpated because their absence suggests aortic coarctation. Neurologic evaluation should include funduscopic examination for such hypertensive changes as hemorrhages, infarcts, and disc edema. In addition, testing of the pupillary light reflex and visual acuity, and observation for sensorimotor symmetry should be included. Abdominal examination may reveal the presence of a bruit or palpable kidneys, implicating a renovascular or renal cause for the hypertension.

Ancillary investigations depend on the severity of the child's hypertension. In the child with severe hypertension, a number of laboratory studies are appropriate. Complete blood count, electrolytes, blood urea nitrogen, serum creatinine, and uric acid and urinalysis are warranted in the asymptomatic child with severe hypertension. In addition, urine culture should be obtained in all girls and in boys with known renal pathologic conditions. In the child with hypertensive emergency, early intravenous access should also be established.

In symptomatic children with hypertension, further evaluation includes an electrocardiogram and chest radiograph. These tests help evaluate myocardial function and the extent of damage from hypertension, as well as the presence of CHF. Although several additional sophisticated and/or invasive studies exist for the evaluation of hypertension, these are rarely part of the routine ED assessment.

In some instances, the cause of hypertension is already known, as in a child with end-stage renal disease, or is immediately apparent, as in an adolescent who has used cocaine. When the cause is not readily identified, a systematic approach is indicated (Fig. 35.1). Because diseases of the genitourinary tract are among the more common sources for hypertension in children, a logical starting point is to ascertain whether the history suggests prior urinary infection, whether the physical examination identifies signs of renal disease (e.g., edema or an abdominal bruit of renal artery stenosis), or whether the urinalysis is abnormal. Of the cardiovascular causes, coarctation of the aorta is the most likely to manifest in a toddler or older child with previously undiagnosed hypertension. Physical examination in patients with this lesion is notable for femoral pulses that are absent or diminished compared with those in the upper extremities. When a careful evaluation of the renal and cardiovascular systems is not revealing, a detailed neurologic examination is in order because any condition accompanied by increased intracranial pressure may elevate the systemic blood pressure. The history and signs of head trauma (see Chapter 105) are usually obvious but may be occult when injuries in young children are not witnessed or are intentionally inflicted. The emergency physician should specifically examine the fundi for papilledema and ascertain the presence of ataxia or other focal neurologic findings. Although the endocrine disorders are relatively rare, careful history taking and a directed physical examination may identify temperature sensitivity, obesity, a goiter, abdominal striae, or abnormal pigmentation suggestive of hyperthyroidism or Cushing's syndrome. Intermittent headaches and flushing occur with pheochromocytoma. Finally, specific questioning about the ingestion of illicit drugs or other medications and a toxicologic screen are appropriate when no other cause for hypertension is apparent. A negative evaluation for a source of an elevation of blood pressure in the ED is compatible with, but not sufficient for, the diagnosis of essential hypertension. Follow-up is always indicated, usually accompanied by further testing in patients under the age of 10 years.

FIGURE 35.1. Diagnostic approach to acute hypertension in a previously healthy child. (See Fig. 35.2 for initial triage and stabilization for significant or severe hypertension.)

FIGURE 35.2. Approach to the initial ED triage and stabilization of the hypertensive child.

MANAGEMENT

The decision to treat a child with hypertension in the ED setting depends on the acuteness of the rise in blood pressure, the presence of symptoms, preexisting medical problems, and the extent of end-organ damage (Fig. 35.2).

For children with hypertensive emergencies (i.e., blood pressure associated with evidence of end-organ damage or dysfunction), treatment must be rapid and, at the same time, cautious. There is a compelling reason for this conservative approach. Under normal conditions, the cerebral vasculature autoregulates cerebral blood flow, maintaining flow at a relatively constant level despite variations in the blood pressure. Thus, as blood pressure rises, the cerebral vasculature constricts, and as blood pressure falls, the vasculature normally dilates. However, when blood pressure rises significantly higher than normal, the range of pressures over which cerebral autoregulation occurs shifts to higher values, particularly in those with chronic hypertension. Overaggressive lowering of these hypertensive values may bring the blood pressure below the “new” lower limit of autoregulation. At this point, vessels are maximally dilated and ischemia may occur, leading to neurologic deficits, including infarction of the optic nerve; thus, attention to vision and the pupillary reflex provides a means of monitoring for this problem. In most emergent cases, it is recommended that blood pressure be reduced gradually—generally by about 25% over several minutes to several hours, depending on the severity of the emergency. Management of hypertensive emergencies is discussed further in Chapter 86.

The choice of which drug to use in the ED treatment of a child with hypertensive crisis depends on the severity of the patient's hypertension, the patient's current medications, the suspected cause of the hypertension, and the organs involved. Thus, hypertension caused by a catecholamine-secreting tumor (pheochromocytoma) might best be controlled with an a-blocking agent such as phentolamine. On the other hand, if hypertension is associated with an intracerebral bleed, medications that cause an increase in cerebral blood flow, such as nifedipine and nicardipine, are best avoided.

In addition to treating the elevation in blood pressure, the child with complications of hypertension also may require treatment for the specific complications. Thus, the child with seizures or CHF often requires the standard treatment for those problems in addition to antihypertensive therapy. However, when other complications are thought to be secondary to severe hypertension, treatment of the hypertension should take precedence. Of course, attention to airway, breathing, and circulation are to be given priority over all other therapeutic interventions.

Specific Therapy

Generally, only children presenting with hypertension that falls into the categories of hypertensive emergency or hypertensive urgency require pharmacologic intercession in the ED. As mentioned, the medication used depends on a number of factors, including the treating physician's familiarity with the antihypertensive agents.

Hypertensive Emergencies

Children with hypertension and major end-organ abnormalities such as CHF, encephalopathy, or seizures require immediate blood pressure reduction. Careful attention to airway, breathing, and circulation is followed by establishment of vascular access and treatment with one of the following parenteral medications (Table 35.5).

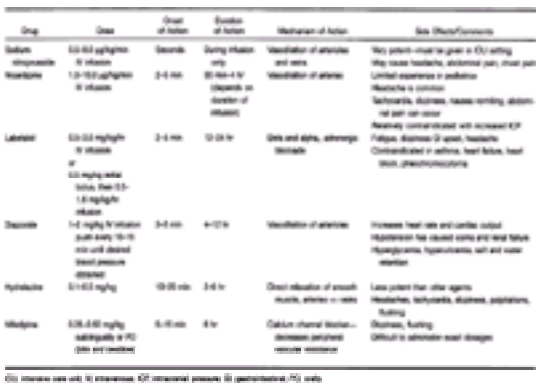

Table 35.5. Drugs Commonly Used for the Treatment of Hypertensive Emergencies in Children

Sodium Nitroprusside

Nitroprusside is a powerful vasodilator, affecting the smooth muscle of both the resistance and capacitance vessels. Its onset of action is almost immediate, and its duration of action is extremely short. Because of its venous dilatory effects, nitroprusside reduces preload, thus often improving cardiac output if CHF is present. Nitroprusside is metabolized to thiocyanate, and cyanide is an intermediary in its metabolism. Consequently, cyanide and thiocyanate toxicity must be considered a risk of its use, although the circumstances under which these develop have been poorly characterized.

Nitroprusside is given as an intravenous infusion, starting at a dosage of 0.5 mg/kg/min and increasing as needed to 8.0 µg/kg/min. The patient should be kept in the recumbent position because of the frequency of orthostatic hypotension. The degree of drop in blood pressure is dose-related; thus, the infusion should be started at the low end of the dosage range and titrated to achieve the desired blood pressure levels. The average dosage required for control of hypertension is approximately 3.0 µg/kg/min. Because nitroprusside has an extremely short half-life, blood pressure returns to pretreatment levels within 1 to 10 minutes of cessation of the infusion. Patients treated with nitroprusside should be admitted to an intensive care unit for blood pressure monitoring.

Nicardipine

Nicardipine is a calcium channel blocker that is effective in controlling elevated blood pressure when administered intravenously. It acts by reducing peripheral vascular resistance without reducing cardiac output. It has also been shown to diminish both cardiac and cerebral ischemia. Although there is relatively little literature on nicardipine dosing in children, recent studies suggest that an infusion rate of 1 to 10 µg/kg/min is effective. Because its onset of action is 2 to 5 minutes, the infusion can be started at the low end of this range and titrated upward. The half-life of nicardipine is approximately 40 minutes, although its duration of action after cessation of administration increases with duration of the infusion. Thus, nicardipine's effect on blood pressure generally diminishes within 30 minutes of discontinuing an infusion of less than 2 hours' duration, but its effect remains for up to 4 hours after discontinuing a 12- to 20-hour infusion. Excessive reductions in blood pressure, although uncommon, can be reversed by administration of calcium. *Experience with nicardipine in children is extremely limited; thus, this drug should be used with foremost caution.* Because it elevates intracranial pressure, nicardipine should generally be avoided in patients with increased intracranial pressure.

Labetalol

Labetalol is a combined a- and b-adrenergic blocking agent with a rapid onset of action (usually 5 to 10 minutes) when given intravenously. Because marked orthostatic hypotension can occur with its use, the patient should be kept in the supine position during and for some time after administration.

When administered for hypertensive emergencies, labetalol may be given as an initial minibolus of 0.5 mg/kg followed by a constant infusion of 0.5 to 1.5 mg/kg/hr, titrated to achieve the desired blood pressure. Alternatively, some prefer to give successive miniboluses of 0.3 to 1.0 mg/kg as often as every 10 to 15 minutes as needed. Others start with an infusion of 0.5 mg/kg/hr titrated slowly to a maximum of 3 mg/kg/hr. Labetalol can be somewhat difficult to titrate to effect; thus, it should be used with foremost caution. Because labetalol is a b blocker, it should not be used in patients with asthma, heart block, or CHF. It is also contraindicated for the treatment of hypertension secondary to pheochromocytoma.

Diazoxide

Diazoxide has a structural similarity to the thiazide diuretics but exerts its primary effect on arterial smooth muscle, causing vasodilation of mainly the resistance vessels. Although its rapid intravenous infusion rarely causes the blood pressure to drop below the normal range, there have been reported cases of coma and renal failure associated with hypotension after diazoxide infusion. Consequently, its use should be accompanied by careful monitoring.

Diazoxide has traditionally been given as a rapid bolus injection of 5 mg/kg per dose. However, less hypotension has been noted when the drug is given as frequent, small boluses of 1 to 2 mg/kg over 5 to 10 seconds every 10 to 15 minutes until the desired blood pressure is obtained. The effect of diazoxide is noted within 3 to 5 minutes, and its duration of action is generally between 4 and 12 hours.

Hypertensive Urgencies

The following drugs have less potency and/or a slower onset of action than those just discussed. As a result, they are more appropriate for hypertensive crises not accompanied by life-threatening manifestations.

Nifedipine

Nifedipine is a calcium channel blocker that can be given by the sublingual, oral, or rectal route. Recently, it has been shown to be effective for the treatment of hypertensive urgencies in children. It acts by decreasing peripheral vascular resistance.

Nifedipine is administered sublingually in a dose of 0.25 to 0.5 mg/kg (up to a maximum of 20 mg). Alternatively—perhaps preferably—the capsule can be chewed and swallowed. Onset of action is within 5 to 15 minutes; duration of action is approximately 6 hours. Facial flushing is a common side effect of nifedipine administration.

Hydralazine

Hydralazine is an arteriolar vasodilator that can be given intramuscularly but has even faster onset of action when given intravenously (10 to 20 minutes). Because hydralazine is less potent than several of the other parenteral antihypertensives, it may not be the drug of choice when life-threatening signs or symptoms are evident.

Hydralazine is given at a starting dose of 0.1 mg/kg intravenously and may be increased to 0.5 mg/kg. Its duration of action is 3 to 6 hours. Reflex tachycardia is a relatively common side effect and often necessitates the addition of a b-adrenergic blocking agent.

Other Agents

Several other agents have been used in the treatment of hypertension in children, including trimethaphan, minoxidil, methyldopa, reserpine, and clonidine. Because these agents often take considerably more time to lower blood pressure than those previously discussed and have a more serious profile of side effects, they are generally not considered the best choice for management of hypertensive emergencies.

SUMMARY

It is not unusual that a child presenting to the ED will be found to have an elevation in blood pressure. In many such cases, the blood pressure will normalize with rest or acclimation to the environment. Occasionally, however, the elevation in blood pressure will be sustained. In children with asymptomatic hypertension and no target organ involvement, the emergency physician must ensure adequate follow-up. Hypertension that affects or threatens to affect end organs, on the other hand, requires evaluation and initiation of treatment in the ED (Fig. 35.2). Indeed, in severe or life-threatening cases, blood pressure reduction will need to be instituted before the cause of the hypertension is known.

CHAPTER 36

Immobile Arm

SARA A. SCHUTZMAN, MD

Department of Pediatrics, Harvard Medical School, and Division of Emergency Medicine, Children's Hospital, Boston, Massachusetts

An infant or child brought for evaluation of an “immobile arm” is not moving the limb because of pain or weakness. The evaluation is often challenging because most of these children are preverbal; therefore, the history is second- or third-hand if available at all. The patient is unable to report symptoms or localize pain, and the physical examination often is difficult because of the child's fear of strangers. These children can be considered as having an upper extremity equivalent of “limp”; by using historical information, physical findings, selective radiologic studies, and laboratory tests, the physician can evaluate and treat children with this complaint.

DIFFERENTIAL DIAGNOSIS

Table 36.1 lists most conditions that cause decreased use of the arm. Trauma is the most common cause of decreased arm movement in children. Any injury from the clavicle to the fingertips can cause pain in a child and lead to diminished use of the limb; these injuries range from serious (fracture or dislocation with neurovascular compromise) to a simple contusion. Most young children with diminished arm use have a radial head subluxation (“nursemaid's elbow”), fracture, or soft-tissue injury. Although one can often elicit a history of trauma, the diagnosis must be considered even in its absence because of unwitnessed events in preverbal children or, less commonly, intentional injuries inflicted by caretakers who are not forthcoming. With musculoskeletal injuries, the child may have an obvious abnormality such as a deformity or a contusion or more subtle findings of localized tenderness or decreased arm movement. Children with hemophilia may have hemarthrosis or hematoma with minimal trauma. Radiographs are useful for demonstrating most fractures or dislocations but may appear normal with Salter type I fractures and nursemaid's elbow, as well as with contusions and other minor soft-tissue injuries.

Table 36.1. Differential Diagnosis of the Immobile Arm

Although much less common than trauma, infection may also cause decreased use of an arm. There may be a history of fever, and onset of arm disuse often is less abrupt than with trauma. The infection can be located at any point from the shoulder to finger and may be superficial (e.g., cellulitis, paronychia) or deep. Arthritis and osteomyelitis often have associated localized swelling, warmth, and tenderness; infected joints usually have limited, painful range of motion. With more severe infections, the child may be febrile and appear ill (especially if bacteremic). Laboratory findings may include elevated white blood cell count and sedimentation rate (ESR) or C-reactive protein (CRP), and blood cultures may yield the offending organism. Acutely, radiographs often are nondiagnostic; if arthritis or osteomyelitis is suspected, arthrocentesis and technetium bone scan should be considered.

Other inflammatory causes of arm pain include noninfectious arthritis and myositis. In addition to a swollen, tender joint, children with arthritis caused by postinfectious, Lyme, and rheumatologic diseases may have multiple joint involvement, rash, fever, adenopathy, heart murmur, hematuria, or bloody stools. If the examination suggests an inflammatory arthritis but cannot exclude a septic process, arthrocentesis is necessary for definitive diagnosis.

Tumors are an uncommon cause of diminished arm use. The tumors can be benign or malignant and of bone, cartilage, or muscle, or they may represent neoplastic infiltration of bone marrow (e.g., leukemia, neuroblastoma). Tumors usually are less acute in onset; cardinal symptoms may include pain and, perhaps, increasing mass or joint swelling, although the lesions may be asymptomatic. Occasionally, tumors lead to a pathologic fracture. Systemic complaints, including fever, malaise, and weight loss, may be present. Physical examination may reveal localized tenderness, joint swelling, or a mass of the soft tissue or bone. With leukemia or neuroblastoma, fever, abdominal mass, hepatosplenomegaly, or pathologic adenopathy also may be found. Plain radiographs are of obvious importance; lesion location and radiologic appearance (density and peripheral margin) can be diagnostically significant. Complete blood count (CBC) and ESR or CRP are helpful in screening for possible infection or bone marrow neoplasm.

Children with neurologic abnormalities will have diminished use of an arm because of weakness, with or without pain. An isolated monoplegia may be caused by a radiculopathy, plexopathy, or neuropathy that results from compression,

inflammation, or injury. Trauma, particularly traction on the arm, commonly leads to neurologic abnormalities (e.g., brachial plexus injury from birth); however, nontraumatic conditions may have an abrupt onset with no apparent antecedent illness. The child will have diminished arm movement and weakness, and he or she may even experience pain; unlike the previously discussed causes of arm disuse, however, the pain (if present) usually is not reproducible with palpation and is not accompanied by swelling or redness. Reflexes may be diminished or absent. It is important to identify any associated neurologic abnormalities because facial or leg weakness may be subtle but would point to a lesion in the central nervous system.

Children with hemoglobinopathies (most commonly sickle cell disease) may present with decreased arm use because of vaso-occlusive crisis, causing ischemia or infarction of bone marrow with acute bone pain. Long bones are commonly affected; however, young children often have involvement of the small bones of the hands and feet (dactylitis). Usually, no precipitating events are identified. The child is in pain and has localized tenderness and swelling of the involved areas; associated warmth and erythema may be present. Acutely, no bony abnormalities show on radiographs. Because the “hand–foot syndrome” may be the first clinical manifestation of sickle cell disease, all African-American children with unexplained limb pain or swelling must be screened for hemoglobinopathy if not tested previously. It also is particularly important to consider septic arthritis and osteomyelitis in children with sickle cell disease because they are susceptible to infection and the clinical findings may overlap with bone infarction, particularly if fever and leukocytosis are present.

Several other much less common processes can cause decreased upper limb use. These include avascular necrosis of the humeral head or capitellum in otherwise healthy children and reflex sympathetic dystrophy. Table 36.2 lists common causes of diminished arm use. Table 36.3 lists life- and limb-threatening causes of diminished arm use.

Table 36.2. Common Causes of Diminished Arm Use

Table 36.3. Life- and Limb-Threatening Causes of Diminished Arm Use

EVALUATION AND DECISION

The evaluation of the child who has diminished arm movement consists of a complete history, a thorough physical examination, radiographic studies, and selected laboratory tests, when indicated. Based on these findings, appropriate management can be undertaken.

A history of any trauma should be ascertained. Details of the event may provide clues to the type of injury incurred; a fall onto an outstretched hand may cause a wrist, forearm, or elbow injury, whereas a sudden arm pull by a caretaker can cause dislocation or subluxation of the radial head (nursemaid's elbow). Some children with radial head subluxation may have a mechanism of injury other than a pull. If an immediate causative traumatic event is not elicited, the duration, course, and pattern of diminished arm use should be clarified. Fever, malaise, rash, or weight loss may give clues to a systemic illness. If the patient is an infant, it should be determined whether the arm disuse was from birth: a difficult delivery may lead to clavicular fractures or brachial plexus injuries. Infants do not always mount a febrile response to infection and may have only nonspecific symptoms of diminished feeding, increased sleeping, lethargy, or irritability. General medical history should include any history of inflammatory process, hemophilia, or sickle cell disease.

After a careful history, a complete physical examination should be performed. Fever should be noted and may indicate infection or, less likely, inflammatory or neoplastic processes. Observation and inspection, sometimes from a distance of several paces, can provide information that might otherwise not be obtainable (because many children cry when approached or touched by a stranger). The position of the arm should be noted. A child with nursemaid's elbow often holds the arm pronated and slightly flexed with obvious diminished movement, although often without apparent discomfort. A child with neurologic abnormality may hold the arm limply at the side of the body. Close inspection for areas of deformity, redness, swelling, or bruising should be noted. Observation of the child's reach and grasp for an interesting object can provide information about the active range of motion and neurologic function. While distracting the child, the physician should palpate the limb systematically from clavicle to fingertips to identify areas of warmth, swelling, or tenderness. Joints should be assessed for warmth, swelling, tenderness, and range of motion; however, if a history of trauma is present, manipulation can be deferred until an acute fracture has been excluded. Neurovascular integrity of the arm should be assessed carefully. A thorough general examination that notes rash, other joint abnormalities, hepatosplenomegaly, adenopathy, abnormal mass, and neurologic status should be performed.

Plain radiographs are one of the most useful studies for evaluating the child with diminished arm use. They may reveal a fracture or dislocation, joint effusion, or lytic bone lesion. If a discrete area of tenderness is identified, radiographs of that location, including the joint above and below, should be obtained. If the focus of pain is not apparent, it may be necessary to obtain radiographs of the entire limb from clavicle and shoulder to fingers.

A CBC may help in the diagnosis of infection, inflammation, malignancy, or hemoglobinopathy. Although nonspecific, an

ESR or CRP may be useful in differentiating inflammatory or infectious processes from other causes.

Other tests helpful in selected cases include blood culture (if an infectious process is suspected), hemoglobin electrophoresis (if sickle cell disease is a possibility), and technetium bone scan (for osteomyelitis, septic arthritis, aseptic necrosis). Arthrocentesis is imperative if septic arthritis is a possibility, and if osteomyelitis is suspected, evaluation and treatment should proceed urgently.

When a child is brought for evaluation of diminished arm use, the physician should first determine whether this decrease in mobility resulted from a specific traumatic event (Fig. 36.1). If the history is classic for radial head subluxation, the patient is holding the arm pronated and slightly flexed, and there is no localized tenderness or swelling, the physician may attempt reduction. If the child does not regain full use of the arm quickly, as in most other cases of trauma, radiographs should be obtained. For many conditions, the radiographic studies make the diagnosis (e.g., fracture, dislocation). Normal radiographs in the setting of acute trauma usually imply soft-tissue injury, and the patient should be treated symptomatically with close follow-up, provided that neurovascular integrity is established. If radiographs appear normal but the child has reproducible tenderness localized to the epiphyseal plate, the patient should be treated for a Salter type I fracture. Occasionally, a child with a nursemaid's elbow may have an atypical history (e.g., “fell onto arm”); if radiographs exclude a fracture but the patient is holding the arm in a characteristic position, a reduction should be attempted.

FIGURE 36.1. Approach to the child with diminished arm use.

Children with neurologic abnormalities should be evaluated urgently to localize the site and cause of the impairment; the appropriate subspecialist (neurologist, neurosurgeon) should be involved.

If the child has no clear history of trauma but is afebrile and has no obvious localizing findings of infection, the limb should be evaluated radiographically. Abnormalities revealed might include fracture, dislocation, tumor, or effusion. If radiographs are normal in these children, one could consider obtaining a CBC, ESR or CRP, blood culture, or hemoglobin electrophoresis to evaluate for occult infectious or inflammatory processes.

Children who are febrile, have signs of localized inflammation (e.g., warm, swollen joint), or have evidence of systemic illness should have CBC, ESR or CRP, and blood culture obtained in addition to radiographs. Based on specific findings, further evaluation might include arthrocentesis, bone scan, or rheumatologic tests. When the initial history, physical examination, laboratory tests, and radiographs localize site and cause of the pathology, the physician can begin specific treatment.

A few children with no history of trauma in whom a thorough initial evaluation is unrevealing will have a nursemaid's elbow. Therefore, an attempt at reduction is warranted in selected cases. Children with persistently diminished arm movement who are afebrile and nontoxic and who have no localizing findings, normal neurovascular function, and normal laboratory tests likely have an occult soft-tissue injury and can be treated as outpatients. A few of these children may have indolent pathologic processes or occult fractures; therefore, close follow-up must be ensured. These patients should be reevaluated every few days until normal arm use is regained or until evidence of a pathologic process develops. If arm disuse persists, a more extensive evaluation to diagnose or exclude occult fracture, infection, tumor, or collagen vascular disease is in order.

CHAPTER 37

Injury—Ankle

ANGELA C. ANDERSON, MD

Department of Pediatrics, Brown University School of Medicine, and Department of Pediatric Emergency Medicine, Rhode Island Hospital, Providence, Rhode Island

Young children with ankle injuries may complain of pain anywhere from their midcalf to their toes because it is often difficult for children to localize pain. Conversely, disease in the lower leg and foot can cause referred pain to the ankle.

The ankle joint is composed of three bones: the tibia, the fibula, and the talus. The bony prominence of the distal fibula constitutes the lateral malleolus, whereas the prominence of the distal tibia forms the medial malleolus. The physes are located one to two fingerbreadths above the distal ends of the tibia and fibula.

The ankle ligaments are attached to the physes. The distal tibial physis is the most commonly injured growth plate in the lower extremities. It is second only to the distal radius in the incidence of physeal injuries.

Growth plates and bone are weaker than ligaments. Consequently, ankle trauma in children under 14 to 15 years of age is much more likely to cause fractures of the physis and the adjacent epiphysis and/or metaphysis than ligamentous injuries or sprains.

DIFFERENTIAL DIAGNOSIS

A number of traumatic injuries may cause ankle pain (Table 37.1). Although trauma is the most common cause of ankle pain in children, infectious, rheumatologic, inflammatory, neoplastic, and hematologic abnormalities also should be considered (Table 37.2). Again, a complaint of ankle pain may result from a lesion anywhere between the knee and the toe, particularly in the preverbal child. The most common injuries vary according to age (Table 37.3).

Leg	Sprains
Tibial fractures	Contusions
(toddler's fracture)	Osteochondritis dissecans
Fibular fractures	Hemarthrosis
Contusions	*Foot*
Compartment syndrome	Fractures
of the calf	Talar
Ankle	Navicular
Fractures	Fifth metatarsal (Jones fracture)
Distal tibial	Calcaneal
Distal fibular	Sprains
Physeal	Contusions

Table 37.1. Differential Diagnosis of Traumatic Injuries That Cause Ankle Pain

Trauma	Brodie's abscess (subacute osteomyelitis of the distal tibia)
Fractures	*Rheumatologic*
Sprains	Juvenile rheumatoid arthritis
Contusions	Rheumatic fever
Osteochondritis dissecans	Reiter's syndrome
Hemarthrosis	*Hematologic*
Inflammatory	Sickle cell disease (pain crisis)
Tendonitis	Hemophilia (hemarthrosis)
Synovitis	*Osteochondroses (avascular necrosis)*
Periostitis	Köhler's disease (navicular)
Sever's disease (calcaneal apophysitis)	Freiberg's disease (second metatarsal)
Infectious	*Tumors*
Osteomyelitis	Ewing's sarcoma
Soft-tissue abscess	Osteoid osteoma
Septic joint	

Table 37.2. Differential Diagnosis of Ankle Pain

Toddler	Child	Adolescent
Spiral fracture of tibia	Salter I fracture of distal fibula	Ankle sprain
Soft-tissue contusion	Soft-tissue contusion	Soft-tissue contusion

Table 37.3. Common Injuries Associated with Ankle Pain According to Age

Ankle Fractures

Fractures of the ankle account for 5.5% of all fractures in pediatrics. The system used to classify ankle fractures in children differs from the one used in adults because of the presence of growth plates and the possible implications of physeal injuries. The Salter-Harris classification is most commonly applied, as described in Chapter 115.

Inversion ankle injuries in the preadolescent most commonly cause a Salter type I fracture of the distal fibula (Fig. 37.1). Clinically, the patient has swelling about the lateral malleolus and tenderness at the distal fibular physis. Fractures confined to the physes may not be visible on a routine radiograph.

FIGURE 37.1. Inversion injury.

In severe inversion injuries, the distal fibular fracture just described may be accompanied by a fracture of the medial malleolus (Fig. 37.2). This medial malleolus fracture is usually a Salter type III or IV fracture of the distal tibia. These patients will have tenderness at the medial malleolus as well as the distal fibular physis.

FIGURE 37.2. Severe inversion injury.

Fractures resulting from eversion of the ankle are usually a combination of a Salter type II fracture of the lateral tibia and a transverse fracture of the fibula (Fig. 37.3). The fibular fracture is relatively high (4 to 7 cm above the fibular physis).

Therefore, it is important to examine the full length of the fibula in patients with ankle injuries.

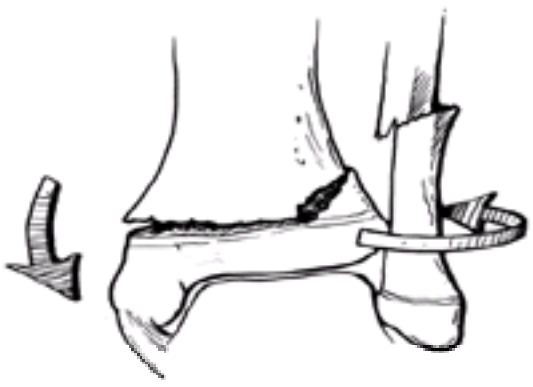

FIGURE 37.3. Eversion injury.

Direct axial compression of the ankle is uncommon but can cause a Salter type V injury to the distal tibia.

External rotation injuries are responsible for lesions known as transitional fractures. Transitional fractures occur during adolescence when closure of the growth plates is beginning. Closure of the distal tibial physis starts in the center of the bone and then spreads medially, posteriorly, and finally, laterally. The distal tibial physis closes before the distal fibular physis.

As skeletal maturity (and physeal closure) progresses, the relative strengths of various parts of the tibia change. As a result, the same mechanism of injury may cause very different fracture patterns depending on the patient's age. The juvenile fracture of Tillaux and the triplane fractures are examples of transitional fractures.

A juvenile Tillaux fracture, in which a fragment of bone is torn off the lateral border of the tibia by the anterior tibiofibular ligament (Fig. 37.4 and Fig. 115.63), is a Salter type III injury of the distal tibia. This fracture is seen almost exclusively in patients between the ages of 12 and 14 years because closure of the medial aspect of the distal tibial physis begins around this time, whereas the lateral aspect remains open and, consequently, less stable for an additional 18 months. The greater the skeletal maturity of the patient, the more lateral the epiphyseal fracture line occurs.

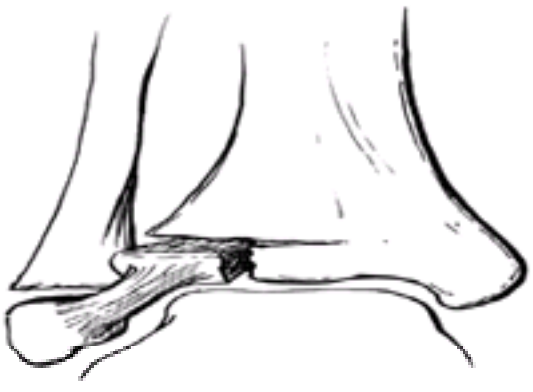

FIGURE 37.4. Juvenile Tillaux, Salter-Harris type III fracture of the distal tibial physis; the medial part of the tibial physis is fused.

Diagnosis of these fractures may be difficult because routine radiographs may not show the fracture line well. If displacement is minimal, the only radiographic sign may be a slight widening of the lateral tibial physis or a faint vertical fracture line through the epiphysis on anteroposterior (AP) or oblique views. In some cases, the only finding may be local tenderness in the area of the lateral tibial physis. Multiple oblique views, computed tomography (CT), or conventional tomography may be needed to adequately delineate the extent of the fracture.

Growth arrest and angular deformity are rare because these fractures occur at the time of physeal closure. However, ankle joint arthritis may complicate the long-term outcome if the diagnosis is missed or the reduction is inadequate.

Triplanar fractures are characterized by a fracture line that runs in three planes: coronal, sagittal, and transverse. They are a combination of a juvenile Tillaux and a Salter type II fracture of the distal tibia. Two types of triplane fractures have been reported. The first is a three-fragment fracture (Fig. 37.5). The first fragment is the same as the one found in the juvenile Tillaux fracture—a fragment of epiphysis torn off the anterolateral quadrant of the tibia. The second fragment is the remaining medial part of the epiphysis, which is attached to a posterior spike of metaphyseal bone. The third fragment is the tibial shaft.

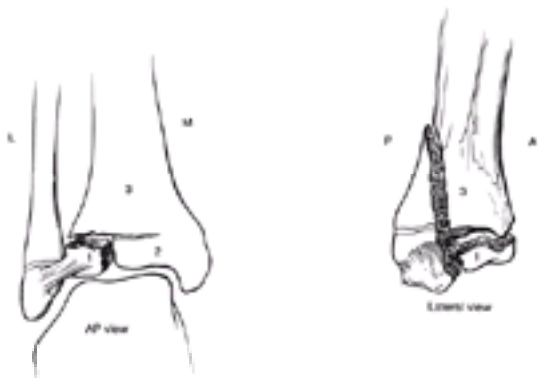

FIGURE 37.5. Three-fragment triplanar fracture. *L,* lateral; *M,* medial; *P,* posterior; *A,* anterior.

A two-fragment fracture has also been reported. The first fragment is again the lateral tibial epiphysis, but it is attached to a posterior spike of metaphyseal bone. The second fragment is the remaining medial epiphysis and is attached to the tibial shaft (Fig. 37.6).

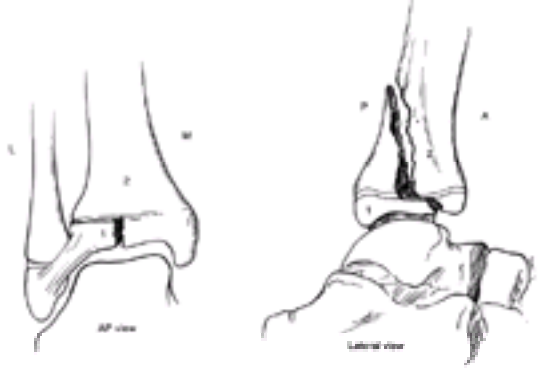

FIGURE 37.6. Two-fragment triplanar fracture. *L,* lateral; *M,* medial; *P,* posterior; *A,* anterior.

Radiographically, triplanar fractures have the appearance of a Salter type III fracture on the AP view and a Salter type II fracture on lateral view. If only the AP view is obtained, it may be difficult to distinguish these fractures from the juvenile fracture of Tillaux. The key to diagnosis is the posterior metaphyseal spike seen on the lateral film.

Ankle Sprains

Ankle sprains in the child or preadolescent are less common than fractures because the ligaments in this age group are much stronger than growth plates or even bone. If a ligamentous injury occurs in a child with an open growth plate, an associated avulsion fracture is almost always present. However, once skeletal maturity is reached, ankle sprains become the most common of sports injuries.

Inversion injuries cause 85% of ankle sprains. The most commonly injured structures are the lateral ligaments. Three lateral ligaments support the ankle joint: the anterior talofibular (ATFL), the calcaneofibular (CFL), and the posterior talofibular (PTFL) (Fig. 37.7). The ATFL is the weakest and most commonly injured of the three. The CFL is intermediate in strength and rarely is injured without an associated tear of the ATFL. The PTFL is the strongest and least injured of the lateral ligaments. Because its fibers run horizontally, only extreme dorsiflexion will stress the PTFL. The peroneus brevis tendon also traverses the lateral aspect of the ankle joint and can be injured by inversion stress. It inserts at the base of the fifth metatarsal.

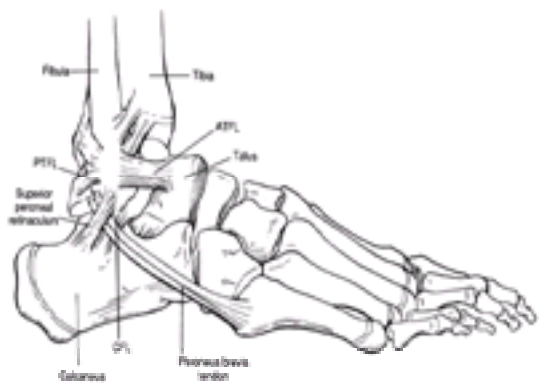

FIGURE 37.7. Lateral view of the ankle. *ATFL,* anterior talofibular ligament; *PTFL,* posterior talofibular ligament; *CFL,* calcaneofibular ligament.

Eversion injuries account for 15% of ankle sprains. The deltoid ligament, which supports the medial aspect of the ankle, is most commonly affected by this mechanism (Fig. 37.8). It is made up of deep and superficial fibers. Eversion may also cause disruption of the tibiofibular syndesmosis, which connects the distal tibia and fibula.

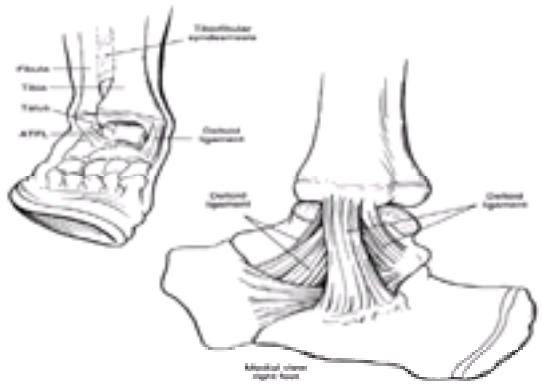

FIGURE 37.8. Ankle eversion injury. *ATFL,* anterior talofibular ligament.

Classification of Ankle Sprains

There are many systems of classification for ankle sprains. Table 37.4 provides guidelines that can be used in grading injuries to the lateral ligaments.

Table 37.4. Classification of Ankle Sprains

Injuries Associated with Ankle Sprains

Approximately 7% of ankle sprains are accompanied by osteochondral fractures of the talus. The medial dome is more commonly fractured than the lateraldome. Avulsions of the peroneus brevis tendon from the base of the fifth metatarsal have been observed in up to 14% of patients with ankle ligament ruptures. If this injury occurs in a child younger than 15 years of age, the avulsed fragment is usually an apophysis and is considered a Salter type I injury. In the older patient, the displaced portion represents a bony fragment and is known as a Jones fracture.

EVALUATION AND DECISION

History

Attempting to obtain a reliable history from patients with ankle injuries can be frustrating. It is a rare occasion when a patient says, “I sustained an inversion injury while playing basketball!” More commonly, the description is, “I twisted it, and it hurts.” Nevertheless, the mechanism of injury, if obtained, can provide a clue to the diagnosis. Other questions include: When did the injury occur? Did swelling occur immediately or gradually? Is there a history of any previous injury to that limb? and Does the patient have a history of any other medical problems—osseous, neurologic, or muscular disease?

A history of fever, rash, or other joint involvement combined with a history of minimal or no trauma suggests nontraumatic diagnoses such as septic joint, arthritis, or collagen vascular disease.

Physical Examination

General Inspection

The physician should look for obvious deformities, open wounds, loss of anatomic landmarks, local swelling, and ecchymosis. If an obvious deformity is present, manipulation of the extremity should be kept to a minimum and neurovascular status assessed promptly. Any break in the skin may communicate with the joint space or constitute an

open fracture. The need for antibiotic coverage must be evaluated immediately.

Neurovascular Evaluation

The physician should palpate the dorsalis pedis and posterior tibial arteries. Skin temperature, color, and capillary refill should be noted. The absence of pulses or the presence of pallor requires immediate attention. A Doppler device may help identify pulses.

Vascular compromise is usually caused by a posterior dislocation. Traction reduction of the deformity should be attempted as rapidly as is feasible by performing the following steps: 1) sedate the patient; 2) apply longitudinal traction to the foot; 3) if relocation is not accomplished in step 2, apply longitudinal traction and pull the foot in a posterior-to-anterior direction; and 4) immobilize the ankle and obtain radiographic studies. If the vascular status has not been compromised, the physician should continue with the examination and evaluate the nerves that cross the ankle. Soft touch and pain sensation of the foot should be tested.

Bony Palpation

All three bones of the ankle joint (the tibia, the fibula, and the talus) should be traced, searching for areas of point tenderness. It is important to palpate the distal tibial and fibular physes because fractures in these areas may not be evident on a radiograph. Any tenderness found along a physis should be considered a Salter type I fracture at the least, even if radiographic studies are negative. Also, the only clue to a juvenile fracture of Tillaux may be tenderness at the lateral tibial physis. The physician should remember to palpate the fibula proximal to the ankle joint. External rotation and triplanar injuries may be associated with high fibular fractures.

Finally, the foot should be examined. This should include palpation of the dome of the talus. This is performed most easily with the foot in plantar flexion. The base of the fifth metatarsal should be palpated. Tenderness here suggests an avulsion of the peroneus brevis tendon.

Once one area of point tenderness is found, examination of the entire joint should continue. A single injury may cause many abnormalities.

Ligament Palpation

The physician should palpate for tenderness along all three lateral ligaments, remembering that each one arises from the distal fibula. The ATFL can be further tested by inverting and plantar flexing the foot. This will increase pain if injury to this ligament is present. More than 4 cm of swelling in an area of lateral ligament tenderness is highly suggestive of significant ligament injury.

The superficial fibers of deltoid ligament on the medial aspect of the joint should be examined. The deep fibers are intra-articular and nonpalpable; therefore, rupture may be present without much medial tenderness. Isolated injuries to the deltoid are rare because of the great strength of this ligament. If the deltoid ligament has been damaged, the tibiofibular syndesmosis is usually disrupted along with it.

Injuries to the tibiofibular syndesmosis may be explored by squeezing the midshafts of the tibia and fibula together, externally rotating the foot, or forcefully dorsiflexing the ankle with the patient supine. Exacerbation of pain with these maneuvers suggests syndesmonic disruption.

Stability Testing

An attempt should be made to assess the stability of the ankle joint. However, stability testing in the immediate postinjury period may be limited significantly by pain, swelling, and/or muscle spasm. Several maneuvers are useful, but they are generally not performed if an ankle fracture is present.

- *Anterior drawer test*: The anterior talofibular ligament is the only structure that prevents forward subluxation of the talus. The anterior drawer test is performed to assess the anterior stability of the ankle joint and the integrity of the ATFL (Fig. 37.9). The test is positive if the foot can be pulled forward by more than 4 mm or if there is a significant difference in the degree of anterior movement in the injured ankle compared with the normal ankle.

FIGURE 37.9. *Top,* The anterior drawer test is performed by placing the patient's heel in the palm of the examiner's hand with the ankle at a 90-degree angle to the long axis of the leg. The examiner gently, but firmly, moves the heel and foot forward *(arrow). Bottom,* In the talar tilt maneuver, the heel is firmly adducted *(arrow)* and assessed for increased laxity or instability compared with the noninjured side.

- *Talar tilt test:* This test is used to examine the lateral stability of the ankle joint. It is performed by firmly adducting the heel and looking for increased laxity compared with the noninjured joint (Fig. 37.9). Both the anterior talofibular and calcaneofibular ligaments must be torn to cause gross lateral ankle instability.

Radiographic Imaging

With the advent of cost containment, a number of recent studies have evaluated the use of specific physical findings to predict which patients should have radiographs of the ankle taken. The Ottawa Ankle Rules suggest that radiographs need be obtained only if there is pain near the malleoli and one or both of the following: 1) inability to bear weight (four steps) immediately after the injury and in the emergency department; or 2) bone tenderness at the posterior edge or tip of either malleolus. These criteria apparently predict ankle fractures in adults with 100% sensitivity. Another study evaluated the use of the same criteria to predict ankle fracture in children and found the same results. However, the sample size was small, and there was a paucity of children under 10 years of age; therefore, further investigation is required before these criteria can be adopted safely in the pediatric population.

Radiographic evaluation of the ankle should include at least three views: AP, lateral, and mortise. If tenderness of the proximal fibula is noted, full-length views of the fibula are essential. Tenderness at the base of the fifth metatarsal mandates visualization of this area on the lateral film. If radiographic findings are questionable, consideration should be given to obtaining comparison views of the noninjured ankle.

Areas of soft-tissue swelling should be noted. This may be the only clue to a Salter type I fracture of the distal fibula. Stress films to evaluate growth plate injuries are rarely necessary and may cause further damage. Ultrasound has also been used to evaluate children who have tenderness over the lateral malleolus but normal ankle radiographs; this can help assess the possibility of an occult Salter-Harris type I fracture of the distal fibular physis. However, this practice is not currently the standard of routine care.

The value of stress films to assess ligament damage is also questionable. Severe pain and muscle spasms often prohibit stress maneuvers. Arthrography may be more helpful but is seldom indicated in the acute setting. This method uses the location of extravasated contrast material in the ankle joint to identify ligamentous ruptures.

CT of the ankle is often necessary to fully evaluate triplane fractures.

Approach to Diagnosis

The approach (Fig. 37.10) to the evaluation and diagnosis of traumatic ankle injuries relies primarily on physical findings and the results of radiographic evaluation. Initially, pulses and sensation are assessed. Loss of pulses or sensation suggests a fracture or dislocation and the need for a rapid reduction; when available without delay, orthopedic consultation is advisable. After immobilization to prevent further compromise and the provision of analgesia, a radiograph should be obtained immediately. If neurovascular status is adequate and the general inspection reveals no obvious abnormalities, the remainder of the physical examination should be continued as described previously.

FIGURE 37.10. Evaluation and diagnosis of traumatic ankle injuries.

Next, the area should be examined for open wounds. If open wounds are present, the physician should fashion a sterile saline dressing and immobilize the extremity before obtaining a radiograph. In addition, the administration of intravenous antibiotic therapy and tetanus prophylaxis should be considered.

If radiographic studies indicate a fracture or dislocation, the specific injury should be treated (see Chapter 115). Analgesia should be administered as needed.

If no fracture is evident on radiography but tenderness is elicited over a physis, the diagnosis of a Salter type I injury is made and appropriate immobilization performed. A negative radiograph in the absence of bony tenderness suggests the diagnosis of contusion or ligamentous injury. The diagnosis of a grade II or III sprain is rendered in the patient with joint instability. If the ankle is stable but pain is elicited with ligamentous stress or palpation, a grade I sprain is diagnosed.

TREATMENT

Fractures

Fracture reduction is usually accomplished by reversing the mechanism of injury. Closed reduction and a short leg cast are usually adequate for Salter-Harris type I and II fractures of the distal tibia and fibula. Often, younger children require placement of a long leg cast, even for minor fractures, because of their ability to accidentally (or intentionally) slip out of short leg casts.

One recent study recommends the use of a tubular bandage (Tubigrip, Seton Health Care PLC) and crutches—in lieu of a short leg plaster cast—in patients with clinically suspected but nonradiographically evident Salter-Harris type I fractures of the distal fibula. The group treated with the tubular bandage had a shorter time to recovery; however, further study is required to determine whether this method is adequate.

Some displacement can be accepted in younger patients because of their ability to remodel. Salter type III and IV injuries involve the articular surface and are therefore less stable. They require anatomic realignment, often by open reduction. A long leg cast is commonly applied in any rotational injury.

Sprains

A common approach to the treatment of ankle sprains is described by the mnemonic *RICE* (rest, ice, compression, elevation). This treatment approach should be initiated within 36 hours of the injury.

- *Rest* The patient is allowed to ambulate or exercise only if the activity causes no pain or swelling during the activity or within 24 hours. Otherwise, crutches and light weight bearing are recommended until ambulation without pain is possible.
- *Ice* The patient should apply ice directly to the ankle for 20 minutes every 2 hours, if possible, for the first 48 hours after injury.
- *Compression* The goal of compression is to keep (and/or push) fluid out of the area of the ankle joint. This can be accomplished using an elastic bandage starting at the foot and wrapping proximally toward the ankle. For additional compression, any bulky padding can be applied to the malleoli and then secured with an elastic wrap.
- *Elevation* To help decrease or prevent swelling, the patient should elevate the ankle as often as possible.

Splinting

If swelling or pain is severe, a stirrup and/or posterior splint should be applied to the ankle. Air splints can also be used; they allow dorsiflexion and plantar flexion while maintaining medial and lateral stability.

Rehabilitation

Early rehabilitation shortens the period of disability considerably. Plantar flexion and dorsiflexion exercises are initiated as soon as possible, followed by toe raises and inversion/eversion exercises.

Orthopedic Referral

Absolute indications for orthopedic referral include 1) obvious deformity with growth plate involvement; 2) neurovascular compromise; 3) suspected syndesmotic injury; 4) a grade III sprain; and 5) locking of the ankle.

CHAPTER 38

Injury—Head

SARA A. SCHUTZMAN, MD

Department of Pediatrics, Harvard Medical School, and Division of Emergency Medicine, Children's Hospital, Boston, Massachusetts

PEDIATRIC HEAD TRAUMA

Head injuries in children are common, accounting for 600,000 emergency department (ED) visits annually. Although most of these injuries are minor, head trauma causes significant pediatric morbidity and mortality. Trauma is the leading cause of deaths in children older than 1 year of age, and central nervous system (CNS) trauma is the most common cause of death among injured children. In 1986, approximately 7,000 children died from head injuries, and it is estimated that each year an additional 29,000 children under 19 years of age suffer permanent disability.

The most common mechanisms of injury for the entire pediatric group are falls (37%), motor vehicle (18%) and pedestrian (17%) accidents, and bicycle injuries (10%); most fatal injuries occur because of motor vehicle–related injuries. The mechanism of pediatric head injury varies with age; younger children are more likely to fall or be abused, whereas older children often are injured in sporting or motor vehicle accidents (in addition to falls).

Many of the serious neurologic complications of head injury are evident soon after the traumatic event; however, some life-threatening injuries can appear initially as trivial head trauma. To manage head injuries best, the physician must approach the child in a systematic manner to address all injuries (because global resuscitation is the first priority of cerebral resuscitation), identify and treat any neurologic complications, and prevent ongoing cerebral insult.

PATHOPHYSIOLOGY

Neurologic injury after head trauma is related to the unique physiology and pathophysiology of the brain and the intracranial environment. The brain is a semisolid structure bathed in cerebrospinal fluid (CSF) and covered by the fine inner pia-arachnoid membrane and the outer thick fibrous layer of dura, all of which are encased in the skull, which is covered by the five-layer structure of the scalp. After infancy (when the skull sutures fuse), the cranial vault becomes a stiff and poorly compliant housing for the brain. Because the intracranial volume is relatively fixed, any change in the volume of one of the intracranial components (blood, brain, and CSF) must occur at the expense of the others; if the other components do not decrease proportionally, intracranial pressure (ICP) will increase.

Brain injury occurs in two phases: primary and secondary. The primary injury is the mechanical damage sustained at the time of trauma and can be caused by direct impact of the brain against the internal calvarial structures, by bone or foreign bodies projected into the brain, and by shear forces delivered to the white matter tracts. Secondary brain injury is further neuronal damage sustained after the traumatic event to cells not initially injured. This results from numerous causes, including hypoxia, hypoperfusion, and metabolic derangements, and may result from sequelae of the primary injury (e.g., cerebral edema, expanding intracranial mass) or be caused by extracranial injuries (e.g., hypotension from excessive blood loss, hypoxia from pulmonary contusion). The clinician's goal is to identify and treat any complications of primary brain injury to limit further neuronal damage by secondary brain injury.

One of the most common causes of secondary brain injury is cerebral ischemia resulting from diminished cerebral blood flow. Cerebral perfusion pressure (CPP) is related to the difference between the mean arterial pressure (MAP) of blood flowing to the brain and the ICP. In the healthy child, blood flow to the brain is maintained at a constant rate over a wide range of systemic blood pressures by means of autoregulatory changes in the cerebrovascular resistance so that the brain does not suffer ischemia or excessive blood flow during periods of relative hypotension or hypertension, respectively. With severe injuries, this autoregulatory control may be lost and the cerebral blood flow can become directly dependent on the CPP; with low MAP or increased ICP, inadequate blood flow and cerebral ischemia results. In addition to potential for causing decreased cerebral blood flow and ischemia, increased ICP, if left unchecked, can lead to brain herniation and compression. This may be caused by a number of posttraumatic conditions, including cerebral edema and expanding intracranial mass.

Clinical symptoms of increased ICP or herniation include headache, vomiting, irritability, lethargy, visual abnormalities (double vision, depressed acuity), and gait abnormalities or weakness. Signs include depressed level of consciousness, abnormal vital signs (bradycardia, hypertension, respiratory irregularity), cranial nerve palsies, hemiparesis, and

decerebrate posturing. The classic findings in transtentorial herniation are headache, decreasing level of consciousness followed by ipsilateral pupillary dilation (third cranial nerve [CN] palsy), and contralateral hemiparesis or posturing. If the process continues unchecked, dilation of the opposite pupil, alteration in respirations, and ultimately, bradycardia and arrest ensue. For a more detailed description of the anatomy, pathophysiology, and treatment of specific head injuries, see Chapter 105.

DIFFERENTIAL DIAGNOSIS

Head trauma may cause injuries of the scalp, skull, and intracranial contents. Although each is discussed here separately, the clinician must remember that these injuries may occur alone or in combination, and all potential injuries must be kept in mind when dealing with each.

Scalp

The scalp consists of five layers of soft tissue that cover the skull; contusions and lacerations of this structure are common results of head trauma. The outermost layers of the scalp are skin and the subcutaneous tissue; edema and hemorrhage here may produce a mobile swelling. The third layer, the galea aponeurotica, is a strong membranous sheet that connects the frontal and occipital bellies of the occipitofrontalis muscle. The remaining two layers, deep to the galea, are the loose areolar tissue and pericranium. Subgaleal hematomas may result from more forceful blows if vessels in the fourth layer bleed and dissect the galea from the periosteum, or they may be signs of an underlying skull fracture. In subperiosteal hematomas, or cephalohematomas, the swelling is localized to the underlying cranial bone and most often occurs with birth trauma. Scalp lacerations may occur with or without underlying contusions or fractures and often require suturing.

Skull

Linear, diastatic, depressed, compound, and basilar skull fractures may result from head trauma. Linear fractures account for 75 to 90% of skull fractures in children and often manifest with localized swelling and tenderness. The significance of linear fractures is debated, but their potential importance is twofold. Their presence reflects the degree of traumatic impact; because the force required to fracture a child's skull is significant, risk of an intracranial injury (ICI) is significantly more likely (as much as 10 to 20 times) with a fracture. The second feature important in linear skull fractures derives from their location; those that cross the path of a major vascular structure (middle meningeal artery, large dural sinuses) signal potential for intracranial hemorrhage from these vessels.

Diastatic fractures are traumatic separations of cranial bones at one or more suture sites. A depressed skull fracture is present when the inner table of the skull is displaced by more than the thickness of the entire bone. These may be palpable and are diagnosed with tangential skull radiographs or computed tomography (CT). Compound fractures are those that communicate with lacerations.

Basilar skull fractures often are difficult to detect on routine radiographs or CT scans; however, their location produces clinical signs that lead to the diagnosis. Fractures of the petrous portion of the temporal bone may cause hemotympanum, hemorrhagic or CSF otorrhea, or Battle's sign (bleeding into mastoid air cells with postauricular swelling and ecchymosis). Fracture of the anterior skull base may cause a dural laceration with subsequent drainage of CSF into paranasal sinuses and rhinorrhea. Anterior venous sinus drainage may cause blood leakage into the periorbital tissues (“raccoon's eyes”). Given the location of basilar skull fractures, associated CN palsies may occur. CT scan is indicated to try to localize the area of fracture and to identify any associated intracranial pathology (which occurs in approximately 20% of children with basilar skull fractures who have a Glasgow Coma Scale [GCS] score of 15 and a nonfocal neurologic examination).

Intracranial Injury

Insults to intracranial contents include functional derangements without demonstrable lesions on CT scan (concussion, posttraumatic seizures), hemorrhage (cerebral contusion, epidural hematoma, subdural hematoma, subarachnoid hemorrhage, and intracerebral hemorrhage), and acute brain swelling. Penetrating brain injuries rarely occur in children.

Concussion

Concussion is the most minor brain injury and is characterized by posttraumatic alteration in mental status that may or may not involve loss of consciousness. No consistent associated pathologic lesion in the brain has been identified. The child may have a depressed level of consciousness, pallor, vomiting, amnesia, and confusion; however, the clinical picture usually normalizes within several hours without specific therapy.

Posttraumatic Seizures

Posttraumatic seizures can be divided temporally into immediate, early, and late, and they occur in 5 to 10% of children hospitalized for head trauma.

Immediate seizures occur within seconds of the trauma and probably represent traumatic depolarization of the cortex. They usually are generalized and rarely recur.

Early seizures occur within 1 week of the trauma (most occur within 24 hours) and often are the result of focal injuries (contusion, laceration, ischemia, edema). Skull fractures, intracranial hemorrhage, and focal signs all are associated with increased risk of early posttraumatic seizures; therefore, an early seizure should prompt investigation of these

possibilities.

Late seizures occur more than 1 week after the traumatic event and may be attributed to scarring associated with local vascular compromise, distortion, and mechanical irritation of the brain. These seizures are more likely to occur in children with severe head injuries, dural lacerations, and intracranial hemorrhages. A substantial number of patients will have subsequent seizures.

Cerebral Contusion

Cerebral contusion is a bruising or crushing of brain and often results from blunt head trauma. The site of contusion may be a “coup” lesion, with the injured cerebral cortex directly beneath the site of impact (with or without skull fracture), or a “contrecoup” lesion, with damage opposite the site of impact; the contusion is demonstrable by CT. Children with cerebral contusion may have had loss of consciousness (not imperative), may show a depressed level of consciousness or symptoms of vomiting or headache, and may have focal neurologic signs or seizures.

Epidural Hematoma

Epidural hematoma (EDH) is a collection of blood between the skull and dura. An overlying fracture is present in 60 to 80% of cases, and depending on the location and vascular structure involved, the hemorrhage may be of arterial or venous origin; injury to the middle meningeal artery often is responsible for temporal EDH. The classic pattern of a lucid interval between initial loss of consciousness and subsequent neurologic deterioration occurs in only a minority of children with EDH. Furthermore, patients occasionally may develop EDH after relatively minor trauma with no history of loss of consciousness. Although many children present with significant lethargy, focal neurologic signs, or a clinical pattern consistent with temporal lobe herniation as the hematoma expands, some children with EDH are alert, have a nonfocal neurologic examination, and have only symptoms of headache or persistent vomiting; nevertheless, rapid deterioration can ensue.

Subdural Hematomas

Subdural hematomas (SDH) occur as a result of bleeding between the dura and the arachnoid membranes covering the brain parenchyma. They may result from direct trauma or from shaking injuries and result from tearing of the cortical bridging veins or from bleeding from the cortex itself. Subdural hematomas may be bilateral, and often, there is an associated underlying brain injury. Skull fractures occur in only a minority of cases. Children with SDH often have seizures, may present with evidence of acutely elevated ICP, or may have more nonspecific signs of vomiting, irritability, or low-grade fever. Physical examination often reveals an irritable or lethargic infant or child with a bulging fontanel who may or may not have neurologic abnormalities. CT scan commonly demonstrates crescent-shaped subdural collections.

Intracerebral Hematoma

Posttraumatic intracerebral hematomas are unusual in children. Blood within the parenchyma usually is the result of severe focal injury or penetrating trauma, usually manifests with severe neurologic compromise, and often portends a poor prognosis.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage may occur after head trauma (including shaking injuries in infants) and may cause headache, neck stiffness, and lethargy in the child.

Acute Brain Swelling

The most common diagnosis in children with severe head injury (GCS score of less than 8) is diffuse cerebral swelling; in one study, this occurred in 50% of cases, whereas intracranial hemorrhages were less common at 20% of cases. These children have a depressed level of consciousness and may have focal neurologic signs or symptoms of herniation.

Penetrating Injuries

Penetrating head injuries are uncommon in children and may be caused by bullets, teeth (e.g., dog bites), or other objects (e.g., dart, pencil, pellet) penetrating the skull. These injuries have obvious potential for extensive damage to the brain and intracranial vessels.

EVALUATION AND DECISION

The clinical spectrum of head injury in children varies from a small contusion of the scalp with no neurologic sequelae to severe intracranial trauma that causes death. The general approach is essentially the same as with any child who presents with trauma, paying particular attention to potential CNS damage. Following the ABCs (airway, breathing, and circulation) of resuscitation, the physician must systematically evaluate and stabilize the child with head trauma. The goals of management are to identify complications of the head trauma and to prevent secondary brain injury. Because some complications of head trauma may not manifest immediately, the assessment period includes the initial evaluation in the ED and a more extended observation period, either in the hospital or as an outpatient, as clinically indicated. Specific therapy will vary, based on specific diagnosis in each case, and may include supportive care and possible neurosurgical intervention. Although complications are more common in children with severe head injury, they also occur in children with apparently minor head trauma; thus, all patients merit some degree of scrutiny.

The immediate management of the child varies with the degree of compromise. A brief initial assessment is done to

determine immediate stability. In the older child, verbal response to a question often establishes the adequacy of the airway, ventilation, and cognitive function. If the child is unconscious or has unstable vital signs, immediate resuscitation is initiated to ensure a patent airway (with cervical spine immobilization), effective ventilation, and adequate tissue perfusion (see Chapter 1); efforts to decrease possible increased ICP may be indicated depending on the degree of neurologic compromise (see Chapter 105). The child with airway and hemodynamic stability and with only mild to moderate depression of mental status can undergo a more timely evaluation to identify subtle or occult abnormalities.

Clinical Assessment

History

The history should be obtained from the patient (if age and level of consciousness permit) and from any witnesses to determine the nature and severity of the impact as well as the prehospital course. Specifics of the traumatic event should include how, when, and where the trauma occurred as well as details such as height of a fall, type of impact surface, and type and velocity of striking objects. Occurrence of loss of consciousness should be determined as well as duration. If the event was not witnessed and the patient is amnestic, the clinician should assume that loss of consciousness occurred. Occurrence of seizure activity (including details of time of onset posttrauma, duration, and focality) as well as the child's level of alertness since the injury should be noted; in addition, the presence of vomiting, irritability, ataxia, and abnormal behavior are all signs of possible brain injury. Vomiting after a head injury is common; however, more than several hours of unremitting vomiting may signal intracranial abnormalities. If the child is verbal, he or she should be questioned about presence of headache or neck pain, amnesia, weakness, visual disturbances, or paresthesias. In many cases, elicited symptoms may be the only evidence of underlying CNS injury. In infants, symptoms of ICI may be subtle or absent; therefore, the clinician should pay particular attention to any alteration in behavior in this age group. Progression or resolution of any symptoms, neurologic signs, and level of consciousness since the traumatic episode must be defined clearly. One should also inquire about the patient's medical history and factors predisposing to head trauma (e.g., seizure disorder, gait disturbance, bleeding diathesis, alcohol abuse, illicit drug use). When there are discrepancies in the history, when the history does not fit the physical findings, or when there is a skull fracture or ICI in a young child without a history of significant trauma, one should suspect nonaccidental injury.

Physical Examination

After a primary survey with appropriate resuscitation, a thorough physical examination should be performed with special emphasis on the vital signs, head and neck, and the neurologic examination. Bradycardia may be a sign of increased ICP, even in the alert or minimally drowsy child; it is of particular concern when associated with hypertension, abnormal breathing pattern, depressed level of consciousness, or neurologic abnormality. Bradycardia also may be seen with spinal cord injuries caused by unopposed parasympathetic tone; in those cases, it often is associated with hypotension, flaccidity, a sensory level, and absent deep tendon reflexes. Tachycardia may reflect hypovolemia (especially if associated with hypotension), hypoxia, or anxiety. Isolated head injuries rarely cause hypovolemia (except in infants with large subgaleal or intracranial hematomas); therefore, hypotension should alert one to an extracranial source of hemorrhage.

The head should be inspected and palpated carefully for scalp swelling, lacerations, irregularities of the underlying bony structure, and fontanel fullness (in infants). Signs of basilar skull fracture (periorbital or postauricular hemorrhage in the absence of direct trauma, hemotympanum, CSF otorrhea, or rhinorrhea) and retinal abnormalities (hemorrhage or papilledema) should be noted. All children with depressed mental status, a mechanism of injury suggesting a significant force, or neck pain should have cervical spine immobilization at least until its integrity has been confirmed radiographically; one should note cervical abrasions, deformity, or tenderness—findings that may indicate underlying cervical spine injuries.

Neurologic examination encompasses assessment of the child's mental status as well as cranial nerve, motor, sensory, cerebellar, and reflex functions. Serial examinations are important in the child with head trauma to document improvement or deterioration. The GCS is a convenient way to quantify level of consciousness and monitor neurologic progression. The GCS scores patient performance in three areas: eye opening, verbal ability, and motor ability. It also assesses level of alertness, mentation, and major CNS pathways (Table 38.1); an individual's score may range from a low of 3 to a high of 15. The scale has been modified for more age-appropriate behaviors in infants (Table 38.2). Although ICIs are more common in a child with a low GCS score, even a child with a score of 13 to 15 may harbor life-threatening complications of head trauma (e.g., EDH), especially if neurologic abnormalities are present. Further evaluation of mental status includes assessing orientation and memory. Subtle signs (irritability and high-pitched cry) may indicate underlying abnormalities in infants.

Activity	Best Response	Score
Eye Opening	Spontaneous	4
	To verbal stimuli	3
	To pain	2
	None	1
Verbal	Oriented	5
	Confused	4
	Inappropriate words	3
	Nonspecific sounds	2
	None	1
Motor	Normal spontaneous movements	6
	Localizes pain	5
	Withdraws to pain	4
	Abnormal flexion (decorticate rigidity)	3
	Abnormal extension (decerebrate rigidity)	2
	None	1

	Withdraws to pain	4
	Abnormal flexion (decorticate rigidity)	3
	Abnormal extension (decerebrate rigidity)	2
	None	1

Table 38.2. Modified Coma Scale for Infants

CN function is assessed by checking for facial symmetry, corneal reflexes, presence of a gag reflex, full extraocular movements, pupillary size, and pupillary reactivity. In the comatose patient or in the child with possible neck injury who is uncooperative, lateral gaze may be tested by caloric stimulation of the vestibular apparatus (but not the “doll's eye” maneuver) once tympanic membrane integrity has been established.

Examination of the motor system to evaluate both CNS and spinal cord function varies with age and level of consciousness. The alert patient should have individual muscle groups tested and gait evaluated. The child with a depressed level of consciousness may have motor responses elicited by noxious stimuli (e.g., sternal rub, nailbed pressure). Deep tendon reflexes and Babinski's sign also should be evaluated. Obviously, a complete physical examination with attention to possible thoracic, abdominal, pelvic, and extremity injuries should be performed.

Radiographic Investigation

Complications of head trauma may be identified with radiographic studies, which include plain radiographs of the skull and cervical spine and CT scans of the head; specific studies are indicated based on the child's history and physical findings. Although magnetic resonance imaging (MRI) is an additional imaging modality for the cranial contents, limited availability and prolonged study time limit its use for evaluation of acute trauma at this time. All children with significant head trauma should be evaluated for associated cervical spine injuries; this evaluation will be clinical, with or without radiographic studies, based on the specific circumstances (see Chapter 106).

CT provides excellent images of the intracranial contents and therefore is the diagnostic modality of choice when intracranial pathology is suspected. Indications include history of penetrating trauma, loss of consciousness (particularly if more than brief) or seizure, altered level of consciousness, focal neurologic abnormalities, presence of full fontanel, skull fracture, and persistent vomiting or progressive headache. Many authors now recommend performing a CT scan in patients with any loss of consciousness because the incidence of ICIs in alert children with nonfocal neurologic examinations who lost consciousness and underwent CT is approximately 3 to 6%; however, only a small number of these children require neurosurgical intervention. Because children younger than 24 months of age are difficult to assess, cannot report symptoms, have impaired skull integrity, are at risk for abuse, and often are minimally symptomatic with ICI, the clinician should favor a particularly low threshold for obtaining CT scans for patients in this age group who have head trauma and any symptoms. The younger the age, the more difficult to assess and the higher the incidence of ICIs (and particularly of occult or asymptomatic intracranial injuries); although this is a continuum, the clinician should have a very low threshold for obtaining CT scans for infants younger than 2 to 3 months of age who have trauma, unless trivial, even without symptoms. In all cases, the patient's condition must be stabilized before transfer to the neuroradiologic suite; the patient should be monitored appropriately and accompanied by a health care professional with medication and equipment necessary for resuscitation.

Over the years, one of the most controversial issues in the management of head trauma has been indications for skull radiographs. Inherently, skull radiographs are of limited value in that they reveal primarily bony abnormalities, giving little or no information about ICIs. The presence of a skull fracture, however, may imply significant impact with a higher likelihood for ICI, particularly if the fracture crosses the path of a major vessel. Although clearly any child for whom there is significant concern for ICI should undergo CT scan, there may still be a small role for skull radiographs in certain select circumstances when immediate CT is not warranted, yet significant chance of fracture exists to justify the test. Data suggest that a substantial number of children younger than 12 months of age who have ICIs are minimally symptomatic; however, most of the asymptomatic children will have an associated skull fracture. Aside from being less costly, one advantage of obtaining skull radiographs is that children do not require sedation, which is necessary for many young children who undergo CT (especially those 4 to 24 months of age). One reasonable approach to imaging is to use skull radiographs as a screening tool in children with scalp findings (because most fractures are associated with swelling or scalp abnormalities) or with a history of significant trauma (e.g., a fall of more than 3 feet) who do not have other symptoms of ICI. Children with fractures identified on skull radiographs should then undergo CT scans because they are at increased risk for associated ICI. Other indications for skull radiographs include a suspicion of depressed fracture or penetrating trauma and the possibility of a foreign body.

Approach

The goals of management are to define specific anatomic lesions (e.g., skull fracture, ICI) and to prevent secondary brain injury. Pediatricians and emergency physicians will be the initial clinicians to evaluate and manage most children with head trauma. Neurosurgical consultation should be considered for all children with penetrating trauma, prolonged loss of

consciousness, abnormal mental status or neurologic examination, skull fractures, and intracranial complications. The urgency of neurosurgical involvement varies with the acuity of the patient's clinical condition.

One approach (Fig. 38.1) to diagnosing complications of head trauma involves determining whether a penetrating injury has occurred. If so, brain or vascular injury is likely, and emergent CT scanning and neurosurgical consultation are mandated in addition to stabilization.

FIGURE 38.1. Approach to the child with head trauma. *GCS*, Glasgow Coma Scale; *ICI,* intracranial injury; *CT,* computed tomography.

If the head injury has resulted from blunt trauma, it must be determined whether an ICI is present. Suggestive history includes loss of consciousness (especially if more than brief); prolonged, focal, or early seizure; and definite bony abnormality or underlying condition that predisposes to ICI (e.g., coagulopathy). Physical findings indicative of possible intracranial abnormalities include a GCS score of less than 15, focal neurologic abnormalities, a definite palpable bony depression, and signs of a basilar skull fracture. If any of these findings is present, then, in addition to supportive therapy, CT scan and possible neurosurgical consultation are indicated. Abnormalities on the CT scan might include intracranial hemorrhage, diffuse cerebral swelling, or skull fracture; if the CT scan is normal, concussion or extracranial injury has likely occurred.

If these findings are not present, the child will be alert with a nonfocal neurologic examination. The drowsy child who quickly becomes alert or the child with a history of momentary loss of consciousness who is alert with a nonfocal examination may show no evidence of intracranial complications; however, the child may have had more than a trivial head injury. If these patients do not undergo a CT scan, they should be observed in the ED for at least 4 to 6 hours after the injury for signs and symptoms of complications, including neurologic abnormalities, mental status depression, persistent vomiting, and progressively severe headache. A CT scan should be obtained if these signs or symptoms develop. As previously stated, discrete abnormalities may be identified on CT scan; however, if the scan is normal, the child has experienced a concussion or extracranial injury.

Children likely to display abnormalities on skull radiographs but in whom immediate imaging of intracranial contents is not indicated include those who are awake and alert but in whom there is a history of a foreign body, possible penetration of the bony calvarium, or question of a palpable bony irregularity. Another relative indication for skull radiographs is a significant subgaleal hematoma, especially if it overlies the middle meningeal groove. One should also consider obtaining skull radiographs in infants under the age of 1 year with a history of a fall of more than 3 feet onto a hard surface or with a palpable hematoma (if they have not undergone CT) because an infant's skull has limited ability to withstand trauma.

Skull radiographs may show an extracranial or intracranial foreign body, may reveal a fracture, or may be normal. Obviously, immediate CT scan (with neurosurgical consultation) is mandated for patients with an intracranial foreign body because neuronal or vascular damage is likely. CT is also indicated if skull radiographs demonstrate a skull fracture because this significantly increases the likelihood of an associated ICI. The child with normal skull radiographs and examination who is alert has likely experienced an extracranial injury or a concussion.

The remaining children who sustained impact of minimal force, had no loss of consciousness, and are alert and asymptomatic with normal examinations likely have only minor head trauma with or without extracranial injuries, including contusions and lacerations. Home observation is appropriate management for most of these patients. Rarely, intracranial complications develop in these children, causing symptoms hours after the traumatic event; therefore, caretakers should be given a printed list of signs and symptoms indicative of increased ICP with instructions to check the child at regular intervals and to return to the ED if symptoms occur. The caretakers must be reliable and able to return with the child if necessary, and there must be no suspicion of abuse or neglect; otherwise, admission for observation in the hospital should be considered (Table 38.3).

Traumatic force not life-threatening	No intracranial abnormalities on CT (if obtained)
Glasgow Coma Scale score of 15	Reliable caretakers who are able to return if necessary
Nonfocal neurologic examination	No suspicion of abuse or neglect
No significant symptoms	
No history of prolonged loss of consciousness (or normal CT if it did occur)	

CT, computed tomography.

CHAPTER 39

Injury—Knee

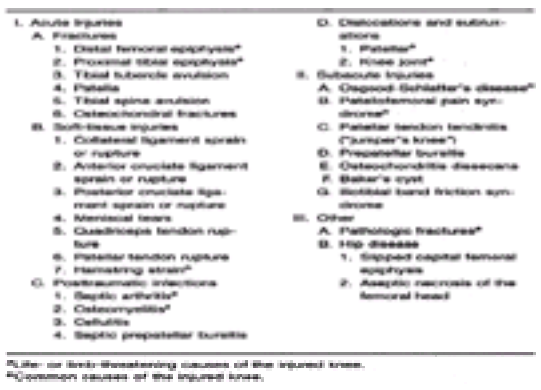
MARC N. BASKIN, MD

Department of Pediatrics, Harvard Medical School, and Department of Pediatric Emergency Medicine, Short Stay Unit, Children's Hospital, Boston, Massachusetts

Acute pain or injury to the knee is a common complaint in the emergency department (ED). Many injuries are minor and require only limited therapy; others, however, require consultation with an orthopedist, either in the ED or for subsequent evaluation after pain and inflammation subside. The emergency physician can provide appropriate therapy or determine the need for consultation, based on a comprehensive history, physical examination, and an appropriate radiographic evaluation.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of acute and chronic knee injuries is summarized in Table 39.1. The pertinent anatomy is illustrated in Figure 39.1 and Figure 39.2.



I. Acute Injuries
- A. Fractures
  1. Distal femoral epiphysis*
  2. Proximal tibial epiphysis*
  3. Tibial tubercle avulsion
  4. Patella
  5. Tibial spine avulsion
  6. Osteochondral fractures
- B. Soft-tissue injuries
  1. Collateral ligament sprain or rupture
  2. Anterior cruciate ligament sprain or rupture
  3. Posterior cruciate ligament sprain or rupture
  4. Meniscal tears
  5. Quadriceps tendon rupture
  6. Patellar tendon rupture
  7. Hamstring strain*
- C. Posttraumatic infections
  1. Septic arthritis*
  2. Osteomyelitis*
  3. Cellulitis
  4. Septic prepatellar bursitis
- D. Dislocations and subluxations
  1. Patella*
  2. Knee joint*

II. Subacute Injuries
- A. Osgood-Schlatter's disease*
- B. Patellofemoral pain syndrome*
- C. Patellar tendon tendinitis ("jumper's knee")
- D. Prepatellar bursitis
- E. Osteochondritis dissecans
- F. Baker's cyst
- G. Iliotibial band friction syndrome

III. Other
- A. Pathologic fractures*
- B. Hip disease
  1. Slipped capital femoral epiphysis
  2. Aseptic necrosis of the femoral head

*Life- or limb-threatening causes of the injured knee.
†Common causes of the injured knee.

Table 39.1. Differential Diagnosis of the Injured Knee

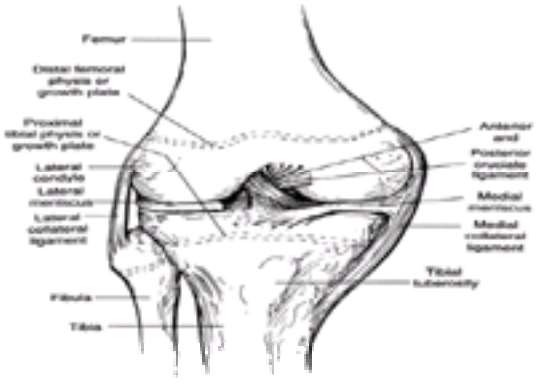


FIGURE 39.1. Anatomy of the knee—anterior view (patella removed).

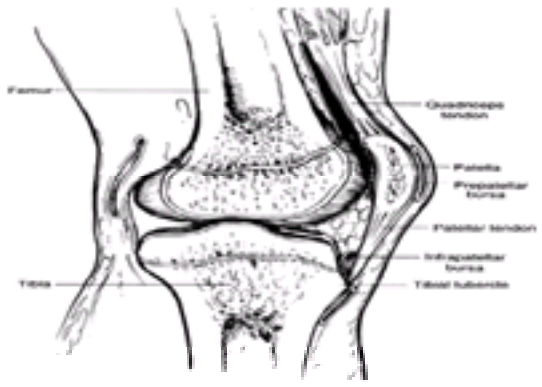

FIGURE 39.2. Anatomy of the knee—sagittal section.

Acute Injuries

Fractures

When first described in the 1800s, a separation fracture of the distal femoral epiphysis (wagon-wheel injury) usually occurred when a child's leg was caught in a wagon wheel, the child's thigh or torso stopped against the wagon, and the knee hyperextended. Now, this injury occurs most commonly during contact sports or in car accidents. It is classified by the Salter-Harris pattern (Chapter 115) and by the displacement of the epiphysis (usually lateral or medial). The injury usually follows significant direct (e.g., being run over by a car's wheels) or indirect (e.g., being hit during contact sports from the lateral side with the foot fixed by cleats) trauma. The patient has severe pain, refuses to bear weight, and experiences joint and soft-tissue swelling and possibly deformity. Distal neurovascular status should be assessed because compromise of the popliteal artery occurs in 1% of cases and peroneal nerve injury occurs in 3% of cases. Usually, radiographs are diagnostic but may be normal if the injury is a nondisplaced Salter-Harris type I fracture. Lateral and anteroposterior (AP) stress views may be necessary.

Separations of the proximal tibial epiphysis are more rare than those of the distal femoral epiphysis and also are likely to involve vascular compromise because of the proximity of the popliteal artery to the posterior aspect of the tibial epiphysis. The patient will have severe pain, limited range of motion (ROM), and commonly, a hemarthrosis. If displaced, the knee will be deformed. Distal neurovascular status should be assessed. Usually, radiographs are diagnostic but may be normal if the injury is a nondisplaced Salter-Harris type I fracture. Lateral and AP stress views may be necessary.

Acute traumatic avulsion of the tibial tubercle is caused by acute stress on the knee's extensor mechanism. The quadriceps muscle group extends the knee by way of the patella and the patellar ligament. The patellar ligament inserts on the tibial tuberosity and may avulse it during sudden acceleration (e.g., beginning a jump) or deceleration (e.g., landing after a jump). The patient will have tenderness and swelling over the tibial tubercle and is unable to extend the knee fully. A lateral radiograph is diagnostic.

Fractures of the patella are more common in adults because the child's patella is surrounded by cartilage, protecting it from direct trauma. A medial avulsion fracture suggests that the mechanism was a patellar dislocation that spontaneously reduced. The patient's knee will be swollen and tender and will resist full extension. A radiograph is diagnostic, although a bipartite patella may be confused with an acute fracture. The curved radiolucent line associated with a bipartite patella usually is in the superior lateral quadrant, a rare area for a fracture, and should not be associated with the soft-tissue swelling and effusion seen with a fracture.

Analogous to an adolescent who ruptures the anterior cruciate ligament, children sustain avulsion fractures of the tibial spine at the point where the anterior cruciate ligament inserts. The tibial spine is incompletely ossified and may avulse before the ligament ruptures. The patient will have a hemarthrosis and will be unable to bear weight. If the patient tolerates an examination, the Lachman test (Fig. 39.3) may be positive because the injury is similar mechanically to an anterior cruciate ligament tear. AP, lateral, and intercondylar or tunnel view radiographs will show the avulsed fragment. The visible ossified fragment may be small because the tibial spine is mostly radiolucent cartilage.

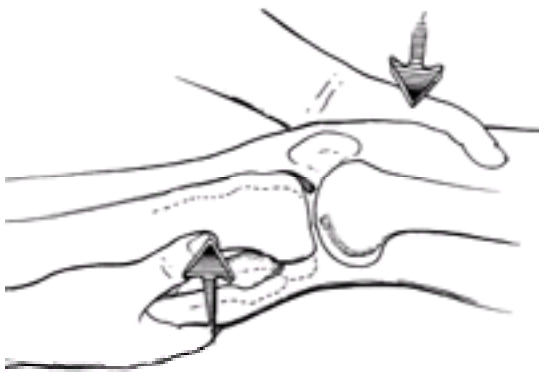

FIGURE 39.3. Testing for anterior cruciate ligament injury with the Lachman test. Flex the knee 20 to 30 degrees, support the thigh with one hand, and grasp the calf with the other hand. Move the tibia forward on the femur. Observe the tibial tubercle for movement and feel for excessive forward movement of the tibia in relation to the femur.

Osteochondral fractures are fractures of articular cartilage and underlying bone not associated with ligamentous attachments. These fractures usually involve the patella and occur during patellar dislocations or may involve the femoral condyle. Occasionally, a patient sustains a direct blow to the knee, but more commonly, the knee is injured during a twisting injury. The patient has severe pain, holds the knee flexed, and refuses to bear weight. Often, the patient has immediate swelling of the knee consistent with a hemarthrosis. Because the fragment may be in the intercondylar notch, radiographs need to include an intercondylar or tunnel view.

Dislocations

Patellar dislocation occurs as the quadriceps muscles pull along the patellar tendon to extend the knee. If the vastus medialis fibers do not keep the patella in the intercondylar groove, the patella may dislocate laterally. This often recurrent injury rarely occurs from direct force but rather happens more often during dancing or gymnastics. The patient may feel or hear a ripping or popping sensation or sound. The patient complains of intense pain and holds the knee flexed. The patella is visible more laterally than normal. The dislocation may be reduced before radiographs are taken. If the history is consistent with dislocation but the patient is no longer in pain and has a normal examination, he or she may have subluxated the patella. The patient is observed carefully for a high-riding or laterally displaced patella. Measurement is made of the quadriceps or Q angle formed by a line drawn from the anterior superior iliac spine to the midpatella and one drawn from the midpatella to the tibial tubercle. For men, the average Q angle is 14 degrees; for women it is 17 degrees. An angle above 20 degrees is abnormal. A patellar apprehension test is performed by gently attempting to move the patella laterally. If the patient becomes apprehensive or grabs the examiner's hand, this suggests that he or she has subluxated the patella. Radiographs are always obtained to rule out an associated avulsion fracture of the patella or femoral condyle.

