Basic to all vesicobullous (blistering) disorders is the disruption of cellular attachments. Blister formation, therefore, follows intracellular degeneration, intercellular edema (spongiosis), or damage to the anchoring structures associated with the basement membrane (half-desmosomes, basal lamina, anchoring fibrils). The location of these changes, as seen in Table 67.1, can help the physician ascertain a specific diagnosis. When histologic information is not readily available or nondefinitive, however, the historical and clinical features of the case must be relied on.

Type of Blister	Site of Formation	Disease
Subcorneal blister	Subcorneal	Impetigo
Blister from intracellular degeneration	Upper epidermis	Bullous congenital ichthyosiform erythroderma Epidermolysis bullosa of hands and feet Friction blisters
Spongiotic blister Viral blister	Intraepidermal Intraepidermal	Incontinentia pigmenti Variola Herpes simplex Varicella-herpes zoster
Blister from degeneration of basal cell	Subepidermal	Epidermolysis bullosa simplex Lichen planus Lupus erythematosus
Blister from degeneration of basement zone	Subepidermal	Epidermolysis bullosa, dystrophic type Urticaria pigmentosa Bullous pemphigoid Dermatitis herpetiformis Erythema multiforme, dermal type Drug-induced TEN

SSSS, staphylococcal scalded skin syndrome; TEN, toxic epidermal necrolysis.

Table 67.1. Pathologic Diagnosis of Vesicobullous Eruptions

Such an approach is outlined in Figure 67.1. The key features used in this algorithm to distinguish the various entities are a characteristic clinical appearance, chronicity and/or presence at birth, associated fever or systemic illness, distribution of lesions, and the child's age. The diagnosis of vesicobullous lesions in children younger than 1 month of age is not discussed in this chapter. Figure 67.1 also outlines the frequency and potential severity of these diseases.

FIGURE 67.1. The diagnostic approach to the child with vesicobullous lesions. *TEN,* toxic epidermal necrolysis; *EM,* erythema multiforme; *HSP,* Henoch-Schölein purpura; *SSSS,* staphylococcal scalded skin syndrome; *SLE,* systemic lupus erythematosus.

CHARACTERISTIC CLINICAL APPEARANCE

Many times, the appearance of a rash is so characteristic that a diagnosis becomes obvious. Such is the case with the conditions listed in Table 67.2.

Rhus dermatitis	Urticaria pigmentosa
Other contact dermatitides	Herpes simplex
Erythema multiforme	Varicella
Herpes zoster	

Table 67.2. Vesicobullous Rashes with Characteristic Clinical Appearance

Linear or geometric areas of vesiculation are the best clues to the presence of allergic contact dermatitis (see Chapter 99). The shape of the dermatitis provides the information that helps identify the offending agent. A history of playing in a shrubbed area, camping, hiking, or being near burning leaves is helpful. Because children brush against poison ivy leaves, vesicles often are in a line and on exposed surfaces (e.g., the face, extremities). A round group of vesicles on the back of the wrist would point to contact sensitivity to nickel contained in the metal case of a wristwatch.

Dermatomal distribution of vesicles or bullae usually indicates the presence of herpes zoster. On rare occasions, in infants, the same appearance may represent herpes simplex infections. A positive Tzanck smear indicates the presence of the herpes virus. Viral cultures or rapid slide tests using monoclonal antibodies are necessary to differentiate herpes simplex from herpes zoster.

Target or iris lesions are pathognomonic of erythema multiforme. The lesion has a dusky center that may blister and has successive bright red bordering rings. At times, a doughnut-shaped blister occurs.

Pigmented lesions that blister after stroking or trauma (Darier's sign) indicate the release of histamine from a mast cell collection. This collection may be isolated (mastocytoma of the wrist) or generalized (urticaria pigmentosa). Blistering of such lesions generally occurs only until 2 years of age. After this time, only urtication occurs.

A delicate “tear drop” vesicle is characteristic of varicella (chickenpox). Lesions usually begin on the upper trunk and neck. A progression through papules, vesicles, and crusts occurs rapidly (6 to 24 hours). All stages are present in an area at any given time. Mucous membranes are involved. Fever and malaise usually are present but are variable.

DURATION

If there is no characteristic clinical appearance, the duration of the rash must be considered. If it has been present for 4 weeks or more, it should be considered chronic. Rashes that come and go but take not more than 4 weeks to disappear completely are not considered chronic.

Chronic Rash (Duration 4 Weeks or More)

If the blistering disease has been present since birth (congenital), consider the diagnoses listed in Table 67.3.

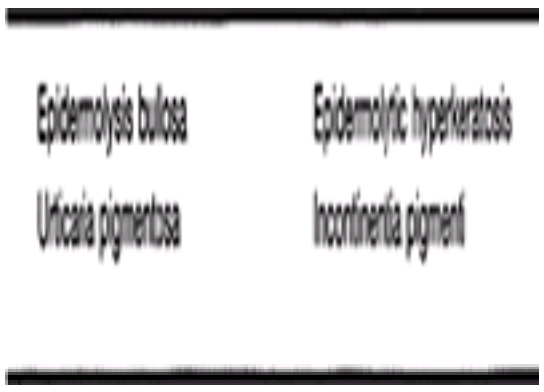

Table 67.3. Congenital Blistering Diseases

Epidermolysis Bullosa Syndromes

Blisters usually occur in areas predisposed to trauma or friction (Fig. 67.2). See Table 67.4 for differentiation of the various types.

FIGURE 67.2. Infant with epidermolysis bullosa simplex.

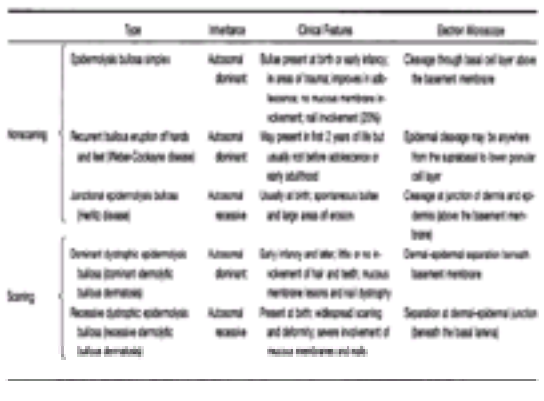

Table 67.4. Epidermolysis Bullosa Syndromes

Urticaria Pigmentosa

Mast cell disease (mastocytoma or urticaria pigmentosa) may cause blistering up until 2 years of age. The pigmented solitary lesion most often occurs on the arm near the wrist (Fig. 67.3). Lesions may be generalized. When a pigmented lesion feels infiltrated, the physician should think of its cause. Gentle mechanical irritation of such lesions causes urtication or blistering (Darier's sign).

FIGURE 67.3. Infant with mastocytoma that has blistered because of trauma.

Epidermolytic Hyperkeratosis (Congenital Bullous Ichthyosiform Erythroderma)

Epidermolytic hyperkeratosis, an autosomal-dominant trait, is categorized under the ichthyotic syndromes. Children with this problem have recurrent bullous lesions during infancy and childhood. The skin has a background of erythema, scales, and peels. The flexures are always affected, as are the palms and soles.

Incontinentia Pigmenti

Incontinentia pigmenti, a rare condition, occurs almost exclusively in females. Inflammatory bullae erupt in crops in a linear distribution for the first several weeks to months of life (Fig. 67.4). These affected areas then go on to a warty stage. Finally, swirl-like pigmentation occurs but not necessarily in the areas previously involved with warty or blistering lesions. During the vesicobullous stage, a high degree of peripheral eosinophilia occurs (18 to 50%).

FIGURE 67.4. Linear arrangement of lesions (blisters in some cases) in a child with incontinentia pigmenti.

If the blistering is noncongenital, chronic bullous dermatosis of childhood (Fig. 67.5), dermatitis herpetiformis, and bullous pemphigoid should be considered. These conditions can be differentiated as outlined in Table 67.5.

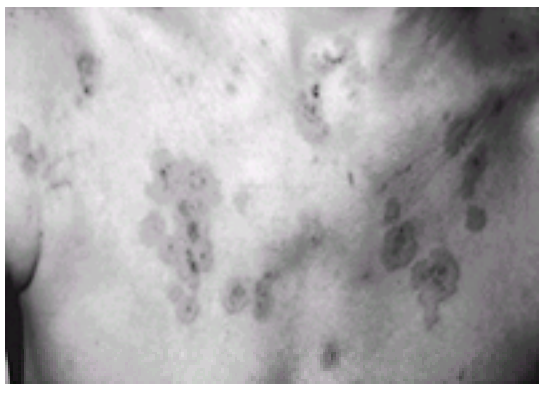

FIGURE 67.5. Chest of patient with chronic bullous dermatosis of childhood. Notice the resemblance to erythema multiforme.

	Bullous Disease of Childhood	Bullous Pemphigoid	Dermatitis Herpetiformis
Type of lesions	Large, tense, clear bullae; annular plaques with active vesicular borders	Large, tense bullae	Grouped papulovesicles, bullae or urticarial lesions
Distribution	Scalp, lower trunk, genitals, buttocks, inner thighs	Trunk and flexor surfaces of extremities	Back, buttocks, scalp, extensor surfaces of extremities, often symmetric
Pruritus	None to severe	Mild	Intense
Mucous membrane involvement	No	Yes	No
Duration	Months to years	Months to years	Months to years
Immunofluorescence	+ or -	+	+
	Linear IgA basement membrane	Linear IgG on basement membrane	Granular IgA at tips of dermal papilla
	(- circulating IgA)	(- circulating IgG)	of uninvolved perilesional skin
Treatment	Sulfapyridine or dapsone	Corticosteroids	Sulfapyridine or dapsone

Table 67.5. Noncongenital Chronic Blistering Disease

Child Who Is Ill

When the blistering lesions occur acutely, it must be determined whether the child is febrile or ill. Conditions that cause such systemic findings with associated blisters include those listed in Table 67.6.

Chickenpox	Herpes simplex
Hand-foot-mouth	Staphylococcal scalded skin syndrome
Viral (nonspecific) + other	Systemic lupus
Drug reaction (TEN, EM)	Atypical measles
Henoch-Schönlein purpura	Smallpox
Nonspecific vasculitis	

TEN, toxic epidermal necrolysis; *EM*, erythema multiforme.

Table 67.6. Blistering Diseases Associated with Fever and/or Systemic Illness

Varicella (Chickenpox)

For more information about varicella, see the section immediately preceding.

Hand–Foot–Mouth Disease

Caused by coxsackievirus A16, hand–foot–mouth disease is fairly characteristic. Vesicles are present on the palms, on the soles, and in the mouth. Other parts of the body may be involved. Fever, malaise, and abdominal pain may be present.

Viral (Nonspecific) and Other Causes

Vesicles have been described in association with other coxsackievirus types (A4, A5, B1, B4), echovirus, reovirus, and *Mycoplasma pneumoniae* infections. These children usually are ill.

Drug Reactions

The presence of vesicles or bullae may indicate a drug reaction. Involvement of palms, soles, mucous membranes, or the presence of target lesions are other possible clues that this problem exists. Therefore, the intake of prescribed and over-the-counter preparations must be investigated.

Drug-induced toxic epidermal necrolysis (TEN) may be associated with blisters. Histology that shows separation of dermis from epidermis excludes the staphylococcal-induced problem. Also, the staphylococcal scalded skin syndrome (SSSS) rarely occurs in children older than 6 years of age. A drug reaction should be considered in children older than 6 years old. The histology of SSSS demonstrates separation just below the stratum corneum.

Children with severe drug reactions may be very toxic. High fevers, malaise, joint problems, and the like can occur.

Henoch-Schölein Purpura

Children with Henoch-Schönlein purpura (HSP) may have blisters because of the severe involvement of blood vessels (vasculitis) in the typical distribution that occurs in this condition. Associated systemic problems include arthritis, abdominal pain, kidney disease (hematuria and/or proteinuria), and seizures.

Nonspecific Vasculitis

Children with vasculitic blisters, at times hemorrhagic, may be sick with fever, malaise, and other symptoms. Some go on to well-defined collagen vascular disease, whereas others smolder, with no diagnosis ever being made.

Herpes Simplex

Primary infection with this virus may cause fever and regional lymphadenopathy. The first encounter for young children usually is herpetic gingivostomatitis. Vesicles involve the lips and the rest of the mouth. These children often are uncomfortable and commonly refuse to eat or drink.

Herpes progenitalis may produce fever and local lymphadenopathy as well. Characteristic clusters of vesicles occur on an erythematous base. Often, erosions or ulcerations evolve on the vulva or penis. Diagnosis can be confirmed by a Tzanck smear that shows aggregates of multinucleated giant cells (see Chapter 99) or a rapid slide test (immune-specific immunofluorescent antibody placed on cells scraped from the blister base).

Systemic Lupus Erythematosus

Although not characteristic, bullous lesions can occur in systemic lupus erythematosus (SLE). Multisystem involvement suggests the diagnosis. Laboratory confirmation, which may include a skin biopsy and lupus band test, in conjunction with the complete clinical picture, is necessary for diagnosis.

Palm and Sole Involvement

If the child is not ill, the physician should search for blisters on the palms and soles. The child's age helps differentiate some disorders (Table 67.7).

Child <3 Years Old	*Any Age*
Scabies	Drug reaction
Acropustulosis of infancy	Friction blisters or burns
Syphilis (transiently at birth)	Dyshidrotic eczema
Adolescent or Older	Vasculitis (e.g., Henoch-Schönlein purpura)
Tinea pedis or manus	Frostbite
"Id" reaction	
Epidermolysis bullosa of hands and feet	

Table 67.7. Acute Vesicobullous Diseases Involving Palms and Soles

CHILD YOUNGER THAN 3 YEARS OLD

Scabies

Infants and very young children can have vesicobullous lesions on the palms (Fig. 67.6), soles, head, and face. It is important to not be misled by this distribution and appearance. Generally, the mother is infested as well and exhibits the typical appearance of this disorder.

FIGURE 67.6. Blisters on hands of child infested with scabies.

Acropustulosis of Infancy

The appearance of pruritic vesicopustules between 2 and 10 months of age on the palms and soles (Fig. 67.7) in African-American children suggests acropustulosis of infancy. Vesicles often involve the lateral aspects of the fingers, palms, and soles. This condition was commonly diagnosed as dyshidrotic eczema in the past. Cyclic eruptions occur every 2 to 3 weeks, lasting 7 to 10 days. Spontaneous disappearance occurs at 2 to 3 years of age.

FIGURE 67.7. Note vesicles and pustules on child with acropustulosis of infancy.

Syphilis

Congenital syphilis may produce transient blisters on the palms and soles immediately after birth. “Snuffles,” rhagades, condyloma lata, and violaceous to reddish-brown macules should be sought on the palms and soles. Hepatosplenomegaly is often present. Osteochondritis is an early and common sign. Severe tenderness of a limb may cause pseudoparalysis of Parrot. The serologic test for syphilis is always positive in children with clinical manifestations.

ADOLESCENT OR OLDER

Tinea Pedis or Manus

Certain organisms that cause tinea pedis or manus (e.g., Trichophyton mentagrophytes) induce a severe inflammatory reaction on the hands and feet. Vesicobullous lesions erupt on the palms, instep, or medial aspect of the foot. A potassium hydroxide (KOH) preparation confirms the presence of hyphae in either location.

“Id” Reaction

If an adolescent's palms have blisters, the physician should look at the feet. Patients with tinea pedis may have allergic reactions to dissemination of antigen. A KOH preparation of the lesions on the palms will be negative for fungus.

Epidermolysis Bullosa of the Hands and Feet

For more information, see Epidermolysis Bullosa Syndromes in this chapter (Table 67.4).

ANY AGE

Drug Reaction

For more information about drug reactions, see Child Who Is Ill in this chapter.

Friction Blisters or Burns

Blistering on the palms and soles appears after trauma to the skin. The trauma often is related to a new activity (e.g., golfing, rowing, football) or to new, possibly poorly fitted, shoes.

Occasionally, accidental burns or burns secondary to child abuse are seen. Abused children may have had cigarette burns or have had their feet dipped in scalding water.

Dyshidrotic Eczema (Pompholyx)

A recurrent rash with episodes of vesicles that involve the palms, soles, and lateral aspects of the fingers is called dyshidrotic eczema. On occasion, large bullae occur. The problem generally is bilateral. Often, there is a personal or family history of atopy. A KOH preparation or fungal culture of scrapings from the palms or soles generally is negative.

Vasculitis

Vasculitis, also called HSP, may involve the palms and/or soles. See the section Child Who Is Ill in this chapter for more information.

Frostbite

Fingers, toes, feet, nose, cheeks, and ears are affected by extreme cold. After exposed areas are damaged by the cold temperature, symptoms occur on rewarming. Erythema, swelling, and burning pain occur at first, followed by vesicles and bullae (at times hemorrhagic [Fig. 67.8]) within 24 to 48 hours.

FIGURE 67.8. Frostbite. Child played in the snow for a prolonged period on a cold day wearing sneakers.

Extremities

If there is no involvement or minimal involvement of the palms and soles and the rash is concentrated on the extremities, insect bites, vasculitis, burns, frostbite, and bullous impetigo should be considered.

INSECT BITES

Insects generally bite exposed skin surfaces. Therefore, heaviest involvement occurs on the head, face, and extremities. Mosquito bites occur in the warm weather months, whereas flea bites occur during the whole year. Historical information includes contact with pets, camping trips taken, and involvement in outdoor activities. When blisters are present, the more characteristic urticarial papules usually are present in other locations. If not, confusion with bullous impetigo is easily ruled out with a Gram stain (negative for bacteria).

VASCULITIS

Concentration of hemorrhagic bullae on the extremities and buttocks indicates HSP. The lower extremities are the area most often involved because of settling of immune complexes, cryoglobulins, and so forth in that location.

BURNS

Exposed areas are commonly involved. Children accidentally rub against hot objects, causing burns and blistering. In cases of child abuse, children are burned intentionally with cigarettes (often mistaken for lesions of impetigo) or other heated objects. At times, children are submerged in scalding water. Usually, both lower extremities are involved.

BULLOUS IMPETIGO

In bullous impetigo, *Staphylococcus aureus* usually is present in pure culture. The bullae initially are filled with a clear fluid that rapidly becomes cloudy. The lesions tend to spread locally. Regional lymph nodes usually are not enlarged.

LABORATORY EVALUATION

If there is no clear idea about what caused the blister, the laboratory tests described next can be helpful.

Gram Stain

The Gram stain of fluid from an intact blister will be positive in impetigo and in a secondarily infected lesion. It will be negative, however, in all other conditions.

Tzanck Smear

Multinucleated giant cells will be present on a Tzanck smear (see Fig. 99.7) of material scraped from the base of an intact, freshly opened vesicle caused by herpes simplex, herpes zoster, and varicella.

Rapid Slide Test (Direct Immunofluorescence)

Fluorescent-tagged monoclonal antibody is placed on cells scraped from the blister base and can differentiate herpes simplex virus (HSV)-1, HSV-2, or varicella-zoster virus. Results can be available in 1 to 2 hours.

Bacterial or Viral Cultures

Occasionally, cultures help confirm an etiologic diagnosis when Gram stain, Tzanck smears, and direct immunofluorescence (DIF) are negative or indeterminate.

Skin Biopsy

For perplexing cases undiagnosed by clinical and/or simple laboratory evaluation, dermatologic consultation and skin biopsy are required.

On histologic examination, many characteristic changes can be found that lead to a definitive diagnosis (Table 67.1). Lichen planus, SLE, TEN, SSSS, and vasculitis are some of the diseases that can be identified by histologic studies.

If the picture on histology is compatible with erythema multiforme, DIF should be considered. DIF will be negative in erythema multiforme but will be positive in bullous pemphigoid (linear immunoglobulin G [IgG] on basement membrane), dermatitis herpetiformis (granular IgA at tips of dermal papillae of uninvolved perilesional skin), and chronic bullous disease of childhood (linear IgA on basement membrane). DIF can be negative in chronic bullous disease of childhood

(CBDC).

Indirect immunofluorescence can be done to test for circulating antibodies. Circulating IgG is found in bullous pemphigoid; circulating IgA is found in CBDC.

CHAPTER 68

Respiratory Distress

DEBRA L. WEINER, MD, PhD

Department of Pediatrics, Harvard Medical School, and Department of Emergency Medicine, Children's Hospital, Boston, Massachusetts

Respiratory distress is one of the most common chief complaints of children seeking medical care. It accounts for nearly 10% of all pediatric emergency department visits and 20% of visits of children less than 2 years of age. Twenty percent of patients admitted to the hospital and 30% of those admitted to intensive care units are admitted for respiratory distress. Primary respiratory processes account for approximately 5% of deaths in children less than 15 years of age and 20% in infants. In addition, respiratory distress contributes substantially to deaths in patients with other primary processes. Respiratory arrest is one of the five leading causes of death in pediatric patients, along with congenital anomalies, trauma, neoplasm, and cardiac disease. Respiratory distress results from interruption of the respiratory or ventilatory pathway. The cause of respiratory distress may be within the respiratory system or within organ systems that control or impact on respiration. Respiratory failure is caused by an inability to meet metabolic demands for oxygen (O_2) or by inadequate carbon dioxide (CO_2) elimination. Young children are at particular risk of respiratory distress because of their respiratory anatomy and physiology. Rapid evaluation and aggressive treatment of respiratory distress, as well as anticipation and prevention of impending respiratory distress and failure, are essential to optimize outcome. Respiratory distress is usually reversible, but failure to treat the condition may result in cardiac arrest with long-term neurologic sequelae or death.

PATHOPHYSIOLOGY

Respiration is a complex multisystem process. The primary goals of respiration are to meet metabolic demands for oxygen and to eliminate carbon dioxide. Secondary functions include acid-base buffering, host defense, and hormonal regulation. The upper airway or conducting zone, which includes the nose, nasopharynx, oropharynx, larynx, trachea, major bronchi, and terminal bronchioles, serves as a conduit for air movement. The lower airway, or respiratory zone, consists of the acini and interstitium. Each acinus originates from a terminal bronchiole and includes respiratory bronchioles, alveolar ducts, sacs, and alveoli. The interstitium, which consists of the alveolar walls and interstitial septa, is the fibrous structural framework of the lower airway. Exchange of O_2 and CO_2 between the lungs and the blood occurs at the alveolocapillary membrane and depends on adequate and appropriately matched ventilation and perfusion.

Control of respiration is mediated by central and peripheral neural mechanisms. Respiration is an intrinsic brainstem function of the respiratory centers of the medulla. The dorsal respiratory group produces rhythmic inspiration while the ventral respiratory group controls expiration. Respiration is modulated by impulses within the brain and between the brain, respiratory system, blood, cerebrospinal fluid, and peripheral tissues. In the pons, the apneustic center increases the duration and depth of inspiration while the pneumotaxic center shortens duration and depth of respirations. Central chemoreceptors in the medulla respond to changes in the pH of cerebrospinal fluid. Peripheral chemoreceptors in the carotid and aortic bodies respond to changes in O_2, CO_2, and pH in arterial blood. In the airways, lungs, and chest wall, stretch, juxtacapillary, and irritant reflex mechanoreceptors respond to lung volume, changes in pulmonary microvasculature, chest wall muscle activity, and environmental irritants. Respiration is further influenced by the cerebellum, which alters respiration with postural change; by the hypothalamus, which controls respiration on a moment-to-moment basis; by the limbic system, which modulates respiration in response to emotion; and by the motor cerebral cortex, which controls volitional respiratory activity, including hyperventilation and hypoventilation and speech. Afferent information is transmitted to the brain primarily by the vagus (cranial nerve [CN] X) from the aortic body and mechanoreceptors, the glossopharyngeal (CN IX) from the carotid body, and the spinal motor neurons from muscle proprioceptors. Efferent impulses are transmitted from the brain via the vagus and spinal nerves to the larynx, trachea, bronchi, bronchioles, and acini; the glossopharyngeal to the pharynx; the hypoglossal (CN XII) to the tongue; and the spinal accessory (CN XI) to accessory muscles. Impulses are also transmitted via spinal motor neurons in the anterior

spinal horn to the cervical nerves (C2–C4), the phrenic nerve (C3–C5), and the intercostal nerves (T1–T12), which innervate accessory muscles, the respiratory diaphragm, and intercostal muscles, respectively. The muscles and bones of the chest wall provide structural support and, along with the muscles of the abdomen, impact on lung excursion, and thus movement of air in and out of the lung. Cardiovascular and lymphatic drainage maintain the fluid balance of the lung and thus impact on gas exchange.

Respiratory distress results from dysfunction or disruption of the respiratory/ventilatory pathway and/or systems that control or modulate respiration. Respiratory failure is the inability to meet the metabolic demand for O_2 (hypoxia) or the inability to eliminate CO_2 (hypercapnia). Criteria for defining respiratory failure vary widely; one set of criteria is presented in Table 68.1. Hypoxia can be categorized based on mechanism. Hypoxic or arterial hypoxemia is the most common type of hypoxemia. It results from an inability to deliver adequate oxygen to the blood. Most often, this type of hypoxia results from hypoventilation secondary to airway obstruction, central respiratory depression or impairment, neuromuscular or skeletal insufficiency, or restricted lung expansion. Other causes of hypoxemic hypoxia include low atmospheric P_{O_2} (e.g., high altitude), diffusion impairment (e.g., pulmonary edema, pulmonary fibrosis, acute respiratory distress syndrome [ARDS], oxygen toxicity), anatomic or physiologic shunt (e.g., atelectasis, pneumonia, abnormal pulmonary blood flow), or increased metabolic demand (e.g., exercise, systemic illness). Anemic hypoxia is the result of inability of the blood to deliver adequate oxygen to tissues as a result of decreased hemoglobin oxygen carrying capacity. It is caused by inadequate red cell number (decreased production, increased destruction, loss), low erythrocyte hemoglobin concentration (anemia), abnormal hemoglobin, carboxyhemoglobin, or methemoglobin. Hypokinetic, ischemic, or stagnant hypoxia also results in an inability of the blood to transport oxygen to the tissues. This type of hypoxia is caused by decreased blood flow to a localized area secondary to compromised cardiac output (e.g., cardiac failure), poor tissue perfusion (e.g., shock), sludging (e.g., polycythemia), or obstructed flow (e.g., vascular obstruction). Histotoxic hypoxia results from inability to metabolize oxygen at the tissue level as a result of inactivation of metabolic enzymes by a chemical such as cyanide. Hypercapnia is caused by inadequate alveolar ventilation (e.g., central nervous system [CNS] depression, spinal cord injury, neuromuscular disease, diaphragmatic dysfunction), ventilation-perfusion imbalance with relative hypoventilation (e.g., restrictive airway disease, pulmonary embolism), or increased CO_2 production (e.g., metabolic/endocrine disturbance). Hypercapnia often contributes to respiratory failure as a result of hypoxemia and is less commonly the primary cause.