In a child, the knee joint itself rarely dislocates; usually, the distal femoral or proximal tibial epiphysis separates first. Dislocation occurs only with trauma that involves significant force, such as a high-speed motor vehicle accident. The knee appears obviously deformed with the tibia or femoral condyles abnormally prominent in an anterior or posterior dislocation, respectively. Disruption of the popliteal artery may occur with the dislocation, and the resulting hypoperfusion may be limb-threatening. Posterior tibial and dorsalis pedis pulses and peroneal nerve function must be documented; radiographs will confirm the diagnosis.

Soft-Tissue Injuries

Medial or lateral collateral ligament injuries are rare when the epiphysis is open because the involved ligaments are stronger than the growth plate. The lateral collateral ligament inserts on the fibular head proximal to the physis, and the medial collateral ligament (MCL) inserts on the tibia distal to the physis. In older patients, the MCL may be damaged by a blow to the lateral side of the knee during contact sports or stress during a skiing accident, when the athlete “catches an edge” and falls forward with the leg rotated externally. Severe collateral ligament injury may be associated with anterior cruciate ligament (ACL) or meniscal damage. On examination, the knee may be swollen only minimally but will be tender over the involved ligament. The knee then should be tested for lateral laxity in full extension (associated with more severe injuries) and in 30 degrees of flexion (associated with less severe injuries), as shown in Figure 39.4. Orthopedic referral may be indicated if the examination reveals lateral or medial laxity.

FIGURE 39.4. Testing for collateral ligament injury. Test the knee in full extension and in 30 degrees of flexion. To test for medial collateral ligament injury, hold and apply force to the medial side of the ankle with one hand and apply pressure over the fibular head with the other hand. To test for lateral collateral ligament injury, hold and apply force to the lateral side of the ankle with one hand and apply pressure just below the medial side of the knee with the other hand. If the knee “opens up” laterally or medially more than the uninjured knee, the collateral ligament is injured.

Anterior cruciate ligament injuries occur in many scenarios but usually involve rotational forces on a fixed foot. The patient often reports the sensation of a “pop.” The joint usually swells rapidly as a result of hemarthrosis and has a marked decrease in ROM. The Lachman test (Fig. 39.3) is sensitive in detecting ACL injuries but may be falsely negative soon after the injury when the knee is swollen and painful. Examining the uninjured knee can be helpful for comparison. Arthroscopy or magnetic resonance imaging (MRI) is often needed for definitive diagnosis. ACL injuries are rare before adolescence because in a child, the ACL's insertion point, the tibial spine, is incompletely ossified. Therefore, the same force that would produce an ACL injury in an adolescent will cause an avulsion fracture of the tibial spine in a child.

Posterior cruciate ligament injuries are extremely rare and usually result from direct force on the tibial tubercle, pushing the tibia posteriorly on the femur. The posterior drawer sign will be present in most cases (Fig. 39.5).

FIGURE 39.5. Testing for posterior cruciate ligament injury with the posterior drawer test. With the patient supine and the knee flexed to 90 degrees, sit on the patient's foot to stabilize it. Attempt to force the tibia posteriorly. Posterior movement greater on the injured side than on the uninjured side is abnormal and suggests a posterior cruciate ligament injury.

The menisci are tough fibrocartilage pads that help distribute the body's weight over the femoral and tibial condyles. They can be injured when the knee is twisted during weight bearing. The patient may report a popping sensation and the feeling of the knee “giving out.” More chronically, the patient may report that the knee suddenly refuses to extend fully, “locking up,” and then suddenly “unlocking.” Joint-line tenderness is almost always present but must be differentiated from the tenderness associated with collateral ligament injuries. An effusion is commonly detected. Acutely, the injury may be difficult to diagnose because the patient has significantly reduced ROM, making the classic McMurray's sign difficult to elicit (Fig. 39.6). The Apley compression test (Fig. 39.7) requires less knee flexion and may be easier for the patient to tolerate. Radiographs generally are normal. A subluxating patella, ACL injury, or osteochondral fracture also may cause a popping sensation, and the patellofemoral pain syndrome may be associated with “giving way” of the knee.

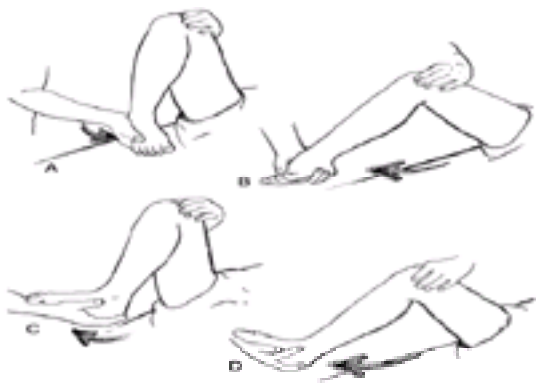

FIGURE 39.6. A–D. Testing for meniscal injury with the McMurray test. Grasp the patient's foot with one hand and place the other hand over the joint lines. Fully flex and extend the knee while alternately internally and externally rotating the tibia. The injured meniscus may be felt as a grinding or snapping sensation as the knee is manipulated.

FIGURE 39.7. Testing for meniscal injury with the Apley compression test. With the patient prone and the knee flexed to 90 degrees, apply pressure to the heel while the tibia is rotated. If this produces pain that resolves when the tibia is distracted from the femur while rotated, a meniscal injury should be suspected.

The quadriceps or patellar tendon can rupture acutely, especially in an older athlete who jumps or falls a great distance. The tendon will be tender directly over the rupture, and the patella may be positioned abnormally. A hemarthrosis may be present, and radiographs may show the abnormally positioned patella.

The three hamstring muscles (semitendinosus, semimembranosus, and the biceps femoris) flex the knee and may be strained in young athletes. The semitendinosus and semimembranosus insert along the medial popliteal space, and the biceps femoris tendon runs laterally. The patient may describe an acute pain or even a pop in the back of the thigh. Often, this injury presents subacutely with posterior thigh and popliteal knee pain when the hamstrings are strained by

repetitive use.

Posttraumatic Infection

Although not considered injuries, acute infections may present after a vague history of trauma. Physical findings of acute infection are present. The most common disorders are septic arthritis, osteomyelitis, cellulitis, and septic prepatellar bursitis.

Subacute Injuries

Many subacute knee problems manifest acutely in the ED. Osgood-Schlatter's disease of the tibial tubercle may lead to similar symptoms as a traumatic avulsion of the tubercle; however, with Osgood-Schlatter's disease, the symptoms have been noted for days or weeks. The symptoms of Osgood-Schlatter's disease are exacerbated by squatting or jumping, but they do not cause the same disability as an acute avulsion. The disease is usually seen in patients between 10 and 15 years of age. It may be caused by recurrent contractions of the patellar tendon during knee extension, traumatizing the tendon's insertion on the tibial tubercle during the child's growth spurt. The patients have localized tenderness and occasionally swelling over the tibial tubercle. The patient will refuse to extend the knee against force (e.g., perform a deep-knee bend) and have difficulty going up or down stairs, although they may have a normal gait on a level surface. To eliminate the possibility of a neoplasm, the physician should always obtain radiographs. They will either be normal or show irregularity of the tubercle.

Patellofemoral pain syndrome (PFPS) or chondromalacia patella may be caused by malalignment of the extensor mechanism of the knee. The patella transmits the force of the quadriceps muscles to the patellar tendon to extend the knee. The vastus lateralis, vastus intermedius, and rectus femoris pull the patella slightly laterally and need to be balanced perfectly by the vastus medialis to keep the patella tracking across the articular cartilage correctly. Medially squinting patellae and patella alta predispose patients to PFPS. Some of these patients have chondromalacia patella, with softening of the cartilage. The patient with PFPS has patellar pain with running and especially going down inclines or stairs. The patient also may have the sensation of the knee giving out when descending, although an actual fall usually does not occur. The patient has pain when sitting for a prolonged time with the knee flexed at 90 degrees. The pain disappears once the patient is ambulatory. This is called the movie sign. On examination, the patient may have the malalignment just mentioned, tenderness of the articular surface of the patella, and a positive patellar stress test. This test is performed with the patient in the supine position with the knee fully extended. The patient is asked to relax the quadriceps so that the physician can move the patella. With the patella pulled inferiorly, the physician should gently press down on it and ask the patient to tighten the quadriceps. (A younger patient should be asked to “push the knee into the examination table.”) This will move the patella superiorly as the physician continues to press down. A patient with PFPS will have acute pain with this maneuver; radiographs, however, are normal.

Patellar tendon tendinitis, or “jumper's knee,” occurs in patients during their growth spurt, especially those involved in jumping (knee extension) sports. The knee is tender on the inferior pole of the patella and the adjacent patellar tendon, but not on the tibial tubercle; radiographs generally are normal.

Prepatellar bursitis occurs after acute or chronic trauma to this bursa, which overlies the patella. The patient will have swelling over the anterior aspect of the knee, especially over the patella. A septic bursitis may need to be ruled out by needle aspiration.

Osteochondritis dissecans is the separation of a small portion of the femoral condyle with the overlying cartilage. The patient usually is an adolescent with a 1- to 4-week history of nonspecific knee pain. The physical examination may be normal or the femoral condyle may be tender. Because AP and lateral radiographs may not show the lesion, a tunnel or intercondylar view should be obtained.

Iliotibial band syndrome usually occurs in older runners who complain of pain over the lateral aspect of the knee. The iliotibial band moves in an anterior or posterior direction across the lateral femoral condyle as the knee flexes and extends. This repetitive movement may cause the pain. When examined, the patient is tender over the lateral femoral epicondyle, palpable 2 cm above the joint line. Radiographs are normal.

The Baker's cyst is a herniation of the synovium of the knee joint or a separate synovial cyst located in the popliteal fossa. The patient complains of popliteal pain and swelling only if the cyst enlarges. The sac can be palpated in the posterior medial aspect of the popliteal space and may be transilluminated. For the most part, radiographs will be normal or show soft-tissue swelling.

In any patient with knee pain, with or without a history of trauma, benign (e.g., osteochondroma and nonossifying fibroma) and malignant tumors (e.g., osteosarcoma or Ewing's sarcoma), the various causes of monoarticular arthritis (see Chapter 57), and hip disease that may present with knee pain (e.g., slipped capital femoral epiphysis or aseptic necrosis of the femoral head) must be considered.

EVALUATION AND DECISION

Four points are critical in the patient's history: 1) the activity and forces that led to the injury (e.g., direct or indirect force, direction of the force, and whether the foot was planted); 2) any sensations or noises (e.g., “locking,” “pops,” “snaps,” “rips,” or “tears”); 3) the initial location of the pain; and 4) the timing of any swelling.

The possibility of abuse in young children must always be considered, especially if the injury is unexplained, the history is implausible, or the seeking of medical care was delayed unreasonably.

Most severe injuries (ACL or meniscal injuries) occur when the patient is involved in high-velocity weight-bearing activities, especially running and making sharp cuts or being subjected to direct valgus stress. Non–weight-bearing injuries (e.g., diving) usually result in patellar dislocation or subluxation only. Direct trauma to the front of the knee may cause posterior cruciate ligament injuries or patellar fractures, whereas lateral to medial (valgus) forces may cause collateral or cruciate ligament damage or fractures. Distinct popping noises or tearing sensations are reported in ACL injuries and patellar subluxation. Locking of the knee often may be reported in meniscal injuries, but not immediately after the injury. Although the knee may “hurt all over” when seen in the ED, the patient may be able to localize the initial pain. Meniscal or collateral ligament injuries cause pain on the lateral or medial aspect of the knee, whereas ACL injuries hurt just inferior to the patella, and Osgood-Schlatter's disease is painful a few centimeters inferior to the patella over the tibial tubercle. Swelling within 2 hours strongly suggests hemarthrosis and an associated ACL injury, meniscal injury, or osteochondral fracture. Swelling after 4 to 12 hours is more likely to be an isolated effusion without an associated fracture or ligamentous injury.

In subacute injuries, inquiry is made about hip or groin pain because the hip and knee share sensory nerves. Legg-CalvéPerthes disease or a slipped capital femoral epiphysis may cause knee pain. The patient is asked about changes in physical activities or footwear. A sensation of the knee giving way without actually falling when going down stairs or inclines may be elicited in patellofemoral pain syndrome (i.e., chondromalacia patella), whereas exacerbation doing deep-knee bends suggests Osgood-Schlatter's disease.

Examination of the patient should include walking and standing to check for medially deviated “squinting” patellae. The knees are inspected and palpated in two positions, sitting relaxed with the knees at 90 degrees and supine. When sitting, the knees are inspected for swelling, bony changes (e.g., swelling over the tibial tubercle in Osgood-Schlatter's disease), joint-line tenderness (meniscal injuries), and quadriceps atrophy. The knee should be extended and flexed while inspecting for patellar tracking and palpating for crepitations.

With the patient supine, inspection and palpation are repeated over the joint line, collateral ligaments, patella, and tibial tuberosity. If the knee appears swollen, an effusion is sought. Normally, synovial fluid coats the patellar surface but does not separate the patella and femur. When fluid separates the two bones, a sharp pat on the patella results in the sensation of a tap as the two bones meet. If the joint contains a large amount of fluid, the patella will not touch the femur but will feel as if it is sitting on a cushion. The ROM of the knee and quadriceps strength are documented.

The physician should test for collateral and cruciate ligament damage, meniscal injuries, patellar subluxation, and patellofemoral pain syndrome, using the appropriate maneuvers (Table 39.2). Each test is described in the appropriate differential diagnosis section.

Maneuver	Diagnosis
Collateral laxity test (Fig. 39.4)	Collateral ligament injury
Lachman test (Fig. 39.3)	Anterior cruciate ligament injury
Posterior drawer test (Fig. 39.5)	Posterior cruciate ligament injury
McMurray test (Fig. 39.6)	Meniscal injury
Apley compression test (Fig. 39.7)	Meniscal injury
Patellar apprehension test	Patellar subluxation
Patellar stress test	Patellofemoral pain syndrome

Table 39.2. Summary of Diagnostic Maneuvers for the Injured Knee

Distal pulses, the posterior tibial, and the dorsalis pedis should be palpated, and the peroneal nerve function should be assessed. The deep peroneal nerve enervates the ankle dorsiflexors. The extensor hallucis longus can be tested by opposing dorsiflexion of the great toe. The deep peroneal nerve supplies sensation to the web space between the great and second toes. Patients with knee symptoms should have a careful hip examination because aseptic necrosis of the femoral head or a slipped capital femoral epiphysis may present with knee pain.

All patients with acute knee injuries should have AP and lateral radiographs, and if indicated, a patellar (or skyline view) radiograph should be taken. If the injury is more chronic, an intercondylar or tunnel view should also be taken to evaluate for osteochondritis dissecans.

Figure 39.8 summarizes an approach to the child with an acutely injured knee. If the initial evaluation suggests vascular compromise, traction and reduction of the knee should be attempted and an emergency orthopedics consultation should be obtained. If the patella is obviously dislocated, it may be reduced before obtaining radiographs. Postreduction radiographs and a careful examination for physeal tenderness then can exclude the diagnosis of a fracture. If the patient's knee is too painful or swollen to allow a complete examination or if the patient has a hemarthrosis, ligament or meniscal damage should be suspected, and the knee should be immobilized for a maximum of three days until seen by an orthopedic surgeon.

FIGURE 39.8. Approach to the patient with an acute knee injury.

If the patient tolerates an examination, a series of maneuvers may suggest collateral ligament injury, cruciate ligament injury, meniscal injury, or patellar subluxation as the diagnosis (Table 39.2 summarizes the diagnostic maneuvers for the knee). Next an assessment for popliteal tenderness to exclude a Baker's cyst or hamstring strain is performed. Finally, if no signs of infection or hip disease exist, the patient may have a tendon rupture or a mild sprain, strain, or contusion.

Often, a patient may come to the ED with a history of trauma and knee pain that has been present for more than 1 or 2 days (Fig. 39.9). In addition to the standard AP, lateral, and patellar views, a tunnel or intercondylar view should be taken to exclude a fracture, tumor, and osteochondritis dissecans. If the initial knee and hip examinations do not suggest a diagnosis and no signs of infection exist, the diagnostic maneuvers in Table 39.2 should be completed. The patient may have an old collateral ligament, cruciate ligament, or meniscal injury and may require an orthopedic referral.

CHAPTER 40

Injury—Shoulder

MARC N. BASKIN, MD

Department of Pediatrics, Harvard Medical School, and Department of Pediatric Emergency Medicine, Short Stay Unit, Children's Hospital, Boston, Massachusetts

This chapter focuses on the diagnosis of the child with an overtly painful, injured shoulder (for the preverbal child with a possible shoulder injury presenting with an immobile arm, see Chapter 36). Children have different causes for their shoulder injuries than do adults because of their open growth plates, and young patients may be more difficult to examine because of anxiety and limited verbal skills. Figure 40.1 shows the important bony anatomy.

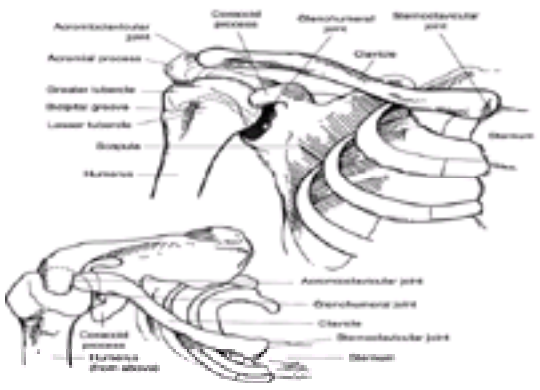

FIGURE 40.1. Anatomy of the shoulder.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis depends mainly on exactly where the patient has pain. In this chapter, injuries are described anatomically, from the sternoclavicular joint to the humeral shaft (Table 40.1 and Table 40.2).

Sternoclavicular joint	Rotator cuff
Dislocation*	Impingement
Sprain	Tear
Clavicle	Humerus
Physeal separation of medial end of the clavicle	Fracture of proximal humeral physis
Fracture	Stress fracture of proximal humeral physis ("Little League shoulder")
Contusion ("shoulder pointer")	Fracture of shaft
Osteolysis	Biceps tendon tendinitis
Acromioclavicular joint dislocation or sprain ("shoulder separation")	Pathologic fracture*
Scapula fracture	Referred pain (from)
Glenohumeral joint	Myocardium*
Dislocation ("shoulder dislocation")	Diaphragm*
Subluxation	Neck
	Thoracic outlet syndrome

*Potentially life-threatening conditions.

Table 40.1. Differential diagnosis of the injured Shoulder

Clavicle fracture	Humerus
Glenohumeral joint	Fracture of proximal humeral physis
Dislocation ("shoulder dislocation")	Fracture of shaft
Subluxation	

Table 40.2. Common Causes of the Injured Shoulder

Physeal (growth plate) separations of the medial clavicle are caused by indirect trauma that forces the shoulder medially and separates the growth plate. This injury mimics the sternoclavicular dislocations seen in adults. Before 18 years of age, injury to the sternoclavicular joint causes physeal separations because the epiphysis of the medial clavicle begins to ossify between 13 and 19 years of age and fuses between 22 and 25 years of age. At that time, a similar injury will cause sternoclavicular joint dislocations. Most separations are anterior, and the patient has swelling and tenderness over the sternoclavicular joint. Anteroposterior (AP) and superiorly projected lordotic radiographs comparing both clavicles may not visualize the lesion. Computed tomography (CT) or magnetic resonance imaging (MRI) is usually necessary to delineate the lesion. If the dislocation is posterior, the aorta or trachea may be injured; the child may remain asymptomatic or complain of choking or difficulty breathing. If the growth plate and ligaments are not disrupted by the injury, a simple sprain has occurred.

The clavicle is a commonly fractured bone in children, most often in the middle or lateral third of the bone. The clavicle is subject to any medially directed force on the upper limb (e.g., a fall on an outstretched hand) but is most commonly fractured by a direct blow. Although subclavian vessels and the brachial plexus are just beneath the clavicle, they are rarely injured because the subclavius muscle is interposed between the bone and vessels and the thick periosteum of the clavicle rarely splinters. A neonate's birthing injury or an infant's greenstick fracture of the clavicle may go unnoticed until the focal swelling of the developing callus is noted. In the older child, the arm droops down and forward, and the head may be tilted toward the affected side because of sternocleidomastoid muscle spasm. Localized swelling, tenderness, and crepitations may be noted. A radiograph will confirm the diagnosis. Rarely, a radiograph obtained because of clavicular trauma will show a congenital pseudarthrosis, or false joint of the clavicle.

Older children with a clavicular contusion or “shoulder pointer” may have swelling and tenderness over the distal clavicle. This injury can be differentiated from an acromioclavicular (AC) joint sprain by careful physical examination (the tenderness should be localized to the distal clavicle and not over the AC joint) and radiographs (see the section on AC joint separation).

Osteolysis of the distal clavicle with resorption of the bone may develop after minor injuries to the clavicle. Patients experience chronic pain and mild swelling 2 to 3 weeks after the initial injury. Radiographs are diagnostic.

AC joint injuries usually cause fractures of the distal clavicle in patients less than 13 years of age. Older children may injure the AC joint (“shoulder separations”) either by a direct blow to the shoulder or by transmitted force from a fall on an outstretched hand. The child will have pain with any motion of the shoulder and tenderness over the AC joint. In a first-degree sprain, the clavicle is not elevated above the acromion. In second- and third-degree sprains, swelling and elevation should be present. Bilateral “stress view” radiographs of the AC joint may be obtained to compare the separation on the normal and affected sides. A shoulder pointer contusion of the distal clavicle can be differentiated by tenderness limited to the distal clavicle and a normal radiograph. Cosmetic deformities and degenerative changes of the distal clavicle may complicate these injuries, even with appropriate therapy.

Scapula fractures are rare in pediatrics and usually occur only after major direct trauma such as a motor vehicle accident or a fall from a height. The child will have tenderness over the scapula. The patient often sustains other more life-threatening injuries (e.g., head injuries, rib fractures, pneumothoraces).

Shoulder or glenohumeral joint dislocations are rare in children less than 12 years old. These injuries become common in adolescence as the skeleton matures. The glenohumeral joint is shallow, allowing a wide range of motion, but increasing the risk of dislocation. The patient is injured when an already abducted and externally rotated arm is forcibly extended posteriorly. This action leverages the humeral head out of the glenoid fossa. The trauma can damage the axillary nerve or fracture the humeral head. More than 95% of all dislocations are anterior, and less than 5% are posterior. The patient will be in severe pain, supporting the affected arm internally rotated and slightly abducted (i.e., the patient cannot bring the elbow to his or her side). The shoulder contour is sharp, unlike the smooth contour of the opposite shoulder, and the acromion is prominent (Fig. 40.2). Sensation over the shoulder, especially laterally (axillary nerve distribution), and distal pulses should be documented. Radiographs should always be obtained because a humeral head or even a clavicular fracture may mimic a shoulder dislocation. An AP, transcapular lateral (Neer's), and an axillary view will show the location of the dislocation and the presence of any fractures.

FIGURE 40.2. An older adolescent patient with left anterior glenohumeral joint dislocation. Notice the sharp contour of the shoulder, the fullness below the glenoid fossa, and the prominent acromion.

If the patient has a history consistent with dislocation but has more range of motion than expected and the radiograph is normal, the patient may have spontaneously reduced a dislocated shoulder or only sprained the ligaments overlying the glenoid fossa and subluxated the glenohumeral joint. An apprehension test should be performed (Fig. 40.3).

FIGURE 40.3. The apprehension test to evaluate for shoulder subluxation. The patient's shoulder should be abducted passively and rotated externally. If this elicits apprehension or pain, the test is positive. If not, the examiner then should apply anteriorly directed pressure to the posterior aspect of the humeral head. If this elicits pain, then the test also is positive, and the patient's shoulder may have subluxed.

Actual tears of the rotator cuff are rare before 21 years of age. However, if the rotator cuff muscles are weak, the humeral head is displaced upward during overhead motion and may impinge the tendon of the supraspinatus muscle as it runs below the acromion. Impingement symptoms usually occur with repetitive overhead motions (e.g., throwing a ball). The pain is poorly localized. The patient may have mild tenderness under the acromion when the arm is abducted and may have increasing pain when the arm is abducted passively between 80 and 120 degrees. A test for impingement is illustrated in Figure 40.4. If the impingement test produces pain below the acromion in an adolescent athlete, the patient may have a lax glenohumeral joint. Plain radiographs are usually normal, and an MRI may be necessary.

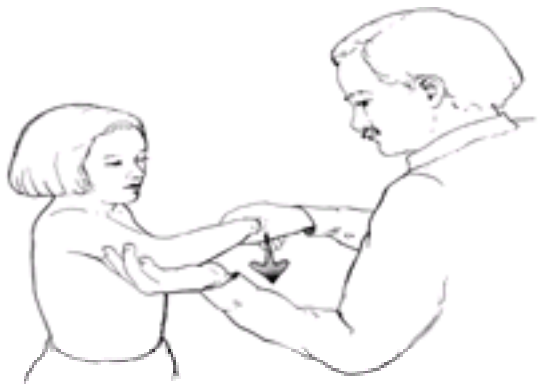

FIGURE 40.4. The impingement test to evaluate for impingement of the supraspinatus tendon. The patient's arm should be held in internal rotation and 90 degrees of forward flexion. Force the forearm downward by bringing the humeral head up against the acromion. Pain localized below the acromion suggests impingement.

Because the ligamentous attachments are stronger than the growth plate, fracture separations of proximal humeral epiphysis occur until the patient's epiphysis closes between 16 and 19 years of age. The injury occurs because of direct or indirect trauma, such as a backward fall or an attempt to break a fall with a hand. The patient usually has mild swelling and local tenderness. AP and lateral radiographs confirm the diagnosis, although in patients under the age of 6 years, the injury may be difficult to visualize because the epiphysis is mainly cartilaginous. Even in older patients, slight widening of the epiphysis may be difficult to see, and comparison views of the uninjured shoulder may be necessary.

Stress fractures of the proximal humeral epiphysis, or “Little League shoulder,” are caused by repetitive internal rotation of an abducted, externally rotated shoulder during the throwing motion. The child has diffuse shoulder pain that worsens after throwing. The proximal humerus may be tender, and radiographs show widening of the proximal humeral epiphysis.

Transverse or comminuted fractures of the humeral shaft may occur from direct trauma, whereas spiral fractures usually occur from indirect trauma (e.g., a fall on a hand). If the history is implausible, inconsistent from one caretaker to another, or the patient is less than 2 years of age, the child should be evaluated for physical abuse. The patient will have obvious pain, tenderness, and local deformity. Care must be taken not to miss an associated neurovascular injury because the radial nerve runs along the humeral shaft. Radial nerve damage results in weakness of wrist extension and anesthesia of the skin between the first and second metacarpals. Radiographs help rule out a pathologic fracture (e.g., through a unicameral bone cyst or tumor).

Shoulder pain is rarely related to tendinitis of the tendon of the long head of the biceps. This tendon runs through the bicipital groove just anterior and medial to the greater humeral tuberosity. The tendon moves within the groove during

internal and external rotation. The patient often has chronic pain and tenderness over the bicipital groove.

A painful shoulder or fracture that follows minimal trauma may be caused by a benign or malignant tumor or by nonneoplastic bone lesions. Osteochondromas (exostoses) are outgrowths of benign cartilage from the bone adjacent to the epiphysis and present with a mass adjacent to a joint. The nonossifying fibromas (called fibrous cortical defects if smaller than 0.5 cm) are common asymptomatic lesions that may lead to pathologic fractures.

The malignant chondroblastoma is a rare tumor, but its most common location is the proximal humerus. The patient often has joint pain from effusion associated with this tumor. Osteogenic sarcomas and Ewing's sarcoma are more common but involve the humerus in only 10% of cases

Unicameral and aneurysmal bone cysts are asymptomatic until the bone fractures, but they are not neoplastic lesions. Unicameral cysts are more likely to affect the humerus.

Shoulder pain also may be referred from the neck (e.g., cervical disc herniation), myocardium, or diaphragm (e.g., a splenic hematoma) after trauma to those areas.

Thoracic outlet syndrome, with compression of the medial cord of the brachial plexus (C8–T1) may rarely present as shoulder pain. The pain and anesthesia most commonly follow the dermatome of the ulnar nerve. The pain may be reproduced by 180 degrees of forward flexion; radiographs should include the neck to exclude a cervical rib.

EVALUATION AND DECISION

Initially, the patient's neurovascular status is assessed and fracture stabilization provided, if necessary (Fig. 40.5).

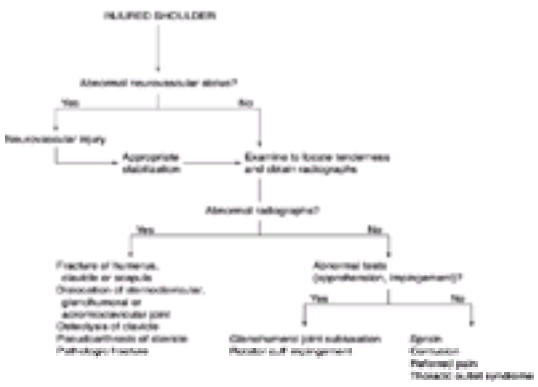

FIGURE 40.5. Approach to the patient with an injured shoulder.

For an isolated shoulder injury, the pain should be localized as specifically as possible and the mechanism of injury determined. An attempt is made to determine whether the trauma was direct or indirect and to ascertain what position the shoulder was in when the injury occurred. If the pain is chronic, the position or motion that most exacerbates the pain is determined (e.g., throwing a ball). The patient is asked about any distal paresthesias, associated pain, and trauma (e.g., neck, chest, abdomen). The possibility of abuse in young children should always be considered, especially if the injury is unexplained, the history is implausible, or the seeking of medical care was delayed unreasonably.

Initially, the patient is observed without clothes over the shoulder for positioning of the arm, swelling, deformity, or any asymmetry. Then, one asks the patient to point with one finger to the most painful area. This observation period before the formal physical examination is especially important in a young, anxious child and helps prioritize the rest of the evaluation.

If the child seems anxious, the uninjured side is examined first. The examiner carefully palpates the entire shoulder from sternoclavicular joint to the shaft of the humerus. Swelling and tenderness at the sternoclavicular joint suggests a physeal separation or dislocation at this site. The clavicle is covered only by a thin platysma muscle and a fracture is easily seen and palpated. Just lateral to the clavicle is the AC joint. Elevation of the clavicle above the acromion or tenderness of the articulation suggests AC joint dislocation (“shoulder separation”) or contusion. With the shoulder in external rotation, palpation just lateral to the acromion will locate the greater tuberosity of the humerus. Just in front of the greater tuberosity is the tendon of the long head of the biceps within the bicipital groove. Pressure may produce exquisite tenderness in this area, so palpation should be gentle; if uncertainty about a finding of tenderness exists, a comparison with the examination of the uninjured side is helpful. Finally, the proximal humeral shaft and the scapula are palpated.

During the neurologic evaluation, it is important that sensation is tested over the deltoid muscle because the axillary nerve may be damaged during a shoulder separation

Next follows an examination of the patient's active and passive range of motion (Fig. 40.6), checking for abduction, adduction, forward flexion, backward extension, internal rotation, and external rotation. Internal and external rotation can be observed easily in a child by asking the patient to touch behind the neck (external rotation) and lower back (internal rotation).

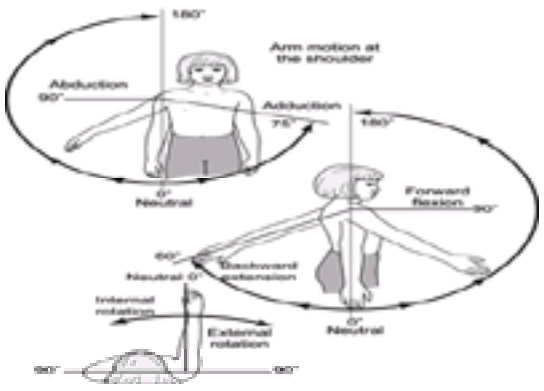

FIGURE 40.6. Range of motion of the shoulder joint.

Once the pain has been localized, appropriate radiographs are obtained, and when indicated, two additional specific tests are performed: the apprehension test for shoulder subluxation and the impingement test for rotator cuff impingement (Fig 40.3 and Fig 40.4).

As previously discussed, patients with normal radiographs and negative maneuvers are most likely to have sprains or contusions, but occasionally, they may be experiencing referred pain.

CHAPTER 41

Jaundice—Unconjugated Hyperbilirubinemia

KENNETH D. MANDL, MD, MPH

Department of Pediatrics, Harvard Medical School, and Division of Emergency Medicine, Children's Hospital, Boston, Massachusetts

Jaundice—a yellowish discoloration of the skin, tissues, and bodily fluids—indicates an elevated serum bilirubin concentration. Hyperbilirubinemia results from increased production or impaired excretion of bilirubin. Both physiologic and pathologic etiologies may give rise to unconjugated (or indirect) hyperbilirubinemia; to distinguish, the clinician must consider the patient's age, the rate of increase and peak level of serum bilirubin, and the historical features of the case. Prompt evaluation and therapy for unconjugated hyperbilirubinemia are particularly important for infants less than 1 week old. If bilirubin levels rise too high, these young infants risk developing neurodevelopmental deficits as well as kernicterus.

PATHOPHYSIOLOGY

Bilirubin is formed from the degradation of hemoglobin and other heme-containing proteins. Heme protoporphyrin becomes oxidized, producing biliverdin, which then is reduced to form bilirubin. In the blood, bilirubin is bound to albumin. The liver uptakes bilirubin for conjugation by a glucuronyl transferase, and then excretes the conjugated form into bile. The net balance of its entry into and removal from the circulation determines serum bilirubin concentration. In the newborn infant, multiple factors contribute to jaundice, including high bilirubin load from increased red blood cell (RBC) volume and decreased red cell survival, as well as impaired plasma binding, liver uptake, conjugation, and excretion of bilirubin.

Older children and adults normally have serum bilirubin concentrations below 1 mg/dL and appear jaundiced with a bilirubin level above 2 mg/dL. Newborn infants becomes visibly jaundiced when their serum bilirubin concentration is above 5 mg/dL. In conjugated, or direct, hyperbilirubinemia, the conjugated (or direct reacting) portion of the serum bilirubin exceeds 2.0 mg/dL and is more than 15 to 30% of the total. Otherwise, the hyperbilirubinemia is unconjugated, or indirect (see Chapter 42).

In neonates, hyperbilirubinemia may be associated with neurotoxicity, encephalopathy, and kernicterus. Kernicterus is a rare but devastating neurologic disorder with characteristic yellow staining in the basal ganglia and other brain regions.

DIFFERENTIAL DIAGNOSIS

For patients with primarily unconjugated hyperbilirubinemia who are beyond the neonatal period, the most common causes are hemolytic processes resulting in overproduction of bilirubin (Table 41.1). Extravascular blood in a concealed hemorrhage may also be metabolized into supraphysiologic concentrations of bilirubin. Infants and children with jaundice may have enzyme deficiencies or other conditions that impair the hepatic uptake or conjugation of bilirubin. Upper gastrointestinal (GI) obstruction generally causes conjugated hyperbilirubinemia but may occasionally be associated with an unconjugated hyperbilirubinemia. In the neonatal period, physiologic and breast milk jaundice are common. The potential for maternal–fetal blood group incompatibility is critical to recognize.

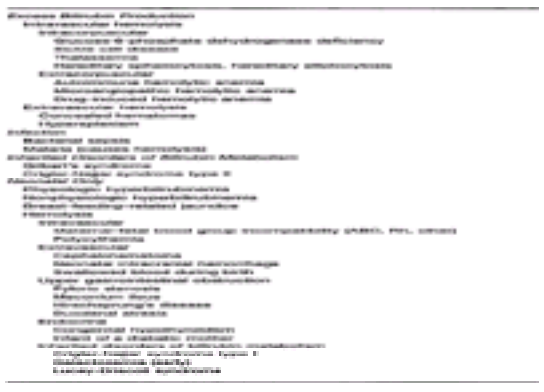

Table 41.1. Causes of Primarily Unconjugated Hyperbilirubinemia

Excess Bilirubin Production

The numerous causes of hemolysis may be classified as intravascular or extravascular. Intravascular hemolysis may be further divided into intracorpuscular and extracorpuscular defects (Table 41.1). Inborn errors of metabolism, such as glucose-6-phosphate dehydrogenase (G6PD) deficiency, may result in destruction of RBCs. This disorder is common in African-American and Asian children as well as those of Mediterranean origin. Patients with G6PD deficiency who are exposed to oxidant stress (e.g., fava beans, sulfa drugs) may have acute rapid hemolysis. Neonates with G6PD deficiency have an increased risk of jaundice that is only partially attributable to hemolysis.

Hemoglobinopathies, including sickle cell disease, can result in hemolysis, as can the impairments in hemoglobin chain synthesis that occur in the thalassemias. Defects in the RBC membrane found in hereditary spherocytosis and hereditary elliptocytosis increase the fragility of the corpuscles. Extracorpuscular causes of RBC destruction include the autoimmune, microangiopathic, and drug-induced hemolytic anemias.

Hematomas, pulmonary hemorrhages, and other collections of extravasated blood undergo hemolysis and, if sufficiently large, can elevate serum levels of unconjugated bilirubin. Various hypersplenic states, including splenic sequestration crisis in sickle cell disease, may result in anemia with accompanying hemolysis and hyperbilirubinemia.

Infection

Jaundice may be a harbinger of serious infection. Bacterial endotoxins reduce bile flow and can cause hyperbilirubinemia. The neonate with jaundice as well as poor feeding, lethargy, or fever should be evaluated for sepsis and urinary tract infection. However, sepsis is exceedingly rare among well-appearing jaundiced neonates who have no additional signs or symptoms, occurring at a rate considerably below 1%. Malaria, caused by *Plasmodium* species, is endemic in tropical regions. In patients with malaria, a high degree of parasitemia may result in massive hemolysis presenting with jaundice.

Inherited Disorders of Bilirubin Metabolism

Gilbert's syndrome is a common cause of mild, intermittent, unconjugated hyperbilirubinemia that occurs in as many as 6% of the population. Patients with Gilbert's syndrome have a partial deficiency of glucuronyl transferase. They generally do not present until late childhood or early adolescence, when they may develop nonspecific abdominal pain, nausea, and mild jaundice during an intercurrent illness. Other liver function studies are normal, and there is no evidence of hemolysis or hepatosplenomegaly. The serum bilirubin rarely exceeds 5 mg/dL.

Crigler-Najjar syndrome is characterized by the absence or deficiency of the enzyme bilirubin glucuronyl transferase. Type I, the more severe form, manifests soon after birth and is associated with high morbidity and mortality. Type II, the milder form, caused by an incomplete enzyme deficiency, typically presents in infancy or later in childhood but has been reported to first appear as late as adolescence. The type II form is generally treatable with phenobarbital.

Special Considerations in the Neonate

Physiologic Neonatal Hyperbilirubinemia

Most newborns develop a mild hyperbilirubinemia; approximately 60% manifest clinical signs of physiologic jaundice. Physiologic jaundice peaks between 3 and 5 days of life in the term infant and requires no treatment. Because at high levels bilirubin may be associated with neurotoxic effects, careful attention should be paid to distinguishing physiologic from nonphysiologic jaundice.

Nonphysiologic Neonatal Hyperbilirubinemia

One to two percent of newborns require readmission within the first week of life, and up to 85% of these readmissions are for nonphysiologic neonatal hyperbilirubinemia. Jaundice in the term newborn is nonphysiologic if it is conjugated or appears within the first 24 hours of life. Other indications that jaundice is not physiologic are a peak serum total bilirubin concentration of 17 mg/dL or higher in the breast-fed infant and 15 mg/dL or higher in the formula-fed infant. Also, infants with persistence of jaundice beyond the first week of life, or whose serum bilirubin level increases more than 5 mg/dL per day, should be followed closely for nonphysiologic jaundice. Risk factors for nonphysiologic neonatal hyperbilirubinemia include history of a sibling with hyperbilirubinemia, breast-feeding, lower gestational age, maternal diabetes, bruising (from birth trauma), and Asian race. Dehydrated neonates may develop unconjugated hyperbilirubinemia.

Breast-Feeding and Jaundice

Breast-fed newborns develop a greater degree of hyperbilirubinemia more often than do formula-fed newborns. Breast-milk jaundice, occurring in 1% of newborns, is associated with the breast milk itself and may be hormonally mediated or related to intestinal excretion and resorption of bile. Many cases of jaundice in breast-fed infants are caused by nonoptimal breast-feeding practices that result in dehydration.

Hemolysis

Birth trauma, when associated with a cephalohematoma, extensive bruising, or swallowed maternal blood, can result in hyperbilirubinemia. Intracranial, pulmonary, or other concealed hemorrhage also can lead to extravascular hemolysis. Similarly, polycythemia, caused by delayed clamping of the cord or maternal–fetal or fetal–fetal transfusion (in multiple gestations), increases the RBC mass and causes jaundice in neonates.

When maternal antibodies are produced against fetal red cell antigens, the neonate can develop a Coombs' positive isoimmune hemolytic anemia. The risk of kernicterus in infants with hyperbilirubinemia as a result of isoimmune hemolytic anemia is much greater than the risk in infants with nonhemolytic causes of jaundice. Fetal Rh and A and B blood group antigens are most commonly etiologic in the hemolysis syndrome, although dozens of antigens have been implicated. Rh-negative mothers may become sensitized to an Rh-positive fetus during pregnancy and mount an antibody response to a fetus during a subsequent pregnancy. Administration of Rhogam to Rh-negative mothers who have not yet developed anti-Rh antibodies can prevent Rh isoimmunization. ABO hemolytic disease of the newborn generally occurs in infants with A or B blood groups whose mothers have type O blood. Maternal anti-A and anti-B antibodies are produced and can result in hemolysis with a positive direct Coombs' test.

Upper Gastrointestinal Obstruction

Pyloric stenosis, meconium ileus, Hirschsprung's disease, duodenal atresia, and other causes of upper GI obstruction may present with jaundice and clinical signs of obstruction. In neonates, obstruction can increase enterohepatic circulation or decrease the enzyme activity responsible for bilirubin uptake, resulting in unconjugated hyperbilirubinemia. In contrast, older children and adults with upper GI obstruction and jaundice generally have a conjugated hyperbilirubinemia.

Endocrine Disorders

Unconjugated hyperbilirubinemia may be the presenting sign of congenital hypothyroidism, preceding other manifestations by several weeks. The mechanism probably relates to reduced bile flow. Other signs that may be present include persistent poor feeding, prolonged jaundice, constipation, and hypotonia. Infants of diabetic mothers are also at increased risk of jaundice, with as many as 19% developing nonphysiologic hyperbilirubinemia.

Inherited Disorders of Bilirubin Metabolism

Very high, rapidly rising levels of bilirubin not responsive to phototherapy raise concern for Crigler-Najjar syndrome type I or Lucey-Driscoll syndrome. Lucey-Driscoll syndrome is probably caused by an inhibition of glucuronyl transferase. Infants with galactosemia may exhibit an unconjugated hyperbilirubinemia during the first week of life. Older infants with galactosemia tend to have a conjugated hyperbilirubinemia. Infants with galactosemia usually also present with vomiting, failure to thrive, poor feeding, abdominal distension, and hypoglycemia.

EVALUATION AND DECISION

An approach to the patient with unconjugated hyperbilirubinemia is outlined in Figure 41.1. Hemolysis and Gilbert's syndrome are the most common cause of jaundice in the patient beyond the neonatal period (Table 41.2). During the neonatal period, physiologic jaundice and breast-feeding–related jaundice are the most likely causes. The differential diagnosis is broad, and evaluation should always begin with a detailed history and physical examination.

Table 41.3. Life-Threatening Causes of Primarily Unconjugated Hyperbilirubinemia

History

A general clinical history may help guide the workup. An infant who has been lethargic or apneic or a child who has been ill and febrile may require evaluation for serious bacterial infections (Table 41.3). A neonate with persistent or bilious emesis may have an upper GI obstruction.

The clinician should ascertain whether there are factors predisposing a patient to jaundice. One such factor is a family history of jaundice or anemia or a racial or ethnic origin associated with hemolytic anemias. African-American race and Mediterranean ancestry are associated with G6PD deficiency. Additional causes of jaundice run in families or have racial predisposition. African-American patients are much more likely to have sickle cell disease. Mediterranean and Asian children have a higher incidence of thalassemia. East Asian neonates are more likely to develop nonphysiologic hyperbilirubinemia. A history of drug ingestion may lead to the diagnosis of drug-induced hemolysis. A dietary history may identify an agent such as the fava bean that induces hemolysis in patients with G6PD deficiency. Residence in or travel to sub-Saharan Africa, South East Asia, or parts of Central and South America carries a risk of exposure to malaria.

Special Historical Considerations in the Neonate

For the newborn, timing of the onset of icterus is critical. Most jaundice that appears before the first 24 hours of life is pathologic. Maternal blood type and Rhogam status should be ascertained to establish risk factors for isoimmune hemolytic anemia. Previous bilirubin levels and the results of Coombs' testing should be ascertained. Feeding practices influence development of jaundice; a breast-fed infant is at risk for breast-feeding–related jaundice, including jaundice resulting primarily from dehydration. Knowledge of weight gain or loss may help judge hydration status.

Physical Examination

The general appearance of the patient will help guide the clinician as to the likelihood of a serious underlying condition such as bacterial sepsis. In the neonate, poor feeding, lethargy, apnea, tachypnea, and temperature instability are highly concerning.

The sclera and skin should be examined closely under adequate light. In a patient with dark skin, palms and soles may be less pigmented and easier to assess for icterus. Gentle pressure with one finger to blanch the skin facilitates inspection of skin color. In neonates, jaundice progresses in a cephalocaudad direction. Newborns with jaundice below the knees and on the palms have the highest levels of serum bilirubin. Pallor may indicate anemia from hemolysis or bleeding.

Presence of a cephalohematoma or large areas of ecchymosis may point to an extravascular hemolysis as the cause of hyperbilirubinemia. Hepatomegaly may indicate underlying liver dysfunction. Splenomegaly can indicate a hypersplenic state such as splenic sequestration in sickle cell disease. Splenomegaly may also be present in lupus, which is associated with an autoimmune hemolysis. In a neonate with jaundice and vomiting, an abdominal mass suggests upper

GI obstruction.

Laboratory Testing

The serum bilirubin level should always be determined. Jaundiced patients beyond the neonatal period should be evaluated for anemia with a complete blood count (CBC) and reticulocyte count. Those with evidence of anemia and/or hemolysis should have a peripheral blood smear examined microscopically. Characteristic abnormal morphology such as sickle cells, spherocytes, or elliptocytes may be identified. Helmet and fragmented cells are diagnostic of a microangiopathic hemolytic anemia, such as that occurring in hemolytic uremic syndrome. Malarial ring forms may be apparent. Nucleated RBCs and Howell-Jolly bodies indicate a sustained hemolysis. Patients with anemia or hemolysis should also have a Coombs' test performed to look for evidence of autoimmune hemolysis. Testing for G6PD should be performed if the patient has risk factors or a consistent clinical presentation. Hemoglobin electrophoresis may be used to diagnose hemoglobinopathies such as sickle cell disease and thalassemia. If hepatomegaly is present or if there is no evidence of anemia, liver function studies should be performed. Patients with no laboratory abnormalities other than serum unconjugated bilirubin below 5 mg/dL have Gilbert's syndrome, a benign condition.

Special Laboratory Considerations in the Neonate

In neonates, it may be important to determine the rate of rise of serum bilirubin with serial measurements. The clinician must know whether a newborn has a set-up for maternal–fetal isoimmune anemia. Therefore, either the mother's blood and Rh type and antibody status should be obtained, or the infant's blood type should be determined and Coombs' testing performed. A neonate with probable physiologic jaundice does not need to undergo an anemia or hemolysis workup if he or she has no family history of hemolytic disease, no maternal–fetal blood group incompatibility, and no physical stigmata of anemia.

If clinical signs of obstruction are present, the patient should undergo appropriate laboratory testing such as abdominal radiographs, ultrasound, or upper GI series with contrast. The neonate with fever or ill appearance should be evaluated for serious bacterial infection, with peripheral white blood cell count, urine analysis, and cerebrospinal fluid analysis as well as blood, urine, and cerebrospinal fluid cultures. Results of the newborn screen for congenital hypothyroidism may be available. The newborn with symptoms of congenital hypothyroidism needs to have a determination of T_4 level. A newborn with poor feeding, vomiting, or failure to gain weight should be evaluated for galactosemia. If the newborn with galactosemia has already started feeds, the urine will contain reducing substances (Clinitest positive) but no glucose.

Approach

Beyond the Neonatal Period

In all children with jaundice, a total bilirubin level with fractionation and CBC should be performed. If a patient appears acutely ill, the physician should proceed with the appropriate evaluation and treatment for sepsis. Among well-appearing patients, the hematocrit determines the likely diagnostic possibilities and appropriate studies.

Anemia

Anemic children are suspect for having hemolytic processes, including autoimmune hemolytic anemia, hemoglobinopathies (e.g., thalassemia or sickle cell anemia), enzyme deficiencies (e.g., G6PD), red cell membrane defects (e.g., spherocytosis), hypersplenism, drug reactions, hemolytic uremic syndrome, and malaria. Extravascular hemolysis and resultant jaundice occur occasionally in children with concealed blood loss or large hematomas. A family history of hemolytic anemia and severe jaundice, particularly among children of Mediterranean descent, suggests G6PD deficiency, whereas abnormal RBC morphology points to sickle cell anemia, hereditary spherocytosis, or heredity elliptocytosis. Additional clues on the peripheral smear include helmet and fragmented cells in hemolytic uremic syndrome and ring forms in malaria.

A positive Coombs' test is seen with autoimmune hemolytic anemia. In patients with splenomegaly, hemolysis may lead to jaundice. Finally, drug reactions and unusual hemolytic anemias should be considered.

Normal Hematocrit

When unconjugated hyperbilirubinemia occurs without anemia, abnormal liver function studies (transaminases, prothrombin time, and partial thromboplastin time) differentiate hepatic disease from inherited disorders of bilirubin metabolism. Among these latter disorders, only Gilbert's syndrome, which produces a mild elevation in the serum bilirubin level, is at all common.

Neonatal Period

As for older children, an ill appearance and/or fever suggest sepsis. Other disorders likely to cause lethargy include bowel obstruction, hypothyroidism, and inborn errors of metabolism, such as galactosemia. Among well-appearing neonates, the presence of anemia serves as an important point in the differential diagnosis.

Anemia

The foremost consideration is the infant with indirect hyperbilirubinemia and anemia is isoimmune hemolytic disease, caused by blood group incompatibility, because this disorder may lead to kernicterus. The diagnosis can be established by determining the blood group and Rh status of the maternal–infant dyad in combination with a Coombs' test in the infant. Other disorders that produce jaundice include enzymatic and structural disorders of the red cells (e.g., G6PD,

hereditary spherocytosis) and the poorly understood occurrence of jaundice in infants of diabetic mothers.

Normal Hematocrit

In the absence of anemia, extravascular hemolysis is a common cause of jaundice in the newborn, with the breakdown of hemoglobin occurring in a cephalohematoma, large ecchymosis, or from swallowed blood. In addition, polycythemic infants are prone to jaundice. Also, hemolysis of even small amounts of hemoglobin may markedly elevate the serum bilirubin level in the infant with an immature liver. Thus, the same disorders that are diagnosed in anemic infants may occur in the jaundiced neonate with a normal hematocrit.

Most infants with indirect hyperbilirubinemia will have a negative evaluation for the disorders previously listed. If the bilirubin level is less than 12 mg/dl, rises slowly, and resolves before 8 days of age, one can diagnose physiologic hyperbilirubinemia without further laboratory studies. When these conditions are not met, the most likely cause for the jaundice is the hormonal impairment of bilirubin conjugation. Other possibilities, either alone or in combination with breast milk, include Crigler-Najjar and Lucey-Driscoll syndromes.

MANAGEMENT

For patients beyond the neonatal period, the management of hyperbilirubinemia is primarily directed at identification and treatment of the underlying cause. In some cases of severe hyperbilirubinemia, such as those caused by Crigler-Najjar syndrome type II, phenobarbital may be indicated. In contrast, newborns with jaundice require careful monitoring and sometimes specific therapies for hyperbilirubinemia because the neonatal central nervous system is susceptible to the toxic effects of bilirubin. The emergency physician may initiate the management of term newborn infants with jaundice and arrange hospitalization or subsequent follow-up after discharge. Infants discharged home from their birth hospitalization on the first or second day of life are at increased risk of readmission for hyperbilirubinemia. The management of premature infants with hyperbilirubinemia is highly specialized and not discussed here.

The goal of neonatal hyperbilirubinemia management is to prevent neurotoxicity, encephalopathy, and kernicterus. The jaundiced newborn needs to be kept well hydrated, and enteral feeding should be encouraged to promote bilirubin excretion. When bilirubin levels rise significantly, phototherapy and exchange transfusion may be indicated.

Phototherapy can be initiated with either an overhead bank of lights or a fiberoptic light source in a blanket. The optimal wavelength is 425 to 475 nm. Phototherapy primarily promotes 1) photoisomerization of unconjugated bilirubin to a less toxic isomer, which is excreted in the bile, and 2) structural isomerization of bilirubin to lumirubin, which is excreted in the bile and urine.

Indications for phototherapy and exchange transfusion vary according to the age of neonate. For the term neonate who develops jaundice after the first day of life and has no evidence of hemolysis, indications for phototherapy and exchange transfusion are shown in Table 41.4. When there is evidence of isoimmune hemolysis, phototherapy should be started immediately and a neonatologist should be consulted regardless of bilirubin level.

	Total Serum Bilirubin Level (mg/dL)			
Age (h)	Consider Phototherapy[b]	Phototherapy	Exchange Transfusion if Intensive Phototherapy[c] Fails	Exchange Transfusion and Intensive Phototherapy
<24	—	—	—	—
24–48	≥12	≥15	≥20	≥25
49–72	≥15	≥18	≥25	≥30
>72	≥17	≥20	≥25	≥30

Adapted with permission from the American Academy of Pediatrics practice parameter for management of hyperbilirubinemia in the healthy term newborn.
[b]Term infants who are clinically jaundiced at <24 hours old are not considered healthy and require further evaluation.
[b]Phototherapy at these total serum bilirubin levels is a clinical option, meaning that the intervention is available and may be used on the basis of individual clinical judgment.
[c]Intensive phototherapy should produce a decline of total serum bilirubin of 1 to 2 mg/dL within 4 to 6 hours and the total serum bilirubin level should continue to fall and remain below the threshold level for exchange transfusion. If this does not occur, it is considered a failure of phototherapy.

Table 41.4. Management of Hyperbilirubinemia in the Healthy Term Newborn[a]

During phototherapy, the baby should be undressed to maximize the exposed surface area of the skin. Intensive phototherapy with two banks of lights or two fiberoptic blankets will improve efficacy. When using overhead lights, the infant's eyes must be shielded and maintenance fluid requirements are increased. Phototherapy is relatively contraindicated in patients with conjugated hyperbilirubinemia because it can cause the “bronze baby syndrome.”

When bilirubin levels are toxic, exchange transfusion may be necessary. Exchange transfusion is most commonly indicated in infants with hemolytic disease. Generally, fresh irradiated reconstituted whole blood is pushed in through an umbilical vein catheter while blood is pulled out through an umbilical artery catheter. Careful monitoring is necessary. Complications include electrolyte and acid-base disturbances, hemolysis, and infection.

For jaundiced, breast-fed infants, the interruption or discontinuation of breast-feeding should be discouraged. Any of several management strategies, however, are accepted: 1) the infant may be observed while normal breast-feeding continues; 2) if bilirubin levels are high (Table 41.4), the infant may continue to breast-feed while receiving phototherapy; 3) breast-feeding may be supplemented with or without administration of phototherapy; and 4) breast-feeding may be interrupted and formula may be substituted with or without administration of phototherapy.

CHAPTER 42

Jaundice—Conjugated Hyperbilirubinemia

JONATHAN I. SINGER, MD

Departments of Emergency Medicine and Pediatrics, and Department of Emergency Medicine, Wright State University School of Medicine, Dayton, Ohio

The presence of jaundice in a child can be a useful indicator of occult pathology. The finding of icterus should set in motion a careful diagnostic search to elucidate the cause. The ultimate goal, to identify precisely the cause of the clinical syndrome, may rest in some cases with the longitudinal caretaker. In all cases, however, the emergency physician at first visit must separate patients whose admission can be temporized from those who require urgent intervention and/or immediate hospitalization.

PATHOPHYSIOLOGY

Unconjugated bilirubin is largely a product of converted heme from senescent red blood cells. Unconjugated bilirubin is transported from extrahepatic reticuloendothelial cells to the liver, bound to albumin. Albumin is detached as the bilirubin gains entry into the hepatocyte. In the liver cell, bilirubin is conjugated with glucuronide by the action of uridine diphosphate glucuronyl transferase. The soluble conjugated diglucuronide then is secreted across the canalicular membrane into the bile. In the intestine, as a result of the activity of bacterial flora, bilirubin is converted to urobilinogen. A portion of urobilinogen is reabsorbed into the portal circulation and is taken up by the liver cells, only to be reexcreted into the bile. A small percentage of urobilinogen escapes into the systemic circulation and is excreted in the urine. The unabsorbed urobilinogen is excreted in the stool as fecal urobilinogen.

In hepatocellular disease, the damaged liver may be unable to excrete the conjugated bilirubin produced in normal amounts. Or, in the absence of hepatic damage, regurgitation into the plasma of conjugated bilirubin may result from functional cholestasis, disruption of the hepatic architecture, or extrahepatic biliary obstruction. In most instances of jaundice primarily related to hepatic disease, the plasma exhibits elevated concentrations of unconjugated and conjugated bilirubin. Overt mechanical obstruction of bile excretion leads to raised plasma levels of conjugated bilirubin, and only as secondary liver damage occurs do unconjugated bilirubin levels rise.

DIFFERENTIAL DIAGNOSIS

Conjugated hyperbilirubinemia, defined as an elevated total bilirubin with greater than 30% direct reacting, always is pathologic. The differential diagnosis includes a variety of structural defects, infections, hepatotoxins, inborn errors of metabolism, and familial syndromes (Table 42.1).

Table 42.1. Causes of Conjugated Hyperbilirubinemia in Infants and Children

Although only a few diseases commonly cause conjugated hyperbilirubinemia (Table 42.2), all are serious. In addition, several less common conditions are important considerations because they are life-threatening (Table 42.3).

Infancy	Childhood
Idiopathic cholestasis	Viral hepatitis
Biliary atresia	Hepatotoxins
Perinatal infections (TORCH)	
Sepsis/urinary tract infection	

Table 42.2. Common Causes of Conjugated Hyperbilirubinemia

Fulminant hepatic failure	Abdominal crisis, sickle hemoglobinopathy
Septicemia	Hepatorenal syndrome
Intra-abdominal sepsis	Reye syndrome (usually anicteric)
Pyogenic liver abscess	
Suppurative cholangitis	
Peritonitis	

Table 42.3. Life-Threatening Causes of Conjugated Hyperbilirubinemia

EVALUATION AND DECISION

It is convenient to divide the approach to patients with conjugated hyperbilirubinemia by age, focusing first on those less than 8 weeks old and then on those who are older. A suitable framework for the evaluation of the infant in the first 8 weeks of life focuses on duration of symptoms and mode of presentation. The most important considerations in the evaluation of the older patient are the presence of chronic disease, predisposition to biliary tract disturbances, and exposure to contagion and hepatotoxins (Fig. 42.1).

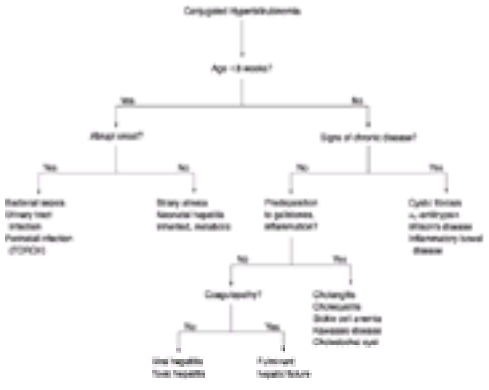

FIGURE 42.1. Approach to the patient with conjugated hyperbilirubinemia.

Infants Less Than 8 Weeks Old

The onset of conjugated hyperbilirubinemia in the first 2 months of life may be abrupt or insidious. Infants with generalized viral infections acquired in utero and during the birthing process are more likely to present shortly after birth. Perinatal cytomegalovirus (CMV) infection, rubella, toxoplasmosis, herpes simplex, and syphilis may account for irritability, jitteriness, seizures, microcephaly, hepatomegaly, icterus, and petechiae.

The diagnosis of sepsis or urinary tract infection should be considered in any infant who abruptly develops icterus. Hyperbilirubinemia may occur antecedent to blood cultures becoming positive and may precede findings of anorexia, vomiting, abdominal distension, fever, hepatomegaly, or alterations in respiratory pattern or sensorium. The precise mechanism of jaundice that complicates these infections is not completely understood. Sepsis, if accompanied by hepatic hypoperfusion, can be associated with prolonged biochemical and histologic changes within the liver. Similarly, children with prolonged congestive heart failure or postoperative repair of congenital heart disease may develop jaundice and abnormalities in biochemical tests of liver function. This is called ischemic hepatitis.

Infants with intrahepatic and extrahepatic biliary atresia have a failure of bile secretion associated with a significant hyperbilirubinemia. Although symptoms vary in onset, they usually are less acute than those seen in the infectious states. Infants affected with atresia generally appear well, with the exception of jaundice and hepatomegaly. Infants with

complete obstruction pass clay-colored stools. Failure to thrive may be a delayed manifestation.

The characteristic clinical pattern with idiopathic cholestasis consists of onset of jaundice in the second or third week of life. Initially, stool color is normal, but the stools may become acholic after several weeks. The presence of acholic stools may make it difficult to differentiate between obstructive jaundice caused by hepatocellular disease and that caused by obstruction of the biliary tree.

The inherited and metabolic conditions (e.g., galactosemia, tyrosinemia, cystic fibrosis; a_1-antitrypsin deficiency) associated with conjugated hyperbilirubinemia are typically insidious in onset. Although of a diverse nature, these diseases largely are characterized by inconstant jaundice, failure to thrive, developmental delay, and metabolic derangements. Unexplained fatality in the sibship or unexplained pulmonary, gastrointestinal, neurologic, or psychiatric disturbance in other family members may provoke diagnostic consideration.

The priorities for the emergency physician are to diagnose medically treatable infections, to identify metabolic disorders for which effective therapy is available, and to detect extrahepatic obstructive lesions that are amenable to surgical correction. The evaluation begins with cultures of cerebrospinal fluid, blood, urine, and stool. Infants also should have complete blood and platelet counts and should be tested for prothrombin time, hepatic enzymes (AST, ALT, and GGT), ammonia, albumin, total protein and protein electrophoresis, alkaline phosphatase, electrolytes, blood urea nitrogen, creatinine, and blood sugar. Urine should be tested for reducing substances. Additional studies useful for the longitudinal care physician include sweat iontophoresis, a_1-antitrypsin, TORCH and HBV serology, immunoglobulin M (IgM), urine examination for CMV, red blood cell galactose1-phosphate uridyltransferase activity, stool examinations, abdominal ultrasonography, and hepatobiliary scintigraphy.

Inpatient observation is appropriate in this age group because the diagnosis rarely can be established in the emergency department (ED). Empiric therapy for sepsis or urinary infection often is warranted, pending culture results.

Children More Than 8 Weeks Old

In the evaluation of conjugated hyperbilirubinemia beyond infancy, it is necessary to know whether there has been exposure to contagion or a potential for sexual or vertical transmission of infections such as hepatitis or human immunodeficiency virus (HIV). Other risk factors for hepatitis (e.g., needle sticks, hemodialysis, transplant, transfusion of blood products or factor use) need to be excluded. The physician should pursue possible exposure to industrial toxins or foods previously implicated in hepatic injury (e.g., carbon tetrachloride, yellow phosphorus, tannic acid, alcohol, mushrooms of the Amanita species). The emergency physician must inquire about use of acetaminophen, salicylates, erythromycin estolate, ceftriaxone, rifampin, iron salts, nitrofurantoin, oxacillin, methimazole, tetracycline, trimethoprim–sulfamethoxazole, diphenylhydantoin, isoniazid, and para-aminosalicylic acid (PAS). The presence of prior episodes of jaundice, acholic stools, and/or abdominal pain may suggest an underlying disorder, predisposing the patient to obstruction of the biliary tree. Other historical points include the presence of fever, arthralgia, arthritis, conjunctivitis, rash, pruritus, vomiting, diarrhea, weight loss, color of the urine, abnormal bruising or spontaneous bleeding, and changes in mental status.

An examination that focuses on ongoing physical signs of liver disease may result in greater accuracy in clinical evaluation of the older jaundiced patient. These signs include skin changes (spider angiomata, excoriations, palmar erythema) and peripheral edema. The abdominal examination should include observations of the venous pattern, presence of ascites, mass, or peritoneal irritation. There should be an estimation of liver size, contour, and tenderness, as well as an estimate of spleen size. The clinician should exclude cardiovascular dysfunctions such as hypoxemia, systemic venous congestion, and low cardiac output. Observations should be made of mental status and neuromuscular changes.

Patients with cystic fibrosis, a_1-antitrypsin deficiency, Wilson's disease, or inflammatory bowel disease tend to have symptoms that remit and relax. However, slow progression is the rule. Patients with a_1-antitrypsin deficiency may have onset of respiratory or hepatic complaints at any age. Similarly, infants who have failure to thrive from cystic fibrosis may develop obstruction at any age in the extrahepatic or intrahepatic ducts and, transiently or persistently, may exhibit jaundice. Patients with ulcerative colitis and Crohn's disease may become symptomatic intermittently with episodes of cholestasis. The degree of hepatic derangement and expression of neurologic abnormality is variable with Wilson's disease. Patients typically exhibit dysarthria, tremors, rigidity, or psychic disturbances before the diagnosis is entertained. Rarely, patients at a younger age without prodromal events have acute jaundice and hepatomegaly and progress to hepatic failure.

Biliary calculi and acute inflammation of the gallbladder are uncommon causes of conjugated hyperbilirubinemia in the pediatric population. However, a subset of patients is predisposed to these complications. Cholelithiasis may complicate any of the hemolytic anemias, particularly in patients with sickle hemoglobinopathies. These patients have increased incidence of both liver and gallbladder disease. Liver or gallbladder dysfunction accounts for the jaundice when more than 10% of an elevated bilirubin in a patient with sickle cell disease is conjugated. Cholecystitis may accompany a variety of acute focal infections, such as pneumonia or peritonitis, and may occur in the course of bacterial sepsis. In this event, shock and hyperpyrexia may divert the clinician from the deranged biliary system. In less severe cases, fever, nausea, vomiting, abdominal distension, and right upper quadrant pain are prominent features of cholecystitis. Right upper quadrant abdominal mass, pain, and jaundice constitute the classic triad in the diagnosis of choledochal cyst. The clinical recognition may be delayed until there is a complication, such as cholangitis. An acute, painful right upper quadrant mass associated with jaundice also may occur in the course of acute hydrops of the gallbladder from Kawasaki disease or systemic streptococcal infection.

In the previously healthy child, the most common cause of conjugated hyperbilirubinemia is acute hepatitis. The illness may be abrupt in onset, with fever, urticaria, and arthralgia as primary manifestations. More often, the illness is insidious. Viral hepatitis is characterized by low-grade fever and gastrointestinal complaints such as anorexia, malaise, nausea,

vomiting, and abdominal pain before the jaundice. Liver enlargement with hepatitis (A, B, C, and non-A, non-B, non-C), varicella, herpesvirus, coxsackievirus, echovirus, Epstein-Barr virus, and adenovirus infection is inconstant. Hepatic tenderness is a more reliable finding. Rarely, ascites can accompany hepatitis virus infection. Splenomegaly is the rule with Epstein-Barr virus but is unusual with the other agents. On occasion, hepatitis may be associated with a distinctive erythematous papular eruption localized to the limbs (Gianotti disease).

Toxic hepatitis, unlike viral hepatitis, does not have a prolonged prodrome. Acute nausea, vomiting, and malaise are followed in 1 to 2 days by alterations in mental status and deterioration of liver function. Most patients with toxic hepatitis will have an identifiable exogenous precipitant. Children with fulminant hepatic failure typically experience anorexia, nausea, vomiting, malaise, and fatigue—all symptoms indistinguishable from those expected with viral hepatitis. The patient's jaundice becomes more profound, and vomiting becomes protracted. Hyperexcitability, mania, and subtle psychomotor abnormalities may be seen. Coagulopathy, ascites, and sudden decrease in liver size are often the prelude to the development of frank neuromuscular signs.

The objectives of the emergency physician are to render supportive care to those icteric patients with infectious and metabolic derangements and to identify those cases in which jaundice is caused by mechanical obstruction or hepatic failure. The impression based on a targeted history, physical examination, and clinical algorithms can be bolstered with the following laboratory examinations: complete blood count, platelet count, prothrombin time, total and direct bilirubin, transaminase, alkaline phosphatase, electrolytes, blood urea nitrogen, and creatinine. Urinalysis, culture, and toxicologic screen should be considered. Chest and abdominal radiographs are indicated when there are pulmonary parenchymal complaints or significant abdominal findings. Other laboratory tests that are often available immediately and that may provide useful information in specific circumstances are serum ammonia, albumin, total protein, cholesterol, pH, and carbon dioxide. If available, abdominal sonography or computed tomography may be helpful occasionally. In no circumstance will results of several important blood and urine tests be of immediate use. Such studies, which are appropriate, include serum for bile acids, ceruloplasmin, protein electrophoretic pattern, serologic evidence of recent infection (e.g., Ebstein-Barr virus, mycoplasmal or hepatitis profiles), polymerase chain reaction assays, and enzyme-linked immunosorbent assay and autoantibody test. Urinary analysis includes assessment of organic acids and copper. These investigations may be helpful, however, to the longitudinal caretaker who must maintain a vigilant watch over the jaundiced patient.

Children more than 8 weeks old with conjugated hyperbilirubinemia should be admitted to the hospital at the time of their presentation in all cases in which life-threatening conditions may exist (Table 42.3). Inpatient treatment also is suggested when intravenous fluids are necessary to treat symptomatic hypoglycemia or electrolyte imbalance and when operative intervention may prove necessary. Icteric patients who have been diagnosed previously with confidence and who have exacerbation of their symptoms may require admission to reappraise their status. The physician also may be influenced to admit the patient when poor parenting or geographic barriers inhibit consistent observations. Admission also is indicated for patients who require further diagnostic intervention, such as liver biopsy or scintigraphy, to arrive at a definitive diagnosis.

CHAPTER 43

Limp

SUSANNE KOST, MD

Jefferson Medical College, Philadelphia, Pennsylvania, and A. I. duPont Hospital for Children, Wilmington, Delaware

Limping is a common complaint in the pediatric acute-care setting. A *limp* is defined as an alteration in the normal walking pattern for the child's age. The average child begins to walk between 12 and 18 months of age with a broad-based gait, gradually maturing into a normal (adult) gait pattern by the age of 3 years. Normal walking should appear smooth and effortless, although it involves a complex integration of the nervous and musculoskeletal systems. A normal gait cycle can be divided into two phases: stance and swing. The stance phase, the time from the heel striking the ground to the toe leaving the ground, encompasses about 60% of the gait cycle. The swing phase involves a sequence of hip then knee flexion, followed by foot dorsiflexion and knee extension as the heel strikes the ground to begin the next cycle.

The causes of limping are numerous, ranging from trivial to life-threatening, but most children who limp do so as a result of pain, weakness, or deformity. Pain results in an antalgic gait pattern with a shortened stance phase. The most common causes of a painful limp are trauma and infection. Neuromuscular disease may cause either spasticity (e.g., toe-walking) or weakness, which results in a steppage gait to compensate for weak ankle dorsiflexion. The Trendelenburg gait, characterized by a pelvic tilt away from the affected hip, is common in congenital or acquired hip disorders. A vaulting gait may be seen in children with limb-length discrepancy or abnormal knee mobility. A stooped, shuffling gait is common in patients with pelvic or lower abdominal pain.

The evaluation of a child with a limp demands a thorough history and physical examination, using an age-based approach. Toddlers generally provide the greatest diagnostic challenge because a history of trauma may be unclear, and the ability to describe or localize pain may be lacking. In all age groups, a detailed history of the circumstances surrounding the limp should be obtained, with focus on the issues of trauma, pain, and associated fever or systemic illness. The physical examination must be complete because limping may originate from abnormalities in any portion of the lower extremity, nervous system, abdomen, or genitourinary tract. The location of the pain may not represent the source of the pathology; for example, hip pain may be referred to the knee area. Laboratory and imaging studies should be tailored to the findings in the history and physical examination, keeping in mind an appropriate age-based differential diagnosis.

DIFFERENTIAL DIAGNOSIS

The extensive differential diagnosis of the child with a limp may be approached from several angles: by disease category, location of pathology, or age of the child. Table 43.1 presents the differential diagnosis by disease category; Table 43.2 organizes the differential diagnosis by age and location of pathology. The most common causes of limp are outlined in Table 43.3, and potentially life- or limb-threatening conditions are listed in Table 43.4. This section reviews the differential diagnosis within the framework of an algorithmic approach (Fig. 43.1).

FIGURE 43.1. Algorithmic approach to the child with a limp. *RSD,* reflex sympathetic dystrophy; *CBC,* complete blood count; *SCFE,* slipped capital femoral epiphysis; *AVN,* avascular necrosis; *DDH,* developmental dysplasia of the hip; *LCP,* Legg-Calvé-Perthes disease.

Trauma or Overuse	*Congenital*
Fracture	Vertical talus
Stress fracture	Tarsal coalition
Soft-tissue injury	Other congenital limb abnormalities
Spondylolisthesis	Spinal dysraphism
Herniated nucleus pulposis	Inguinal hernia
Infectious	*Neurologic*
Septic arthritis	Muscular dystrophy
Osteomyelitis	Peripheral neuropathy
Lyme arthritis	Reflex sympathetic dystrophy
Cholitis	*Neoplasia*
Pelvic inflammatory disease	Benign bone tumors
Inflammatory	Malignant bone tumors
Transient synovitis	Leukemia
Reactive arthritis	Intra-abdominal tumors
Rheumatic disease	Sacral tumors
Appendicitis	Spinal cord tumors
Developmental or Acquired	*Metabolic*
Developmental dysplasia of the hip	Rickets
Blount's disease	Hyperparathyroidism
Limb length discrepancy	*Hematologic*
Torsional deformities	Sickle cell disease
Avascular necrosis	Hemophilia
Slipped capital femoral epiphysis	
Tarsal coalition	

Table 43.1. Differential Diagnosis of Limp by Disease Category

	Long Bone	Skin/Soft Tissue	Any Joint	Hip	Knee	Ankle/Foot	Spine
Toddler	Fracture Toddler's Salter type I Periostitis Osteomyelitis Vaso-occlusive crisis Congenital anomaly	Contusion Strain Foreign body Immunization Infection	Septic arthritis Reactive arthritis Rheumatic disease Systemic JRA Hemarthrosis	Transient synovitis DDH	Occult trauma Blount's disease Referred hip pain	Poor shoe fit Occult trauma Vertical talus Kohler's disease	Dysraphism Infection Tumor
School age	Fracture Salter type I Discrepant limb length Osteomyelitis Tumor Vaso-occlusive crisis	Contusion Strain Myositis Growing pains Infection	Sprain Reactive arthritis Rheumatic disease SLE, HSP, RAF Septic arthritis Lyme arthritis	Transient synovitis JRA	Baker's cyst Referred hip pain	Poor shoe fit Salter type I fracture Tarsal coalition Kohler's disease	Dysraphism Infection Tumor
Adolescent	Fracture Osteomyelitis	Contusion Strain PFPS	Sprain Reactive arthritis IBD, SLE Septic arthritis Gonococcal Lyme arthritis	SCFE Legg-Calvé-Perthes disease Osteochondritis dissecans Chondromalacia Baker's cyst Referred hip pain	Osgood-Schlatter's disease Osteochondritis dissecans Chondromalacia Baker's cyst Referred hip pain	Poor shoe fit Hallux rigidus Bunion Freiberg's disease Sever's disease	Scoliosis Herniated disc Infection Tumor

JRA, juvenile rheumatoid arthritis; DDH, developmental dysplasia of the hip; EM, erythema multiforme; NSAID, nonsteroidal anti-inflammatory drug; AVN, avascular necrosis; RSD, reflex sympathetic dystrophy; IBD, inflammatory bowel disease; SLE, systemic lupus erythematosus; SCFE, slipped capital femoral epiphysis.

Table 43.2. Differential Diagnosis of Limp by Age and Location of Pathology

Trauma	*Rheumatic Disease*
Fracture	*Other Hip Disorders*
Soft-tissue injury	Developmental dysplasia
Overuse injuries	Legg-Calvé-Perthes disease
Transient Synovitis	Slipped capital femoral epiphysis
Infection	
Septic arthritis	
Osteomyelitis	

Table 43.3. Common Causes of Limp

Septic arthritis	Slipped capital femoral epiphysis
Osteomyelitis	Epidural abscess
Tumor	Appendicitis
Developmental dysplasia of the hip	

Table 43.4. Life- or Limb-Threatening Causes of Limp

The most common cause of limping in all ages is trauma, either acute or repetitive microtrauma (stress fractures). Older children who limp as a result of trauma can generally describe the mechanism of injury and localize pain well. The toddler and preschool age groups, with their limited verbal ability and cooperation skills, often provide a diagnostic challenge. A common type of injury in this population (often not witnessed) is the aptly named “toddler's fracture,” a nondisplaced spiral fracture of the tibial shaft that occurs as a result of torsion of the foot relative to the tibia. Occult fractures of the bones in the foot also occur in young children. Initial plain radiographic findings may be subtle, or at times nonexistent, but will become apparent in 1 to 2 weeks. Bone scans will identify these lesions sooner. Another fracture often lacking initial radiographic confirmation is a Salter-Harris type I fracture, which presents as tenderness over a physis after trauma to a joint area. Stress fractures may also lack overt radiographic findings. Common sites for overuse injury include the tibial tubercle (Osgood-Schlatter's disease), the anterior tibia (“shin splints”), and the calcaneous at the insertion of the

Achilles tendon (Sever's disease). More information on the subject of fractures is found in Chapter 115.

Trauma may also induce limping as a result of soft-tissue injury. Although children are more likely to sustain fractures than sprains and strains, the latter can occur. Joint swelling and pain out of proportion to the history of injury raises the possibility of a hemarthrosis as the initial presentation of a bleeding disorder (see Chapter 87). Severe soft-tissue pain and swelling in the setting of a contusion or crush injury suggests compartment syndrome. With compartment syndrome, pain is exacerbated by passive extension of the affected part; pallor and pulselessness are late findings. Severe pain of an entire limb out of proportion to the history of injury suggests reflex sympathetic dystrophy (RSD). RSD is most common in young adolescent girls. It may be accompanied by mottling and coolness of the extremity, presumably as a result of abnormalities in the peripheral sympathetic nervous system.

A limp that is accompanied by a history of fever or recent systemic illness is likely to be infectious or inflammatory in origin. However, the absence of fever does not preclude the possibility of a bacterial bone or joint infection, and many infections are preceded by a history of minor trauma. Septic arthritis is the most serious infectious cause of joint pain and limp. It is more common in younger children and typically presents with a warm, swollen joint. Exquisite pain with attempts to flex or extend the joint is characteristic of septic arthritis, and the degree of pain with motion serves as a helpful clinical sign in distinguishing bacterial joint infection from inflammatory conditions. A common diagnostic challenge is differentiating septic arthritis from transient (or toxic) synovitis in a young child with fever, limp, and pain localized to the hip. Transient synovitis, a postinfectious reactive arthritis, generally follows a milder course. It is usually preceded by a recent viral respiratory or gastrointestinal illness. Acute-phase reactants may be elevated in both conditions, although usually less so in synovitis. A joint effusion, which is better visualized with ultrasound than plain films, may be present in both. Orthopedic consultation for joint aspiration may be required for a definitive diagnosis because a septic hip is a surgical emergency requiring open drainage. Osteomyelitis is another potentially serious infectious cause of limp, although the presentation is typically more chronic than that of a septic joint. Osteomyelitis, which is also more common in younger children, presents with pain and occasionally warmth and swelling, usually over the metaphysis of a long bone. A reactive joint effusion may be present. Occasionally, osteomyelitis and septic arthritis will coexist. More detailed discussions of both septic joint and osteomyelitis are found in Chapter 84 and Chapter 123.

Rheumatic conditions that may result in limp are numerous; many are accompanied by systemic symptoms and characteristic skin rashes. Examples include Lyme disease, Henoch-Schönlein purpura, erythema multiforme, acute rheumatic fever, juvenile rheumatoid arthritis, and systemic lupus erythematosus. Occasionally, limping from arthralgia will precede the development of the arthritis and systemic involvement. An approach to the child with joint pain is found in Chapter 57, and a detailed discussion of arthritis is found in Chapter 101.

In the absence of obvious trauma, fever, or systemic symptoms, the next step in the approach to the differential diagnosis of a limp is to determine the focality of the findings and the degree of pain. Localized pain suggests repetitive microtrauma, bone tumor, or an acquired skeletal deformity. Repetitive microtrauma may be responsible for avascular necrosis of the foot bones in two locations: the tarsal navicular bone (Köhler's disease) in younger children and the metatarsal heads (Freiberg's disease) in adolescents. Both benign and malignant bone tumors may present with a painful limp. Benign lesions include bone cysts (unicameral or aneurysmal), fibrous dysplasia, and eosinophilic granulomas. Osteoid osteoma, caused by a painful nidus of vascular osteoid tissue, is another benign lesion unique to young people. The most common malignant pediatric bone tumors are osteogenic sarcoma and Ewing's sarcoma. Bone tumor pain may be acute or chronic, with acute pain usually related to a pathologic fracture. Examples of acquired skeletal abnormalities causing painful limp include tarsal coalition and osteochondritis dissecans. Tarsal coalition occurs as a result of gradual calcification of a congenital cartilaginous bar between tarsal bones; it presents most commonly as a painful flatfoot in school-aged children. Osteochondritis dissecans is related to separation of articular cartilage from underlying bone; it most commonly affects the knees of adolescent boys.

Localized findings without pain suggest congenital or slowly developing acquired limb abnormalities. Three disorders of the hip fit into this category, each of which is characteristic of a specific age group. Developmental dysplasia of the hip (DDH) includes a spectrum of abnormalities ranging from mild dysplasia to frank dislocation. Most affected children with access to primary care are diagnosed with abnormal hip abduction on routine examination in infancy. Occasionally, the diagnosis will be missed, and the child then presents at the onset of walking with a painless short-leg limp, or waddling gait if bilateral, with weakness of the abductor musculature. Legg-Calvé-Perthes (LCP) disease, an avascular necrosis of the capital femoral epiphysis, presents in young school-aged children as an insidious limp with mild, activity-related pain. Slipped capital femoral epiphysis (SCFE) presents in young, typically obese, adolescents with an externally rotated limp. The amount of pain experienced is related to the rate of displacement of the epiphysis, ranging from none to severe. LCP and SCFE are more common in boys. Other acquired skeletal deformities that may cause painless limp include limb length inequality, Blount's disease (with marked bowing of the proximal tibias), and torsional deformities. Baker's cyst of the popliteal tendon may cause limping with minimal local discomfort.

Limping in the absence of localized limb findings suggests a systemic (or nonlimb) source such as the spine or abdomen. A painful limp without localization or with migratory bone pain suggests a hematologic or oncologic cause such as sickle cell disease or leukemia. Limping with bilateral leg pain localized to the muscles, especially the calves, suggests myositis. Benign acute childhood myositis is common during influenza epidemics. Recurrent diffuse aches after periods of vigorous activity, usually worse at night, suggest benign hypermobility syndrome or “growing pains.” A painless, poorly localized limp may occur with metabolic bone disease (e.g., rickets). Spinal problems that can cause leg pain, weakness, or limp include dysraphism, vertebral infection, spondylolisthesis, and herniated disc. *Spinal dysraphism* refers to a spectrum of abnormalities in the development of the spinal cord and vertebrae ranging from obvious (myelomeningocele) to occult (tethered cord). Associated neurologic and musculoskeletal findings, including pain, atrophy, high arches, and tight heel cords, may develop in early childhood. Vertebral infection typically presents with fever and back pain. Spondylolisthesis and herniated disc are rare in young children but may be seen in adolescents who complain of back pain or radicular pain. Intra-abdominal pathology that can result in limp includes appendicitis, pelvic or psoas abscess, and renal disease. Solid tumors, most commonly neuroblastoma, can cause limp through retroperitoneal irritation or extension into the spinal canal. Likewise, a sacral teratoma may affect the nerves of the cauda equina or sacral plexus. Testicular pain may present with limping in a boy who is reluctant or embarrassed to admit the true source of his

discomfort.

EVALUATION AND DECISION

The conditions that lead to a presentation of limp range from mundane (poorly fitting shoes) to life-threatening (leukemia). The role of the pediatric acute-care physician is to rule out the possibility of life- and limb-threatening pathologic conditions. The serious conditions include bacterial infection of the bone or joint space, malignancy, and disorders that threaten the blood supply to the bone, such as avascular necrosis (AVN) and SCFE. Often, a definitive diagnosis will not be reached in the emergency department, and the patient will require follow-up with the primary care physician or specialist. Figure 43.1 provides an algorithmic approach to the child with a limp.

History

The history in a limping child should include information about the onset and duration of the limp, the family's perception of the origin of the problem, and associated symptoms such as pain, fever, and systemic illness. When pain is present, the physician should inquire about the location and severity. A history of trauma should be addressed, keeping in mind the inherent difficulty in obtaining an accurate trauma history in very young children. Conversely, obvious trauma in the absence of a consistent history raises the question of inflicted injury. In more chronic presentations, any cyclical or recurrent patterns should be noted. Stiffness and limp primarily in the morning suggest rheumatic disease, whereas evening symptoms suggest weakness or overuse injury. A history of joint or limb swelling should be investigated, with attention to the degree of swelling as well as any migratory or recurrent patterns.

The medical history should include birth and developmental history. Breech position is associated with DDH, and mild cerebral palsy may present in childhood with abnormal gait. History of viral infections, streptococcal pharyngitis, medication use, and immunizations may provide clues to the cause of limping. A family history of rheumatic or autoimmune disease, inflammatory bowel disease, hemoglobinopathy, or other bleeding disorders may help facilitate diagnosis. Finally, the review of systems should include questions about past trauma, infections, neoplasia, endocrine disease, metabolic disease, and congenital anomalies.

Physical Examination

The physical examination in a limping child should begin with observation of the child's gait. Ideally, the child should be observed walking in bare feet and wearing minimal clothing, preferably in a long hallway. The physician should attempt to observe the child unobtrusively to avoid gait changes caused by self-consciousness. The observer should note the symmetry of stride length, the proportion of the gait cycle spent in stance phase, hip abductor muscle strength (with abnormal strength manifested by Trendelenburg or waddling gait), in-toeing or out-toeing, and joint flexibility. Muscle strength may be tested by asking the child to run, hop, and walk on toes and heels.

After observing the child in action, the physician should perform a complete examination with attention to the musculoskeletal and neurologic systems. The musculoskeletal examination begins with inspection of the limbs and feet for swelling or deformity. The spine should be inspected for curvature, both standing and bending forward, and the soles of feet and toes should be checked for foreign bodies and callouses. The bones, muscles, and joints should be palpated for areas of tenderness; range of motion of all joints should be checked; and limb lengths (from anterior superior iliac spine to medial malleolus) and thigh and calf circumference should be measured for asymmetry. The neurologic examination should include inspection of the spine for lumbosacral hair or dimple (indicating possible spinal dysraphism), and testing of strength, sensation, and reflexes. The abdomen and external genitalia should be examined for tenderness or masses, and the skin for rashes. A rectal examination may be indicated if sacral pathology is suspected. Finally, wear patterns on the child's shoes may provide clues to the nature and duration of the limp.

Laboratory and Imaging

Plain radiographs remain a mainstay of the workup of a limping child. They provide an excellent means of screening for fracture, effusion, lytic lesions, periosteal reaction, and avascular necrosis. In a child with an obvious focus of pain, the radiographs may be obtained with views specific to that area, noting that children with knee pain may have hip pathology. The need for comparative views (of the normal extremity) depends on the experience of the physician interpreting the films. Some radiographic findings can be subtle, and comparison with the opposite side may be helpful. In a young child or a child lacking obvious focus for the limp, anteroposterior (AP) and lateral views of both lower extremities (including the feet) should be ordered as an initial screen. In toddlers lacking a focus of pain and in older children in whom hip pathology is suspected, AP and frog-leg lateral views of the pelvis are required. The frog-leg lateral view, obtained with the hips abducted and externally rotated, allows excellent visualization of the femoral heads. These radiographs should always include both hips to enable comparison of the femoral heads and width of the joint spaces. Radiographs of the spine are necessary if the child has neurologic signs or symptoms.

In children whose limp is associated with fever or systemic illness, laboratory studies, including a complete blood count (CBC) and an erythrocyte sedimentation rate (ESR), are indicated. In some institutions, a C-reactive protein (CRP) is obtained as a more sensitive acute-phase reactant. These studies serve as screens for infection, inflammation, malignancy, and hemoglobinopathy. Laboratory studies are also indicated in the absence of fever if the child has been limping for several days without evidence of trauma on plain films. Children with evidence of infection or inflammation with a joint effusion may require arthrocentesis for definitive diagnosis. In areas of endemic Lyme disease, a Lyme titer is a reasonable initial screening test in a patient with arthritis. A creatine phosphokinase (CPK) level may be helpful if muscle inflammation is suspected.

When the initial history, physical examination, imaging, and laboratory evaluation indicate the cause of the limp, specific treatment can be initiated. Abnormalities in the initial workup without a definitive diagnosis should prompt further imaging or laboratory studies. Bone scintigraphy is more sensitive than plain radiographs for occult fracture, infection, avascular

necrosis, and tumor; however, it is not specific for a given pathologic process. Computed tomography (CT) is an excellent imaging modality for cortical bone; it serves as a useful diagnostic adjunct in certain fractures, bony coalitions, and bone tumors. Ultrasound (US) is the preferred modality for diagnosing hip effusions; it is also useful for guiding needle aspirations of the hip joint. Magnetic resonance imaging (MRI) is useful in imaging the spinal cord, avascular necrosis, and bone marrow disease.

If the initial workup in a limping child is completely normal, including screening radiographs and laboratory studies, the child may be followed closely as an outpatient. These children should be examined every few days until improvement is noted or a cause is determined. If the limp persists beyond 1 to 2 weeks without a diagnosis, further workup or consultation with a specialist is indicated.

CHAPTER 44

Lymphadenopathy

RICHARD MALLEY, MD

Department of Pediatrics, Harvard Medical School, and Divisions of Emergency Medicine and Infectious Diseases, Children's Hospital, Boston, Massachusetts

Lymphadenopathy is defined as swelling of the lymph nodes. Swollen lymph nodes are a common presenting sign in children, mainly because children have more pronounced lymphoid responses to inflammation than adults do, and they also have relatively more lymphoid tissue. Because the differential diagnosis of lymphadenopathy is extensive, it is helpful to distinguish localized from generalized lymphadenopathy. *Localized, or regional, adenopathy* generally occurs in response to a focal infectious process, although rarely other causes may need to be considered. Because a large number of organisms can cause localized adenopathy, it is often helpful to differentiate between acute and subacute/chronic regional adenopathy. *Generalized lymphadenopathy* is defined as enlargement of more than two noncontiguous lymph node regions. The most common causes of generalized adenopathy are systemic infections (bacterial or viral), autoimmune diseases, and neoplastic processes.

DIFFERENTIAL DIAGNOSIS

Acute Regional Adenopathy

The clinician caring for a child with acute regional adenopathy will benefit from knowledge of the anatomic distribution of nodes in the area and their drainage areas, as described in Table 44.1. The location of lymphadenopathy is often suggestive of a possible cause. For instance, in the head and neck region, swollen nodes are often a response to focal infectious processes occurring in areas that drain in the region of the nodes. Occipital nodes most commonly enlarge in response to bacterial or fungal scalp infections or to chronic inflammation such as occurs in seborrheic dermatitis. Because preauricular nodes drain the conjunctiva and lateral eyelids, these often enlarge in viral conjunctivitis. Epidemic keratoconjuctivitis caused by adenoviruses often presents with an enlarged preauricular node. The combination of conjunctivitis and ipsilateral preauricular adenopathy is called oculoglandular syndrome, or Parinaud's syndrome. Another infection that can present as Parinaud's syndrome is chlamydial conjunctivitis, also called neonatal-inclusion conjunctivitis. Chlamydial conjunctivitis, which generally presents within 5 to 7 days after birth, is diagnosed by the finding of intracytoplasmic inclusion bodies in conjunctival scrapings or, more commonly, by detection of the pathogen by immunofluorescent staining of ocular secretions. Parinaud's syndrome is also occasionally seen in cat-scratch disease, tularemia, and listeriosis. Similarly, the presence of submaxillary and submental nodes points to the possibility of an infectious process in the oral cavity. Therefore, the physician should perform a careful oral and dental examination in these cases. Dental abscesses or gingival infections may be responsible for lymphadenopathy in these regions.

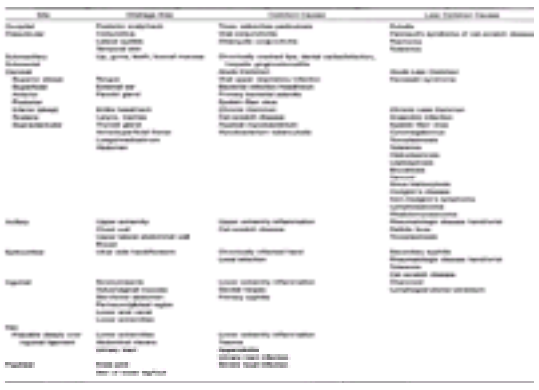

Table 44.1. Regional Adenopathy

The differential diagnosis of cervical adenopathy is more extensive, mainly because the anatomy of the region is more complex. As can be seen in Table 44.1, nodes in the cervical region can be divided into three areas: the superior deep nodes below the angle of the mandible, the superficial cervical nodes found anteriorly and posteriorly along the sternocleidomastoid muscle, and the inferior deep nodes at the base of the neck. Enlargement of superior deep or superficial nodes raises the possibility of a lingual, external ear, or parotid gland process. In contrast, the inferior deep

nodes have a much wider drainage area, including the head and neck, upper extremities, and the thoracic and abdominal regions. Swelling of these nodes, in particular scalene and supraclavicular nodes, can be the first sign of occult thoracic or abdominal pathology, such as malignancy. Therefore, nodes found in these regions must be investigated carefully, with thorough physical examinations and, if necessary, radiographic examinations.

By far, the most common cause of acute cervical adenopathy is a viral upper respiratory tract infection. In these cases, lymph nodes are generally symmetrically enlarged and are soft and minimally tender, if at all. The reactive adenopathy may persist for 2 to 3 weeks beyond the resolution of the viral illness, but there should be no progression in the size or extent of the adenopathy. Bacterial cervical adenitis is also a common cause of cervical lymphadenopathy in children, particularly in pre–school-age children. It is usually caused by group A b-hemolytic *Streptococcus* or *Staphylococcus aureus*, although anaerobes (usually penicillin-sensitive) may also be involved, particularly in oral infections. A history of a sore throat may be present in a minority of patients. Bacterial adenitis is most often unilateral and presents with firm, tender, and warm lymph nodes. In addition to the cervical area, other common sites of involvement include submaxillary, inguinal, and axillary nodes. If left untreated, these nodes may become erythematous and eventually fluctuant. Drainage of the nodes is sometimes required, even in appropriately treated cases (see Chapter 84).

Epstein-Barr virus (EBV), the agent of infectious mononucleosis, commonly causes posterior cervical lymphadenopathy in older children and adolescents. EBV infections do not always cause generalized adenopathy. The classic presentation of a child with EBV includes malaise, fever, an exudative tonsillopharyngitis, and hepatosplenomegaly. Facial edema may accompany significant EBV adenopathy, presumably reflecting obstructed lymph drainage. Younger children and infants with EBV infection may present less typically with fever alone or with symptoms suggestive of a mild upper respiratory infection. The diagnosis is made most easily with the detection of a positive heterophile agglutinating antibody (monospot), although it is important to remember that this test may be falsely negative in children under the age of 7 years.

A rarer, but important, cause of acute cervical lymphadenopathy is Kawasaki disease, a systemic febrile syndrome of as yet undefined cause (see Chapter 101. Kawasaki disease, also called mucocutaneous lymph node syndrome, occurs most often in children less than 4 years of age and is rare after 8 years of age. It is important to diagnose Kawasaki disease early because prompt treatment with intravenous gamma globulin can prevent coronary artery aneurysms, the most serious complications of this illness. The cervical lymphadenopathy in Kawasaki disease, seen in approximately 50 to 70% of patients, occurs during the early phase of the illness and may be unilateral or bilateral. The nodes are firm and mildly tender and should be at least 1.5 cm in diameter. The presence of a large node in the cervical area, in association with fever of greater than 5 days' duration, bilateral conjunctival injection with limbal sparing, mucous membrane involvement, peripheral edema or erythema, and a polymorphous truncal rash, should alert the physician to the possibility of this disorder.

Axillary adenopathy is commonly present with any infection or inflammation of the upper extremities. Most commonly, injuries to the hand, such as occur after falling or with puncture wounds or bites, may present with concomitant axillary adenopathy. Similarly, epitrochlear nodes, which are not normally palpable in children, may become inflamed after infections of the third, fourth, or fifth finger; medial portion of the hand; or ulnar portion of the forearm. Most commonly, these infections are caused by pyogenic bacteria (e.g., *S. pyogenes, S. aureus*), but depending on the inciting event, other pathogens may be responsible (e.g., *S. moniliformis, Spirillum minus* in rat-bite fever).

Inguinal adenopathy most often results from lower extremity infection, although sexually transmitted diseases may also be responsible. For example, acute genital infection with herpes simplex virus (HSV)-2 often presents with tender inguinal adenopathy, occasionally as the only sign. Similarly, chancroid, lymphogranuloma venereum, and syphilis may present with inguinal nodal swelling and tenderness. The presence of genital lesions, which may be either painful (as in HSV or chancroid) or painless (as in syphilis), offers clues to these diagnoses. Therefore, careful history taking and physical examination are necessary to exclude these possibilities. Enlarged iliac nodes are palpable deeply over the inguinal ligament and become inflamed with lower extremity infection, urinary tract infection, abdominal trauma, and appendicitis. Of note, iliac adenitis, which can present with fever, limp, and inability to fully extend the leg, may mimic the signs and symptoms of septic hip arthritis. Unlike in hip disease, however, hip motion is not limited on examination. Iliac adenitis may also be confused with appendicitis, but the pain initially occurs in the thigh and hip rather than in the periumbilical region or right lower quadrant.

Chronic Regional Adenopathy

Numerous agents can cause chronic regional lymphadenopathy. Organisms such as *Bartonella* (the etiologic agent of cat-scratch disease), mycobacteria, and atypical mycobacteria are most commonly responsible for chronic adenopathy. Cat-scratch disease, caused by *Bartonella henselae*, is a relatively common cause of chronic axillary or cervical adenopathy (see Chapter 84). Cat-scratch disease is characterized by a history of exposure to kittens (although other animals have also been implicated) and the development of a primary lesion at the site of a scratch. The primary lesion is 2 to 5 mm in size and is typically papular initially, and it may then progress to a pustule. About 2 weeks later, lymphadenopathy develops proximal to the site of the lesion. Typically, the nodes are enlarged but may or may not be inflamed. Lymphangitis does not occur in cat-scratch disease. Fever is present in only about 30% of patients. Other symptoms, such as seizures, may occur but are rare. The diagnosis of cat-scratch disease is confirmed by serology.

Tuberculous cervical lymphadenitis, otherwise known as scrofula, most commonly involves the posterior cervical nodes. Scrofula has become less common in the United States, although recent epidemiologic studies in this country have suggested that the incidence of tuberculosis is rising. A history of exposure to an individual with active tuberculosis is often elicited, and several family members may have positive skin tests. Pulmonary and other systemic symptoms, such as fever, fatigue, and weight loss, are often present. The affected nodes are typically bilateral, fixed, and matted. Fluctuance is a late and rare finding in tuberculous adenitis. The diagnosis of tuberculous cervical lymphadenitis is made by a combination of skin testing, chest radiographs, and if possible, culture data from the involved node.

In contrast, atypical mycobacterial adenitis usually involves young children, less than 5 years of age, and is generally unilateral. The node is rarely more than 3 cm in size. Overlying skin may turn a deep purple and gradually thins, developing a parchment-paper appearance. Fluctuance and ulceration occur commonly. Infected patients generally appear well, with a notable absence of any systemic symptoms. Chest radiographs are normal. A clear history of exposure to atypical mycobacteria (e.g., acquiring the infection via a fish tank) is the exception rather than the rule. Diagnosis is made by culture of the infected node. Treatment generally involves excision of the node, although recently reports of treatment with newer macrolides have suggested a possible role for antimicrobial therapy of these infections.

Other less common causes of chronic adenopathy deserve mention. A prolonged heterophile-negative adenopathy unresponsive to a trial of antibiotics should raise suspicion for one of these possibilities. Cytomegalovirus (CMV) infection, which is characterized by cervical adenopathy, pharyngitis, and atypical lymphocytosis, may cause prolonged adenopathy in younger children. Toxoplasmosis typically presents as a single, nontender posterior cervical node. Brucellosis, associated generally with axillary and cervical lymphadenopathy, and tularemia with cervical adenopathy, are rare infectious causes of chronic adenopathy in children.

Noninfectious etiologies may also cause chronic regional adenopathy. Various malignancies, such as Hodgkin's disease, lymphosarcoma, neuroblastoma, and rhabdomyosarcoma, may all present with chronic cervical lymphadenopathy (see Chapter 100). For example, Hodgkin's disease usually presents as a slowly growing, painless firm node in the upper third of the neck. Lymphosarcoma also presents as a firm painless node, but it occurs in younger children than those with Hodgkin's and more commonly involves extranodal sites such as tonsils. Rhabdomyosarcoma, the most common solid tumor of the head and neck in children, often involves the nasopharynx, middle ear, mastoid, or orbit, but it can also occur as a painless mass anywhere in the head and neck.

In African-American children, sarcoidosis must be entertained in a child with bilateral chronic cervical adenopathy. Scalene nodes are involved in more than 80% of cases. An abnormal chest film, with hilar adenopathy and peribronchial fibrosis, suggests sarcoidosis. Sinus histiocytosis, a benign form of histiocytosis, can present as a large painless cervical adenopathy. The clinical presentation often includes fever, anemia, leukocytosis, and elevated erythrocyte sedimentation rate. Although the initial clinical presentation may be confused with lymphoma, the disease usually has a benign course, with resolution over a prolonged period.

Generalized Lymphadenopathy

Various systemic illnesses are associated with generalized lymphadenopathy (Table 44.2). The most common causes of generalized lymphadenopathy include bacterial or viral illnesses that disseminate systemically. As an example, the high incidence of vomiting and abdominal pain in streptococcal pharyngitis has been attributed to abdominal node inflammation and swelling, suggesting a more systemic pattern of adenopathy in streptococcal disease. Rarer bacterial causes of generalized lymphadenopathy include bacterial illnesses such as brucellosis and leptospirosis, diagnoses that may be suggested by occupational or dietary history. Common viral causes of generalized adenopathy include EBV or CMV mononucleosis, rubella, and measles in parts of the world where the disease is endemic. Another cause of generalized adenopathy includes human immunodeficiency virus (HIV) infection. HIV infection in children can present with persistent generalized adenopathy, hepatosplenomegaly, and failure to thrive. Generalized lymphadenopathy may occasionally be the only presenting symptom in a child with vertical HIV infection.

Systemic Infection	*Autoimmune Disease*
Bacterial	Juvenile rheumatoid arthritis
Bacteremia	Systemic lupus erythematosus
Scarlet fever	Serum sickness
Subacute bacterial endocarditis	Autoimmune hemolytic anemia
Syphilis	*Primary Lymphoid Neoplasm*
Tuberculosis	Hodgkin's disease
Brucellosis	Non-Hodgkin's lymphoma
Viral	*Metastatic Neoplasm*
Varicella	Acute lymphocytic leukemia
Rubella	Acute myelogenous leukemia
Rubeola	Neuroblastoma
Epstein-Barr virus	*Histiocytosis*
Cytomegalovirus	Letterer-Siwe
Human immunodeficiency virus	Histiocytic medullary reticulosis
Fungal	*Storage Disease*
Histoplasmosis	Gaucher's disease
Coccidioidomycosis	Niemann-Pick's disease
Parasitic	*Drugs*
Toxoplasmosis	Phenytoin
Malaria	Isoniazid
	Miscellaneous
	Hyperthyroidism

Table 44.2. Generalized Adenopathy

Noninfectious systemic disease may also present with generalized adenopathy. Approximately 70% of patients with systemic lupus erythematosus (SLE) or juvenile rheumatoid arthritis (JRA) manifest generalized adenopathy during the acute phase of illness (see Chapter 101). The lymphadenopathy of serum sickness often occurs in the presence of the exanthem but may be seen without rash. The lymphadenopathy of autoimmune hemolytic anemia coincides with each episode of hemolysis.

Neoplastic disease that causes generalized adenopathy may be primary to the lymph node as in Hodgkin's and non-Hodgkin's lymphoma, or it may be metastatic to the node with invasion of the node by extrinsic malignant cells as in leukemia or neuroblastoma (see Chapter 100). Hodgkin's disease, as discussed previously under regional adenopathy, usually manifests as cervical adenopathy. In contrast, non-Hodgkin's lymphoma may present with rapidly enlarging, diffuse adenopathy, often accompanied by abdominal pain, vomiting, and diarrhea secondary to abdominal node involvement. Another neoplastic condition that can present with generalized adenopathy includes leukemia. Approximately 70% of patients with acute lymphocytic leukemia (ALL) and 30% of patients with acute myelogenous leukemia (AML) have generalized adenopathy (see Chapter 100). These children usually appear ill, having other

systemic signs—hepatosplenomegaly, anemia, and thrombocytopenia with petechiae, purpura, and hemorrhage.

Histiocytosis presents as a spectrum of disease, ranging from a benign, isolated eosinophilic granuloma found in a long bone of an older child to the malignant multiorgan histiocytic infiltration found in infants with Letterer-Siwe disease (see Chapter 100). Lymphadenopathy often occurs in histiocytosis and can be an isolated finding; however, it usually occurs in association with other manifestations of disease.

Rarer causes of systemic adenopathy include lipid storage diseases (Gaucher's and Niemann-Pick's disease), which can cause diffuse adenopathy and are almost always associated with hepatosplenomegaly. Bone marrow biopsy, showing lipid-laden histiocytes, is diagnostic.

Certain drugs, most notably phenytoin (Dilantin), are associated with generalized adenopathy, appearing 1 to 2 weeks after drug initiation and disappearing 3 to 4 weeks after the drug is discontinued. This generalized adenopathy may or may not be associated with other systemic signs (hepatosplenomegaly, pruritic rash, fever, anemia, and leukopenia).

Finally, hyperthyroidism can be associated with a nonspecific lymph node hyperplasia, but one should see other signs and symptoms of the illness, such as tachycardia, hypertension, diaphoresis, weight loss, goiter, lid lag, and hyperreflexia, on physical examination.

Life-Threatening Lymphadenopathy

Several disorders associated with lymphadenopathy, primarily but not exclusively oncologic, can be life-threatening (Table 44.3). The superior vena cava (SVC) syndrome is an example of life-threatening adenopathy. The SVC is a thin-walled vessel with low intravascular pressure that is approximated tightly to the right mainstem bronchus and completely encircled by the lymph nodes that drain the thoracic cavity. SVC syndrome is obstruction of the SVC, usually caused by massive adenopathy, and manifests as dilated chest wall and neck veins, facial edema, and plethora. Drowsiness or stupor, called “wet brain” syndrome, may also be seen. Superior mediastinal syndrome is a variant of SVC syndrome, with additional respiratory symptoms caused by trachea or bronchus compression. In contrast with patients with SVC syndrome, those with superior mediastinal syndrome present in respiratory distress with coughing and wheezing.

Superior vena cava syndrome	Acute myelogenous leukemia
Hodgkin's disease	Neuroblastoma
Non-Hodgkin's lymphoma	Letterer-Siwe disease
Neuroblastoma	Coronary artery aneurysm
Bone marrow failure/multiorgan infiltration	Kawasaki disease
Acute lymphocytic leukemia	

Table 44.3. Life-Threatening Conditions Associated with Lymphadenopathy

Almost all patients with SVC or superior mediastinal syndrome have a malignant etiology (see Chapter 100). In children, Hodgkin's and non-Hodgkin's lymphoma are the most common causes, followed by metastatic neuroblastoma. Emergency physicians who treat patients with SVC syndrome must be careful to administer all intravenous therapy in the lower extremities. Poor circulation in the upper extremities and torso because of SVC obstruction results in poor drug distribution and places the patient with SVC syndrome at increased risk of thrombus formation.

EVALUATION AND DECISION

The clinician who evaluates lymphadenopathy is faced with an extensive differential diagnosis. A meticulous history and physical examination can help focus the evaluation of the patient. Historical data that need to be obtained include the time of onset, the rate of growth, and the duration of symptoms. Lymphadenopathy of more than 3 weeks' duration is considered chronic. The presence and duration of fever, history of rash or pruritus, cough, weight loss, anorexia, and nausea are important systemic symptoms. Recent illnesses must be considered, particularly because lymphadenopathy may persist for 2 to 3 weeks after the resolution of common viral illnesses. Certain medications, most notably phenytoin (Dilantin) and isoniazid, can cause generalized lymphadenopathy. In addition, the presence of certain risk factors, such as young cats in the home (cat-scratch disease) or other animals (e.g., dogs, rabbits, rats), exposure to patients with active tuberculosis, consumption of unpasteurized milk, or exposure to fish tanks (atypical mycobacteria), among others, need to be ascertained. Finally, the clinician must ask whether any prior treatment, such as antibiotic therapy or attempted aspiration with cultures, has been initiated. For example, children with atypical mycobacterial adenitis may present to the emergency department after a prolonged course of antistaphylococcal antibiotic therapy failed to reduce the size of the node. Knowledge of the response to specific antimicrobial therapy can often guide the physician to exclude certain diagnoses.

The physical examination should include a careful determination of the size of the enlarged nodes and documentation of the number of nodes involved to provide an adequate baseline for follow-up. In general, lymph nodes larger than 1 cm are significant in any location. The presence of erythema, warmth, and tenderness often points to an acute pyogenic bacterial process. In most disease processes that cause lymphadenopathy in children, the nodes will be firm, rubbery,

and mobile. Lymph nodes fixed to underlying tissues or located in deeper fascial planes are rare in children, but when present, they should prompt the physician to consider early surgical evaluation. Finally, because several systemic diseases manifest a specific pattern of adenopathy, examination of all lymph node regions must be performed. Likewise, hepatosplenomegaly, rash, and other signs of systemic involvement must be sought.

The approach to the patient with lymphadenopathy focuses initially on the history and examination findings as noted, with emphasis on the distribution of enlarged nodes: regional or generalized (Fig. 44.1). Regional lymphadenopathy should be categorized as acute or subacute/chronic.

FIGURE 44.1. The diagnostic approach to the child with lymphadenopathy. *PPD,* purified protein derivative; *EBV,* Epstein-Barr virus; *CMV,* cytomegalovirus; *CBC,* complete blood count; *HIV,* human immunodeficiency virus.

The most common causes of acute regional lymphadenopathy include reactive hyperplasia, acute bacterial adenitis, and EBV infection (infectious mononucleosis). Findings of acute inflammation, such as erythema and tenderness, point to bacterial adenitis. The emergency physician must decide whether the patient would benefit from aspiration and drainage of the lymph node, particularly if the lesion is fluctuant and easily amenable to the procedure. Treatment of acute bacterial adenitis should include antistaphylococcal and antistreptococcal antibiotics as well as careful follow-up. It is important to note and to inform the patient's parents that these infections often are slow to resolve and may eventually require incision and drainage despite adequate antimicrobial therapy (see also Chapter 84).

The presence of systemic symptoms may suggest other causes of acute regional adenopathy. For example, the presence of pharyngitis, hepatosplenomegaly, and periorbital edema should suggest EBV infection. In the absence of any respiratory compromise, the treatment of EBV infection is supportive. Several days of high fever, rash, and swelling of the extremities in the presence of a large node should alert the physician to the possibility of Kawasaki disease. Early identification of these patients is essential in preventing serious sequelae of this disease. Therefore, a low index of suspicion for Kawasaki disease is prudent.

The evaluation of subacute or chronic regional adenopathy includes consideration of various infectious and noninfectious causes. Exposure to cats should alert the physician to the possibility of cat-scratch disease. The possibility of tuberculosis or atypical mycobacteria can be evaluated by placing a positive purified protein derivative (PPD) test on the patient or can be elicited by a history of exposure to a patient with active tuberculosis. Malignancies and chronic systemic disorders (sarcoid) are less common causes of subacute or chronic regional adenopathy. Either the location (e.g., supraclavicular) or persistence of the node points to a neoplastic disease or to another serious process.

The evaluation of generalized lymphadenopathy involves consideration of systemic diseases that may be associated with adenopathy. The presence of systemic signs of illness, such as weight loss and fever, may be seen in subacute bacterial endocarditis, HIV, tuberculosis, brucellosis, and syphilis. A recent, brief febrile illness, at times with a rash, is characteristic of EBV, tuberculosis, mononucleosis, or acute HIV infection. Signs of toxicity suggest less commonly encountered causes (tumors, collagen vascular disease, sarcoid). In the absence of toxicity, and particularly if the adenopathy begins to resolve within 4 weeks of presentation, the diagnosis of reactive hyperplasia is most likely.

The decision to perform a biopsy on an enlarged node remains a clinical one. In general, early node biopsy should be considered in all neonates with lymphadenopathy and in older children who are ill with systemic symptoms, persistent fever, or weight loss. Deep inferior cervical or supraclavicular adenopathy with or without an abnormal chest film showing hilar adenopathy should be aggressively pursued with biopsy. Beyond this, in the face of an otherwise negative diagnostic workup that included a complete blood count, tuberculosis skin test, EBV heterophile, and chest film, serial measurement over a period of weeks showing progressive or rapid enlargement of the affected node raises suspicion for malignant disease and biopsy should be strongly considered. Biopsy should also be considered if an enlarged node fails to regress in size after approximately 6 weeks of observation.

CHAPTER 45

Neck Mass

CONSTANCE M. MCANENEY, MD and RICHARD M. RUDDY, MD

Department of Pediatrics, University of Cincinnati College of Medicine, and Division of Emergency Medicine, Children's Hospital Medical Center, Cincinnati, Ohio

Neck masses are common in children, and the diagnosis encompasses a multitude of disorders. By definition, neck masses include any visible swelling that disturbs the normal contour of the neck between the shoulder and the angle of the jaw. In the pediatric population, the four basic classifications of neck lesions are congenital, inflammatory, traumatic, and neoplastic. Congenital anatomic defects of the neck are often inapparent or minimally recognizable at birth but develop into significant cystic masses later. Included in this category are cystic hygromas, branchial cleft cysts, hemangiomas, thyroglossal duct cysts, and dermoids. It is important to have a working understanding of the embryology of the neck to assist in diagnosis and treatment. Inflammatory masses are the most common and usually represent structures normally present, such as lymph nodes that are undergoing changes from the infectious causes. By far, the most common causes of neck masses in children are reactive adenopathy and adenitis. Traumatic neck masses are usually caused by hematoma surrounding vital structures and may lead to significant distress. Malignant lesions of the head and neck must be ruled out, but fortunately, they are fairly uncommon and are often from the cancer of the lymphatic system.

True medical emergencies arise if neck masses compromise adjacent vital structures, including the airway, carotid blood vessels, and cervical spinal cord. In rare cases, the principal threat to life is from systemic toxicity. Infection that leads to septicemia or the effects of excess hormone secretion in thyroid storm can lead to uncompensated shock. Most large neck masses do not encroach on vital structures because their growth points outward. Embarrassment about personal appearance or a concern of malignancy may be factors, however, in the initiation of the emergency department (ED) visit.

This chapter first emphasizes recognition of masses that represent true emergencies (Table 45.1). Then, the approach to nonemergent, but commonly seen, lesions is described (Table 45.2). Table 45.3 lists causes of neck masses of children by origin.

Hematoma secondary to trauma
Cervical spine injury
Vascular compromise or acute bleeding
Late arteriovenous fistula
Subcutaneous emphysema with associated airway or pulmonary injury
Local hypersensitivity reaction (sting/bite) with airway edema
Airway compromise with epiglottitis, tonsillar abscess, or infection of floor of mouth or retropharyngeal space (with adenopathy)
Bacteremia/sepsis associated with local infection of a cyst (cystic hygroma, thyroglossal, or branchial cleft cyst)
Non-Hodgkin's lymphoma with mediastinal mass and airway compromise
Thyroid storm
Mucocutaneous lymph node syndrome with coronary vasculitis
Tumor—leukemia, lymphoma, rhabdomyosarcoma, histiocytosis X

Table 45.1. Life-Threatening Causes of Neck Mass

Lymphadenopathy secondary to viral or bacterial infection
Cervical adenitis (bacterial)
Hematoma
Benign tumors—lipoma, keloid
Congenital cyst (squamous epithelial cysts)

Table 45.2. Common Causes of Neck Mass

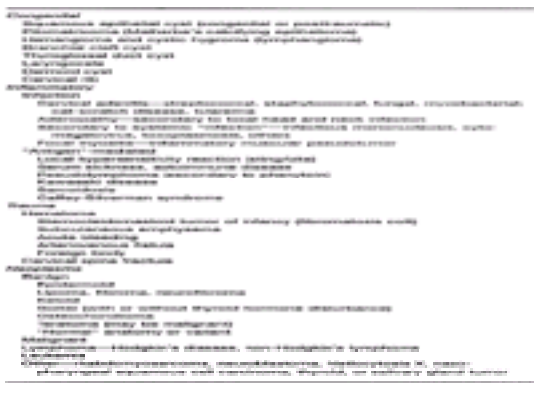

Table 45.3. Differential Diagnosis of Neck Mass by Etiology

EVALUATION AND DECISION

The initial history and physical examination should screen rapidly for airway or vascular compromise with consideration of integrity of the cervical spine. The presence of stridor, hoarseness, dysphagia, and drooling indicates respiratory compromise. The quality of breathing, level of consciousness, and integrity of the cervical spine should also be assessed. Appropriate resuscitative measures should be taken if respiratory or vascular compromise is evident. The cervical spine should be immobilized if there is history of trauma or the initial evaluation leads to suspicion. Table 45.1 lists disorders that constitute true emergencies because of local pressure on vital structures or because of systemic toxicity.

Child with Neck Mass and Respiratory Distress or Systemic Toxicity

Trauma from vehicular accidents, falls from heights, or sports injuries may cause bleeding or hematoma formation near vital structures such as the carotid artery or trachea. If the trauma involves the cervical spine, a hematoma may occur over fractured vertebrae. Even mild injuries may lead to severe hemorrhage and compression of vital structures of the neck in children who have clotting factor disorders (i.e., hemophilia) or platelet disorders (i.e., idiopathic thrombocytopenic purpura). Symptomatic arteriovenous fistulas may appear weeks after neck trauma. The emergency physician should be wary of severe trauma or ecchymoses with an insignificant “history” and should consider possible child abuse or an acquired bleeding problem. The progression of a pneumomediastinum to pneumothorax can be rapid and requires close observation of the tachypneic child with a “crepitant” neck mass. Acutely, this may be caused by trauma to the chest and rib cage or by severe airway obstruction caused by asthma or a foreign body. In children with obstructive lung diseases, such as asthma and cystic fibrosis, high transpulmonary pressure generated in these diseases forces air through small alveolar leaks into the mediastinum or pleural space. This may produce a pneumomediastinum that dissects into the neck. Anaphylactic reaction with neck swelling may precipitate an acute emergency if the swelling compromises the airway. Severe, local reactions to bee stings or to other sensitizing allergens may cause enough tissue edema to obstruct the trachea.

Infections associated with life-threatening processes include retropharyngeal, lateral pharyngeal, and peritonsillar abscesses. Rarely, epiglottitis may present with associated cervical adenitis or the appearance of submandibular mass from ballooning of the hypopharynx. These patients may have cervical adenitis and concomitant dysphagia, drooling, and stridor. Occasionally, branchial cleft cysts or cystic hygromas become infected and progress to mediastinitis, or laryngoceles may become acutely infected and obstruct air flow. Massive tonsillar hypertrophy with infectious mononucleosis or dental infection that spreads to the floor of the mouth (Ludwig's angina) and neck may cause neck masses and airway compression. More recently, children with human immunodeficiency virus (HIV) infection (see Chapter 85) are reported to have parotitis or generalized lymphadenopathy, particularly visible in the neck as a presenting complaint. Children may have hyperthyroid symptoms as part of the presentation of a neck mass. Similarly, patients with the mucocutaneous lymph node syndrome often have cervical lymphadenopathy and, on rare occasions, have active life-threatening vasculitis of the coronary vessels.

Neck tumors in children may become large enough to encroach on vital structures. Cystic hygromas and hemangiomas occasionally enlarge sufficiently enough to interfere with feeding or to obstruct the airway. Lymphoma, an uncommon but important cause of neck mass, is suggested especially by painless enlargement (often of supraclavicular nodes) that occurs over several weeks in the older school-age child. When mediastinal nodes are involved, the patient may rapidly develop a blockage of the intrathoracic trachea that is accentuated on lying down. These children may be fine when sitting, but when supine, the anterior mediastinal masses compress the trachea, causing the airway to collapse. Other tumors, such as rhabdomyosarcoma, leukemia, neuroblastoma, and histocytosis X, are life-threatening because of local invasion and metabolic and hematologic effects.

Child with Neck Mass and No Distress

Most children in the ED with a neck mass are not in distress; the leading diagnoses are reactive adenopathy and acute lymphadenitis from viral or bacterial infection. A common concern, however, is which neck mass bears the diagnosis of

malignancy and requires biopsy or further evaluation.

History

A careful history, establishing the duration of signs and symptoms as well as ascertaining the involvement of other organ systems (fatigue, weight loss, night sweats, adenopathy elsewhere), often suggests the diagnosis. Location of the mass, size and shape of the mass, duration of symptoms, and a history of injury are important. The patient's age at discovery of the lesion should be noted because those found early in infancy increase the risk of a cyst of congenital origin. Birth trauma, with bleeding into the sternomastoid muscle, may cause torticollis, which presents at several weeks of age with a neck mass. It is important to note that not all congenital lesions present at birth or in the first months of life. They are brought to medical attention with acute infection or inflammation, sometimes as a recurrent unilateral neck mass in young infants. Changes in the size of the mass with time or with a child's growth should be noted. Presence of a dimple or sinuses, history of drainage, and other symptoms of infection may assist in making the diagnosis. History of exposure to an infectious agent, including streptococcal pharyngitis, infectious mononucleosis, and cat-scratch disease, should be sought. Systemic symptoms that suggest serum sickness or pseudolymphoma ought to prompt an exposure history for medications (e.g., antibiotics, phenytoin, respectively). Figure 45.1 describes a pathway to facilitate some of the differential diagnoses by category.

FIGURE 45.1. Evaluation of the child with a neck mass.

Physical Examination

After assessment for critical emergency is done, the clinician should perform a thorough examination on a child with a neck mass. It is often valuable to examine the patient thoroughly and then come to examine the area of the head and neck last. Palpation of the mass, noting its location, size, shape, relationship, and attachment to normal structures in the neck, should be completed. Figure 45.2 diagrams the locations of many of the causes of neck mass. It is important to ascertain whether crepitation is present and the degree to which an inflammatory mass is fluctuant. The surrounding area should be palpated for additional lesions (10 to 20% of branchial lesions are bilateral) and to evaluate normal structures of the neck such as the thyroid gland, sternomastoid muscles, trachea, and cervical spine. Inspection of the oral cavity should be performed, noting oral mucosa, dentition, and the orifices such as Stenson's duct (parotid gland) and other glands. The presence of movement of the mass with swallowing or with protrusion of the tongue is important. The examination of the head should be meticulous, including the scalp, ears, sinuses, and nasopharynx.

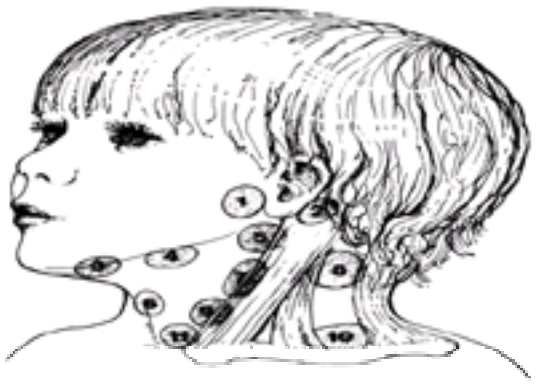

FIGURE 45.2. Differential diagnosis of neck mass by location.
Area 1. Parotid: Cystic hygroma, hemangioma, lymphadenitis, parotitis, Sjögren's and Caffey-Silverman syndrome, lymphoma.
Area 2. Postauricular: Lymphadenitis, branchial cleft cyst (1st), squamous epithelial cyst.
Area 3. Submental: Lymphadenitis, cystic hygroma, sialadenitis, tumor, cystic fibrosis.
Area 4. Submandibular: Lymphadenitis, cystic hygroma, sialadenitis, tumor, cystic fibrosis.
Area 5. Jugulodigastric: Lymphadenitis, squamous epithelial cyst, branchial cleft cyst (1st), parotid tumor, *normal*--transverse process C2, styloid process.
Area 6. Midline neck: Lymphadenitis, thyroglossal duct cyst, dermoid, laryngocele, *normal*--hyoid, thyroid.
Area 7. Sternomastoid (anterior): Lymphadenitis, branchial cleft cyst (2nd, 3rd), pilomatrixoma, rare tumors.
Area 8. Spinal accessory: Lymphadenitis, lymphoma, metastasis (from nasopharynx).
Area 9. Paratracheal: Thyroid, parathyroid, esophageal diverticulum.
Area 10. Supraclavicular: Cystic hygroma, lipoma, lymphoma, metastasis,*normal*--fat pad, pneumatocele of upper lobe.
Area 11. Suprasternal: Thyroid, lipoma, dermoid, thymus, mediastinal mass.

(Modified with permission from May M. Neck masses in children: diagnosis and treatment. Clin Pediatr 1976;5:17.)

Details of chronicity, size, and progression and evidence of inflammation help distinguish between infection and neoplasm. Characteristics that some authors have found associated with malignancy include masses that are firm and larger than 3 cm in diameter, nonpainful, progressively enlarging, ulcerating, deep to fascia or fixed to tissue, or discovered in a newborn. These criteria are sensitive but not specific for cancer. Even with these characteristics, most lesions are benign congenital cysts or inflammatory masses. The length of time the “node” is present is not discriminating in that, often, inflammatory nodes that are biopsied have been present for longer than 3 to 6 months.

During auscultation of the chest, special attention should be paid to inspiration because extrathoracic airway obstruction from the trachea or upper airway may produce only faint stridor. Respiratory distress or wheezing that worsens in the supine position may be an early sign of an anterior mediastinal mass. The physical examination should be completed, looking for signs of systemic illness as a cause for the neck mass. The general appearance and color of the child is important, as is the presence of hepatosplenomegaly or an abdominal mass, indicating a high suspicion for a malignancy. Signs of thyroid hormone excess or deficiency may be associated with a goiter. Rashes, generalized lymphadenopathy, and fever may indicate an inflammatory or oncologic process. Failure to thrive or weight loss may be found with a number of causes of infection or oncologic illness, including HIV disease, histiocytosis X, and others.

DIFFERENTIAL DIAGNOSIS

Congenital Masses

Thyroglossal duct cysts are the most common congenital cyst of the neck. They develop along the line of descent of the thyroid gland in the neck anywhere from the base of the tongue to the sternal notch. Thyroglossal duct cysts are usually midline, adjacent to the hyoid bone, and diagnosed in children 2 to 10 years of age. Thyroglossal duct cysts are soft, nontender, smooth, and may move when the child swallows or protrudes the tongue. If infected, they may be warm and erythematous and drain externally. Antibiotics (for mouth and skin flora), warm compresses, and incision and drainage (if indicated) should be initiated for signs of infection. Complete excision is the treatment of choice after complete resolution of infection.

Cystic hygromas are cystic lymphatic malformations occurring in the posterior triangle of the neck. Most are identified at birth, but some may be recognized after injury or upper respiratory infection when “herniation” has occurred after crying, coughing, or other forceful Valsalva maneuvers. Cystic hygromas appear discrete, soft, mobile, nontender, and vary greatly in size. Extension to the mediastinum is rare but can occur and can be seen on chest radiographs. Respiratory distress can occur in infants with large masses compressing the airway. Infection is uncommon, but signs of it would be as expected. Ultrasonography is useful in establishing if the mass is cystic. Computed tomography (CT) imaging can determine extent and involvement of surrounding structures. Spontaneous regression is rare; therefore, complete excision is the treatment of choice.

Branchial cleft anomalies are lesions most commonly occurring from defects in the development of the second branchial arch, giving rise to firm masses along the anterior border of the sternocleidomastoid muscle. Branchial cleft sinuses are painless and present with drainage at the junction of the middle and lower thirds of the sternocleidomastoid muscle. Cysts that are usually fluctuant, mobile, and nontender may occur if the sinus tract becomes blocked. Probing or injecting the tract may lead to infection. Ultrasonography may be useful in identifying cystic structures. Treatment with antibiotics with complete resolution of infection is necessary if the sinus or cyst is infected. Excision of the entire tract and cyst is important to prevent recurrence.

Hemangiomas are common head and neck lesions identified in infancy. They are three times more common in females than in males. Hemangiomas are soft, mobile, nontender, and bluish or reddish in color. They tend to get larger in the first year of life and then involute over the next several years. Rare complications include thrombocytopenia from platelet consumption, disseminated intravascular coagulation, hemorrhage, airway obstruction, congestive heart failure, ulceration, infection, and necrosis. Treatment for most hemangiomas is conservative and nonoperative because the issues are almost solely cosmetic and short term. Other treatments are reserved for rapidly growing lesions that are impairing vision or hearing or are life-threatening.

Neonatal torticollis results from sternocleidomastoid fibrosis and shortening of the muscle. Presenting symptoms of torticollis occur in the first 3 weeks of life, with the infant holding his or her face and chin away from the affected side and the head tilted toward the fibrous mass. The mass is firm and seems attached to the muscle. Physical therapy, including massage, range-of-motion exercises, stretching exercises, and positional changes, is the preferred treatment. Facial and cranial asymmetry can develop without intervention. Surgical intervention is rarely needed.

Inflammatory Masses

Cervical lymphadenopathy is the most common reason for neck masses in children. Up to 90% of children between the ages of 4 and 8 years can have cervical adenopathy without obvious associated infection or systemic illness. Lymphadenopathy in newborns and young infants is rare and warrants investigation. Supraclavicular lymphadenopathy is considered pathologic and should be biopsied. Etiology for cervical adenopathy includes bacterial or viral infection either from local, regional, or systemic illness. Anterior cervical nodes drain the oropharynx and become enlarged with upper respiratory, oral, and pharyngeal infections. Posterior cervical lymph nodes drain the scalp and nasopharynx and become enlarged with inflammation or infection in these areas. With treatment of the underlying infection, cervical lymphadenopathy should resolve.

Cervical lymphadenitis occurs when acute infection is present within the lymph node (see Chapter 84). Bacteria are the most common causes and include penicillin-resistant *Staphylococcus aureus* and group A b-hemolytic streptococci. Common presentation is usually one or more cervical lymph nodes that become acutely enlarged, tender, warm, and erythematous after an upper respiratory illness, pharyngitis, tonsillitis, or otitis media. Systemic symptoms of fever and malaise may be present. Treatment includes antibiotics and warm soaks. If the patient appears toxic, admission and treatment with intravenous antibiotics is appropriate. Without antibiotic treatment, enlargement with the development of fluctuation and regional cellulitis may progress. Most cases of acute cervical lymphadenitis resolve with antibiotics. If fluctuation is present, needle aspiration is indicated. The purulent fluid should be sent for Gram stain and culture with antibiotic selection based on test results. If resolution of the lymphadenitis does not occur after needle aspiration and antibiotics, incision and drainage should be performed.

Cat-scratch disease is another common cause of lymph node enlargement in children. Typically, regional lymph nodes enlarge 2 to 4 weeks after a cat scratch (usually a kitten). The lymphadenopathy can be cervical if the head or neck have been scratched. Fever and malaise may have been present initially and usually a single node is involved. The area around the lymph node is warm, tender, indurated, and erythematous. *Bartonella henselae* is the organism most likely responsible. Serologic titers for antibody and polymerase chain reaction assays are available in some laboratories. Warthin-Starry silver stain of the lymph node or inoculation site will identify the organism. Management is symptomatic with resolution in 2 to 4 months. Needle aspiration provides relief to those with tender, suppurative nodes and aids in the diagnosis. Surgical excision is unnecessary and can lead to formation of a draining sinus. Antibiotics should be considered for acutely ill patients with systemic symptoms. Rifampin, trimethoprim–sulfamethoxazole, and ciprofloxacin have been shown to be effective.

Mycobacterial infection of the cervical lymph nodes are most often caused by the atypical strains of *Mycobacterium avium-intracellulare and M. scrofulaceum*. The enlarged lymph nodes are generally submandibular in region and red, rubbery, and minimally tender to palpation. If systemic manifestations are present, an immune deficiency should be considered. On the other hand, clinical systemic signs of tuberculosis accompany cervical lymphadenopathy caused by *M. tuberculosis*. The supraclavicular lymph nodes are commonly involved. Children with suspected mycobacterium infection should have a purified protein derivative (PPD) tuberculin skin test and chest radiograph performed. An excisional biopsy may need to be performed to differentiate between tuberculous and nontuberculous mycobacteria as the offending organism. The PPD tuberculin test may be negative in atypical mycobacterium infections. Treatment for atypical mycobacterial cervical lymphadenitis is complete surgical excision. Incision and drainage results in a draining sinus. Treatment for *M. tuberculosis* lymphadenitis is the same as for pulmonary tuberculosis: 6 to 9 months of antituberculosis chemotherapy.

Cervical lymphadenitis can be the result of viral infections, most commonly mononucleosis. Classically, the patient has diffuse lymphadenopathy with prominent cervical lymphadenopathy and large, hypertrophied tonsils. *Epstein-Barr virus* is the most common cause of mononucleosis. Systemic symptoms of fever, malaise, and the presence of hepatosplenomegaly are common. Exudative pharyngitis may be present, and the throat should be cultured for group A b-hemolytic streptococci. If bacterial pharyngitis is present, the child should be treated with antibiotics. Generally, treatment for mononucleosis is supportive. Corticosteroids (prednisolone at 1 mg/kg per day) have been found useful in reducing tonsillar inflammation and preventing airway compromise.

Kawasaki disease (mucocutaneous lymph node syndrome) is associated with a single enlarged cervical lymph node, conjunctival injection without drainage, erythematous mouth, cracked lips, strawberry tongue, erythematous rash, induration of the palms of hands and soles of the feet, and fever of at least 3 days' duration. The cause is unknown but is thought to be infectious. Anti-immune therapy should be initiated if the diagnosis is strongly suspected. An echocardiogram should be performed to rule out coronary artery aneurysms.

Neoplasms

Fortunately, neoplasms of the head and neck in children are less commonly seen than infection or congenital lesions. Presentation is usually a painless, firm, fixed cervical mass. Systemic symptoms may not be present. Differentiating between a benign and malignant lesion can be difficult. Cervical lymphadenopathy that does not resolve with standard therapy should raise suspicion for a malignancy. Neoplastic etiologies for neck mass in children include Hodgkin's and non-Hodgkin's lymphoma, rhabdomyosarcoma, neuroblastoma, thyroid carcinoma, and nasopharyngeal carcinoma. As described in the section on evaluation, duration and characteristics of the neck mass will lead to increased risk of cancer. If a malignancy is suspected, a complete blood count, chest radiograph, and selective CT or magnetic resonance imaging (MRI) should be obtained. Treatment is individualized according to specific tumor and extent of disease (see Chapter 100 and Chapter 121).

LABORATORY TESTING

The clinical impression should be used to ascertain the need for laboratory studies or radiologic imaging. Many of the common conditions are inflammatory or acute infections, and no studies need to be done. Oxygenation may be determined by pulse oximetry. In processes for which the risk of critical airway obstruction is pending, the utility of the arterial blood gas adds little initially, and the stress may lead to worsening of the obstruction. A complete white blood count and differential are most helpful when an oncologic cause is suspected. When bleeding from trivial trauma is being considered as a cause of neck mass, the platelet count, prothrombin time, and partial thromboplastin time should be obtained. Consider also a bleeding time when a coagulopathy is in the differential. Serum thyroid hormone levels and thyroid-stimulating hormone (TSH) may be warranted for goiter. Throat culture for streptococcal disease (or a Rapid Strep screen) should be obtained when pharyngitis is found. A monospot or, preferably, Epstein-Barr virus titers should be done to confirm infectious mononucleosis.

Cervical spine radiographs need to be obtained for trauma patients when instability or fracture of the cervical spine is

suspected. Facial or mandibular films may be necessary to evaluate for some lower face trauma or for oral infections. Soft-tissue lateral neck films are helpful to evaluate for intraoral, retropharyngeal, or airway infectious problems. More specific diagnostic imaging uses CT with cuts to evaluate the sinuses and other cavities with better detail. In the child with respiratory distress, a chest radiograph is necessary to view the mediastinum, pleura, and lung for infection, tumor, pneumothorax, or pneumomediastinum. Ultrasound may be useful in defining the mass; a cystic mass with linear septations is characteristic of a cystic hygroma. Other masses (lymphadenopathy, thyroglossal duct) and fibromatosis colli (congenital torticollis) have fairly definitive patterns. Although not specific, the finding of calcification within a mass may suggest a teratoma or neuroblastoma. In some instances, the use of CT or MRI has improved the diagnostic accuracy.

In studies in which biopsies of neck masses were obtained, several authors have found preoperative diagnoses to be correct as infrequently as 60% of the time. Biopsy of the lesion is required when the suspicion is high for malignancy. As in adults, fine needle aspiration in children is becoming more popular at some centers because it offers high sensitivity and specificity for tumors. This may reduce the need for open biopsies as often as 75% of the time by identifying inflammatory or self-limiting processes.

THERAPY

In the ED, the clinical evaluation most often reveals adenopathy that requires no acute therapy or adenitis that necessitates a course of systemic oral antibiotics and local care. Important to the approach to adenitis is the follow-up in several days to monitor clinical response and need for aspiration and drainage. When the mass is suspicious for tumor or congenital cyst, surgical consultation for biopsy or excision is indicated. Hospitalization and institution of definitive therapy are indicated for the patients with neck masses who present with systemic toxicity, airway compromise, or severe local disease.

CHAPTER 46

Neck Stiffness

NATHAN KUPPERMANN, MD, MPH

Departments of Emergency Medicine and Pediatrics, and Emergency Medicine, University of California at Davis, School of Medicine, Sacramento, California

Neck stiffness is an important chief complaint in children evaluated in the emergency department. Commonly, neck stiffness is accompanied by neck pain. However, certain clinical conditions may lead a child to hold the neck in an abnormal posture without neck pain. The underlying causes of neck stiffness or malposition in children range from relatively benign (e.g., cervical adenitis) to life-threatening (e.g., meningitis, fracture or subluxation of the cervical spine).

Torticollis (meaning “twisted neck” from the Latin roots tortus and collum) is a variation of neck stiffness. The child holds the head tilted to one side and the chin rotated in the opposite direction, reflecting unilateral neck muscle contraction. This may result from various pathologic processes and may or may not be associated with neck pain. Torticollis is often congenital and muscular in origin; however, it can also be associated with acquired processes such as trauma, infectious or inflammatory illnesses, central nervous system (CNS) neoplasms, drug reactions, and a variety of different syndromes.

This chapter reviews the differential diagnosis of neck stiffness or malposition, including torticollis, both with and without neck pain, in children. The proposed algorithm at the end of the chapter will help distinguish potentially life-threatening from benign causes of neck stiffness, while providing a broad differential diagnosis for this important clinical finding.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of neck stiffness is best organized around a few important historical/clinical questions: 1) Is there a history of trauma? 2) Is there evidence of an infectious or inflammatory process (e.g., history or presence of fever)? and 3) Is there evidence of spinal cord involvement? Table 46.1 lists most causes of neck stiffness in children, Table 46.2 lists the common causes, and Table 46.3 lists the life-threatening causes. The following description categorizes the causes of neck stiffness in children by underlying mechanism and severity.

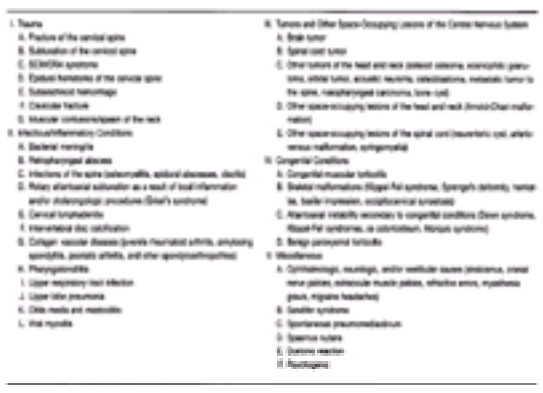

Table 46.1. Causes of Neck Stiffness or Malposition

I. Trauma	C. Pharyngotonsillitis and other upper respiratory tract infections
A. Minor trauma (cervical muscular contusions, strains, and spasm)	D. Viral myositis
B. Clavicular fracture	E. Muscle spasm
C. Rotary atlantoaxial subluxation	F. Rotary atlantoaxial subluxation
II. Infectious/Inflammatory Conditions	III. Congenital Conditions
A. Bacterial meningitis	A. Congenital muscular torticollis
B. Cervical lymphadenitis	IV. Miscellaneous
	A. Dystonic reaction

Table 46.2. Common Causes of Neck Stiffness or Malposition

I. Trauma	III. Tumors and Other Space-Occupying Lesions of the Central Nervous System
A. Injuries to the cervical spine (fractures, subluxation, SCIWORA, epidural hematoma)	A. Brain tumor
B. Subarachnoid hemorrhage	B. Spinal cord tumor
II. Infection	C. Other tumors and space-occupying lesions of the head, neck, and spinal cord
A. Bacterial meningitis	IV. Congenital Conditions
B. Retropharyngeal abscess	A. Atlantoaxial instability secondary to congenital conditions
C. Infections of the spine (osteomyelitis, epidural abscesses, discitis)	
D. Atlantoaxial subluxation with anterior displacement of the atlas as a result of local inflammation	

Table 46.3. Life-Threatening Causes of Neck Stiffness or Malposition

Neck Stiffness Associated with Trauma

Potentially Life-Threatening Causes

Trauma to the neck is a common cause of neck pain and stiffness in children (see Chapter 106). Fortunately, serious injuries to the cervical spine (fractures, subluxations) in children are uncommon. These injuries generally occur in the upper cervical spine, as opposed to neck injuries in adults, which more commonly involve the lower cervical spine. Neck injuries in children most commonly result from motor vehicle–related accidents, sports injuries, and falls.

Fractures of the Cervical Spine

Fractures of the cervical spine in children are uncommon, occurring in 1 to 2% of hospitalized pediatric trauma patients. Although some children with fractures of the cervical spine are unresponsive at the time of evaluation, most are alert and verbal, complain of neck pain, and have no demonstrable neurologic deficit. At the minimum, the cervical spine should be immobilized and multiple-view radiographs of the cervical spine should be obtained on any child with an altered level of consciousness, pain or stiffness of the neck, any neurologic deficits, or distracting painful injuries; they should also be obtained in those who are unable to perceive pain (as a result of alcohol or drugs) or describe their symptoms.

Subluxation of the Cervical Spine

Subluxations of the cervical spine are more common than fractures and may result from minor trauma (e.g., falls from low heights) as well as more severe trauma (see Chapter 106). The most commonly occurring of these is rotary atlantoaxial subluxation, which generally does not compromise the spinal canal because the transverse ligament of the atlas remains intact. Rotary subluxation typically causes neck pain and torticollis. Sternocleidomastoid (SCM) spasm and neck tenderness are localized to the same side as the head rotation in contrast to inflammatory muscular torticollis, in which the spastic, tender SCM muscle is opposite to the direction of head rotation. Neurologic deficits are rare in patients with rotary subluxation. With rotary atlantoaxial subluxation, an anteroposterior open-mouth radiograph typically shows the rotation of C1 on C2, with the odontoid in an eccentric position relative to C1. Computed tomography (CT) scans of the neck can confirm equivocal cases. Most patients with rotary subluxation can be treated with a soft collar and anti-inflammatory medications. Traction and immobilization are necessary for more severe rotary subluxation or if reduction is not achieved by conservative measures.

Atlantoaxial subluxation with compromise of the spinal canal results from ligamentous laxity or rupture and resultant anterior movement of the atlas on the axis. Children with Down syndrome are susceptible to atlantoaxial subluxation because of laxity of the transverse ligament of the atlas. Radiographic findings of atlantoaxial subluxation may include a widened predental space and prevertebral soft-tissue swelling. Treatment involves immobilization and cervical traction.

SCIWORA Syndrome

The ligamentous laxity and hypermobility of the pediatric cervical spine predispose children to spinal cord injuries without radiographic abnormality (SCIWORA syndrome). This may occur in more than 50% of children with cervical spinal cord injuries. Children younger than 8 years of age are most susceptible. Various mechanisms, including longitudinal distraction, hyperflexion, hyperextension, and ischemia to the spinal cord, may result in SCIWORA syndrome. Children with SCIWORA syndrome generally experience significant or progressive paralysis within 48 hours of a traumatic injury. Some children, however, may have transient neurologic symptoms that remit, then recur within the next day with worsening neurologic abnormalities.

Therefore, a careful neurologic history and examination are necessary for any child with traumatic injury to the neck, even in the absence of radiographic abnormalities. Cervical spine immobilization and hospitalization should be seriously considered even for children with transient neurological deficits.

Epidural Hematomas of the Cervical Spine

Epidural hematomas of the cervical spine are uncommon but may occur even after apparently minor trauma. These may compress the spinal cord, leading to progressive neurologic symptoms and signs. Magnetic resonance imaging (MRI) of the spinal cord clearly demonstrates this injury. Emergent neurosurgical consultation and surgical decompression are indicated.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage after trauma may lead to neck stiffness but is accompanied by headache and/or other physical findings of head trauma.

Generally Non–Life-Threatening Causes

Clavicular Fracture

Fracture of the clavicle in children is common and may cause torticollis because of SCM muscle spasm. However, the diagnosis is usually clear because pain is localized to the clavicle and not to the neck.

Traumatic Muscular Contusions of the Neck

Blunt trauma to the neck may result in neck pain as a result of muscular contusion and/or spasm. This is a diagnosis of exclusion, however, and should not be entertained until a detailed physical (neurologic) examination and radiographs of the cervical spine exclude the possibility of a more serious injury. Treatment should include a soft cervical collar and analgesic medication.

Neck Stiffness Associated with Infectious/Inflammatory Conditions

Potentially Life-Threatening Causes

Bacterial Meningitis

Bacterial meningitis is the most important infectious cause of neck stiffness and is almost always accompanied by fever. Children with meningitis typically have findings of neck stiffness on physical examination, although this may not be apparent in young infants and in children with meningeal infection who lack an inflammatory response. Since the introduction of the *Haemophilus influenzae* type b protein conjugate vaccine, the two most common bacterial pathogens causing meningitis in children are *Neisseria meningitidis* and *Streptococcus pneumoniae.* Children with meningococcal meningitis with minimal cerebrospinal fluid (CSF) pleocytosis may not have significant neck findings. However, these children generally have a toxic clinical appearance because the lack of CSF pleocytosis often indicates overwhelming infection. Torticollis has also been reported in patients with bacterial meningitis, although far less commonly than meningismus.

Retropharyngeal Abscess

There are several other important infectious processes for which neck stiffness and usually fever are presenting signs. Retropharyngeal abscess is an infection that occupies the potential space between the posterior pharyngeal wall and the anterior border of the cervical vertebrae. Most commonly caused by group A streptococcus, oral anaerobic organisms and *Staphylococcus aureus,* these infections cause clinical toxicity, drooling, and stridor. Neck stiffness often is an associated clinical finding in children with these infections. Lateral radiographs of the neck reveal soft-tissue swelling anterior to the upper cervical vertebral bodies.

Infections of the Spine

Infectious processes involving the spine (osteomyelitis, epidural abscess, discitis) in children can involve the cervical region, although they occur most commonly in the thoracic and lumbar areas. Localized pain, fever, and elevation of erythrocyte sedimentation rate (ESR) generally accompany all of these infections. Vertebral osteomyelitis occurring in the cervical spine may lead to neck stiffness. Vertebral osteomyelitis is usually bacterial in origin (most commonly caused by *S. aureus*) but may be caused by mycobacteria (tuberculous or nontuberculous) as well. If the cervical spine is involved, radiographs of this area may reveal destruction of the vertebral body, local soft-tissue swelling, or narrowing of the disc space. Radionuclide scanning will reveal uptake at areas of increased metabolic activity of the spine before bony destruction is visible on radiography of the spine.

Although uncommon, spinal epidural abscesses are associated with significant morbidity and mortality. Epidural abscesses may occur in the cervical spine, although lower spine involvement is much more common. When these abscess occur in the cervical region, severe neurologic deficits may occur, and emergent neurosurgical referral is essential.

Infectious discitis is uncommon in children. This disease is often caused by infection with *S. aureus,* although bacterial cultures are commonly negative and the cause has been debated. Most children with infectious discitis are younger than 3 years of age. Disease is usually in the lumbar or thoracic vertebrae rather than in the cervical region, with lower back pain and limp being the most common presenting complaints (see Chapter 51). If conventional radiography is nondiagnostic, technetium bone scanning or MRI is helpful.

Generally Non–Life-Threatening Causes

Atlantoaxial Subluxation as a Result of Local Inflammation and/or Otolaryngologic Procedures

Atlantoaxial subluxation rarely may occur as a result of inflammatory processes in the head and neck region (e.g., rheumatoid arthritis, systemic lupus erythematosus, tonsillitis, pharyngitis) or after otolaryngologic procedures (e.g., tonsillectomy, adenoidectomy). This condition, also called Grisel's syndrome, is believed to occur as a result of ligamentous laxity after an infectious or inflammatory process. The subluxation is rotary, with or without displacement of the atlas, depending on the degree of involvement of the transverse ligament of the atlas. Most children with Grisel's syndrome have torticollis and neck pain, often localized to the SCM muscle. Fever and dysphagia are common as well. The child's head is tilted to one side and rotated to the side opposite of the facet dislocation. Routine radiographs of the neck may or may not reveal asymmetry between the facet joints and increased space between the dens of the axis and the anterior arch of the atlas. High-resolution CT scan with three-dimensional reconstruction is the best way to visualize the subluxation. Most commonly, the condition is mild and there is no anterior displacement of the axis. If mild, the condition usually responds to analgesic medication, physical therapy, and a soft collar. In the uncommon likelihood of severe disease (and certainly in the rare likelihood of spinal cord compression), neurosurgical consultation should be obtained because cervical traction and immobilization are needed. In addition to treating the subluxation, antibiotics to treat an underlying bacterial infection, if present, are needed.

Cervical Lymphadenitis

Cervical lymphadenitis, either acute or chronic, is a common cause of neck stiffness. The child with this condition typically has tender swelling over the lateral aspect of the neck, with or without fever. Most cases of cervical lymphadenitis are caused by *S. aureus* or group A streptococcus; however, other bacteria, mycobacteria, and noninfectious conditions may be involved (including *Rochalimaea,* the cause of cat-scratch disease, and Kawasaki disease). A purified protein derivative (PPD) skin test to screen for tuberculosis and empirical antibiotics to treat the most common bacterial pathogens are usually sufficient therapy.

Intervertebral Disc Calcification

Intervertebral disc calcification (IDC) in children is an uncommon, generally self-limited condition in which the nucleus pulposus of one or more intervertebral discs calcifies. Both the underlying cause of the condition and the cause of acute symptoms are unknown. It is generally thought that acute symptoms are secondary to some inciting event (e.g., mild trauma, viral infection) that results in an inflammatory response, possibly because of the release of calcium crystals. Children typically present with 24 to 48 hours of neck pain associated with neck stiffness or torticollis; fever is often present as well. A lumbar puncture may be necessary to exclude the possibility of meningitis or parameningeal infection. The ESR is usually elevated in IDC, and leukocytosis occurs in one-third of patients. Radiographs of the spine usually show the disc calcification, and CT scans help localize the calcification within the nucleus pulposus. The calcification resorbs spontaneously, and the disease is generally benign and self-limited, although disc protrusion and cord compression uncommonly may occur. Most importantly, one must distinguish acute infectious discitis (see previous discussion) from IDC. Distinguishing features include the lack of disc calcification and the single disc involvement of acute infectious discitis (IDC may involve one or more discs). Furthermore, infectious discitis is most common in the lumbar spine, whereas IDC in children more commonly involves the cervical spine. Finally, radiographic changes demonstrating erosion of vertebral bodies and collapse of disc spaces are seen with infectious discitis, but not with IDC.

Collagen Vascular Disease

Collagen vascular disease (see Chapter 101) in children may involve the cervical spine and lead to neck stiffness and/or pain. Children with juvenile rheumatoid arthritis may have either insidious or acute onset of symptoms, which commonly include neck stiffness. However, isolated cervical disease is unusual. Cervical involvement in ankylosing spondylitis is a late finding, as it is in other spondyloarthropathies. Girls with psoriatic arthritis, however, may have cervical involvement preceding sacroiliac and lumbar involvement.

Other Infectious/Inflammatory Conditions

Pharyngotonsillitis and upper respiratory tract infections may cause neck pain, although this is generally localized to tender cervical lymph nodes. Torticollis (i.e., Grisel's syndrome) may be seen as well. If neck pain is posterior in location and accompanied by fever, a lumbar puncture should be strongly considered to exclude the possibility of meningitis. Similarly, the diagnosis of viral myositis involving the neck can be made only after excluding the possibility of meningitis in a child with neck pain and fever. Otitis media and mastoiditis have also been reported as causes of torticollis. Upper lobe pneumonia may cause pain referred to the neck. Muscle spasm as a cause of torticollis is a diagnosis of exclusion after eliminating the possibility of more serious underlying causes.

Neck Stiffness Associated with Space-Occupying Lesions of the Central Nervous System

Potentially Life-Threatening Causes

Space-occupying lesions of the brain and spinal cord may lead to neck stiffness, malposition, pain, and/or torticollis. Even if the histology of these lesions is benign, they are potentially life-threatening because of the complications of intracranial pressure elevation and the potential for brain and spinal cord compression.

Brain Tumors

Children with tumors of the posterior fossa, the most common location for pediatric brain tumors, may present with head tilt or torticollis. Posterior fossa tumors may cause any of a number of other symptoms and signs (vomiting, headache, ataxia, disturbances in vision including diplopia, papilledema, cranial nerve deficits, corticospinal or corticobulbar signs). Head tilt may result from attempts to compensate for diplopia. However, neck stiffness is thought to result from irritation of the accessory nerve by the cerebellar tonsils trapped in the occipital foramen or by tonsillar herniation.

Spinal Cord Tumors

Tumors of the spinal cord are uncommon in children and account for a small fraction of all CNS tumors in childhood. The most common of the spinal cord tumors is astrocytoma. Typically, spinal cord tumors cause pain at the site of the tumor and neurologic defects (sensory and motor defects, impaired bowel and bladder function), but symptoms may be very slow to develop, often leading to delays in diagnosis. Spinal cord tumors may also cause torticollis. In one reported case, chiropractic manipulation of a child with persistent torticollis and a spinal cord tumor resulted in quadriplegia. Patients with these tumors may also hold their heads in a forward flexed position (“hanging head sign”). An MRI of the spine should be obtained on any child with symptoms and signs suggestive of spinal cord tumor and emergency neurosurgical consultation should be obtained.

Other Space-Occupying Lesions of the Head and Neck

Nasopharyngeal carcinoma is an uncommon tumor in children but may present with epistaxis, neck pain, and cervical adenopathy. Diagnosis requires a high index of suspicion. Other tumors of the head and neck, including orbital tumors, acoustic neuromas, osteoblastomas, and metastatic tumors to the spine, may cause torticollis. Arnold-Chiari malformations may also cause torticollis.

Other Space-Occupying Lesions of the Spinal Cord

Other uncommon space-occupying lesions of the cervical spine such as neurenteric cysts, arteriovenous malformations, and syringomyelia may also cause neck pain and stiffness, generally accompanied by neurologic findings. Early diagnosis by MRI is essential.

Generally Non–Life-Threatening Causes

Benign Tumors of the Head and Neck

Osteoid osteoma is a benign bone tumor that typically affects older children and adolescents. Pain is the typical presenting symptom, often worse at night. If the osteoma is in the cervical spine, neck pain results. Plain radiography is usually diagnostic (showing a well demarcated radiolucent lesion surrounded by sclerotic bone), and treatment is surgical. Eosinophilic granulomas and bone cysts are other benign (and rare) lesions of the spine that may cause neck pain.

Congenital Causes of Neck Stiffness

Neck stiffness and/or torticollis from congenital abnormalities are usually not life-threatening. These congenital causes are usually muscular or skeletal in origin.

Congenital Muscular Torticollis

Congenital muscular torticollis is the most common cause of torticollis in infancy. The etiology of this condition is unclear but is thought to be related to birth trauma causing an injury to the SCM muscle with hematoma formation, followed by fibrous contracture of the muscle. Other theories include those suggesting intrauterine malposition, infection, neurogenic causes, and intrauterine compartment syndrome of the SCM muscle. On examination, a palpable mass can often be detected in the inferior aspect of the SCM. The mass is generally not present at birth but appears in the neonatal period. The head is held in the characteristic position, with the patient's chin pointing away from the affected, contracted SCM muscle. Craniofacial asymmetry is commonly found to some degree in these patients, typically with contralateral flattening of the occiput and ipsilateral depression of the malar prominence. Radiographs of the cervical spine are necessary to exclude other causes of torticollis. Treatment is conservative with passive stretching of the involved muscle. If the deformity persists after 6 to 12 months, surgical release of the SCM is required (fewer than 5% of cases).

Skeletal Malformations

Klippel-Feil syndrome is characterized by congenital fusion of a variable number of cervical vertebrae, which may result in atlantoaxial instability. The cause of this syndrome is unknown. It is often associated with many other bony abnormalities, and significant scoliosis develops in more than 50% of affected children. Limitation in range of motion of the neck is the most common physical sign. In addition to limited neck motion, the classic triad also includes a low hairline and a short neck; the triad, however, is seen in fewer than half of patients.

Sprengel's deformity is characterized by congenital failure of the scapula to descend to its correct position. The scapula rests in a high position in relation to the neck and thorax. In its most severe form, the scapula may be connected by bone to the cervical spine and limit neck movement.

Hemiatlas is a malformation of the first cervical vertebra, which may cause severe, progressive torticollis. In time, the deformity becomes fixed; therefore, posterior fusion is recommended. Basilar impression is a condition resulting from anomalies at the base of the skull and vertebrae, which lead to a short neck, headache, neck pain, and cranial nerve

palsies due to compression of the cranial nerves. Many congenital conditions, including Klippel-Feil syndrome, achondroplasia, and neurofibromatosis, may cause basilar impression. Commonly associated with basilar impression is occipitocervical synostosis, a condition in which fibrous or bony connections between the base of the skull and the atlas cause neck pain, torticollis, high scapula, and several neurologic symptoms.

Atlantoaxial Instability

Several congenital conditions may be associated with atlantoaxial instability and predispose the patient to cervical subluxation. In addition to Down and Klippel-Feil syndromes, these include other skeletal dysplasias and os odontoideum (aplasia or hypoplasia of the odontoid). Children with these conditions should be screened for atlantoaxial instability. Morquio syndrome is a mucopolysaccharidosis resulting in flattening of the vertebrae and multiple skeletal dysplasias. The odontoid process of the axis is underdeveloped and may lead to atlantoaxial subluxation.

Other Congenital Causes

Benign paroxysmal torticollis of infancy presents as recurrent episodes of torticollis in association with pallor, agitation, and vomiting. Typical onset is between 2 and 8 months of age, and the condition tends to remit by 2 to 3 years.

Miscellaneous Causes of Neck Stiffness

Head tilt, neck stiffness, and/or torticollis has been reported in several other conditions, some of which are life-threatening and others generally benign.

Ophthalmologic, Neurologic, and/or Vestibular Causes

Head tilt or neck malposition may result from abnormalities of vision (strabismus, cranial nerve palsies, extraocular muscle palsies, refractive errors) or the vestibular apparatus. The child attempts to correct for the disturbance through changes in neck position. Careful ophthalmologic and neurologic examinations of the child with head tilt are necessary to exclude these possibilities. Torticollis has also been reported in patients with migraine headaches.

Myasthenia Gravis

Patients with myasthenia gravis may develop torticollis, but ptosis, impairment of extraocular muscular movement, and other cranial nerve palsies are generally earlier signs.

Sandifer Syndrome

Sandifer syndrome is the constellation of torticollis, gastroesophageal reflux, and hiatal hernia. Children with this syndrome may have recurrent vomiting and failure to thrive.

Spontaneous Pneumomediastinum

Spontaneous pneumomediastinum may present with neck pain and torticollis. A history of severe coughing and/or retching is usually elicited. Crepitus is generally palpated along the neck. Initial therapy is directed at the underlying disease process.

Spasmus Nutans

Spasmus nutans is an acquired condition of childhood, characterized by nystagmus, head nodding, and torticollis. Children with these findings typically become symptomatic in the first 2 years of life. The condition is generally benign and self-limited. However, some children with the symptoms of spasmus nutans have underlying brain tumors. Therefore, imaging of the brain is necessary to exclude this possibility.

Dystonic Reaction

Certain drugs with dopamine-2 receptor antagonism can cause acute dystonic reactions with torticollis. These include many neuroleptic and antiemetic agents, such as haloperidol, prochlorperazine, and metoclopramide. Treatment with diphenhydramine (1 to 2 mg/kg per dose) may be diagnostic and therapeutic.

Psychogenic

Hysterical patients may present with torticollis. This diagnosis can be made only after excluding other more serious causes.

EVALUATION AND DECISION

The approach to the child with a stiff or malpositioned neck should focus initially on whether there is spinal cord involvement, as detailed in Figure 46.1. For any child with neck stiffness or pain, a history of weakness or paresthesias of the extremities or of functional abnormalities of the bowel or bladder should be sought. In addition, a complete ophthalmologic and neurologic examination should be performed, with the latter focusing on spinal cord function. Included in this examination should be an assessment of muscle strength, sensation, deep tendon reflexes, the Babinski reflex, and anal tone. Extra vigilance must be used if the patient is too young or incapacitated to give an accurate history.

FIGURE 46.1. Approach to the child with stiff or malpositioned neck. *C-spine,* cervical spine radiograph; *MRI,* magnetic resonance imaging; *ENT,* ear, nose, throat; *AVM,* arteriovenous malformation; *CT,* computed tomography; *CBC,* complete blood count; *ESR,* erythrocyte sedimentation rate; *TB,* tuberculosis; *SCM,* sternocleidomastoid.

If spinal cord involvement is detected, neurosurgical consultation and imaging of the cervical spine (radiographs and MRI of the cervical spine) are necessary. Conditions causing cervical spinal cord compromise may rapidly lead to permanent disability or death if not immediately addressed. If secondary to trauma, one should suspect cervical spine fracture or subluxation, spinal epidural hematoma, or SCIWORA syndrome. In the setting of fever, a spinal epidural abscess should be considered. Atlantoaxial subluxation secondary to otolaryngologic diseases or procedures should be considered in children with spinal cord involvement and consistent histories. Finally, spinal cord tumors and other space-occupying lesions should be considered if the development of symptoms is gradual and not associated with trauma or fever.