Clinical	*Laboratory*
Tachypnea, bradypnea, apnea, irregular respirations	Pa_{O_2} <60 mm Hg in 60% O_2[b]
Pulsus paradoxus >30 mm Hg	$Paco_2$ >60 mm Hg and rising[c]
Decreased or absent breath sounds	pH <7.3
Stridor, wheeze, grunting	Vital capacity <15 mL/kg
Severe retractions and use of accessory muscles	Maximum inspiratory pressure <=25 cm H_2O
Cyanosis in 40% O_2[b]	
Depressed or heightened level of consciousness, decreased response to pain	
Weak to absent cough or gag reflex	
Poor muscle tone	

[a]Respiratory failure is likely if two clinical findings and one laboratory finding exist.
[b]Excluding cyanotic heart disease.
[c]Without underlying pulmonary disease.

Table 68.1. Criteria for Respiratory Failure[a]

Infants are at increased risk of respiratory distress compared with children and adults because of anatomic and physiologic differences (Table 68.2). These differences result in greater risk of airway obstruction, less efficient respiratory effort, limited respiratory reserve, and dysfunction of CNS respiratory control.

Difference	Consequence
Nose: infants <4 months obligate nose breathers	Nasal congestion may result in significant respiratory distress
Larynx: higher (C3–C4 vs. C6); funnel-shaped, narrowest at cricoid ring; softer, more elastic	More difficult to intubate Collapses more easily, particularly with head obstruction (i.e., Bernoulli's principle—as the velocity of flow through a collapsible tube increases, the pressure that holds the tube open decreases)
Trachea: one-third diameter of adult at birth, shorter	Poiseuille's law—resistance varies inversely with 4th power of the radius; 1 mm thickening decreases cross-sectional diameter 25% in adult, 75% in child;
	More difficult to intubate/maintain proper depth
Alveoli: elastic fibers less well developed	Alveoli collapse more easily, results in ventilation-perfusion mismatch
Lungs: lower functional residual capacity	Reserve small, therefore limited protection when ventilation is interrupted, Pa_{O_2} decreases more rapidly
Respiratory control apparatus immature—reflexes that inhibit respiration, particularly waning diaphragm reflex, which responds to stretch of lung, are very strong; central nervous system processing of information markedly affected by sleep state, cold, drugs, other metabolic derangements	Apnea or inability to respond appropriately to mechanical respiratory obstruction or increased metabolic demand
Chest wall: more compliant; intercostal muscles immature; ribs more horizontal; diaphragm flatter, fatigues; during rapid eye movement (REM) sleep intercostal muscle movements become uncoordinated	Chest wall more compliant Diaphragm does more work but is less effective

Table 68.2. Anatomic/Physiologic Differences Infant/Child and Adult Airway

DIFFERENTIAL DIAGNOSIS

Establishing a diagnosis for respiratory distress in part depends on localizing the source of the distress to a particular organ system. Respiratory distress may result directly from a disturbance of the upper or lower respiratory system. It may also be caused by inability of the central or peripheral nervous system to interpret or process respiratory requirements, or of the musculoskeletal system to perform the work of breathing. Alternatively, disease or dysfunction of other organ systems may indirectly result in respiratory disturbance by compromising respiratory system function or by stimulating

compensatory respiratory mechanisms (Table 68.3, Table 68.4 and Table 68.5). Treatment of the underlying cause is essential for definitive treatment of the respiratory distress.

Table 68.3. Causes of Respiratory Distress

Neonate	Infant/Child
Nasal obstruction	Peritonsillar abscess
Congenital airway anomalies	Croup
Transient tachypnea	Tracheitis
Respiratory distress syndrome	Foreign body
Meconium aspiration	Bronchiolitis
Pneumonia	Asthma
Sepsis	Allergy
Congenital heart disease	Pneumonia
	Fever
	Sepsis
	Gastroenteritis/dehydration

Table 68.4. Most Common Causes of Respiratory Distress

Foreign body	Pericardial tamponade
Tension pneumothorax	Epiglottitis

Table 68.5. Most Common Acute Life-Threatening Causes of Respiratory Distress

Respiratory System

Conditions may be congenital or acquired. They may be caused by upper or lower airway obstruction or by disorders of the parenchyma or interstitium. Upper airway obstruction is common in infants and young children in part because of their airway anatomy and physiology (see Chapter 72). Manifestations of upper airway obstruction include nasal flaring, stertor or snoring, gurgling, drooling, dysphagia, aphonia, hoarseness, stridor, retractions, and paradoxical chest/abdominal wall movement. In neonates, the common causes include nasal obstruction, congenital upper airway anomalies (particularly laryngotracheomalacia), and congenital or postintubation subglottic stenosis. Common causes for acquired upper airway obstruction in infants and children include adenotonsillar hypertrophy, peritonsillar abscess, croup, foreign body, retropharyngeal abscess, tracheitis, and airway edema from trauma or allergic reaction. Epiglottitis, although less common, is one of the most life-threatening causes of respiratory distress and is a true emergency. The incidence of epiglottitis has declined significantly since routine immunization against *Haemophilus influenzae* B, the pathogen that was responsible for at least 75% of cases. Epiglottitis should be suspected in children who have abrupt onset of fever, dysphagia, drooling, muffled voice, labored respirations, and stridor. Children appear toxic and anxious and assume a sniffing position with protruding jaw and extended neck. These children are at risk of abrupt onset of respiratory arrest from obstruction. Peritonsillar and retropharyngeal abscess may present with symptoms similar to epiglottitis but have more gradual onset. Croup or laryngotracheobronchitis is the most common cause of upper airway obstruction in children 3 months to 3 years of age. Croup causes subglottic narrowing and is characterized by a barky cough, inspiratory stridor, and hoarseness that are worse at night. Viral croup, most often caused by parainfluenza, has an insidious onset following several days of upper respiratory infection symptoms with normal temperature or low-grade elevation. Spasmodic or allergic croup has acute onset, usually with wakening during the night, in a child who was well before going to sleep. Children with recurrent or prolonged croup may have an underlying fixed or functional airway abnormality, most commonly subglottic stenosis or hemangioma. Children with chronic stridor, particularly those less than 2 years of age,

are also likely to have an underlying congenital anomaly. Foreign body aspiration, which has a peak age of occurrence 1 to 5 years, may cause obstruction of the upper or lower airway and is a leading cause of accidental death in toddlers. A history of abrupt onset of choking or gagging is suggestive. Drooling, dysphagia, and stridor suggest an upper airway foreign body, whereas unilateral wheeze, particularly first-time wheeze with acute onset, suggests lower airway position. Presentation, particularly with lower airway foreign body, may be delayed by days to weeks from time of aspiration. Other common causes of lower airway obstruction involve inflammation and bronchospasm and include asthma, allergy, and bronchiolitis. Wheeze, most often diffuse, is usually a predominant feature of these conditions (see Chapter 80). Asthma may be triggered by infection, exercise, environmental irritants, and/or stress. Allergy, usually accompanied by coryza, congestion, mucosal edema, and/or rash, may be in response to environmental exposures, food, or medications. Bronchiolitis, most often caused by respiratory syncytial virus, presents with wheeze in children less than 2 years of age. These conditions cause airway obstruction by decreasing airway lumen secondary to bronchospasm, edema, or thickening of the wall of the lumen. Other causes of lower airway obstruction include filling of the airway lumen by excessive secretions (e.g., from inflammation, infection, toxin such as organophosphate) or aspirated fluids and decreasing of lumen diameter due to loss of radial traction of the airway wall as with emphysema and masses.

Disorders of the alveoli and interstitium involve pus or fluid collection, collapse, and structural or functional abnormality. Alveolar and interstitial disease is characterized by tachypnea, cough, grunting, crackles, rhonchi, wheeze, and decreased and/or asymmetric breath sounds with or without fever. In neonates, transient tachypnea of the newborn and meconium aspiration are common causes. Pneumonia is one of the most common causes of lower airway disease in neonates, infants, and children. Findings are more likely to be localized in the setting of bacterial pneumonia, whereas patients with viral and atypical pneumonias, such as *Mycoplasma,* chlamydia, and pertussis, tend to have diffuse peribronchial, interstitial processes. Less commonly, aspiration, hemorrhage, and pulmonary edema cause fluid collection in the acini and interstitium. Atelectasis, or airway collapse, resulting from loss of air from the pulmonary parenchyma, often occurs secondary to other processes, including pneumonia, particularly viral; bronchospasm; and inadequate lung expansion, most often resulting from pain, neuromuscular disease, or inactivity. Structural and/or functional abnormalities include bronchopulmonary dysplasia, hyaline membrane disease or respiratory distress syndrome, bronchiectasis (most commonly seen in cystic fibrosis), congenital or acquired emphysema, and pulmonary fibrosis (usually from radiation and chemotherapy).

Nervous System

CNS disturbances may result in hypoventilation or hyperventilation, loss of protective airway reflexes, or airway obstruction from loss of pharyngeal tone. These conditions include CNS malformation, immaturity, infection, degenerative disease, seizures, mass, trauma, and intoxication. Focal neurologic deficits, visual disturbances, pupillary abnormalities, papilledema, abnormal muscle tone, and altered level of consciousness suggest CNS processes. Spinal cord trauma and anterior horn cell disease cause bulbar and respiratory muscle dysfunction, which results in airway obstruction and/or hypoventilation. Peripheral neuromuscular (i.e., peripheral nerve, neuromuscular junction, muscle) disorders result in muscle weakness or paralysis. Physical findings that suggest significant chest wall weakness may include hypotonia, hyporeflexia, muscle weakness, weak cry, hoarse voice, cough, gag, shallow or irregular respiratory pattern, and inability to lift the head or extremities.

Chest Wall/Thoracic Cavity

Musculoskeletal deformity or disease involving the support structures of the chest may severely restrict lung expansion, limiting normal ventilatory efforts or attempts at compensatory ventilation for respiratory dysfunction and other systemic disturbances. Intrathoracic conditions that may produce respiratory distress include air leak and space-occupying lesions, including fluid collections and masses. Air leak, is most commonly caused by pneumothorax or tension pneumothorax, which may be traumatic or spontaneous. Pneumothorax occurs when air enters the pleural space either by chest wall penetration (open pneumothorax) or by rupture of lung through the visceral pleura (closed pneumothorax) and causes collapse of the lung. With tension pneumothorax, air is able to enter but not egress. Pneumothorax, in addition to nonspecific signs of respiratory distress, is suggested by chest wall hyperexpansion, decreased breath sounds, and hyperresonance on the side of the air leak. With tension pneumothorax, there is also jugular venous distension (JVD) and deviation of the trachea and mediastinum away from the air leak. Tension pneumothorax decreases venous return and thus cardiac output. It is therefore life-threatening and must be relieved immediately by thoracentesis. The most commonly occurring space-occupying lesion is pleural effusion. Pleural effusion, which may be caused by infection, inflammation, ischemia, trauma, malignancy, major organ failure, drug hypersensitivity, or venous or lymphatic obstruction, is suggested on physical examination by decreased breath sounds and a pleural rub. Mass lesions include congenital or traumatic diaphragmatic hernia, esophageal anomalies, benign or neoplastic masses, and vascular malformations.

Cardiovascular

Congenital and acquired heart disease may result in respiratory distress from decreased cardiac output, reduced oxygen saturation, and/or congestive heart failure (CHF). Compromised cardiac output, most commonly caused by congenital structural heart defects, cardiac arrhythmias, myocarditis, pericardial effusion, pericardial tamponade, or hypotension, may result in insufficient tissue oxygen delivery to meet metabolic demands. Pericardial tamponade causes decreased cardiac output as a result of compromised cardiac filling. It is recognized on physical examination by Beck's triad of arterial hypotension, JVD, and distant heart sounds. It may be caused by infection, inflammation, trauma, or surgery. Acute tamponade may be immediately life-threatening and must be relieved expeditiously by pericardiocentesis. Cardiac anomalies with right-to-left shunting of deoxygenated blood result in reduced oxygen saturation of blood entering the systemic circulation, hence causing hypoxia with cyanosis. Cardiac defects causing left-to-right shunting result in pulmonary overcirculation, pulmonary venous congestion, and pulmonary edema that directly compromises pulmonary function. In children, congenital heart defects are the most common cause of CHF. Other cardiac causes of CHF include valvular heart disease, myocardial dysfunction, arrhythmias, ischemia, and infarction. Metabolic disturbances, sepsis, fluid overload, and severe anemia may also result in CHF. Pulmonary manifestations of CHF include tachypnea, increased work of breathing, dyspnea on exertion, orthopnea, cough, wheeze, and bibasilar rales. Other manifestations

include poor feeding, failure to thrive, fatigue, tiring with feeds, diaphoresis, edema, tachycardia, weak thready pulses, JVD, displaced point of maximum impulse (PMI), cardiac murmur, gallop, rub, cardiomegaly, and hepatosplenomegaly. Vascular causes of respiratory distress include pulmonary embolism, pulmonary hypertension, and pulmonary arteriovenous fistula.

Gastrointestinal

Abdominal obstruction, perforation of hollow viscous, laceration of solid organs, hematoma, contusion, appendicitis, infection, inflammation, ascites, or mass may result in impaired diaphragmatic excursion secondary to abdominal distension and/or pain. Prolonged shallow respiration may result in pulmonary hypoventilation. Gastroesophageal reflux or vomiting, particularly in children unable to protect their airway, may result in pulmonary aspiration.

Metabolic and Endocrine Disturbances

Metabolic disturbances often manifest as compensatory alterations in respiratory status. Metabolic acidosis results in rapid, deep breathing. Hyperammonemia directly stimulates the respiratory center to produce tachypnea, which results in primary respiratory alkalosis with secondary metabolic acidosis. Metabolic disruption of oxygen metabolism is another cause for respiratory distress. Endocrine disturbances that cause alterations in metabolic rate or chemical imbalances also result in respiratory distress.

Hematologic

Inadequate concentrations of hemoglobin or hemoglobin with decreased oxygen-carrying capacity result in deficient oxygen delivery to tissues. Polycythemia results in sludging of blood and therefore compromised oxygen delivery.

EVALUATION AND DECISION

Triage and Stabilization

Every child with significant respiratory distress must be considered to be at potential risk of respiratory collapse. Airway patency, breathing, and circulation should be rapidly assessed and, if compromised, should be established and optimized immediately (Table 68.6). For the child in respiratory arrest, cardiac arrest, if not already present, is imminent. Cardiorespiratory status should be continuously monitored. A health care provider skilled in airway management and resuscitation should remain with the patient at all times. Evaluation that is stepwise and focused is critical for determining the source and severity of respiratory distress. Anticipation and rapid aggressive management are essential for optimizing outcome. In the child who is alert and otherwise healthy, the position that he or she has naturally assumed is likely to be the one that minimizes respiratory distress and thus should be maintained. A child with significant respiratory distress should not be agitated; he or she should be allowed to remain with the parents. Anxiety increases minute ventilation and adds significantly to the child's oxygen consumption. Any patient thought to have ventilatory compromise should be treated immediately with humidified oxygen at the highest concentration available. Supplemental oxygen provides a small but often crucial margin of safety in ensuring adequate cerebral and myocardial oxygenation. In patients with decreased sensorium or neuromuscular disease, a position to optimize airway patency must be established. Airway devices or assisted ventilation may be necessary. For management of cardiorespiratory arrest, resuscitation efforts must be initiated immediately, as detailed in Chapter 1 and Chapter 2.

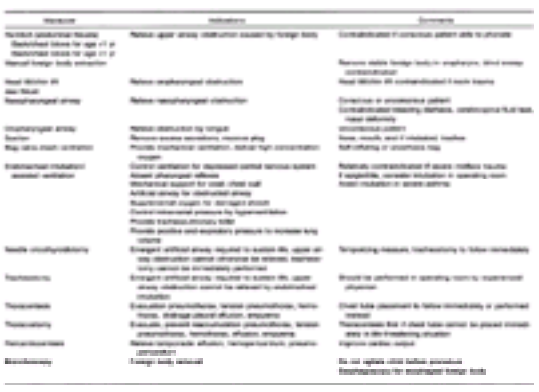

Table 68.6. Life-Saving Maneuvers to Relieve Respiratory Distress

History

A detailed history usually provides important clues to the cause of respiratory distress, but in a critically ill child comprehensive detail should not be obtained at the expense of patient care. A brief history can be obtained while emergent treatment is initiated. Details can follow once the child is stabilized. Information obtained by history should include a description of respiratory and other symptoms, onset and duration of symptoms, possible precipitating factors, exacerbating factors, therapeutic interventions, history of previous similar symptoms, underlying medical conditions, medications, allergies, and immunizations.

Physical Examination

The physical examination should assess the degree of respiratory distress and should identify the site and likely cause of

respiratory distress (Fig. 68.1 and Fig. 68.2). Continuous cardiopulmonary monitoring and frequent assessment are important because respiratory status can change instantaneously. General appearance, level of consciousness, vital signs, respiratory rate, respiratory effort, and adequacy of oxygenation and ventilation give immediate information regarding the severity of respiratory distress and possible sites. Heightened level of consciousness, manifest as restlessness, anxiety, or combativeness, is more likely an early sign of hypoxia, whereas diminished level of consciousness, manifest as somnolence, lethargy, stupor, obtundation, or coma, tends to result from hypercarbia or severe hypoxia. The child's posture may suggest the site of the disturbance. Children with upper airway obstruction tend to assume a sniffing position, an upright sitting posture with neck slightly flexed and head extended. For lower airway obstruction, a tripod position, in which the child is sitting up and leaning forward, may be preferred.

FIGURE 68.1. Approach to the child with respiratory distress. *CNS,* central nervous system; *SpO_2,* percent oxygen saturation; *O_2,* oxygen.

FIGURE 68.2. Approach to the child with respiratory distress (continued). *CNS,* central nervous system.

Vital sign abnormalities provide important clues about the severity of illness and adequacy of compensatory mechanisms. To maintain cardiac output (CO), children are more dependent on increasing heart rate (HR) than on stroke volume (SV) (CO = HR × SV). Tachycardia is one of the early signs of respiratory compromise and is expected because of increased sympathetic tone due to respiratory distress. Bradycardia in a hypoxic child is a late and ominous sign that often signals impending cardiac arrest. Cardiac arrhythmias that compromise cardiac output may result in respiratory distress. Respiratory rate in children varies with age (Table 68.7). Tachypnea is a compensatory mechanism for hypoxia, hypercapnia, and acidosis, and it also occurs with pain, anxiety, and exercise. Although not specific for respiratory distress, tachypnea is one of the findings most consistently present with respiratory distress and is particularly pronounced with lower airway processes. Tachypnea may be the only manifestation of lower respiratory infection in children less than 6 months of age. Bradypnea, or decreased respiratory rate, may reflect central respiratory depression, increased intracranial pressure, diabetic coma, or fatigue of respiratory muscles. It is usually an ominous sign that heralds impending respiratory arrest. Blood pressure is often increased because of anxiety. Pulsus paradoxus, an exaggeration (greater than 10 mm Hg) of the normal decrease in blood pressure during inspiration, correlates well with degree of airway obstruction. Pulses paradoxus is also caused by compromised venous return because of forces on the pericardium that result in decreased cardiac output, particularly during forced inspiration. Hypotension in a child is a late and extremely worrisome finding. It suggests profound shock, significantly decreased cardiac output, and impending cardiorespiratory arrest. Fever results in an increase in the respiratory rate of approximately 3 breaths/minute for each degree centigrade of temperature elevation above normal, due at least in part to an increase in CO_2 production.

Age Group	Breaths/Minute
Neonate	35–50
Older infants/toddlers	30–40
Elementary school age	20–30
Older child/adolescents	12–20

Table 68.7. Normal Respiratory Rates

On inspection, in addition to respiratory rate, one should appreciate depth, rhythm, and symmetry of respirations; the use of accessory muscles; and perfusion. Breathing that becomes progressively more rapid and more shallow results from greater air trapping because airway resistance increases in obstructive lower airway disease. Rapid shallow breathing may also result from chest pain or chest wall musculoskeletal dysfunction. Kussmal's respirations (deep, regular, sighing breaths that may be rapid, slow, or normal in rate) are seen with metabolic acidosis, particularly diabetic ketoacidosis. Cheyne-Stokes respirations (respirations with increasing then decreasing depth alternating with periods of apnea) are seen with CNS immaturity in otherwise normal neonates and infants, particularly during sleep, and with inadequate cerebral perfusion, brain injury, increased intracranial pressure, and central narcotic depression. Biot's, or ataxic, respirations (breaths of irregular depth interrupted irregularly by periods of apnea) suggest CNS infection, injury, or drug-induced depression. Asymmetric chest wall movement and/or expansion suggests unilateral chest wall or thoracic cavity pathology. Nasal flaring and supraclavicular, suprasternal, and subcostal retractions of accessory muscles of respiration usually reflect upper airway obstruction but may occur with lower processes. Intercostal retractions are usually a sign of inadequate tidal volume as a result of lower airway disease. Thoracoabdominal dissociation, also called respiratory alterans or paradoxical breathing, in which the chest collapses on inspiration and abdomen protrudes, is a common sign of respiratory muscle fatigue. Central cyanosis results from reduced ambient oxygen, airway obstruction with impaired oxygenation, alveolar diffusion impairment, cardiac defect with right-to-left shunting, left ventricular heart failure with pulmonary edema, or methemoglobinemia. Cyanosis usually reflects at least 5 g/dL of unsaturated hemoglobin and an oxygen saturation of less than 90%. Cyanosis may not be recognized in severely anemic patients and may be more pronounced in polycythemic patients. Peripheral cyanosis is caused by local vascular changes of the extremities that result in inadequate perfusion or vascular stasis; it is not usually associated with a decrease in systemic oxygen saturation.

Palpation of the chest commonly reveals vibratory rhonchi over the large airways, which suggests fluid in the airway. Tactile fremitus, when increased, suggests bronchopulmonary consolidation or abscess, and when decreased or absent, it suggests bronchial obstruction or space-occupying processes of the pleural cavity. Crepitus on palpation of the chest or neck may reveal subcutaneous emphysema caused by pneumothorax or pneumomediastinum.

Auscultation is particularly useful for localizing the site of respiratory distress (Table 68.8). Stertor, gurgle, dysphonia, aphonia, hoarseness, barky cough, and inspiratory stridor localize the respiratory distress to the upper airway. A lower airway cause is suggested by decreased or asymmetric breath sounds, changes in pitch of breath sounds, expiratory stridor, grunting, and/or adventitial sounds, including crackles, rhonchi, wheeze, rub, bronchophony, egophony, and whispered pectoriloquy. The ratio of inspiratory to expiratory phase of respiration, normally 1:1, is often useful in distinguishing an upper from lower respiratory tract cause of respiratory distress. Respiratory distress from upper airway disease usually results from difficulty of inward air movement. The inspiratory phase is often increased relative to the expiratory phase to between 1:1 and 2:1. Lower airway processes often impede outward air movement and may result in a prolonged expiratory phase with ratios of 1:3 to 1:4. Absence or disappearance of wheeze in a child with continued or worsening respiratory distress may represent severe obstruction and should not be considered reassuring, but rather may herald impending respiratory arrest.

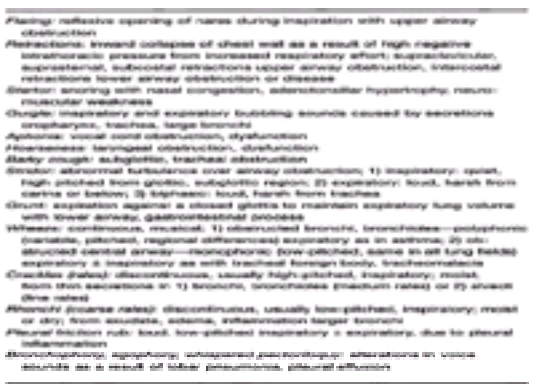

Table 68.8. Localization of Respiratory Distress by Physical Examination Findings

Percussion of the chest may reveal either hyperresonance, suggesting air trapping, or dullness, suggesting an area of consolidation, a mass in the lung or pleural space, or pleural fluid. Air trapping is further suggested by depressed position of the diaphragm. Diaphragmatic excursion can be accessed by measuring the difference between the level of dullness on percussion during full inspiration and full expiration. Poor diaphragmatic excursion may reflect diaphragmatic dysfunction.

The remainder of the physical examination should concentrate on the nervous, cardiac, gastrointestinal, renal, metabolic/endocrine, and hematologic systems, and may reveal pathology of these organ systems that localizes the underlying source of respiratory distress.

Approach

In approaching children with respiratory distress (Fig. 68.1 and Fig. 68.2), the physician should first assess the adequacy

of oxygenation and ventilation and then provide appropriate resuscitation. Patients in extremis (Fig. 68.1) are most likely to have sustained an injury, resulting in conditions such as a tension pneumothorax, flail chest, or cardiac tamponade, or have an obstructed airway, either as a result of aspiration of a foreign body or infection.

For patients with mild to moderate respiratory distress, as well as for those in extremis for whom the most likely diagnoses do not provide an explanation, the physician should proceed with a history, a physical examination, and a determination of oxygen saturation, and deliver supplemental oxygen as indicated. Respiratory distress of any degree calls for an immediate assessment of the airway. Stridor, altered phonation, and/or dysphagia suggests partial obstruction, most likely from infection, anaphylaxis, or foreign body. Assessment of the airway is followed by auscultation of the lungs for rales and wheezes. Children with abnormal auscultatory findings and fever are likely to have pneumonia or bronchiolitis, whereas asthma, bronchiolitis, and foreign body aspiration are common in afebrile patients.

Patients can be further categorized on the basis of tachypnea (Fig. 68.2). Children with rapid respirations and fever are likely to have pneumonia, even in the absence of rales; empyema, pulmonary embolism, and encephalitis are also important considerations. Tachypnea without fever points to trauma, cardiac disease, metabolic disturbances, toxic ingestions, and miscellaneous disorders.