The next issue that should be considered is whether the neck stiffness is the result of an acute traumatic event. If acute trauma is the cause of the neck stiffness, the cervical spine should be properly immobilized (see Chapter 106) and multiple radiographic views of the cervical spine obtained. Fractures and subluxations/dislocations will generally be identified on plain radiography of the cervical spine. Other modalities (e.g., flexion-extension views, CT, MRI) may be useful to detect ligamentous injury, rotary subluxation, or spinal epidural hematomas. Muscle strain and/or contusion is a diagnosis of exclusion in the setting of trauma and neck stiffness after the possibility of more serious conditions are excluded. If other symptoms in addition to the neck stiffness are present, appropriate studies should be obtained. For example, the patient with neck stiffness and headache may have a subarachnoid hemorrhage for which a head CT scan would be indicated. The patient with clavicle fracture may have spasm of the SCM muscle and torticollis. However, tenderness is localized over the injured clavicle, and radiographs will confirm the diagnosis.

Fever in the setting of neck stiffness suggests the presence of an infectious, inflammatory, or neoplastic process. The presence of meningitis must be excluded either clinically or with a lumbar puncture (see Chapter 84). On examination, the presence of meningismus must be determined. A lumbar puncture should be seriously considered in the presence of fever and neck stiffness of any type because meningitis may present with fever and atypical neck signs. Helpful supporting signs include Brudzinski's sign (flexing the neck, eliciting flexion of the knee and hip) and Kernig's sign (with the hip flexed, pain with extension of the leg). Other conditions (e.g., subarachnoid hemorrhage) may also present with fever and meningismus, and a lumbar puncture is helpful in evaluating these conditions as well.

After the presence of meningitis has been excluded in the febrile patient with neck stiffness, the examination should focus on the presence or absence of a cervical mass. If a cervical mass is identified, a history of contact with cats and constitutional symptoms suggestive of malignancy should be elicited. If the cervical mass is tender, a trial of antibiotics directed at the most common bacterial pathogens and the placement of a PPD skin test to screen for tuberculosis may be all that is necessary. If the cervical mass does not respond to an appropriate trial of antibiotics, cat-scratch disease, atypical mycobacterial infection, or malignancy may be the cause.

If no palpable cervical mass is present, a more in-depth evaluation may be necessary, based on the history and physical examination of the child. Radiographs of the cervical spine will diagnose retropharyngeal abscess in the febrile child with stridor, drooling, and neck stiffness and may detect atlantoaxial subluxation in the child with otolaryngologic disease or who has recently had an otolaryngologic procedure. Radiographs of the cervical spine may also be useful in detecting other diseases involving the cervical spine, including vertebral osteomyelitis, infectious discitis, intervertebral disk calcification, and neck stiffness from collagen vascular disease. White blood count or ESR will be elevated in most children with these conditions, as well as those with spinal epidural abscesses and infections of the head and neck (e.g., tonsillitis, mastoiditis). If plain radiography is not diagnostic, technetium scans will identify vertebral osteomyelitis or discitis. CT or MRI of the spine will identify spinal epidural abscesses and can be helpful if routine radiographs are equivocal in several of the previously described conditions. Finally, an upper lobe pneumonia identified on chest film may be the cause of neck stiffness in the febrile child.

In the afebrile child with neck stiffness, the presence of a cervical mass within the SCM suggests congenital muscular torticollis (in an infant) or a SCM hematoma or tear. Radiographs of the cervical spine should be obtained to exclude more serious conditions. If the cervical mass is not within the SCM, a malignancy or atypical infection may be the cause and a complete blood count and biopsy of the mass should be considered.

For the afebrile child with neck stiffness and/or malposition of the neck and no cervical mass, a careful ophthalmologic and neurologic examination should be performed to exclude the possibility of a brain tumor, other space-occupying lesions of the brain, visual disturbances, and vestibular disturbance causing the abnormal neck posture. Often, the patient does not have true neck pain but is attempting to correct for these disturbances through changes in head position. A head CT scan is necessary to exclude the possibility of a space-occupying lesion of the brain, including brain tumor.

The child with myasthenia gravis generally has ptosis and weakness of extraocular muscles and may develop torticollis. A trial of intravenous edrophonium chloride (Tensilon) is diagnostic because symptoms will improve immediately; however, edrophonium chloride should not be given to young infants, who are especially prone to this agent's ability to cause cardiac arrhythmias. Children with torticollis after taking neuroleptic or antiemetic medications will usually respond to intravenous diphenhydramine.

Finally, the child with neck stiffness without fever, cervical mass, or abnormal ophthalmologic or neurologic examination may have any of a number of conditions. Many of the disorders mentioned as typically being associated with fever are commonly seen without fever as well (atlantoaxial subluxation in the child with otolaryngologic diseases or after otolaryngologic procedures, intervertebral disc calcification, collagen vascular disease). Furthermore, infants with congenital muscular torticollis may not have SCM masses that are detectable on physical examination. Some children with neck stiffness may have dysmorphic features, suggesting specific skeletal malformation syndromes or cervical subluxation in a child with Down syndrome. Chronic symptoms may suggest a congenital syndrome, collagen vascular disease, or a neoplastic process, but children with these conditions may also present with acute onset of symptoms. Osteoid osteoma and other benign tumors of the head and neck may be detected by plain radiography of the cervical spine. A chest radiograph is indicated for the child with neck stiffness in association with a history of severe coughing and/or retching because an upper lobe pneumonia or spontaneous pneumomediastinum may be the cause. Finally, if no cause can be identified after a complete history, detailed examination, and careful radiographic and laboratory evaluation, muscle spasm or hysteria may be the cause of torticollis.

In conclusion, neck stiffness and/or malposition may indicate a wide array of medical and traumatic conditions, both life-threatening and relatively benign. A careful examination must be performed to exclude the presence of spinal cord involvement. Trauma and infection are the most important causes of neck stiffness in children, and a history of trauma or fever will help guide the evaluation and decision making. Cervical spine fracture, subluxation/dislocation, and meningitis remain the most important diagnoses to exclude.

CHAPTER 47

Odor—Unusual

ALISON ST. GERMAINE BRENT, MD

Department of Pediatrics, University of South Florida College of Medicine, and Division of Emergency Medicine, All Children's Hospital, St. Petersburg, Florida

The human nose is able to discriminate approximately 4000 odors! Occasionally, parents bring an infant or child to the emergency department (ED) complaining of an unusual smell. Adolescents are more likely to note a new or unusual odor themselves and present to the ED with specific complaints.

Unfortunately, olfaction is a sense that most medical professionals are not trained to use, quantify, or describe. Before the development of sophisticated laboratory tests, clinicians relied heavily on the sense of smell. Even today, early diagnostic clues that can lead the clinician to a more selective workup, rapid diagnosis, and prompt therapeutic intervention may be obtained. In some situations, a prompt diagnosis can be lifesaving or can improve the quality of life.

PATHOPHYSIOLOGY

The olfactory area extends from the roof of the nasal cavity approximately 10 mm down the septum and superior turbinates bilaterally. The exact mechanism of stimulation of the olfactory receptors is unknown. Smell is more acute in the darkness and is believed to be linked to blood cortisol levels.

The unique odor emitted by a person is produced by a combination of body secretions and excretions, particularly those from the oropharynx and nasopharynx and the respiratory tract, plus aromas from the skin and cutaneous lesions, urine, feces, and flatus. The most significant components of odor in healthy humans are the apocrine glands. These secretions are initially odorless, but bacterial breakdown that results in fatty acid production can cause an offensive odor. Body odor is altered by hygiene, metabolism, toxins, infections, and systemic diseases.

When a child is unable to detect odor, anosmia should be considered. When a child complains of strange odors, especially if no one else is able to identify them, temporal lobe epilepsy should be contemplated.

DIFFERENTIAL DIAGNOSIS

A number of conditions, including metabolic disorders, dermatologic conditions, intoxications, infections, foreign bodies, various abnormalities of the body orifices, and a variety of systemic diseases, may result in an abnormal body odor (Table 47.1).

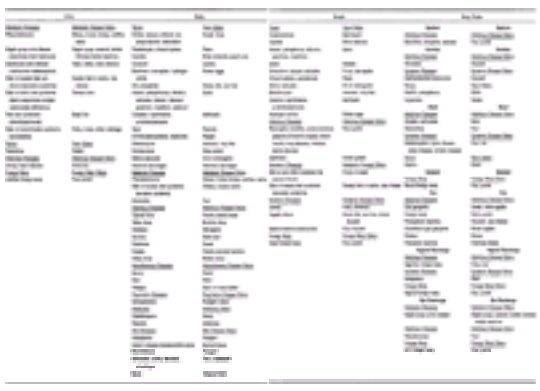

Table 47.1. Clinical Source and Cause of Unusual Odors

Metabolic Disorders Table 47.2)

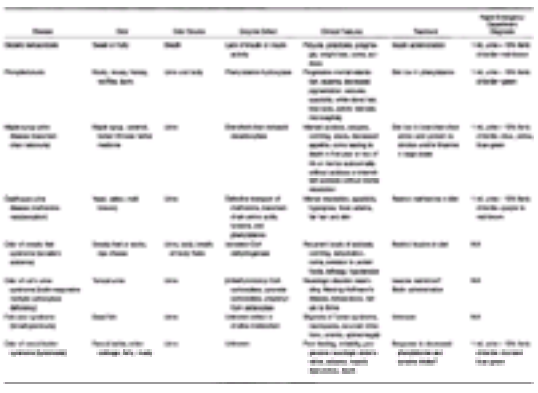

Table 47.2. Metabolic Disease Associated with Unusual Odors

The most common metabolic disorder that has a characteristic odor is diabetic ketoacidosis (DKA). The characteristic breath odor is caused by acetone and is described as sweet or fruity. It is important to note that any condition that results in a marked metabolic acidosis and ketosis will result in the characteristic sweet or fruity breath.

Inborn errors of metabolism that result in altered body, breath, or skin odors are unusual individually, but as a composite, they reflect a significant percentage of life-threatening illnesses of infancy (see Chapter 98). Although definitive diagnosis depends on specific identification of serum and urine amino and organic acid levels, many such conditions are associated with a positive ferric chloride test, which when performed in the ED can yield presumptive diagnosis.

Phenylketonuria is a disorder of amino acid metabolism associated with a deficiency of phenylalanine dehydroxylase and dihydropteridine reductase, which forces use of minor metabolic pathways of phenylalanine, resulting in the buildup of phenylacetic acid. It is the buildup of phenylacetic acid in the sweat and urine that causes a musty, mousy, horsey, wolflike, or barny odor. Clinical features of untreated phenylketonuria include white-blond hair, blue eyes, fair complexion, eczema, microcephaly, hypertonicity, increased risk for pyloric stenosis, seizures, and progressive mental deterioration. Although neonatal screening detects most of these cases, the observation of a characteristic odor in an infant should prompt appropriate laboratory studies, which may include a ferric chloride test in the ED. Prompt diagnosis and dietary restriction of phenylalanine promote a normal outcome.

Maple syrup urine disease is caused by a metabolic defect in the decarboxylation of the ketoacids of the branch chain amino acids (leucine, isoleucine, and valine), which results in their accumulation in the blood. It is apparently a metabolite of isoleucine in the urine that results in the characteristic odor of maple syrup, caramelized sugar, or boiled Chinese herbal medicine. Children with this disorder can have variable clinical manifestations, ranging from decreased appetite, vomiting, and ataxia to progressive acidosis, seizures, coma, and death. Prompt diagnosis and limitation of dietary branched chain amino acids promotes normal development.

Oasthouse urine disease, or methionine malabsorption syndrome, is caused by defective transport of methionine and, to a lesser extent, leucine, isoleucine, valine, tyrosine, and phenylalanine by the intestines and kidneys. The unabsorbed methionine in the gut is broken down by colonic bacteria to a-hydroxybutyric acid, which causes the characteristic odor described as yeast, celery, malt, or a brewery. Clinical presentation includes fair hair and skin, hyperpnea, extensor spasms, fever, edema, and mental retardation. Successful treatment consists of a methionine-restricted diet.

The odor of sweaty feet syndrome, or isovaleric acidemia, is caused by a defect in the catabolism of leucine. The characteristic odor described as sweaty feet or socks or ripe cheese comes from the buildup of isovaleric acid. Clinically, children experience vomiting, dehydration, acidosis, and slowly progressive mental deterioration. Treatment consists of restriction of leucine in the diet.

In the odor of cat's urine syndrome, the enzymatic defects are in the biotin-dependent enzymes b-methylcrotonyl-CoA carboxylase, pyruvate carboxylase, and propionyl-CoA carboxylase. The cause of the distinctive aroma of cat urine is unknown. Clinically, children have failure to thrive, ketoacidosis, and neurologic symptoms similar to Werdnig-Hoffmann's disease. Treatment consists of a low-leucine diet and the addition of biotin.

Fish odor syndrome, trimethylaminuria, results from an unidentified defect that possibly relates to choline metabolism. The dead fish odor in the urine results from buildup of trimethylamine. Clinical presentation includes stigmata of Turner syndrome, normal complement of chromosomes, neutropenia, recurrent pulmonary infections, and abnormal platelet function.

The odor of rancid butter syndrome, tyrosinosis, results from an unidentified defect in metabolism. It is hypothesized that a build-up of a-ketogammamethiolbutyric acid in the urine results in the characteristic smell of rancid butter. Clinical presentation includes poor feeding, irritability, seizures, coma, progressive neurologic deterioration, and early death secondary to infection and liver failure. In some cases, restriction of dietary phenylalanine and tyrosine has been helpful.

Dermatological Conditions

Many dermatologic diseases (Table 47.1) are associated with specific odors. Any cause of hyperhidrosis results in an

offensive body odor. Hidradenitis has a characteristic pungent odor, whereas Darier's disease is noted to have a pervasive aroma of burned tissue. An abscess or cellulitis is identified by the characteristic odors of the responsible microorganisms.

In burn patients, there is the typical odor of charred flesh, which when infected with *Pseudomonas,* takes on a characteristic sweet, grapelike odor.

Toxicologic Considerations

Recognition of a characteristic odor is vital for rapid, accurate diagnosis and treatment of some potentially lethal ingestions before laboratory identification (Table 47.1) (see also Chapter 88).

Penicillins give off an ammoniacal scent, whereas cephalosporins are noted to have a musty odor. Topical benzoyl peroxide, applied in large quantities, emits a pungent, pervasive aroma.

A strong garlic odor is typical of arsenic, arsine gas, phosphorus, tellurium, parathion, malathion, selenium, dimethyl sulfoxide, and thallium. The odor of bitter almonds or peach pits is indicative of cyanide poisoning, in which the degree of excretion of the odor parallels toxicity. Vacor (pyridylmethyl nitrophenylurea), an extremely potent rat poison that works as a potent pancreatic b-cell toxin, caused numerous cases of severe diabetes mellitus after overdose before it was withdrawn from the U.S. market in 1979. It often presented with an odor of peanuts.

Diagnostic odors are found in several sedative-hypnotic medications that primarily have central nervous system (CNS) manifestations. Ethchlorvynol (Placidyl) is a volatile agent that has an aromatic plastic or vinyl-like breath odor. Ingestion results in coma, hypothermia, respiratory depression, hypotension, and bradycardia. An overdose of chloral hydrate can result in CNS depression ranging from slurred speech, ataxia, and incoordination to deep coma, gastritis, and cardiac arrhythmias. It may be seen in children or as an intentional overdose in adults, and it imparts a fruity, pearlike scent. Disulfiram (Antabuse) gives the breath a rotten egg odor because of the sulfide metabolites. The pleasant smell of oil of wintergreen indicates methyl salicylate poisoning.

Infectious Diseases

Many microorganisms produce characteristic odors that suggest the diagnosis of their respective infectious diseases by olfaction alone (Table 47.1) (see also Chapter 84). Omphalitis in the newborn can be life-threatening. It presents with a foul or putrid odor associated with a draining, erythematous umbilical area. Less common infections that have been historically associated with characteristic odors include typhoid's aroma of freshly baked bread, yellow fever's butcher shop smell, smallpox's menagerie odor, scrofula's odor of stale beer, diphtheria's sweet smell, and rubella's scent of freshly plucked feathers.

Foreign Bodies

Foreign bodies are capable of producing a foul odor that results from secondary bacterial colonization or infection. Foreign body odors can be localized to a particular orifice, or they may pervade a patient's clothing, body, and surrounding environment. Foul-smelling, fetid, or feculent odors indicate anaerobic infections, whereas a sickly sweet odor is associated with *Escherichia coli,* and *Clostridia* is associated with a mousy odor.

Orifice Odors

Specific orifice odors can be diagnostic of infectious disease processes.

Oropharynx

A healthy mouth does not give off an offensive odor. Halitosis, or bad breath, is the result of a release of volatile sulfur compounds formed when the oral flora metabolizes amino acids from compounds in the saliva that adhere to the tongue, teeth, and gums. Halitosis is increased in states of diminished solid and liquid intake. Tonsillitis (see Chapter 71 and Chapter 84) has an offensive odor, and group A b-hemolytic streptococcus gives off a characteristic “strep breath” smell. Dental abscesses (see Chapter 124) and acute ulcerative gingivitis (Vincent's stomatitis or trench mouth) are associated with a penetrating, offensive odor. The oropharynx is also the portal of exit for deeper infections. Lung abscesses, empyema, bronchitis, and bronchiectasis result in foul breath and sputum. Nasal foreign bodies in toddlers are usually associated with an odor identified by parents as bad breath.

Nose

Nasal drainage can be clear and odorless or mucopurulent and odiferous. Nasal drainage and bleeding can reflect local infections, foreign bodies, irritations of the nasal passage, and sinus drainage.

Ear

Sterile inner ear fluid is odorless but gives off a rank smell when infected. Acute otitis externa usually is associated with a mucoid drainage, whereas chronic otitis externa produces a purulent, discolored drainage with a foul odor, usually secondary to*Pseudomonas aeruginosa* or *Staphylococcus aureus.*

Genitalia

Vaginal secretions are combinations of vulvar secretions from sebaceous, sweat, Bartholin's and Skene's glands,

transudate through the vaginal wall, exfoliated cells, cervical mucus, endometrial and oviductal fluids, plus vaginal microorganisms and menstrual blood. These secretions are hormonally mediated and vary with the menstrual cycle. Odors are exacerbated by the presence of retained foreign bodies, including tampons and diaphragms.

Bacterial vaginosis (nonspecific vaginitis, *Gardnerella* vaginitis, *Corynebacterium* vaginitis, *Haemophilus* vaginitis, nonspecific vaginosis, and anaerobic vaginosis) is caused by an increase in anaerobic bacteria and a decrease in lactobacilli (see Chapter 94). The anaerobic bacteria act synergistically with *Gardnerella vaginosa* to produce enzymes and aminopeptidases that degrade protein and decarboxylases that convert amino acids and other compounds to amines. The amines produce the characteristic “fishy” odor, which is best detected by alkalinization using 10% potassium hydroxide placed directly on a vaginal swab and smelling immediately. This odor also can be indicative of sexual abuse in children. Vaginal infection with *Trichomonas* often is associated with a fishy odor, whereas *Candida* vaginitis is notably free of odor (see Chapter 94).

A male counterpart, balanoposthitis, is associated with a urethral discharge that produces a fishy odor when alkalinized because of the same process and organisms as occur in bacterial vaginosis.

Urethral Meatus

A urinary tract infection caused by urea-splitting bacteria will emit an ammoniacal odor.

Rectum

Stool odors vary with diet, medications, and microbiologic flora. Various malabsorptive syndromes, such as sprue, cystic fibrosis (see Chapter 96), and Whipple's disease, are associated with foul-smelling stool. The presence of blood in the stool has a distinctive, pungent odor, as does pus. *Shigella* and *Salmonella* (see Chapter 84) have distinctive rank odors.

Systemic Diseases

Several nutritional syndromes (Table 47.1), such as pellagra's stench of sour or musty butter and the putrid or fetid odors of scurvy and gout, have unique odors. Schizophrenia has a characteristic body odor described as heavy, unpleasant, and pungent. The odor-producing substance is *trans*-3-methyl-2-hexanoic acid, which is produced in the sweat. Uremic breath is produced by secondary and tertiary amines, dimethylamines, and trimethylamines that produce a fishy odor. Malignancy—especially when associated with an expanding external mass, bleeding, and necrosis—gives off a trenchant odor because of tissue and cellular breakdown plus gas formation. Hepatic failure gives an odor of “fetor hepaticus” (described as musty, rotten eggs, or garlic) and is noted in the breath or urine. In Crohn's disease (see Chapter 93), the development of gastric fistulae often are heralded by a feculent odor.

A physiologic odor that often heralds the onset of puberty is underarm body odor. This is usually the earliest sign of puberty and precedes all other physical changes. Age of onset is around 6 to 8 years and reflects the onset of adrenarche. Dehydroepiandrosterone sulfate (DHEAS) is the androgen believed to be responsible for the pungent aroma of underarm body odor and can be measured for confirmation. Although the adrenal and hypothalamic–pituitary–gonadal axis are separate systems involved with the onset of puberty, they often become active nearly simultaneously.

EVALUATION AND DECISION

The evaluation of a child who presents to the ED should incorporate all of the senses, including smell (Fig. 47.1). Both presence and absence of odors can be diagnostic. Each person has a unique odor, ranging from pleasant to offensive. Using the sense of smell should be done in stages; an initial evaluation of the prevailing odor of the examination room, followed by attention to overall body odor and identification of odors from individual orifices and body fluids. Body fluids such as ocular, ear, nasal, sinus tract, or umbilical drainage; vomitus; sputum; genital discharge; stool; ulcers; and superinfection of the dermis have unique identifiable odors.

FIGURE 47.1. Evaluation and decision for unusual odors. *DKA,* diabetic ketoacidosis.

Good or poor hygiene is readily detected in a closed examination room. When an unusual odor is detected, the history should include information about medications (topical, oral, or rectal), onset and duration of odor, methods used to alter odor, unusual drainage from body orifices, suspicion of foreign body, fever, and other pertinent symptoms.

In the evaluation of the significance of odors, attention must be paid to the child's age and developmental level. At birth,

infant odors are a conglomeration of their own and their mother's physical environment. After birth, a well-cared-for, healthy infant should have a very pleasing aroma and odorless breath. Offensive body odor in a newborn suggests an inborn error of metabolism, a localized infection such as omphalitis, or neglect. During infancy, inborn errors of metabolism are relatively common (Table 47.3) and potentially life-threatening causes of unusual odor (Table 47.4). Infection localized to the umbilicus, omphalitis, produces a foul odor and is easily diagnosed on the basis of erythema, induration, and discharge. Other sources found in older children (foreign bodies, ingestions, and pharyngitis) are unusual in the infant.

Infants	Localized infections
Inborn errors of metabolism	Stomatitis
Omphalitis	*Adolescents*
Neglect	Localized infections
Toddlers	Pharyngitis
Foreign bodies	Tonsillitis
Otic	Vaginitis
Nasal	Toxins
Vaginal	Alcoholic beverages
Urethral	Puberty
Rectal	

Table 47.3. Common Causes of Unusual Odors

Metabolic Disease	Isopropyl alcohol
Inborn errors of metabolism	Methyl salicyate
DKA	Vacor
Infectious Diseases	*Systemic Disease*
Omphalitis	Uremia
Diphtheria	Liver failure
Lung abscess	Gastrointestinal obstruction
Toxins	Peritonitis
Arsenic	
Cyanide	

Table 47.4. Life-Threatening Causes of Unusual Odor

In an older child, the physician should determine a child's history and whether clinical signs of chronic systemic diseases such as diabetes, liver failure, or uremia are present. The child with ketoacidosis usually appears dehydrated and manifests deep, rapid (Kussmaul) respirations; the breath may smell of ketones. Uremia develops in patients with renal failure who may have short stature, edema, hypertension, and a characteristic fishy odor of their breath. With liver failure, the patient may have jaundice, ascites, lethargy, or mental status changes, as well as breath and urine that takes on the odor of rotten eggs or garlic.

Body odors change with puberty through hormonally induced metabolic changes. The most significant change is the development of axillary odor related to apocrine secretions that are retained or spread by axillary hair. Normal quantities of sweat have a barely perceptible odor, whereas increasing quantities of sweat production cause increasingly noticeable and offensive odor.

Early on, the physician should determine the potential risk of ingestion of a toxic substance. In the adolescent, the risk of a significant ingestion increases and can be life-threatening (Table 47.4). Next, the physician should ascertain whether the odor emanates from a particular body orifice such as the ear, nose, pharynx, vagina, urethra, or rectum. Nasal foreign bodies are particularly common in children between the ages of 1 and 5 years. They may remain hidden for weeks, long beyond the child's memory of placing the object, and eventually, they produce a secondary infection that leads to a foul discharge. In some cases of foreign body, the odor may be so strong that it appears to be generalized. Thus, a careful examination of the various orifices, with particular attention to the nares, always is advisable. The presence or absence of fever is another crucial variable in the evaluation of odor. Fever suggests an infectious cause, either systemic or localized. Pharyngitis and tonsillitis characteristically cause foul odor to the breath, much like a lung abscess. Occasionally, parents state that their child smells as if he or she had a “strep throat.” Although foreign bodies occasionally produce obstruction and a secondary infection of severity sufficient enough to evoke a febrile response, in most cases, the inflammation is localized and the child is afebrile.

In the absence of a known history or obvious findings of chronic systemic disease, a visible foreign body, known ingestion, or fever, the clinician should perform a careful physical examination and a urinalysis. DKA always causes glucosuria and ketonuria, but hepatic or renal failure may be less obvious. In addition, inborn errors of metabolism may first manifest well beyond the newborn period. Foreign bodies may defy routine attempts at visualization and, based on a high index of suspicion, require endoscopy or imaging procedures. Therefore, persistence or an unusual odor or concern for chronic toxicity merits further laboratory evaluation. In cases in which an explanation of the odor is not uncovered, a follow-up evaluation in 2 to 3 days is prudent.

In patients who have died in the ED, a faint fecal odor usually is noted, possibly related to the release of intestinal

contents to the atmosphere. Unique identifiable odors detected at the time of death or autopsy can direct laboratory evaluation toward possible causes of death.

CHAPTER 48

Oligomenorrhea

JAN E. PARADISE, MD

Department of Pediatrics, Boston University School of Medicine, and Child Protection Program, Boston Medical Center, Boston, Massachusetts

In this chapter, possible causes of oligomenorrhea and secondary amenorrhea are reviewed. *Oligomenorrhea* means infrequent menstruation and can be defined for the pediatric emergency physician as an interval of more than 6 weeks between two menstrual periods. If menstrual cycles do not resume within 3 to 6 months, the term *secondary amenorrhea* is applied. Some patients with anovulatory menstrual cycles have oligomenorrhea punctuated by episodes of excessive bleeding. An approach to the evaluation of abnormal vaginal bleeding is presented in Chapter 76.

Oligomenorrhea should be distinguished from hypomenorrhea, a nonpathologic pattern of light but regular menstrual periods. This chapter does not include a separate consideration of primary amenorrhea—that is, failure to menstruate by a specified age, often 16 years. However, some disorders discussed here can produce primary rather than secondary amenorrhea as part of an overall delay in pubertal development.

The differential diagnosis of oligomenorrhea is given in Table 48.1.

I. Hypothalamic-Pituitary Axis Disorders	3. Pelvic irradiation
A. Disorders of weight and/or energy expenditure	4. Autoimmune diseases
1. Anorexia nervosa	B. Hormone-secreting tumors
2. Strenuous exercise	III. Uterine Disorders
3. Marked thinness or weight loss	A. Endometrial destruction
4. Chronic illness	1. Surgical
B. Delayed maturation	2. Tuberculous
C. Psychological stress	IV. Hyperprolactinemia
D. Central nervous system tumors	A. Lactation
E. Pseudocyesis	B. Drugs (see Table 48.2)
II. Ovarian Disorders	C. Pituitary adenoma
A. Ovarian failure	D. Hypothyroidism
1. Gonadal dysgenesis	V. Hyperandrogenism
2. Cancer chemotherapeutic agents	A. Polycystic ovary syndrome
	B. Adrenal disease
	VI. Miscellaneous conditions
	A. Pregnancy
	B. Hormonal contraception
	C. Hypothyroidism or hyperthyroidism

Table 48.1. Differential Diagnosis of Oligomenorrhea Organized by Pathophysiology of Disorder or Condition

EVALUATION AND DECISION

Diagnosis of Pregnancy

“Is she pregnant?” is always the first question to answer in evaluating an adolescent with one or several missed menstrual periods (Fig. 48.1). If the patient is not pregnant, her evaluation can proceed at a more deliberate pace. If she is pregnant, however, prompt diagnosis and referral are important for the teenager who intends to seek a therapeutic abortion, as well as for the one who plans to continue her pregnancy. Early and regular prenatal care are associated with reduced morbidity and mortality among pregnant teenagers and their offspring. Early diagnosis also affords the pregnant adolescent more time to decide on and arrange for a therapeutic abortion, if that is her choice. Because an adolescent under the age of 18 years must obtain parental or judicial consent for a therapeutic abortion, a delayed diagnosis of pregnancy may push the procedure into the second trimester, resulting in higher morbidity and higher cost.

FIGURE 48.1. Differential diagnosis of oligomenorrhea. *T,* testosterone; *LH,* luteinizing hormone; *FSH,* follicle-stimulating hormone; *PCOS,* polycystic ovary syndrome.

Early pregnancy is not always easy to recognize. Symptoms of fatigue, nausea, vomiting (not necessarily in the morning), urinary frequency, and breast growth or tenderness are common, but by no means are they universal or specific. On pelvic examination, the first indications of pregnancy are softening of the lower uterine segment (Hegar's sign) and of the cervix (Goodell's sign) at 4 to 6 weeks after the last menstrual period. By 6 weeks' gestation, the uterus changes from pear-shaped to globular, and by about 8 weeks, the vagina and cervix acquire a bluish hue (Chadwick's sign). These changes occur in ectopic as well as in intrauterine pregnancies. A serviceable rule is that the pregnant uterus grows to about the size of a tennis ball at 8 weeks after the last menstrual period, becomes baseball-sized at 10 weeks, and softball-sized at 12 weeks. When the uterus is retroflexed, its size is more difficult to assess and rectovaginal palpation should be done. After 12 weeks, the uterine fundus is palpable above the symphysis pubis on abdominal examination. Fetal movement can be discerned after about 16 weeks. The fundus reaches the level of the umbilicus at 20 weeks' gestation.

Some patients may report the result of a home pregnancy test. Although manufacturers claim an accuracy rate of 99% for home pregnancy tests, accuracy of patient-administered tests has been as low as 77%, with false-positive test results being somewhat more common than false-negative ones. The emergency physician is well-advised to order a standard laboratory test to confirm the results of a home pregnancy test.

The emergency physician should know which urine or serum pregnancy test is used by his or her laboratory and that test's level of sensitivity. Radioimmunoassays and immunoenzymometric assays detect the core fragment of human chorionic gonadotropin (hCG), regardless of whether the fragment is free or a component of the intact hCG molecule. These tests, commonly known as b-hCG tests, are specific and sensitive, identifying total levels of hCG as low as 5 mIU/mL in serum and 25 mIU/mL in urine. Because the serum concentration of hCG in pregnant patients reaches 100 mIU/mL by about the time of the next anticipated menstrual period, the clinician can detect pregnancy in nearly all patients within about 9 days after conception (before the menstrual period has been missed) and in essentially all patients who have missed a period, including those with ectopic pregnancies that produce abnormally low levels of hCG.

If a patient with one or several missed menstrual periods also complains of abdominal pain or abnormal vaginal bleeding, the diagnosis of *ectopic pregnancy* must be entertained. (The diagnosis of ectopic pregnancy is discussed at greater length in Chapter 76.) Three-fourths of women with ectopic pregnancies experience 1 to 12 weeks of amenorrhea before abnormal bleeding or pain eventually prompts them to seek medical attention. Pelvic inflammatory disease is an important risk factor for ectopic pregnancy (see Chapter 94). The rate of ectopic pregnancy per 1,000 reported pregnancies in the United States increased dramatically, from 4.5 in 1970 to 14.3 in 1986, and (based on outpatient as well as inpatient hospital data) to an estimated 19.7 in 1992. Although ectopic pregnancies occur rarely in adolescents, the increase in sexual activity and pelvic inflammatory disease rates among adolescents during the last quarter century has heightened their susceptibility to ectopic pregnancy. Between 1970 and 1986, the rate of ectopic pregnancy among young women between the ages of 15 and 24 years was 6.1 per 100,000 pregnancies.

Pseudocyesis is a rare cause of amenorrhea in women who believe they are pregnant and who exhibit many presumptive symptoms and signs of pregnancy, including nausea, vomiting, hyperpigmented areolae, galactorrhea, and abdominal distension. The diagnosis is made when a patient who insists that she is pregnant nevertheless has no true uterine enlargement, no demonstrable fetal parts or heart sounds, and a negative pregnancy test. Psychiatric consultation should be obtained for such patients.

Evaluation of Nonpregnant Patients

If the physician can answer “no” to our original question—“Is she pregnant?”—the evaluation of an adolescent with oligomenorrhea can proceed at a more leisurely pace (Fig. 48.1). During the first 2 years after menarche, irregular menstrual cycles are common. The average girl requires about 15 months to complete her first 10 cycles, and some girls take much longer. As a rule, if an adolescent who complains of oligomenorrhea is fewer than 2 years past menarche, is not sexually active, and has no signs suggestive of any specific cause of oligomenorrhea (hirsutism, obesity, galactorrhea, extreme thinness), further investigation is not warranted. She can be considered likely to have maturation that is delayed but within the range of normal. Of course, she should be reassured and followed.

Adolescents with a pattern of oligomenorrhea that has continued for longer than 2 years after menarche or that began after a regular menstrual pattern had already been established need further evaluation. In the interview, historical details about the patient's menstrual pattern, growth, endocrine and central nervous systems, psychological status, and medications should be sought specifically. On physical examination, the patient's height and weight, skin, breasts, and pelvis should be checked carefully. Because galactorrhea is not always spontaneous, the examiner should try to express

fluid manually from the patient's breasts. The completed examination will separate the majority of patients who have no notable abnormalities from a minority with the important findings of hirsutism, obesity, and galactorrhea.

HIRSUTE OR OBESE PATIENTS

Classically, hirsutism, obesity, ovarian enlargement, and amenorrhea or infertility constitute the clinical features of *polycystic ovary syndrome* (PCOS, previously the Stein-Leventhal syndrome). However, patients with PCOS are a heterogeneous group with varying combinations of these features. In one sample of women with polycystic ovaries diagnosed ultrasonographically, 61% were hirsute, 35% were obese, 71% had oligoamenorrhea, and 4% had menometrorrhagia. In another sample of women with polycystic ovaries on ultrasonography, 80% had menstrual irregularities, but the remaining 20% had both regular menstrual cycles and no biochemical evidence of hyperandrogenism. In some cases, clinically evident hyperandrogenism is accompanied by peripheral insulin resistance, hyperinsulinemia, and acanthosis nigricans (HAIR-AN syndrome). Most adolescents with biochemical evidence of PCOS do not have enlarged ovaries.

Pathophysiologically, PCOS involves chronic anovulation in association with hyperandrogenism and, in some patients, hyperinsulinemia. The anovulation results from a mildly increased production rate and circulating level of testosterone, decreased sex hormone–binding globulin (SHBG), and tonically rather than cyclically elevated estrogens. Perhaps as a result of a disturbance in the hypothalamic–pituitary– ovarian feedback system that may occur during puberty or even earlier, patients with PCOS have increases in both the amplitude and frequency of luteinizing hormone (LH) secretion and normal to low follicle-stimulating hormone (FSH) concentrations. Increased amounts of androstenedione and testosterone are secreted by the ovarian theca cells in response to stimulation by LH, and then are not converted to estradiol by aromatase because this enzyme's activity depends on local concentrations of FSH. In patients with hyperinsulinemia, increased insulin binding of insulinlike growth factor-I receptors also appears to augment the production of androgens by ovarian theca cells. The local excess of androgens inhibits the normal development of ovarian follicles. Peripherally, androstenedione is increased and is converted to estrone in adipose tissue. The excess peripheral androgens also cause a decrease in the concentration of SHBG. The resulting higher proportion of testosterone unbound to SHBG can stimulate excessive hair growth, even in patients whose total serum testosterone level (bound plus free) is normal or only minimally elevated. The reduction in SHBG also results in higher circulating levels of free estradiol. The persistently, rather than cyclically, elevated peripheral estrogen concentration stimulates continuing secretion of LH and maintains the state of chronic anovulation.

The goals of treatment for PCOS are to restore monthly menstrual cycles, to minimize hirsutism, to prevent the development of endometrial hyperplasia, and, it is hoped, to reduce the risk of endometrial adenocarcinoma, which occurs with increased frequency among patients with PCOS. Medroxyprogesterone or estrogen–progestin birth control pills are used to suppress ovarian or adrenal androgen production and to stimulate monthly menstrual bleeding.

Partial or late onset *congenital adrenal hyperplasia* is a rare cause of oligomenorrhea associated with hyperandrogenism that is usually indistinguishable clinically from PCOS. Other rare causes, including *Cushing's disease* and *ovarian and adrenal tumors*, should be suspected in patients with hirsutism accompanied by signs of glucocorticoid excess or virilization (marked acne, deepening of the voice, or clitoromegaly), and in those with testosterone levels above 200 ng/dL.

GALACTORRHEA

Hyperprolactinemia occurs in approximately 25% of adult women with secondary amenorrhea but is a much less common cause of oligomenorrhea in adolescents. Nevertheless, the possibility of hyperprolactinemia must be considered in all adolescents with oligomenorrhea because only 40 to 50% of hyperprolactinemic patients have spontaneous or expressible galactorrhea. The constellation of oligomenorrhea, galactorrhea, and hyperprolactinemia can be produced by drugs (Table 48.2) that block pituitary dopamine receptors or interfere in other ways with dopaminergic or serotoninergic central nervous system pathways, by the discontinuation of birth control pills, by cutaneous or neurogenic stimulation of the breasts, and by excessive secretion of prolactin itself (e.g., primary hypothyroidism, pituitary adenoma). Rarely, in hypothyroid patients, hypothalamic thyroid-releasing hormone acts as a prolactin-releasing factor, resulting in galactorrhea. Breast-feeding is an obvious physiologic cause of prolactin secretion and oligomenorrhea. The occasional patient with galactorrhea but a normal prolactin level should be reevaluated periodically in an effort to identify a treatable cause of the problem.

Antipsychotic and Antidepressant Agents	*Drugs Used to Treat Gastrointestinal Disorders*
Amoxapine (Asendin),	Cimetidine (Tagamet)
domipramine (Anafranil)	Metoclopramide (Reglan)
chlorpromazine (Thorazine),	*Antihypertensive Agents*
thioridazine (Mellaril),	Methyldopa (Aldomet)
prochlorperazine	Reserpine (Hydromox, Serpasil,
(Compazine), fluphenazine	others)
(Prolixin), other phenothiazines	Verapamil (Calan, Isoptin)
Haloperidol (Haldol)	*Opiates*
Pimozide (Orap)	Codeine
Risperidone (Risperdal)	Morphine
Thiothixene (Navane)	

Table 48.2. Partial List of Drugs That Can Cause Hyperprolactinemia and/or Galactorrhea

NORMAL AND THIN PATIENTS

Among adolescents who do not have hirsutism, obesity, or galactorrhea, suppression of the hypothalamic–pituitary axis is the most common cause of oligomenorrhea that occurs or persists for at least 2 years after menarche. *Abnormalities of body weight* are probably the most common sources of this central disturbance. A quarter of a century ago, Frisch and McArthur observed that menarche tends to occur only after adolescents have achieved a critical fat-to-body weight ratio of 17% and that, similarly, fat must constitute 22% of body weight for menstrual cycles to reappear in women with secondary amenorrhea. This is in accordance with the clinical observation that many patients with serious chronic illnesses, malnutrition, or rapid weight loss develop amenorrhea. The observations that amenorrhea often precedes substantial weight loss in patients with anorexia nervosa and that amenorrheic ballet dancers experience menarche and resume menses during intervals of rest unaccompanied by weight gain give credence to the hypothesis that psychological stress and energy expenditure deficits may have additional, independent effects on the hypothalamic–pituitary axis.

Accordingly, in assessing the nonpregnant adolescent with oligomenorrhea, one should inquire routinely about potential sources of significant emotional upset (e.g., family disruption, peer difficulties, depression), recent weight loss, chronic illness or other causes of poor weight gain, behavior characteristic of anorexia nervosa (Table 48.3), and *strenuous exercise* (especially long distance running, dancing, or gymnastics).

A. Refusal to maintain body weight over 85% of the expected weight for age or height, with the low weight a result of either weight loss or failure to gain.
B. Intense fear of gaining weight or becoming obese, even though underweight.
C. Disturbed perception of body weight or shape, undue influence of weight or shape on self-evaluation, or denial of the seriousness of the low weight.
D. In postmenarchal females, failure to menstruate during three or more consecutive anticipated cycles. (Menstruation induced by hormonal treatment is excluded.)

Table 48.3. DSM-IV Criteria for the Diagnosis of Anorexia Nervosa

Other diagnostic possibilities for oligomenorrheic patients with no abnormal physical findings include a wide variety of conditions. About half of women using contraceptive *medroxyprogesterone* injections for 12 months have amenorrhea; after 2 years of use, the proportion with amenorrhea is 68%. Amenorrhea also occurs in about 2% of menstrual cycles among patients taking *birth control pills* that contain 50 µg or less of estrogen. However, amenorrhea persisting 12 months after the last injection of medroxyprogesterone or 6 months after birth control pills have been stopped should be evaluated in the standard fashion. The diagnoses uncovered among patients with “postpill amenorrhea” are nearly as heterogeneous as those seen in amenorrheic patients who have never taken birth control pills.

Hypothyroidism and, less commonly, *hyperthyroidism* can produce menstrual irregularities. Many patients with hyperprolactinemia and oligomenorrhea do not have concomitant galactorrhea that would otherwise prompt a medical investigation. Similarly, although hirsutism and obesity are classic features of PCOS, many adolescent patients with oligomenorrhea and the endocrinologic abnormalities of PCOS lack one or both of these signs. A history of hot flashes, antineoplastic chemotherapy, pelvic irradiation, or autoimmune disease suggests the diagnosis of *premature ovarian failure*. *Endometrial destruction* that results from overly vigorous curettage or pelvic tuberculosis is a rare cause of oligomenorrhea.

DIAGNOSTIC PROCEDURES

Patients with oligomenorrhea but few other symptoms or signs of disease require laboratory evaluation to differentiate among the many potential causes of oligomenorrhea after pregnancy has been excluded (Fig. 48.1). Determinations of serum levels of FSH, testosterone (T) or free testosterone (free T), and prolactin are needed in order to corroborate the suspected diagnosis or to categorize the patient whose history and physical examination have provided few diagnostic clues. Other laboratory tests should be performed when warranted by the clinical situation. Prepubertal levels of LH and FSH indicate hypothalamic–pituitary suppression in a postmenarchal patient; this pattern is commonly found. An elevated LH:FSH ratio of greater than 2.5 can be found in about one-third of patients with PCOS. The finding of a mildly elevated total or free T level constitutes strong evidence for a diagnosis of PCOS. FSH values over 40 mIU/mL suggest ovarian failure as the cause for oligomenorrhea. An elevated prolactin level is likely to indicate a pituitary microadenoma in patients who are not using any of the drugs known to cause hyperprolactinemia and galactorrhea (Table 48.2).

The administration of exogenous progestin often is advocated as an in vivo test of ovarian and endometrial function. If the hypothalamic–pituitary axis is producing some gonadotropin, the ovaries are responding with some estradiol production, and the uterine endometrium is growing appropriately, then the addition of exogenous progestin (medroxyprogesterone acetate, 10 mg/day for 7 days) will be followed by at least scanty menstrual bleeding within 7 days after the treatment is completed. This menstrual flow, if it appears, provides the patient and her physician with tangible evidence of the basic integrity of these organs and indicates that anovulation is the source of the amenorrhea. For diagnosis in adolescents, however, laboratory investigation is much preferable to progestin administration because the latter procedure does not pinpoint the cause of the anovulation and because the selection of an appropriate treatment for

oligomenorrhea depends necessarily on the physician's identifying a specific explanation for the disorder.

CHAPTER 49

Oral Lesions

MARK G. ROBACK, MD

Department of Pediatrics, University of Colorado Health Sciences Center, and Department of Emergency Medicine, The Children's Hospital, Denver, Colorado

Oral lesions commonly occur in infancy and childhood and may represent a wide range of illnesses—from benign lesions that completely resolve without intervention to those associated with life-threatening diseases. The differential diagnosis includes a large number of localized congenital and acquired causes; however, lesions associated with systemic disease must also be considered (Fig. 49.1 and Table 49.1). Most often, patients with isolated complaints (e.g., a mouth sore or mass, drooling, pain, fever) represent common, self- limited conditions (Table 49.2). Systemic, and potentially life-threatening, diseases (Table 49.3) may present initially with isolated mouth findings, necessitating a complete history and physical examination in all patients with oral lesions.

FIGURE 49.1. Oral lesions.

Congenital Oral Lesions	**Syphilis**
Epstein's pearls	Acquired (secondary)
Epithelial pearls	Congenital
Bohn's nodules	Hairy tongue
Dental lamina cysts	***Tumorous Oral Lesions***
Natal teeth	Eruption cyst
Sputs (gum boil)	Oral papilloma
Lymphangioma	Fibroma
Hemangioma	Mucocele
Infectious Oral Lesions	Ranula
Candidiasis	Pyogenic granuloma
Herpes simplex virus (HSV)	Rhabdomyosarcoma
Gingivostomatitis—primary	***Oral Lesions Associated with Systemic Disease***
Labialis—recurrent (cold sore)	Systemic Disease
Hand–foot–mouth disease	Stevens–Johnson syndrome
Herpangina	Toxic shock syndrome

Table 49.3. Life-Threatening Causes of Oral Lesions

PATHOPHYSIOLOGY

Oral lesions may result from localized or systemic pathophysiologic processes. Localized causes include congenital masses and cysts, infectious diseases, and oral tumors. Systemic illnesses with prominent oral involvement include a number of infectious and other inflammatory or toxin-mediated conditions. Given the broad spectrum of illnesses presenting with oral lesions, it is convenient to discuss individual causes under specific headings within the differential diagnosis. Several conditions with typical oral lesions exist that do not comfortably fit under any of these headings and are discussed in the section on miscellaneous oral lesions.

DIFFERENTIAL DIAGNOSIS

Congenital Oral Lesions

Most oral lesions present at birth or early infancy represent benign findings. Patients are largely asymptomatic, and the lesions resolve spontaneously.

Epstein's pearls occur in more than 60% of newborns as small, white milia in the midline of the hard palate. These epithelial inclusion cysts are often found in clusters and resolve over the first few months of life. Epithelial pearls are similar to Epstein's pearls and appear as shiny, small white, self-limited lesions that occur on the gums.

Bohn's nodules are also self-limited cysts that appear on the mandibular or maxillary dental ridges. Dental lamina cysts occur on the alveolar ridge of newborns and represent trapped remnants of the dental lamina.

Natal teeth are the premature eruption of primary teeth and are found at birth (natal) or within the first month of life (neonatal). These teeth are either supernumerary or true deciduous teeth and are usually found in the lower incisor region. Natal teeth may lead to ulcerations of the underside of the tongue, called Riga-Fede disease.

Epulis is a congenital fibrous, sarcomatous tumor that arises from the periosteum of the mandible or maxilla. The mass is firm and pedunculated and may regress spontaneously. Excision is required if the epulis interferes with feeding or breathing or for cosmetic reasons.

Lymphangioma is a benign congenital tumor of lymphatic vessels appearing on the tongue, lips or buccal mucosa at birth or in early infancy. Hemangiomas are benign vascular malformations present at birth that may become more apparent as the patient grows. Oral hemangiomas are typically accompanied by vascular lesions elsewhere in the body, especially on the skin.

Infectious Oral Lesions

Infectious oral lesions are typically manifestations of viral infections but may be caused by bacterial or fungal infections as well (see also Chapter 84).

Candidiasis, or thrush, is white plaques on the buccal mucosa, gingivae, and palate that will not “rub off” with a tongue

blade. Caused by *Candida albicans,* thrush is common in neonates and infants. When thrush occurs after infancy, the immune status of the patient must be considered. Oral candidiasis is the most common infection of patients with human immunodeficiency virus (HIV).

The typical lesions of herpes simplex virus (HSV) are groups of vesicles on an erythematous base that may become unroofed and appear as erosions in and around the mouth. Infections may be primary or recurrent. *Herpes gingivostomatitis*, most commonly caused by HSV type 1 (HSV-1), represents primary infection that typically occurs in young children and infants. These patients have pain, fever, and drooling. *Herpes labialis* manifests as recurrent painful lesions that occur on the lips, most often the lower lip. Herpes labialis, or “cold sores,” may be accompanied by an acute febrile illness, extensive sun exposure, or stress.

Hand–foot–mouth disease is characterized by discreet shallow erosions in the mouth, especially on the soft palate, accompanied by erythematous papulovesicular lesions on the hands and feet. High fever may be associated with this enteroviral, typically coxsackievirus, mediated disease that is self-limited in nature. Supportive treatment, specifically antipyretics and adequate oral hydration, is usually sufficient therapy.

Herpangina is also a group A coxsackievirus infection that causes vesicles or ulcers on the pharynx of patients with fever, muscle aches, and malaise.

The characteristic “strawberry tongue” seen in streptococcal scarlet fever is the result of hypertrophic red papillae on a thick white coat. Palatal petechiae are often present as is the typical “sandpaper” papular rash on an erythematous base that blanches on palpation, involving the trunk and back. Streptococcal pharyngitis without exanthem often presents with strawberry tongue and palatal petechiae.

Koplik's spots, pinpoint white macules on markedly erythematous mucous membranes, occur during the prodrome of measles, which includes cough, coryza, conjunctivitis, and fever. By the time the characteristic rash occurs, Koplik's spots typically have resolved.

Varicella lesions occurring in the mouth result in painful vesicles, which may become unroofed, on an erythematous base. Patients may be reluctant to swallow because of pain. Unless bacterial secondary infection occurs, these lesions are self-limited.

Oral lesions commonly associated with HIV-infected patients include candidiasis, hairy leukoplakia, herpes simplex, aphthous ulcers, and necrotizing ulcerative gingivitis. Blue, purple, or red macules, papules or nodules on the palate suggest oral Kaposi's sarcoma, whereas diffuse swelling, discrete nodules, or ulcers of any oral mucosal surface may indicate non-Hodgkin's lymphoma.

The pain, erythema, and swelling of the gingiva seen with dental-alveolar abscesses may be associated with fever and loosening or extrusion of the associated tooth. Significant lymphadenopathy and facial cellulitis may develop. Causative organisms are streptococci and anaerobes, although antibiotic therapy with penicillin is secondary in importance to drainage of the abscess.

Pericoronitis is local infection of the gingiva surrounding an erupting tooth. Although penicillin therapy may be required, good oral hygiene is essential. Lymphadenopathy and facial swelling may accompany pericoronitis.

Acute necrotizing ulcerative gingivitis, also called Trench mouth or Vincent's angina, is a spirochetal infection of the gingiva that occurs in adolescents. Patients report tender, bleeding gums and breath that has a fetid odor. Gums are hyperemic and appear “punched-out” secondary to tissue loss between the teeth. Treatment involves attention to oral hygiene, mouth rinses with a dilute hydrogen peroxide solution, oral penicillin, and debridement of necrotic tissue.

Although infection is present at birth, the oral lesions of congenital syphilis may not become obvious until several months of age. Erythematous papules are seen in the mouth and other mucocutaneous sites. *Hutchinson's teeth*, peg-shaped, superior, central incisors, are not present until later in life. The secondary stage of acquired syphilis is characterized by patches of ulcers or raised lesions in the mouth and is seen in association with generalized rash, fever, malaise, and adenopathy.

Patients receiving long-term antibiotic therapy may develop elongation of filiform papillae of the dorsum of the tongue and a “hairy” appearance from fungal overgrowth called hairy tongue. Hairy leukoplakia of the lateral aspects of the tongue is found in HIV-infected patients in association with intraepithelial proliferation of Epstein-Barr virus infection.

Tumorous Oral Lesions

Eruption cysts are associated with the eruption of teeth and appear on the alveolar ridge and may contain blood.

Oral papilloma are typically benign, although a small percentage of papillomas may become malignant. They are fingerlike extensions from the epithelium of the tongue, gums, lips, or buccal mucosa.

Fibroma is found on the tongue, lips, buccal mucosa, or palate and is a benign, smooth mass with a sessile base.

Ranula is a retention cyst or mucocele of the submaxillary or sublingual ducts. Ranulas are typically seen on the underside of the tongue or on either side of the frenulum on the floor of the mouth.

Mucoceles arise secondary to obstruction of salivary glands. Mucoceles are soft, well-demarcated masses. Patients are

typically asymptomatic. Excision or marsupialization is required.

Pyogenic granuloma represents granulation tissue that develops in response to an irritant such as trauma or foreign body. Most commonly found on the gingiva, pyogenic granulomas are also found on the tongue, lips, and buccal mucosa. Treatment is incision and drainage. Recurrence is common, especially when a foreign body is present.

Although 35 to 40% of cases will present in the head and neck region, rhabdomyosarcoma is a rare malignant tumor of the oral cavity. These lesions are characterized by rapid growth. They are ulcerative in nature and may present with bleeding. Associated signs and symptoms are usually attributed to the mass lesion or obstructive sequelae.

Oral Lesions Associated With Systemic Disease

Stevens-Johnson syndrome, a severe form of erythema multiforme, consists of an inflammatory process that typically involves the skin and mucous membranes. Oral lesions are erythematous plaques on the mucosa of the oral cavity and lips that develop into vesicles or bullae and may become hemorrhagic. This potentially life-threatening disorder is believed to be secondary to a drug reaction or to follow infections.

Toxic shock syndrome may manifest erythema of the oropharynx and a strawberry tongue in patients with a diffuse erythematous macular exanthem, hyperemic mucous membranes, fever, and signs of shock. This toxin-mediated disease is caused by *Staphylococcus aureus* and may be associated with tampon use or nasal carriage of this organism. Toxin-mediated disease associated with streptococci also presents with diffuse erythema of the skin and oropharynx and may progress to septic shock.

Mucositis presents as ulcers, exudate, and pseudomembranes on the gingivae and buccal mucosa of patients with neutropenia oftentimes secondary to chemotherapy. Lesions are extremely painful, and the breath becomes fetid.

Kawasaki disease is a potentially life-threatening disorder that typically presents with an array of findings, including prolonged fever, rash, lymphadenopathy, nonpurulent conjunctivitis, and edema of the hands and feet. Oral changes of Kawasaki disease include red, dry, cracked lips; erythematous oropharynx; and strawberry tongue. Therapy is directed toward prevention of coronary aneurysm development.

The inflammatory lesions of Crohn's disease may occur in any portion of the gastrointestinal tract. Oral lesions, seen most often in adolescents and young adults, consist of ulcers, polypoid papulous hyperplastic mucosa, and edema found on the lips, gingiva, vestibular sulci, and buccal mucosa. Immunosuppressive therapy with steroids and azathioprine has yielded mixed results.

Chronic, recurrent ulcers surrounded by erythema and gray exudate are found anywhere in the oral cavity in patients with Behçet's syndrome. Similar lesions occur on the skin, and the genitourinary tract may also be involved. Behçet's syndrome is rare, affecting older children and adolescents, usually boys.

More than 15 types of hereditary epidermolysis bullosa have been described. This rare, vesiculobullous condition effects mucous membranes and teeth as well as the skin. Scarring may lead to restriction of mouth opening.

Miscellaneous Oral Lesions

Aphthous stomatitis is ulceration of the oral epidermis of unknown cause. These recurrent lesions typically present as 5- to 10-mm ulcerations with a rim of erythema on the buccal mucosa, lips, and lateral aspect of the tongue. The lesions are painful, but patients do not experience fever. The lesions resolve spontaneously after 7 to 10 days.

Geographic tongue represents a benign inflammatory disorder that results in migratory smooth annular patches on the tongue. Although typically asymptomatic, patients may complain of pain. Geographic tongue is typically seen in children less than 4 years of age. No treatment is required.

Gingival hyperplasia is seen in patients receiving long-term anticonvulsant therapy with phenytoin. There appears to be an etiologic interaction with poor dental hygiene. The gingivae undergo fibrous enlargement but are not inflamed or painful. Gingival fibromatosis is an inherited form of gingival hyperplasia.

Leukoplakia of the oral mucosa develops secondary to chronic smokeless tobacco use. These painless, leathery, white patches or plaques occur in areas of greatest tobacco exposure, typically on the mucosa of the buccal sulcus. Significant exposure to tobacco may result in dysplasia or carcinoma.

EVALUATION AND DECISION

When evaluating patients with complaints of oral lesions, it is important to consider a myriad of associated signs and symptoms. The patient's age, general health and appearance, presence of an exanthem or fever, and whether the lesions are painful must be considered before the mouth is examined. Once the lesions are identified, they should be further characterized by color, type, and location.

Neonates with oral lesions can be divided into two groups based on the morphology of the lesions. Discrete masses usually represent congenital disorders, most of which are self-limited. Candidiasis, which involves the oral cavity more diffusely, is also common.

Among older children, toxic-appearing patients require immediate evaluation for potentially life-threatening disease. Patients with conditions listed in Table 49.3 have associated findings such as diffuse cutaneous rash, hyperemia of other

mucous membranes, or poor perfusion indicative of shock. However, Stevens-Johnson syndrome may cause isolated oral lesions initially and then rapidly progress to systemic involvement.

Once life-threatening causes have been considered, additional history and physical examination may lead to diagnosis of other systemic diseases. Weight loss, abdominal pain, and diarrhea with or without blood suggest Crohn's disease, whereas genital ulceration in an adolescent boy points to Behçet's syndrome or secondary syphilis.

The presence of rash and fever makes disorders of infectious etiology more likely. Measles, varicella, scarlet fever, and hand–foot–mouth disease are generally diagnosed by history and physical examination alone. Laboratory evaluation might include a throat culture for streptococci, and serologic testing for measles or HIV when these infections are suspected.

Infectious causes of oral lesions without exanthem may display obvious findings such as cachexia and alopecia in the neutropenic patient with mucositis, or they may be relatively localized to the oropharynx as in herpangina, herpes gingivostomatitis or labialis, and dental infections, which may or may not have fever and lymphadenopathy.

Oral lesions without overt signs of systemic disease are mostly congenital or tumorous in nature. Lesions found in the newborn and during infancy are largely self-limited, and most will resolve spontaneously. A few, including lymphangioma, hemangioma, and congenital epulis, may require intervention.

Children and adolescents experience an array of oral lesions not associated with obvious signs of systemic disease that are typically further delineated by considering the type of lesion (i.e., mass, vesicle, ulcer) and whether they are painful. Most of these processes require little or no therapy. Rhabdomyosarcoma is an obvious exception to this observation.

CHAPTER 50

Pain—Abdomen

RICHARD M. RUDDY, MD

Department of Pediatrics, University of Cincinnati College of Medicine, and Division of Emergency Medicine, Children's Hospital Medical Center, Cincinnati, Ohio

Abdominal pain is a common complaint of children who come to the emergency department (ED). Children with abdominal 50pain have a sensation of “discomfort,” varying from mild to agonizing, often hard to describe, and localized to the abdomen. Although most children with acute abdominal pain have self-limiting conditions, the pain may herald a serious medical or surgical emergency. Abdominal pain tests the clinician's talents for uncovering the cause and for calming the family. The diverse causes include acute surgical diseases (e.g., appendicitis, strangulated hernia, trauma to a viscus); intra-abdominal medical ailments (e.g., gastroenteritis, food poisoning, ulcer disease, urinary infections); extra-abdominal conditions (e.g., pneumonia, tonsillitis, contusions of muscle and bone); systemic illnesses (e.g., “viral syndrome,” leukemia, diabetes mellitus, sickle cell anemia); and functional abdominal pain. Clearly, the most difficult challenge continues to be making a timely diagnosis of appendicitis and other causes of an acute condition in the abdomen early enough to reduce the rate of complications.

PATHOPHYSIOLOGY

Abdominal pain can be stimulated by at least three neural pathways: visceral, somatic, and referred. Visceral pain generally is a dull, aching sensation primarily in the midabdominal, epigastric, or lower abdominal regions. Distension of a viscus stimulates nerves locally, initiating an impulse that travels through autonomic afferent fibers to the spinal tract and central nervous system (CNS). The nerve fibers from different abdominal organs overlap and are bilateral, accounting for the lack of specificity to the discomfort. Children perceive the sensation of visceral pain generally in one of three regions: the epigastric, periumbilical, or suprapubic midline area. Somatic pain usually is well localized and intense (often sharp) in character. It is carried by somatic nerves in the parietal peritoneum, muscle, or skin unilaterally to the spinal cord level from T6 to L1. An intra-abdominal process will manifest somatic pain if the affected viscus introduces an inflammatory process that touches the innervated organ. Referred pain is felt at a location distant from the diseased organ, either as a sharp, localized sensation or as a vague ache. Afferent nerves from different sites, such as the parietal pleura of the lung and the abdominal wall, share pathways centrally. All three types of pain may be modified by the child's level of tolerance. Psychogenic and environmental factors augment or inhibit the “sensation” to varying degrees in different persons. It is amazing that at times pain may be minimal with an appendiceal abscess and, conversely, severe with functional etiology.

Certain illnesses that cannot be explained neurophysiologically are associated with abdominal pain. These include conditions such as tonsillitis with high fever, viral syndromes, and streptococcal pharyngitis (although there may be painful intra-abdominal lymphadenopathy as in mesenteric lymphadenitis syndrome). Other systemic or local conditions may present with abdominal pain as a primary manifestation. Despite abdominal pain appearing localized, the examination needs to be complete. The principal causes of abdominal pain in children and adolescents are summarized in Table 50.1. Table 50.2 highlights those disorders that are life-threatening.

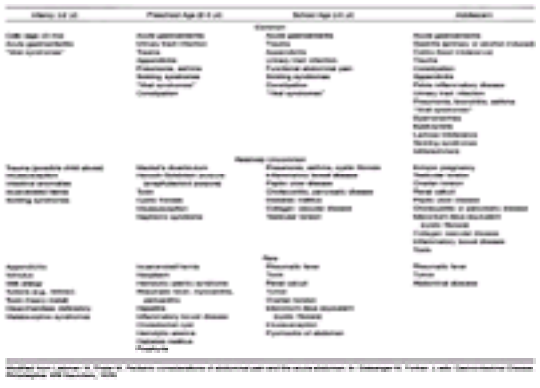

Table 50.1. Causes of Acute Abdominal Pain

Table 50.2. Life-Threatening Causes of Acute Abdominal Pain

EVALUATION AND DECISION

The evaluation of the child with abdominal pain is an important and challenging task. The assessment must focus on any history of trauma, the patient's age, the onset and chronicity of the pain, the related symptoms and pertinent history, and the physical findings (Fig. 50.1).

FIGURE 50.1. Evaluation of the child with abdominal pain.

Abdominal Pain With Trauma

Abdominal pain associated with trauma is covered in detail in the trauma section (see Chapter 103, Chapter 104, and Chapter 108). The first priority is the primary survey, with assessment of cardiovascular status (vital signs and clinical peripheral perfusion), altered breathing, and the extent of neurologic and visible injuries, while simultaneously establishing intravenous access. Exposure of the patient occurs during this initial assessment. The physician should perform a rapid, gentle physical examination to separate superficial injury (e.g., muscle contusion) from significant intra-abdominal trauma (e.g., splenic rupture or hepatic hematoma). In children who are unstable at presentation and have obvious serious or multiple injuries or a severe mechanism of injury (penetrating injury, severe blunt trauma, fall from above 20 feet, ejection from a vehicle, impact velocity more than 35 miles per hour), a rapid, aggressive workup is indicated. It is best to pass a large-bore nasogastric tube to avoid gastric distension. Radiographs (e.g., chest and abdomen with pelvis) and laboratory tests (e.g., complete blood count [CBC], urinalysis, alanine aminotransferase [ALT] and aspartate aminotransferase [AST], and amylase) are indicated in most such cases and with any objective findings. Children with localized and acute pain after blunt trauma may appear surprisingly well but have significant solid organ or hollow viscus trauma. When an intra-abdominal injury is suspected in a stable patient, an urgent computed tomographic (CT) scan should be obtained to assist in pinning down a diagnosis.

Abdominal Pain without Trauma

In assessing the child who develops abdominal pain without a history of trauma, the first priority is stabilization if the child is seriously ill. Attention to airway, breathing, and circulation (ABCs) is critical because cardiorespiratory disease and shock may present with abdominal pain as the major complaint; abdominal emergencies left untreated can lead to cardiorespiratory failure. The next priority is to identify the child who requires immediate or potential surgical intervention, whether for appendicitis, intussusception, or other congenital or acquired lesions. Third, an effort is directed to diagnose any of the medical illnesses from among a large group of acute and chronic abdominal and extra-abdominal inflammatory disorders that require emergency nonsurgical management. Table 50.2 lists life-threatening causes of abdominal pain by age groups. Finally, the physician is left to deal with a host of self-limiting or nonspecific causes of abdominal pain, including nonorganic etiologies. The algorithm presented in this chapter for the approach to abdominal pain without trauma has been designed on the basis of three branch points: age; chronicity; and the presence of obstruction, peritonitis, or a mass.

Infant Less Than 2 Years Old

The infant less than 2 years old with abdominal pain is the most difficult to evaluate because the child cannot describe or localize the complaint. To the parent, the pain may consist of “crying out,” of constantly drawing the legs up with sudden movements or jerks, of being inconsolable, of moaning with lethargy, or of irritability accentuated with fondling or rocking.

Acute Pain

In evaluating the uncomfortable infant, as described in the algorithm, the clinician looks first at the onset of “pain,”

separating acute from recurrent. Then, an evaluation is made of additional symptoms as they occurred chronologically. The bowel pattern (last stool, consistency, diarrhea), presence of fever, and amount of vomiting along with timing are noted. Obstruction may present with isolated vomiting, and a low-grade fever suggests an inflammatory process, including peritonitis. Diarrhea as an early feature often heralds gastroenteritis. Cough (sometimes with posttussive emesis) may suggest pneumonia, bronchiolitis, or asthma. The story of episodic colicky pain with interposed quiet intervals, even in the absence of a “currant jelly” stool, makes one suspicious of intussusception or, occasionally, midgut volvulus.

The physical examination must be used in conjunction with the history to determine which diagnosis should be pursued aggressively. An ileus, manifesting clinically with distension and absent bowel sounds, often accompanies surgical conditions, sepsis, and infectious enterocolitis. Ileus may be seen with pneumonia or a urinary tract infection (UTI). If an abdominal mass is palpable, intussusception, abscess, or neoplasm (commonly of renal origin) is likely. An incarcerated hernia and intussusception are the most common causes of obstruction in this age range. Inguinal hernias may incidentally incarcerate during febrile illnesses in young, crying infants or may be a cause of abdominal obstruction. Signs of partial or complete obstruction with peritonitis indicate a perforated viscus from intussusception, volvulus, or occasionally, appendicitis or Hirschsprung's disease. Rectal examination helps define pelvic masses, localize tenderness in retrocecal appendicitis, and identify a currant jelly stool in some cases of intussusception.

On auscultation of the chest, locally decreased or tubular breath sounds or adventitious sounds (i.e., crackles) suggest pneumonia. A “silent” pneumonia, particularly in a lower lobe, may present with abdominal pain and normal chest and abdominal examination. Atelectasis from the splinting secondary to abdominal pain may manifest with decreased breath sounds. Abdominal pain and pallor can occur in neoplasia, as with bleeding into an abdominal Wilms' tumor, hepatoma, or neuroblastoma. The presence of pallor and pain also raises the possibility of sickling hemoglobinopathies with the development of either a vaso-occlusive crisis or a splenic sequestration. Abdominal pain may be associated with jaundice when rapid hemolysis is related to acute splenic enlargement or with every dysfunction in acute hepatitis. If bruising is noted, hemophilia or leukemia may be the cause of abdominal pain in the ill child. At times, an intra-abdominal vasculitis that causes pain may precede the rash of Henoch-Schönlein purpura.

Chronic Pain

When apparent abdominal pain is recurrent or chronic in infants less than 3 months of age and is not accompanied by other findings or symptoms, the physician often makes a diagnosis of “colic” (see Chapter 17). However, several serious uncommon causes of recurrent abdominal pain in infancy must be considered. These include recurrent intussusception; malrotation with intermittent volvulus; milk allergy syndrome; and various malabsorptive diseases such as cystic fibrosis, celiac disease, and lactase deficiency.

Laboratory Testing

In most instances, the history and physical examination lead the emergency physician to the diagnosis. When the cause is gastroenteritis, most infants and toddlers have a history and physical examination clearly suggestive of this diagnosis and need no further evaluation. When clinical evidence of obstruction, peritonitis, or a mass is present, a CBC and urinalysis are always indicated. It may be wise to obtain these tests when appendicitis is under consideration but the history and physical examination are nondiagnostic. Serum electrolytes, glucose, and blood urea nitrogen (BUN) are not always helpful but should be obtained with peritonitis, obstruction, mass, dehydration, and renal diseases. Abdominal radiographs may be useful in confirming obstruction or the presence of a mass; a barium or air-contrast enema is indicated urgently in the case of suspected, uncomplicated intussusception. Ultrasound may yield preliminary findings that, in the right setting, suggest the need for a therapeutic study for intussusception. An upper gastrointestinal (GI) series may help delineate malrotation, and an intravenous pyelogram, renal scan, or abdominal or renal ultrasound is indicated if abnormalities of the kidney are likely.

Child 2 to 5 Years Old

Similar to the infant, the child who is 2 to 5 years of age usually has an organic cause of abdominal pain. The most common causes of abdominal pain are inflammatory processes, such as gastroenteritis and UTI. As with the younger child, the emergency physician must first ascertain whether the abdominal pain is acute or chronic in onset. With acute pain, the clinician should look for surgical conditions. The ill-appearing child with subacute symptoms may still harbor surgical diseases with complications (e.g., ruptured appendix). In every case, the physician must search for signs of obstruction, peritoneal inflammation, or peritonitis before attributing the cause to a nonsurgical disease.

Acute Pain

The preschool child may be able to describe pain and other symptoms verbally. Although such history is not consistently reliable, it almost always is to be taken seriously. More difficult to detect is the true chronologic order of symptoms. Classic presentations for surgical diseases are rarely volunteered, but occasionally, they may be elicited. Symptoms such as anorexia and vomiting suggest distension of an intra-abdominal viscus; rectal bleeding points to infectious enterocolitis, intussusception, Meckel's diverticulum, or more rarely, inflammatory bowel disease (IBD). Extra-abdominal complaints, such as cough, sore throat, and headache, are commonly present; they often indicate a viral syndrome, pharyngitis, or pneumonia. Urinary symptoms may occur with pyelonephritis, and polydipsia with polyuria may herald the onset of diabetes mellitus with abdominal pain from ketoacidosis. Children with known past intra-abdominal pathology or surgery may develop complications of their prior illnesses.

The physical examination helps separate acute abdominal conditions with peritoneal inflammation or obstruction from less emergent and more common conditions. The most important surgical causes of abdominal pain are acute appendicitis, often with an atypical presentation, and occasionally, intussusception or malrotation. The presence of guarding or persistent abdominal tenderness with gentle palpation warns the emergency physician of a serious

abdominal emergency. Persistent right lower quadrant pain or tenderness on palpation alone suggests a need for surgical evaluation in the ED. This is the most consistent finding in patients discharged to home with early appendicitis. Usually, during a quiet, relaxed examination, the pain from gastroenteritis abates; other “referred” abdominal pains (e.g., from pneumonia or tonsillitis) often seem to disappear when the child is reassessed in a calm fashion. Ill children with abdominal pain occasionally have life-threatening diseases (Table 50.2) or the more uncommon diseases (Table 50.1). The physical examination of such patients may show jaundice (hepatitis, hemolytic anemia), rash or arthritis (Henoch-Schönlein purpura), cardiac murmurs (rheumatic fever), friction rubs (pericarditis), or “acetone” on the breath (diabetes mellitus).

Chronic Pain

A history of recurrent abdominal pain suggests conditions such as sickle cell anemia, inflammatory bowel disease (IBD), cystic fibrosis, or asthma. Chronic constipation can occur in children between 2 and 5 years of age, but true psychogenic or other nonorganic abdominal pain is fairly uncommon in this preschool age group.

Laboratory Testing

The use of the laboratory parallels its role in young infants. A CBC and urinalysis may be useful in this age range, either to point toward or away from an inflammatory process such as appendicitis. If the appendix has not ruptured, the white blood cell (WBC) count is usually normal or minimally elevated. WBC counts that are higher than 16,000 to 18,000/mm ^{3} suggest an acute bacterial infection or complicated intra-abdominal process, such as an abscess. A grossly abnormal urinary sediment points to UTI or, occasionally, glomerulonephritis but does not exclude an inflamed appendix that is lying anteriorly near the bladder. Occasionally, a hemoglobin electrophoresis is needed to confirm the diagnosis of sickling syndromes.

Radiographic findings are usually normal or nonspecific in children with GI infections or appendicitis;therefore, a normal film should not reduce the suspicion of potential surgical disease. Radiographic signs of appendicitis include localized bowel obstruction (a sentinel loop), an appendicolith, or obliteration of the psoas shadow. Radiographs are of greater benefit in younger children in whom atypical presentations are more common. An abnormally thickened intestinal mucosa from IBD or ascites from nephrotic syndrome favors the diagnosis of these nonsurgical emergencies. Chest radiographs may detect lower lobe pneumonia or asthma with atelectasis in this age group. Once again, the recent literature suggests that abdominal ultrasound may help establish a diagnosis in children with atypical abdominal pain, particularly of genitourinary origin.

Child 5 to 12 Years Old

The preadolescent child adds another dimension to the spectrum of abdominal pain—that of nonorganic or psychogenic illness. The leading organic causes of abdominal pain still are inflammatory and include gastroenteritis, appendicitis, and UTIs. Occasionally, the child is the victim of chronic disease (Table 50.1). Colicky abdominal pain is more rarely associated with intussusception than in younger children. Usually a “lead” point for an intussusceptum is seen in older children (e.g., mesenteric adenitis, lymphoma, polyp, cystic fibrosis, anaphylactoid purpura). Abdominal pain with other symptoms may herald the presentation of inflammatory bowel, collagen vascular, ulcer, gallbladder, pancreatic, or liver disease. Constipation is a common cause of acute abdominal pain in older children, especially in the those with delayed development.

Acute Pain

The history of abdominal pain generally is reliable in the older child. The presence of fever, cough, vomiting, and/or sore throat suggests an infectious cause. Associated diarrhea may be from infectious colitis, IBD, or an appendiceal abscess irritating the bowel. A genitourinary history of discharge or suspicion of sexual abuse may be difficult to elicit in this age range but must be sought. With UTIs, urinary frequency and dysuria usually occur. Finally, pain that begins periumbilically and migrates to the right lower quadrant after several to 24 hours suggests appendicitis, a more common diagnosis in the older child.

The findings on physical examination, including the rectal and genitourinary examination in girls, are often revealing in this age group. Localized tenderness in the right lower quadrant or diffuse tenderness with involuntary guarding raise the suspicion of appendicitis or other diseases that cause peritonitis. As in younger children, it is critical to assess for an atypical presentation of appendicitis. Careful extra-abdominal examination is paramount to discover many of the infectious causes of abdominal pain. Rectal examination should be performed along with visualization of the genitalia in the young girl while in the knee–chest or frog leg position (see Chapter 94).

Chronic Pain

Chronic abdominal pain may occur as a result of many of the conditions listed in Table 50.1. Important considerations are chronic infection with an enteric pathogen and IBD. When the history and physical examination suggest a mild, self-limiting disease or a nonorganic basis for the abdominal pain, however, the emergency physician should refrain from overusing the laboratory or radiography department to allay the parents' fear of organicity. It often is difficult to provide reassurance and counseling in the busy ED to enmeshed parents and their child with recurrent abdominal pain; however, time spent in this endeavor can be worth the effort. Most important is the recognition that the child feels real pain, despite reinforcement of the idea that an organic diagnosis is not likely to be forthcoming. Counseling needs to be tailored to the level of sophistication of the family. Sometimes, revisits to the ED or acute-care office setting may be necessary for reappraisal of an acute episode if referral to a primary physician cannot be arranged.

The syndrome of functional abdominal pain precipitates more than 80% of outpatient physician visits by children for abdominal pain. The presentation of such pain is generally episodic, emanating from the umbilicus and, by definition, has

no organic cause. The pain rarely occurs during sleep and has no particular associations with eating, exercise, or other activities. There may be a positive family history of GI symptoms or migraine. The child's growth and development are normal, and the abdominal examination is unremarkable; occasionally, mild midabdominal tenderness, without involuntary guarding, is elicited. If performed, screening tests such as a CBC, sedimentation rate, and urinalysis all are normal.

The emergency physician's task is to allay any fears of serious organic disease during the acute episode, which is not always easy. At the same time, the physician must support the child, who is truly feeling pain. Because the long-term solution to a functional complaint is generally not in the realm of the ED, the physician should explain all of the organic illnesses that the pain is *not* felt to be and suggest a nonorganic cause of the pain. The emergency physician should provide an avenue for continued supportive follow-up through referral to the primary physician.

Laboratory Testing

In most children over the age or 5 years with abdominal pain, laboratory tests are needed only to confirm a diagnosis that is suspected clinically. If appendicitis is being considered, a CBC and urinalysis should be obtained unless the history and examination appear diagnostic, wherein clinical pathway studies have demonstrated minimal need for laboratory testing. Before appendiceal rupture, the WBC count usually is minimally elevated and the urinalysis is normal. With perforation, the WBC count usually rises above 16,000/mm ^{3}, and pyuria occurs occasionally. Again, radiographic findings with appendicitis may include a normal film, a sentinel loop, an appendicolith, or obliteration of the psoas shadow. In patients with significant fever, a chest radiograph may assist in the evaluation. When IBD is suspected in the child with abdominal pain, a sedimentation rate may prove useful because it is almost invariably elevated with this group of disorders. In addition, a CBC and serum protein to evaluate for anemia or hypoalbuminemia can be useful. Often, other laboratory tests are indicated to corroborate clinical findings (e.g., chest radiograph in lower lobe pneumonia; urinalysis and culture for pyelonephritis or cystitis). Only the rare, complicated patient with abdominal pain requires a battery of tests.

Adolescent More Than 12 Years Old

The adolescent patient, particularly the female, taxes the emergency physician's skills, generating an extensive differential diagnosis of both life-threatening and less serious but common causes for abdominal pain (Table 50.1 and Table 50.2). Of the gynecologic causes, potentially catastrophic ectopic pregnancies and the more common pelvic inflammatory disease (PID) head the list in importance.

Acute Pain

The history of acute abdominal pain needs to be explored carefully to avoid missing a pertinent diagnosis. The location of the pain and its character may assist in differentiating the acute surgical abdomen from gastroenteritis or psychogenic pain. A menstrual history and ascertainment of sexual activity are essential. Obtaining this information is often difficult, however, and one must assume that pregnancy and sexually transmitted diseases are possible despite rigorous denials of sexual contact. Sensitivity to the family regarding this possibility is important. Obviously, a complete physical assessment of the teenage girl routinely includes a pelvic examination.

Acute pain with peritonitis in the adolescent boy usually results from appendicitis. Assessment also must include that for testicular torsion or epididymitis. The adolescent girl with peritoneal findings may have appendicitis, PID, or less commonly, cholecystitis or ectopic pregnancy.

Boys without peritoneal signs often have gastroenteritis or a viral syndrome. Girls are more prone to UTIs or pyelonephritis; ectopic pregnancy, although uncommon, must be considered because this diagnosis may not produce peritoneal irritation before rupture. Gravid girls may be suffering from a complication of pregnancy or any of the usual disorders that cause abdominal pain as listed in Table 50.1 and Table 50.2.

Chronic Pain

Chronic abdominal pain in the adolescent is similar to that in the younger child, with the exception of an increased prevalence of IBD and the need in girls to consider long-standing gynecologic ailments such as dysmenorrhea, endometriosis, and chronic PID. It is particularly difficult to establish the cause of chronic pain when dealing with adolescents on an episodic basis, making appropriate referral essential.

Laboratory Testing

The use of the laboratory in diagnosing abdominal pain is similar to that for the child, with the exceptions of the need for abdominal or pelvic ultrasound, pregnancy testing, or microbiologic evaluations for sexually transmitted diseases. In the ED, the postmenarchal girl with abdominal pain should have a pregnancy test (see Chapter 48) when pregnancy is suspected or no definite diagnosis has been made. Ultrasound often is helpful to establish the location of a gestational sac or to evaluate the adnexa for a possible mass. In equivocal cases of gynecologic disorders versus an acute appendiceal inflammation, ultrasound and CT have been helpful in eliciting the cause of pain. Appropriate cultures and microscopic examinations for sexually transmitted diseases often are indicated. Recently, laparoscopic evaluation has been used increasingly as both a diagnostic and therapeutic procedure for older children and adolescents.

SUMMARY

Abdominal pain is one of the most common complaints of children who seek treatment in the ED. The history and physical examination should distinguish most cases that require surgical intervention or admission to the hospital;

laboratory tests are indicated only to confirm diagnoses suspected clinically.

Inflammation, usually in the form of gastroenteritis, is the most common organic cause at all ages for abdominal pain. Acute surgical conditions that are not always easy to diagnose, however, must be excluded. Appendicitis, which is often atypical, is by far the most important diagnosis to exclude, especially in the older child and adolescent. Reexamination during the same visit or in the next 6 to 12 hours and surgical consultation often are necessary to decide on the need for hospitalization or surgery.

Nonabdominal causes of abdominal pain should receive consideration in children of all ages. A particularly common cause of abdominal discomfort in the older child is recurrent, functional pain.

CHAPTER 51

Pain—Back

HOWARD M. CORNELI, MD

Department of Pediatrics, University of Utah School of Medicine, and Primary Children's Medical Center, Salt Lake City, Utah

As a rule, back pain in children is meaningful until proved otherwise. If back pain is less common in children than in adults, it is also far more likely to signify pathology. Furthermore, children are subject to conditions causing back pain that are seldom seen in adults, and the common causes in adults occur uncommonly in children. The diagnosis may be difficult because children have less ability to describe their pain and, in younger children, even to localize it.

DIFFERENTIAL DIAGNOSIS

In the famous joke, Dr. Loeb asks the medical student how he arrived at the correct diagnosis of splenic sarcoma and the student replies, “What else causes back pain?” A complete list of causes might run for pages, but for our purposes, we can divide the likely childhood causes into a few categories (Table 51.1 and Table 51.2).

Table 51.1. Cause of Back Pain

I. Traumatic	C. Pneumonia
A. Compression fracture	D. Urinary tract infection
B. Spondylolysis/spondylolisthesis	III. Neoplastic
II. Infectious	A. Benign tumors
A. Discitis	B. Malignant tumors
B. Vertebral osteomyelitis	

Table 51.2. Common Causes of Back Pain in Children

Trauma is a major problem in children. Spinal trauma is covered in Chapter 125, and cervical spine injuries are covered in Chapter 106. Acute injury, especially with axial loading, may cause compression fractures, which are more common in children. Compression fractures present with localized pain over the affected vertebra or vertebrae. Radicular pain may develop and may occasionally be so severe as to cause a sympathetic ileus and vomiting. The signs of back strain and lumbar disc herniation are similar to those in the adult, but in adolescence, these diagnoses should be made with caution, and in childhood, they are distinctly rare.

Injury may be less obvious when it is chronic or recurrent. Especially common among adolescents is spondylolysis. This represents a weakening or discontinuity of the pars interarticularis, which connects the vertebrae at the facet joints. The condition is believed to be associated with overuse and microfractures. If the vertebra slips forward on the one beneath, the resulting condition is called spondylolisthesis. Either condition can cause back pain, most often in the lower lumbar area or at the L5–S1 level. These lesions often present during the adolescent growth spurt and are associated with

repeated lifting and back extension, especially in sports. Another condition linked to overuse, Scheuermann's disease, is seen especially in adolescents as anterior wedging of several vertebrae, especially in the thoracic spine. This condition is painful in about half of cases.

Rare but dangerous causes of back pain deserve special vigilance in the child (Table 51.3). A spinal epidural hematoma may follow a fall or blow, sometimes presenting days later, or it may arise spontaneously, especially in patients with bleeding disorders or those who are receiving anticoagulant therapy. Back pain may only briefly precede symptoms of spinal cord compression. Spinal epidural abscess may present with back pain, low-grade fever, and signs of spinal cord compression. Percussion usually elicits spinal tenderness. Appreciation of the signs of spinal cord compromise should lead to emergent neurosurgical referral.

I. Traumatic	D. Meningitis
A. Spondylolisthesis	E. Transverse myelitis
B. Spinal epidural hematoma	F. Spinal epidural abscess
II. Infectious	G. Aortic dissection
A. Discitis	III. Neoplastic
B. Vertebral osteomyelitis	A. Malignant tumors
C. Paraspinal, retroperitoneal abscess, or pyomyositis	B. Benign tumors
	C. Leukemia/lymphoma

Table 51.3. Serious Causes of Back Pain in Children

Infectious causes of back pain are many. Infection in the back itself may prove difficult to diagnose. Vertebral osteomyelitis and discitis present in a similar fashion. A limp or failure to bear weight may be more obvious than back pain in the young child, who is most susceptible to these infections.

Paraspinal or psoas abscess and pyomyositis in paraspinal or pelvic muscles may present as back pain. Iliac osteomyelitis and sacroiliac joint infection also may present as back pain. Osteomyelitis of the ribs occurs rarely. The more rare infections include spinal tuberculosis (Pott's disease) and brucellosis, in which small vertebral abscesses may accompany lymphadenopathy and hepatosplenomegaly.

Infections outside the musculoskeletal axis that cause back pain include urinary tract infection (UTI), which may cause flank pain with or without upper tract infection; pneumonia; and meningitis. These infections in children may lack the obvious symptoms seen in older patients. The young child with a UTI often shows no urinary symptoms as such, although fever or gastrointestinal symptoms may occur. Pneumonia can be surprisingly silent. Cough may be minimal. Auscultation and percussion are of limited sensitivity in the small chest. Meningitis occasionally may be identified by parents primarily as back pain. This is especially true in infants who are noted to fuss when moved; a parent may note that it hurts the child to move the back. Myalgias and generalized backache may be seen in influenza, mononucleosis, streptococcal pharyngitis, and other generalized infections. Postinfectious conditions include transverse myelitis, which may follow an upper respiratory infection; back pain may precede weakness by as much as 1 to 2 days.

Abdominal conditions that may present as back pain include pancreatitis, in which the steady, penetrating pain radiates prominently to the back. Gallbladder pain may radiate to the back as well, and appendicitis, especially in a retrocecal location, can cause radiation to the back or pain and tenderness in the flank.

Collagen vascular diseases that cause back pain include ankylosing spondylitis and juvenile rheumatoid arthritis (with sacroiliitis), especially pauciarticular type II disease. Both of these conditions chiefly affect boys over 8 years of age. The back is notably stiff to flexion, especially in the lumbar region. Spondylitis also may be seen in association with Reiter syndrome, regional enteritis, ulcerative colitis, and psoriasis.

A painful, rapidly progressive scoliosis or atypical curvature suggests serious spinal pathology, often with neuromuscular involvement. Idiopathic scoliosis demonstrates back pain only in the most severe cases.

A host of neoplastic causes, both benign and malignant, may present with back pain (Table 51.1). These are not so rare that they can be ignored in any evaluation of back pain. Ewing's sarcoma may mimic infection, with fever, leukocytosis, and rarefaction of bone on radiographs. Leukemia, and especially lymphoma, may present as back pain.

Sickle cell disease and other hemoglobinopathies may cause back pain. Dissecting aortic aneurysm has been reported rarely in children, usually with hypertension or with Marfan's syndrome and other connective tissue disorders. Table 51.1 lists other miscellaneous causes of back pain.

Psychogenic back pain should be diagnosed with caution in children. The young child lacks the psychological machinery for conversion and the motivation to malinger. Even in adolescents, an overly prompt diagnosis of functional pain may lead to neglect of organic illness. Psychosomatic pain may be suggested, however, by a cheerful affect when describing symptoms, by disproportional school absence, or by unusual family dynamics, especially in the adolescent patient. Even if suspicion of a psychological component exists, a thorough investigation should be undertaken to exclude organic causes.

EVALUATION AND DECISION

The first task in a child with back pain is to rule out any sign of neurologic involvement. (Fig. 51.1). Conditions that affect the spinal cord are seen often enough in children that their gravity should be borne in mind throughout the evaluation. The history should be reviewed for limb weakness or disuse or for a change in function of the bowel or bladder. Although seen with some purely musculoskeletal problems, limp in the presence of back pain should suggest possible spinal cord involvement (see Chapter 43). A thorough examination of spinal cord function is indicated in any child with back pain of unknown cause. This should include evaluation of muscle bulk, tone, and strength; sensitivity to pinprick in addition to light touch; the deep tendon reflexes and Babinski reflex; and anal tone, the anal contracture reflex, and in boys, the cremasteric reflex. When any neurologic compromise is suspected, additional sensory examination of proprioception, heat, and cold is warranted. Any suspicion of spinal cord involvement warrants prompt neurosurgical consultation.

FIGURE 51.1. Approach to the diagnosis of back pain. *WBC,* white blood cell; *ESR,* erythrocyte sedimentation rate.

Systemic symptoms should be carefully reviewed. Fever, fatigue, poor appetite, weight loss, or a decrease in walking or weight bearing usually signify a worrisome illness. Night pain that awakens the patient from sleep is associated with spinal tumor and, if relieved by aspirin or nonsteroidal anti-inflammatory drugs, suggests osteoid osteoma or osteoblastoma. Sciatica may signify disc herniation, especially in the adolescent athlete or laborer.

A history of trauma is important in evaluating back pain but may be misleading in the young child whose frequent minor injuries may be seen by the parents as the trigger for a problem that actually is nontraumatic. Adolescents with stress injuries may not identify trauma in connection with back pain. Certain injury histories suggest specific diagnoses; vertical loading of the spine, as when a child lands in a seated position after a fall, often is associated with compression fractures of the vertebrae.

In adolescents with back pain, a history should be sought of sports-related, lifting-related, or work-related exposures to back stress. Weight lifters, gymnasts, football players, and participants in many similar sports have well-known tendencies to hyperextend the back. Unfortunately, not all teenagers who develop stress injuries are engaged in such easily identified activities. As excessive competition in sports is introduced to younger and younger children, such injuries may be seen earlier in childhood.

Fever is likely, of course, to signify infection, and infection both in the back and in adjoining areas is a common cause of back pain. However, fever is sometimes seen with neoplastic and collagen vascular causes of back pain. Even more importantly, children with musculoskeletal infections are afebrile at presentation in a significant proportion of cases.

Age may be suggestive of cause. The preschool child is unlikely to have overuse injuries, spondylolysis, or ankylosing spondylitis; however, infectious causes are more likely at this age. Family history may be positive in ankylosing spondylitis and related conditions. History may reveal an underlying disease, chronic inactivity (in the bedridden child), or drug therapy that may cause osteoporosis, which increases the risk of bony injury, especially compression fracture.

Chronicity of back pain may suggest collagen vascular conditions, Scheuermann's disease, or perhaps, a developmental defect in the spine, but tumors may progress slowly with chronic back pain being the only noted symptom. Likewise, the acute onset of pain or neurologic symptoms often may be the first signs of a chronic (but expanding) mass lesion.

In addition to the neurologic examination previously mentioned, the physical examination should cover the appearance of the spine; percussion of the spine, ribs, and flank; palpation of the sacroiliac and paraspinal areas; rotation of each hip as well as straight-leg raising; and rectal and genital examinations. (Hydrometrocolpos has been reported as a cause of back pain, even in premenarchal girls.) Flexibility of the spine should be checked, especially to flexion and extension, and unusual kyphosis, lordosis, or scoliosis should be noted. Careful chest and abdominal examinations and the absence of meningeal signs require documentation.

In many cases, the cause of back pain remains obscure even after a thorough history and physical examination. Here, the physician faces an important decision. In the younger child, it is appropriate to seek consultation or to proceed to imaging studies. Plain films may reveal a narrowed disc space in discitis; bone scan may reveal discitis or vertebral osteomyelitis, even in the absence of fever and bony changes; magnetic resonance imaging (MRI) may reveal a spinal or paraspinal tumor. In the preteen or teenage patient, a history of likely back strain (or the appearance of clues to psychosomatic pain previously mentioned) may warrant a trial of empiric therapy; even here a complete physical examination and screening radiographs and laboratory studies should be documented, and close follow-up should be

ensured. (Further treatment of the varying causes of back pain is discussed in specific sections of this book.)

Plain radiography of the spine is much more likely to be revealing in children with back pain than in adults. Plain films should be ordered in cases with trauma, with exacerbation by activity (as may be the case in spondylolysis and spondylolisthesis), when chronicity or progression are noted, or when the diagnosis remains uncertain. Although two-view studies may show compression fractures, spondylolisthesis, discitis, and lesions of the vertebral body, oblique views are recommended with any history of trauma or possible stress-induced injury to assess integrity of the pars interarticularis. Plain chest radiography is indicated when pneumonia is considered.

Bone scintigraphy is most useful for the definition of osteomyelitis, discitis, or other early osseous pathology when radiography proves unrevealing. Newer single-photon emission computed tomographic (SPECT) scans may reveal stress injury, such as spondylolysis, before it is seen on planar bone scans or plain radiographs. Radiolabeled white blood cell scans may detect paraspinal infection or abscess.

Computed tomography (CT) remains a useful method for emergent evaluation of trauma or when lesions outside the spine are suspected. However, this technique is limited in its ability to delineate densities within the bony spinal canal and to study the alignment of spinal structures in the vertical axis without special methods or reconstructions. MRI overcomes these limitations and provides highly detailed longitudinal images of the spine, the canal, the cord, and other tissues. MRI is preferred for evaluations of possible intraspinal pathology. It has largely supplanted myelography.

Laboratory investigations are directed by the presentation. A complete blood count and sedimentation rate are often useful. Urinalysis, serum amylase, and biliary studies may rule out abdominal pathology. Sickle cell preparations or hemoglobin electrophoresis may be indicated. Other evaluations may be used selectively.

In summary, back pain in children warrants more concern and closer investigation than back pain in adults. Because back pain is less common in children, we can afford to pay closer attention, and because it more often implies significant pathology, we must do so.

CHAPTER 52

Pain–Chest

MARY D. PATTERSON, MD and RICHARD M. RUDDY, MD

Department of Pediatrics, University of Cincinnati College of Medicine, and Division of Emergency Medicine, Children's Hospital Medical Center, Cincinnati, Ohio

The complaint of chest pain uncommonly represents a life-threatening emergency in children, in contrast to the same complaint in adults. Recently, the epidemiology has changed with the increase of cocaine abuse in which chest pain, myocardiopathy, and even myocardial infarction (MI) may occur. Although heart disease is an uncommon source of chest pain in children, the fear of a cardiac origin for the pain may evoke anxiety in the child or in the parents. Thus, a careful approach to the patient is imperative even in the pediatric setting. This chapter first briefly reviews the pathophysiology of chest pain, then outlines the differential diagnosis in children, and finally presents the evaluation, as appropriate in the emergency department (ED).

PATHOPHYSIOLOGY

To understand the possible origins of chest pain or discomfort, it is important to review how this sensation is transmitted. Musculoskeletal pain is produced by irritation of these tissues and is transmitted through the sensory nerves. The stimulus is carried through the nerve in the dermatomal or intercostal distribution to the dorsal root ganglia, up the spinal afferents, and into the central nervous system (CNS). This local, peripheral, sharp pain also can be produced by primary dorsal root irritation in the spine. Because of overlap of nerve distribution, pain may be sensed in locations distal to the irritation. For example, the third and fourth cervical nerves evoke pain as far caudally as the nipple line of the chest.

Tracheobronchial pain is transmitted by vagal afferents in the large bronchi and trachea to fibers in the cervical spinal column. Dull, aching, or sharp pain is felt in the anterior chest or neck. The irritation or sensation of cough is transmitted in a similar fashion. Pleural pain arises in the pain-sensitive parietal pleura and then travels through the intercostal nerves in the chest wall, giving rise to sharp, well-localized pain. The visceral pleura is insensitive to pain. The intercostal or phrenic nerves transmit diaphragmatic pain. Peripheral diaphragmatic irritation may cause local chest wall pain because of the intercostal innervation. Central diaphragmatic stimulation travels by the phrenic nerve, with the distribution of pain referred to the shoulder of the affected side.

The esophagus appears to be more pain sensitive in its proximal portion. Pain is transmitted by afferents to corresponding spinal segments, with resultant anterior chest or neck pain. The pericardium is innervated by portions of the phrenic, vagal, and recurrent laryngeal nerves, as well as by the esophageal plexus. This appears to give rise to various sensations, including chest or abdominal pain, dull pressure, and even referred anginalike pain.

Other mediastinal structures, such as the aorta, have pain fibers in the adventitia of the vessel wall. They transmit pain through the thoracic sympathetic chain to the spinal dorsal roots, giving rise to sharp, variably localized chest pain. Cardiac pain probably is transmitted by a number of routes, including the thoracic sympathetic chain and the cardiac nerves through the cervical and stellate ganglia. It has been proposed recently that pain arises from abnormal ventricular wall movement and stimulation of the pericardial pain fibers. These routes account for the sensation of cardiac chest pain as pressure or crushing pain substernally or as sharp pain in the shoulder, neck, or arm.

DIFFERENTIAL DIAGNOSIS

A differential diagnosis of chest pain in children is included in Table 52.1. Most chest pain in children is caused by acute respiratory disease, musculoskeletal injury, anxiety, or inflammation (Table 52.2). Often, the physician does not make a causative diagnosis of the chest pain and calls it idiopathic in origin. This idiopathic chest pain actually may be unrecognized organic disease, such as gastroesophageal reflux. Although much less common, chest pain in association with cardiorespiratory distress demands immediate attention. Table 52.3 lists the life-threatening causes of chest pain by disease and mechanisms for decompensation.

Table 52.1. Causes of Chest Pain

Functional (anxiety/psychosomatic)
Musculoskeletal contusion/strain
Costochondritis/myositis
Cough or respiratory infections (bronchitis, pneumonia, pleurisy, upper respiratory infections)
Asthma
Gastroesophageal reflux
Idiopathic

Table 52.2. Common Causes of Chest Pain

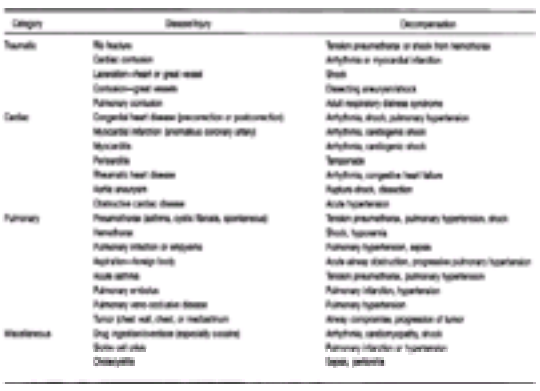

Table 52.3. Life-Threatening Causes of Chest Pain

In the case of trauma, cardiac or pulmonary compromise may arise from direct injury to the heart, great vessels, or lung (see Chapter 107). Chest pain in the nontraumatized, yet dyspneic or cyanotic patient, most often stems from a respiratory problem, such as acute pneumonitis, empyema, pleurisy, asthma, or pneumothorax (either spontaneous or associated with cystic fibrosis [CF] or asthma). Rarely does severe chest pain in an acutely ill child result from an MI (see Chapter 8) that comes from aberrant coronary vessels, other underlying cardiac diseases (aortic stenosis), an acute arrhythmia, pericardial disease, or pulmonary embolus. Pediatricians do not often think of pulmonary embolus early on. Usually, this may have associated risk factors, such as recent trauma, particularly spinal injury, or known cardiorespiratory problems. More recently, acute chest pain associated with ischemia, arrhythmia, or myocardiopathy may be secondary to acute or chronic cocaine exposure. Other toxins have cardiac effects also. Nonorganic chest pain may appear to cause respiratory distress in the hyperventilating teenager (see Chapter 131), but close examination should distinguish this syndrome from serious problems.

Chest pain in children usually occurs without associated cardiorespiratory signs or symptoms, often as a chronic problem. By the time of the ED visit, the pain has often resolved. Mild to moderate strain or injury from exercise or trauma may produce a contusion or rib fracture. Inflammation of nerves, muscles, bones, costochondral junctions, the esophagus, or the lower respiratory tract often causes organic chest pain. Both respiratory infection (pneumonia or bronchitis) and allergic respiratory disease (asthma) are important causes to consider. Spontaneous pneumomediastinum and pneumothorax may occur in patients with reactive airway disease, CF, or as a result of barotrauma (e.g., Valsalva maneuver, forceful vomiting or coughing). Aspiration of a foreign body into the trachea or esophagus may occur without such history in a toddler or even in an older child. Unrecognized disease rarely causes isolated chest pain in a child who otherwise appears well, but the physician should consider drug exposure (e.g., cocaine, methamphetamine, nicotine, b-agonist abuse). In addition, attention should be paid to diagnosing the rare patient with progressive obstructive heart disease, angina, mitral valve prolapse, or early pericardial or myocardial inflammation (see Chapter 82). A large group of children (up to 50%) will be left whose pain best fits into an anxiety-induced or idiopathic category. Every individual evaluation must be started, however, with a broad differential diagnosis in mind to ensure proper diagnosis and management of the child with chest pain.

EVALUATION AND DECISION

Child with Thoracic Trauma

The first step in evaluating the child with chest pain is to perform a thorough history and physical examination. If any evidence of trauma to the chest exists (see Chapter 107), the patient requires rapid evaluation and may need immediate resuscitation as well (Fig. 52.1A). Correction of cardiac or respiratory insufficiency may diagnose, as well as treat, the cause of chest pain. Alveolar ventilation should be assessed for adequacy and bilateral symmetry to distinguish acute respiratory failure from hemothorax or pneumothorax. In children with chest trauma, tachycardia with hypotension generally is caused by hypovolemia secondary to a hemothorax, hemopneumothorax, or vascular injury. Reduced cardiac output and perfusion, however, also may be secondary to a rhythm disturbance (from a myocardial contusion, tension pneumothorax) or cardiac tamponade (which causes muffling of the heart sounds and pulsus paradoxus). A discrepancy of the pulse or blood pressure between the extremities points to aortic diseases, such as traumatic avulsion or aneurysm, as the cause of chest pain. Ruptured esophagus and tracheobronchial disruption may result from rapid deceleration injuries and may present with chest pain, respiratory distress, and hypotension.

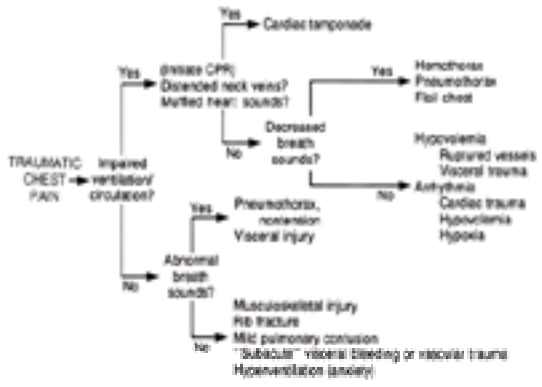

FIGURE 52.1A. Diagnostic approach to traumatic chest pain. *CPR*, cardiopulmonary resuscitation.

Many children with thoracic injuries but no respiratory distress also complain of chest pain. Although a careful examination is mandatory in an effort to exclude significant intrathoracic trauma, the cause of the pain usually resides in the chest wall: contusions of the soft tissues or rib fractures. A history of significant trauma even in the absence of cardiovascular abnormality dictates that radiographs and an electrocardiogram (ECG) be obtained. Rib fractures in young infants suggest child abuse. In older children, a predisposing cause for fracture (e.g., bone cyst, tumor) should be sought.

Child with No Thoracic Trauma

Initially, the physician needs to assess for cardiorespiratory instability. Next, the physician should inquire about a history suggestive of prior cardiorespiratory disease (Fig. 52.1B). Children with respiratory illnesses such as asthma or CF are at risk for pneumothorax, acute respiratory failure from mucous plugging or pneumonitis, and acute pulmonary hypertension. Severe hypoxemia may accompany their chest pain. Auscultatory findings, such as rales or wheezing, may be minimal when obstructive pulmonary disease is moderately severe. In the child with a history of cardiac arrhythmias (see Chapter 82), congenital heart disease, cardiac surgery, or pericardial effusions, chest pain may signal an exacerbation of the underlying problem. Although uncommon in children, acute pulmonary embolus should be considered when chest pain with the sense of impending doom and/or risk factors (e.g., obesity, birth control pills, pregnancy, collagen vascular disease, nephrotic syndrome, cigarette smoking, recent surgery, a positive family history) is present. Pulmonary embolus may occur as a complication of an underlying disease, medical therapy, or surgical repair.

FIGURE 52.1B. Diagnostic approach to atraumatic chest pain. *CPR*, cardiopulmonary resuscitation; *CF*, cystic fibrosis.

In the absence of prior cardiopulmonary disease or trauma, the approach must be directed toward unmasking evidence for any of the serious cardiorespiratory illnesses listed in Table 52.3. In particular, chest pain associated with exertion, syncope, or palpitations is concerning. A history of untreated Kawasaki disease or hyperlipidemia has been associated with MI at an early age. However, most children with chest pain will be found to have less severe acute inflammatory

processes of the respiratory tract or musculoskeletal system or a psychosomatic disturbance.

Infectious diseases of the respiratory tract are associated with fever, malaise, cough, and coryza and may involve several family members simultaneously. A first asthmatic attack should be suspected when an associated night cough, history of wheezing, or family history of atopy is present. The physical examination in asthma shows a prolonged expiratory phase of respiration, variable degrees of chest hyperinflation, and wheezing accentuated by a forced expiratory effort. In musculoskeletal inflammation, one should be able to elicit tenderness of the chest wall and a “trigger point,” where palpation reproduces the pain. Reproduction of the pain by a “hooking maneuver” performed over the lower anterior ribs implicates the “slipping rib syndrome.” Pain following a dermatome unilaterally suggests intercostal neuritis; children with zoster (shingles) may have pain preceding the development of rash.

When focal, peripheral pain is found without a trigger point, the physician should consider pain referred from areas of sensory nerve overlap. A relationship of the pain to eating or swallowing suggests esophageal disease, and often, the physical examination may appear normal. Some of these patients will have a thin body habitus and/or cardiac findings of mitral valve prolapse. A foreign body (e.g., a coin) in the proximal esophagus commonly manifests with chest discomfort and drooling in the young child. Similarly, an aspirated foreign body may cause dull, aching chest pain associated with cough. Auscultation and plain radiographs of the chest do not always reveal the object or signs of an obstructed upper or lower airway. “Texidor's twinge,” or pericardial “catch,” is a relatively common cause of short duration and sharp pain in healthy teenagers and young adults, often related to exercise and located in the left substernal region. It may be produced by stretching of the supporting ligaments of the heart and is easily distinguishable from angina by its sudden, stabbing onset, a duration of less than 60 seconds, and the absence of referral to other areas. Cigarette smoking has been associated with chest pain in teenagers and adults.

A thorough examination usually uncovers evidence of the cardiac and respiratory causes of chest pain listed in the tables. In addition to the usual cardiac and pulmonary examination, one should search for trigger points on the chest wall and changes in pain associated with positional changes. Chest pain relieved by leaning forward is consistent with pericarditis; whereas that which is worsened by reclining may represent gastroesophageal reflux or hiatal hernia. Extrathoracic abnormalities, such as a rash or arthritis, may provide clues to collagen disorders (see Chapter 101) or other systemic illness. Marfan's syndrome should be suspected in the tall, thin patient whose upper extremity span exceeds his or her height. During examination of the heart and lungs, it is useful to relate normal findings to the child and family because this reassurance often serves as the major “treatment” of self-limiting or functional problems.

Laboratory studies sometimes are indicated to help confirm a diagnosis or to relieve the anxiety of the child or family. Pulse oximetry is a quick and inexpensive screen that is helpful in determining the severity of any suspected pulmonary disease. Chest radiographs may reveal findings consistent with asthma, pneumonitis, pleurisy, or spontaneous pneumothorax. Foreign bodies ingested and lodged in the esophagus can be visualized if radiopaque (e.g., coins). In the cervical esophagus, they will lie flat in the posteroanterior view of the chest. However, foreign body aspiration most often manifests by hyperinflation or atelectasis on radiographs because most tracheobronchial foreign bodies are not radiopaque. Inspiratory and expiratory films or decubitus chest radiographs may help demonstrate focal hyperinflation (i.e., the lobe with an obstructed bronchus remains inflated in expiration or when placed on the down side on a decubitus film). The wide mediastinum from an aortic aneurysm, abnormal cardiac silhouette related to a pericardial effusion or cardiomegaly, rib fractures or bone changes of metabolic bone derangements, and cysts all produce characteristic radiographic changes. A calcified ring may be visualized in approximately one-third of patients with a history of Kawasaki disease. The presence of atelectasis may suggest mucous plugging or may be subtle evidence of pulmonary infarction from an embolus or a vaso-occlusive crisis of sickle cell anemia.

An ECG should be performed if cardiac disease is suspected. The ECG will be normal in most cases in which the physical examination is unremarkable. It may show signs of cardiac strain or ischemia with valvular heart disease, diseases of outflow obstruction, or angina. Acute cocaine exposure may present with classic signs of myocardial ischemia or myocardiopathy. A decreased QRS wave voltage and electrical alternans suggest the presence of a pericardial effusion in the child with muffled heart sounds. Arrhythmias, such as atrial fibrillation and supraventricular tachycardia, may be identified by careful evaluation of a rhythm strip.

Studies other than chest radiographs and ECGs are rarely necessary. An elevated leukocyte count with a shift to the left may point toward infection as the cause of pain. Examination of a peripheral smear and a hemoglobin electrophoresis are indicated in the child suspected of having sickle cell disease as the cause of chest pain. If an intra-abdominal source for chest pain from diaphragmatic irritation is under consideration, a serum amylase may be obtained when considering pancreatitis. If a right-sided subdiaphragmatic abscess is possible, alanine aminotransferase (ALT) or aspartate transferaminase (AST) elevation may reveal the inflammatory nature of the process further delineated by ultrasound or computed tomography (CT) scan. Esophageal causes of chest pain often may be diagnosed clinically in the ED with a trial of antacid therapy. To confirm the findings of a hiatal hernia, esophagitis, or a nonopaque foreign body, a barium study or endoscopy may be required. Pulmonary embolus, presenting occasionally in the older teenager or debilitated patient, may be suspected clinically. Low Pa_{O_2} and/or ECG abnormalities are suggestive. This suspected diagnosis requires the performance of nuclear ventilation-perfusion scans or angiography for confirmation. Toxicologic screens are useful if the patient is considered at risk of drug abuse, particularly cocaine, or the diagnosis remains unclear.

A large group of children with chest pain will have no evidence of organic disease and no history of underlying cardiorespiratory disease or trauma. They may have a family history of chest pain. Often, there will be a stressful situation that has precipitated the episode. Complaints of chest pain and other somatic aches often are chronic, with no abnormalities noted on the physical examination. Such children have psychogenic chest pain. To elicit the predisposing factors, the physician should interview the child and family away from the chaos of the ED, if possible. Often, a chest radiograph and an ECG are helpful in allaying parental fears of cardiac disease. Definitive ongoing management, however, requires referral to a primary care physician.

SUMMARY

Chest pain in children is a relatively uncommon sign of serious disease but often has great importance to the patient or family. Most cases can be diagnosed by the emergency physician from the history and physical examination alone, although at times, a chest radiograph or an ECG is helpful. The physician should always consider drug-induced chest pain (especially associated with cocaine) and other life-threatening conditions. Psychogenic chest pain is a common occurrence and may be chronic or related to an acute stressful event. The possibility of cardiac disease needs to be addressed directly by the examining physician to alleviate fully the patient's (or family's) anxiety. The most common causes of organic chest pain are musculoskeletal (traumatic or inflammatory) and infectious disorders, usually self-limiting or easily treated diseases. Occasionally, serious abdominal, pulmonary, or cardiac problems require immediate attention.

CHAPTER 53

Pain—Dysphagia

***RONALD A. FURNIVAL, MD and †GEORGE A. WOODWARD, MD**

** Department of Pediatrics, University of Utah School of Medicine, Department of Pediatric Emergency Medicine, Primary Children's Medical Center, Salt Lake City, Utah;*

† Department of Pediatrics, The University of Pennsylvania School of Medicine, and Emergency Transport Services, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

The primary function of swallowing is the ingestion, preparation, and transport of nutrients to the digestive tract. Secondary functions of swallowing are the control of secretions, clearance of respiratory contaminants, protection of the upper airway, and equalization of pressure across the tympanic membrane through the eustachian tube. Dysphagia is defined as any difficulty or abnormality of swallowing. Dysphagia is not a specific disease entity but is a symptom of other, often clinically occult, conditions and may be life-threatening if respiration or nutrition are compromised. Odynophagia (pain on swallowing) or sialorrhea (drooling) may also be present in the dysphagic pediatric patient. This chapter briefly presents the normal anatomy and physiology of swallowing, the differential diagnosis of disturbances of this process, and the evaluation and treatment of the pediatric patient with dysphagia.

PATHOPHYSIOLOGY

Swallowing begins in utero as early as the 16th week of gestation, playing an important role in gastrointestinal development and regulation of amniotic fluid volume. By the 34th week of gestation, this complex process, involving 26 muscles, 6 cranial nerves (V, VII, IX, X, XI, XII), and cervical nerves C1–C3, is functional, although incompletely coordinated with breathing. In the first few days after birth, each infant develops an individual pattern of sucking, swallowing, and breathing, usually with a 1:1 or 1:2 ratio of breaths per suckle, to prevent aspiration of material into the larynx. This stage of suckling, or suckle feeding, is primarily under medullary control, with minimal input from the cerebral cortex. A transitional period begins at 6 months of age, as the cortex gradually exerts more control over the preesophageal phase of swallowing, allowing for the introduction of solid foods. The preesophageal region depends on normal sensorimotor function of cranial nerves V, VII, IX, and XII, which enervate voluntary skeletal muscles of the face, tongue, and neck, as well as the involuntary muscles of the posterior pharynx. Swallowing in the esophageal region remains an autonomic process, with vagal sensorimotor control coordinating peristalsis of the upper striated and lower smooth muscle of the esophagus. By 3 years of age, the swallowing pattern is mature, although the pediatric patient, unlike the adult, may regress to a less mature stage if normal swallowing is disrupted.

To facilitate suckle feeding and breathing, the infant oropharynx is anatomically different from the adult, with a relatively larger tongue, smaller oral cavity, and more anterior and superior epiglottis and larynx. As the face and mandible grow, the oropharynx enlarges, creating more room for the eventual voluntary use of the tongue and dentition, and the larynx descends, eventually allowing for mouth breathing. Although breathing continues to cease during swallows, the older child depends less on close coordination between eating and breathing.

A normal swallow, using the suckling infant as an example, begins with rhythmic movement of the lips, tongue, and mandible. These parts function as a unit, creating negative intraoral pressure, while also compressing the nipple. The milk expressed from each suckle is stored in the posterior oral cavity until a larger fluid bolus is formed. As the tongue delivers the bolus to the pharynx, the nasopharynx is closed off by the posterior tongue and by elevation of the soft palate. The larynx elevates to a position under the tongue, closing the airway, as the epiglottis inclines to direct the bolus posterior. A pharyngeal wave of contraction sweeps the bolus toward the upper esophagus, where the cricopharyngeal sphincter relaxes, allowing passage into the esophagus. As the esophagus begins peristaltic contractions and the bolus moves past a relaxed lower esophageal sphincter into the stomach, the airway reopens, the cricopharyngeal sphincter constricts to close the upper esophagus, and respirations resume. Dysphagia can result from disruption of normal mechanisms at any stage of the swallowing process.

DIFFERENTIAL DIAGNOSIS

The differential diagnostic list for dysphagia is extensive and is commonly divided into preesophageal or esophageal disorders (Table 53.1). Preesophageal causes of dysphagia are further subdivided into anatomic categories, including nasopharyngeal, oropharyngeal, laryngeal, and generalized problems. Infectious and inflammatory disorders of either anatomic region may disrupt swallowing, whereas neuromuscular problems tend to be predominantly preesophageal, given the autonomic function of the esophagus. However, the esophagus can be affected by motility disorders intrinsic to smooth muscle. Finally, the differential diagnosis includes several systemic conditions that may affect the normal swallowing process.

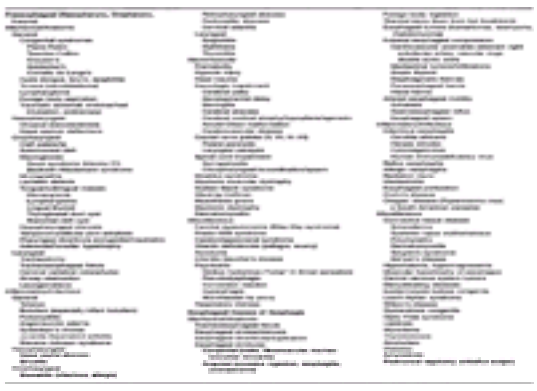

Table 53.1. Differential Diagnosis of Dysphagia

In the adult patient, dysphagia most commonly results from a variety of neuromuscular disorders, whereas the pediatric patient more often has swallowing difficulty from congenital, infectious, inflammatory, or obstructive causes (Table 53.2). In the newborn or infant, swallowing may be disturbed as a result of prematurity, often associated with respiratory and neurologic disabilities. Gastroesophageal reflux is common in infants, although in a small percentage of patients, it may persist into childhood with reflux esophagitis. Ingestion or aspiration of a foreign body must always be considered in the toddler who has either the acute or chronic onset of dysphagia.

Newborn/Infant	*Child*
Prematurity	Foreign body aspiration/ingestion
Tracheoesophageal fistula	Caustic ingestion
Choanal stenosis/atresia	Infectious
Birth trauma	Neurologic impairment (cerebral palsy, mental retardation, head trauma)
Congenital abnormalities	Inflammatory
Gastroesophageal reflux	
Respiratory illness	
Neurologic/neuromuscular disease	
Infectious (botulism, candidiasis, herpetic esophagitis)	
Inflammatory	

Table 53.2. Common Causes of Dysphagia

Life-threatening causes of dysphagia may involve airway compromise, serious local or systemic infection, and inflammatory disease (Table 53.3). The newborn may have a congenital anatomic abnormality such as tracheoesophageal fistula, with aspiration of swallowed fluid into the lungs, or may have traumatic injury to the upper airway and esophagus from iatrogenic instrumentation in the delivery room. The older child may have a foreign body in the airway or esophagus, with the possibility of complete airway obstruction (see Chapter 29). Numerous infectious processes may present with dysphagia and can threaten airway integrity. These include epiglottitis, retropharyngeal abscess, Stevens-Johnson syndrome, and central nervous system (CNS) infections.

Foreign body aspiration/ingestion	Polio
Tracheoesophageal fistula	Diphtheria
Upper airway obstruction	Central nervous system infection/ abscess
Traumatic esophageal perforation	Stevens-Johnson syndrome
Epiglottitis	Corrosive ingestion
Retropharyngeal abscess	Laryngeal paralysis
Botulism	
Tetanus	

Table 53.3. Life-Threatening Causes of Dysphagia

EVALUATION AND DECISION

The evaluation of dysphagia in the pediatric patient begins with a detailed history, including pregnancy and delivery, family history, feeding history, growth and development, and a history of other illness (Table 53.4). An accurate and complete history should suggest the diagnosis in approximately 80% of patients. Prenatal polyhydramnios, maternal infection, maternal drug or medication use, bleeding disorders, thyroid dysfunction, toxemia, or irradiation may lead to swallowing problems in the newborn or infant. Fetal neurologic development may be altered by prenatal difficulties and may result in dysphagia after birth. Maternal myasthenia gravis may also cause temporary feeding problems in the newborn.

Table 53.4. Important Historical Features for Dysphagia

A history of traumatic delivery may result in neurologic injury or laryngeal paralysis. Newborn intubation may be associated with trauma to the trachea, larynx, or esophagus, as well as hypoxic brain injury. A history of prematurity, developmental delay, failure to thrive, hypotonia, or associated congenital abnormalities may indicate a neuromuscular cause for dysphagia. The feeding history should include acute or chronic onset of symptoms, age at onset, weight loss, failure to thrive, and type and amount of food the child eats. Presence of fever, pain, respiratory symptoms, facial color, stridor, liquid or solid food intolerance, vomiting, regurgitation, drooling, voice change, position during feeding, and the timing of symptoms in relation to feedings should also be documented. For example, the infant with an upper airway obstruction may become fatigued or begin coughing and choking shortly after beginning to eat. Anatomic abnormalities of the trachea, larynx, or esophagus commonly present in infancy as respiratory problems during feeding, although vascular lesions that result in extrinsic compression of the esophagus may remain silent until the introduction of solid foods, and occasionally into adulthood. Gastroesophageal reflux in infants may manifest as vomiting shortly after feeding or with a history of nighttime cough or emesis. Intrinsic lesions, from inflammation, tumor, or foreign body, may create problems with solid food but cause no difficulty with liquids. Infants with previously unrecognized neuromuscular disorders commonly present initially with dysphagia, particularly for liquids; drooling; prolonged feeding time; weak suckle; or nasal reflux of swallowed material. A history of fever may indicate an aspiration pneumonia or other infectious or inflammatory causes of dysphagia.

The child with dysphagia should undergo a thorough general physical examination, initially focusing on the patient's cardiopulmonary status. Evidence of respiratory distress or cardiovascular compromise should be treated promptly in the appropriate manner, as outlined elsewhere in this text (see Chapter 1, Chapter 2, and Chapter 5). Assurance of a secure and stable airway should precede attempts to examine the oropharynx or to remove a foreign body (see Chapter 29).

In the stable dysphagic patient, evaluation of head size and shape, facial structure, mandibular development, tongue disproportion, and ear configuration may provide evidence of an underlying congenital abnormality, such as Pierre-Robin, Treacher-Collins, Crouzon's, and Goldenhar's syndrome. Evaluation of nasal airway patency in the infant can be determined by gently passing an 8-Fr catheter through the nares into the stomach. If the catheter fails to pass easily, choanal stenosis, atresia, or esophageal obstruction must be considered. Inspection of the oral cavity, pharynx, and neck may reveal a cyst, mass, localized infection, or inflammatory cause for dysphagia. Cervical auscultation over the thyroid cartilage during feeding may note evidence of aspiration if upper airway breath sounds are abnormal or if the timing of breathing and swallowing is uncoordinated. The pulmonary examination may also detect signs of aspiration or respiratory compromise, including elevated respiratory rate, increased respiratory effort, stridor, stertor, rales, rhonchi, wheezing, or change in voice quality. Neurologic examination may reveal an altered level of arousal from an underlying brain injury or depressed sensorium from drugs or infection that may limit effective swallowing. Examination of the cranial nerves, particularly V, VII, IX, X, and XII, may reveal abnormalities from traumatic or surgical injury, tumor, or congenital disorder. Evaluation of muscle tone, strength, and reflexes in consideration of other neuromuscular causes of dysphagia completes the general physical examination.

Provided oral intake is not contraindicated by an expected procedure or intervention, observation of a typical feeding, given by a parent or primary caretaker, may help elucidate the cause of dysphagia. The manner of presentation of food to the patient, the consistency and amount given, patient position, duration of feeding, regurgitation (oral or nasal), agitation or behavior change, or the development of respiratory symptoms may further guide the diagnostic evaluation. Patients with upper airway obstruction may have an exacerbation of symptoms when attempting to drink. Patients with lesions such as tracheoesophageal fistula, vascular rings, or esophageal obstruction may begin coughing and choking soon after drinking without any initial difficulty. However, esophageal disorders such as extrinsic compression, strictures, tumors, or altered motility commonly are clinically silent and typically require use of radiographic or direct visual techniques for diagnosis.

Evaluation of the stable dysphagic patient may proceed on the basis of age and acute versus chronic onset of symptom development (Fig. 53.1). The neonate and young infant will require evaluation techniques and consideration of the age-related differential diagnoses outlined in Table 53.2, whereas the older child with an acute onset of dysphagia generally requires a more urgent approach. Witnessed or suspected foreign bodies, either ingested or aspirated, should be investigated with plain radiographs (or contrast studies if a radiolucent object is considered) and, if identified, emergently removed (see Chapter 29). A history of neck trauma or caustic ingestion should lead to the suspicion of aerodigestive tract abnormalities. These patients may present dramatically with neck pain, drooling, and evidence of facial or other trauma, but they may also have a subacute presentation (see Chapter 88, Chapter 106, and Chapter 112). Presence of fever or signs of systemic illness may result from potentially life-threatening infectious or inflammatory conditions (Table 53.3). Less severe problems (gingivostomatitis or thrush) may present with mouth lesions and can be managed on an outpatient basis after careful assessment of hydration status. Severe problems, including Stevens-Johnson syndrome, herpetic esophagitis, and diphtheria, may be disc overed on a detailed examination and

may require inpatient management.

FIGURE 53.1. Evaluation scheme for the child with dysphagia or odynophagia. *Radiographic options:* neck, chest, abdomen, inspiratory/expiratory films, lateral decubitus films, fluoroscopy, contrast studies, ultrasonography, echocardiography, angiography, computed tomography, magnetic resonance imaging. *Laboratory options:* complete blood count, blood gas, cultures, toxin identifications, nutritional and electrolyte profile. *Consultant's options:* pediatrics, general surgery, otolaryngology, gastroenterology, neurology, infectious disease, cardiology, pulmonology, rheumatology, oncology, nutrition, speech therapy, occupational therapy.

Patients with a nonacute history of swallowing difficulty can be evaluated and treated as shown in Figure 53.1. The initial emphasis with these patients lies more in determination of nutritional status and development issues than in acute emergency department (ED) intervention, although prolonged feeding difficulty can develop into a life-threatening problem. The child with obvious anatomic abnormalities, neurologic impairment, specific syndromes, or a tracheostomy may need referral to appropriate subspecialists after initial evaluation. The child without obvious anatomic or neurologic abnormality who has weight loss or failure to thrive may be evaluated as an outpatient.

Radiographic evaluation of the stable dysphagic patient usually begins with an examination of the airway and soft tissues of the neck, looking for evidence of a foreign body, mass, airway impingement, or other abnormality. A chest radiograph may suggest aspiration pneumonia, congenital heart disease, or mediastinal abnormality or, as in the patient with achalasia, demonstrate fluid levels within an enlarged esophagus. Computed tomography (CT) scan, echocardiography, or angiography may further identify problems suspected from initial studies.

A videofluoroscopic swallowing study (VFSS or modified barium swallow) is currently the gold standard for evaluating preesophageal disorders. The patient is fed a typical solid or liquid diet (mixed with contrast material) by his or her parent or caretaker, while the radiologist records the preesophageal and esophageal swallowing phases on videotape. With a swallowing specialist present, such as a speech–language pathologist, the feeding presentation and position, consistency, amount, and type of foods can be varied, both to diagnose problems resulting in dysphagia or aspiration and to evaluate possible therapeutic interventions. This dynamic study may reveal evidence of aspiration, nasopharyngeal reflux, motility disorders, obstructions, masses, cricopharyngeal dysfunction, fistulas, inflammatory processes, or other causes of dysphagia. VFSS differs from the standard barium swallow (BS) or upper gastrointestinal (UGI) series in that it does not use pure contrast but instead uses food mixed with contrast in an attempt to simulate the normal feeding pattern as closely as possible. VFSS is less effective than a UGI series or BS at diagnosing gastroesophageal reflux or lower esophageal, gastric outlet, and small bowel abnormalities (Fig. 53.2), but it is superior in identifying preesophageal causes of dysphagia.

FIGURE 53.2. Upper gastrointestinal series (UGI) of a 14 year old girl presenting with dysphagia. The UGI demonstrates a significantly dilated upper esophagus, with a functional spasmodic obstruction of the lower esophagus, characteristic of achalasia.

Fiberoptic endoscopy under local or general anesthesia may be indicated for suspected mass lesion, stricture, caustic ingestion, inflammatory lesion, or foreign body. Endoscopy may also be used to obtain biopsy specimens to aid in diagnosis. In addition, nasopharyngoscopy allows direct visualization of the swallowing process and can document aspiration and functional esophageal disorders.

Other tests, such as a complete blood count, appropriate cultures in the febrile patient, or arterial blood gas for the

patient with respiratory distress, also may be indicated. Cervical ultrasonography has been used to identify abnormalities with the tissues and function of the palate, tongue, and floor of the mouth but is less useful than contrast studies for assessing airway problems and aspiration. Manometry may be useful in the dysphagic patient with an esophageal motility disorder, but it is better tolerated and more typically used in adults. Esophageal pH testing or radionuclide scintigraphy (milk scans) may document previously unsuspected gastroesophageal reflux. Additional neurologic testing may include studies of brainstem-evoked responses, peripheral nerve conduction, or electromyography.

Treatment of dysphagia is dictated by the diagnosis. Disorders with the potential to become life-threatening should be treated in the hospital under the care of appropriate specialists. If nutrition has been severely compromised from chronic dysphagia, one should consider nasogastric, nasojejunal, or gastrostomy tube feedings. Many pediatric facilities have developed multidisciplinary feeding/swallowing teams to provide subspecialty expertise, while maintaining continuity and coordination of patient care. Such pediatric teams may include developmental or general pediatricians, speech–language pathologists, pulmonologists, otolaryngologists, gastroenterologists, neurologists, nutritionists, psychologists, occupational or physical therapists, and social service workers. If such a specialty service is not available, involvement of appropriate individual specialists for the management of the patient with dysphagia is imperative as mentioned in Figure 53.1. However, therapy for many disorders can be initiated on an outpatient basis. Gastroesophageal reflux and resultant esophagitis can often be successfully managed with small volume thickened feeds, positioning, and elevation of the head of the bed. Medical therapy consists of liquid antacids, cisapride (a gastric motility agent), and H_2-blockers. Mycostatin will be helpful in candidal esophagitis, whereas herpetic esophagitis often is self-limiting.

Pediatric dysphagia is an uncommon complaint in the pediatric ED but may be the presenting symptom for a wide variety of underlying clinical problems. The history and physical examination first must focus on potentially life-threatening causes and will often lead to a specific diagnosis. Causes of dysphagia not identified from the initial evaluation may require radiographic or subspecialty referral for further diagnostic and therapeutic management.

CHAPTER 54

Dysuria

GARY R. FLEISHER, MD

Department of Pediatrics, Harvard Medical School, and Division of Emergency Medicine, Children's Hospital, Boston, Massachusetts

Dysuria, or the sensation of pain when voiding, stems from irritation of the bladder, the urethra, or both. The sensation is produced by the contraction of the bladder and the peristaltic activity of the urethra, both of which stimulate the pain fibers of the edematous and erythematous mucosa. In addition, 1) young children may complain of painful urination when they are instead experiencing related symptoms, such as pruritus, and 2) parents may interpret various nonspecific statements or behaviors by their children as indicative of painful urination.

Dysuria is a commonly reported symptom that has a number of different causes (Table 54.1), but it usually stems from one of several common disorders of childhood and adolescence (Table 54.2). Most children with dysuria as a chief complaint have disorders of the genitourinary tract. Although patients with urethritis secondary to systemic illnesses may have dysuria as one of their many symptoms, it is only occasionally the principal reason for a visit to an emergency department (ED).

I. Systemic Conditions
  A. Stevens-Johnson syndrome
  B. Reiter's syndrome
  C. Behçet's syndrome
II. Localized Conditions
  A. Infection
    1. Pyelonephritis
    2. Cystitis
      a. Viral
      b. Bacterial (*Escherichia coli* and other organisms)
    3. Urethritis/balanitis
      a. *Neisseria gonorrhoeae*
      b. *Chlamydia* species
      c. Herpes simplex
      d. Other
  B. Chemical Irritation
    1. Detergents
    2. Fabric softeners
    3. Perfumed soaps
    4. Bubble baths (?)
    5. Medication
  C. Trauma
    1. Local injury
    2. Masturbation
  D. Miscellaneous
    1. Hypercalciuria/urinary stones
    2. Labial adhesions
    3. Psychogenic dysuria
III. Complaints Misinterpreted as Dysuria
  A. Pinworms
  B. Sexual abuse

Table 54.1. Causes of Dysuria

Disorder	Cause	Age	Fever	Tenderness
Pyelonephritis	*E. coli* other bacteria	All	Common, >38.8°C	Flank
Cystitis	Viruses*E. coli* other bacteria	All	Occasional, <38.8°C	Suprapubic
Infectious arthritis	*N. gonorrhoeae* *C. trachomatis*	Adolescents	None	Prominent joint (occasional)
Chemical/traumatic arthritis	Physical insult	Children	None	None

Table 54.2. Differential Diagnosis of Common Causes for Dysuria

Most diseases causing dysuria are self-limited or easily treated; however, the rarely seen systemic causes of urethritis or the spread of some bacterial pathogens beyond the genitourinary tract may be life-threatening (Table 54.3)

Stevens-Johnson syndrome
Gonococcal urethritis/vaginitis (when complicated by pelvic inflammatory disease or systemic spread)

Table 54.3. Life-Threatening Causes of Dysuria

DIFFERENTIAL DIAGNOSIS

Systemic Conditions (Table 54.1)

Stevens-Johnson syndrome is a severe manifestation of erythema multiforme, which may affect the mucous membranes throughout the body, producing conjunctivitis, oral ulceration, and urethritis. The rash that occurs in most patients often has the appearance of target lesions. Although usually self-limited, in some cases, pulmonary involvement leads to death.

Reiter's syndrome is characterized by conjunctivitis, arthritis, and urethritis. Rarely diagnosed, it is more common in males.

Also rare, Behçet's syndrome is another multisystem disease that may cause urethral ulceration and dysuria.

Localized Conditions (Table 54.1)

Infection of the genitourinary tract is the predominant cause of dysuria. Pyelonephritis is the most serious of these disorders, usually manifesting with fever, often above 39°C (102.2°F), and flank pain or tenderness (older children and adolescents). Patients with cystitis may or may not have fever, which is usually low grade, and suprapubic pain or tenderness. Urethritis is a more localized infection, which often produces a discharge. In adolescents, *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are the most common pathogens. When herpes simplex causes urethritis, vesicles are usually apparent on examination. Younger children may develop a nonspecific bacterial urethritis with involvement of the glans penis (balanitis) or both the glans and the prepuce (balanoposthitis). In the setting of an urban ED, infectious urethritis and/or cervicitis may be the source of isolated dysuria in up to 30% of adolescent girls and often goes undiagnosed when only a urine specimen, and not a cervical swab, is sent for culture.

In young children, certain drugs taken systemically and topical exposures to a variety of chemicals have been reported to irritate the urethral mucosa; however, these findings have not been well documented. Potential local irritants include detergents, fabric softeners, perfumed soaps, and possibly bubble baths. These patients have either no physical findings or only mild erythema but no discharge.

Minor injury is another relatively common cause of urethral irritation. In older children and adolescents, normal self-exploratory sexual play, masturbation, voluntary sexual activity, or sexual abuse may be the source of the trauma. As for patients with chemical urethritis, the examination is generally unremarkable.

The passage of a stone is an uncommon cause of dysuria in children. In these cases, the dysuria is usually proceeded by flank pain and is often accompanied by hematuria. Generally, urinary stones in children develop in the setting of anatomic abnormalities and/or recurrent infection. Exceptions to this rule are children who are otherwise healthy but have idiopathic hypercalciuria; these children may develop calculi. In addition, these patients have been reported to complain of dysuria even in the absence of an observable stone.

Labial adhesions occur relatively often in young girls. Although they are most often asymptomatic, they may cause dysuria on occasion.

Throughout childhood and into adolescence, a complaint of dysuria may be psychogenic in origin, occurring in the absence of inflammation in the genitourinary tract.

Complaints Misinterpreted as Dysuria (Table 54.1)

Enterobius vermicularis (pinworms) infests the perianal area, but occasionally spreads to the vagina in young girls. The pruritus that accompanies this infestation may be expressed as dysuria.

Young children who have experienced sexual abuse may complain of pain in their genital area or may exhibit behaviors that are interpreted by adult observers as indicative of genital pain. These patients may appear in the ED with a chief complaint of dysuria.

EVALUATION AND DECISION

When evaluating a child with dysuria, the physician should ask about trauma and exposure to chemicals such as detergents, fabric softeners, perfumed soaps, bubble baths, and medications that have been reported to irritate the mucosal lining of the urethra or bladder. A negative history for injury may not be accurate because most trauma is not recalled by young patients or, in the case of masturbation or abuse, may be denied. The detection of sexually transmitted diseases, a common cause of dysuria in adolescents, may be facilitated by obtaining a history about the nature and extent of sexual activity.

Some children may have a suggestive constellation of symptoms and signs in addition to dysuria. As examples, the adolescent girl with abdominal and pelvic discomfort probably has pelvic inflammatory disease and the 6-year-old child with fever and flank pain most likely has pyelonephritis. Various systemic disorders (Table 54.1) may cause conjunctivitis, oral ulceration, arthritis, and cutaneous lesions.

In addition to a routine physical examination, special attention should be directed to the genitourinary tract. A swollen or edematous urethral meatus or a discharge from the urethra or vagina will localize the source of the symptoms in an otherwise well child to the genitalia, obviating the need to look extensively for other diseases. In particular, vesicles occur with infections caused by herpes simplex. Labial adhesions are easily recognized on inspection in young girls.

The most important tasks for the emergency physician are to recognize the rare but serious systemic syndromes and to diagnose or exclude infections (Fig. 54.1). If the history and general examination do not suggest a systemic condition, the next step is to examine the genitalia. Lesions, such as vesicles or ulcers, in this area are seen with Stevens-Johnson and Behçet's syndrome, but they more likely represent an infection with herpes simplex, even in the preadolescent child.

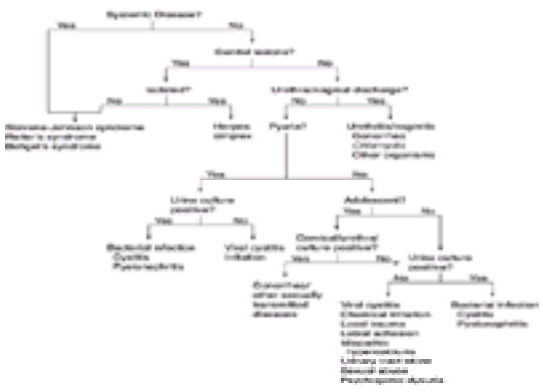

FIGURE 54.1. Approach to the diagnosis of dysuria.

A urethral or vaginal discharge suggests an infection of the genitalia: urethritis in the boy, and urethritis or vaginitis in the girl. *N. gonorrhoeae* is an organism that commonly causes disease in this area. A Gram stain often provides a clue to the diagnosis. In prepubertal girls or boys of any age, the finding of Gram-negative intracellular diplococci points to the diagnosis of gonorrhea. In contrast, because nonpathogenic organisms that colonize the vagina after puberty have the same appearance as *N. gonorrhoeae* on Gram stain, the smear is an unreliable tool in teenage girls. A urethral or vaginal culture should be obtained for confirmation and susceptibility testing. Postpubertal patients may be treated in the ED, but treatment in young children should await the results of cultures because of medical-legal implications.

If no discharge is seen, the physician should obtain a urinalysis and urine culture. A positive result on testing by dipstick (leukocyte esterase and/or nitrites) or the finding of pyuria (more than 5 to 10 white blood cells per high-power field) increases the likelihood of bacterial infection (urethritis, cystitis, or pyelonephritis) but does not prove the diagnosis. Inflammatory conditions, such as chemical urethritis, and nonbacterial infections may also evoke a leukocyte response. Thus, the physician may choose to allow the results of cultures to guide the management of children with pyuria, rather than immediately beginning antibiotic therapy, unless fever and flank pain point to pyelonephritis.

In the young child with dysuria in the absence of pyuria, local trauma and chemical irritation are the most likely causes for the pain. Because a few children with urinary tract infections (UTIs) do not have either a positive result on testing by dipstick or pyuria, most physicians obtain a urine sample for culture, particularly from febrile patients. On the other hand, some experts would argue that the likelihood of infection is low enough in the absence of positive indicators on urine analysis that no further testing is needed. Adolescents require cultures of the genital tract to diagnose mild gonococcal or chlamydial infections.

When no other cause for dysuria is found in a prepubertal girl who has adhesions of her labia minora, these adhesions may be responsible for the painful urination. Most girls with labial adhesions, however, are asymptomatic. Thus, infection or another cause for dysuria should be excluded in girls with this finding.

A few patients with a normal examination and negative cultures may complain persistently of dysuria. In this setting, idiopathic hypercalciuria provides a potential diagnosis. If suspected, the diagnosis can be confirmed by measurement of calcium excretion in the urine. Another possible explanation is that the patient is experiencing vaginal pruritus secondary to pinworms. Confirmation of this diagnosis requires either identification of the larvae or ova or a response to a trial of mebendazole.

Last, the physician should give consideration to both sexual abuse and psychogenic dysuria. In most of these cases, further evaluation outside of the ED will be needed.

INITIAL MANAGEMENT

When a specific diagnosis has not been established and the physician is awaiting the results of cultures, therapy directed at the symptom of dysuria can provide some relief. Generally, a dilute urine causes less irritation than a concentrated one, so a generous fluid intake should be recommended. For the child over 6 years of age, phenazopyridine (Pyridium) at a dosage of 100 mg given three times per day may be helpful as a urinary tract anesthetic.

CHAPTER 55

Pain—Earache

AMY M. ARNETT, MD

Department of Pediatrics, Boston University School of Medicine, and Department of Pediatric Emergency Medicine, Boston Medical Center, Boston, Massachusetts

Ear pain is a common symptom of many different conditions in or around the ear (Table 55.1, Table 55.2 and Table 55.3). Preverbal children may present with fussiness, crying, or waking intermittently at night. Children may have difficulty differentiating tinnitus from ear pain. Ear pain may be otogenic or nonotogenic in origin. A complete history and physical examination is necessary, focusing not only on the ear but on adjacent areas and those regions innervated by nerves which also innervate the ear. Areas that might be a source of referred pain include the oral cavity, larynx, pharynx, and cervical spine; rarely, referred pain may be from a site below the clavicles. Patients with accompanying central nervous system symptoms, vertigo, or cranial nerve deficits need more extensive evaluation.

Table 55.1. Causes of Earache

Otogenic	Nonotogenic
Acute otitis media	Dental caries or abscess
Otitis externa	Pharyngitis
Foreign body	Sinusitis
	Cervical adenopathy

Table 55.2. Common Causes of Earache

Hemotympanum secondary
to basal skull fracture
Local spread of acute
otitis media to:
mastoid cavity—subperiosteal abscess with acute mastoid osteitis
vascular structures—lateral sinus thrombosis
intracranial region—meningitis, extradural abscess, subdural empyema,
focal encephalitis, brain abscess
temporal bone—facial nerve paralysis
inner ear—labyrinthitis

Table 55.3. Life-Threatening Causes of Earache

DIFFERENTIAL DIAGNOSIS

Otogenic Causes

Trauma is usually evident by physical examination. Hematomas of the pinna resulting from blunt trauma may occur over the cartilaginous portion or upper half of the ear lobe between the perichondrium and the underlying cartilage. The hematoma may appear as a boggy, purple swelling. Sterile aspiration and a molded pressure dressing are necessary to avoid pressure necrosis of the underlying cartilage and a resulting “boxer's” or “cauliflower” ear.

The most common complication of ear piercing is superimposed infection—usually with *Staphylococcus aureus.* Treatment involves removal of the foreign body, the earring, and administration of an oral antistaphylococcal antibiotic such as dicloxacillin or a topical antibacterial ointment. Nickel earrings may cause earlobe dermatitis. These earrings should be replaced with gold or stainless steel earrings, and topical corticosteroids should be applied.

Preauricular pits are asymptomatic until they become infected. Physical examination reveals a warm, erythematous, tender area anterior to the tragus. Treatment includes oral antibiotics to cover skin flora, occasional incision and drainage, and referral for eventual resection.

Frostbite of the auricle is painful. The ear usually appears pallid secondary to vasoconstriction. With thawing, it becomes hyperemic and edematous, and vesicles may appear. It is treated by rapid rewarming with application of moist gauze or cloths soaked in water 37.8° to 40°C (100° to 104°F). Vesicles should be left intact. Analgesics are given for pain control. No debridement of damaged tissue is done until full demarcation of tissue loss is determined.

Furunculosis is a Gram-positive, usually staphylococcal infection of a hair follicle at the external auditory meatus that causes marked pain and occasional otorrhea. This generally occurs in the cartilaginous part of the canal and may cause cervical adenopathy. Treatment consists of heat application to encourage spontaneous drainage. Topical antistaphylococcal treatment or oral antistaphylococcal antibiotics such as dicloxacillin are rarely indicated. If spontaneous drainage does not occur, incision and drainage may be necessary. Coalescence of furuncles produces a carbuncle or abscess, which requires drainage.

Herpes zoster oticus, or Ramsay Hunt's syndrome, is a painful viral infection characterized by vesicles on the auricle, the external auditory meatus, and occasionally, the tympanic membrane (TM). It is caused by a residual viral infection of the seventh and eighth cranial nerves. Complications include facial paralysis, hearing loss, and vertigo. Other cranial nerves may be affected. Although this normally presents in adults, it may occur at any age. Patients in the early stages may be treated with acyclovir; otherwise, treatment is mainly symptomatic.

Otitis externa (OE) usually presents in warm, humid weather. Because swimming can predispose the canal to this condition, it is often called swimmer's ear. The initial presenting symptom may be pruritus. Scratching the canal may damage the skin and predispose the area to secondary bacterial infection. Ear pain, itching, and discharge are the primary complaints. Examination reveals a tender auricle, a mildly erythematous canal with edema, and foul-smelling, gray–green discharge. *Pseudomonas aeruginosa, S. aureus, Proteus*, and *Streptococcus* are causative organisms. Treatment includes cleaning and acidifying the ear canal, and possible antibiotic coverage for Gram-negative and Gram-positive organisms. An otic suspension combining antibiotics and an acidic medium with hydrocortisone for anti-inflammatory effect is the usual treatment. A wick may be used if the canal is too edematous to allow the drops to enter. If there is any accompanying cellulitis, oral antibiotics should be added. Ear plugs for swimmers and acidifying drops after swimming can be suggested to prevent recurrence. A serious complication of OE is malignant or necrotizing external otitis, which is a fulminant bacterial otitis externa with *P. aeruginosa*. This may extend beyond the limits of the external auditory canal, producing cellulitis, chondritis, osteitis, osteomyelitis, and facial nerve paralysis. These patients require further evaluation with computed tomography (CT), bone scan or gallium scan, otorhinolaryngology (ORL) consultation, and probable admission for combination intravenous antibiotics.

Impacted cerumen in the canal is a common cause of ear pain or discomfort. Ear wax removal is often necessary for evaluating ears. Careful immobilization is essential. Removal under direct visualization through an otoscope is ideal. An ear curette or small cotton swab may be used. Hard cerumen may cause bleeding with removal when adherent to the canal. The wax may be softened with a ceruminolytic agent, then irrigated with warm water. A plastic syringe attached to the plastic tubing end cut from a butterfly needle may be used. A water jet device may also be used, but it must be set on low pressure to prevent damage to the TM. A perforated TM is a contraindication to irrigation. An antibiotic/hydrocortisone otic suspension as prophylaxis to prevent OE after canal irritation or irrigation is sometimes recommended.

Foreign bodies can elicit a painful inflammatory reaction. Physical examination visually confirms a foreign body. Treatment is accomplished by removal with an ear curette, alligator forceps, or irrigation with warm water. Inflamed canals may be treated with topical antibiotic/hydrocortisone otic drops.

Otomycosis is a fungal infection of the external canal. It may be acute or chronic, primary or secondary to bacterial infection and prolonged use of antibiotic drops. *Aspergillus* and *Candida* are the most common pathogens. The primary complaint may be pruritus. On physical examination, the canal contains gray, white, or blackish debris that resembles dirty cotton and has an erythematous and edematous canal wall. Treatment consists of cleaning and acidifying the ear

canal and possibly applying topical antifungal drops such as nystatin.

Dermatoses of the ear can cause ear discomfort as well. Seborrheic dermatitis and psoriasis can affect the external auditory canal and produce scaling or drainage. The primary complaint may be itching. Usually, other areas are affected as well, including the retroauricular region and scalp. Removal of crusts can be helpful. Topical treatment consists of hydrocortisone.

Acute otitis media (AOM) is the most common illness resulting in office visits to physicians who care for children (see also Chapter 84). In 1990, approximately 25 million office visits in the United States were related to AOM. Reasons attributed to children having more infections include eustachian tube dysfunction secondary to its more horizontal position and shorter length in the child compared with the adult, immature or impaired immunology, and day-care center exposure. History often includes recent viral upper respiratory infection followed by deep-seated otalgia, fever, and decreased hearing. The three major bacterial pathogens are *Streptococcus pneumoniae* (pneumococcus), nontypeable *Haemophilus influenzae*, and *Moraxella catarrhalis. Streptococcus progenes, S. aureus,* and Gram-negative enteric bacilli are rare causes. The four major criteria when examining the TM for AOM are position, color, translucency, and mobility. AOM may show a hyperemic, opaque, bulging TM with poor mobility. The drum may be bulging with serous fluid or yellow pus in the middle ear space. The auricle is usually normal. A conductive hearing loss may result from accumulation of fluid in the middle ear and impairment of the drum motion. Treatment is administration of an oral antibiotic for 10 days. Amoxicillin remains the drug of choice because of its safety, low cost, and good taste. If symptoms do not abate in 48 hours, the patient should be examined, with consideration for changing therapy to cover resistant strains of *Haemophilus, Moraxella,* or pneumococcus. Second-line antibiotic choices include second- and third-generation cephalosporins, loracarbef, ampicillin/clavulanate, azithromycin, or intramuscular ceftriaxone. Oral decongestants, antihistamines, and intranasal decongestants have not proven to be effective. Approximately one-third of children have sterile effusions, which are presumed to be viral or unresolved effusions from previously treated infections. Pain may be treated with analgesics, such as acetaminophen or ibuprofen orally. Topical anesthetic drops may be used to provide temporary relief if there is no perforation. For those with tympanic perforation and purulent drainage, a topical antibiotic drop, such as an antibiotic/hydrocortisone otic suspension, is sometimes given to treat the inflammatory reaction in the ear canal. Perforated TMs usually heal spontaneously, but they may lead to more chronic unhealed perforations, cholesteatoma, or tympanosclerosis. Children with significant recurrent infections may require further evaluation for immunologic problems and/or an ORL consultation for myringotomy tube placement.

Although rare, dangerous complications of AOM include local spread to the mastoid cavity, soft-tissue and vascular structures of the neck, intracranial region and temporal bone, or inner ear. On examination for subperiosteal abscess with acute mastoid osteitis, the pinna may be displaced inferiorly and anteriorly with obliteration of the postauricular crease as a result of swelling. The ear drum may appear gray, not bulging or perforated. This most commonly occurs in infants 4 to 12 months old. Treatment includes antimicrobials and, in some cases, drainage. Facial or abducens nerve paralysis is rarely associated with AOM and is treated with antibiotics and consideration of surgical nerve decompression. Because of the location of the middle ear and mastoid air cells adjacent to the posterior and middle cranial fossa and sigmoid venous sinus of the brain, infection may spread to these adjacent structures, leading to intracranial complications such as meningitis, extradural abscess, subdural empyema, focal encephalitis, brain abscess, lateral sinus thrombosis, and otitic hydrocephalus. All patients with facial or abducens nerve palsy, vertigo, or central nervous system signs require further radiographic evaluation, such as CT scan.

Otitis media with effusion (OME) or serous otitis media is an inflammation of the middle ear in which a collection of liquid is present in the middle ear space, which is usually mucoid or serous without signs or symptoms of infection. These represent 25 to 35% of all otitis cases. In 1994, the U.S. Department of Health and Human Services published a Clinical Practice Guideline for treating otitis media with effusion in children 1 to 3 years of age, developed with the cooperation of several expert advisory groups. Although most effusions resolve spontaneously, the length of time for resolution is variable and there is significant concern regarding conductive hearing loss during this critical age of speech and language development. Physical examination should include pneumatic otoscopy to test TM mobility. Tympanometry may be used to confirm an effusion. For healthy children with no craniofacial or neurologic abnormalities or sensory deficits, the effusion may be managed with observation or antibiotic therapy. For OME, bacterial pathogens are identified in about one-third of children. Many studies have shown that antibiotics provide only temporary resolution of fluid. Steroids, antihistamines, and decongestants are not recommended. Chronic effusions may require tympanostomy tube placement for drainage by ORL.

TM perforation may be caused by pressure from fluid behind the membrane or by external trauma. Trauma often occurs with compressive injuries such as a slap with an open hand or injuries from instruments such as cotton-tipped applicators being placed into the ear canal. Pain may be severe immediately after the injury, but it becomes duller with time. Most perforations heal spontaneously. The use of prophylactic antibiotic ear drops is controversial—if chosen, most suggest suspension over solution. Oral antibiotics are reserved for injuries from contaminated objects or those in a location believed to be infectious. If the perforation involves more than 20% of the drum, a referral for possible repair is needed. Acute hearing loss, facial paralysis, and severe vertigo associated with the perforation call for ORL evaluation because of possible ossicular damage or direct injury to the facial nerve or labyrinth.

Bullous myringitis is a painful, usually viral but possibly bacterial or mycoplasma infection of the TM characterized by serous or hemorrhagic vesicles or blebs. Treatment consists of analgesics and possible oral antibiotics.

Hemotympanum secondary to basal skull fracture may be a serious finding on examination of the ear. The TM may appear dark red or purple secondary to the blood behind it. These patients may have other findings consistent with basal skull fractures such as Battle's sign—ecchymoses behind the ear, raccoon eyes—periorbital ecchymoses, or cerebrospinal fluid (CSF) drainage from the nose or ears. A CT scan to determine the extent of the injuries is indicated. Often, no therapy is needed and antibiotic prophylaxis is controversial.

Aerotitis, or acute barotitis, is a special type of AOM caused by middle ear barotrauma. A sudden change in altitude in an airplane or the pressure exerted during deep sea diving can cause eustachian tube closure and produce a severe and

painful pressure change in the middle ear with extravasation of blood into the middle ear space. The drum may appear blue because of bleeding behind it. The patient has severe pain and hearing loss. Physical examination reveals a hemorrhagic TM. The process is self-limited, lasting 2 to 3 days and resolving spontaneously. Treatment consists of analgesics for pain and decongestants to encourage opening of the eustachian tube. Myringotomy is performed only for severe pain or persistent fluid.

Cholesteatomas may be visualized in the middle ear. These cystlike structures, which consist of epithelial cells and cholesterol, may be congenital or acquired, often secondary to previous perforation with residual TM epithelial cells in the middle ear. Enzymes formed within the sac may cause erosion of adjacent bones. Although rare, abnormal growths in the canal or middle ear must be evaluated for possible neoplasm and should be referred for evaluation by ORL.

Nonotogenic Causes

Inflammation, infection, neoplasm, or trauma along the course of any nerves innervating the auricle or the external auditory canal, including cranial nerves V, VII, IX, and X and cervical nerves C2 and C3, can produce pain that the patient may interpret as originating in the region of the ear. Therefore, a full head and neck examination, as well as radiographic examinations may be necessary to disclose the cause of ear pain.

The trigeminal nerve (V) supplies some of the most common areas of referred ear pain, including those of dental origin such as erupting teeth or abscesses and oral mucosal ulcerations from aphthous ulcers or viral stomatitis. Sinusitis, sialadenitis, or lymphadenitis in these regions may also cause pain. Early mumps may present as ear pain before obvious parotid swelling.

Facial nerve (VII) pain may be a precursor of Bell's palsy or herpes zoster oticus.

The glossopharyngeal nerve (IX) supplies the oropharynx, nasopharynx, and posterior third of the tongue. Inflammation of these areas, such as with pharyngitis or tonsillitis, is another common cause of referred earache. Peritonsillar abscess or cellulitis may produce unilateral pain. Earache may also occur after adenotonsillectomy. Nasopharyngeal or oropharyngeal tumors, such as lymphoma or rhabdomyosarcoma, although rare in children, may be associated with ear pain.

The vagus nerve (X) supplies the base of the tongue, larynx, and trachea. Inflammatory or mass lesions in these areas may refer pain to the ear.

Cervical nerves C2 and C3 supply the mastoid and posterior pinna; therefore, ear pain may result from cervical spine injuries, arthritis, or disc disease as well as any generalized neck disorder.

When otologic examination is normal and no pathology is found in the distribution of the cranial or cervical nerves the pain may be psychogenic, especially in a person with anxiety or depression. Also, children may not be able to describe tinnitus and refer to it as pain. Certain drug ingestions such as quinine, quinidine, salicylates, nicotine, ethacrynic acid, and aminoglycosides are possible causes.

EVALUATION AND DECISION

A history is always important in determining the cause of pain or discomfort and should include questions about other ear symptoms, including tinnitus, hearing loss, vertigo, drainage, and itching, as well as systemic symptoms, such as fussiness, crying when lying down, upper respiratory infection, fever, and alteration in oral intake. Children may have difficulty describing pain. Parents may attribute pulling on ears or fussiness to ear pain. Preverbal children being evaluated for suspected ear pain need close evaluation for other causes of their fussiness.

Physical examination should always be complete, especially in children who are not old enough to verbalize that their fussiness is ear pain. Most children do not like to be immobilized for evaluation of the ears and throat, so otoscopy and visualization of the pharynx should be the last part of the examination. Initial examination of the ear includes the auricle and external auditory canal, followed by the middle ear by pneumatic otoscopy. Important aids to the examination include positioning of the child and removal of cerumen. The child may be positioned on the parent's lap or shoulder or placed supine on the examination table. Cerumen removal may be accomplished with the use of a small, cotton-tipped applicator; wire loop or plastic cerumen curette; irrigation with warm water; or application of cerumenolytics before irrigation.

Particularly important components of the examination include the external ear, the auditory canal, the TM, the surrounding structures of the head and neck, and the neurologic evaluation (Fig. 55.1).

FIGURE 55.1. Approach to the diagnosis of earache.

EXTERNAL EAR EXAMINATION

External problems are usually obvious on initial examination. Trauma, erythema, or vesicles on the auricle may be easily seen. Palpation of the area around the ear may reveal swelling or tenderness either from nodes, mastoiditis, parotitis, or preauricular pit infection.

Abnormal Otoscopy

Otogenic causes are readily diagnosed by visualization with otoscopy. Inflammation in the canal or middle ear, foreign bodies, abnormal lesions, perforations, or cholesteatomas may be seen. Evaluation of the TM for signs of infection includes describing position, color, degree of translucency, and mobility. Erythema alone is not sensitive as a predictor of infection because it may occur from increased blood flow with crying. Mobility is evaluated by applying pressure to the rubber bulb attached to the otoscope with a good seal in the canal and looking for inward movement with positive pressure and outward movement with negative pressure. Purulent discharge in the canal may be wicked out with cotton to better visualize the TM for a perforation or foreign body. Any patient with accompanying vertigo, facial nerve palsy, hemotympanum, or central nervous system symptoms requires further evaluation with CT scan.

Normal Otoscopy

A normal otoscopic evaluation should prompt a search for referred pain. Evaluation of the cervical spine, oropharynx, and neck should reveal possible sources of inflammation from shared sensory nerves. Radiographs to evaluate dental sources are usually not required emergently. A history of possible drug ingestions should be obtained. If there is a clinical suspicion of disease in the nasopharynx or larynx, an examination with a nasopharyngoscope may be needed. A patient with a completely normal examination and no other accompanying complaints should be referred back to his or her physician for follow-up before a psychogenic cause is given.

CHAPTER 56

Headache

CHRISTOPHER KING, MD

Departments of Emergency Medicine and Pediatrics, University of Pittsburgh School of Medicine, and Department of Emergency Medicine, University of Pittsburgh Medical Center (UPMC) Presbyterian Hospital, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania

Headache is a common complaint of pediatric patients in the emergency department (ED). It is estimated that by the age of 15 years, up to 75% of children have experienced headaches, although most are cared for at home. Parents may seek medical care if the child has a new-onset headache that is particularly painful and does not respond to nonprescription medications, if the child complains of progressively more severe headaches, or if the child has headaches that are recurrent over days, weeks, or months. Children with known migraine headaches are normally seen by a physician only when their standard medication regimen is not effective. Headache as an isolated complaint is a relatively unusual presentation in pediatric patients; it is more often one of a number of symptoms, such as fever, lethargy, sore throat, neck pain, and vomiting.

Like other challenging presentations, headache is seen with regularity and is almost always benign, but in a small subset of patients, it can portend a potentially life-threatening illness. Just as it can be difficult to identify the one child with appendicitis from a succession of patients with viral gastroenteritis, so too the clinician's skill can be tested in distinguishing which child among the many with headache has a serious underlying process. Therefore, the primary responsibility of the emergency physician is to make this important discrimination between “bad” headaches and benign headaches.

Fortunately, this can almost always be done successfully after a thorough history and physical examination. Laboratory and radiographic tests are rarely needed in the acute evaluation of headache in pediatric patients. One notable exception to this rule, however, is brain tumor. Although most serious illnesses (e.g., meningitis, encephalitis, ruptured vascular anomaly) will be apparent after an initial evaluation, the presence of a brain tumor may not be. The history can be subtle, and the examination is commonly unrevealing, often leading to a delay in diagnosis. Therefore, characteristics of headaches caused by a brain tumor are described in detail in this chapter. Above all, the key to propermanagement of these patients is ensuring appropriate follow-up care.

PATHOPHYSIOLOGY

For a headache to occur, there must obviously be some noxious stimulus that affects one or more pain-sensitive structures. Injury to an area that is insensitive to pain, as occurs with certain types of stroke syndrome, may cause significant morbidity but will not manifest as headache. It is therefore useful to consider the sensory innervation of the head and neck. All extracranial structures are sensitive to pain. Thus, processes that affect the sinuses, oropharynx, scalp, neck musculature, and so on, often cause patients to complain of headache. By contrast, some intracranial structures are sensitive to pain and some are not. For example, the brain, ependymal lining, choroid plexus, and much of the dura and pia-arachnoid over the hemispheres are insensitive to pain. Pathologic processes affecting these areas can cause headache, but only by impinging on adjacent pain-sensitive structures. The most pain-sensitive intracranial structures are the proximal portions of the large cerebral arteries at the base of the brain, the venous sinuses, and the large cerebral veins.

Various physiologic mechanisms come into play in causing headache. Painful stimuli can be broadly categorized as resulting from vascular effects, muscle contraction, inflammation, and traction/compression (Table 56.1). Examples of each of these types of headache etiology are described in the following discussion of differential diagnosis. It should be noted that visual problems are an unlikely cause of significant headaches in children. A child with persistent headaches that have previously been attributed to “eye strain” may therefore deserve a more careful evaluation.

I. Vascular	IV. Traction/Compression
A. Febrile illness	A. Increased intracranial pressure
B. Migraine	1. Cerebral edema
C. Systemic hypertension	2. Hydrocephalus
D. Hypoxia	3. Intracranial hemorrhage or hematoma
II. Muscle Contraction	4. Brain abscess
A. Tension	B. Tumor
B. Fatigue	C. Lumbar puncture
III. Inflammation	V. Others
A. Intracranial infections	A. Posttraumatic
1. Meningitis	B. Psychogenic
2. Encephalitis	C. Ocular
B. Dental infections	
C. Sinus infections	

Table 56.1. Pathophysiologic Classification of Headaches

Attempting to predict the neuroanatomic location of a pathologic process using only the site of headache pain described by a child is often difficult. In part, this is attributable to the unpredictable displacement of structures caused by a mass lesion. In addition, the extremely complex relationships of the various nerves involved in pain sensation of the head and neck lead to unexpected patterns of referred pain. Thus, a posterior fossa lesion can cause frontal or orbital pain, and supratentorial lesions may result in pain localized to the occiput or the back of the neck.

DIFFERENTIAL DIAGNOSIS

A comprehensive discussion of the various causes of headache in pediatric patients is beyond the scope of this chapter. The conditions described here are those most likely to be seen in acute- and emergency-care settings (Table 56.2) and those with the greatest potential for imminent morbidity or mortality (Table 56.3).

Vascular	Muscle Contraction
Febrile illness	Tension
Migraine	Fatigue
Inflammatory	Others
Sinus infections	Psychogenic
Dental infections	Ocular
	Posttraumatic

Table 56.2. Common Causes of Headache

Vascular	Traction/Compression
Hypertension	Increased intracranial pressure
Hypoxia	Tumor
Inflammatory	Hemorrhage/hematoma
Meningitis	
Encephalitis	

Table 56.3. Life-Threatening Causes of Headache

Vascular

Headaches associated with vascular changes are believed to be caused primarily by vasodilation, although the exact mechanism has yet to be fully described. One common example of this type of headache is migraine. Migraine headaches are typically chronic and remitting, with a characteristic pattern that is easily described by the patient or parents. Often, a strong family history of migraines is present. For the emergency physician, the main issue with patients with migraines is generally pain control because the diagnosis is already known. However, a significant change in the quality, severity, or timing of headaches in these patients may represent a separate and potentially more serious problem. In such cases, the clinician should not be dissuaded by the existing diagnosis from pursuing an appropriate workup as indicated.