Febrile children without tachypnea may have apnea or bradypnea as late manifestations of CNS infection. In afebrile patients, considerations include the myriad causes of CNS depression, spinal cord injury, neuromuscular disease, and neonatal apnea. Diagnostic tests should be used selectively to rule out diagnoses suggested by history and physical examination (Table 68.9). Nearly all patients with respiratory distress should have oxygenation tested by pulse oximetry. Arterial blood gas, more useful for lower than upper respiratory processes, and chest radiograph are the tests most likely to be helpful in the diagnosis of respiratory failure and determination of its cause.

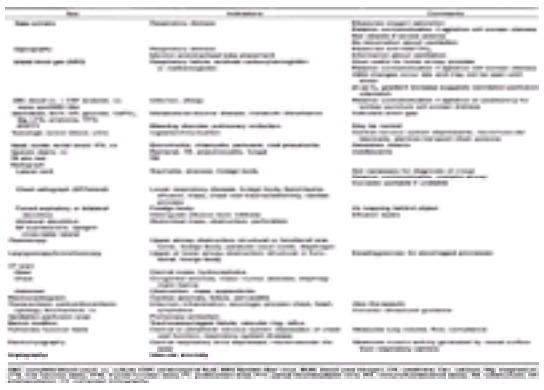

Table 68.9. Diagnostic Studies for Evaluation of Respiratory Distress

Treatment

Regardless of the cause of respiratory distress, aggressive treatment must be initiated immediately to rapidly restore oxygenation and ventilation. Airway patency, if inadequate, must be established. In the patient with decreased sensorium, positioning of the airway by chin lift (contraindicated if neck injury is suspected) or jaw thrust may relieve soft-tissue obstruction of the airway. The oral cavity should be cleared of secretions, vomitus, blood, and visible foreign matter. The unconscious patient may benefit from placement of an oropharyngeal airway or endotracheal intubation. In the alert patient with suspected soft-tissue obstruction of the airway, a nasopharyngeal airway may improve airway patency. Placement of a nasogastric tube to decompress a distended abdomen often improves respiratory effort by allowing full expansion of the lungs. The child in whom airway patency cannot be maintained or adequate ventilation and oxygenation cannot be established likely requires endotracheal intubation. Indications for intubation directly related to respiratory distress include respiratory failure or impending failure, apnea, airway obstruction, inability to handle secretions, and risk of aspiration.

SUMMARY

Respiratory distress is one of the most common chief complaints of children seeking medical care. The causes of respiratory distress are numerous and varied. History and physical examination provide important clues that allow rapid localization of the site of impairment. The underlying cause must be identified and may be within the respiratory system or organ systems that control or impact respiration. Any disorder that causes respiratory distress may be life-threatening. Airway and ventilatory problems not only must be recognized, but also must be anticipated and addressed aggressively. The underlying cause must also be treated. Patients must be monitored continuously and frequently reassessed. Airway, breathing, and circulation must be established and maintained. Diagnostic evaluation of body fluids, radiologic studies, direct visualization, and specialized tests of organ function must be performed prudently so that respiratory status is not further compromised.

CHAPTER 69

The Septic-Appearing Infant

STEVEN M. SELBST, MD

Department of Pediatrics, Thomas Jefferson University, and Division of Emergency Medicine, A. I. duPont Hospital for Children, Wilmington, Delaware

A young infant may be brought to the emergency department (ED) because he or she “just doesn't look right” to the parents. Even inexperienced parents whose first baby is just a few weeks old may notice when their child is unusually sleepy, fussy, or not drinking as well as usual. To the physician in the ED, such an infant may appear quite ill with pallor, cyanosis, or ashen color. There may be notable irritability or lethargy, and fever may or may not be present. The infant may be found to have tachypnea, tachycardia, or both. Hypotension or other signs of poor perfusion also may be apparent.

Generally, an ill-appearing infant, such as the one already described, will be considered immediately to have sepsis and will be managed reflexly. Although this may be the correct approach in most cases, the physician should remember that several other conditions can produce a septic-appearing infant.

The purpose of this chapter is to establish a differential diagnosis for infants in the first 2 months of life who appear quite ill. An approach to the evaluation and management of such an infant is discussed.

DIFFERENTIAL DIAGNOSIS

Numerous disorders (Table 69.1) may cause an infant to appear septic. The most common of these disorders (Table 69.2) include certain bacterial infections and viral syndromes. The remaining disorders, although uncommon, demand diagnostic consideration because they are potentially life-threatening, yet treatable.

Infectious Diseases	Inborn errors of metabolism
Bacterial sepsis	Hypoglycemia
Meningitis	Drugs/toxins—aspirin, carbon monoxide
Urinary tract infection	*Renal Disorders*
Viral infections—Enterovirus, respiratory syncytial virus, herpes simplex	Posterior urethral valves
Pertussis	*Hematologic Disorders*
Congenital syphilis	Severe anemia
Cardiac Disease	Methemoglobinemia
Congenital heart disease	*Gastrointestinal Disorders*
Supraventricular tachycardia	Gastroenteritis with dehydration
Myocardial infarction	Pyloric stenosis
Pericarditis	Intussusception
Myocarditis	Necrotizing enterocolitis
Kawasaki disease	Appendicitis, volvulus
Endocrine Disorders	*Neurologic Disease*
Congenital adrenal hyperplasia	Infant botulism
Metabolic Disorders	Shunt obstruction, infection
Hyponatremia, hypernatremia	Child abuse—intracranial hemorrhage
Cystic fibrosis	

Table 69.1. Differential Diagnosis of the Septic-Appearing Infant

Urinary tract infection	Congestive heart failure
Viremia	Gastroenteritis with dehydration

Table 69.2. Most Common Disorders That Mimic Sepsis

Sepsis

Sepsis (Chapter 84) should always be considered when the emergency physician is confronted with an ill-appearing infant. The signs and symptoms of sepsis may be subtle. The history may vary, and some infants may seem to be ill for several days, whereas others deteriorate rapidly. Likewise, any one or combination of symptoms, such as lethargy, irritability, diarrhea, vomiting, anorexia, or fever, may be a manifestation of sepsis. Fever generally is an unreliable finding in the septic infant; most septic infants younger than 2 months of age will be hypothermic instead. On physical examination, a septic infant may be pale, ashen, or even cyanotic. The skin is often cool and may be mottled because of poor perfusion. The infant may seem lethargic, obtunded, or irritable. There is often marked tachycardia, with the heart rate approaching 200 beats/minute, and tachypnea may be noted (respiratory rate above 50 breaths/minute). If disseminated intravascular coagulopathy (DIC) has developed, there may be scattered petechiae or purpura may be evident. If meningitis is also present, a bulging or tense fontanelle may be found. Likewise, if the infection has localized elsewhere, there may be otitis media, abdominal rigidity, joint swelling, or tenderness in one extremity, or possibly chest findings such as rales. Finally, if the disease process has progressed, the infant may develop shock and may be hypotensive.

The laboratory often is helpful in suggesting a diagnosis of sepsis; however, definitive cultures require time for processing. A complete blood count (CBC) may reveal a leukocytosis or left shift. In addition, a coagulation profile may show evidence of DIC, and blood chemistries may reveal hypoglycemia or metabolic acidosis. If localized infection is suspected, aspiration and Gram stain of urine, joint fluid, spinal fluid, or pus from the middle ear may reveal the offending organism. Similarly, a chest radiograph may show a lobar infiltrate if pneumonia is present. A Gram stain of a petechial scraping may also reveal the responsible organism.

Viral Infections

Overwhelming viral infections may mimic sepsis in the young infant. In one study of *enteroviral infections* in the neonate, it was noted that 25% of infants younger than 1 month of age developed a sepsislike illness. Respiratory distress was present in all of these infants; and hemorrhagic manifestations, including gastrointestinal bleeding and bleeding into the skin, were commonly seen. Seizures often occurred, as well as icterus, splenomegaly, congestive heart failure, and abdominal distension. In this series and in others, the mortality rate for enteroviral infections in neonates was high. This infection is indistinguishable from bacterial sepsis except that bacterial cultures will be negative, whereas viral isolates from stool and cerebrospinal fluid (CSF) may confirm the offending enterovirus.

Epidemics of *respiratory syncytial virus* (RSV) occur in the wintertime, and babies younger than 2 months old may present with apnea or respiratory distress with cyanosis. Those born prematurely or with previous respiratory or cardiac disorders are especially susceptible to apnea. These infants often appear septic, but knowledge of illness in the community and a predominance of wheezing on chest examination may lead to the suspicion of RSV bronchiolitis. Still, some infants develop wheezing later in the course, and thus, the initial diagnosis is difficult. A rapid slide test for RSV, if available, will be quickly diagnostic. Culture for RSV requires several days. A CBC may show a lymphocytosis, but because of stress, a left shift can also be found. Chest radiographs may show diffuse patchy infiltrates and, possibly, lobar atelectasis.

Another viral infection to consider is *herpes simplex,* which usually causes systemic symptoms and encephalitis at 7 to 21 days of life. Neonates present with fever, coma, apnea, fulminant hepatitis, pneumonitis, coagulopathy, and seizures, which are often difficult to control. History of maternal genital herpes should lead to suspicion of systemic herpes infection in the neonate. In most cases, however, the mother is completely asymptomatic. Ocular findings such as conjunctivitis or keratitis may be noted, as well as focal neurologic findings. If vesicular lesions are present on the skin, this infection should be strongly considered. However, they are present in only one-third to one-half of patients. When this infection is suspected, a Tzanck smear or direct fluorescent antibody staining of a scraped vesicle may provide rapid diagnosis. An electroencephalogram (EEG) or computed tomography (CT) scan may also be helpful. The diagnosis is confirmed by culture of a skin vesicle, mouth, nasopharynx, eyes, urine, blood, CSF, stool, or rectum.

Pertussis is another infection to consider when evaluating a very ill infant. Apnea, seizures, and death have been reported in this age group. Parents may report respiratory distress, cough, poor feeding, and vomiting (often posttussive). History of exposure to pertussis may be lacking because the infant usually acquires the disease from older children or adults who have only symptoms of a common upper respiratory infection. Physical examination will distinguish the infection from sepsis if the infant has a paroxysmal cough. The characteristic inspiratory “whoop” after a coughing paroxysm is common in young infants. Auscultation of the chest is usually normal; tachypnea and cyanosis may be present. Initial laboratory studies may not identify the condition. The CBC in young infants may fail to show a marked

lymphocytosis as expected in older patients with pertussis. Likewise, the chest radiograph may not show the typical “shaggy right heart border”; atelectasis or pneumonia may be present. Nasopharyngeal culture for *B. pertussis* is confirmatory. Polymerase chain reaction technique can reliably identify the condition from nasopharyngeal specimens.

Infants with *congenital syphilis* may present in the first 4 weeks of life with extreme irritability, pallor, jaundice, hepatosplenomegaly, and edema. They may have pneumonia and often have painful limbs. Snuffles and skin lesions are common. Although these infants may appear to be ill on arrival in the ED, their histories reveal that they also have been chronically ill. Certainly, if a history of maternal infection is obtained, the diagnosis should be considered. Laboratory tests will be helpful in that radiographs of the infant's long bones may reveal diffuse periostitis of several bones. A serologic test is needed to confirm the diagnosis.

Cardiac Diseases

In addition to infections, cardiac disease should be considered with a very ill infant. An infant with underlying *congenital heart disease* (CHD), such as ventriculoseptal defect, valvular insufficiency, valvular stenosis, hypoplastic left heart syndrome (HLHS), or coarctation of the aorta, may present with congestive heart failure and clinical findings similar to those of an infant with sepsis. There may be tachycardia and tachypnea, as well as pallor, duskiness, or mottling of the skin. Cyanosis is not always present. There may also be sweating or decreased pulses and hypotension caused by poor perfusion. However, a careful history and physical examination may help the physician differentiate CHD with heart failure from sepsis. For instance, a chronic history of poor growth and poor feeding may suggest heart disease. Also, the presence of a cardiac murmur may suggest a structural lesion. Moreover, a gallop rhythm, hepatomegaly, neck vein distension, and peripheral edema may lead one to consider primary cardiac pathology. Intercostal retractions and rales, rhonchi, or wheezing are nonspecific findings and may be present on chest examination in either heart failure or pneumonia. In a young baby, difference between upper and lower extremity blood pressures suggests coarctation of the aorta. If cardiac output is inadequate, however, pulse differences may not be detected. Normal femoral pulses do not exclude a coarctation because the widely patent ductus arteriosis provides flow to the descending aorta.

Laboratory evaluation is essential in establishing cardiac disease as the cause of an infant's moribund condition. A chest radiograph often shows cardiac enlargement and may show pulmonary vascular engorgement or interstitial pulmonary edema rather than lobar infiltrates (as in pneumonia). The electrocardiogram (ECG), may be helpful in revealing certain congenital heart lesions. For instance, in HLHS, the ECG invariably shows right-axis deviation, with right atrial and ventricular enlargement. The ECG often is a nonspecific indicator of cardiac decompensation however, and an echocardiogram is more helpful. Finally, a CBC may be helpful in that the absence of leukocytosis and left shift may make sepsis a less likely consideration. Rarely, an infant with anomalous or obstructed coronary arteries will develop myocardial infarction and appear to be septic initially. Such young infants may have dyspnea, cyanosis, vomiting, pallor, and other signs of heart failure; however, these infants usually have cardiomegaly on chest radiograph. This will prompt the physician to perform an ECG, which usually shows T-wave inversion and deep Q waves in leads I and AVL. Echocardiogram and cardiac catheterization with contrast are needed to confirm the diagnosis.

In addition to CHD, certain *arrhythmias* may cause an infant to appear ill. For instance, a young baby with *supraventricular tachycardia* (SVT) often presents with findings similar to those of a septic infant. This arrhythmia may be idiopathic (50%), associated with CHD (20%), or related to drugs, fever, or infection (20%). Often young infants with SVT go unrecognized at home for 2 days or more because initially, they have only poor feeding, fussiness, and some rapid breathing. As this condition goes untreated, however, the infants will develop congestive heart failure and may present with all the signs of sepsis, including shock. Because fever can be a precipitating cause of the arrhythmia, the condition obviously is confused with sepsis. However, a careful physical examination will make the diagnosis of SVT obvious. Particularly, the cardiac examination will reveal such extreme tachycardia in the infant that the heart rate cannot even be counted. It is usual for the heart rate to exceed 250 to 300 beats/minute in such infants. With this information, laboratory aids can confirm the diagnosis. An ECG will show regular atrial and ventricular beats with 1:1 conduction, whereas P waves appear different than sinus P waves and may be difficult to see at all. They are often buried in the T waves. Moreover, a chest radiograph may show cardiomegaly and pulmonary congestion.

Additional cardiac pathologies to consider include *myocarditis* and *pericarditis*. Pericarditis may be caused by bacterial organisms such as *Staphylococcus aureus;* myocarditis usually results from viral infections such as coxsackie B. In infants, these often are fulminant infections and the baby with such a condition will appear critically ill, with fever and grunting respirations often present. A complete physical examination may help the physician distinguish these conditions from sepsis in that signs of heart failure may be seen and unexplained tachycardia is often present. Also, pericarditis may produce neck vein distension and distant heart sounds if a significant pericardial effusion exists. In addition, a friction rub may be present. Laboratory tests may be helpful in that a chest radiograph will show cardiomegaly and a suggestion of effusion if pericarditis is present. The ECG will show generalized T-wave inversion and low-voltage QRS complexes, especially if pericardial fluid is present. Also, ST-T wave abnormalities may be seen. The echocardiogram will confirm the presence or absence of a pericardial effusion and poor ventricular function in the case of viral myocarditis. The CBC will not distinguish these infections from sepsis because leukocytosis is common and a left shift may be present.

Kawasaki disease with associated coronary artery aneurysms is very rare in young infants and is associated with a poor prognosis. A baby with Kawasaki disease may present with cyanosis and shock. Usually, history reveals prolonged and unexplained fever, rash, and mucous membrane inflammation. The physical examination may distinguish this illness from sepsis if there is a diffuse, raised, erythematous rash or cracked red lips, swollen hands and feet, conjunctivitis, and cervical lymphadenopathy. However, these classic features, found in older infants and children, may be absent in young babies. Routine laboratory studies may not differentiate this condition from sepsis either. A CBC may reveal leukocytosis and/or thrombocytosis. CSF usually shows a pleocytosis, with a lymphocytic predominance. Sterile pyuria is sometimes noted. In some cases, findings consistent with myocardial ischemia or an arrhythmia may be noted on ECG. Normal findings or nonspecific abnormalities are more common. Coronary artery aneurysms may be discovered with an echocardiogram, making the diagnosis highly likely.

Endocrine Disorders

Certain endocrine disorders can also mimic sepsis. For instance, infants with *congenital adrenal hyperplasia* (CAH) may present in the first few days or weeks of life with a history of vomiting, lethargy, or irritability. On arrival, signs of marked dehydration may be present, with tachycardia and possibly hypothermia. The recent history may be revealing in that such infants may have been poor feeders since birth and the symptoms may be progressive over a few days. The physical examination can be extremely helpful in establishing the diagnosis in females if ambiguous genitalia are noted. The laboratory evaluation also is helpful in that the presence of marked hyponatremia with severe hyperkalemia should make CAH a likely diagnosis. Other nonspecific laboratory findings in this disorder include hypoglycemia, acidosis, and peaked T waves or arrhythmias on ECG. Specifically, the finding of elevated 17-hydroxyprogesterone and renin with decreased aldosterone and cortisol in the serum confirms the diagnosis of CAH.

Metabolic Disorders

Various metabolic disorders can also look like sepsis and should be considered in the differential diagnosis. Prolonged diarrhea or vomiting can produce *dehydration, electrolyte disturbances,* and *acid-base abnormalities* such that an infant will appear quite ill. For instance, young infants with diarrhea may develop marked hyponatremia caused by iatrogenic water intoxication. Such infants may appear extremely lethargic, with slow respirations, hypothermia, and possibly, seizures.

A special cause of hyponatremic dehydration to consider is *cystic fibrosis* (see Chapter 96). The history in these cases may not be helpful initially, except that the infant usually gets very ill in hot weather. The mother may report poor intake, poor growth, and increased lethargy. Only with specific questioning might the mother report that the baby's skin tastes “salty” or that the baby had meconium plug syndrome (transient form of distal colonic obstruction secondary to inspissated meconium) as a newborn or prolonged neonatal jaundice. In some cases, pulmonary symptoms such as cough, tachypnea, or pneumonia may have been treated earlier in life. On examination, the dehydrated baby looks much like any other septic infant. However, laboratory tests that show profound hypoelectrolytemia, especially when not accounted for by gastrointestinal losses, should suggest cystic fibrosis. A sweat test will help confirm the diagnosis.

Likewise, dehydrated infants with *hypernatremia* may be lethargic or irritable, with muscle weakness, seizures, or coma. Infants with persistent vomiting may have hypochloremic alkalosis with hypokalemia, and they may appear weak or have cardiac dysfunction (see Chapter 86). In addition, rare inborn errors of metabolism such as *inherited urea cycle disorders* may produce vomiting in young infants, who will then present with lethargy, seizures, or coma resulting from metabolic acidosis, hyperammonemia, or hypoglycemia (see Chapter 98). *Hypoglycemia* also can be secondary to sepsis, certain drugs, or alcohol intoxication. It is thus essential to evaluate the electrolytes, blood sugar, and possibly, plasma ammonia levels in young infants with significant symptoms of gastroenteritis, lethargy, or irritability.

Another metabolic problem to consider is that of *toxins* (see Chapter 88). Obviously, young infants are incapable of accidental ingestions, but well-meaning parents may rarely cause salicylism in their attempts to aggressively treat fever with aspirin (despite current Reye's syndrome warnings). Affected infants can then present with vomiting, hyperpnea, hyperpyrexia, or convulsions and coma. In such cases, the history of medication given is crucial because the physical examination will not distinguish this ill baby from the infant with sepsis. The laboratory evaluation may lead to the suspicion of some metabolic problem because abnormalities of sodium, blood sugar, or acid-base balance often are found. Moreover, hypokalemia can be seen in salicylism as well as in abnormal liver function or renal function studies. An elevated salicylate level in the serum confirms the diagnosis of aspirin poisoning, but in chronic poisoning, the aspirin level may be relatively low despite a fatal course.

Carbon monoxide poisoning may present as an unknown intoxication when families are unaware of a defective heating system in the home. The young baby may have a history of sluggishness, poor feeding, and vomiting. A more careful history generally reveals that other family members are also ill with headache, syncope, or flulike symptoms. Their symptoms may improve after leaving the home environment. The classic “cherry red” skin color may be lacking, and physical examination may reveal only lethargy. Elevation of the carboxyhemoglobin level is diagnostic.

Renal Disorders

A young infant may also appear extremely ill because of renal failure or dysplasia. Such renal failure could be caused by *posterior urethral valves* that cause bladder outlet obstruction, especially in males. About one-third of those cases are diagnosed in the first week of life, but more than half go undetected for the first few months of life. The parents may give a history of vomiting or poor appetite, or they may say that the baby has not grown well or that the infant's abdomen appears swollen. On physical examination, hypertension or an abdominal mass (hydronephrosis) may be detected, as well as urinary ascites. Laboratory tests will elucidate the diagnosis even more. Suprapubic ultrasound may demonstrate the dilated posterior urethra and bladder, strongly suggesting posterior urethral valves. A voiding cystourethrogram (VCUG) should be obtained; this will show a dilated posterior urethra, hypertrophy of the bladder neck, and trabeculated bladder. The serum creatinine and blood urea nitrogen may be markedly elevated. Of course, urosepsis is a possible complication of posterior urethral valves.

Hematologic Disorders

It is also important to consider hematologic disorders when confronted with a critically ill infant. Any infant with severe *anemia* caused by aplastic disease, hemolytic process, or blood loss can look quite ill (see Chapter 87). In addition to anemia, disorders of hemoglobin such as *methemoglobinemia* can cause an infant to appear toxic. Although the chronic forms are uncommon inherited disorders of hemoglobin structure or enzyme deficiency, transient methemoglobinemia in infants occasionally is caused by environmental toxicity from oxidizing agents, such as nitrates found in some specimens of well water. This intoxication presents in very young infants with cyanosis, poor feeding, failure to thrive, vomiting,

diarrhea, and then lethargy. In other patients, the oxidant stress is less obvious. Methemoglobinemia has been described in infants with gastroenteritis and acidosis. Often, the associated diarrhea is severe, and it has been thought that the infectious agent that causes the diarrhea or the secondary metabolic acidosis may produce an oxidant stress that leads to methemoglobin formation. On examination, such infants have been described as toxic and lethargic, with hypothermia, tachycardia, tachypnea, and hypotension. They often appear mottled, cyanotic, or ashen. One key to the diagnosis of methemoglobinemia is that oxygen administration does not affect the cyanosis, yet no cardiac problem exists. Also, laboratory tests show a profound acidosis (pH 6.9 to 7.2), yet the Pa_{O_2} is normal despite the cyanosis. Leukocytosis and thrombocytosis are present. The blood itself may appear chocolate brown (most easily noted when a drop of blood on filter paper is waved in the air and compared with a normal control), and methemoglobin levels will be elevated up to 65% (normal 0 to 2%). Hemoglobin electrophoresis will be normal, except in rare cases of Hemoglobin M, as is the glucose-6-phosphate dehydrogenase (G6PD) assay in most cases. Prerenal azotemia may be noted. With appropriate treatment, the methemoglobin level returns to normal. However, death can occur from methemoglobinemia in infants.

Gastrointestinal Disorders

Gastrointestinal disorders can cause an infant to appear acutely ill. *Gastroenteritis,* even without electrolyte disturbances, can lead to profound dehydration. In a very young infant with little reserve, this can quickly lead to lethargy and even shock. Bacterial infections such as salmonella may cause sepsis in a young infant, and viral agents may mimic this. A history of bloody diarrhea may suggest this diagnosis. Stool cultures will diagnose bacterial infections, but a few days are needed for isolation. Viral isolation takes even longer. In the ED, a stool smear may reveal polymorphonuclear leukocytes, suggesting bacterial infection. A CBC with many band forms and a white blood cell (WBC) count in the normal range suggest *Shigella.* Laboratory tests are otherwise not helpful. Fluid resuscitation may improve the infant's appearance and make dehydration the likely diagnosis. However, sepsis cannot often be ruled out in the ED regardless of laboratory studies and initial therapy.

Also, *pyloric stenosis* in the young infant causes severe vomiting. This is most often seen in male infants 4 to 6 weeks old. An infant with pyloric stenosis may present to the ED with significant dehydration and may be lethargic. Usually, no fever is present. A careful history reveals that vomiting is the predominant feature of the illness, and there may be a positive family history for pyloric stenosis. The physical examination may reveal an abdominal mass, or “olive,” in 25 to 50% of cases, which would strengthen the diagnosis of pyloric stenosis. Electrolytes typically show hypochloremia and hypokalemia, and alkalosis is prominent. Plain films of the abdomen, a barium study, or ultrasound of the upper gastrointestinal tract may be needed to confirm the diagnosis.

Another gastrointestinal disorder to consider is *intussusception*. Although this rarely occurs in infants younger than 5 months old, it has been noted in some infants 2 to 3 months old. These infants may present with vomiting, fever, or signs of abdominal pain (e.g., legs drawn up, irritability). The infant may appear to have spasms of pain during which he or she is fretful. This can be followed by apathy and listlessness. Diarrhea may be seen, and if the typical currant jelly stool is noted, the diagnosis of intussusception should be strongly suspected. On physical examination, an abdominal mass may be palpated or bloody stool found on rectal examination. The laboratory may show nonspecific abnormalities such as leukocytosis and possibly anemia on CBC. However, a plain film of the abdomen will show evidence of small bowel obstruction, and a barium enema will show a filling defect usually near the ileocecal valve. A history of colicky behavior and the physical findings point to a gastrointestinal lesion rather than to sepsis.