Headaches accompanying fever are also thought to be mediated by vascular effects. Because fever is such a common symptom, this is probably the most common cause of headaches in pediatric patients seen in the ED. Hypertension is

another possible cause of vascular headaches in children. Hypertension causes not only global changes in cerebral vasculature, but also possibly a component of increased intracranial pressure that leads to headache.

Finally, hypoxia is a potent stimulus for cerebral vasodilation and can produce headaches on that basis. Therefore, children with an acute hypoxic insult (e.g., carbon monoxide poisoning) or those with disease states that predispose to hypoxia (e.g., cystic fibrosis, cyanotic heart disease) may present with headaches resulting from an acute process or an exacerbation of an underlying illness.

Muscle Contraction

Headaches can be caused by contraction of the scalp or neck muscles. This is the classic “tension” headache that so often plagues adults. These headaches usually occur when a patient has experienced prolonged periods of mental or emotional stress. This leads to recurrent episodes of muscle tension and/or spasm, which cause muscle soreness. The patient can often localize a specific site where the pain is felt, and the involved muscles may be tender to palpation. Although muscle contraction is an unlikely cause of headache in younger children, the stress of life during adolescence will often produce this type of headache. Onset is typically at the end of the day. A headache that is present on arising in the morning or that awakens a patient from sleep would be an unusual manifestation of muscle contraction.

Inflammation

A wide variety of inflammatory conditions can result in headache, ranging from benign to potentially life-threatening entities. Children with bacterial meningitis or encephalitis may present with headache, although this is usually only one of a constellation of symptoms, such as fever, lethargy, neck pain, confusion, or coma. Headache is unlikely to be the sole complaint in these patients. However, an older child or adolescent who has viral meningitis can present with a severe headache, minimal or mild neck discomfort, and no other signs of significant illness. Fortunately, viral meningitis is a benign process in most cases. Rare causes of inflammatory headache include retroorbital cellulitis or abscess and cerebral abscess. Focal findings on neurologic and/or ocular examination will normally provide clues to these unusual diagnoses.

Headaches can also be caused by inflammatory processes affecting other structures of the head and neck. For example, pediatric patients with pharyngitis caused by group A streptococcus will often complain of headaches. Indeed, the classic presentation for streptococcal pharyngitis in children is sore throat, fever, headache, and abdominal pain. In a child who has difficulty localizing pain, otitis media and otitis externa can also present as headache. Pediatric patients with sinusitis will sometimes complain of facial or periorbital pain, although younger children may simply have a persistent nasal discharge. Dental abscess can be overlooked as a cause of headache-type pain because it is a relatively uncommon finding in children. Therefore, a careful examination of the teeth and gingiva should be performed for all pediatric patients with unexplained headaches. Finally, inflammation of the temporomandibular joint (TMJ syndrome) is a rare cause of unilateral headaches in children. These patients typically report increased pain while chewing and have point tenderness over the mandibular condyle.

Traction/Compression

Headaches can be caused by mass effect from a pathologic lesion that produces traction and/or compression involving pain-sensitive intracranial structures. For the emergency physician, the most important conditions in this category are intracranial hemorrhage and brain tumor. An intracranial hemorrhage produces displacement of surrounding tissues and, in cases of more significant bleeding, increased intracranial pressure. In the pediatric population, this is most often the result of a severe head injury (see Chapter 105). However, in rare cases, a child can have a nontraumatic intracranial hemorrhage from a ruptured vascular anomaly (e.g., an arteriovenous malformation), which leads to bleeding into the brain parenchyma and ventricles. As with other vascular events, this type of hemorrhage is characterized by the abrupt onset of severe pain. By contrast, headaches resulting from a brain tumor typically have a more insidious onset. The child will often complain of progressively worsening headaches for several weeks or even months. Additional symptoms, such as persistent vomiting or gait abnormalities, may also be present. Unfortunately, the physical examination can be normal during the early phase of the illness, and as mentioned previously, this commonly leads to a delay in diagnosis. Other processes that cause headache as a result of traction and compression include pseudotumor cerebri, hydrocephalus, and persistent spinal fluid leak after lumbar puncture.

Psychogenic

Although less common than in adults, headaches of psychogenic origin are seen in children as well. Possible causes include school avoidance behavior, malingering with secondary gain issues, and a true conversion disorder. These patients often have a history of chronic headaches that have been unresponsive to various treatment methods, and they may have undergone a battery of tests without receiving a diagnosis. Parents of these children are usually worried and frustrated. Their reasoning in coming to the ED after an extensive prior workup is often simply “to get another opinion.” For the emergency physician, establishing definitively that a child's persistent headaches are the result of a psychogenic cause is generally impossible. Obviously, this should be considered a diagnosis of exclusion. However, if the history and physical examination do not suggest a more serious cause of headaches, the best management approach is to communicate genuine concern about the patient, attempt to allay some of the parental fears, and ensure appropriate outpatient follow-up.

EVALUATION AND DECISION

As stated previously, the diagnosis for pediatric patients presenting with headache will be evident in all but a small minority of cases after a thorough history and physical examination. Laboratory tests and imaging modalities are rarely needed. Even if a definitive diagnosis cannot be established immediately, the identification of a potentially life-threatening cause of headaches will almost always be possible before the child leaves the ED. Concern about the

possibility of a more serious cause warrants aggressive use of whatever diagnostic or therapeutic interventions are indicated, such as a computed tomography (CT) scan of the head, lumbar puncture, or intravenous antibiotics. Occasionally, a child with a suspected brain tumor will be appropriately discharged from the ED without undergoing any diagnostic tests. Such a disposition assumes that proper follow-up for such patients can be arranged and that magnetic resonance imaging (MRI) of the head will be performed within 24 to 48 hours. An approach to the diagnostic evaluation of a child with headaches is outlined in Figure 56.1.

FIGURE 56.1. Approach to the diagnosis of headache.

Clinical Assessment

History

Before proceeding to specific questions about headache symptoms, the clinician should inquire about the general health of the patient, particularly during the hours leading up to the current presentation. For example, the presence of a high fever, decreased activity, and poor oral intake is suggestive of an serious inflammatory cause such as meningitis. A patient with these same symptoms who also has an abrupt change in mental status may have encephalitis. If a child has been relatively well but has complained of headache associated with persistent nasal discharge (especially if it is purulent), this may be caused by a sinusitis. A child with tooth pain, ear pain, or sore throat may also have a readily apparent reason for headaches.

After general health issues are covered, the clinician should then obtain a complete history regarding the headache itself. As with many illnesses, the cause of headaches can usually be diagnosed with a high degree of accuracy solely based on history; the physical examination is often merely confirmatory. One of the more important points to investigate is the mode of onset. A headache that starts abruptly and causes extreme pain may represent a vascular event such as a ruptured arteriovenous malformation, whereas a headache with a more gradual onset would be inconsistent with this diagnosis. It is sometimes useful to question the patient about the severity of the pain, although in younger children, this history may not always be reliable. A youngster who is smiling and playing with toys may nod “yes” in response to the question “Is the pain very, very bad?” In such cases, the description of the severity of pain must obviously be correlated with the child's clinical appearance. Questions about the quality of pain (e.g., boring, throbbing) are often less useful in children for similar reasons.

The frequency and duration of headaches can also provide valuable clues about the origin of headaches. A child who complains of constant pain for several days without respite (i.e., goes to sleep with it, wakes up with it) will commonly have a tension headache or, perhaps more likely, a psychogenic headache. On the other hand, a patient who presents with headaches that have progressively become more frequent or prolonged may have a more serious underlying condition. Similarly, a child with headaches that have steadily worsened in severity over time warrants careful evaluation, again given the limitations of a child's description of pain. Parents can often help clarify such situations. For example, they may report that the child previously complained of headaches while continuing to play, but now the headaches cause the child to stop what he or she is doing, lie down, and hold his or her head crying. Such a progression of symptoms over several days or weeks will in most cases be a sufficient indication for performing a CT scan or MRI of the head before the child leaves the ED.

The time and circumstances of occurrence are also important historical points to ascertain. For example, headaches that are present when a child arises each morning or that awaken a child at night should raise suspicion about a possible brain tumor. In contrast, headaches that occur only later in the day are typically related to stress and result from muscle contraction. In addition, any precipitating events that consistently cause or exacerbate a headache should be identified. If an older child has a headache that is significantly worse when leaning down (e.g., to pick up something off the floor), this is most likely to be caused by sinusitis, although in rare cases, this history may be present in a child with a brain tumor.

Any relevant details about the patient's medical history and family history should routinely be obtained. As mentioned previously, children with cystic fibrosis or congenital heart disease may have headaches caused by worsening hypoxia. Likewise, a child with renal disease may develop headaches in response to an elevated blood pressure. In general, the most important question regarding family history is whether anyone has had migraine headaches. It should be remembered, however, that many people use the term *migraine* rather broadly to refer to any type of severe headache. Therefore, the clinician may find it useful to describe typical migraine symptoms before questioning parents about this aspect of the history. Abrupt onset of headache in several family members may suggest carbon monoxide poisoning.

Before leaving this subject, it is worth reemphasizing the importance of a thorough history in developing an appropriate clinical suspicion of a possible brain tumor. A variable period of time exists when a child with a brain tumor will

experience headaches before any abnormal physical findings are apparent. Making a presumptive diagnosis of brain tumor as a likely cause of headaches during this early stage of the illness will therefore depend entirely on the history. In their classic article, Honig and Charney described several historical points that are characteristic of children with brain tumor headaches (Table 56.4). Although no single pathognomonic response on history unerringly establishes the diagnosis, eliciting one or more of these findings should certainly raise the level of concern that a child's headaches may be caused by a brain tumor.

Nocturnal headache or pain on arising in the morning
Worsening over time (severity, frequency, and/or duration)
Associated with vomiting (although may also occur with migraine), especially if vomiting gets progressively worse
Behavioral changes
Polydipsia/polyuria (craniopharyngioma)
History of probable neurologic deficits (e.g., ataxia/incoordination/"clumsiness," blurred vision, or diplopia)

Reprinted with permission from Honig PJ, Charney EB. Children with brain tumor headaches: distinguishing features. Am J Dis Child 1982;136:121–141.

Table 56.4. Characteristic Historical Findings of Brain Tumor Headaches in Children

Physical Examination

Finding an abnormality on the physical examination of a child with headaches will be a relatively rare event. Nevertheless, a thorough head-to-toe examination should be performed in every case because identification of even a subtle finding (e.g., early papilledema) can significantly alter the course of evaluation and treatment. As with all children seen in the ED, the first step of the examination is to assess the patient's appearance. Does the child look sick or well? Does the child appear to be in severe pain, mild pain, or no pain at all? This initial evaluation represents the first important branch point in the decision algorithm for patients with headache (Fig. 56.1). Thus, a child who appears ill may have a more serious underlying condition, such as meningitis or an intracranial hemorrhage, requiring a rapid examination and prompt initiation of treatment.

The vital signs should also be assessed, particularly the temperature and blood pressure. Although omitting the blood pressure reading for younger children is a tendency, this is never acceptable for a patient who has headaches. Significant hypertension, usually resulting from undiagnosed renal disease, is a rare but potentially dangerous cause of headaches that can affect children of any age. Consequently, if a blood pressure is not taken initially by triage personnel, this must be performed as part of the child's evaluation in the ED. Measuring basic growth parameters for a pediatric patient with headaches can also provide valuable information. Macrocephaly may be the result of hydrocephalus, and short stature can be associated with a craniopharyngioma that causes impaired pituitary function.

The head and neck examination will sometimes reveal an obvious source of headache in a child. The scalp should be examined for evidence of head injury. Even when no history of trauma exists, the child may have had an unwitnessed event, or the history may be intentionally misleading with a victim of child abuse. Tenderness of the scalp or neck muscles is often present with headaches resulting from stress and muscle contraction. The eyes should be examined to detect any abnormalities in pupillary responses or extraocular movements. A sluggish pupil may be caused by an expanding mass lesion that causes compression of the third cranial nerve, and pain with extraocular movements may be elicited with a retroorbital cellulitis or abscess. The eyegrounds should also be carefully examined for signs of papilledema. The clinician may find an otitis media or otitis externa when the ears are examined. Streptococcal pharyngitis as a cause of headaches may be evident as swelling, erythema, and exudates of the tonsillar pillars. Facial tenderness and erythema are sometimes seen in children with maxillary or frontal sinusitis. The teeth and gingiva should be examined for evidence of inflammation or abscess. Nuchal rigidity can be a sign of meningitis, intracranial hemorrhage, or in rare cases, brain tumor. If a child has a ventricular shunt, assessment of shunt function should be performed when appropriate (see Procedures).

Examining the skin is also important for the child with headaches. Because the skin and central nervous system have a common embryologic origin, cutaneous lesions are sometimes seen with neurologic disorders. For example, a child with numerous hyperpigmented spots scattered over the body (café-au-lait spots) most likely has neurofibromatosis. Similarly, children with tuberous sclerosis will almost always have several small, hypopigmented spots (ash leaf spots) that are more apparent when viewed under a Wood's ultraviolet lamp.

Every child with a complaint of headaches obviously needs a complete neurologic examination. Any new focal finding suggests the presence of a focal lesion, such as a tumor or hemorrhage. Some children with migraine headaches develop focal neurologic abnormalities as part of their migraine syndrome (e.g., ophthalmoplegia), but parents can normally confirm that this is not a new problem. As mentioned previously, the mental status of a child with headaches must always be carefully assessed. A diminished level of consciousness may be the result of encephalitis, a large intracranial hemorrhage, or significantly elevated intracranial pressure. To the extent that the child can cooperate, cranial nerve function should also be evaluated. Cranial nerve abnormalities may result from an elevated intracranial pressure or direct compression by a mass lesion. Sensory and motor function should be examined, although here again the ability of a younger patient to cooperate may be limited. A reasonable evaluation can be accomplished by observing the child's gait while walking and/or running and by assessing the child's dexterity in performing age-appropriate activities, such as transferring a toy from hand to hand and tying shoe laces. Any evidence of gait abnormalities or deficits in fine motor

coordination warrants further investigation.

Laboratory and Radiographic Testing

By far, most children presenting in an acute-care setting with headache as the chief complaint will not require any laboratory tests. Most will have minor problems, such as otitis media, viral illness with low-grade fevers, or tension headaches. Laboratory testing rarely provides any useful information in such cases. Certainly, the child with a possible serious infectious process causing headaches can require a variety of tests, including a complete blood count, blood cultures, and lumbar puncture. Yet these patients are more likely to have other symptoms such as high fever and lethargy, rather than headache, as the primary complaint. Should a lumbar puncture be necessary for a child, it is important to remember that an emergent head CT scan should be obtained first when an intracranial space-occupying lesion is in the differential diagnosis. Failure to do this could theoretically lead to a herniation syndrome resulting from differential in cerebrospinal fluid (CSF) pressure. Serum electrolytes, blood urea nitrogen, creatinine, and a urinalysis should be obtained for any child with headaches who is found to have an elevated blood pressure. The patient with a ventricular shunt who has fever and headaches will likely require a shunt tap by a neurosurgical consultant. Finally, a child with a suspected subarachnoid hemorrhage should undergo a lumbar puncture if the head CT scan is negative. This is necessary because a small hemorrhage may not be detected by CT, and in such cases, blood in the CSF is the only diagnostic finding. However, this is an uncommon situation in the pediatric population.

As with laboratory testing, few children with headaches who come to the ED will require an emergent imaging study. In general, plain radiographs of the skull are of little or no value for these patients. A child with a ventricular shunt may require a shunt series, but this includes radiographs of the entire course of the shunt and not simply skull radiographs. Likewise, sinus radiographs are rarely indicated in pediatric patients because the diagnosis almost always is made on clinical grounds. Occasionally, a child with multiple episodes of an apparent sinus infection will require a CT scan of the sinuses, but this is normally done as an outpatient.

The two modalities currently in use that provide the best radiographic information about intracranial abnormalities are CT and MRI. Each has certain advantages and disadvantages. At present, CT is available on a more emergent basis, making it the test of choice to evaluate patients at risk for problems such as intracranial hemorrhage, cerebral edema, and herniation syndrome. CT is especially useful for patients with head trauma. However, CT does not offer the quality of image resolution provided by MRI. Smaller lesions, particularly those of the posterior fossa and brainstem, are more reliably detected by MRI. This is true even when the CT scan is performed using contrast material. Consequently, MRI is superior for children suspected of having a brain tumor who have a normal neurologic examination and no signs of elevated intracranial pressure. If these patients undergo a head CT scan in the ED, they will likely also require an outpatient MRI. Such duplication of testing is costly and usually unwarranted. Lack of availability is the primary drawback of MRI. In most institutions, an MRI is difficult if not impossible to obtain on an emergent basis, particularly after hours. As discussed in the following, the emergency physician must take these as well as other factors into account in determining which, if any, imaging modality is indicated for a child with headaches.

Treatment and Disposition

Patients with headaches caused by a potentially life-threatening process (e.g., meningitis, encephalitis, ruptured vascular anomaly) require specific treatment approaches discussed elsewhere in this textbook. Children with headaches that are presumptively diagnosed as benign can almost always be successfully treated with acetaminophen or ibuprofen. The various options available for treating pediatric migraine patients are described in Chapter 83.

Although most children complaining of headache can be safely discharged from the ED with an appropriate follow-up plan, some will require admission to the hospital for further evaluation and treatment. For example, a child with headaches who is found to be hypertensive must be admitted both for management of the blood pressure and investigation of the underlying cause. Patients with migraine who have intractable headache pain may also warrant admission to receive a more effective analgesic regimen. The child with a ventricular shunt who has severe headaches will usually require a shunt series, a CT scan of the head, and neurosurgical evaluation. If neurosurgical consultation is not immediately available, the patient should be transported to an appropriate receiving facility.

A potentially confusing issue that the emergency physician will inevitably face is how to properly manage a child who is suspected of having a brain tumor. Should all of these patients have a brain imaging study in the ED? As discussed previously, the resolution of even a contrast-enhanced head CT scan is inferior to MRI for detecting certain types of tumors. Also, a small but finite risk is associated with the administration of contrast material. On the other hand, MRI is generally far more difficult to obtain on an emergent basis than CT. What then is the appropriate diagnostic approach?

Without question, a child with headaches who has papilledema or a focal neurologic finding must have an immediate head CT scan, usually enhanced with contrast material as deemed necessary by the radiologist. Similarly, a patient who has headaches associated with visual changes, frequent vomiting, or other signs of elevated intracranial pressure requires an emergent head CT scan. Because mass lesions that cause such changes are usually larger and more easily detectable, the potential reduction in image resolution is more than offset by the greater speed with which a head CT scan can be performed. Time, not image quality, is the critical factor for these patients.

But what about the child with a suspicious history (e.g., increasing frequency or duration of pain, headaches that awaken the child from sleep or occur every morning) who has a normal neurologic examination and no signs of elevated intracranial pressure? In most cases, such patients can be safely discharged from the ED with an outpatient MRI scheduled within 24 to 48 hours. A delay in diagnosis of 1 or 2 days is usually acceptable if this allows the appropriate diagnostic study to be performed. Obviously, parents must be clearly instructed that any sign of deterioration, such as mental status changes or vomiting, requires that the child be immediately returned to the ED for a reevaluation.

CHAPTER 57

Joint Pain

RICHARD J. SCARFONE, MD, MCP

Department of Pediatrics, The University of Pennsylvania School of Medicine, and Department of Pediatric Emergency Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Arthritis and arthralgia are common reasons for children to seek care in the emergency department. Arthritis is joint inflammation marked by swelling, warmth, and limitation of motion, whereas arthralgia is simply pain without inflammation of the joint space. The diagnostic approach is challenging because the differential diagnosis is lengthy (Table 57.1), clinical and laboratory findings are rarely specific for a particular disease, and the disease pattern for many of the conditions listed is often greatly variable. Among the most common causes of joint pain in children are bacterial infections, trauma, and postinfectious conditions (Table 57.2). Although rare, several life-threatening causes (Table 57.3), including acute rheumatic fever and leukemia, must be considered. This chapter serves as a guide to the approach to the child with arthritis or arthralgia, with an emphasis on historical points and physical examination findings that can serve to narrow the diagnostic possibilities.

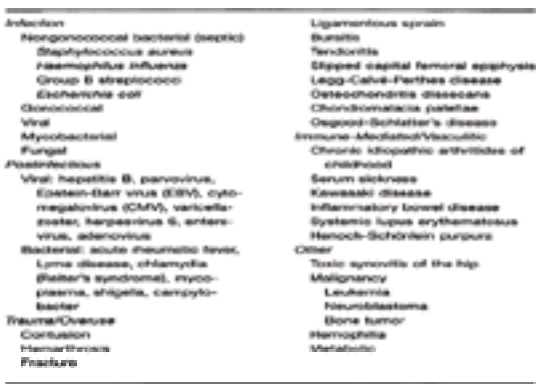

Table 57.1. Joint Pain—Differential Diagnosis

Nongonococcal bacterial (septic)	Postinfectious (reactive)
Gonococcal	Traumatic hemarthrosis
Lyme disease	Serum sickness
Toxic synovitis of the hip	Henoch-Schönlein purpura

Table 57.2. Common Causes of Joint Pain

Acute rheumatic fever
Kawasaki disease
Malignancy
Leukemia
Neuroblastoma
Bone tumor

Table 57.3. Life-Threatening Causes of Joint Pain

DIFFERENTIAL DIAGNOSIS

The possible causes of joint complaints in children are extensive (Table 57.1), but infectious and traumatic causes are the most common (Table 57.2). Children between 6 to 24 months of age have the highest incidence of nongonococcal bacterial (septic) arthritis, and boys are affected twice as often as girls. Septic arthritis results primarily from the hematogenous dissemination of an organism into the joint or the bony metaphysis. The diagnosis of septic arthritis of the hip should not be delayed because pressure in the joint space will compromise the vascular supply to the femoral head, leading to necrosis.

Among adolescents, disseminated gonococcal infection with polyarthritis occurs three to five times more often in girls, often during menstruation. Of note, few patients report lower abdominal pain or vaginal discharge concurrently and cultures of blood and synovial fluid are typically negative. The highest yield for establishing the diagnosis is by Gram stain of the skin lesions showing Gram-negative intracellular diplococci or by culturing the cervix, rectum, or throat.

In the absence of a clear history of a tick bite, Lyme disease is a challenging clinical diagnosis because only about 40 to 70% of children have the characteristic erythema migrans rash, constitutional symptoms may be mild, and serologic tests have a high incidence of false positivity. The diagnosis relies on the specific Western Blot confirmation of a positive serology.

Toxic synovitis is a poorly understood inflammation of the hip joint afflicting children 3 to 6 years of age. The diagnosis is typically made on clinical grounds, and this self-limited disease does not result in joint destruction.

Reactive, or postinfectious, arthritis is probably more common than septic arthritis. Arthritis secondary to various enteric infections is not rare in children and parvovirus B19 is also a common cause of acute arthritis in adolescents and young adults. *Chlamydia trachomatis* infection of the genitourinary tract should be considered in any sexually active adolescent with new onset arthritis. With postinfectious arthritis, no clear evidence supports that antimicrobial treatment modifies the disease course.

Traumatic injuries to a joint may cause periarticular swelling or an effusion indicative of a hemarthrosis. A host of other conditions may come to light in the setting of minor trauma but may be only indirectly related to that trauma.

Less common is chronic arthritis with an incidence of 5 to 10 per 100,000 children less than age 16 years. These diseases are characterized by arthritis persistent for at least 6 weeks in the absence of a defined diagnosis. For purposes of this discussion, we will group these disorders under the heading chronic idiopathic arthritides of childhood (CIAC). CIAC is much less benign than previously believed, with about 40% of children from all disease subtypes continuing to have active joint inflammation, and 20% of children having severe functional limitations after 10 years or more of follow-up. There may be a relatively limited window of opportunity in the first 2 years of disease to limit joint disease. Thus, it is imperative that a primary care physician suspect the diagnosis and make the appropriate referral.

EVALUATION AND DECISION

Figure 57.1 depicts an algorithm for the diagnostic approach to the child with joint pain. In evaluating such children, one should inquire about a history of trauma, fever, the specific joint(s) involved, duration, rash, tick bites, sexual risk factors, intravenous drug use, and recent illnesses. Radiographs of the affected joint are particularly useful in the setting of trauma or acute monarthritis without an obvious cause. A complete blood count and erythrocyte sedimentation rate are generally indicated for children with joint pain in the absence of trauma. For the febrile child with monarthritis and a joint effusion, an arthrocentesis will guide the evaluation. Finally, ultrasound is superior to plain radiographs in the detection of a hip effusion.

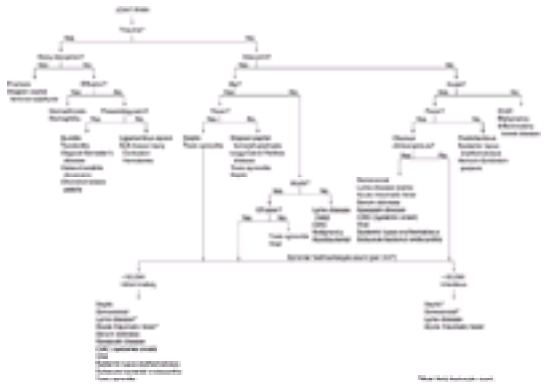

FIGURE 57.1. A diagnostic approach to joint pain. *CIAC,* chronic idiopathic arthritides of childhood.

A key initial point in the history is whether trauma preceded the pain. Because it is easy to be led astray by parents trying to recall what traumatic event could have led to the child's symptoms, one should remember that if the mechanism was not severe enough to immediately prevent the child from continuing an activity, it is unlikely to be the cause of a significantly swollen and painful joint.

On the other hand, if there was a definite traumatic event preceding the onset of symptoms, particularly in the absence of fever, one can proceed with that aspect of the evaluation.

A radiograph will detect fractures or a slipped capital femoral epiphysis. Radiographs aid in determining whether associated swelling is caused by a joint effusion or is simply soft-tissue swelling outside of the joint, a distinction that is often difficult to make on physical examination alone. In the setting of acute trauma and in the absence of fever, an effusion is indicative of a hemarthrosis and is rarely a diagnostic or therapeutic indication for performing an arthrocentesis because the patient will typically experience only temporary relief followed by a rapid reaccumulation of blood.

In the absence of an effusion, inquiries about the duration of symptoms should be made. Children with conditions such as bursitis, tendonitis, and Osgood-Schlatter's disease typically have chronic, low-grade pain and may inadvertently come to medical attention after minor trauma. New-onset periarticular swelling and pain immediately after acute trauma suggests ligamentous or other soft-tissue injury.

In the absence of trauma, monarthritis of the hip is uniquely problematic. In particular, bacterial infections of this and other joints are the most serious because of the rapidity with which destruction of cartilage can occur. The most important determinant of the outcome of a septic arthritis is the length of delay between the onset of infection and the institution of therapy. Unlike most other causes of fever and arthritis, in more than 90% of affected children, septic arthritis involves only a single joint, usually of the lower extremity; neonates, however, may have polyarthritis. Because just 60 to 70% of children with septic arthritis are febrile at presentation, the absence of fever does not preclude the diagnosis. However, if the child allows full range of motion, the diagnosis is unlikely.

A child with acute onset of monarthritis of the hip or any other large joint, defined by the presence of an effusion and marked by severely restricted range of motion, with or without fever, needs an arthrocentesis. The synovial fluid should be analyzed for glucose and protein, cell count and differential, Gram stain, and culture. Most patients with septic joints will have a decreased glucose level and greater than 50,000 white blood cells per cubic millimeter with a neutrophil predominance, but in one study, one-third had counts of less than 25,000/m ^{3}. In addition, Gram stain is negative in about 25% of patients, synovial fluid cultures are negative in about 25%, blood cultures are negative in about 50%, and 20 to 30% with septic arthritis have a peripheral white blood cell count of less than 10,000. The erythrocyte sedimentation rate is almost always elevated, with a median value of 50 mm in one case series. Thus, laboratory evaluation is used simply to confirm the clinical suspicion but should not be relied on to make the diagnosis.

In contrast to septic arthritis, children with toxic synovitis of the hip typically appear well; often present with a limp; may have only mildly elevated temperatures; allow almost complete range of motion of the affected joint; and the complete blood counts, erythrocyte sedimentation rates, and radiographs are typically normal. Usually, the physician can make a clinical diagnosis of toxic synovitis, but in a small subset, septic arthritis cannot be ruled out before the completion of an arthrocentesis. The disease is self-limited, usually lasting less than 1 week.

A slipped capital femoral epiphysis must not be missed. About half of patients will provide a history of trauma. This condition is most often seen in obese adolescent boys. Most children have chronic pain, although some have an acute limp with hip or knee pain and restricted range of motion. Plain radiographs (frog-leg view of the hip) showing a widened epiphysis and caudal displacement of the femoral head establish the diagnosis.

Legg-Calvé-Perthes disease, a condition of uncertain cause, occurs overwhelmingly in boys, with an onset between 4 and 8 years of age. The pain, which may be localized to the hip or referred to the thigh or knee, is insidious in onset. The aseptic necrosis of the femoral head will be manifest on plain radiographs as a small, osteopenic femoral head with a widened joint space.

Historical and physical examination findings help narrow the choices among the many causes of fever and polyarthritis (Table 57.4). The ill-appearing adolescent with migratory arthritis, tenosynovitis involving the extensor tendons of the wrist or ankle, and scattered crops of vesiculopustules on an erythematous base should be strongly suspected for gonococcal arthritis. Joint involvement with Lyme disease has two distinct patterns. In early disseminated disease, the child may develop episodic migratory polyarthritis, affecting mainly large joints. Each episode lasts a few days, helping distinguish it from idiopathic chronic arthritis. Two weeks to 2 years (mean 6 months) after the tick bite, 6% develop an intermittent monarthritis, typically of the knee, ankle, or wrist. The joint is significantly swollen but only mildly painful, and patients are usually afebrile at this stage. Painful migratory joint pain involving five or more joints in a school-age child with recent evidence of a group A streptococcal infection should raise the concern for acute rheumatic fever. Evidence of carditis, erythema marginatum, subcutaneous nodules, and positive serology for antistreptococcal antibodies support the diagnosis. The presence of diffuse urticaria and angioedema accompanying arthralgia or arthritis, especially 3 to 10 days after initiation of an antibiotic, helps distinguish serum sickness from other causes of polyarthritis and fever. Kawasaki disease is characterized by high and persistent fever, conjunctival injection without exudate, mouth and lip swelling and cracking, swelling and erythema of the hands and feet, a nonspecific rash, and lymphadenopathy. Ten days or so after the disease onset, there may be desquamation of the fingers and toes, myocardial dysfunction, and thrombocytosis; about 30% of patients will also develop arthritis or arthralgia. Daily temperature spikes exceeding 40°C (104°F), especially if accompanied by a transient pink rash, suggests one of the CIAC (formerly called Still's disease). A common viral-related arthritis is that caused by hepatitis B infection. The arthritis precedes the symptoms of hepatitis and resolves when the jaundice appears. During the 1- to 3-week prodromal phase, polyarthritis may be accompanied by moderate fever and sometimes by an urticarial or maculopapular rash. Parvovirus B19 causes a similar clinical syndrome in young women with a sudden onset of symmetric, self-limited polyarthritis, particularly in the hands. With subacute bacterial endocarditis, musculoskeletal symptoms are variable, ranging from asymptomatic joint effusions to frank arthritis of up to three joints. Preexisting congenital heart disease, a prolonged fever, a new murmur, and splinter hemorrhages may all be clues to the diagnosis of this rare entity in children.

Usually Febrile at Presentation	*May or May Not Be Febrile at Presentation*
Nongonococcal bacterial (septic)	Leukemia
Gonococcal	Mycobacterial
Acute rheumatic fever	Postinfectious (reactive)
Chronic idiopathic arthritides of childhood (systemic onset)	Lyme disease
Subacute bacterial endocarditis	Systemic lupus erythematosus
Serum sickness	Inflammatory bowel disease
Kawasaki disease	

Table 57.4. Fever and Joint Pain

A joint aspiration is rarely necessary to establish a diagnosis for a child with polyarthritis and fever or to rule out a septic process in this setting. If an arthrocentesis is obtained, typically the synovial fluid will be sterile and the leukocyte count will characterize the process as inflammatory (Fig. 57.1).

Postinfectious arthritis is one of the more common causes of acute polyarthritis without fever. One to two weeks after a bout of enteritis or urogenital infection (Reiter's syndrome), a child may develop an asymmetric postinfectious (reactive) polyarthritis, predominantly involving large joints of the lower extremities. The severity of the antecedent illness has little correlation with the arthritis, and the intensity of synovitis and fever is mild or absent at this stage.

As with many of the diseases discussed to this point, systemic lupus erythematosus (SLE) has a variable clinical presentation with regard to musculoskeletal involvement. In fact, no two patients have an identical pattern of immune complex formation or clinical disease expression. A symmetric polyarthritis involving peripheral joints of the hands or feet may be seen. However, small effusions of the knee are also common with active disease and the arthritis may be intermittent or migratory as well. Patients with this type of arthritis are usually afebrile, yet high fever may be a prominent finding. Although arthritis is 1 of the 11 diagnostic criteria for SLE established by the American College of Rheumatology, it is uncommon for SLE to present with isolated arthritis. Arthritis of the small joints, a positive test for antinuclear antibodies (ANA), and abnormalities of the skin, kidneys, or central nervous system should raise the clinician's suspicion for SLE.

Henoch-Schönlein purpura (HSP) is rarely a diagnostic challenge thanks to the presence of petechiae and purpura in the characteristic below-the-waist distribution. Classically, children will also have polyarthritis, colicky abdominal pain, and nephritis. As with the rash, periarticular swelling usually involves joints below the waist.

The CIAC are marked by their duration, typically 6 months or longer. That they appear at several points in the diagnostic algorithm reflects their diversity. Some children will have systemic distribution of symptoms, whereas others will have monoarticular or oligoarticular disease, and fever or rash may or may not be present. Tests for rheumatoid factor and ANA in children are unhelpful. When performed as a screen, rheumatoid factor tests are rarely positive and, when positive, are as likely to be in children with other diseases as in children with chronic arthritis.

In the absence of fever, chronic pain of one or more joints may also indicate malignancy. Specifically, leukemia or neuroblastoma can both present with true joint swelling, as can bony tumors. Pallor, weight loss, and other constitutional complaints, as well as anemia or cytopenias, would support this diagnosis.

A large joint oligoarthritis occurs as an extraintestinal complication of inflammatory bowel disease in about one-third of children, usually during times of active disease. Clues to the diagnosis include abdominal pain, hematochezia, anemia, and weight loss.

In summary, this review of joint pain in children should serve as a guide to the diagnostic evaluation. The clinician must choose from many different causes, each with variable and nonspecific characteristics. In addition, laboratory studies are rarely specific for a particular disease. However, by asking the appropriate questions, performing a careful physical examination, and selectively obtaining adjunct studies, the clinician can follow the correct diagnostic path.

CHAPTER 58

Pain—Scrotal

CATHERINE E. PERRON, MD

Department of Pediatrics, Harvard Medical School, and Division of Emergency Medicine, Children's Hospital, Boston, Massachusetts

Acute scrotal swelling or pain in a child should be considered a potential surgical emergency. Although some causes of acute scrotal swelling may be benign and require no more than observation and reassurance to the patient and parent, other causes may lead to the rapid loss of a testis if diagnosis and treatment are delayed. The patient with such a complaint should be evaluated promptly. Many diagnoses in cases of scrotal pain are most reliably made clinically, differentiating by age, historical features relating to the evolution of pain and associated symptoms, and physical examination findings.

PATHOPHYSIOLOGY

The anatomic structures contained in the scrotum include the testes; the epididymis; appendages of the testis; and the nerve, vascular, and lymphatic structures that constitute the spermatic cord and traverse the inguinal canal into the scrotum (Fig. 58.1). The anatomy of the testicle, its related structures, and the layers of tissue that surround each testicle in the scrotum may each relate to the pathology seen in this area. The descent of the testis through the inguinal canal from the abdomen until its eventual position in the scrotum also contributes to the risk of pathology in the scrotum and associated groin area. Pathophysiologic causes of acute conditions of the scrotum include ischemia, inflammation, trauma, and tumor. Because these processes often alter blood flow to structures within the scrotum, appropriate imaging modalities when correlated with clinical history and examination are often useful in coming to the correct diagnosis.

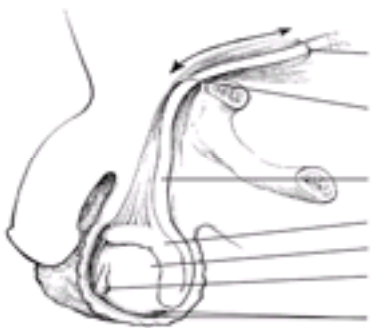

FIGURE 58.1. Anatomy of the scrotal contents.

DIFFERENTIAL DIAGNOSIS

Table 58.1 lists the principal causes of acute scrotal swelling and Table 58.2 provides the most common diagnoses by age.

Painful Scrotal Swelling	*Painless Scrotal Swelling*
Torsion of testis	Hydrocele
Torsion of appendage of testis	Hernia
Trauma—hematocele, hematoma, epididymitis, testicular rupture	Varicocele
	Spermatocele
Epididymitis	Idiopathic scrotal edema
Orchitis	Henoch-Schönlein purpura
Hernia—incarcerated	Kawasaki disease
Tumor—acute hemorrhage	Testis tumor
	Antenatal torsion of the testis

Table 58.1. Causes of Acute Scrotal Swelling

Infancy	*Adolescence*
Hydrocele	Epididymitis
Hernia	Torsion of the appendix testes
Childhood	Torsion of the testes
Hernia	Trauma
Torsion of the appendix testes	
Torsion of the testes	
Trauma	

Table 58.2. Common Causes of Acute Scrotal Swelling

Causes of Painful Scrotal Swelling

Torsion of the Testis

Testicular torsion is the most significant condition causing acute scrotal pain and represents a true surgical emergency. It is the most common cause of acute painful scrotal swelling in children, accounting for approximately 30% of cases of acute scrotal pain. Testicular torsion is more common in the newborn period and during the early stages of puberty. Approximately two-thirds of cases of intravaginal torsion occur in children between the ages of 12 and 18 years, overlapping the peak incidence of appendage torsion.

Torsion results from an inadequate fixation of the testis to the intrascrotal subcutaneous tissue (Fig. 58.2), resulting in the so-called “bell-clapper” deformity. The testis, which hangs more freely within the tunica vaginalis in this deformity, may rotate, producing torsion of the spermatic cord, venous engorgement of the testis, and subsequent arterial infarction (Fig. 58.3).

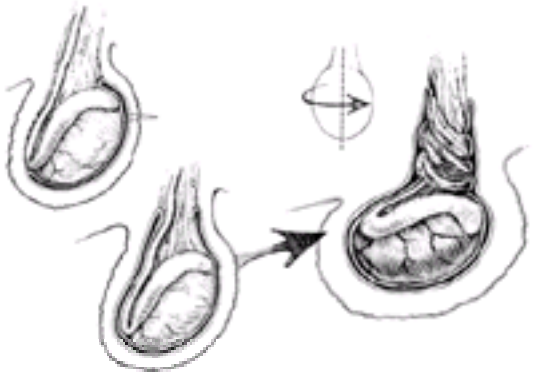

FIGURE 58.2. Torsion testis abnormality of testicular fixation—bell-clapper deformity—permits torsion of spermatic vessels with subsequent infarction of the gonad. *Epid.*, epididymis.

FIGURE 58.3. Torsion of testis. **A.** Swollen, diffusely tender testis high in the scrotum (from twisting of cord structures). **B.** Surgically exposed testis showing torsion of cord structures. Testis was infarcted and was removed.

The sudden onset of severe scrotal pain and tenderness, often with radiation to the abdomen, and associated nausea and vomiting is typical. Often, these episodes have their onset in the early morning. At other times, they may be associated with sports activity or mild testicular trauma that may be perceived by the patient as cause of the pain. A history of trauma often is misleading in patients with testicular torsion. The patient may recall prior episodes of similar pain that resolved spontaneously, suggesting intermittent torsion and spontaneous detorsion.

With torsion of the testis, typically the testis is acutely swollen and diffusely tender and usually lies higher (“horizontal or transverse lie”) in the scrotum than its contralateral mate. Because the pain may be referred to the abdomen, it is essential that the genitalia are examined carefully in every child who complains of abdominal pain. There may be overlying erythema of the skin of the scrotum. The cremasteric reflex is usually absent with testicular torsion but may be present in early or incomplete torsion. Urinalysis is usually negative.

Time is important in establishing the diagnosis of torsion of the testis. If a testis has been twisted sufficiently to fully obstruct its blood supply for more than 6 to 12 hours, surgical detorsion is unlikely to salvage the gonad. It is impossible to determine clinically, however, whether the torsion has been partial or total. Therefore, it is an oversimplification to assume that if symptoms have been present for more than 6 to 12 hours, an irreversible situation has developed that would preclude any attempt at testicular salvage. The duration of symptoms does not always determine functional recoverability.

Although the diagnosis continues to be established most reliably by a skilled examiner familiar with acute scrotal lesions in children, diagnostic imaging studies may be valuable. Nuclear testicular scanning or Doppler sonography reveals decreased or absent arterial blood flow within the affected testicle when compared with its mate. It must be stressed that if the history and physical examination strongly suggest testicular torsion or if any appreciable time would be lost in arranging for these studies, the preferred course is to proceed with surgical exploration or an attempt at manual detorsion (see Fig. 58.5) if surgical intervention is not readily available.

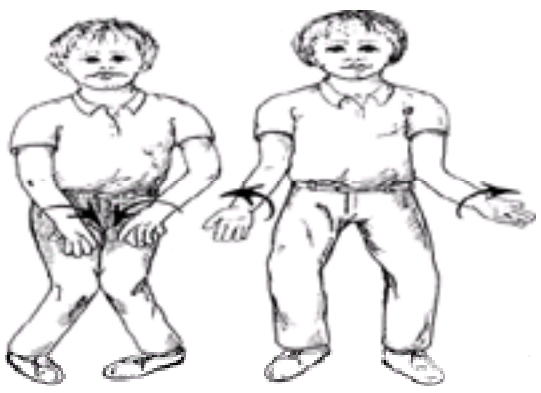

FIGURE 58.5. Torsion of testis. Because torsion typically occurs in a medial direction, manual detorsion should be attempted initially by rotating the testis outward toward the thigh.

The testicular nuclear perfusion scan with technetium-99 pertechnetate is helpful (Fig. 58.4) but has limitations. Technetium is injected and the scrotum scanned. Impeded blood flow to the torsed testicle results in a cold spot. The presence of a hydrocele, abscess, hematoma, or scrotal hernia may result in decreased counts on that side of the scrotum and may be confused with a torsion of the testis. False-negative scans may occur from spontaneous detorsion or in cases of late torsion in which a severe degree of overlying scrotal edema may be associated with sufficient, increased vascularity to obscure the underlying ischemic testis. Doppler flow ultrasound can assess anatomy and blood flow. Limitations associated with Doppler sonography must also be recognized, particularly related to small, lower flow prepubertal testes and the operator-dependent nature of this test. False-negative ultrasounds may occur for reasons similar to those discussed for nuclear scan. Another pitfall encountered with use of both sonography or nuclear scan is incomplete or intermittent torsion in which the study may indicate normal, increased, or decreased flow, depending on timing.

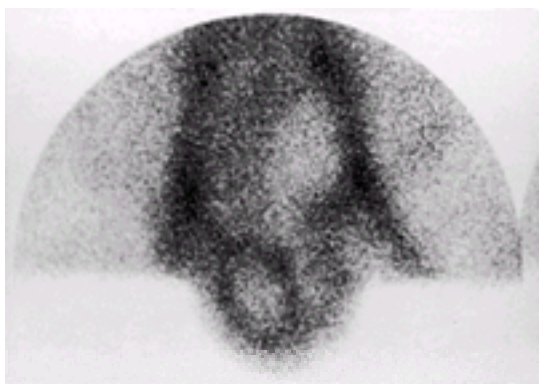

FIGURE 58.4. Torsion of testis (several days old). Testicular scan (technetium-99m) shows central photopenic area surrounded by photon dense area reflecting inflammatory reaction around necrotic testis.

The therapy for testicular torsion is surgical exploration, detorsion, and fixation of both the torsive and contralateral testicles. If a child is seen within a few hours of the onset of his torsion, before severe scrotal swelling has ensued, it may be possible to accomplish detorsion of the spermatic cord manually and thus restore blood supply to the testis. The Doppler ultrasound stethoscope provides a noninvasive evaluation of testicular blood flow and is a useful adjunct in manual detorsion of the testis. Initial examination reveals decreased arterial flow to the affected testis, compared with the contralateral one. Intravenous fentanyl (1 to 3 µg/kg) or morphine (0.1 mg/kg) is administered just before attempting detorsion. Because torsion typically occurs in a medial direction, the detorsion should be carried out by rotating the testis outward toward the thigh (Fig. 58.5). Relief of pain and reposition of the testis in a lower position in the scrotum suggests a successful outcome. This can be confirmed with the Doppler stethoscope by noting a return of normal arterial pulsations to the testis. Although successful completion of manual detorsion may avoid the necessity of an emergency anesthetic for surgical reduction, it does not remove the necessity for a fixation of the testis to prevent the recurrence of this condition. An orchiopexy of the affected testis, as well as of the contralateral one, which is malfixed in more than 50% of cases, is recommended during the same hospitalization.

Torsion of Testicular Appendage

Several vestigial embryologic remnants are commonly attached to the testis or epididymis that may twist around their base, producing venous engorgement, enlargement, and subsequent infarction. Appendage torsion is most common in boys aged 7 to 12 years but can occur at any age. Scrotal pain is the usual presenting feature, although the pain is typically less severe and more indolent in onset than the pain associated with testicular torsion. Although there may be associated nausea, vomiting, and diaphoresis, these symptoms are less common than with torsion of the testis.

If the child is seen early after the onset of pain, scrotal tenderness and swelling may be localized to the area of the twisted appendage, typically on the superior lateral aspect of the testis. It may be possible to hold the testis gently and have the patient point to the specific point of pain. If this site is indicated to be the upper pole of the testis with the remainder of the testis being nontender, the diagnosis of a torsion of a testicular appendage is likely. Although the classic “blue dot” sign of an infarcted appendage may be visible, often it cannot be seen because of overlying edema. In some cases evaluated later in the clinical course, the degree of scrotal tenderness and edema increases to the point at which differentiation from torsion of the testis becomes difficult. Nuclear scanning or Doppler sonography demonstrates normal or increased flow to the affected testicle and epididymis compared with the opposite side, representing the inflammation that occurs with torsion of the appendage. Occasionally, surgical exploration may be required to be certain that a torsion of the testis is not present.

If the examiner is confident in the diagnosis of a torsion of an appendix testis, surgical exploration is not needed. The child should be sent home with analgesics/anti-inflammatories, support to the scrotum, and instructions to rest quietly. The pain usually resolves in 2 to 12 days, but in most cases, pain should improve somewhat within a few days. The patient should return in 48 hours, having had nothing to eat or drink on the morning of the return visit. In most cases, the child's pain will have lessened, and nothing further is indicated. Occasionally, however, a child will seem to have a disproportionate degree of discomfort from the torsion of these tiny appendages. For these children, removal of the appendage may shorten their morbidity. In the older, cooperative child, this may be carried out under a spermatic cord block, but in most cases, a general anesthetic is required. Contralateral scrotal exploration for this condition is not indicated.

Trauma/Hematocele

In children, most trauma to the scrotum results from a direct blow to the perineum or a straddle injury that forcefully compresses the testicle against the pubic bone. Penetrating injuries are less common, and the small size and greater mobility of the prepubertal testis make testicular injuries rare in this group.

Scrotal trauma includes a spectrum of injuries that ranges from minimal scrotal swelling to rupture of the testis with a tense, blood-filled scrotum (Fig. 58.6A). Unless the testis clearly can be felt to be normal and without significant tenderness, urgent surgical evaluation should be undertaken. Often scrotal ultrasound examination is useful (Fig. 58.6B). When any question of testicular rupture remains, surgical exploration is indicated. This approach is based on two facts: 1) a ruptured testis has the best salvage rate when surgically repaired, and 2) testicular torsion may present with a spurious history of trauma.

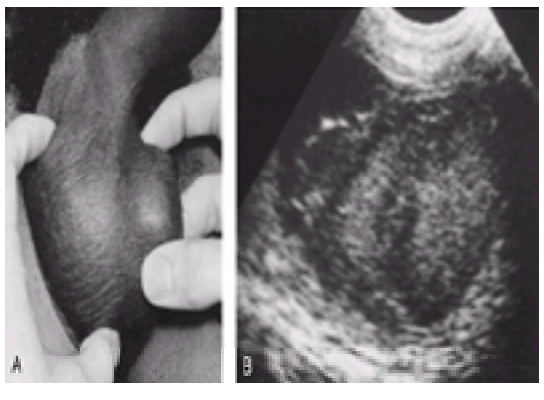

FIGURE 58.6. Rupture of testis. **A.** Testicular swelling and tenderness following kick to scrotum. **B.** Ultrasound examination of testis: central linear sonolucent area reflects site of testicular rupture. Surgical repair resulted in a well-preserved gonad.

A hematocele, or blood within the tunica vaginalis, may represent severe testicular injury. An obvious ecchymosis of the scrotal wall in the setting of trauma suggests a hematocele. Sonography can identify the fluid collection within the tunica because blood is more echogenic than hydrocele fluid. Scrotal exploration is indicated if testicular rupture is present, or in cases of large hematoceles, which heal more readily after surgical drainage.

Scrotal trauma can also result in an intratesticular hematoma or laceration of the tunica albuginea. Ultrasound can assist in determining the location of blood. Any question or indication of testicular laceration requires surgical exploration and drainage of the hematoma with repair of the laceration. If the tunica albuginea can be determined to be intact, no surgical intervention is necessary.

Traumatic epididymitis is local inflammation, resulting from blunt trauma to the scrotum, which usually occurs within a few days. Typically, short-lived acute pain associated with trauma is followed by a pain-free period after which pain returns. On examination, scrotal erythema, edema, and tenderness of the epididymis may be found. In this noninfectious variety of epididymitis, the urinalysis is negative. Sonography is helpful to rule out any more severe injury and will demonstrate hyperemia associated with the inflammation. Treatment is supportive.

If a scrotal laceration is present, it is essential that the testis and spermatic cord be evaluated for possible injury. This may require an examination under general anesthesia or an inguinal cord block with more severe injuries. For simple scrotal lacerations, careful hemostasis and closure of the laceration with chromic catgut is sufficient.

Epididymitis/Orchitis

Epididymitis is an infection or inflammation of the epididymis, which is most commonly seen in adolescents and adults. It is rarely seen in prepubertal boys in whom it is often associated with a urinary tract infection caused by structural abnormalities of the urinary tract. At any age when epididymitis is associated with a urinary tract infection and in all prepubertal boys with epididymitis, urinary tract imaging with sonogram and voiding cystourethrogram are necessary to rule out a structural problem.

The onset of swelling and tenderness is typically more gradual than with torsion of the testis or a testicular appendage. Associated symptoms of urinary frequency and dysuria may be present. Early on, the epididymis may be selectively enlarged and tender, readily distinguished from the testis. With time, inflammation spreads to the testis and surrounding scrotal wall, making localization impossible. Although elevation of the scrotum relieves pain in epididymo-orchitis (Prehn's sign) but causes increased pain in torsion, this finding has not been found to be reliable in children. The cremasteric reflex should be preserved.

Although white cells in the urinary sediment are seen more often in epididymitis than in torsion, they are not consistently present. A culture of the urine should always be obtained, as well as a culture of any penile discharge or the urethra in any sexually active male. Color Doppler sonography typically demonstrates an increase in size and blood flow to the affected testis and epididymis. Nuclear scan shows increased activity in the affected testis (Fig. 58.7).

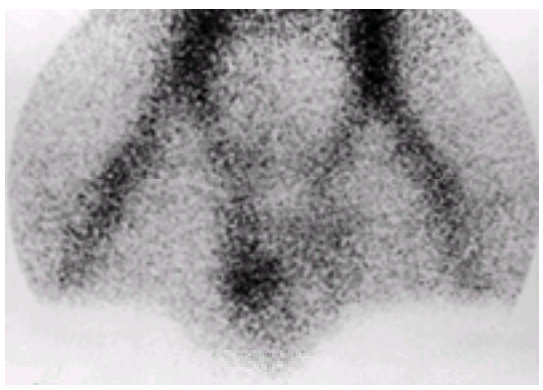

FIGURE 58.7. Epididymitis. Testicular scan (technetium-99m). Diffuse photon dense area in scrotum reflects uptake of radionuclide into inflamed epididymis.

Treatment consists of analgesics, sitz baths, elevation of the scrotum, and antibiotics. Trimethoprim–sulfamethoxazole (40 mg/kg per day sulfamethoxazole) and tetracycline (20 mg/kg per day) achieve best levels in epididymal tissue. In the older boy, as in the adult, *Chlamydia trachomatis* may account for many cases, and the patient should be treated for chlamydia and gonorrhea with doxycycline and ceftriaxone or suitable alternatives. Other organisms, including those bacteria responsible for urinary tract infections, should be considered in the younger boy. The patient should be warned that this process is frustratingly slow to resolve and that he may have several weeks of gradually subsiding discomfort and scrotal swelling.

Orchitis

Orchitis is an inflammation or infection of the testis resulting from the extension of epididymitis, rarely as hematogenous spread of a systemic bacterial infection, or following certain viral infections, including mumps. Other viruses implicated include adenovirus, Epstein-Barr virus, coxsackievirus, and echoviruses. Although rare before puberty, orchitis occurs in about 18% of postpubertal boys with mumps parotitis. In 70% of cases, it is unilateral. It results in testicular atrophy, but not necessarily sterility, in 50% of affected testes. Fortunately, it is much less common since the advent of vaccine against mumps. The onset of mumps orchitis occurs from 4 to 6 days after parotitis manifests. Although rare, orchitis has been reported in the absence of parotitis. Adrenocorticotropic hormone (ACTH) and corticosteroids in adults may produce some degree of local relief of symptoms, but the course of mumps orchitis is not altered.

Causes of Painless Scrotal Swelling

Hydrocele

An accumulation of fluid within the tunica vaginalis that surrounds the testis—a hydrocele—may be seen with torsion of the testis or an appendage, epididymitis, trauma, or tumor. In these cases, examination of the underlying testis is abnormal. If the testis can be felt to be normal and the hydrocele is not associated with any abnormality of the overlying scrotal soft tissues, it is much more likely to be a simple hydrocele. In the infant, this is the result of fluid being left in place after the processus vaginalis has closed. When the size of the hydrocele has no history of waxing or waning, it may simply be observed. Usually, the fluid will be reabsorbed in the first 12 to 18 months of life.

If the hydrocele has a clear-cut history of changing in size (often with crying or exertion), particularly if it is associated with thickening of the cord structures as they are felt against the pubic tubercle (the silk-glove sign), then the processus vaginalis is patent and the diagnosis is that of a communicating hydrocele (Fig. 58.8). Here the patent processus vaginalis does not generally close spontaneously and may enlarge to permit the development of hernia. Surgical exploration and high ligation of the processus vaginalis with a wide opening of the tunica vaginalis to complete the decompression of the hydrocele is appropriate treatment. Because a scrotal hernia may be confused with a hydrocele, aspiration should never be carried out in children.

FIGURE 58.8. Hydrocele. Waxing and waning of size indicates a communicating hydrocele with a patent processus vaginalis, requiring surgical correction.

Occasionally, a hydrocele of the cord presents as a scrotal swelling just above the testis. Differentiation from an incarcerated hernia may be difficult and occasionally may require surgical exploration. Surgical treatment like that for a hydrocele of the testis is appropriate.

Hernia

Although most inguinal hernias present in children with a mass in the groin, occasionally the hernia may extend and present as a scrotal swelling. An incarcerated hernia may produce pain in some patients. The diagnosis and treatment of inguinal hernias is discussed in Chapter 118.

Varicocele

A usually painless scrotal swelling caused by a collection of abnormally enlarged spermatic cord veins, called a varicocele, is most commonly found on routine examination of asymptomatic boys aged 10 to 15 years. Most varicoceles occur on the left, representing spermatic vein incompetence caused by the left spermatic vein draining into the renal vein at a sharp angle, whereas the right spermatic vein drains into the inferior vena cava.

On occasion, a varicocele can present with mild pain or discomfort. The hemiscrotum appears full but does not have overlying skin changes. The testis and epididymis should be palpated to be normal. A mass of varicose veins described as “a bag of worms” can be appreciated above the testicle. Standing and supine examination often reveals the varicocele, which is more prominent when standing. Doppler ultrasound is diagnostic, demonstrating both normal flow to the testis and the collection of tortuous veins. Some large varicoceles may require internal spermatic vein ligation and may have some impact on testicular size and fertility. Most varicoceles are asymptomatic and benign.

Spermatocele

Located above and posterior to the testicle in postpubertal boys, spermatoceles are sperm-containing cysts of the rete testes, ductuli efferentes, or epididymis. Multiple or bilateral spermatoceles may occur. On examination a small, nontender mass that transilluminates may be appreciated distinct from and posterior to the testicle. These masses must be differentiated from a hydrocele or tumor. Sonography may confirm the location distinct from the testis and help distinguish a spermatocele from tumor. Referral to a urologist is indicated for the excision of large uncomfortable spermatoceles or for aspiration to differentiate a hydrocele from a spermatocele. Otherwise, no specific treatment is needed.

Idiopathic Scrotal Edema

Idiopathic scrotal edema is a rare entity that represents only 2 to 5% of acute scrotal swellings in otherwise normal children. Typically, a prepubertal child presents with the rapid onset of painless but notable edema of the scrotal wall that may be bilateral and may extend up onto the abdominal wall. The skin of the scrotum may be erythematous. The child is usually afebrile and urinalysis is negative. Through the edematous scrotum, the testes can be felt to be normal in size and nontender. This edema of the scrotal wall is of unknown origin, although it is believed to represent a form of angioneurotic edema. Insect bites, allergic reactions, cellulitis, and contact dermatitis can also be contributors to localized scrotal swelling. No specific therapy has been demonstrated to be effective. Bed rest and scrotal elevation may help. Children spontaneously begin to improve within 48 hours, regardless of treatment. Occasionally, scrotal edema is seen secondary to diseases that cause generalized edema and/or ascites, such as nephrosis and cirrhosis.

Henoch-Schönlein Purpura

Occasionally, a child may be seen with a petechial rash on the scrotum as the initial presentation of this systemic vasculitic syndrome characterized by nonthrombocytopenic purpura, arthralgia, renal disease, abdominal pain, and gastrointestinal bleeding. More typically, the rash begins on the lower extremities or buttocks and later may involve the scrotum. If the associated swelling is not great, the cord structures and testes can be felt to be uninvolved and normal. In other cases with severe swelling, surgical exploration may be necessary to rule out testicular torsion, which rarely has been noted to coexist. When skin lesions are present the diagnosis of Henoch-Schönlein purpura (HSP) must be suspected. Occasionally, the acute scrotum is the dominant presenting symptom. Ultrasound may help rule out testicular torsion in these instances.

Kawasaki Disease

Another vasculitis that can produce scrotal swelling and mild pain is Kawasaki disease, which has characteristic features including fever, adenopathy, rash, conjunctivitis, and irritability. Although discussed in detail elsewhere (see Chapter 101), it is important to note the association of scrotal swelling with this systemic disease to avoid unnecessary surgical explorations or delay in diagnosis of the underlying vasculitis.

Testis Tumor

Testicular or paratesticular tumors are rare in children. They usually present as painless, unilateral, firm to hard scrotal swellings. Leukemic infiltration of the testis may present bilaterally. There may be an associated hydrocele. In children less than 2 years of age, the tumor usually is a yolk sac carcinoma or teratoma. After puberty, germinal cell tumors, as found in the adult population, are seen. Evaluation of a solid testicular mass involves an initial testicular ultrasound examination usually followed by surgical exploration through a groin incision to permit control of the spermatic vessels and a possible radical inguinal orchiectomy.

Antenatal Torsion Testis (Newborn)

A newborn boy may present with a painless, smooth, testicular enlargement that usually is dark in color. There should be no or minimal edema of the overlying scrotum. This is extravaginal torsion of the testis and probably occurs during the late period of embryonic development, as the testis descends into the scrotum. At this time, the testicular tunics are not yet attached to the scrotal tissue, and torsion of the entire testis with its tunics can occur. Even though the conventional course of action has been surgical exploration, salvage of the testis has been rare. It has been argued that the contralateral testis may be malfixed and at risk for subsequent torsion and therefore should undergo surgical fixation. Torsion has been reported rarely, however, and current practice is simply to observe these children. After 4 to 6 months, the torsed testis usually has been resorbed.

EVALUATION AND DECISION

Although this chapter is entitled scrotal pain, the most efficient approach to the differential diagnosis is through consideration of the important entities causing painful versus painless scrotal swelling. This approach is outlined in Figure 58.9. Testicular torsion, torsion of an appendage, orchitis, epididymitis, and trauma related injuries to the scrotum or testicles are further discussed as the common etiologies for painful scrotal swelling. Hemorrhage into a tumor, incarcerated hernias, HSP, and Kawasaki disease may cause either painful or painless scrotal swelling. No one aspect of the history or physical examination may be diagnostic, but collectively the clinical findings often suggest a diagnosis. More recently available adjunctive radiologic studies may be helpful when the clinician is fully aware of their capabilities and limitations.

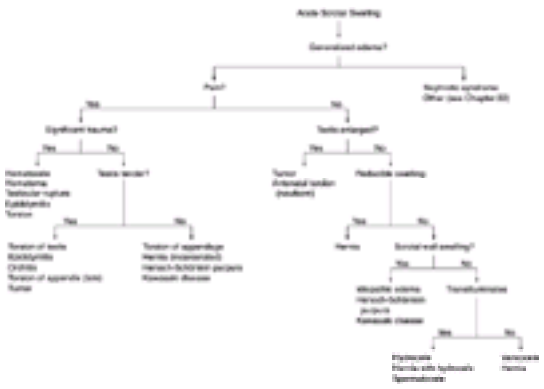

FIGURE 58.9. Diagnostic approach to acute scrotal swelling.

Initial Approach

As a first step in the evaluation of the child with a complaint of scrotal swelling or pain, the physician should determine whether the child is suffering from a generalized edematous state, such as the nephrotic syndrome. When the problem in localized to the scrotum, patients can be divided into those who have a painless swelling and those who are experiencing pain.

In the immediate neonatal period, antenatal torsion may cause painless scrotal enlargement. Beyond infancy, the most common causes (Table 58.2) are hernias and hydroceles; a hernia is often reducible. The physician must also consider idiopathic scrotal edema, spermatocele, and varicocele. Both Kawasaki disease and HSP may involve the scrotal sac and cause swelling that is either painless or mildly painful. When the swelling is within the scrotum, rather than involving the scrotal sac, possible diagnoses include hydrocele, hernia (reducible if incarcerated and nonreducible), spermatocele, and hydrocele.

Painful swelling may follow a well-documented injury, in which case the likely diagnoses are hematocele, hematoma, testicular rupture, and traumatic epididymitis. The physician should bear in mind that boys with testicular trauma often give a history of having had an incidental minor injury. Nontraumatic scrotal pain raises the suspicion of a testicular torsion, particularly if the testis is tender. Unless the diagnosis of a systemic disorder (HSP, Kawasaki disease) is obvious, the patient is an adolescent with the classic signs of epididymitis, or an incarcerated hernia is reduced, imaging via Doppler ultrasound or nuclear scan is usually indicated. All patients in whom torsion is suspected, after an initial evaluation by the emergency physician, require a surgical consultation.

History

The age of the child should be considered in evaluating scrotal pain and/or swelling, but overlaps in characteristic age at presentation exist. Testicular torsion occurs in the newborn or early pubertal age range. Torsion of an appendage of the testis, HSP, idiopathic scrotal edema, and Kawasaki disease commonly occur in the prepubertal age group. Epididymitis is more common in adolescents but may occur in prepubertal boys.

Onset of pain is more abrupt in testicular torsion, whereas, the pain of appendage torsion and epididymitis is more gradual. Children may have difficulty pinpointing the onset of pain and even the exact location of their pain because they may not initially localize sensation to the scrotum, but rather often complain of lower abdominal pain. Questions about recent activity and behavior may indicate a more insidious course. Nausea and vomiting often accompany testicular torsion, and fever and symptoms of urinary tract infection may suggest epididymitis or other inflammatory diseases (vasculitides).

A history of trauma should always be addressed recognizing the difference between significant trauma associated with severe acute pain and minor trauma to which the pain of torsion may mistakenly be attributed by the patient. Prior scrotal pain may also indicate intermittent torsion.

A history of prior genitourinary surgeries should be elicited because predisposition to urinary tract infections and epididymitis may be related to genitourinary abnormalities or prior instrumentation. Prior surgery for hernias, hydroceles, and undescended testis, unless associated with other genitourinary or anal rectal abnormalities, does not suggest a predisposition to infection. In addition, torsion can occur despite prior scrotal surgeries thought to secure the testis.

Physical Examination

Examination of the child with scrotal pain and/or swelling should be both careful and organized. Initial observation of the patient's gait, resting position, and facial expression are helpful. Writhing or an especially quiet supine posture versus active movement may best indicate the degree of pain. Observation of associated skin changes, presence and location of swelling, and the natural position of the testicle in the scrotum while standing should then be appreciated. The cremasteric reflex elicited by stroking the upper inner thigh should cause the testicle to elevate when intact. Next the lower abdomen, inguinal canal, and cord should be palpated. Finally the scrotum and its contents should be sequentially palpated. Asking the patient to localize his pain with one finger at this time may be especially helpful. The unaffected hemiscrotum should always be palpated first. Knowledge of the location and specific attempt at palpation of the appendix testis and epididymis is beneficial before palpation of the testis itself (Fig. 58.2). Appreciation of swelling, tenderness, and consistency should be noted for all intrascrotal structures. Transillumination may be helpful in some cases (Fig. 58.9).

Imaging Modalities

Technetium-99 pertechnetate radioisotope scanning has been used to assess testicular blood flow. In a child with torsion, little or no isotope appears in the testis, whereas normal or increased activity in the affected testis is associated with epididymitis and appendage torsion. This study provides no information about anatomy and, in addition to a procedure time of approximately 30 minutes, often requires some time in gathering staff, achieving intravenous access, and preparing the isotope. The interpreter of this study must also be confident in differentiating blood flow to the testis versus the scrotal wall.

Color Doppler imaging with pulsed Doppler allows both visualization of scrotal anatomy and intratesticular arterial blood vessel flow determination and comparison. This study can differentiate scrotal wall from testicular blood flow. With appropriate experience, Doppler imaging has comparable accuracy to that of nuclear scanning. This study is noninvasive and requires less preparation, making it more readily available. The operator-dependent nature of the study and the need for clinical correlation must be heeded. Torsion is diagnosed when blood flow is diminished or absent, as compared with the contralateral testis. Any doubt in interpretation or concern about the adequacy of the signal should result in consideration of surgical exploration.

CHAPTER 59

Pallor

ALAN R. COHEN, MD

Department of Pediatrics, The University of Pennsylvania School of Medicine, and Division of Hematology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Rosy cheeks in children always have been valued highly by grandmothers and other trendsetters in American life. Unfortunately, the loss or absence of this pleasing pink color is a relatively common problem in childhood. The development of pallor can be acute and associated with a life-threatening illness, or it can be chronic and subtle, occasionally first noted by someone who sees the child less often than the parents. The onset of pallor can provoke anxiety for parents who are familiar with descriptions of the presentation of leukemia in childhood. In some instances, only reassurance may be needed, as in the case of a light-complexioned or fair-skinned, nonanemic child. Even if there is a hematologic cause for the pallor, it often is a temporary condition readily amenable to therapy. Pallor can portend a severe disease, however, and when acute is onset, it can herald a true pediatric emergency for which rapid diagnosis and treatment are needed.

The degree of pallor depends on the concentration of hemoglobin in the blood and the distribution of blood in the blood vessels of the skin. Any condition that decreases the concentration of hemoglobin or alters the distribution of blood away from the body's surface may present as pallor. Clinically, pallor caused by anemia usually can be appreciated when the hemoglobin concentration is below 8 to 9 g/dL, although the complexion of the child and the rapidity of onset may influence this value. The hematologic causes for pallor in children are discussed later, and further details regarding their management may be found in Chapter 87. Nonhematologic causes of pallor are outlined briefly in Table 59.1.

Physiologic ("fair-skinned")	Respiratory distress
Shock: septic, hypovolemic, neurogenic, cardiogenic, anaphylactoid	Skin edema
	Pheochromocytoma
Hypoglycemia and other metabolic derangements	

Table 59.1. Pallor Without Anemia

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the major hematologic causes of pallor in children is outlined in Table 59.2. The concentration of hemoglobin in the blood can be lowered by three basic mechanisms: decreased erythrocyte or hemoglobin production, increased erythrocyte destruction, and blood loss. The most common causes of pallor and anemia seen in the emergency department (ED) are iron deficiency, infections, and blood loss (Table 59.3), but several less common diseases remain important considerations.

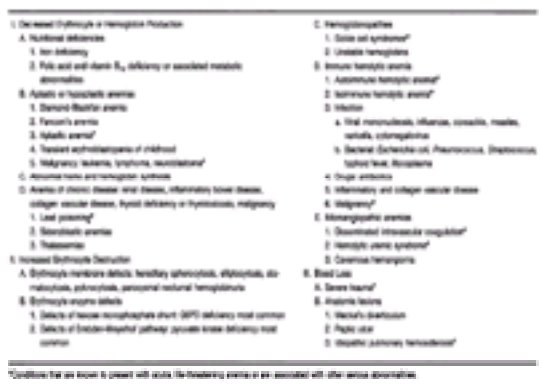

Table 59.2. Pallor With Anemia

Decreased Erythrocyte or Hemoglobin Production	Increased Erythrocyte Destruction
Iron deficiency	Sickle cell syndromes
Aplasia	Autoimmune hemolytic anemia
	Viral, bacterial, or parasitic infections
	Blood Loss

Table 59.3. Relatively Common Causes of Pallor or Anemia

Decreased Production of Hemoglobin and Red Cells

Nutritional Anemias

In children, the most common cause of decreased hemoglobin production is nutritional iron deficiency. This condition usually is seen in the first 2 years of life, at which time the dietary iron content often is insufficient to meet the demands of the rapidly increasing red cell mass. Premature infants are particularly likely to develop iron deficiency anemia because iron stores at birth are less than those found in term infants, whereas the growth (and therefore expansion of the red cell mass) of the premature infant often is faster than that of term infants. The early exhaustion of iron stores in premature babies may result in pallor by 6 months of age; in normal infants, signs of iron deficiency anemia are uncommon before 10 to 12 months.

The infant with severe iron deficiency usually is irritable and very pale. The lack of iron in the diet may be readily apparent or may be recognized only after careful questioning, particularly regarding the daily consumption of cow's milk. The hemoglobin concentration may be as low as 2 g/dL at the time of diagnosis. Severe anemia may result in a compensatory increase in cardiac output. Conditions that complicate anemia, such as fever, may make further demands on the heart and thereby provoke the development of congestive heart failure (see Chapter 82).

The red cells are markedly microcytic and hypochromic in severe iron deficiency anemia. Variation in red cell size and shape usually is present, and elongated, pencil-like cells are particularly common. The percentage of reticulocytes may be elevated moderately, but the absolute reticulocyte count is low. Treatment usually is instituted before confirmatory laboratory studies are available. This rarely poses a problem, however, because the diagnosis often can be made on the basis of the history alone. The rapidity of the assay for free erythrocyte protoporphyrin, which is increased in iron deficiency anemia, makes this test particularly useful in the evaluation of the severely anemic child. Serum iron and ferritin levels have too long of a turnaround time to be of much value in the emergency management of anemia, but they are valuable confirmatory tests.

Other nutritional anemias, such as vitamin B_{12} or folic acid deficiency, are uncommon in children in the United States and rarely develop in the absence of a grossly altered diet, extended hyperalimentation, intestinal resection, or chronic diarrhea. Unusual alterations of B_{12} and folic acid absorption and metabolism may cause symptoms similar to those of the nutritional megaloblastic anemias. Megaloblastic anemia is rarely severe enough to be life-threatening. The condition is characterized by normochromic, macrocytic red blood cells, hypersegmented neutrophils and an elevated serum level of lactic dehydrogenase (LDH). The diagnosis of nutritional disorders is confirmed by the finding of low serum levels of folic acid or vitamin B_{12} and the response to folic acid or vitamin B_{12} replacement therapy.

Hypoplastic and Aplastic Anemia

Pallor usually is the first sign of aplastic or hypoplastic anemia. Diamond-Blackfan syndrome is a congenital hypoplastic anemia commonly detected in the first few months of life. The anemia can be severe at the time of diagnosis. The red cells are normocytic or macrocytic. The reticulocyte count is low. The white cell count is low in approximately 10% of affected patients, but thrombocytopenia occurs only rarely. The diagnosis is made by examination of a bone marrow aspirate that shows markedly reduced or absent erythrocyte precursors. The second major congenital hypoplastic

anemia is Fanconi's anemia, a syndrome characterized by pancytopenia and associated abnormalities, including hyperpigmentation and hypopigmentation, microcephaly, strabismus, small stature, mental retardation, and abnormalities of the thumbs and radii. Unlike Diamond-Blackfan syndrome, all three cell lines of the bone marrow are affected, and the hematologic abnormalities rarely develop before 3 to 4 years of age. The anemia is normochromic and macrocytic.

Acquired aplastic anemia also can present with severe pallor in children. The anemia usually is associated with granulocytopenia and thrombocytopenia. The condition often is idiopathic but has been associated with exposure to certain drugs and chemicals (chloramphenicol, benzene, pesticides), radiation, and viral infections (especially hepatitis). The diagnosis is made by an examination of the bone marrow.

Transient erythroblastopenia of childhood (TEC) is a condition often associated with a recent viral illness and is characterized by moderate to severe anemia caused by diminished red cell production. The mean corpuscular volume (MCV) usually is normal at the time of diagnosis. The white cell count is normal or moderately decreased; the platelet count is normal. The reticulocyte count is decreased, and the Coombs test is negative. Bone marrow examination shows reduction or absence of erythrocytic precursors initially, followed by erythroid hyperplasia during recovery. Transient erythroblastopenia that occurs in the first 6 months of life may be difficult to distinguish from Diamond-Blackfan anemia. Spontaneous recovery ultimately confirms the diagnosis of TEC.

Hypoplastic anemia can be the presenting symptom of childhood malignancies. The pallor can be severe, and although all three cell lines of the bone marrow usually are affected, anemia may be the only notable hematologic abnormality. The diagnosis can be suspected from the presence of other symptoms or findings such as lymphadenopathy, bruising, limb pain, gum bleeding, or an abdominal mass.

Patients with hemolytic anemias such as spherocytosis or sickle cell disease may develop red cell aplasia, usually in association with parvovirus B19 infection. Decreased red cell production in the face of ongoing hemolysis causes an exacerbation of the anemia. The usually elevated reticulocyte count falls to inappropriately low levels, often less than 1%. Although the platelets and white cells are generally unaffected, they may be mildly deceased. Red cell transfusions are appropriate if the anemia is associated with cardiovascular signs or symptoms or if continuing reticulocytopenia indicates that the anemia is likely to become severe before the usual spontaneous recovery after 3 to 7 days. Hematologically normal children with underlying (but sometimes unrecognized) immunologic disorders may also develop parvovirus-induced anemia as a result of prolonged viremia.

Disorders of Heme and Globin Production

Pallor may be the presenting sign of nonnutritional disorders of hemoglobin synthesis, including the sideroblastic anemias and thalassemia syndromes. These disorders are characterized by a microcytic, hypochromic anemia. Sideroblastic anemia may be inherited (sex-linked) or acquired. Iron use within the developing red cell is abnormal, accounting for the presence of diagnostic ringed sideroblasts in the bone marrow. The serum iron and ferritin levels usually are markedly elevated.

In the thalassemias, production of the globin portion of the hemoglobin molecule is defective. Cooley's anemia (b-thalassemia major) presents with severe pallor usually between 6 and 12 months of age, as the fetal hemoglobin (HbF) level declines but the normal rise in adult hemoglobin (HbA) production fails to occur because of reduced or absent b-globin production. Although b-thalassemia is often associated with Mediterranean ancestry, this disease and related disorders (e.g., E-b thalassemia, HbH disease) also are seen commonly in children of Southeast Asian, Indian, Pakistani, and Chinese background. The presence of hepatosplenomegaly and characteristic red cell morphology, including marked variation in red cell shape, makes this diagnosis readily apparent.

Lead poisoning affects heme synthesis, but significant anemia is unusual unless blood lead levels are markedly elevated. Iron deficiency is common in children with increased lead levels and usually accounts for the microcytic anemia found in these patients. If a concomitant hematologic disorder cannot be found in the anemic patient with plumbism, particular care should be given to the possibility of severe lead intoxication.

Systemic Disease

Numerous disorders that are not primarily hematologic may be associated with pallor and anemia. Occasionally, pallor is the only presenting finding of a serious systemic disorder. Chronic inflammatory diseases, such as juvenile rheumatoid arthritis (JRA) and ulcerative colitis, often are accompanied by a normocytic or microcytic anemia related to impaired iron use. The serum iron is reduced. The low iron-binding capacity distinguishes the anemia of chronic inflammation from the anemia of iron deficiency. Similar clinical and laboratory findings may be associated with chronic infections such as acquired immunodeficiency syndrome (AIDS) and subacute bacterial endocarditis. Other diseases in which anemia may be a prominent component include chronic renal disease, hyperthyroidism, and hypothyroidism. The anemia in these disorders is not severe enough to be considered a hematologic emergency unless complicated by other hematologic abnormalities. However, the anemia may be the first clue to an underlying disease in which early treatment may improve the outcome substantially.

Increased Red Cell Destruction

The numerous conditions associated with shortened red cell survival can be congenital, as in the case of the hemoglobinopathies and membrane and enzyme defects, or acquired, as in the case of autoimmune hemolytic anemia, drug-associated hemolytic anemias, disseminated intravascular coagulation (DIC), and hemolytic uremic syndrome (HUS). The hemoglobin levels in these disorders can be normal, slightly depressed, or so low as to be life-threatening. This level is determined by the severity of the defect and the patient's ability to respond to the presence of a shortened red cell survival. Compensation is achieved by an increase in erythrocyte production as is evident from the elevated

reticulocyte count that usually is found in these conditions.

An alteration in the patient's ability to compensate for increased red cell destruction may result in a severe, life-threatening exacerbation of the underlying anemia (see the previous section). This aplastic crisis, the result of a transient decrease in erythrocyte production in the presence of shortened red cell survival, should be suspected in a patient with a known hemolytic anemia who develops increasing pallor and anemia associated with a reticulocyte count much lower than usual. Unfortunately, when the hemolytic anemia has not been diagnosed previously, the recognition of an aplastic crisis can be difficult because the findings are similar to those of transient erythroblastopenia of childhood or congenital erythrocyte hypoplasia (i.e., anemia with low or absent reticulocytes). Examination of the bone marrow may be helpful in distinguishing these disorders because production of early red cell precursors often has resumed shortly after detection of an aplastic crisis. Often, the diagnosis of an aplastic crisis is made only after the aplasia has ended and the underlying hemolytic anemia is apparent. After resolution of a suspected aplastic crisis, every effort should be made to uncover any underlying condition that might cause shortened red cell survival. The differential diagnosis of such conditions is presented next.

Membrane Disorders

The degree of pallor associated with anemia caused by erythrocyte membrane abnormalities depends on the hemoglobin level. In rare instances, patients with hereditary spherocytosis, the most common of the membrane disorders, may develop significant anemia and pallor in the newborn period. Moderate or severe anemia is less common in the other membrane disorders, such as hereditary elliptocytosis and hereditary stomatocytosis. The anemia of the erythrocyte membrane disorders is accompanied by reticulocytosis. The red cell morphology often permits the diagnosis to be made from the peripheral smear. Because these disorders often are inherited in an autosomal dominant fashion, a family history of anemia, splenomegaly, splenectomy, or cholecystectomy may be helpful. However, a particularly severe form of spherocytosis occurs as an autosomal recessive disorder, and some children with more typical disease lack an informative family history. Consequently, the diagnosis should not be dismissed in the absence of other affected family members.

Infantile pyknocytosis is a hemolytic anemia seen during the first few months of life and is characterized by distorted and contracted erythrocytes and burr cells. The disorder may be associated with pallor and hyperbilirubinemia. Spontaneous recovery usually occurs by 6 months of age.

Enzyme Disorders

Erythrocyte enzymatic defects, such as pyruvate kinase deficiency and certain variants of glucose-6-phosphate dehydrogenase (G6PD) deficiency, may be associated with pallor from increased red blood cell destruction. In the latter disorder, pallor may be accentuated by acute hemolytic crises after exposure to oxidant stress (e.g., naphthalene-containing mothballs, drugs, acidosis). Although alterations in red cell morphology sometimes are found in these enzyme disorders, assays of specific enzymes or substrates are required for definitive diagnosis.

Hemoglobinopathies

Pallor may result from the low hemoglobin level found in patients with sickle cell anemia and related hemoglobinopathies. Acute accentuation of pallor can result from an aplastic crisis, a complication of hemolytic disorders that is particularly common in sickle cell anemia. During an aplastic crisis, the normally elevated reticulocyte count may fall to zero, and the hemoglobin level may fall as low as 1 to 2 g/dL, resulting in severe pallor and signs of high-output cardiac failure.

The sequestration crisis of sickle cell anemia and related hemoglobin disorders (SC disease, S-b° thalassemia, S-b $^{+}$ thalassemia) results from acute pooling of red cells and plasma in the spleen. The sudden and severe anemia and the hypovolemia associated with this complication constitute a true hematologic emergency and, if untreated, may rapidly lead to death. The presence of increased pallor and acute enlargement of the spleen in a patient with a sickling disorder should prompt immediate investigation of a possible sequestration crisis. Although this complication rarely occurs in children with homozygous sickle cell disease or S-b° thalassemia after the age of 5 years, sequestration crises may occur much later in children with sickling disorders such as SC disease or S-b $^{+}$ thalassemia, in which early splenic infarction is less common.