Several other unusual but important gastrointestinal disorders have to be considered in infants. *Necrotizing enterocolitis* (NEC) occurs in premature infants in the first few weeks of life and can also occur in term infants, usually within the first 10 days of life. A history of an anoxic episode at birth or other neonatal stresses may suggest NEC. These infants are quite ill, with lethargy, irritability, anorexia, distended abdomen, and bloody stools. Radiographs of the abdomen may be helpful and usually show pneumatosis cystoides intestinalis caused by gas in the intestinal wall. Neonatal *appendicitis* is a rare event, but several cases have been reported to closely mimic sepsis. The mortality for this disorder is close to 80%, and perforation obviously worsens the prognosis. Thus, rapid diagnosis is essential. The most common presenting signs include irritability, vomiting, and abdominal distension on examination. There may also be hypothermia, ashen color, and shock as the condition progresses, as well as edema of the abdominal wall, localized to the right flank, and possibly, erythema of the skin in that area. The WBC count may be elevated, with a left shift, and there may be a metabolic acidosis, as well as DIC. Abdominal radiographs may show a paucity of gas in the right lower quadrant, evidence of free peritoneal fluid, or a right abdominal wall thickened by edema. Other unusual gastrointestinal emergencies to consider include *volvulus*, perforation caused by *trauma* from enemas or thermometers, and *Hirschsprung's enterocolitis*.

Neurologic Diseases

Neurologic problems should be considered in the evaluation of a critically ill infant. For instance, an unusual process that produces a sepsislike picture is *infant botulism*. This illness is produced by neurotoxins elaborated by *Clostridium botulinum.* An infant with botulism is often lethargic at presentation to the ED, with a weak cry and, possibly, signs of dehydration. These infants usually are afebrile. A thorough history may help distinguish botulism from sepsis. If constipation has preceded the acute illness, botulism should be seriously considered. The disease also is associated with the ingestion of honey, breast-feeding, a recent change in feeding practices, and a rural environment. The parents may note a more gradual progression with this illness. On physical examination, infants with botulism are notably hypotonic and hyporeflexic and may have increased secretions caused by bulbar muscle weakness. Also, the presence of a facial droop, ophthalmoplegia, and decreased gag reflex are consistent with botulism, whereas they remain unusual findings with a septic infant. Laboratory evaluation (cultures) should rule out bacterial illness. Moreover, abnormal (decreased) pulmonary function tests such as the measurement of maximal inspiratory force and vital capacity lend supportive evidence to the diagnosis of botulism. Finally, specific tests will confirm the diagnosis of botulism. A stool specimen to identify toxins of *C. botulinum* may be diagnostic but requires considerable time for identification. However, electromyography will show decreased muscle action potential with the “staircase” phenomenon in this disease. The

WBC count is normal in botulism.

A young baby with a ventriculoperitoneal shunt in place because of hydrocephalus can develop serious complications that cause the baby to appear extremely ill. *Shunt infection* could present with fever and irritability in a young infant. Abdominal pain or tenderness may be found on examination, as well as erythema or pus around the shunt itself. The definitive diagnosis is made by shunt aspiration under sterile conditions, but other causes of fever, such as meningitis, should be ruled out first. *Shunt obstruction* may result in increased intracranial pressure that causes a young infant to present with a history of lethargy or poor feeding. On examination, the baby may have bradycardia, apnea, coma, opisthotonic posturing, bulging fontanelle, or cranial nerve VI palsy. The shunt may be found to pump poorly. Laboratory tests such as radiographic evaluation of the shunt may be helpful if it shows a disconnection. Otherwise, a CT scan will demonstrate ventricle size and indicate the adequacy of shunt function.

Child Abuse

Intracranial hemorrhage that results from child abuse (see Chapter 128) must be considered in the very ill infant. It must be emphasized that the absence of bruises on an infant does not rule out child abuse. Vigorous shaking of an infant, followed by throwing the baby against a soft surface such as a mattress or sofa, can produce subdural or subarachnoid hemorrhages. The history may or may not be helpful in establishing a diagnosis. The parents may note that the child seemed to be in respiratory distress at home; only a few may admit to shaking the infant. On examination, the infant may appear gravely ill with apnea, bradycardia, hypothermia, bradypnea, and possibly, seizures. However, a careful physical examination may suggest abuse rather than sepsis. For instance, bruises may be present elsewhere on the body. More often, no external evidence of trauma is present. However, respiratory distress without stridor or lower airway sounds may be apparent, leading to the consideration of a central nervous system cause. The head circumference is often at the 90th percentile, and the fontanelle may be full or bulging. Retinal hemorrhages often are found, strongly suggesting trauma or intracranial hemorrhage rather than meningitis. Some neurologic signs may be confused with meningitis, such as nuchal rigidity, irritability or coma, seizures, or posturing. The laboratory is helpful in confirming suspicions of intracranial bleeding. Although the CBC often shows a leukocytosis and thus is confusing, the spinal fluid from a shaken baby usually is bloody. A computed axial tomography (CAT) scan or magnetic resonance imaging (MRI) usually demonstrates a small posterior, interhemispheric subdural hematoma. Such shaken babies have a high incidence of serious morbidity and mortality.

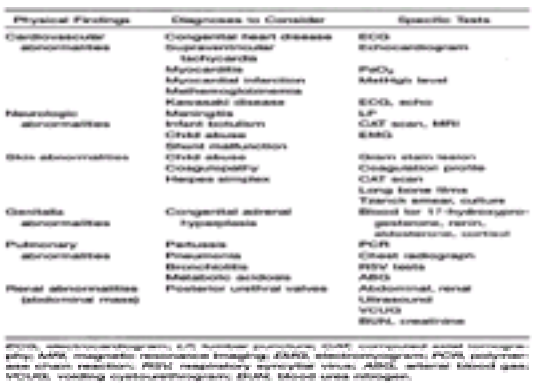
EVALUATION AND DECISION

Any infant who is critically ill in the first few months of life should initially be presumed to have sepsis. Because such illness is a life-threatening situation that may respond to early treatment, it is imperative to stabilize the child rapidly (Fig. 69.1). After airway, breathing, and circulation have been restored, vascular access should be obtained. Unless another diagnosis is immediately obvious, it is best to give intravenous antibiotics while pursuing alternative diagnoses. If time permits, cultures should be sent to the laboratory before giving antibiotics. Use of prostaglandins should be considered if cardiogenic shock is suspected.

FIGURE 69.1. Initial approach to the septic-appearing child.

A complete history should be obtained. It is important to learn of any previous medical problems such as known heart disease or failure to thrive. The time of onset of symptoms, exposure to infection, medications given at home, and specific symptoms noted by the parents must be determined. Next, careful physical examination must be performed because specific findings may lead to a diagnosis other than sepsis (Table 69.3). After the physical examination, a complete laboratory evaluation should be performed. All sick infants should have a blood culture and urine culture obtained by a urethral catheter or suprapubic bladder tap. A lumbar puncture also should be performed unless physical findings point strongly to a diagnosis other than sepsis or the infant is too ill to tolerate the procedure. A chest radiograph is also essential to look for pulmonary infection and to evaluate the heart size. A CBC should be obtained; leukocytosis will add support to a suspicion of sepsis but also may be found in various other disorders, including viral infections, myocarditis, pericarditis, intracranial bleeds, NEC, appendicitis, intussusception, and methemoglobinemia. Because metabolic problems (disturbances in acid-base balance, electrolytes, blood sugar) can result from sepsis or be the primary problem that mimics sepsis, all sick infants should have chemistries to evaluate serum sodium, potassium, chloride, glucose, and bicarbonate. If hyponatremia is found, water intoxication, aspirin toxicity, cystic fibrosis, and CAH should be considered. If there is also a marked hyperkalemia, CAH is most likely. If there is hypochloremic alkalosis or alkalosis alone, then pyloric stenosis, aspirin toxicity, or gastroenteritis should be considered. If there is hypoglycemia, it should be considered secondary to poor glucose reserves in an ill infant or related to drug (aspirin) toxicity, inborn errors of metabolism, CAH, or methemoglobinemia. If the serum bicarbonate is low, this should be confirmed with an arterial blood gas. Then, if acidosis is present, poor perfusion caused by shock should be considered, as well as dehydration,

drug toxicity, methemoglobinemia, appendicitis, CAH, and inborn errors of metabolism, as primary problems.



Physical Findings	Diagnoses to Consider	Specific Tests
Cardiovascular abnormalities	Congenital heart disease	ECG
	Supraventricular tachycardia	Echocardiogram
	Myocarditis	PaO_2
	Myocardial infarction	Met-Hgb level
	Methemoglobinemia	
	Kawasaki disease	ECG, echo
Neurologic abnormalities	Meningitis	LP
	Infant botulism	CAT scan, MRI
	Child abuse	EMG
	Shaken impairment	
Skin abnormalities	Child abuse	Gram stain lesion
	Coagulopathy	Coagulation profile
	Herpes simplex	CAT scan
		Long bone films
		Tzanck smear, culture
Genitalia abnormalities	Congenital adrenal hyperplasia	Blood for 17-hydroxyprogesterone, renin, aldosterone, cortisol
Pulmonary abnormalities	Pertussis	PCR
	Pneumonia	Chest radiograph
	Bronchiolitis	RSV tests
	Metabolic acidosis	ABG
Renal abnormalities (abdominal mass)	Posterior urethral valves	Abdominal, renal Ultrasound
		VCUG
		BUN, creatinine

Table 69.3. Approach to the Septic-Appearing Infant with Characteristic Physical Findings

Finally, if laboratory tests are not revealing for a specific disorder or the patient does not improve quickly as an inpatient receiving antibiotics, stool and CSF isolates for viruses should be considered.

If the physical examination suggests a specific problem, it may be necessary to obtain additional laboratory tests (Table 69.3). For instance, if the examination reveals pallor, cyanosis, or cardiac abnormality (muffled heart sounds, murmur, unexplained tachycardia, or arrhythmia) the physician should consider various cardiac disorders and possibly methemoglobinemia. An ECG, arterial blood to measure PaO_2, and possibly an echocardiogram should then be obtained. If there are unusual neurologic findings, such as a bulging fontanelle, a lumbar puncture should be performed to rule out meningitis, as well as blood studies mentioned previously. The presence of seizures should prompt a CT scan, EEG, and culture and treatment for herpes simplex virus. Also, if marked hypotonia is present, an electromyogram (EMG) may help diagnose botulism. Retinal hemorrhages may suggest an intracranial bleed, and thus a CAT scan, MRI, and lumbar puncture would be valuable studies. Likewise, if there is abdominal distension, rigidity, mass, or bloody stools, this would indicate a gastrointestinal emergency. In such cases, abdominal radiographs, ultrasound, or barium studies would be important diagnostic aids, but a workup for sepsis may still be indicated.

Furthermore, if the physical examination reveals bruises or purpura, further evaluation for child abuse, coagulopathy, and sepsis should be considered. In addition, long bone radiographs, coagulation profile (including platelet count), and Gram stain of the purpura may then be desirable. If vesicular lesions are seen on the skin, a Tzanck smear and culture for herpes should be obtained. If ambiguous genitalia are noted, blood should be drawn for 17-hydroxyprogesterone, renin, aldosterone, and cortisol to rule out CAH (see Chapter 97). Last, if wheezing is detected on chest examination, a nasopharyngeal swab should be sent for rapid slide detection of RSV or for culture of RSV.

CHAPTER 70

Seizures

VINCENT W. CHIANG, MD

Department of Pediatrics, Harvard Medical School, and Division of Emergency Medicine, Children's Hospital, Boston, Massachusetts

Seizures are the most common neurologic disorder in childhood and among the more common symptoms that lead to an emergency department (ED) visit. Studies have shown that 4 to 6% of all children will have at least one seizure in the first 16 years of life. These can range from a self-limited, nonrecurring episode to a prolonged, life-threatening event. The pediatric emergency physician must have a fundamental knowledge of all aspects of seizure management, including initial stabilization, determination of cause (differential diagnosis), appropriate definitive treatment, and patient disposition.

BACKGROUND

A *seizure* is defined as a transient, involuntary alteration of consciousness, behavior, motor activity, sensation, and/or autonomic function caused by an excessive rate and hypersynchrony of discharges from a group of cerebral neurons. A *convulsion* is a seizure with prominent alterations of motor activity. *Epilepsy*, or seizure disorder, is a condition of susceptibility to recurrent seizures.

Seizures may be *generalized* or *partial.* Generalized seizures reflect involvement of both cerebral hemispheres. These may be convulsive or nonconvulsive. Consciousness may be impaired and this impairment may be the initial manifestation. Motor involvement is bilateral. Types of generalized seizures include absence (petit mal), myoclonic, tonic, clonic, atonic, and tonic-clonic (grand mal) seizures.

Partial (focal, local) seizures reflect initial involvement limited to one cerebral hemisphere. Partial seizures are further classified on the basis of whether consciousness is impaired. When consciousness is not impaired, the seizure is classified as a *simple* partial seizure. Simple partial seizures may have motor, somatosensory/sensory, autonomic, or psychic symptoms. When consciousness is impaired, the seizure is classified as a *complex* partial seizure. Both simple and complex partial seizures may evolve into generalized seizures (e.g., Jacksonian march).

Status epilepticus is the condition of prolonged seizure activity (more than 20 to 30 minutes) or persistent, repetitive seizure activity without recovery of consciousness in between episodes.

A *postictal* (decreased responsiveness) period usually follows the seizure. During this time, the patient may be confused, lethargic, fatigued, or irritable; also, headache, vomiting, and muscle soreness may occur. In general, the length of the postictal period is proportional to the length of the seizure. For brief seizures, there may be few or no postictal symptoms. Transient focal deficits (e.g., Todd's paralysis) may occur during the postictal period, but one must first rule out a focal central nervous system (CNS) deficit.

PATHOPHYSIOLOGY

The underlying abnormality in all seizures is the hypersynchrony of neuronal discharges. Cerebral manifestations include increased blood flow, increased oxygen and glucose consumption, and increased carbon dioxide and lactic acid production. If a patient can maintain appropriate oxygenation and ventilation, the increase in cerebral blood flow is usually sufficient to meet the initial increased metabolic requirements of the brain. Brief seizures rarely produce any lasting effects. However, prolonged seizures may result in permanent neuronal injury.

Systemic alterations may occur with seizures and result from a massive sympathetic discharge, leading to tachycardia, hypertension, and hyperglycemia. Failure of adequate ventilation, especially in patients in whom consciousness is impaired, can lead to hypoxia, hypercarbia, and respiratory acidosis. Patients with impaired consciousness may be unable to protect their airway and are at risk for aspiration. Prolonged skeletal muscle activity can lead to lactic acidosis, rhabdomyolysis, hyperkalemia, hyperthermia, and hypoglycemia.

DIFFERENTIAL DIAGNOSIS

It is important to remember that a seizure does not constitute a diagnosis but is merely a symptom of an underlying pathologic process that requires a thorough investigation (Table 70.1). Often, no underlying condition is “identified,” and the diagnosis of idiopathic epilepsy is made. However, it is important not to exclude potentially treatable causes prematurely. For instance, seizures that result from metabolic derangements (e.g., hyponatremia, hypoglycemia) are often refractory to anticonvulsant therapy until the abnormality is corrected. Furthermore, every effort should be made to rule out a potentially life-threatening cause of seizures (e.g., intracranial injury or hemorrhage, meningitis, ingestions) before a less serious diagnosis is accepted.

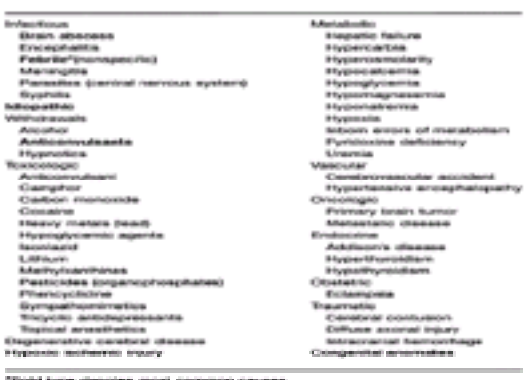

Table 70.1. Etiology of Seizures

Although the diagnosis of a seizure is often made in the ED on the basis of the clinical history, other childhood paroxysmal events are often mistaken for seizure activity (Table 70.2). Every attempt should be made to differentiate these events from seizures to ensure appropriate diagnosis, correct treatment, and accurate prognosis. Each episode or “spell” should be evaluated by examining the preceding events, the episode itself, and the nature and duration of the postictal impairment. If any of these features seem atypical, an alternative diagnosis should be considered.

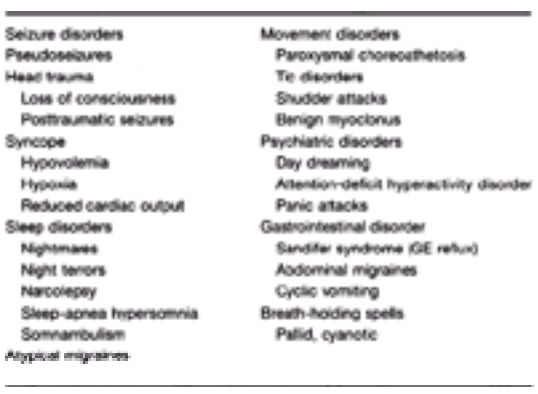

Table 70.2. Differential Diagnosis of Paroxysmal Events

Syncope, or the transient loss of consciousness that results from inadequate cerebral perfusion or substrate delivery, is the most common alternative diagnosis given to patients who present for evaluation of a seizure episode (see Chapter 73). Further complicating matters is the fact that a small percentage of patients with syncope exhibit some sort of convulsive movement. Although vasovagal episodes or orthostatic hypotension are the most common causes for syncope, it is important to evaluate these patients for potential underlying cardiac disease.

Breath-holding spells are common, affecting 4 to 5% of all children (see Chapter 131). They typically present between the ages of 6 and 18 months and disappear by age 5 years. The two types of breath-holding spells—cyanotic and pallid—have common features, including a period of apnea and an alteration in the state of consciousness. Usually, some initiating event (e.g., pain, fear, agitation) triggers the episode. The diagnosis is based on the clinical findings, and the prognosis is excellent.

A variety of movement disorders can mimic seizures. Paroxysmal choreoathetosis is often associated with a positive family history and exacerbated by intentional movement. Tic disorders can be manifested by twitching, blinking, head-shaking, or other repetitive motions. These are usually suppressible and are not associated with any loss of consciousness. Shudder attacks are whole body tremors similar to essential tremor in adults. Benign myoclonus of infancy can look like infantile spasms but is associated with a completely normal electroencephalograph (EEG).

Sleep disorders, such as somnambulism, night terrors (preschool-age children), and narcolepsy (typically in adolescents) can often be diagnosed based on the history alone (see Chapter 131). Infants with gastroesophageal reflux may exhibit torticollis or dystonic posturing (Sandifer syndrome). Atypical migraines and pseudoseizures are often diagnosed after other causes are excluded.

INITIAL STABILIZATION

The first priority in the seizing patient is to address the ABCs (airway, breathing, circulation) (see Chapter 1). An adequate airway is necessary to allow for effective ventilation and oxygenation. Patients with impaired consciousness as part of their seizure are at risk for obstruction (the tongue, oral secretions, emesis), aspiration (loss of protective reflexes), and hypoventilation. Simple maneuvers such as the jaw thrust or suctioning of the oropharynx may improve compromised air flow. The use of adjunctive airways (oral or nasopharyngeal) may also help maintain an adequate airway. In patients who are actively seizing, it may be difficult to insert these adjuncts and the patient may be injured if the intervention is forced. Furthermore, in patients for whom trauma is a possibility, these maneuvers must be undertaken with cervical spine (C-spine) immobilization. In patients in whom the airway remains unstable despite these actions, endotracheal intubation is warranted. When it is necessary to use a muscle relaxant to intubate a seizing patient, one should use the shortest-acting agent possible. The presence of motor activity may be the only clinical manifestation of seizure and a long-acting muscle relaxant will mask the ongoing seizure activity.

The patient's circulatory status must also be closely monitored. Seizures generally cause a massive sympathetic discharge that results in hypertension and tachycardia. Continuous cardiac monitoring and intravenous access should be obtained. Blood samples, including rapid blood glucose testing, should be acquired at this time in an attempt to establish a diagnosis. Peripheral intravenous (IV) access, which is often difficult in the pediatric age group, may be nearly impossible in the actively seizing patient. Intraosseous and/or central venous access may be required in the patient with prolonged seizures.

Once the respiratory and circulatory functions have been assessed and maintained, efforts should be directed at making a diagnosis and stopping any ongoing seizure activity. As long as adequate ventilation and oxygenation are maintained, long-term sequelae are unlikely to result from a transient seizure. The initial increase in cerebral blood flow compensates for any increase in brain metabolic requirements. Consensus management suggests the initiation of anticonvulsant treatment for anyone who has been seizing for more than 10 minutes. This likely represents all patients who are brought to the ED actively seizing.

EVALUATION AND DECISION

History

As a result of the numerous potential causes of seizures, as well as the large number of events that can be mistaken for a seizure, a focused history is important. The parent or caretaker needs to carefully describe the episode and the preceding events. Was there a warning (aura) that the patient was about to have an event? Was there a loss of consciousness, tongue biting, or incontinence? Did the event involve the entire body or only a portion? How long did the event last? How was the patient acting after the event was over?

In addition to the episode itself, the preceding events also are crucial. Was there a history of trauma? toxin exposure or ingestion? fever? other systemic signs of illness (e.g., headache, ataxia, vomiting, diarrhea)? Does the child have an underlying seizure disorder, history of seizures, or other neurologic problems? Is the child taking any anticonvulsants? If yes, was there a recent change in medications or is there a chance that the patient could have a subtherapeutic level? Any other significant medical history (including abnormal developmental history)? Any significant surgical history (including placement of a ventricular shunt)? Family history of seizures? Other medication use? Distant travel history (neurocysticercosis is one of the leading worldwide causes of seizures)?

Physical Examination

With the history, a directed physical examination is performed to look for a possible cause of the seizure. Vital signs, including temperature, need to be obtained. An elevated temperature points to a potential infectious cause. The entire body needs to be examined for evidence of trauma, either as a preceding cause or as a result of falling during the seizure episode. The skin should be examined for rashes or other congenital skin lesions. Dysmorphic features may be associated with other congenital CNS anomalies. Stigmata of underlying hepatic, renal, or endocrinologic disorders should also be noted.

The head should be carefully examined for swelling, deformity, or other signs of trauma. The presence of a ventricular shunt should be noted. The pupils are studied for shape, size, reactivity, and equality. The fundi are examined for the presence of retinal hemorrhages or papilledema. The tympanic membranes are examined for the presence of hemotympanum or for a source of potential infection. The mouth should be examined for evidence of tongue biting.

The neck is assessed for meningeal irritation. If there is a history or other physical signs of trauma, neck immobilization should be maintained until the C-spine can be “cleared.” Examination of the chest, lungs, and abdomen is performed in the usual fashion. The extremities are examined for evidence of trauma, especially as the result of falling during a seizure.

The neurologic examination may be limited by either ongoing seizure activity or a postictal state and may consist solely of the pupillary examination and an assessment of any asymmetric movements (focality). Any abnormal posturing (decerebrate or decorticate) should be noted.

If there is a question of a possible ingestion, the examination is also directed at uncovering a potential toxicologic syndrome (toxidrome) that may suggest a specific class of drugs or toxins that are responsible for the seizure (see Chapter 88). Important variables include temperature, heart rate, blood pressure, pupil size, sweating, flushing, and

cyanosis.

As the patient recovers from the seizure episode, periodic reassessment is needed to assess for any underlying neurologic abnormalities.

Diagnostic Approach (Figure 70.1)

Once it has been determined that a seizure may have taken place, the initial diagnostic evaluation starts with the history and physical. Laboratory, radiologic, and other neurodiagnostic testing (e.g., EEG) are other tools that can be part of the seizure evaluation.

FIGURE 70.1. Diagnostic approach to seizures. The most common causes are in bold type.

Patients with obvious trauma who are seizing should be treated per Advanced Trauma Life Support (ATLS) guidelines (see Chapter 103), with close attention to possible intracranial injury (see Chapter 105).

Often, patients with a known seizure disorder will present to the ED seizing. Patients known or suspected to be taking anticonvulsants should have drug levels evaluated. A subtherapeutic anticonvulsant level is among the most common reasons for patients to present with seizures.

Many different laboratory tests may reveal a cause for a seizure and as a result suggest a potential treatment. A rapid glucose reagent strip should be performed with the initial blood sample. Hypoglycemia is a common problem that can often precipitate seizure activity. If hypoglycemia is documented or a rapid assessment is not available, treatment with 0.25 to 1 g/kg of dextrose is indicated.

A febrile seizure is defined as a seizure caused by a fever, but this is a diagnosis of exclusion. Other infectious etiologies that can be the direct cause of a seizure (e.g., meningitis) must first be ruled out (see Chapter 28 and Chapter 84). Furthermore, infections not involving the CNS may still be the cause of the seizure through the elaboration of fever. Presence of fever or an elevated white blood cell (WBC) count should direct one to look for a potential infectious cause. Blood cultures should be drawn with the initial samples in patients at risk for bacteremia in an effort to identify a specific pathogen. Urinalysis and chest radiographs can also be used to confirm a source of infection.

A lumbar puncture (LP) with analysis of the cerebrospinal fluid (CSF) is the only way to make the diagnosis of meningitis and should be performed when meningitis is being considered. An elevated CSF protein and CSF WBC count and a low CSF glucose are all suggestive of CNS infection. CSF cultures, Gram stain, latex studies, and polymerase chain reaction (PCR) may identify a specific agent. Ideally, CSF cultures should be obtained before antibiotic therapy is initiated. However, in the critically ill or unstable patient, antibiotics should not be withheld until an LP is performed. Furthermore, in cases in which a potential metabolic disease is being considered, CSF lactate, pyruvate, or amino acid determinations can be used to diagnose a specific disorder. In these cases, it is often helpful to collect an extra tube of CSF to be frozen and used for later analysis. In any patient with suspected elevated intracranial pressure (ICP), an LP should not be performed until head imaging can be done.

Electrolyte abnormalities may also cause seizures, with hyponatremia, hypocalcemia, and hypomagnesemia being most common. In general, the routine screening for electrolyte abnormalities in a seizure patient is a low-yield procedure. Unfortunately, seizures caused by electrolyte derangements are often refractory to anticonvulsant therapy, and patients will continue to seize until the underlying abnormality is corrected. Serum electrolytes should be measured in all seizure patients with significant vomiting or diarrhea; with underlying renal, hepatic, neoplastic, or endocrinologic disease; who are taking medications that may lead to electrolyte disturbances; or who have seizures that are refractory to typical anticonvulsant management. One characteristic scenario involves hyponatremic seizures in infants, typically less than 6 months of age, after prolonged feedings of dilute formula (“infantile water intoxication”). Other patients may be evaluated on a case-by-case basis. Intravenous calcium, magnesium, and hypertonic (3%) sodium should be used to treat the appropriate abnormal condition. In the case of hyponatremia, once the seizure activity has been stopped, the rate of sodium correction must be titrated to avoid possible central pontine myelinolysis.