Immune Hemolytic Anemia

Pallor caused by autoimmune hemolytic anemia usually is acute in onset and may be associated with severe anemia. The presence of only moderate anemia (6 to 8 g/dL) at diagnosis should not detract from consideration of this disease as a hematologic emergency because brisk hemolysis may result in a sudden, additional fall in hemoglobin level. Autoimmune hemolytic anemia usually, but not always, is characterized by a positive Coombs test and an increased reticulocyte count. Spherocytes are commonly seen in the peripheral smear. Other causes of immune hemolytic anemia include infections, drugs, inflammatory diseases, and malignancies.

Microangiopathic Anemia

Alterations in the normal flow of blood through the vascular system may cause increased red cell destruction. In DIC, abnormal fibrin deposition within small blood vessels results in mechanical injury to the erythrocytes. Thrombocytopenia and clotting abnormalities, which often herald the onset of DIC, also may contribute to the anemia by causing diffuse bleeding. The main diagnostic findings are red cell fragments in the peripheral blood smear, platelet and clotting abnormalities typical of a consumptive coagulopathy (see Chapter 87), and the clinical features of a disease such as septic shock, which is associated with DIC.

The increased red cell destruction in HUS and thrombotic thrombocytopenic purpura (TTP) also is caused by

intravascular fibrin deposition. Thrombocytopenia and uremia may lower the hemoglobin concentration even further by causing bleeding, impaired red cell production, shortened red cell survival, and increased plasma volume. In some instances, the anemia may be moderately severe when the uremia is only mild and thrombocytopenia is absent, leaving doubt about the correct diagnosis. In more typical cases, however, the diagnosis is readily apparent from the findings of oliguria, central nervous system abnormalities, increased blood urea nitrogen (BUN), thrombocytopenia, and abnormalities of red cell morphology, including fragments and helmet cells.

The proliferation of blood vessels within a cavernous hemangioma may trap red cells or may initiate a localized consumptive coagulopathy, causing erythrocyte destruction. Anemia is rarely severe unless the thrombocytopenia that is more typical of the disorder causes chronic blood loss.

Blood Loss

Although sudden, massive hemorrhage usually is accompanied by signs of hypovolemic shock, the repeated loss of smaller amounts of blood may be associated with few findings other than pallor. The finding of iron deficiency anemia despite normal dietary iron intake or iron supplementation may be a clue to the presence of chronic blood loss from the gastrointestinal (GI) tract or within the lungs.

EVALUATION AND DECISION

The initial assessment of the child with pallor should include an immediate determination of the degree of illness. Rapid treatment may be imperative for the severely ill child. In the presence of hypovolemic shock, immediate support of vascular volume is required. When high-output cardiac failure from severe anemia occurs, transfusion with small aliquots of packed red cells is necessary. Only after these initial therapeutic efforts have been completed can a thorough evaluation of the anemia proceed.

The presence of an underlying disease that requires immediate therapy may alter the usual approach to the investigation of pallor. For example, iron deficiency may be the most likely explanation for anemia in a pale 1-year-old African-American child with newly diagnosed meningitis, but the early recognition of this hematologic abnormality does not directly affect the management of the patient. If the anemia is caused by sickle cell disease, however, the management of a patient with meningitis may require modification. Therefore, specific studies for sickling disorders should be performed in the initial stages of the evaluation of the anemia in such a patient.

If the child with pallor is not acutely ill, a deliberate search for the cause of pallor should be undertaken (Fig. 59.1). A thorough yet relevant history should be obtained with particular attention to the type of onset of pallor. The slow development of pallor, often noticed only by a family member or friend who sees the child only occasionally, suggests diminished red cell production, as is found in bone marrow aplasia or iron deficiency. However, the acute onset of pallor is consistent with the brisk hemolysis found in autoimmune hemolytic anemia and often is accompanied by jaundice, dark urine, and cardiovascular changes.

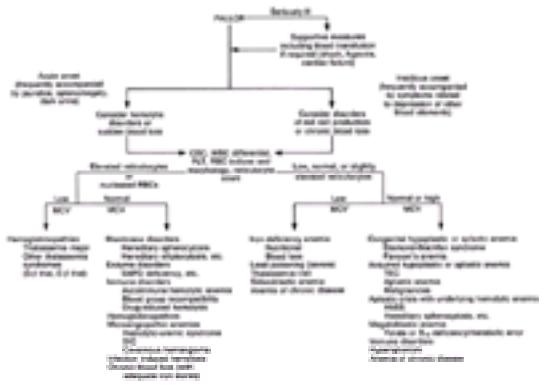

FIGURE 59.1. The diagnostic approach to pallor. *CBC,* complete blood count; *WBC,* white blood cells; *PLT,* platelets; *RBC,* red blood cells; *MCV,* mean corpuscular volume; *G6PD,* glucose-6-phosphate deficiency; *TEC,* transient erythroblastopenia of childhood; *DIC,* disseminated intravascular coagulation.

After establishing the type of onset of the anemia, the history can be directed toward more narrow categories of anemia or specific diseases. A detailed dietary history, with particular attention to milk intake, is important in young children with suspected iron deficiency; excessive consumption of cow's milk often results in iron deficiency. Vitamin B_{12} deficiency may accompany strict vegetarian diets from which meat and egg products are excluded and may occur in breast-fed infants of vegetarian mothers or mothers with pernicious anemia. Nutritional folic acid deficiency is rare and usually can be readily deduced from the presence of severe dietary alterations and evidence of other vitamin deficiencies.

Sources of internal or external blood loss should be carefully sought. Chronic GI bleeding may escape detection until iron deficiency anemia develops. Similarly, small pulmonary hemorrhages associated with idiopathic pulmonary hemosiderosis are often mistaken for other pulmonic processes until several recurrences of iron deficiency anemia suggest a hidden site of blood loss.

If increased bruising or bleeding accompanies pallor, multiple blood elements are probably affected. The circulation time of platelets is short in comparison with that of red cells. Therefore, clinical findings of thrombocytopenia often are present

by the time pallor develops in patients with acquired aplastic anemia, Fanconi's anemia, and acute leukemia.

The family history helps in the diagnosis of hemoglobinopathies and inherited disorders of red cell membranes and enzymes. Because results of previous hemoglobin testing may have been explained inadequately or recalled inaccurately, a negative family history or newborn screening for hemoglobinopathies should not preclude evaluation of the patient's hemoglobin phenotype if a sickling disorder is suspected. The presence of a microcytic anemia unresponsive to iron in the parents suggests a thalassemic disorder. A history of splenomegaly, splenectomy, or cholecystectomy in family members may help identify a hemolytic disorder such as hereditary spherocytosis or pyruvate kinase deficiency. Finally, a well-directed review of systems is essential in looking for systemic disorders such as chronic renal disease, hypothyroidism, or JRA. Pallor may be the presenting complaint in these and other disorders.

In the examination of the severely anemic patient, pallor of the skin and mucous membranes usually is readily apparent. When anemia is less severe or when the skin color is dark, pallor may be appreciated only in the nailbeds and palpebral conjunctivae. Blood pressure (BP) and pulse should be measured to be sure that hypovolemic shock and high-output cardiac failure are neither present nor imminent. If anemia or volume loss is mild, tachycardia may be present, but normal BP is preserved. A systolic flow murmur often is heard if the hemoglobin level is below 8 g/dL. Lymphadenopathy and splenomegaly may suggest a malignancy or an infectious disease such as mononucleosis. When splenomegaly occurs without lymphadenopathy, however, attention is drawn to hemolytic disorders such as hereditary spherocytosis and autoimmune hemolytic anemia or hemoglobinopathies (sickling disorders or thalassemia major). Scleral icterus also may be present in these disorders of shortened red cell survival. The finding of an unusually large and firm spleen in the absence of increasing scleral icterus suggests that red cells are being sequestered (e.g., splenic sequestration crisis of sickle cell disease, hypersplenism).

The skin should be examined for the presence of hemangiomas that might cause microangiopathic anemia. Careful auscultation of the abdomen and head may detect hemangiomas of the viscera. Bony abnormalities associated with red cell disorders include frontal bossing from compensatory expansion of the bone marrow in hemolytic diseases and radial and thumb anomalies found in some patients with Fanconi's anemia.

Numerous classifications of anemia have been used to assist the physician in the laboratory investigation of pallor. Historically, the reticulocyte count and the MCV have been helpful measurements in categorizing causes of anemia. The reticulocyte count can be performed rapidly and, as shown in Figure 59.1, distinguishes anemias caused by impaired red cell production (e.g., iron deficiency, hypoplastic anemia) from those caused by shortened red cell survival (e.g., hemoglobinopathies, membrane disorders). The MCV provides a quick, accurate, and readily available method of distinguishing the microcytic anemias (iron deficiency, thalassemia syndromes) from the normocytic (membrane disorders, enzyme deficiencies, autoimmune hemolytic anemia, most hemoglobinopathies) or macrocytic (bone marrow/stem cell failure, disorders of B_{12} and folic acid absorption or metabolism) anemias.

The reticulocyte count and MCV should be interpreted with caution. As shown in Figure 59.1, disorders of shortened red cell survival are not always characterized by an increased reticulocyte count. For example, reticulocytopenia may occur in autoimmune hemolytic anemia despite active hemolysis and increased erythropoiesis in the bone marrow. Chronic hemolytic disorders, such as sickle cell anemia or hereditary spherocytosis, may first be detected during an aplastic crisis when the reticulocyte count is low. Unless the underlying disorder is recognized, the physician may be misled by this finding. Furthermore, because the reticulocyte count is expressed as a percentage of total red cells, often it must be corrected for the degree of anemia. The easiest way to make this correction is to multiply the reticulocyte count by the reported hemoglobin or hematocrit (HCT) divided by a normal hemoglobin or hematocrit:

$$\text{Reticulocyte count} \times \frac{\text{HCT (pt)}}{\text{HCT (nl)}}$$

For example, a reticulocyte count of 5% in a child with severe iron deficiency anemia and a hematocrit of 6% is not elevated when corrected for the degree of anemia (5% × 6%/33% = 0.9%).

The MCV varies with age, necessitating the use of age-adjusted normal values (Table 59.4). In addition, the measured MCV represents an average value. If microcytic and macrocytic red cells are present in the peripheral blood as, for example, in a patient with combined iron deficiency and B_{12} deficiency, the MCV may remain normal. Therefore, the peripheral smear should be examined carefully to determine whether the MCV reflects a single population of red cells of uniform size or two or more populations of distinctly different size. The red cell distribution width (RDW) is elevated in the presence of increased variation in red cell size.

	MCV (fl)	
Age (yr)	Median	Lower Limit[a]
0.5–2	77	70
2–5	79	73
5–9	81	75
9–12	83	76
12–14:		
Female	85	77
Male	84	76
14–18:		
Female	87	78
Male	86	77

Table 59.4. Age-Related Values for Mean Corpuscular Volume

As shown in Figure 59.1, the reticulocyte count and MCV help in the initial classification of anemia but leave the physician with broad categories of disease, rather than specific diagnoses. In many instances, the history and physical examination, when coupled with these laboratory measurements, permit identification of a particular disorder. Additional laboratory studies and careful examination of the peripheral smear often are required, however, and can be performed readily when the patient is in the ED. The application of these procedures to diseases that are commonly encountered or that are associated with unusually severe anemia is discussed next.

Increased Reticulocytes and Low Mean Corpuscular Value

The thalassemia syndromes associated with moderate or severe anemia can be recognized by the distinctive abnormalities of red cell morphology. In Cooley's anemia (b-thalassemia major), the red cells generally are small but vary markedly in size and shape. Many cells appear to contain little or no hemoglobin; the central pallor extends to the cell membrane. Nucleated red cells, basophilic stippling, and polychromasia reflect active erythropoiesis. The parents of an affected child usually have a low MCV characteristic of thalassemia trait.

Children with HbS-b-thalassemia often have microcytic red cells, although the alterations of red cell morphology are not as dramatic as in Cooley's anemia. Sickled forms are often but not always present. Target cells are common. The solubility tests are positive because of the presence of HbS. Hemoglobin electrophoresis reveals HbS and reduced (less than 50%) or absent HbA.

Increased Reticulocytes and Normal Mean Corpuscular Value

Most membrane disorders can be readily identified by the characteristic changes in red cell shape that lend their names to the diseases (e.g., spherocytosis, elliptocytosis, stomatocytosis). When the diagnosis of a membrane disorder is uncertain, examination of the parents' peripheral smears may be helpful because, in many cases, the inheritance pattern is autosomal dominant.

Abnormalities of red cell morphology are less striking in erythrocyte enzymatic defects. Blister cells and cells with asymmetric distribution of hemoglobin may be found, however, during episodes of active hemolysis in G6PD deficiency. If transfusion is necessary, a pretransfusion sample should be saved for assay of specific enzymes.

The reticulocyte count usually is markedly elevated in autoimmune hemolytic anemia but may be normal or only slightly elevated during the first days of the disease. In rare instances, reticulocytopenia persists. Spherocytes usually are present on the peripheral smear. Clumping of red cells from agglutination may be seen. This agglutination sometimes causes a falsely elevated MCV because the electronic counter measures the volume of red cell couplets or triplets. The direct Coombs test is positive in 90% of cases. Patients with a negative Coombs test present a challenging diagnostic problem because the initial findings may be similar to those in hereditary spherocytosis.

The recognition of homozygous sickle cell disease usually is accomplished by the finding of sickled red cells on the peripheral smear. Rarely, however, such cells are absent, even during an acute illness. Target cells are commonly found in sickle cell disease but are more prominent in HbSC. Solubility tests are positive. Hemoglobin electrophoresis reveals the presence of the abnormal hemoglobin(s) and the absence of HbA. This confirmatory test takes less than 30 minutes to complete and should be performed when important therapeutic decisions depend on the result.

Red cell fragments are found in those diseases characterized by microangiopathic anemia. In HUS or TTP, thrombocytopenia is present, renal or neurologic function is usually impaired, and thrombotic complications may be present. The platelet count also is low in DIC, and clotting studies are abnormal. If intravascular hemolysis is severe, as in anemia associated with certain artificial cardiac valves, hemosiderin may be detected in the urinary sediment.

Low, Normal, or Slightly Elevated Reticulocytes and Low Mean Corpuscular Value

In severe iron deficiency anemia, red cells are markedly microcytic and show substantial variation in size and shape. Elongated red cells (pencil forms) are common. Platelets are often increased. As discussed previously, the erythrocyte protoporphyrin concentration usually is increased in iron deficiency, although values are lower than those found in severe lead poisoning.

Anemia is uncommon in lead poisoning but, when present, resembles the anemia of iron deficiency in its red cell morphology. Basophilic stippling is found in a small percentage of cases. The erythrocyte protoporphyrin is markedly elevated, and the rapid measurement of this compound helps the physician in the ED to distinguish severe lead poisoning, which requires hospitalization and intensive chelation, from iron deficiency, which usually can be treated on an outpatient basis.

Low, Normal, or Slightly Elevated Reticulocytes and Normal or Elevated Mean Corpuscular Value

With the exception of mild macrocytosis, red cell morphology usually is normal in childhood disorders of bone marrow or stem cell failure. Thrombocytopenia and neutropenia are present in aplastic anemia and Fanconi's anemia. Although the platelet count and white count occasionally may be low in patients with Diamond-Blackfan syndrome, the red cells are most severely affected. Erythropoiesis is most severely affected in TEC and acquired pure red cell aplasia, although neutropenia may accompany the former disorder.

The clinical features at the onset of acute leukemia may closely resemble those of aplastic anemia. Examination of a bone marrow aspirate is sometimes required to distinguish these disorders. This procedure rarely is performed in the ED.

Therapy, such as corticosteroids, which might interfere in the interpretation of the bone marrow aspirate, should be withheld until a definitive diagnosis has been made.

As discussed, children with hemolytic disorders may escape detection until pallor is noted during an aplastic crisis when the reticulocyte count is similar to that found in primary disorders of red cell production. An underlying hemolytic disease such as sickle cell anemia or hereditary spherocytosis usually can be recognized during anaplastic crisis, however, by finding characteristic red cells on the peripheral smear. In the autosomal dominant disorders of the red cell membrane, the presence of abnormal erythrocytes in the peripheral blood of one of the parents may support the diagnosis. Solubility tests for HbS or hemoglobin electrophoresis should be performed to detect sickling disorders.

The MCV usually is increased in megaloblastic anemias unless other nutritional disorders are present. Hypersegmentation of the polymorphonuclear leukocytes is characteristic. In severe or long-standing megaloblastic anemia, neutropenia and thrombocytopenia also may be found. In such cases, the findings in the peripheral blood may be similar to those of aplastic anemia or even acute leukemia; examination of the bone marrow and measurement of specific nutrients (B_{12}, folic acid) are necessary to distinguish these disorders.

CHAPTER 60

Polydipsia

RONALD I. PAUL, MD

Division of Pediatric Emergency Medicine, Department of Pediatrics, University of Louisville School of Medicine, and Emergency Department, Kosair Children's Hospital, Louisville, Kentucky

Polydipsia, or excessive thirst, is an uncommon complaint in children. Although fluid consumption varies greatly among individuals, pathologic conditions exist when excessive drinking of fluids interferes with daily life or is accompanied by bizarre behavior, such as drinking from a toilet bowl. Polydipsia is routinely accompanied by polyuria (see Chapter 75). Other accompanying symptoms depend on the underlying cause.

PATHOPHYSIOLOGY

The sensation of thirst and subsequent fluid intake is influenced by complex mechanisms that involve the hypothalamus, extracranial thirst receptors, and kidneys. As water is lost from the body, thirst centers in the hypothalamus are stimulated by an increase in serum osmolality. In response to signals from the hypothalamus, the pituitary gland releases an antidiuretic hormone that causes reabsorption of water in the collecting ducts of the kidney. In addition to physiologic controls of thirst, cortical involvement and social conditioning also play a role and may be responsible for the wide variability in fluid consumption.

DIFFERENTIAL DIAGNOSIS

Diabetes mellitus (DM) is the single most common cause of polydipsia (Table 60.1). Additional prominent symptoms of DM include weight loss and polyuria. Other common causes of polydipsia include sickle cell anemia and diabetes insipidus (Table 60.2). In sickle cell anemia, the chronic sickling of cells in the medulla of the kidney results in a limited ability to concentrate urine and mild polydipsia. In diabetes insipidus, a wide variety of lesions in the hypothalamus and neurohypophysis results in a deficiency of antidiuretic hormone. Also, a rare inherited form of nephrogenic diabetes insipidus exists that may be autosomal dominant or X-linked recessive. In instances in which the cause of diabetes insipidus cannot be readily determined, patients are diagnosed as idiopathic. These patients need frequent reevaluations because many are later diagnosed with intracranial tumors.

Diabetes mellitus	Infection
Electrolyte imbalances	Aneurysm
Hypercalcemia	Intraventricular hemorrhage
Hypokalemia	Hereditary
Bartter's syndrome	Drugs
Catecholamine excess	Methylxanthines
Pheochromocytoma	Diuretics
Neuroblastoma	Lithium
Ganglioneuroma	Renal causes
Cystinosis	Renal tubular acidosis
Diabetes insipidus (antidiuretic hormone deficient)	Nephrogenic diabetes insipidus
Craniopharyngioma	Sickle cell trait
Pituitary adenoma	Sickle cell diseases
Histiocytosis	Interstitial nephritis
Head trauma	Obstructive uropathy
Sarcoidosis	Primary polydipsia
Leukemia	Psychogenic polydipsia
	Neurogenic polydipsia

Table 60.1. Causes of Polydipsia

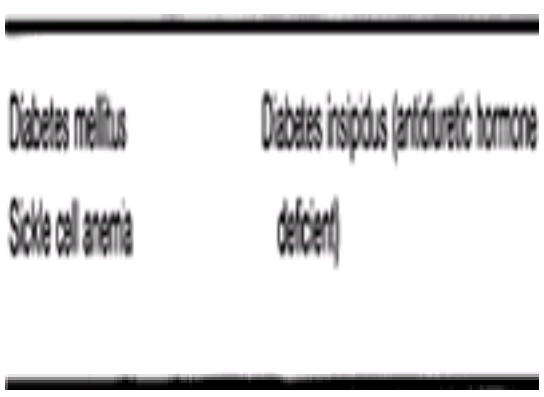

Table 60.2. Common Causes of Polydipsia

Less common metabolic and endocrine causes of polydipsia include electrolyte imbalances, catecholamine excess, and cystinosis. Primary renal causes of hyposthenuria include interstitial nephritis, renal tubular acidosis, medullary cystic disease (nephrophthisis), and obstructive uropathy. In nephrogenic diabetes insipidus, the renal tubule is unresponsive to antidiuretic hormone. Patients with nephrogenic diabetes insipidus usually have onset of symptoms in infancy and present with recurrent episodes of dehydration, fever, failure to thrive, and psychomotor retardation. Pharmacologic causes of polyuria and polydipsia include methylxanthines and diuretics. In addition, chronic lithium therapy may result in nephrogenic diabetes insipidus.

Primary polydipsia is diagnosed when the ingestion of water is in excess of that needed to maintain water balance. It can be caused by an inappropriate psychologic thirst drive (psychogenic polydipsia or compulsive water drinking) or by hypothalamic damage that alters thirst but not antidiuretic hormone release (neurogenic polydipsia).

Most children with polydipsia have serious but nonacute problems. Potential life-threatening conditions may develop, however, in certain circumstances (Table 60.3). Patients with diabetes insipidus or nephrogenic diabetes insipidus may develop severe dehydration if water is withheld for prolonged periods. Conversely, urgent management of hypernatremia is usually unnecessary if patients are able to drink and may be harmful if it is of chronic duration. Diabetic ketoacidosis may be an initial presentation of patients with DM and can result in extreme electrolyte and acid-base imbalances. Patients with primary polydipsia who overload their kidneys' ability to excrete free water may present with hyponatremic seizures. Many of the brain lesions that cause diabetes insipidus can become life-threatening. In fact, diabetes insipidus often is seen in dying patients with severe brain injury.

Diabetes insipidus (antidiuretic hormone deficient)	Diabetes mellitus
Nephrogenic diabetes insipidus	Primary polydipsia

Table 60.3. Life-Threatening Causes of Polydipsia

EVALUATION AND DECISION

When evaluating a child with polydipsia, the physician should seek information from the parent that would characterize the quantity of fluid taken each day and whether the child has used any unusual methods to satiate thirst. A history of nocturnal polydipsia and polyuria is helpful because most children with psychogenic polydipsia do not wake in the middle of the night for fluids. A medical history should include questions on growth and development and past episodes of severe dehydration. Inquiries should be made about known causes of polydipsia such as sickle cell disease, DM, chronic kidney disorders, head trauma, and medications (Fig. 60.1). The physical examination should include a careful evaluation for known systemic and intracranial causes of diabetes insipidus.

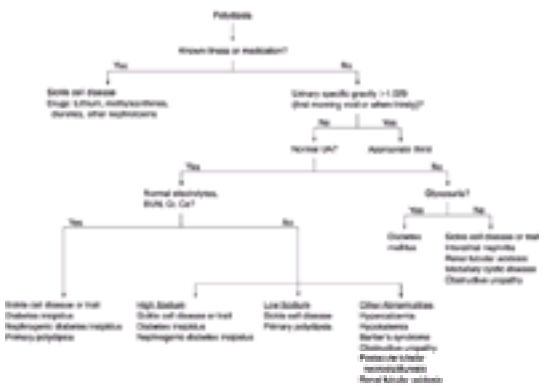

FIGURE 60.1. Diagnostic approach to a child with polyuria.

If the history and physical examination are not revealing, a urinalysis should be obtained. In almost all cases of polydipsia, the urine specific gravity will be low (less than 1.010). A specific gravity greater than 1.020 should represent appropriate thirst. If the urinalysis is abnormal, DM, sickle cell disease or trait, or an intrinsic renal disorder should be suspected. If the urinalysis is normal, electrolytes, calcium, and renal function tests may reveal conditions associated

with electrolyte imbalances. Patients with diabetes insipidus or nephrogenic diabetes insipidus may have hypernatremia if they are examined when dehydrated. A hemoglobin electrophoresis may be needed to determine whether the patient has sickle cell disease or trait. However, patients with sickle cell disease usually have the diagnosis confirmed before the development of tubular dysfunction and polydipsia. Computed tomography (CT) and magnetic resonance imaging scans may be necessary to diagnose intracranial abnormalities.

Patients suspected of having primary polydipsia, diabetes insipidus, and nephrogenic diabetes insipidus require further testing that can be dangerous. These tests should be done under controlled settings and usually are inappropriate in the emergency department.

Patients with primary polydipsia should respond to a water deprivation test by increasing their urine gravity and osmolality. Patients with diabetes insipidus and nephrogenic diabetes insipidus should have rapid weight loss while continuing to excrete urine with a low specific gravity. They may get severely dehydrated if the weight loss is in excess of 3 to 5%. Constant observation needs to be maintained during the water deprivation test to ensure that patients do not covertly consume water and to prevent severe dehydration. A trial of intranasal desmopressin (DDAVP) should distinguish between diabetes insipidus and nephrogenic diabetes insipidus because patients with antidiuretic hormone-deficient diabetes insipidus will respond to the exogenous hormone.

Unfortunately, even these tests are fraught with some inaccuracies. Patients with primary polydipsia who have chronic overhydration and diminished capacity to concentrate urine may have a blunted response to water deprivation. In addition, patients with diabetes insipidus and nephrogenic diabetes insipidus may produce a hypertonic urine if the glomerular filtration rate is decreased as severe dehydration ensues. Radioimmunoassay for antidiuretic hormone can be helpful in confusing cases.

CHAPTER 61

Rash—Eczematous

JAMES M. CALLAHAN, MD

Departments of Emergency Medicine and Pediatrics, SUNY Health Science Center at Syracuse, and University Hospital, Syracuse, New York

Pediatricians often use the terms *eczema* and *atopic dermatitis* interchangeably. To dermatologists, *eczema*, which means “to boil over,” is synonymous with *dermatitis*. Eczema is used to describe a complex of signs and symptoms, including erythema, edema, vesiculation, scaling, and pruritus. This broader use of the term is more appropriate because many disease processes and exposures may cause eczematous rashes (see also Chapter 99). The distinct forms of eczema are labeled by cause, pattern, or associated conditions such as atopy. Physical findings may reflect acute or chronic changes. Acute eczema consists of erythema, edema, exudation, clustered papulovesicles, scaling, and crusting. Chronic eczema is characterized by lichenification (thickened skin with accentuated skin markings), hyperpigmentation or hypopigmentation, and signs of excoriation. Histologic examination usually does not suggest a specific type of dermatitis. Classification and diagnosis of a particular process relies on the history and the pattern of the eczematous process.

DIFFERENTIAL DIAGNOSIS

Atopic Dermatitis

Atopic dermatitis (see Chapter 99) is by far the most common cause of an eczematous rash in children (Table 61.1 and Table 61.2). It is a chronic or relapsing condition characterized by pruritic eczematous eruptions and occurs in up to 10% of the population. Affected persons usually have a personal or family history of allergic rhinitis, hay fever, or asthma. One-half to three-quarters of patients have the onset of symptoms before age 6 months, with up to 90% developing symptoms by 5 years of age. Dry conditions (e.g., the dry weather of winter) or the drying caused by frequent bathing often lead to exacerbations. Stress, sweating, and exposure to environmental allergens (e.g., pollens or dust mite antigen) may also precipitate flares in some individuals. Some infants and young children experience worsening symptoms with exposure to certain foods (e.g., milk protein, peanuts, eggs). A United Kingdom Working Party has established diagnostic criteria for atopic dermatitis (Table 61.3).

Atopic dermatitis	Autoeczematization (Id)
Contact dermatitis	Exfoliative dermatitis*
Allergic	Photoallergic reactions
Irritant	Dermatophyte infections
Nummular eczema	Scabies
Asteotxtic eczema	Molluscum contagiosum
Dyshidrotic eczema	Eczematous rashes associated with
Seborrheic dermatitis	systemic illnesses
Lichen simplex chronicus	

*Condition that is potentially life-threatening.

Table 61.1. Differential Diagnosis of Eczematous Rash

Atopic dermatitis	Dermatophyte infections
Contact dermatitis	Scabies
Allergic	Molluscum contagiosum
Irritant	Pityriasis rosea

Table 61.2. Common Causes of Eczematous Rash

The diagnosis of atopic dermatitis is established when a history of an itchy skin condition exists and at least three of the following criteria are met: • History of involvement of the skin creases such as folds of elbows, behind the knees, front of ankles, or around the neck (including cheeks in children under 10 years of age) • A personal history of asthma or hay fever (or family history of atopic disease in children under 4 years of age) • A history of general dry skin in the last year • Visible flexural eczema (or eczema of the cheeks/forehead and outer limbs in children under 4 years of age) • Onset before the age of 2 years (not used if the child is less than 4 years of age)

Table 61.3. UK Working Party Diagnostic Criteria for Atopic Dermatitis

With acute flares of the disease, lesions are poorly demarcated, erythematous, scaly, and often weepy and crusted. Chronic lesions are poorly defined, thickened, hyperpigmented, and often excoriated. Distribution varies by age. Infants have lesions on the cheeks, trunk, diaper area, and extensor surfaces of the extremities. Children show involvement of the feet and flexor areas such as the antecubital and popliteal fossae and the neck. In adolescents and adults, flexor areas, hands, and feet are usually involved. Xerosis (dry skin), ichthyosis vulgaris (inherited fishlike scaling), keratosis pilaris (chicken-skin appearance caused by cornified plugs in the upper hair follicles), infraorbital eyelid folds (Dennie-Morgan sign), hyperlinear palms, pityriasis alba (scaly hypopigmented patches), and follicular accentuation may be seen in some individuals. Superimposed bacterial (*Staphylococcus aureus* or group A streptococcus), fungal, and viral infections (eczema herpeticum caused by herpes simplex virus) are common and may produce severe exacerbations and associated systemic signs.

Particularly severe or persistent symptoms should prompt the clinician to consider an underlying systemic disorder associated with eczematous eruptions (see the following).

Contact Dermatitis

Contact dermatitis (see Chapter 99) is an inflammatory reaction of the skin caused by an allergic stimulus or primary irritant. The reaction may be of an acute, subacute, or chronic nature. Acute eruptions have intense pruritus, severe erythema, edema, vesicles, and erosions with serous discharge and crusting. A sharp demarcation between involved and unaffected skin usually exists. Subacute reactions have mild erythema, dry scale, less vesiculation, and mild thickening of the skin. Chronic exposures may result in lichenification, fissures, scales, excoriations, and hyperpigmentation. Vesicles are rare.

Allergic Contact Dermatitis

Allergic contact dermatitis is caused by a classic delayed hypersensitivity reaction (type IV). Repeated exposure to the inciting substance causes an allergic sensitization. The eruption is delayed after the initial exposure for up to 7 to 10 days. Repeated exposures can cause the rapid appearance of an acute dermatitis (within 12 hours). Rhus dermatitis, caused by an oleoresin in the sap of poison ivy, poison oak, or poison sumac plants, is the most common cause of allergic contact dermatitis in the United States. The allergen is found in the leaves, roots, and twigs of the plants. Delayed exposure may occur because of contact with clothing, gloves, tools, or even pets that have had contact with the plants. Burning of plants leads to aerosolization of the allergen and may cause a widespread and severe outbreak on exposed skin surfaces. Other plants, flowers, pollens (especially ragweed), clothing, shoes, metals (e.g., nickel in jewelry), cosmetics, adhesive tape, and latex-containing products can also cause an allergic contact dermatitis.

Allergic contact dermatitis is rare in infants because of their impaired ability to react to allergens. By age 3 to 8 years, children react to allergens in a fashion similar to adults. The distribution, shape, and pattern of the rash, as well as a history of possible exposures, may elucidate the cause. Linear eruptions are usually seen, especially with plant contact. Shoe dermatitis is likely to cause an eruption limited to the dorsal toes and instep of the foot. Airborne processes (e.g., smoke containing rhus oleoresin) cause a problem on exposed surfaces, including eyelids, whereas, a photoallergic contact dermatitis involves sun-exposed areas (e.g., rash resulting from use of a sunscreen that contains para-aminobenzoic acid).

Irritant Contact Dermatitis

A primary irritant dermatitis is a nonallergic reaction of the skin caused by a single exposure or a series of brief contacts with an irritating substance. Strong soaps and detergents, saliva, urine, stool contents, fiberglass particles, and bubble baths are common causes in children. Occlusive diapers that promote prolonged exposure of the skin to urine and feces are a major contributor to diaper dermatitis (see Chapter 99).

Nummular Eczema

The term *nummular eczema* is derived from the Latin word for coin. Coin-shaped plaques that are erythematous and contain tiny vesicles, crusts, and at times, excoriations manifest this chronic condition. Lesions usually occur on the extensor surfaces of the hands, arms, and legs. They may be single or multiple and are often symmetric in distribution. Nummular eczema seems to be related to dry skin and irritation rather than to atopy but can be seen in atopic individuals. Central clearing of the lesions may result in an appearance similar to dermatophyte infections. Because of their round shape, lesions may be mistaken for impetigo or granuloma annulare.

Asteatotic Eczema

Asteatotic eczema, also called winter eczema, xerotic eczema, and eczema cracquele, is a pruritic condition in which the skin is dry and cracked with red fissures and some scale. The skin has the appearance of cracked porcelain. The most common sites are the extensor legs, dorsal hands, and extensor forearms. The condition tends to occur in adolescents and older persons during the winter and is associated with overbathing and low humidity.

Dyshidrotic Eczema

Dyshidrotic eczema, also called pompholyx, involves the hands and feet. Patients develop the sudden onset of pruritic, tiny, clustered, deep-seated vesicles that look like tapioca. When the condition persists, scaling, lichenification, and painful fissures occur. Lesions appear on the palms, soles, and lateral fingers. The process may be acute, chronic, or persistent and may be provoked by stress. It is associated with hyperhidrosis, although no clear evidence supports that sweating plays a role in the pathogenesis. Approximately 50% of patients have an atopic background. When it involves the feet, it may be confused with tinea pedis.

Seborrheic Dermatitis

Seborrheic dermatitis (see Chapter 99) is a problem of infants, adolescents, and adults and is characterized by nonpruritic, erythematous, greasy, yellow or salmon-colored plaques in regions of the body that have high concentrations of sebaceous glands. These “seborrheic” regions include the scalp, face (nasolabial folds, eyebrows, eyelids, sideburns, beard), postauricular areas, axilla, groin, and presternal area. The scalp (cradle cap) or diaper area is usually involved first in infants between 2 and 12 weeks of age. The rash may spread to the face, trunk, and neck. It usually clears by 8 to 12 months of age and then recurs after the onset of puberty. Although common in infancy, only about 10% of patients will have recurrence in later life. When the rash is particularly severe, associated with petechiae or systemic signs or symptoms, or particularly recalcitrant to the usual therapies in infancy, an underlying systemic illness or immunodeficiency should be considered (see the following). Severe seborrheic dermatitis has been reported as an early sign of acquired immunodeficiency syndrome (AIDS) in adolescents infected with human immunodeficiency virus (HIV).

Lichen Simplex Chronicus

Lichen simplex chronicus, previously called circumscribed neurodermatitis, refers to a chronic, localized lesion that results from repeated rubbing and scratching. It may occur in any location but has a predilection for the sites that are easily reached such as the arms, legs, ankles, neck, and the anogenital area. It is rare in young children but fairly common in adolescents and adults. It may occur in a preexisting area affected by atopic, seborrheic, or contact dermatitis or psoriasis. Typical lesions are single or multiple oval plaques from 5 to 15 cm in size. The skin is reddened and slightly edematous. Chronic lesions usually consist of well-demarcated areas of dry, thickened, scaly, hyperpigmented or hypopigmented plaques. Marked pruritus occurs.

Autoeczematization

Autoeczematization occurs in the presence of an initial active eczematous rash, such as an allergic contact dermatitis, an irritant dermatitis, or a stasis dermatitis. The patient later develops a more extensive eczematous eruption as a result of autosensitization or autoeczematization. A specialized form of this process is seen with dermatophyte infection, in particular tinea capitis, and is called a dermatophytid or *id reaction.*

Photoallergic Reactions

Photoallergic reactions may occur after systemic or topical administration of various drugs or chemicals that absorb radiant energy, primarily in the ultraviolet A (UVA) range. These reactions may manifest as acute, subacute, or chronic dermatitis in sun-exposed areas. Common agents implicated include phenothiazines, sulfonamides, thiazides, sunscreen components such as para-aminobenzoic acid (PABA), and some fragrances.

Infectious Causes of Eczematous Rashes

Eczematous rashes can result from primary skin infections caused by multiple organisms. Fungi, viruses, and parasites

are the most common causes in children. Pityriasis rosea is thought to result from a viral infection.

Dermatophyte Infections

Skin infection caused by a dermatophyte, also called tinea or ringworm, may cause eczematous lesions. The typical lesion of tinea corporis is an annular, erythematous, scaling plaque. These pruritic, circular plaques may be clinically indistinguishable from nummular eczema. A raised vesicular or pustular border may lead to a correct diagnosis of tinea corporis. Likewise, tinea pedis and tinea manuum may be eczematous and vesicular and may mimic dyshidrotic eczema of the feet or hands. Tinea pedis and tinea manuum certainly do occur in prepubertal children, although not as commonly as in adults. Tinea capitis classically presents with scaly, discrete patches of hair loss with black dot hairs and occipital adenopathy. However, it may appear identical to seborrheic dermatitis of the scalp (Fig. 61.1) with greasy yellow scale and should be ruled out before making the diagnosis of seborrhea of the scalp, especially in any child under age 12 who has a scaly scalp.

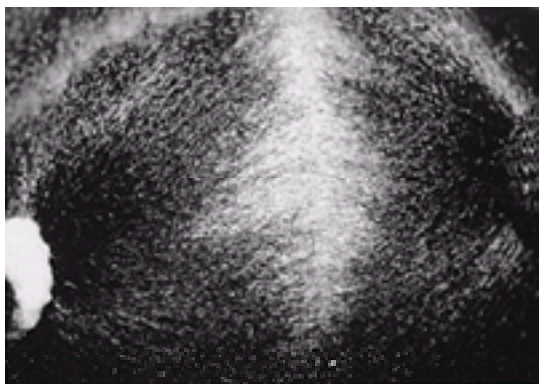

FIGURE 61.1. Seborrheic dermatitis-like tinea capitis in a child.

Scabies

The eruption of scabies (see Chapter 99) is polymorphic with papules, vesicles, nodules, excoriations, crusts, and eczematous plaques. Only a small percentage of patients have the classically described linear tracts or burrows. A particularly severe form of this infestation is termed Norwegian scabies and is characterized by heavy crusting and hyperkeratosis. This is usually seen in immunosuppressed patients. Infants, with their immature immune systems, often have similarly severe infestations; the severity may be related to a delay in diagnosis of scabies in infants and the use of topical steroids in a mistaken attempt to treat an atopic process.

Infants and young children tend to have lesions on the palms, soles, face, and scalp. The lesions may become generalized. Older children and adults are more likely to have involvement of the fingerwebs, flexural regions, breasts, and genital area. Visualization of the mites from skin scrapings under low power on the microscope may confirm this diagnosis; however, a high false-negative rate exists.

Molluscum Contagiosum

The characteristic lesion of molluscum (see Chapter 99) is not eczematous, but rather, is a dome-shaped, waxy papule with a central umbilicated plug. Often, patients develop a surrounding area of dermatitis that may represent a delayed hypersensitivity reaction to a viral antigen. At times, the distinctive papules are barely noticeable within larger eczematous plaques.

Pityriasis Rosea

Pityriasis rosea (see Chapter 99) is common eruption that occurs in epidemics primarily in the spring and autumn. Patients may develop the characteristic herald patch first, then an extensive papulosquamous eruption primarily on the trunk. Lesions may have a “Christmas tree” distribution on the back. In African-American children, an “inverse distribution” of the lesions with involvement of the proximal extremities, inguinal and axillary areas, and the neck is often present, whereas the trunk is relatively spared. Adolescent patients may exhibit a similar and indistinguishable rash as a manifestation of secondary syphilis (see Chapter 84).

Diaper Dermatitis

Diaper dermatitis (see Chapter 99) is possibly the most common cutaneous problem of infancy and young childhood. However, it is not a specific diagnosis, but rather, a group of disorders provoked by the moist, occluded, irritated environment of the diaper region (Table 61.4). Often, a combination of the disorders exists in one patient. The following sections represent the various types of diaper dermatitis.

Irritant dermatitis	Psoriasis
Friction dermatitis	Seborrheic dermatitis
Intertrigo	Letterer-Siwe disease
Candida	Acrodermatitis enteropathica

Table 61.4. Causes of Diaper Dermatitis

Irritant Contact Dermatitis

Irritation from stool and urine, chemicals, soaps, heat, moisture, and sweating may lead to erythematous plaques with minimal scale on the buttocks, perineum, and lower abdomen with sparing of the creases.

Friction Dermatitis

Friction dermatitis is seen on the inner thighs, genitals, buttocks, and abdomen as a mild erythema with a shiny surface caused by chafing in areas of friction.

Intertrigo

Intertrigo results from rubbing and irritation by diapers in a hot climate or from wearing excessive clothing. Erythematous, macerated, exudative plaques appear in the inguinal and intergluteal folds.

Candida

Monilial diaper dermatitis is characterized by beefy red plaques with a fine white scale along the periphery and pinpoint satellite papules and pustules (Fig. 61.2). Candidal diaper dermatitis usually begins in the perianal area. It spreads to involve the perineum and inguinal folds and, in severe cases, extends to the buttocks, upper thighs, lower abdomen, and lower back.

FIGURE 61.2. The erythematous plaques and satellite papules of candidiasis.

Psoriasis

Psoriatic diaper rashes demonstrate bright red, well-demarcated plaques, often with dry, silvery scales (Fig. 61.3). A family history of psoriasis and further cutaneous evidence of psoriasis, such as scalp involvement, nail dystrophy or pitting, intergluteal erythema, and postauricular erythema, is often present. In the diaper area, psoriasis probably flares because of the isomorphic response in which psoriasis appears in sites of epidermal injury.

FIGURE 61.3. Diaper area psoriasis with well-demarcated bright red plaques.

Seborrheic Dermatitis

When the diaper area is involved with seborrheic dermatitis (see Chapter 99), erythema and a greasy yellow scale are seen, especially in the creases. Similar lesions in the axilla and scalp are useful signs to aid in diagnosis.

Letterer-Siwe Disease

Letterer-Siwe disease, the infantile form of Langerhans' cell histiocytosis, often presents with a diaper rash. It is seborrheic in distribution with yellow crusted plaques, infiltrative and hemorrhagic papules, and vesicles.

Acrodermatitis Enteropathica

Acrodermatitis enteropathica, resulting from an inherited problem with zinc absorption, demonstrates bright red plaques in periorificial regions, including the diaper area. The plaques have a serpiginous, erosive border and look much like candida or psoriasis. Patients have associated alopecia, diarrhea, and failure to thrive. A similar eruption has been reported in some infants with cystic fibrosis.

Eczematous Rashes Associated with Systemic Illnesses

Several systemic illnesses may include eczematous rashes as one of their manifestations (Table 61.5). When a patient presents with an eczematous rash that is particularly recalcitrant to treatment, especially severe, or associated with systemic signs or symptoms, these diagnoses should be considered. A patient with severe atopic disease or seborrhea in the absence of a family history may be manifesting a more serious process. Fever, failure to thrive, diarrhea, and recurrent infections may be clues to the presence of an underlying process.

Exfoliative dermatitis	Hyperimmunoglobulinemia E syndrome
HIV infection	Letterer-Siwe disease
Wiskott-Aldrich syndrome	

Table 61.5. Systemic Illnesses Associated with Eczematous Rashes

Exfoliative Dermatitis

Exfoliative dermatitis, or exfoliative erythroderma, is an inflammatory condition of the skin in which generalized erythema and scaling exist. It may be idiopathic or a manifestation of underlying dermatologic or systemic disease (Table 61.6). Medication reactions may also produce a severe bullous disorder: toxic epidermal necrolysis (TEN), in which entire regions of the epidermis may become denuded (see Chapter 99). Some of the more common types of dermatitis (atopic, contact, seborrheic) may cause an exfoliative dermatitis, as well as the more unusual dermatoses such as pityriasis rubra pilaris (a diffuse, salmon-colored papulosquamous eruption) and pemphigus foliaceus (a superficial blistering disorder). When exfoliative dermatitis is seen in an infant, an immune deficiency should be excluded (Fig. 61.4). These immunocompromised infants often have diarrhea, recurrent infections, and failure to thrive. They may have various immune problems, including defective yeast opsonization, impaired neutrophil mobility, elevated serum IgE, and hypogammaglobulinemia. In the past, the term *Leiner's syndrome* was used to describe many of these cases. Exfoliative erythroderma may be the cutaneous presentation of other immune disorders such as Wiskott-Aldrich syndrome, Omenn's syndrome, severe combined immunodeficiency syndrome (SCIDS), HIV infection, and graft-versus-host disease. An exfoliative dermatitis is the only eczematous process that may be potentially life-threatening in the acute phase because of temperature instability, fluid losses through the skin, high-output heart failure, pneumonia, and sepsis.

Atopic dermatitis
Seborrheic dermatitis
Contact dermatitis
Psoriasis
Pityriasis rubra pilaris
Pemphigus foliaceus
Inherited ichthyoses
Cutaneous T cell lymphoma
Lymphoma and leukemia
Medications (sulfonamides, penicillins, cephalosporins, phenytoin, barbiturates)
Immunodeficiency (graft-versus-host disease, Ormenn's syndrome, Wiskott-Aldrich syndrome, severe combined immunodeficiency syndrome, agammaglobulinemia, human immunodeficiency virus infection)
Letterer-Siwe disease
Phenylketonuria

Table 61.6. Causes of Exfoliative Dermatitis

FIGURE 61.4. Infant with exfoliative erythroderma and immunodeficiency.

HIV Infection

About half of children with HIV infection have a “seborrheic looking” dermatitis. Unlike seborrhea, this often persists past age 6 months. Severe, atopic-appearing rashes may also be seen. The diaper area is the most often affected. Children with HIV infection may also have recurrent bacterial infections, diarrhea, failure to thrive, lymphadenopathy, and hepatosplenomegaly, as well as developmental delay. In addition, dermatitis resulting from infectious causes (e.g., bacterial infections, molluscum contagiosum, scabies) may be particularly severe or difficult to treat.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome is an X-linked, recessive disorder in which children have marked thrombocytopenia, eczematous rashes, and immunodeficiency. These patients often develop petechial or purpuric rashes. They have recurrent infections, often caused by encapsulated organisms. Patients may also have autoimmune disorders. Eczematous rashes are usually severe and recalcitrant to therapy.

Hyperimmunoglobulin E (IgE) Syndrome

Hyperimmunoglobulin E syndrome, or Job's syndrome, is characterized by extremely high IgE levels, repeated cutaneous infections, and chronic dermatitis. The rash usually resembles atopic dermatitis. A personal or family history of atopy usually exists, as well as recurrent skin infections (usually staphylococcal or streptococcal), extreme elevation of the serum IgE, impaired neutrophil chemotaxis, and peripheral blood eosinophilia. A subset of patients, usually women, have a tendency to develop large, cold, chronic, and recurrent staphylococcal abscesses of skin and bone, which cause severe scarring and deformity.

Letterer-Siwe Disease

Letterer-Siwe disease, the infantile form of histiocytic disease, often presents as a seborrheic-appearing rash in the diaper area, scalp, postauricular, and axillary regions. The eruption is usually more severe than usual cases of seborrhea, is resistant to therapy, and tends to recur. Cutaneous nodules and purpura suggest this diagnosis. Hepatosplenomegaly, lymphadenopathy, anemia, thrombocytopenia, and osseous lesions are associated findings.

EVALUATION AND DECISION

The most important points in reaching an accurate diagnosis of an eczematous rash include the distribution of the lesions, the patient's age, and the duration of the disease.

Generalized

If a patient presents with a generalized eczematous process, literally red and scaly from head to toe, this suggests an exfoliative dermatitis or erythroderma (Fig. 61.4 and Fig. 61.5B). This condition is unusual in children and has multiple causes. It can be a manifestation of an underlying dermatologic process, a drug reaction, or a systemic illness. Skin biopsy is often necessary to distinguish the cause. If erythroderma is present in infancy, an immune dysfunction should

be considered, especially if the patient has diarrhea, recurrent infections, or failure to thrive.

FIGURE 61.5. A. Diagnostic approach to the child with an eczematous process. **B.** Diagnostic approach to the child with an exfoliative dermatitis.

Extensive but Not Generalized

Eruptions that may be extensive but with some areas of noninvolved skin include atopic dermatitis, seborrheic dermatitis, scabies, autoeczematization reactions, pityriasis rosea, or contact dermatitis (Fig. 61.5A). A family or personal history of atopy, a history of flares and remittance, extreme pruritus, as well as a distribution compatible with the patient's age may lead toward a diagnosis of atopic dermatitis. No specific laboratory tests aid in diagnosis. The diagnosis of seborrheic dermatitis would be made only in infancy and after puberty. Features that help distinguish seborrhea from atopic dermatitis in infancy include minimal pruritus; salmon-colored, greasy plaques; and predominant involvement of the scalp and intertriginous regions. Scabies may look much like atopic dermatitis. However, a history of acute onset, other family members or close contacts with recent onset of a pruritic eruption, and evidence of a polymorphous eruption might aid in this diagnosis. Occasionally, children with scabies have a chronic rash that has been diagnosed as atopic dermatitis, without a history of rash in contacts. One should always be suspicious of scabies, especially if a child aged 3 years or older presents with the recent onset of an eczematous, pruritic rash. Id reactions can be extensive. A history of an initial contact dermatitis or scaly scalp (tinea capitis) followed by a widespread eczematous rash suggests an autoeczematization reaction. Id reactions tend to be worse in areas near the initial rash. An allergic or irritant contact dermatitis could be extensive, depending on the exposure. Eruptions that are unusually severe, persistent, recalcitrant to treatment, or associated with systemic signs should prompt consideration of an underlying systemic illness.

Localized

If an eczematous process is localized to one or a few areas, contact dermatitis, nummular dermatitis, asteatotic eczema, lichen simplex chronicus, photoallergy, scabies, molluscum, or a dermatophyte infection should be considered. The diagnosis of a contact dermatitis is made based on the appearance and distribution of the dermatitis and aided by a history of contact with an allergen. It is often difficult for patients to determine the allergen because of the delayed onset. Therefore, it is important for the physician to suggest some of the more common agents such as poison ivy and nickel. Linear lesions from a plant rubbing against the skin suggest poison ivy exposure. Patch testing may be useful if the allergen is unclear. Photoallergy is suggested by a dermatitis in sun-exposed areas. A raised, slightly vesicular, scaly border implies tinea corporis. However, it is often helpful to perform a potassium hydroxide (KOH) preparation with all these conditions because tinea corporis may mimic any of them. A chronic, pruritic, lichenified plaque suggests lichen simplex chronicus, although an irritant or allergen could play a role in this condition. Eczema within the setting of dry skin, especially on the extensor extremities, suggests asteatotic eczema. In a patient with onset of localized eczematous plaques, one should closely inspect the skin for the tiny, dome-shaped papules of molluscum contagiosum.

Scalp

When the physician evaluates a child with scaly scalp, the child's age and character of the scale can be most helpful (Fig. 61.1 and Fig. 61.6). Newborns often have cradle cap, which can be a manifestation of seborrheic dermatitis, psoriasis, or rarely, atopic dermatitis. It is important to look carefully at the remainder of the infant's skin to see if greasy yellow or bright red plaques are present elsewhere. Cradle cap often persists for several months and may last up to 2 years. In any child with a scaly scalp between 2 years of age and puberty, tinea capitis must be excluded, even in the absence of hair loss. In teenagers, tinea capitis is less likely and seborrhea is again possible. Psoriasis can occur at any age and is characterized by a thick yellow scale that adheres to the hair.

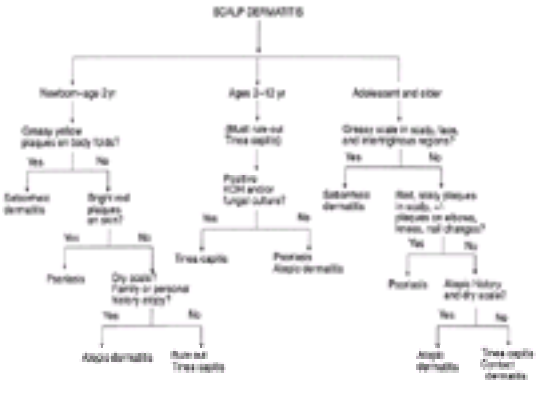

FIGURE 61.6. Diagnostic approach to the child with a scaly scalp.

Hands and Feet

The possibilities for diagnosis when an eczematous process involves the hands and/or feet are psoriasis, dyshidrotic eczema, contact dermatitis, or tinea pedis/manuum. A thorough family history, history of exposure, and a KOH preparation all may be useful.

Diaper Area

In evaluating diaper dermatitis, it is important to pay close attention to the morphology of the lesions (Fig. 61.3 and Fig. 61.7). A bright red, well-demarcated plaque with some scale could be psoriasis, candida, or acrodermatitis enteropathica. One should look at the rest of the skin to see if other sites are involved that suggest psoriasis. A KOH preparation or Gram stain may be useful to look for the spores and pseudohyphae of monilial infection. Hair loss, diarrhea, and a perioral eruption could mean acrodermatitis enteropathica, which could be confirmed by performing serum zinc levels. The most important diagnosis to exclude is Letterer-Siwe disease (Fig. 61.8). A persistent, erosive, or hemorrhagic diaper rash that is unresponsive to treatment is suspicious. One should examine for hepatosplenomegaly, scalp, and gingival involvement. If the rash is more subtle, pink, and scaly, it could be caused by irritation from urine or stool or by friction. Intertrigo would involve the folds and could be macerated or infected secondarily. Greasy, yellow plaques with cradle cap suggest seborrheic dermatitis.

CHAPTER 62

Rash—Maculopapular

KAREN GRUSKIN, MD

Department of Pediatrics, Harvard Medical School, Children's Hospital, Boston, and Department of Pediatrics, Winchester Hospital, Winchester, Massachusetts

Maculopapular rashes are common in pediatric practice, and children often present to the emergency department (ED) for their evaluation and treatment. Before beginning a discussion of specific causes of maculopapular rashes, it is convenient to define the clinical characteristics of these rashes. A *papule* is a small, solid, mostly elevated lesion that is usually smaller then 1 cm in diameter. *Macules* are circumscribed flat lesions that differ from surrounding skin because of their color. Both papules and macules may have any size, shape, or color. Commonly, a rash may have papular and macular components, which leads to the term *maculopapular rash.*

The causes of maculopapular rashes are diverse (Table 62.1) and range from benign to life-threatening (Table 62.2). Common causes include viral exanthems, contact dermatitis, insect bites, and scabies (Table 62.3). The diagnostic approach to these disorders is based on the presence or absence of fever, characteristic clinical appearance, location, and chronicity (Fig. 62.1). Some of these conditions have very characteristic clinical appearances (Table 62.4); however, manifestations of these illnesses can be sufficiently variable that a proportion of the cases are difficult to diagnose.

Infectious	*Fungal*
Viral	Tinea versicolor
Roseola infantum	*Other Infections*
Rubeola	Rocky Mountain spotted fever
Rubella	Mycoplasma (15% of cases)
Erythema infectiosum (fifth disease)	*Etiology Uncertain but Thought to Be Viral*
Varicella (early manifestations before bullae)	Pityriasis rosea
Epstein-Barr virus (10–15% of cases have macular or maculopapular rash)	Kawasaki disease
Molluscum contagiosum (papules)	Papular acrodermatitis
Dengue	**Noninfectious**
"Nonspecific" viral	*Bites and Infestations*
Enterovirus	Insect bites
Echovirus	Scabies
Coxsackie virus	*Miscellaneous*
Adenovirus	Drug reaction
Bacterial	Allergic contact dermatitis
Scarlet fever	Irritant contact dermatitis
Syphilis	Papular urticaria
Disseminated gonorrhea	Erythema multiforme
	Guttate psoriasis
	Pityriasis lichenoides
	Lichen nitidus

Molluscum contagiosum	Insect bites
Scarlet fever	Erythema multiforme

Table 62.4. Maculopapular Rashes That Often Have Characteristic Clinical Appearances

DIFFERENTIAL DIAGNOSIS

Presence of Fever

The potentially life-threatening maculopapular rashes (Table 62.2) are all acute illnesses most commonly associated with fever and significant systemic symptoms. Hence, most patients with these illnesses will appear toxic. Erythema multiforme and rubeola have recognizable clinical appearances, whereas Kawasaki disease, Rocky Mountain spotted fever, and dengue fever require a high level of clinical suspicion. Other, less severe, febrile illnesses associated with maculopapular rashes are listed in Figure 62.1.

Potentially Life-Threatening Illnesses

Erythema Multiforme

EM is believed to result from an immune-mediated acute hypersensitivity reaction to exposure to a sensitizing antigen (see Chapter 99). Common offenders include drugs, especially trimethoprim–sulfasoxazole, cefaclor, and phenytoin; foods, especially nuts and shellfish; and infections by any number of viral, bacterial, protozoal, or fungal organisms. Herpetic and *Mycoplasma pneumoniae* infections rank among the most common infectious causes.

The rash of EM is characterized by diffuse erythematous macules with central clearing often called a target or iris lesion. Lesions may also include erythematous papules, macules, urticarial raised lesions, vesicles, and/or bullae. The distribution is most commonly symmetric and may be noted anywhere on the body with a predilection for the hands and feet, including palms and soles. Lesions may appear in isolation or as a more confluent rash. Based on severity, patients are classified as having EM minor or EM major/Stevens-Johnson syndrome. EM minor is characterized by cutaneous skin involvement alone or mucosal involvement that is limited to one surface (usually the mouth) and minimal systemic symptoms. EM major is characterized by extensive skin and mucosal involvement associated with significant systemic symptoms, including fever, chills, and malaise. Skin involvement can progress to sloughing with significant extravascular

fluid losses. Conjunctivitis and keratitis are a common feature of the major form and can lead to permanent corneal scarring. Pulmonary, cardiac, and renal involvement may occur in especially severe cases.

Treatment is predominantly supportive. Potentially inciting drugs should be immediately discontinued. If pruritus is a feature, antihistamines may provide some relief. Oral topical applications of 1:1 mixtures of diphenhydramine: Kaopectate may provide pain relief from oral involvement. For more severe cases of the disease, patients may require fluid support and/or narcotic oral pain medications. Systemic steroids in the dosage range of 1 to 2 mg/kg per day are of unproven benefit. Patients with ocular involvement should undergo ophthalmologic examination.

Kawasaki Disease

Kawasaki disease is a well-described illness of unknown cause assumed to be infectious in origin because of its epidemiologic and clinical presentation (see Chapter 101). The diagnosis is based on an unremitting fever of at least 5 days' duration and four of the five following features: 1) rash; 2) nonexudative bulbar conjunctivitis with limbal sparing; 3) red cracked lips, strawberry tongue, and erythematous oropharynx; 4) erythema, swelling, and/or induration of peripheral extremities; and 5) a solitary unilateral cervical lymph node of greater than 1.5 cm diameter.

The most commonly associated rash is a generalized pruritic urticarialike exanthem with raised erythematous plaques; however, the rash may also present with an erythematous maculopapular, morbilliform, scarlatiniform, or erythema marginatumlike pattern. The exanthem may be fleeting or persist for 2 to 3 days. During the later stages of the acute phase, periungual desquamation and peeling of the palms, soles, or perineal area develops. Laboratory tests often show a persistently elevated erythrocyte sedimentation rate (ESR) and a markedly elevated platelet count (greater than 750,000/mm^3). The acute phase is usually self-limited but requires accurate diagnosis to prevent the development of coronary artery aneurysms that occur in approximately 20% of cases without therapy. Patients with fever and fewer than four of the previously listed clinical features can be diagnosed with atypical Kawasaki disease if coronary artery disease is detected. Of those patients who develop aneurysms, a small percentage go on to develop heart failure, valvular regurgitation, or myocardial infarction.

No specific laboratory tests are available for diagnosis. Therapy consists of anti-inflammatory agents, specifically high-dose intravenous immunoglobulin (IVIG) and aspirin. IVIG and aspirin initiated within 10 days of the onset of fever decrease the prevalence of coronary artery aneurysms. Therapy should be initiated as soon as the diagnosis is strongly suspected, even if begun more than 10 days after onset of illness. A dosage schedule of 2 g/kg as a single dose of IVIG is recommended. Aspirin is given initially at a high dosage (80 to 100 mg/kg per day divided four times daily) for its anti-inflammatory effect. It can be decreased to 3 to 5 mg/kg per day in one dose after fever has subsided to reduce the likelihood of spontaneous coronary thrombosis. Aspirin is usually continued in patients without evidence of coronary aneurysms until the platelet count and ESR return to normal and may be continued indefinitely for those with coronary artery abnormalities. Echocardiograms should be obtained initially and then at 3 and 8 weeks after onset of illness.

Measles (Rubeola)

Measles was one of the most common viral exanthems before the advent of the vaccine (see Chapter 84). The illness is caused by coming in direct contact with droplets from a person infected with the measles virus—an RNA-containing paramyxovirus. The incubation period is 10 to 14 days. In its classic form, measles has a highly characteristic natural history. Prodromal symptoms are cough, fever, coryza, and conjunctivitis. Two to three days after the onset of the prodrome and 12 to 24 hours before onset of the exanthem, pathognomonic Koplik's spots occur in the mouth. Most typically, they occur on the buccal mucosa opposite the molars as pinpoint white lesions on a red base. However, Koplik's spots may be seen on any of the mucosal surfaces of the oral cavity except the tongue.

The measles exanthem begins on the head as reddish maculopapules and spreads downward during the next 4 to 5 days. Within 1 to 2 days of the onset of a rash on any body part, the discrete maculopapular lesions coalesce to produce the confluent phase of the rash. Hence, within 2 to 3 days of onset, the rash on the face becomes confluent, whereas the rash on the lower extremities still consists of individual maculopapules.

There are two variants of typical measles based on altered immune status of the host. Modified measles occurs in children who have received immune serum globulin after exposure to measles. Measles may still occur, but the incubation will be delayed up to 21 days. The symptoms, although following the usual progression, will be milder. Atypical measles may occur in children previously immunized (almost always with killed vaccine) who have incomplete immunity. Atypical measles is characterized by absence of prodrome, peripheral to central spread of the rash, and variability of individual lesions, which may be macules, hemorrhagic vesicles, or petechiae. Because killed measles vaccine has not been in use for more than three decades, atypical measles is unlikely to occur in children.

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever is caused by *Rickettsia rickettsii* transmitted by the bite of a tick (see Chapter 84). Although initially confined to the Rocky Mountain states (hence its name), confirmed cases have been reported from all parts of the United States with varying ticks as vectors. Rocky Mountain spotted fever is associated with a fatality rate of 5% with antimicrobial treatment and 13 to 40% without such therapy. The primary determinants in patient outcome are early diagnosis and treatment.

The rash of Rocky Mountain spotted fever begins on the third or fourth day of a febrile illness as a maculopapular eruption on the extremities, most commonly the wrists and ankles. Over the next 2 days, the rash becomes generalized by spreading centrally to involve the back, chest, and abdomen. Initially, the rash consists of erythematous macules that blanch on pressure; they then become more confluent and purpuric. Notably, the hemorrhagic rash remains more peripherally distributed with involvement of the palms of the hands and the soles of the feet. The severity of the rash is

proportional to the severity of the disease.

All patients with Rocky Mountain spotted fever have some degree of vasculitis that is the basis for many of the associated systemic symptoms. An overall toxic appearance is common. Systemic symptoms include fever; headache; myalgia; conjunctivitis; periorbital, facial, or peripheral edema; disseminated intravascular coagulation or purpura fulminans; shock; seizures; myocarditis; and heart failure.

Diagnosis is most commonly presumptive, based on clinical presentation with a history of potential tick exposure. The causative organism is not routinely cultured, and complement fixation tests are often negative in the acute phase; however, direct immunofluorescent antibody testing on a punch biopsy is available in some locales. The diagnosis can be confirmed by complement fixation tests in the second or third week of the disease. Some reference laboratories are now offering polymerase chain reaction (PCR) testing.

Therapy with doxycycline or chloramphenicol is highly effective and usually curative when given early in the course of disease. Therapy is continued until the patient is afebrile for at least 2 to 3 days, which usually equals about 7 to 10 days of antibiotic therapy.

Dengue Fever

Dengue fever, a biphasic febrile illness caused by several arthropodborne dengue viruses, is seen in tropical and subtropical areas of almost all continents (including areas of Puerto Rico and the Caribbean basin). Initial constitutional symptoms include sudden onset of high fever, severe headache, myalgia, arthralgia, and abdominal pain. During the course of fever that lasts 2 to 7 days, back and leg pain may be severe, hence the disease's nickname of “breakbone” fever. A hemorrhagic vasculitis can develop in some infections that may lead to shock and death.

Two distinct rashes may be seen, which coincides with the disease's biphasic fever pattern. The first rash is a generalized, transient, macular rash that blanches under pressure and is seen within the first 24 to 48 hours of the onset of systemic symptoms. The second rash coincides with or occurs 1 to 2 days after defervescence and is a generalized morbilliform or maculopapular rash, sparing the palms and soles.

Diagnosis is based on clinical suspicion and potential exposure based on the virus's geographic distribution. Treatment is supportive and may require fluid support and pain control.

Causes of Other Maculopapular Rashes Associated with Fever

Among the other illnesses that are not life-threatening but associated with fever are coxsackie infections, erythema infectiosum, scarlet fever, and early varicella. Harder to diagnose are rashes associated with Epstein-Barr virus, *Mycoplasma* infections, roseola infantum, disseminated gonorrhea, secondary syphilis, nonspecific viral eruptions, and drug-induced rash. It is particularly important to consider the diagnoses of disseminated gonorrhea and secondary syphilis in sexually active or potentially abused children.

Coxsackie Infections

Coxsackie infections of groups A and B (multiple types) can all cause maculopapular exanthems. The classic exanthem of coxsackie A16 infection, also appropriately called hand–foot–mouth disease, is common and easily recognized. Infections may occur in epidemics, most commonly in the late summer or early fall. Multiple infected members within a household are common.

Coxsackie A16 infection begins with a prodrome of low-grade fever, anorexia, mouth pain, and malaise, followed within 1 to 2 days by an oral enanthem and then shortly thereafter by a maculopapular exanthem. The oral lesions begin as small red macules, most often located on the palate, uvula, and anterior tonsillar pillar, which evolve into small vesicles that ulcerate and heal over a 1- to 6-day period. The exanthem begins as maculopapular lesions that develop into small crescent or football-shaped vesicles on an erythematous base. These vesicles, which may be pruritic or mildly tender, are usually located on the dorsal and lateral aspects of fingers, hands, and feet but may develop on the buttocks, arms, legs, and face. The lesions either reabsorb over 2 to 7 days or ulcerate and scab.

The other types of coxsackievirus all cause similar or even indistinguishable exanthems, which may more commonly involve the face, trunk, and proximal extremities. Often, children with these exanthems will be diagnosed with nonspecific viral infections. Other symptoms attributed to coxsackie infection include aseptic meningitis and less commonly myopericarditis, encephalitis, or paralysis.

Diagnosis is usually made clinically, although the virus can be easily cultured. The virus is commonly shed for weeks. Coxsackie infections are self-limiting, so no specific treatment is necessary. IVIG with high antibody titer may be considered for immunocompromised patients or in life-threatening neonatal infections.

Erythema Infectiosum (Fifth Disease)

Erythema infectiosum is a benign disease caused by parvovirus B19, the same virus that can cause aplastic crises in patients with sickle cell anemia. For the normal, nongravid host, fifth disease is of no consequence, with the only systemic symptom being fever in 15 to 30% of cases. On the face is a characteristic, intensely erythematous, “slapped cheek” rash. In addition, a symmetric maculopapular, lacelike rash is seen on the arms then trunk, buttocks, and thighs. In its acute phase, the rash usually lasts only for a few days but can wax and wane in intensity with environmental changes (e.g., exposure to heat or sunlight) for weeks and sometimes months. No specific diagnosis or therapy is necessary. For a chronic infection in an immunodeficient patient, IVIG therapy should be considered. Because parvovirus

is associated with fetal anemia, congestive heart failure, and hydrops, exposed pregnant women should be referred to their physicians to discuss possible parvovirus antibody testing.

Scarlet Fever

Scarlet fever is caused by phage-infected group A streptococcus that makes an erythrogenic toxin. This disease is still seen with regularity but does not appear to be any more serious than group A streptococcal infection without rash. Scarlet fever is most commonly associated with streptococcal pharyngitis but may occur in association with pyoderma or an infected wound.

The diagnosis of scarlet fever can be made in a child with signs and symptoms of pharyngitis who has a fine, raised, generalized maculopapular rash. The skin has a coarse or sandpapery feel on palpation. Typically, there is sparing of the circumoral area, leading to circumoral pallor. There usually is a bright erythema of the tongue and hypertrophy of the papillae, leading to the term strawberry tongue. Pastia's lines, bright red, orange, or even hemorrhagic lines, can occasionally be seen in the axillae or antecubital fossa. The rash generally lasts 3 to 5 days, followed by brownish discoloration in association with peeling of the skin. The peeling may range from small flakes to entire casts of the digits. A rapid streptococcal test or throat culture should be sent to confirm infection. Various antibiotic regimens provide effective treatment (see Chapter 84).

Varicella (Chickenpox)

Although varicella is an easily recognizable vesiculobullous eruption, on occasion, the earliest phase can be confusing. The initial skin manifestations of varicella virus infection are small, red macules. Some of them remain as macules, but most progress to the characteristic papules and then umbilicated, tear-shaped vesicles. The earliest lesions appear on the chest and spread centrifugally, but there are many exceptions to the pattern of spread. Occasionally, a child with mild chickenpox may have only a few scattered macules with only one or two progressing to the more typical vesicular lesions of chickenpox. Of children receiving varicella vaccine, 7 to 8% may develop a mild maculopapular or varicelliform rash within 1 month of vaccination (see Chapter 84).

Epstein-Barr Virus

Between 5 and 15% of patients with Epstein-Barr viral infection, otherwise known as infectious mononucleosis, will have an erythematous maculopapular eruption. Infection in young children is usually inapparent, nonspecific, or so mild that diagnosis is not sought. The older patient between 15 to 25 years more commonly presents for evaluation. In addition, 50 to 100% of patients with infectious mononucleosis receiving concurrent ampicillin will develop a maculopapular rash.

The illness begins insidiously with headache, malaise, and fever, followed by sore throat, membranous tonsillitis, and lymphadenopathy. Splenomegaly is common. The exanthem occurs within 4 to 6 days as a macular or maculopapular morbilliform eruption most prominent on the trunk and proximal extremities. An enanthem consisting of discrete petechiae at the junction of the hard and soft palate occurs in approximately 25% of patients.

Diagnosis is often presumed clinically but may be supported by a positive heterophile antibody (Monospot) test or confirmed by serology. The heterophile antibody test is less sensitive in children younger than 4 years of age. The illness is most commonly self-limited, requiring no therapy. Corticosteroids may be considered for patients with particularly severe tonsillitis (see Chapter 84).

Mycoplasma Infections

Infections with *Mycoplasma pneumoniae* may cause maculopapular rashes in up to 15% of cases. The classic clinical presentation is of a child with malaise, low-grade fever, and prominent cough. The cough is initially nonproductive but may become productive particularly in older children and may persist for 3 to 4 weeks. Physical examination may show bilateral rales. Roentgenographic examination of the chest, if abnormal, most commonly shows diffuse nonspecific infiltrates.

Diagnosis can be suggested by serum cold hemagglutinins, which are present in more than 50% of cases by the beginning of the second week. If further confirmatory studies are needed, acute and convalescent serum sera should be assayed for specific mycoplasmal antibodies by complement fixation or immunofluorescence. Erythromycin or one of the newer macrolides (clarithromycin or azithromycin) is the treatment of choice (see Chapter 84).

Roseola Infantum

Roseola infantum, also called exanthem subitum or 6th disease, has recently been attributed to herpes simplex virus (HSV)-6. The illness is characterized by the onset of a maculopapular rash following a 3- to 4-day febrile illness. The fever is characteristically high. The rash is widely disseminated, appearing as discrete, small, pinkish macules that rarely coalesce beginning on the trunk and then extending peripherally. The occurrence of the rash within 24 hours of defervescence rather than the morphologic appearance of the rash leads to the correct diagnosis. The rash can appear very similar to that seen in measles, but the child with roseola is well appearing and no longer febrile. Diagnosis is made clinically and care is supportive.

Disseminated Neisseria gonorrhea

Disseminated *Neisseria gonorrhoeae* should be considered in sexually active or potentially abused children, especially if associated with a history of vaginal or penile discharge (see Chapter 84). A distinct minority of patients develop disseminated gonorrhea infection through hematogenous spread. Disseminated gonorrhea may cause a range of

cutaneous lesions, including small erythematous papules, petechiae, or vesicle–pustules on a hemorrhagic base. These cutaneous lesions usually develop on the trunk but may occur anywhere on the extremities. An etiologic diagnosis can be established by demonstration of the organism on Gram stain of the skin lesion, positive blood culture, or positive culture of oral or genital sites. Based on resistance patterns, recommended current therapy is ceftriaxone 50 mg/kg per day (maximum 1 g/day) for 7 days. Concomitant sexually transmitted diseases should be sought and treated empirically.

Secondary Syphilis

One needs a high level of suspicion when viewing rashes in sexually active (or potentially abused) children to make the diagnosis of secondary syphilis, caused by the spirochete *Treponema pallidum* (see Chapter 84). Manifestations of secondary syphilis usually occur 6 to 8 weeks after the appearance of the primary lesion, which may have gone unnoticed. The exanthem extends rapidly and is usually pronounced, lasting for only hours or persisting for several months.

The rash is characterized by a generalized cutaneous eruption, usually composed of brownish, dull-red macules or papules that range in size from a few millimeters to 1 cm in diameter. They are generally discrete and symmetrically distributed, particularly over the trunk, where they follow the lines of cleavage in a pattern similar to pityriasis rosea. Papular lesions on the palms and soles as well as the presence of systemic symptoms such as general malaise, fever, headaches, sore throat, rhinorrhea, lacrimation, and generalized lymphadenopathy help differentiate secondary syphilis.

Acquired syphilis is sexually contracted from direct contact with ulcerative lesions of the skin or mucous membranes of an infected individual. Diagnosis may be presumed after a positive nontreponemal test, such as the VDRL slide test, rapid reagin (RPR) test, or the automated reagin test (ART). Diagnosis should be confirmed by a treponemal test such as the fluorescent treponemal antibody absorption (FTA-ABS) test, the microhemagglutination test for *T. palladium* (MHA-TP), or the *T. palladium* immobilization (TPI) test. Definitive diagnosis may also be made by identifying spirochetes by microscopic dark field examination or direct fluorescent antibody tests of lesion exudate or tissue. Penicillin is the treatment of choice unless contraindicated, in which case tetracycline, doxycycline, ceftriaxone, or erythromycin may be substituted. Length of therapy should be based on duration and stage of infection. Concomitant sexually transmitted diseases should be sought and treated empirically.

Nonspecific Viral Exanthems

Many times, a specific diagnosis cannot be made even after considering such factors as exposure history, history of preceding illness, description of eruption, time and site of onset, character of initial lesion, progression, distribution patterns, and occurrence of mucosal lesions. This should not be surprising, given the large number of viruses that can be associated with macular or maculopapular eruptions. A number of enteroviruses and adenoviruses can cause a macular or maculopapular eruption. There is little to distinguish the rash caused by one of these viruses from that of another, based on the location and morphology, with the exception of coxsackie A16 infection, which causes hand–foot–mouth disease. One usually arrives at the diagnosis of nonspecific viral exanthem in a child in whom other diagnoses have been excluded and who may have signs of associated illness or systemic features such as fever. Specific etiologic diagnosis, if required, can be determined by viral isolation and/or a rise in diagnostic titer.

Drug-Induced Rash

Multiple drugs can cause maculopapular rashes in susceptible patients. Most commonly, these rashes have an abrupt onset, are generalized, and may be accompanied by systemic signs such as fever, arthralgia, lymphadenopathy, and hepatomegaly. It is often difficult to distinguish drug eruptions from viral exanthems. This is specially true because the emergency physician is often faced with a child who recently was started on one or several medications (often including an antibiotic) who now presents with the emergence of a rash associated with or following a viral-type illness.

The diagnosis of drug eruption depends on a carefully obtained history, including the duration and frequency of all medications taken by the child during the week preceding the onset of the rash. The presence of eosinophilia suggests, but does not confirm, the diagnosis. Often, the final diagnosis is left to the intuition of the physician. In the case of a severe eruption, the potentially offending drug should be discontinued. In milder cases, which more closely resemble nonspecific viral exanthems, a physician may opt to continue therapy as long as the rash does not worsen. The disadvantage of simply discontinuing any potentially offending drug is that the patient is often labeled as “allergic” to the drug for life. In addition, reactions may be caused by preservatives or dyes in a drug preparation and not by the drug itself.

Illnesses Associated with Maculopapular Rashes without Fever

Maculopapular rashes associated with nonfebrile illnesses tend to be benign. Erythema infectiosum, EM, *Mycoplasma* infections, roseola infantum, secondary syphilis, and nonspecific viral exanthems, which in mild cases may not be associated with fever, have been previously discussed. In approaching the acute afebrile disorders associated with maculopapular rash, it is useful to distinguish between those that cause generalized eruptions and those that cause localized ones. Disorders not usually associated with fever but that cause generalized eruptions include rubella, guttate psoriasis, and pityriasis rosea. Disorders that cause mostly local eruptions include papular acrodermatitis (Gianotti-Crosti syndrome), contact dermatitis, insect bites, and scabies. Some of the maculopapular rashes not associated with febrile illnesses are chronic entities, allowing their duration to help with their diagnosis; examples include lichen nitidus, molluscum contagiosum, papular urticaria, pityriasis lichenoides (Mucha-Habermann disease), and tinea versicolor. Molluscum contagiosum, pityriasis rosea, tinea versicolor, and forms of contact dermatitis also present with clinically recognizable rashes.

Generalized Eruptions Associated with Afebrile Illnesses

Guttate Psoriasis

About one-third of cases of psoriasis begin in the first two decades of life among individuals with a genetic predisposition. The guttate form is even more likely to occur in younger age groups. The rash is characterized by multiple small discrete round or oval macules or papules (up to 1 cm in diameter) with a loosely adherent scale. The lesions develop predominantly on the trunk, but the face and scalp may be involved. The distal extremities, palms, and soles are usually spared. The lesions of guttate psoriasis are not as hyperkeratotic as other types of chronic psoriatic plaques and may respond better to standard psoriasis therapy.

Pityriasis Rosea

Pityriasis rosea is a benign, self-limiting condition that most commonly affects older children and adolescents, although it can occur at younger ages. The cause is unknown but is likely to be viral (see Chapter 99).

Pityriasis rosea follows a characteristic clinical course. The initial lesion, the herald patch, is an oval-shaped plaque that occurs in about 80% of cases. The center of the lesion is flat, whereas the borders are raised, red, and scaly. The herald patch can occur anywhere on the body but is most commonly seen on the trunk, neck, or proximal extremities. The herald patch is often mistaken for tinea corporis. One to two weeks later, a more generalized, sometimes pruritic, rash erupts. The rash is most dense on the trunk, neck, and proximal limbs. The face and distal extremities are relatively spared but may be involved in younger children. Individual lesions are erythematous papulosquamous ovals that often resemble smaller versions of the herald patch. The orientation of the long axis of the ovals tends to conform to the skinfold lines of the trunk, giving characteristic “Christmas tree” pattern of distribution when looked at on the patient's posterior trunk. Atypical distributions (predominantly peripheral) and forms of the individual lesions (papules, vesicles, pustules, urticarial or purpuric lesions) can occur.

Rubella

In a classic case of rubella, the rash, as with measles, begins on the head and spreads downward. The progression occurs over 2 to 3 days, and typically, the rash is entirely gone by the fourth day. The rash always remains macular and never becomes confluent, an important distinguishing characteristic. One-third of all rubella virus infections are clinically silent (i.e., they have no exanthem). A rubella rash may show extensive variation in location, progression, and duration, at times disappearing within 12 hours or being localized to one part of an extremity without any progression. Unlike measles, in which systemic toxicity and fever are the rule, fever is uncommon. Associated symptoms and complaints in rubella include joint pain in about 25% of cases and adenopathy (most commonly suboccipital, postauricular, and cervical). Arthralgia that occurs with a viral exanthem is relatively specific for rubella. Diagnosis is based on clinical presentation, and treatment is supportive.

Localized Eruptions Associated with Afebrile Illnesses

Contact dermatitis, insect bites, papular acrodermatitis, and scabies usually have a localized distribution; however, in extensive cases, all may appear as a more generalized eruption.

Contact Dermatitis

Contact dermatitis may be produced by either a local exposure to a primary irritating substance or by an acquired allergic response to a sensitizing substance (see Chapter 99). When the dermatitis results from a nonallergic reaction of the skin, it is termed an irritant contact dermatitis; when it results from a delayed hypersensitivity to a contact allergen, it is termed an allergic contact dermatitis. Although distinct in etiology, both reactions usually have a localized distribution of the rash, which often assumes the pattern of the irritating or sensitizing agent, and there is generally a sharp demarcation between involved and uninvolved areas of skin. Involved areas are erythematous with variable numbers and combinations of macules, papules, vesicles, and/or bullae.

Irritant dermatitis arises from contact with primary irritating agents such as detergents, soaps, acids, alkalis, or rough sheets/clothes. This disorder is commonly seen in infancy, when the skin is relatively thin and susceptible to mechanical or chemical irritation. Allergic contact dermatitis, typified by rhus dermatitis (e.g., poison ivy, poison oak) or nickel dermatitis (from jewelry or wristwatches), occurs most commonly in older children.

Diagnosis depends on obtaining a thorough history of exposure to probable offending allergens and the presence of a characteristic localized pattern of rash. Treatment for both types of contact dermatitis includes reducing exposure to offending irritants, providing topical or systemic antipruritic agents, and for more severe cases, providing topical or systemic steroids.