Other chemistries can be helpful in identifying specific organ dysfunction as a cause of the seizure activity or as an assessment of systemic injury. An elevated blood urea nitrogen or creatinine suggests uremia as a potential cause. Elevated liver function tests (transaminases or coagulation times) can be a reflection of hepatic failure. Metabolic acidosis or hyperammonemia can suggest an underlying metabolic disorder. In patients with prolonged seizures, an arterial or venous blood gas can help in assessing adequacy of ventilation, and a creatine kinase (CK) can identify

possible rhabdomyolysis.

Toxicologic screening can also be helpful in the seizing patient because certain ingestions are managed with specific antidotes or treatments. Typically, the clinical scenario is the young child with a possible accidental ingestion or the adolescent after a suicide attempt. In general, the toxicologic screen should be directed at agents known to cause seizures (Table 70.1) or those suggested by a clinical toxidrome.

Radiologic imaging of the seizure patient generally consists of a computed tomographic (CT) scan in the acute-care setting. The following situations should be considered emergent: 1) a patient who has signs or symptoms of elevated ICP, 2) a patient who has a focal seizure or a persistent focal neurologic deficit, 3) a patient who has seizures in the setting of head trauma, 4) a patient who has persistent seizure activity, or 5) a patient who appears ill. Until cervical spine injury is ruled out, it is important to remember to maintain C-spine immobilization in patients for whom head trauma is a concern. Patients with transient generalized seizures in whom a cause of the seizure activity is identified probably do not require any further head imaging studies. Patients with transient generalized seizures in whom no cause is identified and who appear clinically well can have their head imaging performed on a nonemergent basis.

A magnetic resonance imaging (MRI) study has several advantages over a CT scan. MRI is better at identifying underlying white matter abnormalities, disorders of brain architecture, lesions in the neurocutaneous syndromes, lesions in the posterior fossa and the brainstem, and small lesions. In general, it is used in patients on a nonemergent basis.

EEG is an important diagnostic tool in the evaluation of seizure types, response to treatment, and prognosis. It is rarely indicated in the acute-care setting.

Emergency Treatment

Prolonged seizure activity is a true medical emergency. In one series, 88 of 239 patients who had convulsive status epilepticus for more than 1 hour had permanent neurologic sequelae. Thus, following stabilization of the ABCs, further treatment is directed at stopping the seizure activity. Although certain causes of seizures may require a specific treatment, anticonvulsant therapy is initiated simultaneously during the evaluation of the seizing patient (Fig. 70.2). The approach to this subject is detailed in Chapter 83, but some emergency treatment guidelines are reviewed here.

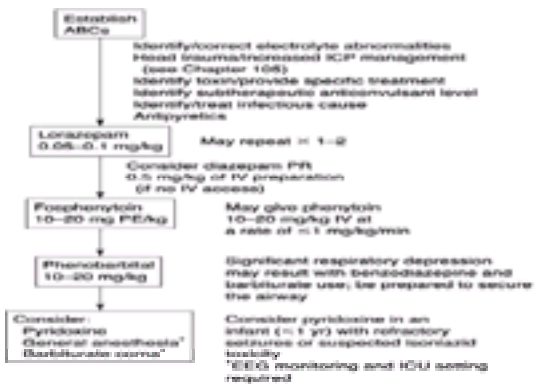

FIGURE 70.2. Management of status epilepticus. *ICP*, intracranial pressure; *PR*, per rectum; *IV,* intravenous; *PE*, phenytoin equivalent; *ICU*, intensive care unit.

The benzodiazepines are the initial drug of choice for the treatment of seizures. Lorazepam (Ativan) has a rapid onset of action (less than 5 minutes) and can be given in the intravenous or intramuscular form. The dose is 0.05 to 0.1 mg/kg with a maximal dose of 4 mg and can be given over 1 to 2 minutes. Its anticonvulsant effects can last for several hours. It may be repeated at 10- to 15-minute intervals, but its effectiveness decreases with successive doses. The major side effects are respiratory depression and sedation (dose dependent), especially when combined with phenobarbital.

Diazepam (Valium) had been the standard initial treatment of seizures for many years before the development of the newer benzodiazepines. Diazepam is similar to lorazepam, but because of its increased lipid solubility, it has a much shorter half-life. Diazepam has an advantage in that it can be given rectally, which is useful when a patient does not have IV access. The IV preparation of the drug should be used when it is given rectally at a dose of 0.5 mg/kg.

Phenytoin (Dilantin) is a second-line agent for the treatment of seizures. The dose is 10 to 20 mg/kg as an initial load. It has several limitations as compared with the benzodiazepines. First, peak CNS concentrations may not be reached until 10 to 30 minutes after its infusion is completed, and thus, it is much slower in onset. Furthermore, it must be administered slowly (no faster than 1 mg/kg per minute) because of concerns of cardiac conduction disturbances, which further lengthens its onset of action. It cannot be given in dextrose-containing solutions.

As a result of the limitations in administration of phenytoin, fosphenytoin (Cerebyx) was created. It is a prodrug whose active metabolite is phenytoin. The drug is dosed as phenytoin equivalents (PE) and the loading dose is 10 to 20 mg PE/kg. The advantages are that it can be given much more rapidly (up to 150 mg PE/minute) and that it may be given in either normal saline or a 5% dextrose–containing solution or intramuscularly.

Phenobarbital (Luminal) is another second-line agent in the treatment of seizures. The loading dose is 10 to 20 mg/kg. Its advantage over phenytoin is that it can be given much more rapidly (100 mg/minute). However, it has an extremely long half-life (up to 120 hours) and a pronounced sedating effect. Furthermore, it can cause significant respiratory depression, especially when given after a benzodiazepine. One must be prepared to intubate a patient who has received both a

benzodiazepine and a barbiturate for the treatment of seizures. It is important to remember that if a patient needs intubation, a muscle relaxant can mask the motor manifestation of seizure activity. With the creation of fosphenytoin, phenobarbital should now be considered a third-line agent.

Paraldehyde was used as a fourth-line agent if the previously discussed therapies had failed to control the seizure activity or when seizing patients had no IV access. It was administered rectally in a corn oil suspension at a dose of 0.3 mL/kg. Its major side effect (besides a foul smell) was metabolic acidosis. Although many centers still have supplies of paraldehyde, it is currently no longer being manufactured.

Pyridoxine deficiency is an uncommon cause of seizures in newborns. One should consider its use in patients less than 1 year of age whose seizure activity is refractory to the other therapies (100 mg). It is also used in the treatment of isoniazid overdose (usual initial dose 70 mg/kg).

If all of the described therapies fail, patients may require general anesthesia to abort the seizures. A variety of agents can be used, such as inhalational anesthetics (e.g., halothane, isoflurane) or large doses of short-acting barbiturates (e.g., pentobarbital). The patient needs both to be intubated (if not already done) and to have continuous EEG monitoring in an intensive care unit. The level of anesthesia should be sufficient to maintain either a flat-line or burst-suppression pattern on the EEG. The anesthesia can be then withdrawn slowly to see if any electrical seizure activity persists.

SPECIAL CONSIDERATIONS

Febrile Seizures

Febrile seizures are the most common convulsive disorder in young children, occurring in 2 to 5% of the population (see Chapter 83). A consensus statement by the National Institutes of Health defines febrile seizures as a seizure occurring between 3 months and 5 years of age that is associated with a fever but without evidence of intracranial infection or other defined cause.

Febrile seizures can be of any type, but most commonly, they are generalized tonic-clonic seizures. They are usually self-limited and last for only a few minutes. Febrile seizures are classified as simple febrile seizures, which last less than 15 minutes and are generalized, and complex febrile seizures, which are prolonged, recur within 24 hours, and are focal. Simple febrile seizures (85%) are much more common. A familial tendency toward febrile seizures exists, but the exact inheritance is uncertain.

After the first febrile seizure, approximately 33% of patients will have at least one recurrence and about 9% will have three or more episodes. The younger the patient is at first presentation, the greater the likelihood of recurrence. Most recurrences (75%) will also happen within 1 year. The exact risk of developing epilepsy after a febrile seizure is unknown, but most studies indicate that it is less than 5%. Risk factors for developing epilepsy after a febrile seizure include abnormal development before the episode, a family history of afebrile seizures, and a complex first febrile seizure.

The treatment of a patient who presents during a febrile seizure is identical to that for other seizure types. The primary goal is the establishment of a clear airway; secondary efforts are then directed at termination of the seizure. However, because most febrile seizures are brief in duration, the typical patient who presents for evaluation of a febrile seizure is no longer seizing upon arrival to the ED. In those instances, if the history is consistent with a simple febrile seizure, the patient has no stigmata of a CNS infection, and the patient's neurologic examination is completely “normal” (the patient may be postictal or slightly hyperreflexive), further evaluation for the cause of the seizure is unnecessary. However, the evaluation should focus on the possible cause of the fever.

It is important to note that typical signs of meningitis may be absent in patients less than 12 to 18 months of age. Furthermore, seizure may be the first presentation of meningitis. Thus, one should strongly consider an LP in all patients less than 12 months who present with a simple febrile seizure, and one should maintain a low threshold to perform one in patients 12 to 18 months of age. LP is recommended in patients with complex febrile seizures or a concerning physical or neurologic evaluation.

Patients who have a simple febrile seizure may be safely discharged to home. Parents should be reassured that febrile seizures are common and that most patients have no further episodes. They need to be cautioned that a recurrence may happen and should be given simple instructions on what to do should another seizure occur. Furthermore, parents should understand that patients with recurrent febrile seizures may still contract meningitis and may require clinical evaluation for this possibility. They can also be instructed on the proper use of antipyretics, even though no studies have been conducted to document that this is effective in reducing the recurrence rate. Finally, any identified source of the fever should be properly treated.

CHAPTER 71

Sore Throat

GARY R. FLEISHER, MD

Department of Pediatrics, Harvard Medical School, and Division of Emergency Medicine, Children's Hospital, Boston, Massachusetts

Sore throat refers to any painful sensation localized to the pharynx or the surrounding areas. Because children, particularly those of preschool age, cannot define their symptoms as precisely as adults, the physician who evaluates a child with a sore throat must first define the exact nature of the complaint. Occasionally, young patients with dysphagia (see Chapter 53) that results from disease in the area of the esophagus or with difficulty swallowing because of a neuromuscular disorder will verbalize these feelings as a sore throat. Careful questioning usually suffices to distinguish between these complaints.

Although a sore throat is less likely to portend a life-threatening disorder than dysphagia or the inability to swallow, this complaint should not be dismissed without a thorough evaluation. Most children with sore throats have self-limiting or easily treated pharyngeal infections, but a few have serious disorders, such as retropharyngeal or lateral pharyngeal abscesses. Even if the reason for the complaint of sore throat is believed to be an infectious pharyngitis, several different organisms may be responsible. Symptomatic therapy, antibiotics, anti-inflammatory drugs, or surgical intervention may be appropriate at times. Most children experience no adverse consequences from misdiagnosis and inappropriate therapy, but a few may develop local extension of infection; chronically debilitating illnesses, such as rheumatic fever; or life-threatening airway obstruction.

DIFFERENTIAL DIAGNOSIS

Infectious Pharyngitis

Infection is the most common cause of sore throat and usually is caused by respiratory viruses, including adenoviruses, coxsackie A viruses, or parainfluenza virus (Table 71.1, Table 71.2 and Table 71.3). Several of the respiratory viruses produce easily identifiable syndromes, including hand–foot–mouth disease (coxsackievirus) and pharyngoconjunctival fever (adenovirus). These viral infections are closely followed in frequency by bacterial infections caused by group A streptococcus *(Streptococcus pyogenes).* In the winter months during streptococcal outbreaks, as many as 30 to 50% of episodes of pharyngitis may be caused by *S. pyogenes*. The only other common infectious agent in pharyngitis is the Epstein-Barr virus, which causes infectious mononucleosis. Although infectious mononucleosis is not often seen in children under 5 years of age (Fig. 71.1), it cannot be considered rare even during these early years of life. More commonly, however, it affects the adolescent. An additional consideration in adolescents with an infectious mononucleosis-like syndrome is human immunodeficiency virus (HIV).

Infectious pharyngitis	Other Causes
Respiratory viruses	Herpetic stomatitis
Group A streptococci	Irritative pharyngitis
Epstein-Barr virus (infectious mononucleosis)	Foreign body
Human immunodeficiency virus	Peritonsillar abscess
Neisseria gonorrhoeae	Retropharyngeal and lateral pharyngeal abscesses
Anaerobic bacteria	Epiglottitis
Group C and G streptococci (?)	Kawasaki disease
Arcanobacterium haemolyticum (?)	Chemical exposure
Mycoplasma pneumoniae (?)	Psychogenic pain
Chlamydia pneumoniae (?)	Referred pain
Francisella tularensis	
Corynebacterium diphtheriae (diphtheria)

Table 71.3. Life-Threatening Causes of Sore Throat

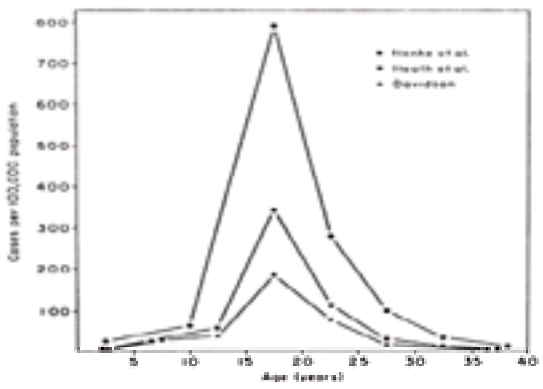

FIGURE 71.1. Incidence by age of infectious mononucleosis in three large studies.

Other organisms produce pharyngitis only rarely; these include *Neisseria gonorrhoeae, Corynebacterium diphtheriae, Francisella tularensis*, and anaerobic bacteria. *N. gonorrhoeae* may cause inflammation and exudate but more often remains quiescent, being diagnosed only by culture. Diphtheria is a life-threatening but seldom encountered cause of infectious pharyngitis, characterized by a thick membrane and marked cervical adenopathy. Oropharyngeal tularemia is rare and should be entertained only in endemic areas among children who have an exudative pharyngitis that cannot be categorized by standard diagnostic testing and/or persists despite antibiotic therapy. Although unusual, mixed anaerobic infections should be considered in the ill-appearing adolescent with a severe pharyngitis because these organisms occasionally lead to sepsis (Lemierre's disease). Other bacteria—group C and G streptococci, *Arcanobacterium hemolyticum, Mycoplasma pneumoniae*, and *Chlamydia pneumoniae*—have been implicated as agents of pharyngitis in adults, but in childhood, their roles remain unproved and their frequency is unknown.

Irritative Pharyngitis/Foreign Body

Drying of the pharynx may irritate the mucosa, leading to a complaint of sore throat. This condition occurs most commonly during the winter months, particularly after a night's sleep in a house with forced hot-air heating. Occasionally, a foreign object such as a fishbone may become embedded in the pharynx.

Herpetic Stomatitis

Stomatitis caused by herpes simplex usually is confined to the anterior buccal mucosa but may extend to the anterior tonsillar pillars. Particularly in these more extensive cases, the child may complain of a sore throat.

Peritonsillar Abscess

A peritonsillar abscess may complicate a previously diagnosed infectious pharyngitis or may be the initial source of a

child's discomfort. This disease is most common in older children and adolescents. The diagnosis is evident from visual inspection, augmented occasionally by careful palpation. These abscesses produce a bulge in the posterior aspect of the soft palate, deviate the uvula to the contralateral side of the pharynx, and have a fluctuant quality on palpation.

Retropharyngeal and Lateral Pharyngeal Abscesses

Retropharyngeal abscess is an uncommon cause of sore throat, usually occurring in children less than 4 years of age. Although most children with this disorder appear toxic and have respiratory distress, a few complain of sore throat and dysphagia without other manifestations early in the course. A soft-tissue radiographic examination of the lateral neck demonstrates the lesion readily, whereas direct visualization often is impossible. Unfortunately, even limited flexion of the neck during the radiograph may cause a buckling of the retropharyngeal tissues that resembles a purulent collection. The physician must insist on a film with the neck fully extended before hazarding an interpretation. If the diagnosis remains uncertain despite adequate radiographs, a computed tomography (CT) scan should be obtained.

Lateral pharyngeal abscesses manifest in a fashion similar to retropharyngeal infections but occur less often. High fever is a common symptom, and both trismus and swelling below the mandible may be seen. To confirm the diagnosis, a CT scan is appropriate.

Epiglottitis

The incidence of epiglottitis, a well-appreciated cause of life-threatening upper airway infection, has declined significantly since the introduction of vaccination against *Haemophilus influenzae* type b. This disease manifests with a toxic appearance, high fever, stridor, and drooling. In every reported series of cases, sore throat appears on the list of symptoms. Although rarely this may be the primary complaint in a child, other more striking findings almost always predominate. Epiglottitis should be excluded easily as a diagnosis in the patient with a sore throat who is without stridor and appears relatively well.

Kawasaki Disease

Kawasaki disease is characterized by high fever along with at least four of the five following findings: 1) conjunctivitis, 2) mucositis, 3) peripheral erythema and/or edema, 4) truncal rash, and 5) cervical adenopathy. The mucositis most commonly involves the lips, but occasionally pharyngitis may be a prominent feature.

Chemical Exposure

Certain ingestions, such as paraquat and various alkalis, may produce a chemical injury to the mucosa of the pharynx. Usually, these findings occur in the setting of a known ingestion and are accompanied by lesions of the oral mucosa. In addition, several systemic inflammatory conditions (Behçet's syndrome and Stevens-Johnson syndrome) may involve the pharynx.

Referred Pain

Occasionally, pain from inflammation of extrapharyngeal structures is described as arising in the pharynx. Examples include dental abscesses, cervical adenitis, and occasionally, otitis media.

Psychogenic Pharyngitis

Some children who complain of a sore throat have no organic explanation for their complaint after a thorough history and physical examination and a throat culture. In these cases, the physician should consider the possibility of anxiety, at times associated with frequent or difficult (globus hystericus) swallowing.

Pharyngitis in the Immunosuppressed Host

Immunosuppressed hosts may develop pharyngitis from any of the previously discussed causes. In addition, these patients exhibit a particular susceptibility to infections with fungal organisms, such as *Candida albicans.*

EVALUATION AND DECISION

The history and physical examination should focus on findings seen with systemic illnesses causing pharyngitis and the appearance of the oral cavity. A medical history of an immunosuppressive disorder or missed immunizations raises the specter of unusual infections. A sudden onset is most characteristic of epiglottis.

Fever, either historical or measured, points to an infection or, less commonly, Kawasaki disease. Toxicity and/or respiratory distress occurs with infections leading to respiratory obstruction, such as peritonsillar, retropharyngeal, and lateral pharyngeal abscesses; epiglottitis; diphtheria; and infectious mononucleosis with severe tonsillar hypertrophy. Conjunctivitis suggests pharyngoconjunctival fever (adenovirus) or Kawasaki disease; generalized adenopathy occurs with infectious mononucleosis and human immunodeficiency virus (HIV); and a rash is seen with scarlet fever (group A streptococcus), Kawasaki disease, and infectious mononucleosis, particularly after the administration of amoxicillin.

The tendency of most clinicians is to assume that one of the common organisms is the cause of pharyngitis in the child with a sore throat. Before settling on infectious pharyngitis, however, the emergency physician should first consider several more serious disorders (Fig. 71.2). Conditions that have immediate life-threatening potential include epiglottitis, retropharyngeal and lateral pharyngeal abscesses, peritonsillar abscess, severe tonsillar hypertrophy (usually as an exaggerated manifestation of infectious mononucleosis), and diphtheria. Generally, stridor and signs of respiratory

distress accompany the complaint of sore throat in epiglottitis and retropharyngeal abscess. Drooling and voice changes are common in children with these two conditions, as well as in patients with peritonsillar abscess and severe infectious tonsillar hypertrophy. In cases of epiglottitis or retropharyngeal abscess that are not clinically obvious, a lateral neck radiograph, obtained under appropriate supervision, is confirmatory. Peritonsillar abscess and tonsillar hypertrophy are diagnosed by visual examination of the pharynx. Diphtheria is rarely a consideration except in unimmunized children, particularly those from underdeveloped nations.

FIGURE 71.2. Diagnostic approach to the child with sore throat.

The next phase of the evaluation of the child with a complaint of sore throat hinges on a careful physical examination, particularly of the pharynx (Fig. 71.2). The appearance of vesicles on the buccal mucosa anterior to the tonsillar pillars points to a herpetic stomatitis or noninfectious syndromes, such as Behçet's or Stevens-Johnson syndrome (erythema multiforme). Uncommonly, a small, pointed foreign body, most commonly a fishbone, becomes lodged in the mucosal folds of the tonsils or pharynx; usually, the history suggests the diagnosis, but an unanticipated sighting may occur in the younger child. Significant asymmetry of the tonsils indicates a peritonsillar cellulitis or, if extensive, an abscess. Clinically, the diagnosis of an abscess is reserved for the tonsil that protrudes beyond the midline, causing the uvula to deviate to the uninvolved side. Kawasaki disease produces a systemic syndrome with a prolonged fever and other characteristic findings that are usually more prominent than the pharyngeal involvement.

The remaining organic diagnoses, once those already discussed have been eliminated by history, physical examination, and occasionally, imaging, include referred pain, irritative pharyngitis, and infectious pharyngitis. Sources of referred pain (otitis media, dental abscess, and cervical adenitis) usually are identified during the examination. Irritative pharyngitis, seen most commonly during the winter among older children who live in homes with forced hot-air heating, produces minimal or no pharyngeal inflammation. It often is transient, appearing on arising and resolving by midday.

Infectious pharyngitis (Fig. 71.3) evokes a spectrum of inflammatory responses that range from minimal injection of the mucosa to beefy erythema with exudation and edema formation. The three relatively common causes are streptococci, respiratory viruses, and infectious mononucleosis (Fig. 71.3). In a few cases, a viral pharyngitis that results from coxsackievirus infection will be self-evident on the basis of vesicular formation in the posterior pharynx or involvement of the extremities (hand–foot–mouth syndrome). Such patients require only symptomatic therapy. A small number of additional patients will have signs of infectious mononucleosis: large, mildly tender posterior cervical lymph nodes; diffuse lymphadenopathy; and/or hepatosplenomegaly. In these children, the physician should obtain a white blood cell (WBC) count with differential and a slide test for heterophil antibody (Fig. 71.4) in an effort to confirm the clinical diagnosis, thereby guiding therapy and discussion of prognosis. Some children, especially those less than 5 years of age, will not have the characteristic lymphocytosis or heterophil antibody response and will require repeated testing or specific serologic assays for antibodies to Epstein-Barr virus. In the rare child with an unusual history, the physician must pursue diagnoses such as gonococcal pharyngitis (sexual abuse, oral sex) or diphtheria (immigration from an underdeveloped nation, lack of immunization).

FIGURE 71.3. Diagnostic approach to infectious pharyngitis in the immunocompetent child.

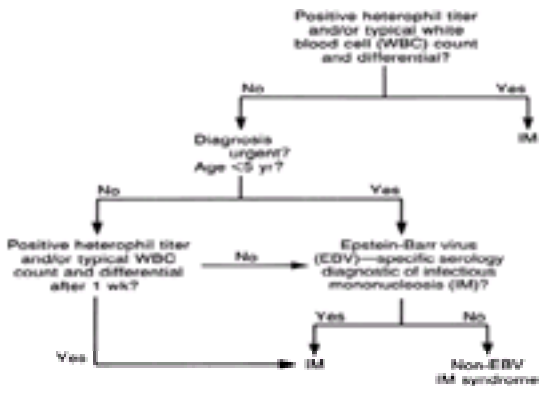

FIGURE 71.4. Diagnostic approach when findings are clinically suggestive for mononucleosis.

Ultimately, most children will have a mildly to moderately inflamed pharynx but no specific etiologic diagnosis based solely on the history and physical examination. Although certain symptoms and signs favor streptococcal infection, none is conclusive. Thus, obtaining a rapid test (latex agglutination or optical immunoassay) for group A streptococcus, followed by a culture, if negative, is prudent. Rapid tests are most helpful when positive because specificity of the tests is high; however, a negative test does not exclude streptococcal infection reliably, although some authorities would be satisfied with a negative optical immunoassay alone. With the recent reported rise in the incidence of rheumatic fever, the accurate diagnosis of streptococcal pharyngitis assumes increasing importance. Generally, symptomatic therapy suffices in the patient with a negative rapid test, although the physician may elect to initiate therapy with penicillin while awaiting the results of the throat culture in selected cases with highly suggestive clinical features.

CHAPTER 72

Stridor

HOLLY PERRY, MD

Department of Pediatrics, Division of Emergency Medicine, University of Connecticut School of Medicine, Farmington, and Pediatric Emergency Department, Connecticut Children's Medical Center, Hartford, Connecticut

Stridor, although a relatively common occurrence, can be frightening to both child and parents. The presence of stridor necessitates a complete and careful evaluation to determine the cause of this worrisome and occasionally life-threatening symptom. This chapter presents the causes of stridor and provides the emergency practitioner with guidelines for initial evaluation and management.

PATHOPHYSIOLOGY

Stridor is an externally audible sound associated with respiration. It is produced by turbulent air flow through large airways. It occurs when a normal respiratory volume of air moves through narrowed airways, which results in the normal laminar flow becoming turbulent. Stridor thus signifies partial airway obstruction.

DIFFERENTIAL DIAGNOSIS

Stridor may occur in a wide variety of disease processes affecting the large airways from the nares to the bronchi but most often arises with disorders of the larynx and trachea (Table 72.1). For the purposes of differential diagnosis, it is helpful to categorize the common causes of stridor as acute or chronic in onset and to further divide acute onset into febrile and afebrile causes (Table 72.2). In addition, life-threatening causes of stridor must be considered during the earliest phases of evaluation (Table 72.3).

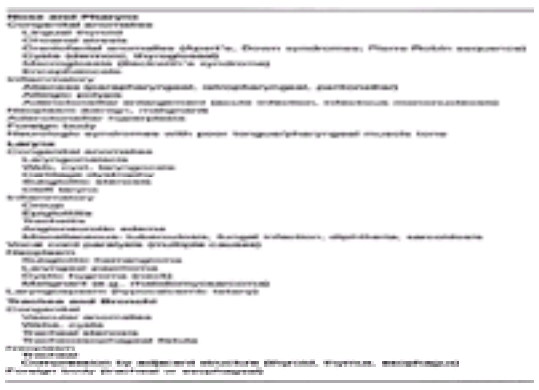

Table 72.1. Causes of Stridor by Anatomic Location

Table 72.2. Common Causes of Stridor

Usually Febrile	Usually Afebrile
Epiglottitis	Foreign body
Retropharyngeal abscess	Angioneurotic edema
Tracheitis	Neck trauma
	Neoplasm (compressing trachea)
	Thermal or caustic injury

Table 72.3. Life-Threatening Causes of Stridor

Stridor with Acute Onset in the Febrile Child

Laryngotracheitis (croup) is by far the most common cause of stridor in the febrile child. However, it is important to consider other diagnoses such as retropharyngeal abscess, epiglottitis, and tracheitis (see Chapter 84). Although rare, these diseases are life-threatening causes of inspiratory stridor. History and physical examination are important tools in determining which patients with inspiratory stridor need further evaluation.

Laryngotracheitis affects children most often between 6 to 36 months of age but is seen throughout childhood. The illness begins with upper respiratory tract symptoms and fever, usually ranging from 38° to 39°C (100.4° to 102.2°F). Within 12 to 48 hours, a barky, “seal-like” cough and inspiratory stridor are noted. Supraclavicular and subcostal retractions may be present. Symptoms are aggravated by crying and ameliorated by cool mist or nebulized epinephrine. Most children appear only mildly or moderately ill.

Tracheitis closely resembles croup except that affected patients generally appear toxic, tend to be older (4 to 6 years), and do not respond as well to cool mist or nebulized epinephrine. Dysphagia is common, and drooling may be present. The verbal child may complain of anterior neck pain or a painful cough. Less severe cases can more closely resemble croup.

Epiglottitis may be divided into disease caused by *Haemophilus influenzaen* or that caused by other pathogens. Patients with *H. influenzae* epiglottitis appear toxic and are febrile. Respiratory distress and a tripod stance are characteristic; drooling is usually present. *H. influenzae* epiglottitis is associated with sudden airway compromise that can be precipitated by manipulation of the oropharynx. Therefore, children in whom *H. influenzae* epiglottitis is strongly suspected should have the airway inspected under controlled conditions.

Epiglottitis caused by pathogens other than *H. influenzae* differs in many important ways from disease caused by *H. influenzae.* It is much more common in adults, has a slower onset, and is more likely to be associated with difficulty swallowing or sore throat. Last, the risk of airway compromise is also less than with epiglottitis caused by *H. influenzae.* However, any child with epiglottitis should be managed as if he or she has disease caused by *H. influenzae.*

The clinical picture of a retropharyngeal abscess is similar to epiglottitis except symptoms appear more gradually. In addition to drooling and stridor, meningismus caused by muscular irritation by the abscess may be present. Physical examination may rarely reveal midline swelling of the pharynx.

Stridor with Acute Onset in the Afebrile Child

A foreign body in either the trachea or esophagus may produce stridor. There may be a history of choking on food or a small object. Physical examination varies, depending on location of the foreign body.

Ingestion of either caustic or hot substances may result in injury to the airway or hypopharynx. Symptoms of airway compromise may be delayed for as long as 6 hours. Drug abuse is yet another potential source of injury: thermal epiglottitis has been reported after inhalation of crack smoke, a screen from a crack pipe, and a marijuana cigarette.

Other causes include spasmodic croup, angioneurotic edema, and trauma (see Chapter 112).

Chronic Stridor

The age at onset narrows the differential diagnosis. Stridor noted shortly after birth is most likely caused by a structural defect. This type of stridor tends to slowly worsen and is severe only when the infant is stressed such as during crying. Laryngomalacia is the most common cause of congenital stridor. Stridor associated with laryngomalacia is positional and is ameliorated by placing the infant in the prone position. Other congenital causes of stridor include laryngeal webs, laryngeal diverticula, vocal cord paralysis, subglottic stenosis, tracheomalacia, and vascular anomalies such as a double aortic arch or a vascular sling. Stridor in infants has also been reported to be associated with gastroesophageal reflux.

Stridor in older children may be caused by papillomas or neoplastic processes. Patients with papillomas generally present between 2 to 4 years of age with complaints of hoarseness and stridor. Neoplastic processes causing tracheal compression can also lead to stridor in the older child.

Psychogenic, also called functional, stridor is an uncommon cause of stridor in the older child. Cases have been reported

in adolescents, with the youngest age being 10 years old. Adolescent girls are diagnosed three times more often with this condition than are males. More than 50% of patients meet diagnostic criteria for a psychiatric disorder. Characteristically, stridor improves when the patient is unaware that he or she is being observed, and it may clear with cough. The diagnosis can be confirmed only by direct laryngoscopy in the symptomatic patient when the vocal cords are noted to be adducted during inspiration.

EVALUATION AND DECISION

The first priority is to ensure that the airway is adequate by assessing level of consciousness, color, perfusion, air entry, breath sounds, and work of breathing, including respiratory rate, nasal flaring, and retractions. Resuscitative measures should be instituted as necessary (see Chapter 5). The child may then be evaluated systematically. In the child with acute onset of stridor, history should focus on associated symptoms such as fever, duration of illness, drooling, rhinorrhea, and history of choking (Fig. 72.1). Immunization status should be verified, particularly *H. influenzae* vaccination. In the case of a child with chronic stridor, important historical points include onset and progression of stridor, as well as ameliorating and aggravating factors.

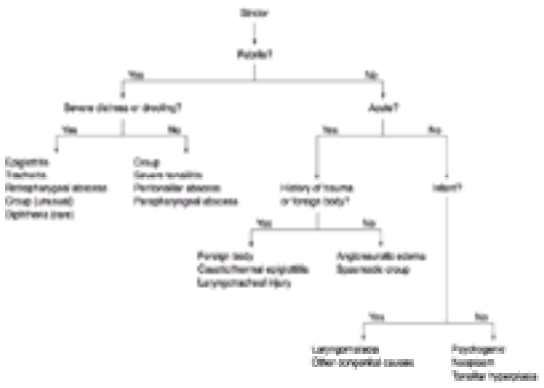

FIGURE 72.1. Diagnostic approach to stridor.

Several characteristics of stridor such as associated phase of respiration, pitch, and length of respiratory phase can help determine the level of obstruction. Inspiratory stridor occurs with obstruction of the extrathoracic trachea, biphasic stridor when both extrathoracic and intrathoracic trachea are involved, and expiratory stridor when only the intrathoracic trachea is involved. The pitch of the stridor also helps determine location. Laryngeal and subglottic obstructions are associated with high-pitched stridor. In contrast, obstruction of the nares and nasopharynx results in lower-pitched snoring or snorting sounds also called stertor. Because the passage of saliva and the flow of air are impeded in pharyngeal obstruction, these patients often have a gurgling quality of breathing. Last, the relative length of inspiratory and expiratory phase may be helpful. In children with laryngeal obstruction, the time of inspiration is greatly increased, whereas expiration tends to be prolonged in bronchial obstruction. Both inspiration and expiration times are increased in patients with tracheal obstruction.

Physical examination should include careful examination of the nares and oropharanyx with particular attention to increased secretions, drooling, visible mass, and abnormal phonation. Regional findings such as adenopathy, neck masses, meningismus, trauma, or bruising should also be sought. Position of comfort should be noted. Children with airway obstruction at the level of the larynx and above usually hyperextend their heads upon their necks and lean forward (“sniffing” position) in an effort to straighten their upper airway and maximize air entry. This posture does not help relieve more distal obstruction. Quality of the voice should be noted as normal, hoarse (vocal cord paralysis, papilloma), weak (neuromuscular disorder), or aphonic (laryngeal obstruction by a foreign body). Response to therapies, such as nebulized racemic epinephrine (croup), should be noted.

Emergency management of the child with stridor depends on its severity and its likely cause. Oxygen, humidified air, nebulized racemic epinephrine, corticosteroids, laryngoscopy, intubation, and even emergency cricothyroidotomy or tracheostomy all have specific roles in the emergency department (ED) management of stridor, depending on its cause (see Chapter 112 and Chapter 121).

Febrile Child

In the febrile child with stridor, the onset is generally acute and the most likely, as well as concerning, diagnostic possibilities are croup, epiglottitis, and bacterial tracheitis. Radiographs of the neck may be helpful in evaluation and should be considered if the practitioner suspects a diagnosis other than croup. If epiglottitis is strongly suspected, a lateral neck radiograph should be obtained in the ED or the child should be taken to the operating room to have direct visualization of the epiglottis under controlled conditions. Abnormal findings on a lateral neck radiograph include increased prevertebral width (retropharyngeal abcess), swollen epiglottis or aryepiglottic folds (epiglottitis), and irregular tracheal borders or stranding across the trachea (tracheitis). Radiographic findings consistent with croup are a narrowed subglottic area on anteroposterior view (the “steeple sign”) and ballooning of the hypopharynx, best appreciated on the lateral view. Airway films must be interpreted with care because they are subject to artifact. To properly interpret the prevertebral space, the lateral neck radiograph must be taken with the patient's head extended and during inspiration. Normal tracheal buckling, which is seen during expiration in a young child, may be misinterpreted as tracheal mass lesion or deviation from an extrinsic mass (Fig. 72.2).

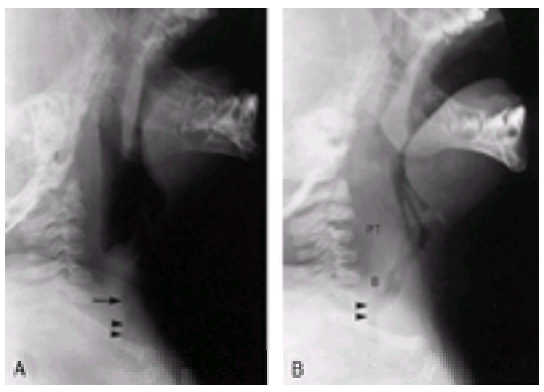

FIGURE 72.2. Inspiratory **(A)** and expiratory **(B)** lateral neck radiographs of a child with upper airway obstruction secondary to a granuloma *(arrow)* in the upper trachea. Note ballooning of the pharynx during inspiration **(A)** and narrowing of the trachea *(arrowheads)* below the level of obstruction. On expiration **(B)** note the normal pharyngeal lumen and dilation *(arrowheads)* of the trachea distal to the obstruction. The "bunching up" of the pharyngeal tissues *(PT)* and the buckling of the trachea **(B)** are normal findings on expiratory films.

Afebrile Child

In the afebrile child with acute onset of stridor, the duration of stridor, the likelihood of foreign body aspiration, and the child's age are all key elements to consider. Emergent otolaryngologic or surgical consultation should be obtained in a child with evidence of airway obstruction if either aspirated foreign body or trauma are likely causes of stridor. Angioneurotic edema, an autosomal-dominant trait, is characterized by rapid onset of swelling without discoloration, urticaria, or pain. Symptoms may occur in affected patients as young as 2 years of age but usually are not severe until adolescence; they may be precipitated by trauma, emotional stress, or menses. A C_1 esterase inhibitor level should be considered if angioneurotic edema is suspected.

A child with chronic stridor generally does not require an extensive evaluation in the ED unless significant respiratory distress is present. The infant with chronic stridor who is otherwise well should be referred back to the private pediatrician or to an otolaryngologist. Once a neoplastic cause is deemed unlikely, the older child with chronic stridor should be referred to otolaryngology for evaluation, including direct visualization of the vocal cords.

Figure 72.1 presents an algorithm that summarizes the ED diagnostic approach to the child with stridor.

CHAPTER 73

Syncope

CARLOS A. DELGADO, MD

Department of Pediatrics, Emory University School of Medicine, and Division of Pediatric Emergency Medicine, Egleston Children's Hospital, Atlanta, Georgia

From the Greek *synkoptein*, meaning “to cut short,” syncope is defined as the temporary loss of consciousness and postural tone, resulting from an abrupt, transient, and diffuse reversible disturbance of cerebral function. Often, the terms *fainting* or *blackout* spells are used. Pathophysiologically, syncope can be explained as a sudden reduction in delivery of substrates such as O_2 or glucose to the brain. Most transient altered consciousness events in children include seizures, syncopes, or hysteric episodes (“fits, faints, or fakes”) and the approach to diagnosis of the former is to exclude the latter two.

Syncope during childhood is generally a benign, isolated event, although in few instances, it can represent potentially life-threatening causes. A thorough history and physical examination, with attention to clues provided by the premonitory signs and symptoms, are usually sufficient to provide the cause of syncope in most cases. An overall incidence in the pediatric population of 0.1 to 0.5% has been reported. Syncope occurs predominantly in teenagers, with a peak incidence occurring between 15 and 19 years. Females were evaluated more commonly than males. It is estimated that at least 50% of all individuals will have a least one syncopal episode during their adolescence. Syncopal events account for 1 to 3% of all emergency room visits, and in this setting, the patient has usually regained consciousness by the time of initial assessment by a physician.

DIFFERENTIAL DIAGNOSIS

Pathophysiologically, all causes of transient and abrupt onset of alterations of consciousness can be best categorized in three broad groups (Table 73.1): 1) true syncope reflecting any mechanism that causes a transient decrease in substrate delivery to the brain (e.g., O_2, glucose, blood); 2) all seizures; and 3) hysterical pseudoloss of consciousness. Most children and adolescents who faint have orthostatic syncope, vasovagal episodes, or breath-holding spells (Table 73.2). This is in marked contrast to adults, who often have cardiovascular disease. Studies report obtaining a definite cause of the syncopal episode in 27% of all pediatric cases, of which migraines were found in 11%, seizures in 8%, and cardiac causes in 6%. Most cases were classified as vasovagal episodes.

1. Transient decrease in substrate delivery to the brain: syncope	3. Hysterical pseudoloss of consciousness
2. Seizures	

Table 73.1. Pathophysiologic Classification of Transient, Paroxysmal, Altered Consciousness

Table 73.2. Common Causes of Syncope

The goal in evaluating syncopal episodes must be to accurately identify the common benign events from the occasional warning signs of serious pathology. The causes of true syncope may be classified into three etiologic categories: *autonomic* (vasovagal), *cardiovascular,* and *metabolic.* Table 73.3 lists the major causes of syncope and conditions that mimic it.

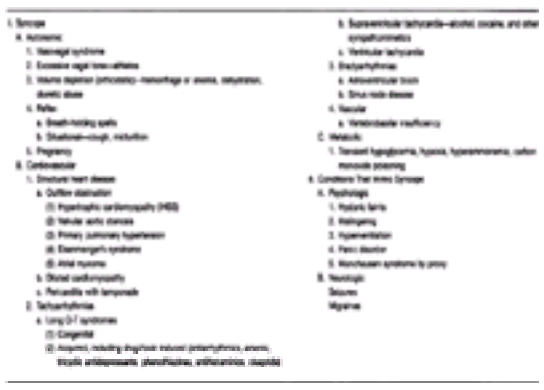

Table 73.3. Classification of Syncopal Episodes

Vasovagal Syncope

Vasovagal syncope is also called neurocardiogenic syncope, vasodepressor syncope, or fainting spell. It is by far the most common cause of fainting in children and adolescents. It accounts for more than 50% of cases of childhood syncope.

The pathophysiologic mechanism of vasovagal syncope is thought to be caused by an exaggerated Bezold-Jarisch reflex. This reflex is responsible for maintaining blood pressure during orthostatic stress. In patients prone to syncope, the cascade of events begins with a decrease in systemic venous return and therefore decreased preload after prolonged upright posture. Enhanced or compensatory sympathetic activity causes an elevation of circulating catecholamines (particularly epinephrine), which increase left ventricular contractility in a relatively empty ventricle. In response, a negative feedback loop via vagal afferents results in sympathetic withdrawal *(hypotensive vasodepressor response)* and augmented vagal tone *(the bradycardic cardioinhibitory response).* The factors that trigger this abnormal response are still unclear. It is probable that a combination of abnormal catecholamine response to orthostatic or other stress, exaggerated ventricular contraction, diminished ventricular volume from venous pooling in the upright position, and enhanced sensitivity of ventricular mechanoreceptors are all involved in the clinical predisposition to recurrent vasovagal syncope.

Most episodes occur while the patient is standing or during a rapid change from a supine or sitting position to standing. Syncope represents a cascade of signs and symptoms that begin with a brief prodrome or presyncopal phase. This progresses to a brief and sudden stage of unconsciousness that typically lasts 1 to 2 minutes and ends with arousal to a previous level of consciousness within a short period.

A syncopal episode may be triggered by a wide array of emotional events such as pain, fear, and anxiety, which increase circulatory catecholamines in response to a real or perceived threat. The prodromal symptoms may include light-headedness, dizziness, nausea, shortness of breath, diaphoresis, pallor, and visual changes. Physical conditions such as anemia, dehydration, exertion, hunger, pregnancy, and/or concurrent illness can predispose to a syncopal event. Other factors include confinement to enclosed or poorly ventilated spaces and environmental heat. The patient may remain nauseated, pale, and diaphoretic for several hours after the syncopal episode.

A full syncope can be avoided if the patient recognizes the prodromal symptoms and assumes a supine or Trendelenburg position. Prognostically, vasovagal syncope is considered a benign illness. A prophylactic approach is taken to prevent symptoms of presyncope or near-syncope. Patient education must be geared toward rapid symptom recognition, allowing the patient to assume a recumbent position and abort a potential syncopal event. Other preventative measures may include avoidance of dehydration and use of salt-enriched diets during athletic activity or environmental stress.

Several other related forms of autonomic syncope are orthostatic hypotensive syncope and situational syncope related to

micturition, defecation, cough, and swallow. Orthostatic hypotensive syncope is associated with an excessive and prolonged fall in blood pressure on assuming the erect posture from a recumbent position. An unusual and uncommon condition, micturition syncope, follows rapid bladder decompression, in which reduced cardiac return is associated with both postural effects and splanchnic vascular stasis. Underlying medical conditions such as anemia or pregnancy may exacerbate the tendency toward any of these vasovagal events.

Another common, usually benign, pediatric variant of vasovagal syncope is that of breath-holding spells, which occur in two forms (see Chapter 131). *Pallid* breath-holding spells result from vagally mediated cardiac inhibition. *Cyanotic* breath-holding spells involve interplay between hyperventilation, Valsalva maneuver, expiratory apnea, and intrinsic pulmonary mechanisms. In pallid breath-holding spells, an inconsequential injury induced by a sudden emotional stimulus such as pain, fright, or anger provokes one or two short cries, followed by pallor and sudden loss of consciousness. In cyanotic spells, the initial result is followed by vigorous crying and breath-holding in expiration, then loss of consciousness. These events typically occur in children between 6 and 18 months of age.

Cardiac Syncope

Syncope caused by significant cardiac or vascular pathology occurs far less often than autonomic syncope. It does not follow the stimuli typical of vasovagal syncope. Hypercyanotic spells, usually associated with tetralogy of Fallot, can occur with any heart defect associated with intracardiac right-to-left shunting. An increase in obstruction to pulmonary blood flow or a fall in systemic vascular resistance can precipitate such a spell. The most common arrhythmia causing syncope with an apparently normal heart structurally is supraventricular tachycardia (SVT), especially in the context of Wolff-Parkinson-White (WPW) syndrome. Arrhythmias occur more often in structurally abnormal hearts. Many drugs and toxins may induce arrhythmias (Table 74.4).

	Syncope, Vasovagal	Metabolic (e.g., hypoxia, hypoglycemia)	Seizure	Breath-holding
Period of Unconsciousness	Usually seconds	Variable	Minutes or longer	Seconds
Prodrome	Fright, pain, "feels faint"	Confusion, altered mental status, ↑ HR, diaphoresis	Occasional aura	Pain, fright → vigorous cry → apnea → LOC
Incontinence	Absent	Absent	May be present	Absent
Confusion on awakening	Absent or mild	Mild	Marked	Absent
Tonic-clonic movements	Occasionally present, if LOC is prolonged	May occur	Commonly present	Rare, may see 1–2 beats
EEG	Normal	Normal	Often abnormal	Normal

EEG, Electroencephalogram; HR, heart rate; LOC, loss of consciousness.

Table 73.4. Differentiating Syncope from Other “Spells”

The diagnosis of prolonged Q-T syndrome is made by documenting the prolongation of the corrected Q-T (Q-Tc greater than 0.45 seconds) interval by Bazett's formula. The prolongation of the Q-Tc interval results from a prolongation of the refractory period of the ventricular myocardium, which places it at risk for “torsades de pointes,” a malignant form of ventricular tachycardia (VT) (see Chapter 82). Prolonged Q-T syndrome can be congenital or acquired. Syncope occurs because of paroxysmal episodes of rapid VT. Of the congenital forms, the Jervell and Lange-Nielsen syndrome is associated with autosomal-recessive deafness. The Romano-Ward syndrome is associated with an autosomal-dominant trait in families with normal hearing. Recent work has identified the genetic basis of the congenital forms of long Q-T syndrome and relates them to the mutant genes coding for abnormal myocardial K^+ channel and, in some cases, inner ear endolymph proteins. Long Q-T syndromes often present as syncope on exercise or exertion and can also masquerade as a seizure. In acquired forms, the Q-Tc will be prolonged as a result of electrolyte abnormalities (hypokalemia, hypocalcemia), increased intracranial pressure (ICP), or medication use or overdose. Drug exposure may be intentional or accidental. A thorough history should include types of medications available at home, possible environmental exposures, and drug use such as psychotropic medications, including tricyclic antidepressants (TCAs) and phenothiazines. Nonsedating antihistamines such as terfenadine (Seldane) and astemizole (Hismanal) or the promotility agent cisapride may be used alone or in combination with other medications such as erythromycin and ketoconazole, which can inhibit the metabolism of these antihistamines and thus prolong the Q-T interval.

Episodic, complete heart block accompanied by syncope may occur in children and adolescents with baseline abnormalities of cardiac conduction. Children who have undergone surgical repair of ventricular defects, such as in Tetralogy of Fallot, are also at risk.

Hypertrophic cardiomyopathy (IHSS), which is associated with recurrent syncope, is a disease that presents with a thickened left ventricular myocardium, resulting in subaortic stenosis that causes obstruction to ventricular outflow. Patients with severe aortic valvular stenosis present with the classic triad of syncopal episodes, anginal chest pain, and dyspnea on exertion.

Noncardiac Syncope and Disorders That Mimic Syncope

Metabolic causes of syncope include hypoglycemia, which often is associated with pallor, dizziness, and diaphoresis and is unrelated to position. Seizures may occur and unconsciousness may be prolonged and will often require the administration of glucose for recovery. Hypoglycemia may be a component of other childhood disorders that include diabetes mellitus, ketotic hypoglycemia, and hepatic enzyme deficiencies. Other metabolic causes of syncope include hypoxia by itself or in association with mild to moderate carbon monoxide poisoning, which is notorious for producing syncope. Recovery occurs when the child is removed from the offending environment. Hyperammonemia may rarely

cause syncope by direct cytotoxic central nervous system effect.

Hyperventilation is associated with high anxiety and emotional events, during which the patient will complain of shortness of breath, tachypnea, chest pain, paresthesias, and light-headedness. It is believed to result from cerebral vasoconstriction in response to self-induced hypocapnia.

Loss of consciousness often occurs with generalized seizures, which may be difficult to distinguish from vasovagal syncope if the event was not witnessed. Seizures are likely to be preceded by an aura and followed by a prolonged postictal state. Neonatal seizures and complex partial seizures may be subtle and particularly difficult to differentiate from syncope (Table 73.4) (see Chapter 70).

Syncopal migraine is rare. It is usually preceded by an aura and followed by severe occipital headache. Basilar artery migraine accounts for 24% of childhood migraines, most often in adolescent girls. It should be considered in patients with severe paroxysmal headaches.

Syncopelike events caused by hysteria are common in the adolescent patient. Characteristic features of the clinical event are helpful in differentiating hysteria from organic causes of true syncope. Hysterical “syncope” may be associated with hyperventilation, usually occurs in the presence of an audience, and lacks true loss of consciousness. No overt or objective prodromal symptoms such as hypotension or bradycardia are recognized. It may occur when the patient is in the supine position, which is virtually unreported with vasovagal syncope. There may be a peculiar fluttering of the eyes behind half-closed eyelids. The patient describes the event in a calm and indifferent manner and vividly recalls the event, suggesting a lack of complete loss of consciousness.

Drug or toxin exposure may be accidental or intentional and, in addition to precipitating arrhythmias as previously noted, may occasionally cause an acute, transient loss of consciousness or gradual altered mental status changes leading to syncope rather than the typical prolonged alterations in consciousness. Such an effect may be more characteristic of carbon monoxide poisoning or abused volatile inhalants, for example (see Chapter 88). Antihypertensives, b blockers, diuretics, antiarrhythmics, and drugs that decrease cardiac output such as barbiturates, TCAs and phenothiazines may cause syncope. Substances of abuse such as alcohol, sedative-hypnotics, and opiates can cause alterations in consciousness that mimic syncope but are usually more prolonged.

EVALUATION AND DECISION

In the era of rising health care costs and cost containment, one must be mindful of the utility and expense of diagnostic studies used to evaluate syncope. Extensive and expensive testing is usually unnecessary. A thorough history and physical examination will often suggest the diagnosis. One should pay attention to the airway, respiratory effort, and hemodynamic stability. Vital signs, including orthostatic blood pressure and pulse oximetry measurements, must be documented and reviewed. In most cases, a complementary electrocardiogram (ECG) screen is useful to rule out symptomatic arrhythmias. This approach, emphasizing primarily clinical features of the syncopal episode, supplemented by ECG evaluation is outlined in Figure 73.1.

FIGURE 73.1. The diagnostic approach to syncope. *ECG,* electrocardiogram; *EEG,* electroencephalogram.