Insect Bites

Virtually all children experience insect bites. Mosquitoes, fleas, and bedbugs are the most common offenders. Diagnosis depends on the season, the climate, exposure to animals, and distribution and appearance of the lesions. In temperate climates, mosquito bites occur exclusively in the warmer months of the year, whereas flea and bedbug bites occur year round as a result of indoor exposure. Often, a series of bites occurs in groups, causing a maculopapular appearance. Local reactions can be extensive and take several days to resolve. Care is aimed at minimizing discomfort with topical or systemic antihistamines and/or topical steroids.

Papular Acrodermatitis (Gianotti-Crosti Syndrome)

Papular acrodermatitis is an eruption of unclear cause that has been associated with hepatitis B and other viral infections in young children. Of affected children, 85% are less than 3 years old. The eruption may follow a low-grade fever or mild upper respiratory symptoms.

The eruption consists of flesh-colored papules that occur anywhere on the body but often concentrate on the extensor surfaces of the arms, legs, and buttock. Lesions are particularly prominent over the elbows and knees. The rash usually lasts 2 to 8 weeks and then disappears. No treatment is needed for the cutaneous eruption; however, a subset of patients with cutaneous lesions develop generalized lymphadenopathy and hepatosplenomegaly. These children should be evaluated for hepatitis. Follow-up in 2 weeks is recommended for patients with only cutaneous involvement to rule out the development of hepatitis.

Scabies

Scabies is a contagious infestation of the *Sarcoptes scabiei* female mite that selects a favorable body site, burrows beneath the stratum corneum, and deposits eggs along the way. In older children and adults, the usual sites of infestation are the anterior axillary lines, the areolae, the lower part of the abdomen, buttocks, genitals, wrists, interdigital webs, and ankles. In young children, the lesions are usually more diffuse and may also occur on the palms, soles, scalp, and neck (see Chapter 99).

The pathognomonic primary lesion may be visible as a linear, gray–brown, threadlike burrow a few millimeters in length, with a central black dot (the mite). The more usual lesions are erythematous papules that may be excoriated and possibly secondarily infected because of intense pruritus. On occasion, generalized urticarial or “id” reactions develop.

Diagnosis is usually based on clinical suspicion, although definitive confirmation can be made by identifying the adult mite on microscopic examination of a scraping of suspicious burrows. The treatment of choice in children is the topical application of permethrin 5% cream, which may be repeated in 2 weeks if necessary. Pruritus often persists for several weeks after the mites have been eliminated. It is advisable to treat close family members or personal contacts with or without evidence of infestation. Because mites are unable to survive away from their human hosts or at high temperatures, clothing, bedding, and stuffed animals should be laundered in hot water (greater than 50°C, or 120°F) or stored away for several days in plastic bags.

Chronic Eruptions Associated with Afebrile Illnesses

Chronic eruptions are defined as those that are usually present for a minimum of 2 weeks.

Lichen Nitidus

Lichen nitidus is a relatively rare, benign skin disorder that occurs most often in preschool and school-age children. It is thought to perhaps be a variant of lichen planus. The eruption consists of groups of tiny, shiny, flesh-colored papules. The lesions commonly occur in lines of local trauma (Köbner's phenomenon) and are most often seen on the trunk, abdomen, forearm, and genitalia. There is no known effective treatment, and the eruption can last for years.

Molluscum Contagiosum

Molluscum contagiosum is caused by a viral infection and consists of discrete flesh-colored papules, usually 2 to 3 mm in diameter, with umbilicated centers (see Chapter 99). Axillary lines of the trunk, the abdomen, genital region, inner aspect of the thighs, and the face are the most common sites of presentation, although any nonhairy surface may be involved. Usually, a child will have approximately 10 scattered lesions; however, on occasion, some may have many more. The lesions tend to persist anywhere from 2 weeks to $1\,{}^{1}/_{2}$ years and may be spread by autoinoculation. Spread can occur between individuals involved in contact sports. The lesions are asymptomatic, with the exception of a minority of patients who develop an inflammatory reaction. Treatment, when deemed necessary, involves techniques such as liquid nitrogen or curettage that minimize scarring and discomfort.

Papular Urticaria

Papular urticaria, a benign condition seen most commonly in young children, is manifested by a chronic or recurrent papular eruption caused by a sensitivity reaction to insect's bites. The lesions are usually papules with a central punctum that may rest on a urticarial base. The lesions are most commonly seen in the warm months, when exposure to insects is most intense. Diagnosis is usually made clinically. Treatment is aimed at minimizing exposure to insect bites and providing therapy with simple sedation, topical calamine, or topical corticosteroid to minimize pruritus.

Pityriasis Lichenoides (Mucha-Habermann Disease)

Pityriasis lichenoides, or Mucha-Habermann disease, is a relatively rare disorder of unknown cause that can appear in childhood and young adulthood. There are two forms: acute and chronic. The acute disease is characterized by a macular, papular, or papulovesicular rash that often is distributed most heavily on the trunk and upper arms. The lesions occur in successive crops rapidly evolving into vesicular, necrotic, and even purpuric lesions. Lesions may leave pocklike scars. Resolution occurs spontaneously but may take several weeks to months and recurrences may occur. Parents may describe these recurrences as “he keeps getting the chickenpox.” The more chronic form may evolve from the acute form or may arise de novo and often lasts for several years. There is no established therapy.

Tinea Versicolor

Tinea versicolor is a superficial skin disease caused by the fungus *Pityrosporum orbiculare* (see Chapter 99). Although adolescents and young adults are most commonly affected, the disorder can occur at any age. The distribution of scaly macular lesions is patchy and occurs most commonly over the upper trunk and proximal arms. Occasionally, the face and other areas of the body can become involved. In summer, affected areas are relatively hypopigmented compared with unaffected skin because the organism blocks the normal tanning of sun-exposed skin. In winter, the affected areas often are relatively darker than unaffected skin because the fungus causes a mild erythema. This phenomenon of variable coloration of the affected skin gives the disease its name.

The diagnosis often is made by recognition of the characteristic rash. Wood's light examination in a darkened room produces a reddish-brown fluorescence. Microscopic examination of scrapings will demonstrate characteristic hyphae and spores in grapelike clusters (“spaghetti and meatballs” appearance). Treatment consists of selenium sulfide shampoos weekly for 3 weeks and then monthly for 3 months. Infection may recur.

EVALUATION AND DECISION

In approaching a child with a maculopapular exanthem, the initial steps are to take a history and to fully examine all cutaneous surfaces. The most important historical features include the duration of the rash (acute or chronic), initial distribution, extent of spread (generalized or localized), ill contacts (including sexual partners of adolescent patients), and any associated systemic symptoms, including fever. The physical examination should include a careful systematic inspection of all mucocutaneous surfaces, with special attention paid to involvement of the oropharynx, palms and soles, extensor or flexor surfaces, scalp, and trunk.

For patients who do not appear ill, certain exanthems will have distinctive patterns that will immediately strike the examiner and make the diagnosis readily apparent. EM, rubella, coxsackie infections, erythema infectiosum, scarlet fever, varicella, molluscum contagiosum, tinea versicolor, pityriasis rosea, and roseola all have recognizable clinical appearances. Many of these illness have characteristic distributions or associated signs and symptoms that aid in their diagnoses. If the pattern of the rash does not evoke an immediate response from the examiner, a more methodical approach is indicated, as outlined in Figure 62.1.

For patients with maculopapular rash who appear particularly ill, the potential diagnoses of rubeola (measles), EM, Kawasaki disease, Rocky Mountain spotted fever, and dengue fever should spring to mind.

Acutely Ill-Appearing Patients

Rubeola and EM both have characteristic rashes that are often associated with oral involvement. Patients with rubeola may have a history of an ill contact and several days of cough, coryza, conjunctivitis, and escalating fever. EM may present with a history of the recent introduction of a medication. Kawasaki disease should be considered in children who have been febrile for more than 5 days and who have or have had conjunctivitis, red lips/strawberry tongue, a solitary enlarged cervical lymph node, and a rash. Clues to the possibility of Rocky Mountain spotted fever or dengue fever may be obtained from a travel history or known cases within the geographic location. Patients with Rocky Mountain spotted fever may have a history of a tick bite, and the hemorrhagic rash characteristically remains more peripherally distributed involving the palms and soles. Dengue fever should be considered in patients with a biphasic fever pattern and musculoskeletal pain.

Other Generalized Febrile Eruptions

An acute, generalized febrile maculopapular exanthem usually is the result of a nonspecific viral or streptococcal (scarlet fever) infection. The disorders that are seen in acutely ill-appearing patients, discussed previously, may present as milder versions and should be considered as possible causes in less acutely ill febrile children with generalized eruptions.

Other viral and bacterial infections may require a higher index of suspicion and confirmatory studies.

Nonspecific viral exanthems most characteristically consist of multiple, closely spaced small papules. The finding of pharyngitis, a strawberry tongue, or intensely erythematous lines in the antecubital fossae points to scarlet fever; however, a throat culture or rapid screening test for streptococcal infection should still be obtained.

Coxsackie infections, erythema infectiosum, and early varicella should be able to be diagnosed based on their clinical appearance. It should be remembered that the eruption of varicella initially is maculopapular; however, close inspection usually reveals a few vesicles by the time the child is brought to medical attention.

The final considerations in febrile patients with generalized maculopapular rash are Epstein-Barr virus infections (infectious mononucleosis), *Mycoplasma* infections, roseola infantum, disseminated gonorrhea, and secondary syphilis. The exanthem of infectious mononucleosis should be suspected in the child or, more commonly, in the adolescent who has streptococcal negative pharyngitis and/or history of taking ampicillin or a closely related antibiotic. For children with nonspecific viral symptoms with prominent cough, *Mycoplasma* infection may be the diagnosis. Roseola infantum should be considered in the child who develops maculopapular rash after fever has defervesced. Last, disseminated gonorrhea and secondary syphilis should be considered in sexually active adolescents and appropriate tests sent for confirmation.

Generalized Afebrile Eruptions

Although nonspecific viral illnesses that cause rash are more often than not associated with fever, a minority of children with viral exanthems remain afebrile. Often, no specific diagnosis is possible. Again, the appearance of a diffuse rash in

an infant or toddler immediately after the defervescence of a high fever indicates the clinical diagnosis of roseola. Similarly, pronounced posterior occipital lymphadenopathy in an unvaccinated child suggests rubella. If a child is taking any medications, drug rash must be considered. Because a drug reaction is difficult to exclude initially, consideration for discontinuing medications is warranted in severe cases. Also common, pityriasis rosea is distinguished by its characteristic predominantly truncal distribution along the skin folds. Rarely does guttate psoriasis present acutely with a diffuse maculopapular eruption.

Localized Eruptions

The most common causes for acute, localized maculopapular eruptions are contact dermatitis and insect bites. Contact dermatitis may be caused by irritation or allergy. History may be helpful in establishing a diagnosis, as in the case of a child who returns from camp with an allergic dermatitis on the arms and legs (rhus dermatitis or poison ivy) or of a teenager who gets an irritant dermatitis of the wrist after wearing a new watch. Irritant reactions are usually exclusively maculopapular, whereas allergic eruptions may become vesicular or eczematous and may also have a characteristic linear appearance. The papules of insect bites usually are isolated lesions, as opposed to the confluent rash seen in contact dermatitis. In temperate climates, insect bites occur most commonly in the summer, but the possibility of bedbugs or fleas should not be overlooked during the colder months. Scabies is a relatively common and potentially difficult diagnosis. Linear lesions and involvement of the web spaces are characteristic, but often, a diagnostic scraping or presumptive therapy is indicated. Gianotti-Crosti syndrome is a rare disorder that produces primarily an eruption limited to the distal extremities. Any of the causes of localized eruptions may appear more generalized in extensive or severe cases.

Chronic Eruptions

Chronic maculopapular eruptions are usually, and more appropriately, seen by physicians in settings other than the ED. However, parents may become acutely concerned about a real or perceived change in a chronic eruption; thus, the emergency physician should be familiar with the more common disorders.

The most commonly seen of the chronic maculopapular eruptions are papular urticaria, molluscum contagiosum, and tinea versicolor. Papular urticaria is most common in warm weather but may occur at any time of the year; the characteristic lesions have an urticarial wheal around a central papule. The papules of molluscum contagiosum have an easily recognizable umbilicated central core. Tinea versicolor consists of hypopigmented and hyperpigmented areas, predominantly on the trunk. This diagnosis can be confirmed by microscopy or culture. Although uncommon, secondary syphilis needs to be considered in any sexually active patient and a serologic test performed as indicated.

CHAPTER 63

Rash—Papular Lesions

PAUL J. HONIG, MD

Departments of Pediatrics and Dermatology, The University of Pennsylvania School of Medicine, and Department of Pediatric Dermatology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Physicians are often confronted by parents who are concerned about “bumps” on their child's skin surface. Most parents will be comforted by a physician's reassurance and recommendations for treatment. Obviously, therapeutic interventions cannot be made until a definitive diagnosis is made. The following algorithm is used to help practitioners diagnose varying papular lesions (Fig. 63.1 and Table 63.1).

FIGURE 63.1. Approach to the diagnosis of papular lesions.

Granuloma annulare (common)	Molluscum contagiosum (common)
Insect bites (common)	Pyogenic granuloma (common)
Juvenile xanthogranuloma	Spitz nevus
Lichen nitidus	Warts (common)
Mastocytomas, urticaria pigmentosa	Xanthomas
Milia (common)	

Table 63.1. Papular Lesions

PAPULES WITH A CHARACTERISTIC CLINICAL APPEARANCE

Many conditions can be diagnosed on sight. The experienced eye can easily distinguish milia from molluscum contagiosum (MC) and warts from the uncommon xanthoma. Papules caused by bites are localized to exposed surfaces (face and extremities). Several clues make the process of separating these entities from one another easier (see section on noncharacteristic clinical appearance).

The distinction between flat warts and xanthomas is more subtle. At times, it is impossible to tell the difference. Because warts are caused by the human papillomavirus, a scratch through any of the lesions may inoculate the virus in the scratch line. This produces flat-topped papules in a linear distribution (a quasi-Köbner's phenomenon—that is, appearance of the primary eruption located elsewhere on the body in the site or sites of trauma). Therefore, linearly arranged yellow, tan, or flesh-colored flat-topped papules should arouse suspicion of the presence of flat warts, especially if the lesions are distributed on the face, back of the hands, and knees—favorite sites for flat warts. Xanthomas are unusual during childhood. When present, however, they usually are associated with elevations of serum lipids. A lipid profile can be helpful in distinguishing these two flat-topped papules from one another. If all else fails, the help of a dermatologist experienced in caring for children can be sought. This is true for any of the entities discussed in this chapter. Skin biopsy is a valuable tool available to the dermatologist and may be required to differentiate many of the entities that are discussed here.

Milia

Milia are 1- to 2-mm firm, white papules. They are produced by retention of keratinous and sebaceous material in follicular openings (orifices from which vellus hairs grow). Newborns often have milia on their face. Fortunately, they disappear by the age of 1 month. Milia can be seen in scars after burns and in healed wounds in patients with epidermolysis bullosa. Persistent milia may be a manifestation of the oral–facial–digital syndrome or hereditary trichodysplasia. Because lesions that are not associated with syndromes disappear spontaneously, no therapy is indicated.

Molluscum Contagiosum

For additional information about MC, see Figure 99.42.

Warts

For additional information about warts, see Chapter 99.

Xanthomas

Papules, plaques, nodules, and tumors that contain lipid are called xanthomas. These lesions can appear on any skin surface and often are associated with disturbances of lipoprotein metabolism (Table 63.2).

Type	Age of Onset	Clinical Presentation	Inheritance
I	Early childhood	Eruptive xanthomas Abdominal pain Hepatosplenomegaly Creamy plasma	AR
IIa	Early childhood	Tendinous xanthomas Xanthelasmas Tuberous xanthomas Corneal arcus	AD
IIb	Early childhood	Same as IIa	AD

Table 63.2. Hyperlipidemias

The most interesting, but the most rare, of hyperlipidemias that arise in the pediatric (infancy to adolescence) age group are type I hyperlipidemias. Fifty percent of patients present with episodic abdominal pain that may be acute at times. Malaise, anorexia, fever, and leukocytosis may be present. The cause of the pain is unclear; however, pancreatitis and splenic infarcts have been hypothesized. Eruptive xanthomas occur in more than 50% of the patients. These are 1- to 4-mm yellow papules that appear in crops on the face, extremities, and buttocks. Their sudden appearance causes significant concern. Hepatosplenomegaly also is commonly present, as are lipemia retinalis and creamy plasma. Patients are found to have increased chylomicrons, slightly elevated cholesterol, and significantly elevated triglycerides. Secondary diseases include pancreatitis and diabetes.

The homozygous form of type IIa hyperlipidemia is seen in children. An elevated low-density lipoprotein (LDL), significantly elevated cholesterol, and mildly elevated triglycerides characterize this disorder. Tendinous and tuberous xanthomas and xanthelasmas are seen clinically. The plane xanthomas (xanthelasmas) may be misinterpreted as flat warts when seen in skin areas away from the eyelids. Secondary disorders include hypothyroidism and nephrotic syndrome. Patients die of atherosclerotic coronary artery disease in their twenties and thirties.

Insect Bites

For additional information about insect bites, see Chapter 99, Mosquitoes and Fleas.

PAPULES WITH A NONCHARACTERISTIC CLINICAL APPEARANCE

When the diagnosis is not obvious, the algorithm presented in Figure 63.1 must be used.

Presence of White or Translucent Core

Milia and MC have white cores. Sidelighting and a magnifying glass may be needed to see the core within the central portion of the papule in MC. Therefore, it is essential to sidelight all papules about which one is not sure. The obvious white core in milia fills the entire papule rather than a small central portion of the papule (as in MC). The other differentiating point is that milia are hard and beady white; MC are more fleshy.

Absence of White or Translucent Core

Rapid Growth of Hemangiomalike Lesions

Hemangiomas generally present within the first month of life. Two lesions that may mimic hemangiomas generally manifest after this period. These lesions are the pyogenic granuloma and Spitz nevus. They are differentiated by the fact that the Spitz nevus has a red, smooth, dome-shaped surface, as opposed to the crusted granular surface of a pyogenic granuloma. The last differentiating point is the common occurrence of bleeding of pyogenic granulomas following minor trauma. Juvenile xanthogranulomas (JXGs) can be red and appear suddenly. They are firm rather than spongy (like a hemangioma), and when blanched, the underlying color usually is yellow.

Spitz Nevus

Spitz nevi appear suddenly between 2 and 13 years of age. Preferred sites of growth include the cheek (15%) (Fig. 63.2), shoulder, and upper extremities. The lesion has a pink to red surface because of numerous dilated blood vessels. Pressure produces blanching of this pink to red color. The lesions can reach a size of 1.5 cm in diameter but are completely benign. Because the histologic appearance of these lesions can be confused easily with a malignant melanoma, an experienced histopathologist should interpret the findings. Most clinicians recommend that Spitz nevi be removed surgically.

FIGURE 63.2. Red papule that appeared 2 months ago and grew rapidly to this size (Spitz nevus).

Pyogenic Granuloma

For additional information about pyogenic granulomas, see Figure 99.38.

Juvenile Xanthogranuloma

JXG can be confused with urticaria pigmentosa or xanthomas. Numerous yellow or reddish-brown papules appear on the face (Fig. 63.3) and upper trunk in the first year of life. The number of lesions may increase until the child is 18 months to 2 years of age. Serum lipid levels are normal, and the Darier's sign (urtication after scratching—see mastocytoma) is negative. The lesions disappear spontaneously after 2 years of age; therefore, intervention is totally unnecessary.

FIGURE 63.3. Blanching erythematous papule on the ala nasae of this child. Biopsy showed this lesion to be a JXG.

NO HEMANGIOMALIKE LESION: YELLOW, TAN, OR BROWN PAPULE

The yellow, tan, and brown papules include the lesions seen in urticaria pigmentosa (a single, large lesion is called a mastocytoma), flat warts, xanthomas, insect bites, and JXGs.

A first step to differentiate the various papules from one another is to scratch them. If urtication (hiving) occurs (Darier's sign) within a short period (3 to 5 minutes), the lesion must contain mast cells (i.e., a mastocytoma or urticaria pigmentosa). Make sure to scratch normal skin to rule out the presence of dermographism. The latter condition will produce a false-positive Darier's sign. When no urtication occurs, blood should be drawn to check lipid levels. If lipid levels are normal, the next step is to differentiate two of the entities (i.e., flat warts and JXGs). Flat warts tend to be grouped, are flat-topped, and can be autoinoculated in scratch lines (pseudo-Köbner's phenomenon). Lesions characteristic for JXGs are not flat-topped, tend to be singular in number (or when multiple are scattered about), and do not demonstrate the Köbner's phenomenon. (This condition is discussed in greater detail later.) The JXG lesions also may look like xanthomas. Unlike xanthomas, however, abnormal lipid levels do not occur with JXGs.

Mastocytoma, Urticaria Pigmentosa

Parents who bring children with mastocytomas or lesions of urticaria pigmentosa to the physician generally describe a single yellow–tan–brown lesion that was present at birth (mastocytoma) or multiple pigmented papules that erupt during the first year of life (urticaria pigmentosa). One important clue is a history of these lesions becoming red (Fig. 63.4), hivelike, or blistered. The lesions may ooze and form crusts much like impetigo; however, they do not respond to antibacterial preparations.

FIGURE 63.4. Erythematous papules representative of urticaria pigmentosa. They will urticate with scratching (Darier's sign).

Physical examination of the lesion provides the next clue. The surface has a peu d'orange appearance at times. Some papules are very yellow and are easily mistaken for xanthomas. When they are tan to brown, they are thought to be raised moles. The clincher is finding a positive Darier's sign (histamine-induced erythema, swelling, and urtication secondary to scratching and subsequent degranulation of mast cells).

Table 63.3 lists medications and physical stimuli that cause mast cell degranulation and histamine and/or prostaglandin D_2 release. These agents should be avoided.

Medications	Physical Stimuli
Alcohol	Rubbing of the skin
Aspirin	Extremes of water temperature
Opiates	
Polymyxin B	
Procaine	
Scopolamine	

Table 63.3. Medications and Physical Stimuli to Be Avoided in Patients

When massive amounts of mediators are released, generalized flushing, persistent diarrhea, or hypotension may ensue. Children with these symptoms require therapy directed against histamine and prostaglandin D_2. The H_1-receptor antagonists (chlorpheniramine) and H_2-receptor antagonists (cimetidine) may be required. In addition, indomethacin is required to inhabit prostaglandin biosynthesis.

Fortunately, with aging, the skin is no longer reactive, and most of the lesions disappear completely.

Juvenile Xanthogranulomas

For additional information about JXGs, see the previous section in this chapter on p. 522.

Warts and Xanthomas

For additional information about warts and xanthomas, see previous sections of this chapter on p. 519.

LESIONS THAT ARE NOT YELLOW, TAN, OR BROWN: FLESH-COLORED LESIONS

Three entities may present as flesh-colored papules: lichen striatus, lichen nitidus, and flat warts. When the papules are arranged linearly, streaming down an extremity or across the face or neck, lichen striatus should be considered. If the papules are not arranged linearly but are tiny pinpoint, flesh-colored papules, lichen nitidus should be considered, especially if a Köbner's phenomenon is present. Flat warts may be flesh-colored.

Lichen Striatus

Lichen striatus is an asymptomatic eruption of unknown cause. The flat-topped papules are arranged linearly and may be confluent. The lesions are flesh-colored to erythematous in Caucasians and hypopigmented in African-Americans. The eruption follows the long axis of an extremity (Fig. 63.5) or may involve any other part of the skin surface (especially the face). Because the eruption resolves spontaneously in 2 years, no treatment is necessary.

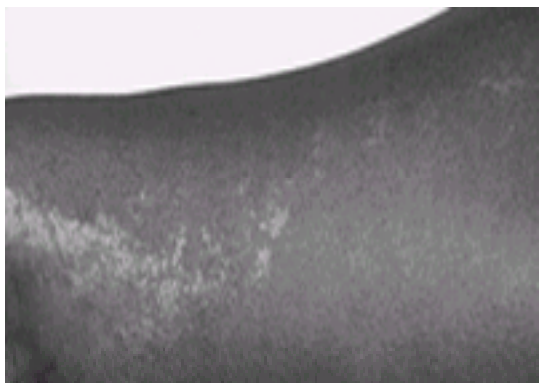

FIGURE 63.5. Hypopigmented papules running linearly along the long axis of the arm in a child with lichen striatus.

Lichen Nitidus

Lichen nitidus is characterized by tiny, pinpoint, flat-topped, flesh-colored papules (Fig. 63.6). The papules often are grouped and are found in scratch lines (i.e., the Köbner's phenomenon). Although any skin surface may be involved, the trunk and genitalia are common sites. The lesions persist for variable periods and generally do not respond to therapy.

FIGURE 63.6. Tiny flesh-colored to hypopigmented papules in a child with lichen nitidus. Note that the papules are arranged linearly (Köbner's phenomenon).

Flat Warts

See previous section about flat warts.

NON-FLESH-COLORED LESIONS

Lichen striatus can be composed of hypopigmented or erythematous papules arranged linearly. Red papules not arranged linearly and concentrated on exposed surfaces usually indicate the presence of insect bites. JXGs can be yellow or reddish-brown. They can be hypopigmented and brown–orange in African-American children. Xanthomas may be yellow or yellow–red. As discussed previously, the serum lipid levels are normal in patients with JXG and elevated in children with xanthomas.

NONCHARACTERISTIC PAPULES

Papules Arranged in Circles—Looks Like Tinea Corporis without Any Scaling

Granuloma Annulare

Granuloma annulare is thought to be an idiosyncratic response to trauma. The location of the changes (i.e., the shins, forearms, back of hands, ankles, and dorsum of the feet) seems to confirm this hypothesis. This skin change may begin as a flesh-colored or violaceous papule that clears centrally as the margins advance, or it may appear as a group of papules arranged in a ringlike configuration (Fig. 63.7). The central portion of the lesion is dusky or hyperpigmented. The key point on physical examination is the lack of scaling. This physical finding distinguishes granuloma annulare from tinea corporis and cannot be stressed enough. The border is firm on palpation, unlike tinea corporis. The rings can be 5 cm in diameter or larger.

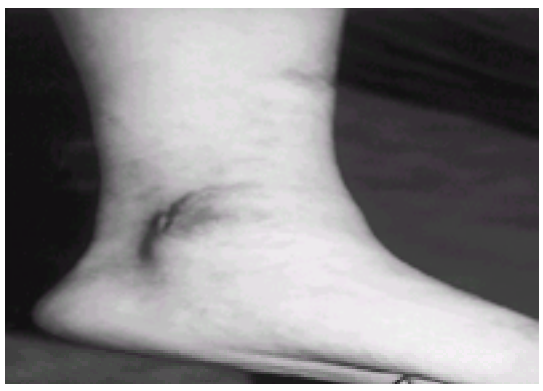

FIGURE 63.7. Note erythematous to violaceous papules arranged in a circle in this child with granuloma annulare.

A potassium hydroxide test would be definitive in ruling out tinea corporis. It would be difficult to obtain scales from a granuloma annulare lesion using this procedure. It is important to diagnose this entity correctly because one can reassure parents that three-quarters of lesions clear spontaneously within a 2-year period. Recurrences are common until children outgrow this tendency. Too often, treatment for tinea corporis is instituted unnecessarily.

If this algorithm has not helped in making a diagnosis, a consultant should be called. Many entities can be difficult to differentiate. A dermatologist often can resolve the matter, however, with a skin biopsy sent for histologic review.

CHAPTER 64

Rash—Papulosquamous Lesions

PAUL J. HONIG, MD

Departments of Pediatrics and Dermatology, The University of Pennsylvania School of Medicine, and Department of Pediatric Dermatology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

PAPULOSQUAMOUS ERUPTIONS

Of skin conditions seen in a pediatric dermatology clinic, 10% are papulosquamous (i.e., have a papular and scaling component). The algorithm contained in this chapter should be used as a guide to differentiate these disorders (Table 64.1 and Fig. 64.1). Each key point that distinguishes one disease from another is discussed here.

Acrodermatitis enteropathica[a]	Pityriasis rosea (common)
Drug eruption, papulosquamous (common)[a]	Pityriasis rubra pilaris
Lichen nitidus	Psoriasis (common)
Lichen planus	Reiter's syndrome
Nummular eczema (common)	Seborrheic dermatitis
Parapsoriasis	Syphilis, secondary (common)

[a]Potentially life-threatening.

Table 64.1. Papulosquamous Skin Disorders

FIGURE 64.1. Algorithm to distinguish papulosquamous lesions.

Presence or Absence of Pruritus

The initial symptom that should be considered is pruritus. Pruritus is absent in the six conditions listed in Table 64.2. Palmar involvement is prominent in secondary syphilis and papulosquamous drug eruptions but is rare in pityriasis rosea. A positive rapid plasma reagin test (RPR) helps differentiate syphilis from pityriasis rosea and a drug eruption. Pityriasis rosea begins with a herald patch, followed by a truncal eruption in a “Christmas tree” distribution. Finally, the Köbner's phenomenon separates lichen nitidus from other entities.

Drug eruption—papulosquamous	Parapsoriasis
Lichen nitidus	Pityriasis rosea
Nummular eczema	Secondary syphilis

Table 64.2. Nonpruritic Papulosquamous Skin Disorders

Conditions That Lack Pruritus

Drug Eruption—Papulosquamous

The diagnosis of a drug eruption is based on the history of current or recent intake of a medication and the disappearance of the eruption after discontinuation of the medication. Drug eruptions may mimic lichen planus, pityriasis rosea, pityriasis rubra pilaris, psoriasis, seborrheic dermatitis, and syphilis (Table 64.3). The cutaneous manifestations of a drug eruption that mimics one of the previously described disorders, however, will be atypical (e.g., lack of a herald patch and typical truncal distribution in a pityriasis rosea look-alike drug eruption or lack of a violaceous color and feathery white buccal changes in a lichenoid drug eruption). Remember that drug eruptions may or may not itch and may or may not have palmar and plantar involvement.

Lichen Planus		*Pityriasis Rosea*
β-Blockers	Isoniazid	Barbiturates
Captopril	Naproxen	β-Blockers
Carbamazepine	α-Penicillamine	Captopril
Chloral hydrate	Phenytoin	Gold
Diazoxide	Spironolactone	Griseofulvin
Furosemide	Tetracyclines	Ketotifen
Gold		Metronidazole
Griseofulvin		Penicillin
Hydrochlorothiazide		Tripelennamine
Pityriasis Rubra Pilaris		*Psoriasis*
β-Blockers		Antimalarials
Seborrheic Dermatitis		β-Blockers
Contraceptives with progesterone (derived from 19-nortestosterone)		Lithium
Testosterone		? Nonsteroidal anti-inflammatory drugs
Syphilis		
Any drug		

Table 64.3. Eruptions That May Mimic Various Papulosquamous Lesions

Lichen Nitidus

Lichen nitidus is a common disorder of children, seen especially in African-Americans. There is a 4:1 male:female predominance. Lichen nitidus involves the abdomen, genitalia (shaft and glans), and extremities with tiny, pinpoint, sharply demarcated, flat-topped, flesh-colored papules. Often, these lesions are closely grouped and are linear. Linear grouping of lesions is caused by the KöAdobner's phenomenon (Table 64.4) (appearance of the primary lesion at sites of trauma), which often occurs in lichen nitidus (Fig. 64.2). The lesions generally are nonpruritic. The course is variable, and the cause is unknown. Therapy is not warranted.

Lichen nitidus
Lichen planus
Psoriasis

Table 64.4. Conditions That Feature the Köbner's Phenomenon

FIGURE 64.2. Note flesh-colored papules in this African-American patient with lichen nitidus. The Köbner's phenomenon also is seen (papules arranged linearly in a scratch).

Nummular Eczema (Xerosis)

For more information about nummular eczema, see Chapter 99.

Parapsoriasis

Parapsoriasis is an uncommon pediatric skin condition. When it occurs, however, the course is chronic and, on rare occasions, may progress to cutaneous lymphoma. The appearance of this eruption is easily mistaken for nummular eczema, psoriasis, tinea corporis, or a lichenoid change. Small oval scaling, erythematous (Fig. 64.3) to yellow–brown macules are concentrated on the trunk. The skin lesions are asymptomatic, and the patient feels healthy.

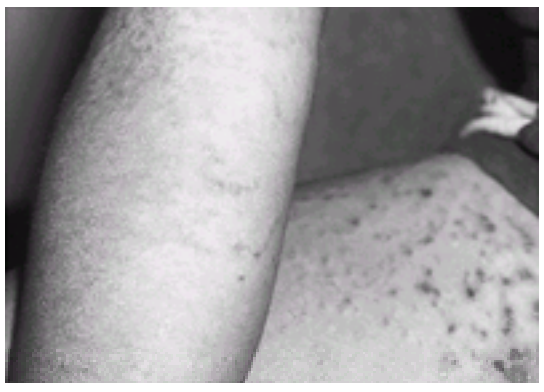

FIGURE 64.3. Red, scaling lesions on arm of child with parapsoriasis.

Treatment is unnecessary because the disease is asymptomatic. Topical steroids may be helpful but may not clear the skin changes. The eruption clears spontaneously after varying periods.

Pityriasis Rosea

For more information about pityriasis rosea, see Chapter 99.

Secondary Syphilis

The secondary phase of syphilis is a great mimicker. Therefore, one must suspect this condition to make the correct diagnosis. The eruption may be localized to the trunk, palms, and soles, as well as to any other skin surface. Other clues should be sought by history and physical examination (a primary chancre, condyloma lata, or white mucous patches on the tongue, buccal, and labial surfaces). Generalized lymphadenopathy usually is present. It may be difficult to differentiate secondary syphilis and pityriasis rosea; however, Table 99.10 (see Chapter 99) may be helpful in separating the two entities clinically.

A positive RPR or fluorescent treponemal antibody (FTA) makes the diagnosis. Remember, a false-negative RPR can occur with antibody excess (the prozone phenomenon). Therefore, dilution of the specimen by the laboratory should be requested if the presence of syphilis is highly suspected. This simple maneuver will result in a positive test for the presence of syphilis.

Color of the Skin Eruption and Pruritus

The eye can discern subtle differences in color. A pruritic papulosquamous eruption that does not look erythematous should suggest four disorders. First, a violaceous (bluish-red) or purple appearance generally indicates lichen planus or a lichenoid drug eruption. However, tones of yellow or salmon (orange–red) suggest the presence of seborrheic dermatitis or an unusual disorder called pityriasis rubra pilaris (PRP). The latter two diseases can be differentiated by looking for yellow thickening of the palms and soles (i.e., in PRP) or knowing that seborrheic dermatitis occurs before 6 months of age or after puberty. Lichen nitidus is obvious when tiny, discrete, flesh-colored papules (white papules in

African-Americans) are found, with some arranged linearly (Köbner's phenomenon).

Violaceous or Yellow- or Salmon-Colored (Orange–Red) Eruptions or Flesh-Colored (Nonerythematous) Eruptions

Lichen Planus

Lichen planus is seen occasionally in pediatric patients as a chronic, pruritic, reddish-blue (violaceous) to purplish eruption. Two to three percent of cases occur in patients younger 20 years old.

The eruption generally involves the flexors of the wrist, forearms, and legs, especially the dorsum of the foot and ankles. The lesions appear as small, violaceous, shiny, flat-topped, polygonal papules (Fig. 64.4). The surface of these papules may have white crosshatching, called Wickham's striae. Lesions may occur in sites of trauma or injury (Köbner's phenomenon). The scalp may be involved, often resulting in a scarring alopecia, called pseudopelade. It is important to examine the buccal mucous membrane for a reticulated or lacelike pattern of white papules or streaks. This finding is characteristic for lichen planus. The nails are often pitted, dystrophic, or ridged (pterygium nails). The lesions in lichen planus can be vesicular or bullous. Hypertrophic and linear lesions occur but are less common. Persistent, severe, postinflammatory hyperpigmentation is common in African-Americans. In two-thirds of patients, the lesions clear within 8 to 15 months. The cause of the disorder is unknown. Topical therapy with steroids can be helpful.

FIGURE 64.4. Note child with red–blue color of flat-topped papules representative of lichen planus.

Seborrheic Dermatitis

For more information about seborrheic dermatitis, see Chapter 99.

Pityriasis Rubra Pilaris

Pityriasis rubra pilaris is characterized by follicular papules and yellow–orange skin that surrounds islands of normal skin. Of patients with PRP, 30% are children.

The onset of the disease is gradual, beginning in the scalp and spreading to involve the face and ears. Acuminate follicular papules with keratotic plugs occur on the back of the fingers, side of the neck, and extensors of the extremities. The skin is generally salmon-colored and scaling. As the eruption progresses, it surrounds islands of normal skin. Yellow thickening of the palms and soles is characteristic (Fig. 64.5). Three subtypes have been described: the familial form has its onset in infancy and childhood; a localized type is found in 60% of cases; and the acquired form occurs in persons more than 15 years of age. The cause of this disease is unknown, although it is a disorder of keratinization. The condition responds to vitamin A and its derivatives.

FIGURE 64.5. Hyperkeratosis of palms and islands of normal skin seen in this child with PRP.

Differentiating the Pruritic, Red Papulosquamous Lesions

Pityriasis rosea also should be included in this part of the algorithm. Because the rash of pityriasis rosea may or may not

itch, the first differentiating point is to inquire about a history of a herald patch and look for the characteristic Christmas tree distribution. If one or both is present, a diagnosis of pityriasis is made. If not, one must look for the Köbner's phenomenon. The Köbner's phenomenon is defined as the appearance of the existing rash in areas of traumatized skin (e.g., in scratches, abrasions, blistered sunburns). This phenomenon is discussed further in this chapter under Psoriasis.

Another clue to the presence of psoriasis is the finding of abnormal nails (e.g., nail pits, flaking, thickened nails). Reiter's syndrome and acrodermatitis enteropathica may also manifest nail abnormalities. These entities can be differentiated from one another by a history or finding of uveitis and/or urethritis (Reiter's syndrome) or diarrhea and/or hair loss (acrodermatitis enteropathica).

Psoriasis

Psoriasis is a chronic papulosquamous disease that makes up 4% of all skin disorders encountered in children. The female:male ratio is 2:1. There is a predisposition for involvement of the scalp, perineum, and the extensor surfaces of the body, particularly the elbows and knees.

One-third of adults with psoriasis experience onset of disease in childhood or adolescence. Psoriasis occurs in 12% of children before the age of 10 years. The major human leukocyte histocompatibility antigens (HLA) are important genetic markers of psoriasis. Of these, HLA-B13 and HLA-BW17 are associated with early onset of disease. The HLA-B13 antigen is associated with a history of antecedent streptococcal infections. The HLA-BW17 antigen is more commonly identified with extensive skin involvement and a strong familial history.

Psoriasis occurs in three forms during childhood: guttate, erythrodermic, and pustular. Any or all of these types may develop with silvery scales into the chronic, plaque-type psoriasis (Fig. 64.6). When a scale is removed, pinpoint areas of bleeding occur on the surface (Auspitz sign). Guttate psoriasis is the most common form, occurring in childhood. Guttate or droplike erythematous papules are scattered over the body. The characteristic silvery scale is only minimally expressed, and the lesions may appear quite red. This form often is preceded by a streptococcal infection. Infants often have involvement in the diaper area as well. Erythrodermic psoriasis is less common and more severe. Onset may be abrupt or gradual, with a diffuse erythema and severe desquamation. In the growing child, there may be associated failure to thrive. Pustular psoriasis is rare and the least commonly occurring form of psoriasis seen in children. Various sized sterile and superficial pustules develop on an erythrodermic background.

FIGURE 64.6. Plaque-type psoriasis in this infant. Note scaling in scalp.

Characteristically small, pitted lesions are seen on the nails in 25 to 50% of patients in all forms of the condition. Eighty percent of children have scalp involvement, especially at the hair margins. A small number of patients develop arthritis between 9 and 12 years of age; some develop it before the onset of the skin eruption. The distal interphalangeal joints of the hands and feet are involved most often. Therapy with topical agents, including steroids, tar derivatives, emollients, and ultraviolet light, help slow the turnover rate of the epidermis.

Reiter's Syndrome

The skin changes seen in Reiter's syndrome look much like those in psoriasis. A symmetric arthritis of major joints, uveitis, and urethritis complete the syndrome. Although most cases occur in young adult men, on occasion, the syndrome will be seen in adolescents. Only 10 cases have been reported in children under 12 years of age. Ninety percent of patients are HLA-B27 positive. A postinfectious cause has been hypothesized.

The palms and soles are the major sites of involvement. Yellow, scaly, hyperkeratotic lesions appear on an erythematous base in those locations. The skin lesions may begin as macules, vesicles, or pustules. The palmar plantar changes have been called keratoderma blennorrhagicum. The scalp and penis also are characteristically involved with psoriasiform lesions. Erythema and superficial ulcerations may be present in the mouth. Abnormalities of the nails (e.g., dystrophy, onycholysis) are common. (See the section on Reiter's syndrome for therapy.)

Acrodermatitis Enteropathica

Acrodermatitis enteropathica is characterized by skin rash, diarrhea, and alopecia. The condition is caused by poor absorption of zinc, with plasma zinc levels under 50 µg/dL. The disease generally begins around 9 months of age (1 week to 20 months).

The infant usually presents with a psoriasiform diaper eruption, followed by similar involvement of periorificial (eyes, ears, nose, and mouth) and acral skin. The skin often is eroded and crusted. These changes may be confused with a severe candida infection (Table 64.5) or impetigo. Because of involvement of the digits and periungual tissues, nail dystrophies often are present. Hair is lost from the scalp, brows, and lashes. The children are irritable, photophobic, and apathetic. Growth retardation is common. Rapid growth occurs with zinc sulfate or gluconate 5 mg/kg per day.

Differential Diagnosis	
Mucocutaneous candidiasis	Histiocytosis X
Biotin deficiency	Multiple carboxylase deficiency
Essential fatty acid deficiency	Psoriasis
Glucagonoma syndrome	Seborrheic dermatitis

Table 64.5. Acrodermatitis Enteropathica

If this algorithm does not lead to a clear diagnosis, many of the entities can be clarified with a skin biopsy or referral to a dermatologist.

CHAPTER 65

Rash—Purpura

ALAN R. COHEN, MD

Department of Pediatrics, The University of Pennsylvania School of Medicine, and Division of Hematology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Blood in the skin or mucosal membranes is referred to as purpura. The sudden, unexplained appearance of purpura in a child is a finding that is disturbing to parents and may prompt an immediate visit to the local emergency department (ED) or physician. This finding also is particularly disturbing to physicians because it may be the presenting sign of many diseases, some benign and others life-threatening, some treated easily and others requiring complex therapy.

When the onset of purpura is accompanied by massive hemorrhage or by bleeding in a critical site such as the central nervous system (CNS), the patient is easily recognized as being dangerously ill and appropriate measures are taken rapidly. When purpura is the only presenting complaint, however, the patient should still be considered as having the potential for life-threatening sequelae of disordered hemostasis. The cause of purpura should be established as rapidly as possible because early treatment may lead to a more favorable outcome. Fortunately, an understanding of the pathophysiology of purpura, a careful history and physical examination, and an appropriate laboratory evaluation usually establish the cause of the bruising. This chapter presents the initial assessment and differential diagnosis of children with purpura. The management of emergency situations associated with these symptoms is discussed in Chapter 87.

PATHOPHYSIOLOGY

Purpura can be subdivided on the basis of its appearance into petechiae and ecchymoses. Petechiae are small (less than 3 mm in diameter), reddish-purple, macular lesions. Ecchymoses are larger lesions that often are tender and, when severe, may be raised above the level of the skin surface. Purpuric lesions do not blanch, a characteristic that distinguishes them from vascular dilation and vascular anomalies. Under normal conditions, a purpuric lesion resolves in a predictable manner. The purple color gradually fades to golden brown as hemosiderin is formed. The golden brown color may then take as long as 6 weeks to resolve. This progressive and characteristic resolution of purpura often is helpful in determining the time and cause of the injury that resulted in purpura. For example, ecchymoses in various stages of resolution may be the major diagnostic finding in cases of child abuse with repeated assaults.

Complex mechanisms maintain vascular integrity and stop the flow of blood when a blood vessel is damaged. Vitamin C and other factors that affect collagen synthesis are required for normal formation of connective tissue within the vessel walls. When a blood vessel is injured, vasoconstriction and retraction usually occur immediately and decrease the flow of blood to the affected area. Facilitated by von Willebrand factor, platelets adhere to the subendothelium of the damaged wall and, in response to the exposed subendothelial collagen, release adenosine diphosphate (ADP). This release reaction causes platelet aggregation at the site of the injury and the formation of a platelet plug that is responsible for primary hemostasis. A decrease in the number of circulating platelets or an intrinsic or secondary alteration in platelet metabolism and aggregation may disrupt this early phase of hemostasis and result in localized or disseminated purpura.

The intrinsic pathway of coagulation also is activated by the exposed collagen (Fig. 65.1). A sequence of enzymatic reactions, beginning with the binding of factor XII to the exposed subendothelium, leads to the formation of a fibrin clot at the site of the injury. A related pathway (extrinsic pathway) is activated by tissue thromboplastin and contributes to the development of the fibrin clot. Factors XII, XI, IX, and VIII contribute exclusively to the intrinsic pathway, whereas factor VII is involved only in the extrinsic pathway. Factors X, V, II (prothrombin), and I (fibrinogen) are shared by both pathways. Defects in the clotting sequence interfere with the formation of a normal clot behind the platelet plug (secondary hemostasis). As is the case in platelet disorders, alterations in the coagulation pathway may be caused by intrinsic abnormalities of the clotting factors or by abnormalities resulting from systemic diseases.

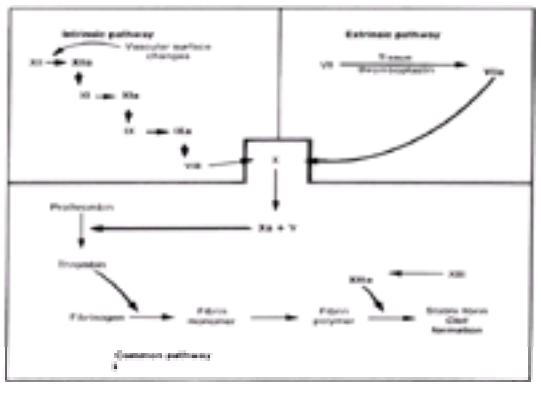

FIGURE 65.1. A simplified version of the coagulation “cascade.” An abnormality in the extrinsic pathway results in a prolonged PT. An abnormality in the intrinsic pathway results in a prolonged PTT. An abnormality in the common pathway results in prolongation of both the PT and the PTT.

Disruption of the normal hemostatic mechanism at any point may result in purpura. Although the pathophysiology is complex and foreboding to most physicians when presented in detail, a basic understanding of altered hemostasis enables the physician to categorize the wide variety of purpuric disorders. With this categorization in mind, the physician becomes more efficient in obtaining a history, performing a physical examination, and selecting the appropriate laboratory tests.

DIFFERENTIAL DIAGNOSIS

A purpuric eruption may result from loss of vascular integrity, thrombocytopenia, disorders of platelet function, or deficiencies of clotting factors. Myriad disorders may cause purpura, but only a few are particularly common (Table 65.1), including trauma, infections, Henoch-Schönlein purpura (HSP), and idiopathic thrombocytopenic purpura (ITP).

Disruption of Vascular Integrity	*Platelet Deficiency or Function Disorders*
Trauma	Idiopathic thrombocytopenic purpura
Viral infections	Sepsis
Henoch-Schönlein purpura	Drug-associated disorders
Rickettsial infection	*Factor Deficiencies*
	Hemophilia

Table 65.1. Common Causes of Purpura

Loss of Vascular Integrity

Purpura may be caused by numerous disorders that disrupt vascular integrity (Table 65.2). The most common cause of purpura from vascular injury in children is trauma. Most active children have bruises, particularly on the anterior aspect of the lower extremities. Occasionally, however, a parent will bring a child to a physician with the complaint that the child bruises unusually easily. A thorough history and physical examination often are sufficient to distinguish the patient who requires further evaluation from the patient who requires only reassurance about normal childhood bruising from trauma. The child's level of activity should be correlated with the degree of bruising. Ecchymoses that might be acceptable in a child who enjoys climbing trees would be most surprising in a child who spends most of his or her leisure time reading. In addition, bruising on an area of the body rarely exposed to trauma (e.g., chest, abdomen, back) or bruising out of proportion to the degree of trauma should be evaluated further. Large, raised ecchymoses rarely are seen in the absence of significant trauma that is easily recalled. A history of sudden onset of excessive bruising without an associated change in activity also suggests an underlying disorder. Even when the history indicates that the ecchymoses can be attributed to repeated episodes of minor trauma, the finding of numerous bruises may be a clue to a subtle neurologic disorder that causes unusual clumsiness.

Trauma: accidental; child abuse[a]
Infection: viral exanthems, infectious mononucleosis, bacterial endocarditis,[a] rickettsial disease,[a] streptococcal infection
Drugs and toxins[a]
Henoch-Schönlein purpura
Vitamin C deficiency
Letterer-Siwe disease
Ehlers-Danlos syndrome
Miscellaneous: acute glomerulonephritis, rheumatic fever, collagen vascular diseases

[a]Conditions that may be life-threatening.

Table 65.2. Causes of Purpura in Children Secondary to Disruption of Vascular Integrity

Foremost in the mind of a physician who cares for children must be the consideration that bruising is caused by child abuse. Suspicion should be raised if the child has presented in the past with unexplained bruising or suspicious injuries; if explanations of the bruises are inconsistent; if bruises are confined to the buttocks, back, or face; if bruises conform to the shape of a belt or cord; or if bruises are in various stages of resolution (see Chapter 128).

Purpura can be the initial manifestation of numerous infectious processes. The purpura may result from a disruption of the vascular integrity by the infecting agent or from the body's reaction to the agent, an infection-induced thrombocytopenia, or disseminated intravascular coagulation (DIC) initiated by the septic process. The latter two disorders are discussed later in this chapter. Capillary damage that results in petechiae or ecchymoses can occur with the viral exanthems and is especially common with rubeola. The child with infectious mononucleosis, bacterial endocarditis, a rickettsial infection, or a streptococcal infection can present with purpura in the absence of coagulation or platelet abnormalities. Rocky Mountain spotted fever should be strongly considered when the patient is from an area in which the disease is endemic or when there is a history of tick exposure, especially in the months of April through October.

The most serious infection that can cause purpura is meningococcemia, and this disorder always must be considered in a child with purpuric lesions. The rapidity with which meningococcemia can progress may warrant the institution of antibiotic therapy in any moderately ill child with purpura until results of cultures are available. Purpura fulminans is a particularly severe form of bleeding caused in part by loss of vascular integrity and may accompany meningococcemia as well as septicemia from other organisms, scarlet fever, varicella, and rubeola. This disorder often is found in association with DIC and is characterized by the sudden onset of large ecchymoses and rapid development of gangrene of the extremities.

Numerous drugs and toxins can cause purpura as a result of increased capillary fragility or vasculitis. The parents of a child with purpura should be questioned closely regarding the recent use of any medications, including over-the-counter drugs and “home remedies.” Drugs that have been implicated include the sulfonamides, iodides, belladonna, bismuth, mercurial compounds, the penicillins, phenacetin, and chloral hydrate. Corticosteroid treatment can cause the appearance of benign purpura, especially striated purpuric lesions just above the buttocks. The lesions resolve with discontinuation of corticosteroid therapy. The appearance of these lesions in a child not taking corticosteroids should cause the physician to search for endogenous corticosteroid production, as in Cushing's disease. Vitamin C deficiency also can present with purpura that ranges from scattered petechiae to substantial ecchymoses, particularly on the lower extremities. Scurvy is rare in the United States but can be seen in patients who receive hyperalimentation with inadequate vitamin C supplementation or in patients with iron overload. The purpuric lesions of scurvy heal rapidly after the administration of vitamin C.

Purpura that results from an aseptic vasculitis within the corium may be the presenting symptom of HSP. The purpuric lesions often are accompanied by pink or brownish-pink macules or maculopapules that later may develop central areas of hemorrhage. They tend to coalesce and usually are located on the lower extremities, buttocks, and lower back. The platelet count is normal in uncomplicated HSP, as are the prothrombin (PT) and partial thromboplastin (PTT) times. Anaphylactoid purpura that resembles HSP also can accompany acute streptococcal infections, rheumatic fever, acute glomerulonephritis, and collagen vascular disorders (see Chapter 101).

Rare disorders of childhood that may be associated with purpura from loss of vascular integrity include Letterer-Siwe disease and Ehlers-Danlos syndrome. Letterer-Siwe disease is a histiocytic disorder with brown, crusted vesiculopapular skin lesions that often are purpuric. Petechiae may also be present. The pathogenesis of purpura in this disorder is uncertain but may be related to the widespread histiocytic infiltration. Ehlers-Danlos syndrome is an unusual defect in collagen synthesis. The altered blood vessel architecture causes capillary hemorrhage; rupture of major blood vessels may occur.

Platelet Disorders

Thrombocytopenia

Thrombocytopenia in childhood may come from shortened platelet survival, decreased platelet production, or platelet sequestration (Table 65.3). However, certain illnesses and drugs may cause thrombocytopenia by more than one mechanism. For example, thrombocytopenia that accompanies viral or bacterial infections may come from decreased platelet production, antiplatelet antibody formation, or the presence of DIC. Similarly, thrombocytopenia associated with sulfonamide therapy may come from diminished platelet production or immune-mediated platelet destruction. Consequently, detailed investigation may be required to determine the mechanism of thrombocytopenia and the appropriate treatment.

Table 65.3. Causes of Childhood Purpura Secondary to Platelet and Coagulation Abnormalities

Increased Platelet Destruction

The most common form of thrombocytopenia in childhood is ITP. This immunologic disorder usually is characterized by the acute onset of petechiae and ecchymoses, although symptoms occasionally occur more gradually. Epistaxis occurs in 10 to 20% of cases. Other bleeding manifestations are much less common. Although ITP occurs in children of all ages, most cases are seen between the ages of 2 and 6 years.

ITP may have no antecedent illness or may follow a mild viral illness by 2 to 6 weeks. The disorder is associated with human immunodeficiency virus (HIV), infectious mononucleosis, cytomegalovirus (CMV) infection, rubeola, mumps, and varicella. A similar relationship between ITP and rubeola and rubella immunization has been observed. ITP may be the first manifestation of a systemic immunologic disorder such as systemic lupus erythematosus (SLE). A careful search for this association is particularly important in older children. The association of ITP with autoimmune hemolytic anemia or neutropenia is called Evans syndrome.

The physical examination of the child with ITP reveals few abnormalities other than purpura. Enlargement of the spleen occurs rarely. At the onset of purpura, the platelet count usually is less than 20,000/mm ^{3}. In the absence of prolonged bleeding or antibodies to other hematologic elements, the hemoglobin concentration and white blood cell (WBC) count are normal. A bone marrow aspirate is sometimes performed to assess megakaryocyte production because the clinical presentation of aplastic anemia or acute leukemia rarely may be indistinguishable from ITP. A bone marrow aspirate is particularly important if treatment with corticosteroids is contemplated because this therapy may obscure the diagnosis of acute leukemia, thereby delaying appropriate therapy and adversely affecting the outcome. Other laboratory studies that may be performed include an antinuclear antibody (ANA) titer as a screening test for collagen vascular disorders and a reticulocyte count and direct Coombs test to detect immune hemolytic anemia.

Thrombocytopenia from shortened platelet survival may be caused by fibrin deposition and platelet consumption as found in DIC and also in hemolytic uremic syndrome (HUS), which is characterized by a microangiopathic anemia and uremia. In this, pallor, purpura, and signs of renal failure usually follow a prodrome of abdominal pain and diarrhea. Thrombotic thrombocytopenic purpura (TTP) is a disorder that resembles HUS in its hematologic aspects but more commonly occurs in adults than in children. However, this disorder has been described in the pediatric age group and may be particularly difficult to distinguish from HUS, although neurologic rather than renal symptoms are more prominent in TTP.

Infants with Wiskott-Aldrich syndrome, an X-linked recessive immunodeficiency disorder, may develop thrombocytopenic purpura beginning in the newborn period. Shortened platelet survival in this disease comes from an intrinsic platelet abnormality. The survival of transfused donor platelets is normal in children with Wiskott-Aldrich syndrome, whereas survival of autologous platelets is shortened. Numerous drugs have been reported to cause thrombocytopenia by the formation of platelet antibodies with resultant increased platelet destruction. The drugs that cause thrombocytopenia that are most commonly used in children include sulfa compounds (including trimethoprim–sulfamethoxazole), valproic acid, phenytoin, acetazolamide, carbamazepine, and quinidine.

Decreased Platelet Production

Diseases associated with decreased amounts of functional bone marrow also may present with thrombocytopenia and purpura. Most notable in this group are the leukemias, neuroblastoma, histiocytosis, and osteopetrosis. Decreased platelet production also may be the result of abnormalities of development of the hematopoietic stem cell (aplastic anemia, Fanconi's anemia, and thrombocytopenia and absent radii), ineffective megakaryocyte development (megaloblastic anemias), or rarely, absence of a humoral factor (presumed thrombopoietin deficiency). Although pancytopenia often is present at the time of diagnosis of bone marrow disorders such as leukemia and aplastic anemia, thrombocytopenia may precede notable alterations in other elements in the peripheral blood.

Numerous drugs have been associated with thrombocytopenia because of decreased platelet production. Any drug capable of causing general bone marrow suppression can produce thrombocytopenia (most antibiotics, anticonvulsants, thiazide diuretics, and the like). Drugs that specifically inhibit megakaryocyte production include the chlorothiazides, estrogenic hormones, ethanol, and tolbutamide.

The circulating platelets in disorders of platelet production usually are older and metabolically less active than those found in most diseases of shortened platelet survival. Consequently, spontaneous purpura often appears at a platelet count of 25,000 to 40,000/mm^3 in leukemia or aplastic anemia but is rare after the first week of ITP unless the platelet count is less than 20,000/mm^3.

Platelet Sequestration

Splenomegaly that comes from numerous causes (e.g., portal hypertension, storage diseases) can result in sequestration of platelets and thrombocytopenia. The spleen is markedly enlarged and very firm in these disorders. Purpura that comes from platelet sequestration alone is rare because the platelet count usually does not fall below 40,000/mm ^{3}. Bleeding may occur, however, when the platelet sequestration is associated with liver disease and clotting abnormalities. Platelet sequestration and consumption also can occur in large hemangiomas (Kasabach-Merritt syndrome).

Disorders of Platelet Function

A clinical picture similar to that seen with thrombocytopenia can occur with a normal platelet count in the presence of a qualitative or functional platelet abnormality. These disorders can be congenital or acquired and, when congenital, can present in infancy with prolonged oozing from venipuncture sites or the umbilical cord, ecchymoses, and petechiae. Glanzmann's thrombasthenia is an autosomal-recessive disorder in which the platelet count is normal but the bleeding time is prolonged, clot retraction is poor, and platelet aggregation and adhesion are absent. Other inherited abnormalities of platelet metabolism (storage pool disease, aspirinlike defect, Bernard-Soulier syndrome) may be associated with purpura, although bleeding is generally not as severe as it is in Glanzmann's thrombasthenia. In addition to shortened platelet survival, platelet dysfunction is found in Wiskott-Aldrich syndrome.

Acquired platelet dysfunction with purpura can occur in the presence of uremia or liver dysfunction and also can be caused by certain medications. Aspirin is the best known of the drugs that cause platelet dysfunction; a single dose of aspirin can alter platelet function for as long as 9 to 10 days. Platelet dysfunction also has been associated with antihistamines, propranolol, phenothiazines, glycerol, guaifenesin, and carbenicillin. These drugs interfere with the release of endogenous ADP and inhibit platelet aggregation and adhesion. Unlike aspirin, however, they cause few, if any, clinical problems.

Factor Deficiencies

Purpura can be the presenting symptom of a congenital or acquired deficiency of coagulation factors. The most commonly encountered congenital deficiencies are von Willebrand's disease, hemophilia A (factor VIII deficiency), and hemophilia B (factor IX deficiency, Christmas disease). Although the latter two disorders have an X-linked recessive mode of inheritance, the de novo appearance of coagulopathy is not uncommon, particularly in children with severe hemophilia A (factor VIII activity less than 1%). Therefore, a family history of affected males may be helpful in establishing the diagnosis of hemophilia, but the absence of such a history does not eliminate this diagnostic possibility.

Congenital Deficiencies

Children with hemophilia often are detected when they develop purpura either spontaneously or after mild trauma. The diagnosis of hemophilia also should be entertained in newborns who develop excessive bleeding after circumcision and in infants with prolonged bleeding from lacerations of the lip, tongue, or frenulum. Prompt recognition of the disorder at this early age allows careful surveillance, appropriate treatment, and early genetic counseling for parents.

Coagulation tests in children with hemophilia A and B reveal a prolonged PTT and normal PT. The bleeding time is usually normal. Specific factor assays will define the particular abnormality. Special care should be taken in establishing the diagnosis of factor IX deficiency in the young infant because the low factor IX levels found in normal infants in the first few days of life may overlap with the factor IX levels found in mild hemophilia B.

Less common congenital factor deficiencies that may cause purpura in children include fibrinogen and factors II (prothrombin), V, VII, X, XI, and XIII. As in hemophilia, specific factor assays will identify the particular abnormality. Alterations in fibrinogen function (dysfibrinogenemias) also are associated with purpura. Fibrinogen levels determined by clotting assay usually are reduced moderately in these disorders.

Von Willebrand's disease is a common bleeding disorder caused by an alteration that adversely affects platelet function as well as clotting. The severity of this autosomal-dominant disorder is extremely variable among affected persons. Although some patients may have spontaneous purpura, others remain asymptomatic and are discovered only after the diagnosis of von Willebrand's disease in a close relative leads to laboratory investigation of other family members. Occasionally, von Willebrand's disease is uncovered when an acquired alteration of hemostasis is superimposed on the inherited abnormality. For example, bruising occurs very easily after aspirin ingestion in many patients with von Willebrand's disease. As in other disorders that affect platelet function, bleeding from mucosal surfaces (epistaxis, menorrhagia) is prominent in von Willebrand's disease. The laboratory abnormalities in von Willebrand's disease are variable and may fluctuate from week to week in the same patient. In its classical form, the disease is characterized by prolongation of the bleeding time, increased PTT, decreased levels of factor VIII coagulant activity and von Willebrand factor antigen, and diminished aggregation of normal platelets when ristocetin is added to the patient's plasma (von Willebrand's or ristocetin cofactor activity). In practice, however, only one or two of the laboratory abnormalities may be found. Indeed, several determinations may be required to detect an abnormality or to confirm the diagnosis of von Willebrand's disease.

Acquired Deficiencies

Causes of acquired deficiencies of clotting factors include DIC, liver disease, vitamin K deficiency, circulating anticoagulants, uremia, and cyanotic congenital heart disease. DIC is a potential complication of infection (bacterial, viral, or rickettsial), extensive burns, severe trauma, malignancies (especially acute promyelocytic leukemia), snake and insect bites, shock, and heat stroke. In DIC, the intravascular consumption of clotting factors may cause purpura because of factor depletion and, in severe cases, may lead to widespread, rapidly progressing purpuric lesions (purpura

fulminans) associated with thrombosis or emboli. Although other signs of serious illness usually are present in the child with purpura caused by DIC, fever and purpura may be the only significant findings in the early stages of severe bacterial infections such as meningococcemia. Further investigations and appropriate therapy should proceed rapidly in such instances.

Laboratory abnormalities in DIC include one or more of the following: a decreased platelet count, prolonged PT and PTT, decreased fibrinogen level, and elevated fibrin split products. A microangiopathic anemia with red cell fragmentation also may be present.

Coagulopathies caused by severe hepatocellular disease or vitamin K deficiency can present with some of the same clinical and laboratory findings as DIC. A comparison of the laboratory values in these three disorders is shown in Table 65.4. Hepatocellular disorders that may cause purpura include Reye syndrome, Wilson's disease, and toxic or infectious hepatitis. Vitamin K deficiency may be associated with malabsorption and chronic diarrhea. Purpura caused by warfarin (Coumadin) therapy or ingestion can resemble vitamin K deficiency clinically. Hemorrhagic disease of the newborn that comes from decreased vitamin K stores at birth can be prevented by the administration of vitamin K routinely following delivery. This important step in normal newborn care may be overlooked, however, when other problems develop in the delivery room, and a careful review of the records may be necessary to ensure that the young infant with purpura actually received vitamin K.

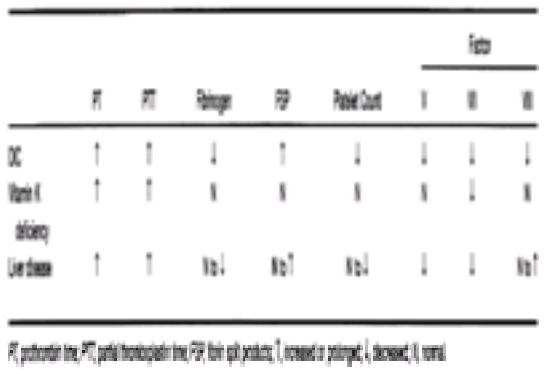

Table 65.4. Comparison of Laboratory Values in Disseminated Intravascular Coagulation (DIC), Liver Disease, and Vitamin K Deficiency

Circulating anticoagulants in children are associated with viral infections, malignancies, and collagen vascular disorders. They usually are characterized by a prolonged PTT that fails to correct with the addition of normal plasma. Because most acquired inhibitors in children, particularly lupus anticoagulants, are not associated with increased bleeding, the identification of an inhibitor in a patient with purpura should not preclude an investigation of other coagulation abnormalities.

Numerous coagulation abnormalities have been demonstrated in vitro in patients with renal disease. However, bleeding is most commonly related to altered platelet function rather than to defects in the fluid phase of coagulation. Abnormalities that resemble those found in DIC have been associated with cyanotic congenital heart disease. Although the coagulopathy seems to be related to the degree of polycythemia, the underlying mechanism remains unidentified.

EVALUATION AND DECISION

The evaluation of a child with purpura must combine speed and skill. The diagnostic approach is outlined in Figure 65.2. Purpura can be the initial sign of a life-threatening meningococcal infection, requiring immediate treatment, or the first sign of child abuse, requiring patient, thorough investigation. The initial approach should be dictated by the general appearance of the child and the presenting vital signs. A well-appearing child with purpura and normal vital signs can be approached with less urgency than a febrile, lethargic child with purpura or a child with hemophilia, purpura of the neck, and respiratory compromise.

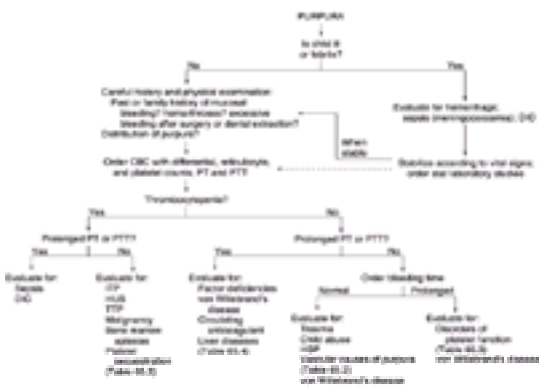

FIGURE 65.2. The approach to the child with purpura. *CBC,* complete blood count; *PT,* prothrombin time; *PTT,* partial thromboplastin time; *DIC,* disseminated intravascular coagulation; *ITP,* idiopathic thrombocytopenic purpura; *HUS,* hemolytic uremic syndrome; *TTP,* thrombotic thrombocytopenic purpura; *HSP,* Henoch-Schönlein purpura.

If the child with purpura appears well or if the more seriously ill child has been given appropriate emergency care, the evaluation of the purpura can proceed in an orderly fashion. The recent and past medical history should be reviewed carefully with the parents and child. Acute onset of purpura after a recent viral illness or immunization is consistent with an acquired disorder such as ITP or a circulating anticoagulant. Recurrent purpura since infancy, however, suggests an inherited abnormality of platelets or clotting factors. Specific inquiries about past surgeries, dental extractions, or significant trauma should be made because the absence of bleeding under these conditions would be unusual in most inherited disorders of even moderate severity. When previous bleeding has occurred, the site of bleeding may be helpful in establishing the alteration in the hemostatic mechanisms. Hemarthroses, a common problem in severe hemophilia, rarely are associated with platelet abnormalities. Conversely, petechiae and subconjunctival hemorrhages are commonly found in children with platelet disorders but occur rarely in hemophilia.

The family history should be reviewed for purpura or bleeding disorders. A positive family history in male relatives on the maternal side suggests factor VIII or factor IX deficiency. A history of bleeding or bruising in numerous family members of both sexes suggests a condition with dominant inheritance such as von Willebrand's disease. As noted earlier, however, a negative family history does not preclude the diagnosis of von Willebrand's disease or hemophilia. A careful review of systems also should be obtained to evaluate underlying conditions such as uremia, hepatic disease, congenital heart disease, and malabsorption that might be associated with a coagulopathy.

The child should be examined carefully to assist in the diagnosis of the specific bleeding disorder and to evaluate hidden areas of hemorrhage. Particular attention should be paid to the skin. The distribution of purpura should be noted. Purpura on the lower extremities and buttocks suggests HSP, and purpuric lesions on the palms and soles often are seen with rickettsial infections. When the purpuric lesion has an unusual shape, such as a folded cord, child abuse should be suspected. Complete neurologic assessment is mandatory when there is suspicion of head trauma in the face of a bleeding diathesis. The eyes should be examined for the presence of conjunctival, scleral, or retinal hemorrhage. The presence of lymphadenopathy or hepatosplenomegaly should be sought. Lymphadenopathy may be present in certain malignancies (leukemias) or viral infections (infectious mononucleosis, CMV) that can present with purpura. Hepatomegaly may signal an underlying hepatic disorder that can cause a coagulopathy. Splenomegaly can be seen in infectious mononucleosis, leukemia, hepatic disease, and the storage diseases. Inflammation or synovial thickening of the large joints is consistent with the hemarthroses seen in hemophilia.

The laboratory approach to a child with purpura also is influenced by the initial presentation and history. Every child who presents with purpura should have a complete blood count (CBC) with a differential and platelet count, a PT, and a PTT. In most hospitals, these tests can be done quickly so that therapy can be chosen or modified on the basis of the results. A decreased hematocrit or hemoglobin concentration may indicate past or present blood loss or bone marrow failure or replacement. The WBC count can give information regarding the possibility of sepsis or leukemia. If sepsis is suspected, the smear should be examined for the presence of toxic granulation, vacuolization, or Döhle bodies. Atypical lymphocytes are seen with many viral infections, especially mononucleosis. Causes of abnormal screening coagulation studies (platelet count, PT, PTT, bleeding time) are outlined in Table 65.5. Depending on the results of these initial tests and the clinical impression derived from the history and physical examination, a more sophisticated laboratory evaluation can be undertaken. If emergency therapy is required before the cause of purpura is known, pretreatment plasma should be saved for later investigation of disorders such as von Willebrand's disease or other inherited factor deficiencies.

Platelet Count (normal 150,000–500,000/mm³)
Decreased: Increased platelet destruction, decreased platelet production, platelet sequestration, some platelet function disorders (see Table 65.3)
Prothrombin Time (normal range may vary between laboratories)
Prolonged: Disseminated intravascular coagulation; vitamin K deficiency; warfarin ingestion; deficiencies of factors II, V, VII, X; abnormalities of fibrinogen; liver disease; renal disease; congenital heart disease
Activated Partial Thromboplastin Time (normal range may vary between laboratories)
Prolonged: Disseminated intravascular coagulation; von Willebrand's disease; deficiencies of factors II, V, VIII, IX, X, XI, XII; abnormalities of fibrinogen; vitamin K deficiency; heparin therapy or sample contamination; liver disease; congenital heart disease
Fibrinogen (normal >150 mg/100 mL)
Decreased: Disseminated intravascular coagulation, liver disease, L-asparaginase therapy, dysfibrinogenemia, afibrinogenemia
Fibrin Split Products (normal <1:20)
Increased: Disseminated intravascular coagulation, liver disease
Bleeding Time (modified Ivy): (normal <8 min, 30 sec)
Prolonged: Idiopathic thrombocytopenic purpura (early) and other thrombocytopenias, von Willebrand's disease, platelet function disorders

Table 65.5. Tests Commonly Used in the Initial Evaluation of Purpura or Suspected Bleeding Disorders

The emergency management of children with purpura is discussed in detail in Chapter 87. However, the general principles are straightforward. When purpura is associated with a serious underlying disorder such as meningococcemia, treatment of that disorder usually is the first priority. Treatment of the coagulopathy is based on the degree and site of bleeding and the actual hemostatic defects. In primary disorders of hemostasis, appropriate replacement therapy is used when the specific alteration is known. When the disease has not been fully defined, broad treatment with one or more blood products may be required while further laboratory studies are performed. In all instances, the standard measures for general emergency care should be used fully during the evaluation and treatment of the purpuric disorders.

CHAPTER 66

Rash—Urticaria

WILLIAM J. LEWANDER, MD

Department of Pediatrics, Brown University School of Medicine, and Department of Pediatric Emergency Medicine, Hasbro Children's Hospital, Rhode Island Hospital, Providence, Rhode Island

Urticaria is a common cutaneous vascular reaction experienced by nearly 20% of the population at some time during their lives. The cause remains unknown in most cases. Urticaria usually is acute and transient, but if it persists for more than 6 weeks, it is called chronic. Although chronic urticaria sometimes is associated with physical agents or systemic illnesses (e.g., viral hepatitis, juvenile rheumatoid arthritis [JRA], systemic lupus erythematosus [SLE], lymphoma), the cause remains unknown in more than 75% of cases.

Urticarial lesions appear as erythematous papules or wheals from edema in the upper dermis with a surrounding flare of erythema caused by vasodilation. They are pruritic, multiple, and of varying size and shape. Individual lesions are transient, usually lasting 12 to 24 hours or less. They often appear suddenly, resolve almost completely, and may reappear. The cutaneous distribution varies, but lesions secondary to physical agents generally are concentrated in those areas of direct stimulation (i.e., dermographism). Lesions of angioedema often are nonpruritic and involve deeper dermal and subcutaneous tissues with swelling that may involve the lips and eyelids.

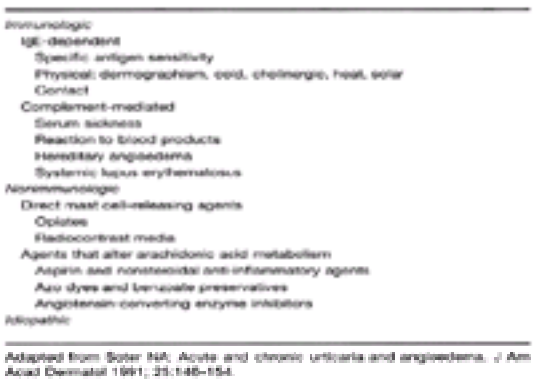
Urticaria may be accompanied by angioedema and is associated with systemic symptoms from direct visceral involvement or from symptoms secondary to the release of circulating chemical mediators. The respiratory, cardiovascular, and gastrointestinal (GI) systems may be involved, resulting in a potential life-threatening reaction. Signs and symptoms may include hoarseness, stridor, shortness of breath, wheezing, and general respiratory distress (from laryngospasm and bronchospasm), as well as hypotension, nausea, vomiting, diarrhea, and abdominal pain.

PATHOPHYSIOLOGY

Urticaria is characterized by superficial dermal edema, vasodilation and transudation of fluid and red blood cells, dilated lymphatics, and a mononuclear perivascular infiltrate. Angioedema occurs when these changes involve the deeper portion of the dermis and subcutaneous tissue. Urticaria and angioedema may occur independently or in association. The release of histamine and various other vasoactive and chemotactic substances from mast cells and basophils appears to play a central role in the pathogenesis.

DIFFERENTIAL DIAGNOSIS

As shown in Table 66.1, urticaria may be classified on the basis of the mechanism responsible for its formation or, if unknown, as idiopathic.



Immunologic
IgE-dependent
Specific antigen sensitivity
Physical: dermographism, cold, cholinergic, heat, solar
Contact
Complement-mediated
Serum sickness
Reaction to blood products
Hereditary angioedema
Systemic lupus erythematosus
Nonimmunologic
Direct mast cell-releasing agents
Opiates
Radiocontrast media
Agents that alter arachidonic acid metabolism
Aspirin and nonsteroidal anti-inflammatory agents
Azo dyes and benzoate preservatives
Angiotensin-converting enzyme inhibitors
Idiopathic
Adapted from Soter NA. Acute and chronic urticaria and angioedema. J Am Acad Dermatol 1981; 31:146–154.

Table 66.1. Classification of Urticaria/Angioedema

Multiple factors—both immunologic and nonimmunologic—are capable of initiating the release of these mediators that result in the histopathologic findings described. The type I hypersensitivity reaction that involves the interaction of an antigen with a mast cell–bound or basophil-bound IgE with release of histamine represents the most common immunologic mechanism. However, type III (immune complex) reactions also can stimulate mediator release through activation of the complement system. Examples include urticaria seen in association with viral hepatitis, infectious

mononucleosis, serum sickness, SLE, and some reactions to blood products. Nonimmunologic causes of urticaria include direct mast cell–releasing agents (e.g., opiates, radio contrast media) and agents that presumably alter arachidonic acid metabolism (e.g., aspirin, nonsteroidal anti-inflammatory agents, azo dyes). Angiotensin-converting enzyme (ACE) inhibitors are believed to enhance bradykinin synthesis.

Genetic factors are important in several relatively rare causes of urticaria and angioedema, including hereditary angioedema, familial cold, and localized heat urticaria. The most common causes of urticaria are listed in Table 66.2. Although idiopathic urticaria is the most common form, it is a diagnosis reached mainly by exclusion. Any variety of urticaria that involves the airway or cardiovascular system is potentially life-threatening.

Foods	*Insect bites*
Peanuts	Hymenoptera venom
Eggs	*Infections*
Chocolate	Hepatitis
Shellfish	Streptococcus
Milk	Infectious mononucleosis
Strawberries	Upper respiratory infection
Food dyes and preservatives	*Physical agents*
Drugs	Cold
Penicillin	Heat
Cytokines	Dermographism
Radiocontrast media	Latex
Aspirin and nonsteroidal anti-inflammatories	
Angiotensin-converting enzyme inhibitors	

[a]Essentially all may be life-threatening if accompanied by systemic reaction (see text).

Table 66.2. Common Causes of Urticaria/Angioedema[a]

EVALUATION AND DECISION

Urticaria is diagnosed by its characteristic appearance and is only rarely confused with erythema multiforme, certain vasculitides (e.g., Henoch-Schönlein purpura), urticaria pigmentosa, or infectious exanthems.

Following clinical recognition, the patient should be evaluated for the presence of an associated systemic reaction that involves cardiopulmonary compromise (outlined in Fig. 66.1). After stabilization, evaluation for a specific cause should begin with a thorough history and physical examination. The cause often remains unknown; however, Table 66.1 and Table 66.2 outline the general classifications and most common identifiable causes of urticaria. In the context of acute onset, the patient must be questioned about specific precipitants, including drugs, foods, and Hymenoptera stings. Febrile patients must be examined for clinical findings suggestive of viral and streptococcal infection, mononucleosis, and hepatitis. Latex allergy is uncommon in the general population, but health care workers and children with spina bifida appear to be at risk for latex allergy. These patients may experience urticaria, conjunctivitis, bronchospasm, and anaphylaxis after contact with or inhalation of latex antigens. Patients with chronic urticaria must be questioned about exposure to parasites or hepatitis, as well as about a family history of urticaria and must be examined for findings suggestive of collagen vascular disease. Laboratory tests generally are not helpful or necessary in the evaluation of acute urticaria.

FIGURE 66.1. Algorithm for the evaluation of urticaria.

Laboratory tests that may be useful in the evaluation of chronic urticaria include complete blood count (CBC) with differential, erythrocyte sedimentation rate (ESR), urinalysis, monospot, antinuclear factor (ANA), and liver function tests. Decreased levels of C_1 esterase inhibitor are found in hereditary angioedema. Stool for ova and parasites should be sent if eosinophilia is present or if symptoms are consistent with this diagnosis. Provocative tests may be tried cautiously if certain physical urticarias are suspected.

If the cause of chronic urticaria cannot be determined or if a severe systemic reaction occurs, referral to an allergist should be considered after initial treatment is instituted.

MANAGEMENT

The initial management of urticaria follows assessment of the patient for a systemic reaction with cardiopulmonary

compromise (i.e., stridor, wheezing, hypotension) (see Chapter 92). If a systemic reaction is present, airway, breathing, and circulation (ABC) should be stabilized. Medications that may be used include oxygen, epinephrine (1:1000) 0.01 mL/kg subcutaneously (which may be repeated in 15 to 20 minutes, maximum dose, 0.3 ml), diphenhydramine 1 mg/kg intravenously/intramuscularly, and volume resuscitation followed by vasopressors (e.g., dopamine) if there is no response. Systemic corticosteroids (i.e., methylprednisolone 1 to 2 mg/kg) are slow to work and inconsistent in their effect. They may suppress the appearance of new urticarial lesions but are indicated only in severe, inadequately controlled cases in which an infectious origin has been excluded.

Although any precipitating factor may result in urticaria accompanied by a systemic reaction, cold, cholinergic and solar urticaria, and hereditary angioedema have been associated with severe attacks. Mortality form hereditary angioedema has been reported to be as high as 30% and generally results from airway obstruction. Danazol, an attenuated androgen, is the preferred long-term prophylactic treatment. Acute attacks often require careful airway management, infusions of fresh-frozen plasma or concentrates of partly purified C_1 esterase inhibitor, and supportive care.

The general management of the more common presentation of urticaria without systemic involvement consists of removing or avoiding the inciting agent (if it can be identified) and providing symptomatic relief with antihistamines of the H_1 class. The two most commonly used oral medications are hydroxyzine (Atarax, 2 mg/kg per day) and diphenhydramine (Benadryl, 5 mg/kg per day) each in three to four divided daily doses for at least 3 to 5 days. Cyproheptadine (Periactin, 0.5 mg/kg per day) also has been found to be effective. If severe pruritus, a rapidly progressing urticarial rash, or angioedema is present, more rapid relief may be achieved with epinephrine (1:1000) 0.01 mL/kg subcutaneously (maximum dose 0.3 mL) and diphenhydramine 1 mg/kg IM. Prolonged sympathetic effect can be maintained with Sus-Phrine 0.005 mL/kg subcutaneously. Recurrent or persistent urticaria sometimes responds to cimetidine (Tagamet, 20 to 30 mg/kg per day) in four divided oral doses. Following or concurrently with treatment, an effort should be made to determine the cause (Table 66.1 and Table 66.2) so that the patient can avoid the precipitating agent.