The goal in evaluating a syncopal child or adolescent is to identify conditions that are associated with a risk of serious injury or are life-threatening. Those potentially life-threatening conditions for which hospitalization is indicated are outlined in Table 73.5.

Presence of cardiovascular disease or abnormal cardiovascular examination—congestive heart failure, arrhythmias	Apnea or bradycardic spells requiring vigorous stimulation
Abnormal ECG—prolonged Q-T interval, tachyarrhythmias, atrioventricular or severe bundle branch blocks	Abnormal neurologic findings—local signs, status epilepticus, signs of meningeal irritation
Chest pain with syncope	Acute toxic ingestions
Cyanotic spells	Orthostatic hypotension resistant to fluid therapy

ECG, electrocardiogram.

Table 73.5. Life-Threatening Causes of Syncope Requiring Hospitalization

A thorough history is the most important part of the evaluation. Parents and relatives often contribute important information to the cause of the syncopal event. A typical vasovagal spell is preceded by a prodromal sign or symptom. Most occur while standing. Stressful situations, emotional upset, and mild physical trauma can trigger such an event.

Syncope occurring during intense physical activity, may identify those patients with potentially fatal conditions. These patients' symptoms may also suggest vagal tone and/or volume depletion caused by dehydration and heat stress. A detailed evaluation should be considered for patients who have syncope during exercise or have a family history of sudden death, myocardial disease, or arrhythmias. A history of palpitations before syncope should alert the physician to the possibility of tachyarrhythmias. Palpitations are also reported in hyperventilation episodes. History is sought regarding medication use, recent food intake, and intercurrent illnesses to consider additional causes of nonvasovagal syncope. A medical history or family history of cardiac or neurodevelopmental disorders is important to elicit in regard to possible cardiac or neurologic causes of syncope. If there are no suggestive historical features of either vasovagal or the more worrisome causes of syncope, it might be prudent to cautiously consider some psychological assessment questions, particularly in well-appearing adolescents.

On physical examination the heart rate and blood pressure should be measured while the patient is supine and standing. In orthostatic hypotension caused by autonomic dysfunction, dehydration, or blood loss, the patient will have an abnormal decrease in systolic blood pressure (greater than 20 mm Hg) or an abnormal increase in heart rate. Palpation of an abnormal apical impulse or peripheral pulses may suggest a structural heart disease. On auscultation, a loud systolic ejection murmur in the midsternum and upper sternum is present in severe aortic stenosis or IHSS, or the diastolic murmur of a rare left atrial myxoma may be heard. A fourth heart sound may be present in hypertrophic cardiomyopathy. The general physical examination should include a careful neurologic examination, auscultation for cervical and carotid bruits, an assessment of hydration status, and consideration of the presence of any toxidromes.

Routine Laboratory Testing

The emergency physician must assess the cardiac status of all children who present with a history of a syncopal episode. While in the emergency department, the patient should be placed on a continuous cardiac monitor for evaluation of heart rate, rhythm, and conduction intervals unless an obvious noncardiac cause is revealed by the clinical examination. An ECG should be included with all initial evaluations for syncope. The rhythm strip would assess the presence of any arrhythmias (SVT, atrioventricular [AV] block, sick sinus syndrome, or prolonged Q-T interval). Particular attention should be paid to the Q-T interval and T-wave morphology for evidence of long Q-T syndrome (see Chapter 82). Q-Tc must be calculated. Voltage criteria to determine ventricular hypertrophy in evaluating obstructive outflow lesions and evidence of preexcitation in WPW syndrome should be sought. The ECG is also helpful in recognizing ectopy and conduction disturbances.

Serum laboratory tests, if indicated, may include a complete blood count, serum glucose, and carboxyhemoglobin determinations. Toxicology screens should be performed in patients suspected of ingestion or illicit drug use. In teenage girls, pregnancy should be ruled out.

Head-Upright Tilt Table Testing

The utility of the head-upright tilt table test in pediatric patients is controversial for the diagnosis of vasovagal syncope. It has emerged as a laboratory method for provoking episodes of neurally mediated (vasodepressor) syncope in susceptible individuals. The patient is placed on a standard tilt table with a foot board. After 15 to 20 minutes of rest, baseline blood pressure and heart rate measurements are done, after which the patient is positioned at an angle of 90 degrees for up to 30 minutes. A test is considered positive if hypotension and bradycardia occur during the tilt. If no syncope occurs, an isoproterenol infusion is started and the patient is then tilted in an attempt to induce syncope.

Such testing may be indicated in the evaluation of children with recurrent unexplained syncope. However, it appears to be more specific (83 to 100%) and less sensitive (43 to 57%) in young patients. Also, caution must be used in interpreting results with isoproterenol because intravascular access and provocative agents may decrease specificity.

Several nonemergent studies or devices may contribute to the diagnostic evaluation in selected patients. An *echocardiogram* may be a helpful diagnostic test for recognition of hypertrophic cardiomyopathy or obstructive disease. *Holter monitoring* is expensive and rarely diagnostic in children and thus is often not included in an initial workup. *Event recorders,* however, are similar in size and appearance and have replaced Holter monitors in many medical centers for the evaluation of children with syncope. A digitally recorded rhythm strip can be transmitted via a telephone line to a receiving and recording device. Lastly, *electroencephalogram (EEG)* is indicated if a seizure disorder is suspected.

THERAPY

Any therapeutic approach to the child with syncope should be individualized based on several issues, including the likely pathologic process, frequency and nature of symptoms, likelihood of recurrence, and risk of adverse outcomes.

If the diagnosis of vasovagal syncope is made, reassurance and education with regard to the benign prognosis of the process is required. Parental and patient education involves learning to identify and avoid precipitating situations. The patient is instructed to recognize prodromal symptoms and then to assume a seated or supine position and elevate his or

her feet to avoid loss of consciousness. Other simple prophylactic measures include avoidance of dehydration, encouragement of salt enriched diets during periods of intense physical activity, and rarely, the use of mineralocorticoids *(fluorocortisone)* to induce salt and water retention.

The patient can be discharged home with home observation instructions that have been explained to the parents or guardians. Follow-up visits with their primary care physician should be arranged and encouraged.

If these measures are unsuccessful, medical management for severe vasovagal events can be directed at breaking the cycle of events that lead to syncope. Pharmacologic therapy with *b-adrenergic blockers* (atenolol or propanolol), which decrease the mechanical stimulation of the cardiac mechanoreceptors, may be indicated. *Disopyramide* acts as an anticholinergic, negative inotropic, and vasoconstrictive agent.

Transdermal scopolamine has been reported to be effective presumably by reducing the vagal tone associated with these episodes. Recently, *sertraline* has been shown to be successful in decreasing the frequency of syncope. Pacemaker implantation for vasovagal syncope is reserved for the rare refractory case that has failed aggressive pharmacologic measures.

Table 73.6 offers guidelines regarding which patients require referral to pediatric subspecialists, such as a cardiologist or neurologist.

Atypical episodes	Syncope associated with abnormal
Recurrent episodes or episodes not resolved with conventional therapy	cardiac history, examination, or ECG
	Family history of sudden death
Exertional syncope	Seizures
Syncope associated with chest pain, arrhythmias, or palpitations	A focal neurologic examination or neurologic abnormality

ECG, electrocardiogram.

CHAPTER 74

Tachycardia/Palpitations

JAMES F. WILEY II, MD

Departments of Pediatrics and Emergency Medicine, The School of Medicine at the University of Connecticut Health Center, and Emergency Medical Services, Connecticut Children's Medical Center, Hartford, Connecticut

Palpitations represent a disagreeable perception of the heart beat by the patient. Descriptions commonly given include “pounding,” “fluttering,” “jumping in the chest,” or a sensation of the heart “stopping.” A high degree of variation in the sensitivity of patients to changes in the heart rate (HR) or rhythm exists. Severe symptoms may be expressed by a patient who actually experiences trivial cardiac events. However, the absence of palpitations by history does not rule out the possibility of a life-threatening arrhythmia. The challenge to the emergency physician is to determine which complaint can be managed in the emergency department (ED) and which merits further consideration by a cardiologist.

PATHOPHYSIOLOGY

The heart is innervated primarily by the vagus nerve (cranial nerve X) and the sympathetic ganglion. Cardiovascular reflexes (e.g., vasovagal bradycardia) are transmitted by the vagus nerve. Pain sensation (e.g., related to myocardial ischemia) travels through afferent fibers associated with the sympathetic ganglia. In most patients, the sensation of the heartbeat is not felt. Children with documented arrhythmias, such as supraventricular tachycardia (SVT) and stable ventricular tachycardia, may not complain of any symptoms. Even patients with heart murmurs audible to the unassisted ear can learn to ignore this obvious cue.

Patients with palpitations often relate an indirect perception of increased force of cardiac contraction, tachycardia, or irregular heartbeat. Increased force of the contraction often is detected when the patient is supine. At times, it may be described as a rushing or pounding in the ears, particularly when the ear is pressed against a pillow. This sensation of a large ventricular stroke volume can be produced by caffeine or alcohol consumption, exercise, and emotional arousal. Tachycardia may be detected even in a preverbal child as parents incidentally note a rapid HR when holding their child, or they observe rapid jugular venous pulsations. In this way, asymptomatic SVT may come to medical attention. Noncardiac causes of tachycardia include exercise, fever, anemia, hyperthyroidism, and rarely, pheochromocytoma. Patients with premature contractions and a compensatory pause may describe the feeling that their hearts “flip-flop” or “stop.” Many patients with premature atrial or ventricular contractions notice the subsequent beat after the initial “short” beat because of the increased stroke volume ejected. Other patients may complain of a choking or full sensation in the neck. Jugular venous pulsation associated with right atrial contraction against a closed tricuspid valve (atrioventricular block with or without atrial tachycardia) can present in this way.

True cardiac arrhythmias arise from various mechanisms that are discussed in Chapter 82.

DIFFERENTIAL DIAGNOSIS

Many conditions may produce palpitations (Table 74.1). Most patients with palpitations do not have significant cardiac pathology (Table 74.2), with the exception of patients with SVT and mitral valve prolapse. Many life-threatening conditions can come to medical attention because of abnormal cardiac sensation (Table 74.3). Wolff-Parkinson-White (WPW) syndrome and the prolonged Q-T syndrome are two potentially lethal diseases that may be diagnosed on a resting electrocardiogram (ECG). A patient with palpitations during exercise should also raise the concern of possible hypertrophic cardiomyopathy, SVT, ventricular tachycardia, or myocardial ischemia. Diagnosis of noncardiac causes of life-threatening palpitations, including hypoxemia, hypoglycemia, hyperkalemia, and hypocalcemia, can be made by characteristic ECG changes, serum electrolyte determinations, rapid bedside glucose, and oxygen saturation measurements.

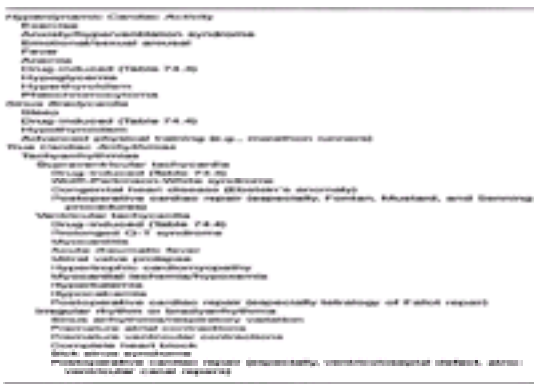

Table 74.1. Differential Diagnosis of Palpitations

Exercise	Supraventricular tachycardia
Anxiety/hyperventilation syndrome	Mitral valve prolapse
Emotional arousal	Premature atrial or ventricular con-
Drug-induced	tractions

Table 74.2. Common Causes of Palpitations

Cardiac	*Noncardiac*
Wolff-Parkinson-White syndrome	Hypoxemia
Prolonged Q-T syndrome	Hypoglycemia
Hypertrophic cardiomyopathy	Hyperkalemia
Congenital heart disease/postoperative cardiac repair	Hypocalcemia
	Pheochromocytoma
Myocarditis/acute rheumatic fever	Drug-induced
Mitral valve prolapse	
Sick sinus syndrome	
Complete heart block	
Myocardial ischemia	

Table 74.3. Life-Threatening Causes of Palpitations

Hyperdynamic Cardiac Activity

Increased HR and contractility are physiologic responses to catecholamine release, like that which may occur with exercise, emotional arousal, hypoglycemia, and pheochromocytoma. Similarly, increased cardiac work accompanies conditions that increase the basal metabolic rate such as fever, anemia, and hyperthyroidism. Sympathomimetic and anticholinergic drugs are among a group of commonly available substances that directly modulate the autonomic nervous system, causing tachycardia, hyperdynamic cardiac activity, and palpitations (Table 74.4).

Sinus or Supraventricular Tachycardia	Nonsedating antihistamines (astemizole, terfenadine)
Ephedrine, pseudoephedrine	Organophosphate pesticides
Amphetamines	Chlorinated hydrocarbons
Cocaine	Digoxin
Albuterol, metaproterenol	Caffeine, theophylline
Antihistamines	Amphetamines
Phenothiazines	Cocaine
Antidepressants	Arsenic
Tobacco	*Bradycardia*
Caffeine, theophylline	β-Adrenergic blockers
Ventricular Tachycardia or Torsades de Pointes	Calcium channel blockers
	Digoxin
Tricyclic antidepressants	Clonidine
Phenothiazines	Sedative/hypnotic agents
Antiarrhythmic agents (e.g., quinidine, procainamide, mexiletine, flecanide, encainide)	Narcotics
	Organophosphate pesticides
Chloral hydrate	

Table 74.4. Drugs That Cause Palpitations/Arrhythmias

Sinus Bradycardia

Low basal metabolic rate associated with hypothyroidism may present with a slow HR and sinus rhythm. Similarly, in the absence of significant sympathetic nervous system input, the HR may slow. This state may be responsible for the sinus bradycardia associated with sleep or with ingestion of drugs such as clonidine, sedative-hypnotics, or narcotics. Advanced physical training results in a highly efficient heart with high ventricular ejection fraction and sinus bradycardia.

True Cardiac Arrhythmias

SVT represents the most common tachyarrhythmia of childhood (see Chapter 82). Possible underlying causes include drug exposure, congenital heart disease, and WPW syndrome. Sympathomimetics in cough and cold preparations are the most common drugs to incite SVT in children. Cardiac lesions associated with SVT include Ebstein's anomaly, repaired dextrotransposition of the great arteries, and single ventricle lesions status post-Fontan operation. Up to 75% of patients with WPW syndrome have a shortened P-R interval or delta wave on resting ECG (see Chapter 82). However, approximately 50% of children with SVT have no physical findings and no ECG abnormalities between episodes. In these patients, descriptions of abrupt onset and rapid termination of palpitations often can be elicited.

Infection, including viral myocarditis and acute rheumatic fever, constitutes one of the most common causes of ventricular tachycardia in children with normal cardiac anatomy. Similarly, ingestion of drugs with quinidinelike effects, such as tricyclic antidepressants, phenothiazines, and antiarrhythmic agents, is a preventable cause of torsades de pointes (polymorphic ventricular tachycardia) and unstable ventricular tachycardia in the otherwise normal child (Table 74.4). Syncope or palpitations associated with exercise may be caused by ventricular tachyarrhythmias that occur in conjunction with hypertrophic cardiomyopathy or myocardial ischemia (usually secondary to congenital anomalies of the coronary arteries). Patients with the prolonged Q-T syndrome have a genetically determined predisposition to fatal ventricular arrhythmias that can be detected by calculation of the corrected Q-T interval on a resting 12-lead ECG (see Chapter 82). Patients who have undergone ventriculotomy for tetralogy of Fallot comprise another group who are at high risk for ventricular arrhythmias as a result of the postoperative development of scarring in the right ventricular outflow tract. Finally, electrolyte disturbances, particularly hyperkalemia, hypocalcemia, and hypomagnesemia, may be causative in a child with palpitations and ventricular tachycardia (see Chapter 86).

Premature atrial contractions produce the most common arrhythmia of childhood, with 50% of normal children experiencing at least one premature atrial contraction per day. Premature ventricular contractions (PVCs) also account for many reports of irregular heartbeat. Although this arrhythmia can herald serious underlying pathology, patients with an unremarkable history, normal physical examination, and unifocal PVCs that disappear with exercise do not require further evaluation. Patients with significant sinus or atrioventricular (AV) node dysfunction as a cause of an irregular or slow heartbeat often have a history of syncope or seizure, slow HR (25 to 50 beats per minute) on examination, a pulmonic flow murmur, or signs of congestive heart failure (CHF). Patients who have undergone intra-atrial repairs (D-transposition of the great arteries and atrial septal defect) are at highest risk for these potentially life-threatening arrhythmias.

EVALUATION AND DECISION

The ill-appearing child with palpitations requires rapid assessment for the presence of hypoxemia, shock, hypoglycemia, or an existing life-threatening arrhythmia. Further evaluation should include measurement of hemoglobin, serum glucose (Dextrostick), serum electrolytes, calcium, and pulse oximetry or arterial blood gas. The presence of heart disease should be assessed by a 12-lead ECG and rhythm strip, followed by continuous monitoring, frequent vital signs, and chest radiographs (Fig. 74.1). Specific arrhythmias should be treated as outlined in Chapter 82.

FIGURE 74.1. A diagnostic approach to palpitations. *ECG,* electrocardiogram; *SVT,* supraventricular tachycardia; *WPW,* Wolff-Parkinson-White; *CHF,* congestive heart failure; *Hgb,* hemoglobin.

The asymptomatic child with palpitations by history also may have an intermittent or continuing arrhythmia. Continuous cardiac monitoring and a resting 12-lead ECG performed while the patient is in the ED increases the likelihood that this abnormality will be detected. Some patients in this category may benefit from Holter or event monitoring, particularly if there is a history of palpitations. Any patient with a history of syncope, congenital heart disease, or particularly, postoperative or exercise-induced palpitations is at greater risk for having a true cardiac arrhythmia as the cause of his or her symptoms. Similarly, the presence of a short P-R interval with the typical delta wave morphology of WPW syndrome or a prolonged corrected Q-T interval (see Chapter 82) indicates the need for further evaluation and consultation by a pediatric cardiologist.

The presence of fever or an upper respiratory infection should prompt the emergency physician to look for signs and

symptoms of myocarditis or acute rheumatic fever. Myocarditis describes inflammation of the muscle wall of the heart. Multiple organisms can cause this pathology, with the most common identified agent being coxsackievirus. Clinical features of this disease are fever, tachycardia out of proportion to activity or degree of fever, pallor, cyanosis, respiratory distress secondary to pulmonary edema, muffled heart sounds with gallop, and hepatomegaly caused by passive congestion of the liver. The ECG findings are nonspecific and include low voltage QRS complexes (less than 5 mm total amplitude in limb leads), “pseudoinfarction” pattern with deep Q waves and poor R wave progression in the precordial leads, AV conduction disturbances that range from P-R prolongation to complete AV dissociation, and tachyarrhythmias such as ventricular tachycardia and SVT. A child with palpitations and clinical findings suggestive of myocarditis requires emergent supportive care (see Chapter 3), echocardiography, and admission to a unit capable of intensive monitoring and rapid treatment of cardiac arrhythmias.

Acute rheumatic fever follows pharyngeal streptococcal infection and is an inflammatory disease that targets the heart, vessels, joints, skin, and central nervous system (CNS). Diagnosis and management of acute rheumatic fever are discussed in Chapter 82.

A detailed history of recent medications or precipitating events may reveal the cause of palpitations in some patients. Ingestion of caffeinated beverages (including soft drinks), cough and cold preparations, and illicit drugs, as well as a smoking history should be ascertained. The patient's emotional state before the onset of palpitations should be discussed to determine the likelihood of anxiety or emotional arousal as the cause of symptoms (see Hyperventilation Syndrome, Chapter 131). The presence of diaphoresis, hypertension, and headache should encourage the consideration of pheochromocytoma, whereas widened pulse pressure and thyroid enlargement suggest hyperthyroidism (see Chapter 97). Anemia may be the cause of symptoms in a patient with pallor (see Chapter 59).

In some patients, an exact cause of palpitations cannot be determined at the time of ED evaluation. Patients with a single episode should have close follow-up arranged with their primary care physicians and should be instructed to return for further evaluation if symptoms recur. Patients with multiple episodes of palpitations deserve further evaluation and consultation with a pediatric cardiologist.

CHAPTER 75

Urinary Frequency in Childhood

ROBERT G. BOLTE, MD

Department of Pediatrics, University of Utah School of Medicine, and Emergency Services, Primary Children's Medical Center, Salt Lake City, Utah

Urinary frequency is a symptom of several commonly encountered, clinical pediatric problems such as urinary tract infection (UTI), urethritis, vulvovaginitis, diabetes mellitus (DM), drug side effect (with caffeine, theophylline, and diuretics), or psychogenic stress. Moreover, urinary frequency may suggest underlying disease processes with life-threatening potential, such as diabetic ketoacidosis, diabetes insipidus, or congenital adrenal hyperplasia, that require emergent diagnosis and management. Therefore, an organized approach in the emergency department (ED) evaluation of this symptom is important for any clinician who provides acute care to children.

Urinary frequency (pollakiuria) is defined as an increase in the number of voids per day. It is a symptom distinct from polyuria (excretion of excessive amounts of urine). Although the two symptoms can be related, most children who present to the ED with frequency have a normal daily urine output, although the individual voids are frequent and small. Frequency also is distinct from enuresis, which is defined as inappropriate urination at an age when bladder control should be achieved.

PATHOPHYSIOLOGY

More than 90% of newborns void during the first day of life. Infants void between 6 to 30 times each day. Over the next 2 years, the number of voidings per day decreases by about half, whereas the volume of urine produced increases fourfold. Children between the ages of 3 and 5 years average 8 to 14 voids per day. By 5 years of age, the number of voids decreases to 6 to 12 times per day. Adolescents average 4 to 6 voids per day. In the school-aged population, urinary frequency usually is defined as voiding more often than every 2 hours.

Normal bladder mucosa is pressure-sensitive and pain-sensitive. An uncomfortable sensation is produced when urine volume approaches the age-dependent capacity of the bladder. Voiding is initiated by relaxation of the striated muscle of the urinary sphincter and an associated contraction of the smooth muscle of the bladder, resulting in bladder emptying. This mechanism is mediated by sacral nerves II–IV. Uncontrolled, “uninhibited” bladder contractions are the normal mechanism for infant and toddler voiding. Uninhibited (parasympathetic-mediated) bladder contractions do not normally occur after toilet training. By 5 years of age, 90% of children have achieved direct voluntary mastery of the voiding reflex and exhibit the adult pattern of urinary control.

Urinary frequency may be caused by reduced bladder capacity, polyuria, or psychologic stress. The urinary volume per voiding will be low if frequency is related to reduced bladder capacity or psychological stress. Moreover, there will not be associated polydipsia. If frequency is secondary to polyuria, the urine volume per voiding will be normal or high, and polydipsia is usually associated (see Chapter 60).

A reduced bladder capacity may be secondary to inflammation of the bladder, changes in the bladder wall induced by distal obstruction, or extrinsic masses pressing on the bladder. When the bladder is inflamed, its pain/pressure sensitivity threshold is significantly decreased, so less stimuli is necessary to initiate the urge to void.

Distal infravesical obstruction leads to bladder muscle hypertrophy because of the increased effort needed to empty the bladder. This hypertrophied muscle has a higher resting tone so that smaller than normal urine volumes are necessary to initiate the desire to void. A decrease in the size and force of the urinary stream and/or straining to urinate may be noted. Eventually, the bladder muscle fatigues and is unable to empty the bladder effectively. This decompensated bladder has an increased residual urine volume with a resultant decrease in the functional bladder capacity. This large, hypotonic bladder contracts poorly, resulting in small, frequent voids.

Extrinsic extravesical masses that impinge on the bladder may cause frequency by interfering mechanically with normal bladder expansion. Extrinsic masses may also stimulate frequent voiding by causing an irritable focus in the bladder wall.

Normal pediatric values for urine output are useful in determining the presence of polyuria. The traditional definition of polyuria is a urinary output greater than 900 mL/m^2 per day. An infant/toddler up to 2 years of age rarely exceeds 500 mL/day. Children 3 to 5 years of age void up to 700 mL/day. Children 5 to 8 years of age have an approximate maximum volume of 1000 mL/day. Children 8 to 14 years of age void up to 1400 mL/day. When polyuria is the cause of urinary frequency, the urine volume per void generally is greater than 2.0 mL/kg.

Polyuria with dilute urine is classically associated with a decreased production of antidiuretic hormone or with impaired

renal responsiveness to circulating antidiuretic hormone. Polyuria with dilute urine also can be seen when the stimulus for antidiuretic hormone release is absent (e.g., chronic water overloading). In all these situations, the specific gravity of the urine seldom is greater than 1.005, and urine osmolality rarely exceeds 200 mOsm/kg. This contrasts with a normal urinary concentrating ability, which is confirmed by a specific gravity of greater than 1.020.

Polyuria with isotonic or slightly hypertonic urine occurs with an osmotic or solute diuresis. Unlike a water diuresis, both urine flow rate and solute excretion are increased. The urine osmolality is never lower than 300 mOsm/kg. However, the urine specific gravity is variable, ranging from 1.010 when the solute is primarily electrolytes and urea (e.g., renal failure, administration of diuretics) to as high as 1.045 when the solute mass is large (e.g., diabetes mellitus, intravenous contrast).

Psychogenic/emotional stress also may induce urinary frequency. Cystometric studies have documented significant anxiety-related increases in intravesical pressure, usually accompanied by a desire to void.

DIFFERENTIAL DIAGNOSIS

A differential diagnosis of urinary frequency is outlined in Table 75.1. In-depth discussions of many of these subjects can be found in other chapters of this textbook (in particular, see Chapter 54, Chapter 60, Chapter 86, Chapter 97, and Chapter 122). The paragraphs that follow highlight selected topics in the differential diagnosis.

Table 75.1. Differential Diagnosis of Urinary Frequency

Frequency often is associated with UTIs, so this diagnosis always must receive significant consideration in the differential. The importance of accurate diagnosis of a pediatric UTI has assumed even greater significance with current urologic recommendations for radiologic evaluation after the first documented infection in preschool-age children of both sexes.

The term *urethral syndrome* refers to an entity that can be seen in adolescent girls, characterized by acute onset of frequency and dysuria with “insignificant” bacterial counts (less than 10^5/mL). Pyuria is generally, but not absolutely, present. Vaginitis is a common cause of the urethral syndrome. *Chlamydia trachomatis* is also a relatively common etiology. The urethral syndrome also can be associated occasionally with *Neisseria gonorrhoeae*. Evidence supports the causal relationship of low-level bacteriuria and symptomatic disease. Therefore, in the context of the urethral syndrome, after all other causes have been excluded, “significant” bacteriuria may be considered as greater than or equal to 10^2 Enterobacteriaceae/mL.

Irritative vulvovaginitis (e.g., secondary to poor hygiene or bubble baths) is a relatively common cause of frequency, usually associated with dysuria but not with pyuria. Frequency may be secondary to urethral trauma secondary to straddle injuries, catheterization, masturbation, or sexual abuse. Pinworms *(Enterobius vermicularis)* occasionally may cause frequency in young girls. Children with pinworm infestation may or may not present with perineal itching. Pyuria and dysuria usually are absent.

Frequency may be a presenting symptom of a pelvic appendicitis or appendiceal abscess. Potential for significant morbidity is obvious. Associated abdominal pain, by history and examination, should be present. Rectal examination may be abnormal (differential tenderness, mass). Pyuria, microscopic hematuria, and proteinuria (but generally not bacteriuria) may also be present.

Frequency may be secondary to a partial distal urethral obstruction. The urinary stream in the male infant or child with posterior urethral valves usually is nonforceful and nonsustained. Straining to urinate also may be noted. A lower abdominal mass (enlarged bladder) may be palpable.

A neurogenic bladder associated with a spinal cord lesion (e.g., tethered cord) may present with urinary frequency. There may be associated lumbosacral abnormalities (hairy patches, cutaneous dimples or tracts, lipoma, or bony irregularities). Decreased anal tone and lower extremity weakness or reflex abnormalities may be noted. An enlarged bladder may be palpable.

It is well recognized that children with urinary tract dysfunction often have associated constipation. Large fecal accumulations may restrict maximal bladder capacity or directly produce symptoms of frequency by stimulating uninhibited bladder contractions. Resolution of the fecal accumulation decreases frequency symptoms.

Pregnancy should always be considered as a cause of frequent urination in the adolescent girl. A lower abdominal mass may be palpable. Adolescent sexual histories are notoriously unreliable.

Uninhibited bladder contractions (“unstable bladder” syndrome) occur involuntarily in children who have failed to gain complete voluntary control over the voiding reflex. This appears to represent a delay in nervous system maturation. A child who attempts to maintain continence must constrict the voluntary urinary sphincter tightly. If the sphincter is relatively weak, urinary frequency associated with urgency and enuresis may result. Girls may exhibit the so-called curtsey sign, so named because the child squats and attempts to prevent leakage by compressing the perineum with the heel of one foot. This maneuver will usually avoid major incontinence, but generally, small amounts of urine leakage occur. If performed, a screening ultrasound examination would reveal normal (minimal) residual urine volumes. With maturity, spontaneous resolution of uninhibited contractions occurs in most cases. In children with significant mental retardation or behavioral disorders, the infantile pattern of spontaneous bladder contraction may persist. Unstable bladder syndrome may also develop in otherwise normal children who have undergone normal toilet training. If symptoms are persistent, a trial of oxybutynin after urologic consultation may be warranted.

Anatomic anomalies of the urogenital tract may result in chronic leakage of urine. Ectopic ureter would an example of such an anatomic defect.

Uncontrolled DM is a potentially life-threatening condition that can present with frequent urination. Polyuria results from a glucose-induced osmotic diuresis. At initial presentation, polydipsia, polyphagia, Kussmaul's respirations, and weight loss also may be present.

In chronic renal failure and in certain diseases of the renal parenchyma (e.g., renal tubular acidosis, Fanconi's syndrome, and Bartter's syndrome), the renal tubules lose their ability to concentrate urine. This leads to polyuria and frequency, with large volumes of relatively dilute urine. A concentration defect also may occur with sickle cell disease or trait and may be evident as early as 6 months of age.

Hypercalciuria has been reported as a significant noninfectious cause of the “frequency-dysuria syndrome” in the pediatric patient, although Brock has recently challenged this association. Onset of symptoms may present throughout the pediatric age range, generally 2 to 14 years of age. Occasionally, hypercalciuria can present in early infancy, in which irritability is a hallmark symptom. Symptoms often spontaneously resolve within 2 months. There may be a positive family history of calcium urolithiasis. When symptomatic, frequency is almost always associated with dysuria. Hematuria (generally microscopic) and crystalluria are often seen. However, the urinalysis may be normal. If the diagnosis is suspected and symptoms persist, studies of urinary calcium excretion and urologic consultation should be considered.

The salt-losing form of congenital adrenal hyperplasia is a life-threatening, although relatively rare, cause of frequency. Excessive urinary excretion of sodium leads to severe water loss and marked dehydration with associated hyperkalemia and hyponatremia. At the initial presentation in early infancy, however, urinary frequency as a symptom generally is not appreciated. Infant girls may exhibit virilization of the external genitalia. Infant boys may demonstrate increased pigmentation of the external genitalia and/or a relatively enlarged phallus.

Diabetes insipidus (DI) is an uncommon, although life-threatening, cause of frequency seen in the ED. It is clinically characterized by polyuria (with resultant frequency) and polydipsia. It is caused by an inability of the kidneys to concentrate urine. This is related to a deficiency in the hypothalamic production of antidiuretic hormone (central DI) or a renal unresponsiveness to antidiuretic hormone (nephrogenic DI). Some causes of central DI (e.g., septo-optic dysplasia) present in the neonatal period. However, most causes of central DI are acquired (e.g., head injury, brain tumors) and, therefore, can present at any age. The most common type of nephrogenic DI in childhood is the X-linked recessive type, which presents in boys during early infancy. If fluids are not accessible or if the thirst sensation is impaired, hypernatremic dehydration develops. If DI is suspected, oral fluids should not be restricted. The child should be admitted to the hospital for evaluation and treatment under strict medical supervision.

Drugs are a relatively common cause of frequency in childhood. Methylxanthines (theophylline, caffeine) and ethanol inhibit production of antidiuretic hormone. Lithium, chronic hypokalemia, hypercalcemia, and vitamin D are also associated with urinary frequency, interfering with renal responsiveness to antidiuretic hormone. Diuretic agents may cause urinary frequency. These agents represent only a few of the many drugs that can cause urinary frequency as a side effect. Therefore, a detailed pharmacology history should be obtained in the child with urinary frequency.

Frequency may occur secondary to the polyuria of water intoxication. Absence of nocturia and enuresis in the presence of polyuria suggests an excessive fluid intake. The serum sodium and osmolality generally are decreased. Psychogenic water drinking is an extremely unusual diagnosis in young children but may present in adolescents. Water intoxication secondary to Munchausen syndrome by proxy would be an unusual presentation of child abuse.

The “extraordinary urinary frequency syndrome” is a relatively recently described entity but probably represents a common cause of urinary frequency in pediatric primary care settings. Average age of onset is about 6 years (with a range of about 2 to 11 years). Daytime frequency occurs as often as every 5 minutes. Dysuria is not present. Nocturia is present in about half the cases but usually occurs only about 1 to 2 times per night. Polydipsia and polyuria are absent. The physical examination is normal. The urinalysis and other laboratory studies also are normal. If the diagnosis of “extraordinary urinary frequency syndrome” is likely, reassurance and follow-up are indicated. Initial radiologic evaluation and pharmacologic therapy are generally unnecessary. Left untreated, frequent voiding resolves spontaneously, usually in about 2 months. The cause is unclear but often has a psychogenic component, with an apparent “trigger” (e.g., school problems, parental death, sibling illness) identifiable in about 40% of cases. More extensive urologic and psychologic evaluation is warranted if isolated urinary frequency persists for more than 6 months.

As an isolated symptom, frequency would be an atypical presentation of pediatric sexual abuse. However, urinary

frequency may be seen in association with pertinent history or physical findings (e.g., vulvovaginal venereal infection or genital trauma), which would be suggestive of sexual abuse.

EVALUATION AND DECISION

The primary role of the emergency physician in evaluating the child with urinary frequency is to exclude significant underlying pathology that may result in morbidity and to identify treatable conditions. When confronted with a child whose chief complaint is frequent urination, the physician should initially determine whether the criteria for true urinary frequency have been met (refer to the section on pathophysiology for age-related normal values). Additional history should then focus on symptoms related to infection of the urinary tract. Are associated symptoms of dysuria, fever, or flank pain also present? Is there a history of prior UTIs? Questions specifically related to DM also should be included (polyuria, polydipsia, polyphagia, weight loss, family history). The presence or absence of nocturia and enuresis are also important historical points. The urine volume per voiding should be determined (large versus small). Generally, the presence of polyuria (copious volumes of dilute urine) is obvious from the history. The onset and duration of the symptoms and the quality of the urinary stream should be documented.

In addition, other historical features may be pertinent. For example, are there symptoms to suggest central DI (polydipsia, nocturia, intracranial pathology)? Is there a history of poor growth, suggesting renal disease? Is there a family history of sickle cell disease or trait? Is the child taking any medications or drugs (including caffeinated beverages) associated with frequency? Is there a history of chronic constipation, vulvovaginal infection/trauma, or pruritus ani? Are there symptoms of abdominal pain, suggesting the possibility of acute appendicitis or appendiceal abscess? In the young boy, what is the quality of the urinary stream? In an adolescent girl, when was her last menstrual period? Is there a family history of urolithiasis or renal disease?

A complete physical examination should be performed, including an accurate blood pressure measurement. The child's growth parameters should be plotted and the blood pressure should be compared with age-specific normal values to screen for hypertension (see Chapter 35). The abdomen should be palpated carefully for the presence of abdominal masses and/or tenderness. Percussion of the flanks should be performed. The lumbosacral area should be examined closely for anomalies (hairy patches, dimples, tracts). Special attention should be focused on the function of sacral nerves II–IV (anal wink and sphincter tone). Unless the diagnosis is readily apparent, a rectal examination should be performed noting tone, tenderness, masses, and the quality and quantity of stool in the rectal vault. The external genitalia should always be thoroughly examined, meticulously searching for signs of infection, trauma, or anatomic abnormalities. Signs of virilization (in the girl) or hyperpigmentation (in the boy) should be evaluated. A thorough neurologic examination with careful attention to the retinal fundi and visual fields is warranted.

The laboratory evaluation is fairly straightforward. A urinalysis (including specific gravity) and urine culture should be performed in all cases. Caution should be exercised in interpreting pyuria and/or bacteriuria from “bag” or “midstream” urine specimens in the infant or toddler. A confirmatory catheterized specimen should be considered in these cases. If a UTI is confirmed, additional elective radiologic evaluation is recommended for all boys and preschool-age girls. Glycosuria obviously suggests the diagnosis of DM.

If the diagnosis is not apparent at this point, serum chemistries (including electrolytes, glucose, blood urea nitrogen, creatinine, and calcium) should be obtained. A sickle cell preparation also should be considered in the African-American child, and a pregnancy test should be done in the adolescent girl. This workup generally is sufficient for those children who do not have both daytime and nighttime symptoms, or anatomic and/or neurologic abnormalities.

In the child with progressive or worrisome symptoms or signs (e.g., nocturia, persistent dysuria, poor urinary stream, straining to urinate, growth failure, hypertension, fixed low urinary specific gravity, anatomic or neurologic abnormalities), urologic and/or nephrologic consultation is recommended. Additional studies may include a screening ultrasonogram of the urinary tract and abdomen, a voiding cystourethrogram, urinary calcium studies, and possible urodynamic investigation. If the presence of polyuria is in doubt, a 24-hour urine collection may be necessary to establish the diagnosis.

A simplified schematic approach to the evaluation of the child with urinary frequency is outlined in Figure 75.1. This schema provides general guidelines, but it is not all inclusive, and the diagnostic categories are not absolute.

CHAPTER 76

Vaginal Bleeding

JAN E. PARADISE, MD

Department of Pediatrics, Boston University School of Medicine, and Child Protection Program, Boston Medical Center, Boston, Massachusetts

Vaginal bleeding can be either a normal event or a sign of disease and, when pathologic, can indicate variously a local genital tract disorder, endocrinologic or hematologic disease, or a complication of pregnancy. During childhood, vaginal bleeding is abnormal after the first week or so of life and before menarche. After menarche, abnormal vaginal bleeding must be differentiated from menstruation, and in turn, menstrual bleeding must be categorized as either normal or excessive. *Menstruation* is defined as the spontaneous, periodic shedding of endometrial tissue and blood.

Menstrual patterns during the first 2 years after menarche vary widely, but it is possible to set outside limits. Ninety-five percent of young adolescents' menstrual periods are between 2 and 8 days long. A duration of 10 days or more is abnormal. An occasional interval of less than 21 days from the first day of one menstrual period to the first day of the next is normal for teenagers, but several short cycles in a row are abnormal. Whether the quantity of a patient's menstrual bleeding is normal can be difficult to determine historically. However, it is uncommon for adolescents to soak more than 6 to 8 perineal pads or tampons a day. Normal menstrual bleeding *never* produces an acute fall in hemoglobin or hematocrit.

Because the relative prevalence of disorders that produce vaginal bleeding correlates more strongly with patients' hormonal status than with their chronologic age, the diagnostic approach outlined in this chapter is presented in two sections divided according to patients' menarchal status (Table 76.1).

I. At Any Time	III. After Menarche
A. Trauma	A. Hormonal contraception
B. Tumor	B. Endometritis
II. Before Normal Menarche	C. Dysfunctional uterine bleeding
A. Hormonal	D. Bleeding diathesis
1. Neonatal bleeding	E. Ectopic pregnancy
2. Exogenous estrogen	F. Spontaneous abortion
3. Precocious puberty	G. Placenta previa
B. Nonhormonal	H. Abruptio placentae
1. Urethral prolapse	
2. Genital warts	
3. Lichen sclerosus	
4. Infectious vaginitis	
5. Foreign body	

Table 76.1. Differential Diagnosis of Vaginal Bleeding

VAGINAL BLEEDING DURING CHILDHOOD

Evaluation and Decision

During the patient's general physical examination, the emergency physician should be particularly alert for signs of hormonal stimulation—breast development, pubic hair growth, a dull pink vaginal mucosa, or physiologic leukorrhea. For the initial examination of the genitalia, an infant or child should be placed in a frog-leg position either on the parent's lap or on the examining table (Fig. 94.2A). The physician then gently separates the child's labia majora and inspects the introitus for a bleeding site. A vaginal speculum should not be used. If the vulva is normal, the child should next be placed in the knee–chest position for examination of her vagina (Fig. 94.2B). In this position, the girl is encouraged to relax her abdominal muscles while the examiner gently separates her labia and buttocks. As air enters the vaginal vault, it falls open, allowing the physician to look for a foreign body, using an otoscope without a speculum as a light source. If

no foreign body is seen, the child is returned to the supine position, and a vaginal specimen for culture is obtained, using either a soft plastic medicine dropper or a cotton-tipped swab moistened with nonbacteriostatic saline solution. Finally, if the interior of the vagina could not be seen well but the examiner suspects a firm foreign body or trauma, a rectal examination should be done to palpate the vagina indirectly and to check for lacerations.

VULVAR BLEEDING

The vulva consists of several structures: the labia majora, the labia minora, the clitoris, and the vaginal introitus. A premenarchal girl with the complaint of vaginal bleeding whose vulva looks abnormal may have a vaginal disorder, a vulvar disorder, or both (Fig. 76.1A).

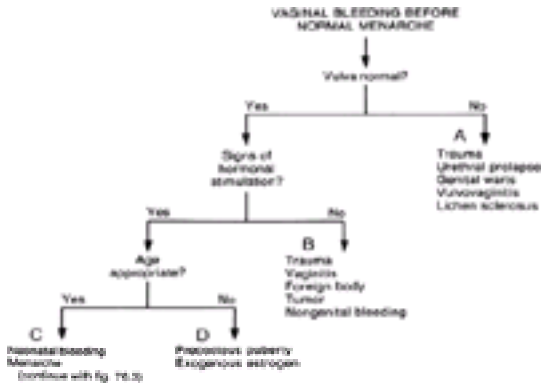

FIGURE 76.1. Diagnostic approach to vaginal bleeding before normal menarche.

Trauma to the vulva often produces lacerations or ecchymoses or both. Any vulvar injury should alert the emergency physician to the possibility of concurrent, potentially serious vaginal or rectal injuries. Vulvar lacerations do not usually bleed excessively, but hematomas can extend widely through the tissue planes, forming large, painful masses that occasionally produce enough pressure to cause necrosis of the overlying vulvar skin. Because even minor periurethral injuries can produce urethral spasm that leads to acute urinary retention, the injured child's ability to void should be checked routinely. The possibility of sexual assault must be considered in the management of every child with a genital injury.

Urethral prolapse (see Chapter 94) is probably the most common cause of apparent vaginal bleeding during childhood. Some patients with urethral prolapse complain of dysuria or urinary frequency, but most have bleeding as their only symptom. A prolapse is diagnosed by its characteristic doughnut shape (Fig. 94.6). The ring of protruding urethral mucosa above the introitus is swollen and dark red with a central dimple that indicates the meatus. When the child is supine, the prolapse is often large enough to cover the vaginal introitus and appears to protrude from the vagina. Bleeding comes from the ischemic mucosa. If the diagnosis is in doubt, one may safely catheterize the bladder through the prolapse to obtain urine. Some patients with small prolapses whose urethral tissue is still pink will improve with the use of sitz baths alone for several days. However, if the prolapsed tissue is dark and necrosing at the time of the patient's first examination or if sitz baths are not effective, elective surgical excision of the prolapsed tissue will be needed within a few days after diagnosis.

Genital warts, like a urethral prolapse, can be recognized by inspection (Fig. 94.12) and can produce bleeding when they are located on the mucosal surface of the introitus or just inside the hymenal ring. Because the presence of such warts in a child indicates that sexual contact may have occurred, cases should be reported to the state child protective services agency (see Chapter 128). Because topical podophyllin can be absorbed through disrupted mucosal surfaces and result in systemic toxicity, bleeding genital warts should be treated surgically.

Vulvar inflammation can be seen in some patients with vaginal bleeding resulting from bacterial or fungal vulvovaginitis. Infections caused by *Shigella* species, group A hemolytic streptococci, *Neisseria gonorrhoeae*, and *Candida albicans* produce vaginal bleeding or bloody discharge in varying proportions of cases. A few children with rectal *Enterobius vermicularis* (pinworm) infestations scratch so vigorously that they excoriate the perineal area and cause bleeding. Pinworm ova can often be discovered by low-power microscopic examination of perianal material that is collected with clear cellophane tape and then attached to a glass slide.

Although bleeding per se is not common, ecchymoses and telangiectasias are frequent clinical manifestations of lichen sclerosus (Fig. 76.2), an uncommon, chronic, idiopathic skin disorder that most often affects the vulva. In this condition, white, flat-topped papules gradually coalesce to form atrophic plaques that involve the vulvar and perianal skin in a symmetric hourglass pattern. Topical treatment with either hydrocortisone or testosterone is helpful in most cases.

FIGURE 76.2. Figure-of-eight pattern of vulvar and perianal hypopigmentation in a 10-year-old girl with lichen sclerosus.

VAGINAL BLEEDING WITHOUT SIGNS OF HORMONAL STIMULATION

Trauma, infection, and foreign bodies are the most common causes of vaginal bleeding during childhood (Fig. 76.1B).

Vaginal bleeding after trauma indicates a potential emergency. A penetrating narrow object can damage the rectum, bladder, or abdominal viscera without producing much external evidence of injury. Because vaginal lacerations do not always produce a great deal of bleeding or pain, the emergency physician cannot rely on the severity of the patient's symptoms to indicate the extent of the injury. When a child sustains a genital injury, the physician must consider the possibility that it was inflicted during a sexual assault.

If the clinician knows or suspects that trauma has occurred, the girl's abdomen should be evaluated carefully. Lower quadrant tenderness may provide a clue to intra-abdominal injury. The vulva is inspected for bruises, and a rectal examination is performed to identify any lacerations. A general principle of management is that patients with penetrating genital injuries, even apparently minor ones, should undergo careful vaginal examination. This may require conscious sedation or general anesthesia, particularly in young children. Laboratory evaluation of the child with vaginal trauma should include a baseline hemoglobin determination and a urinalysis to screen for hematuria that might indicate urethral or bladder injury.

About half of all patients with *Shigella* vaginitis have bleeding that may be more noticeable than the associated discharge. Most patients do not have concurrent diarrhea. Vaginal infections with group A streptococci, *N. gonorrhoeae,* and *C. albicans* also cause bleeding in some cases. A vaginal culture will provide the diagnosis and guide the selection of an appropriate antibiotic. The manifestations and treatment of vaginal infections in children are discussed in more detail in Chapter 94.

Although a chronic, foul-smelling discharge is generally considered the hallmark of a vaginal foreign body, many girls have intermittent scanty vaginal bleeding alone or with an unimpressive discharge. If a foreign body is strongly suspected but the patient's vagina cannot be visualized when she is placed in the knee–chest position, the patient should receive either gentle vaginal lavage (using saline solution, a 50-mL syringe with the plunger discarded, a red rubber catheter, and gravity) or an examination under conscious sedation or anesthesia. Because the most common foreign body—toilet paper—is not radiopaque, pelvic roentgenography is not likely to be helpful and should be avoided.

Genital tumors are a rare cause of vaginal bleeding. Clear cell adenocarcinoma of the vagina or cervix occurs in about 0.2% of daughters whose mothers took diethylstilbestrol or other estrogen-containing drugs during pregnancy. Widespread publicity about this problem resulted in the abandonment of DES treatment in the early 1970s. Adenocarcinoma unassociated with DES exposure occurs rarely. Vaginal bleeding may be the first symptom of this cancer or of another rare malignancy, rhabdomyosarcoma (sarcoma botryoides). Urethral prolapse is sometimes mistaken for a malignant tumor and should be considered in the differential diagnosis.

Occasionally, a patient with a history of bleeding has no abnormalities and no bleeding at the time of the examination. This history should not be dismissed lightly because most parents are good observers, but the patient's urine and stool should also be checked for blood. Vaginal foreign body and inapparent genital trauma are also in the differential diagnosis.

VAGINAL BLEEDING WITH SIGNS OF HORMONAL STIMULATION

During the first 2 to 3 weeks of life, and late in puberty, hormonal fluctuations produce physiologic vaginal bleeding of uterine origin (Fig. 76.1C). Before female infants are born, high levels of placental estrogen stimulate growth of both the uterine endometrium and breast tissue. As this hormonal support wanes after birth, some infants have an endometrial slough that results in a few days of light vaginal bleeding. The bleeding will stop spontaneously and requires no treatment except reassurance for the parents. Occasionally, an adolescent girl is brought to the emergency department (ED) by her family to confirm their belief that she is having her first menstrual period. In this case, if the adolescent's age and degree of pubertal development are appropriate for menarche (Table 76.2), no further evaluation is necessary.

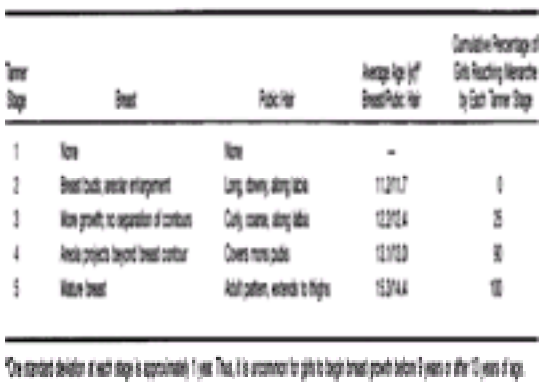

Table 76.2. Chronology of Pubertal Development in Normal Girls

If a girl less than 8 years of age has bleeding that is cyclic or is associated with breast development (thelarche), pubic hair growth (adrenarche), or accelerated linear growth, the various causes of precocious puberty must be given careful consideration in the differential diagnosis (Fig. 76.1D). Such a patient and her parents should be questioned about possible environmental exposure to feminizing hormones (e.g., chronic use of creams or medications containing estrogen). The possibility that a girl early in puberty simply has a nonendocrinologic disorder (foreign body, trauma) must also be considered. If the patient does appear to have precocious puberty, she should be checked in particular for café-au-lait spots (McCune-Albright syndrome) and an abdominal mass (endocrinologically active ovarian tumor or cyst) and referred from the ED to a pediatrician or pediatric endocrinologist for subsequent evaluation and follow-up.

VAGINAL BLEEDING AFTER MENARCHE

Evaluation and Decision

In the discussion to follow, only postmenarchal adolescents with abnormal vaginal bleeding are considered. Accordingly, the first discrimination the emergency physician must make is between those patients whose menstrual bleeding is heavier or more prolonged or more frequent than they would like but is nevertheless normal, and those patients whose bleeding falls outside the limits presented on page 613. In the evaluation of this latter group of patients, it is important to inquire specifically about the patient's menstrual chronology, including her age at menarche, her usual menstrual pattern, and the date of onset of her most recent normal menstrual period. Every patient who has been sexually active, regardless of age, should be asked whether she is or has ever been pregnant. Any current method of contraception should also be ascertained.

Because anovulatory bleeding is almost without exception painless, but approximately 90% of patients with ectopic pregnancy complain of abdominal pain at some time before the diagnosis is established, the physician must inquire carefully about the presence or absence of recent lower abdominal or pelvic pain. Other pertinent historical details include the presence or absence of fainting, fever, easy bruising, sexually transmitted diseases, and trauma.

During the physical examination, the patient's pulse and blood pressure are noted carefully and checked for orthostatic change. If the patient has been injured or is sexually active, a complete pelvic examination is performed. A speculum examination is not necessary for virginal adolescent patients who have not been injured, but a bimanual examination should be carried out routinely because teenagers are not always candid about their sexual activity. If it is more comfortable, bimanual rectoabdominal palpation with the patient in the lithotomy position can be substituted, or the examiner can place one finger intravaginally instead of two.

It is advisable to obtain a rapid qualitative urine pregnancy test early in the evaluation of most postmenarchal adolescents presenting to the ED because of vaginal bleeding (Fig. 76.3). For the occasional parent who finds it difficult to understand the rationale for this test for his or her daughter, it may be helpful to point out that the medical consequences of failing to recognize a pregnant patient can be substantial.

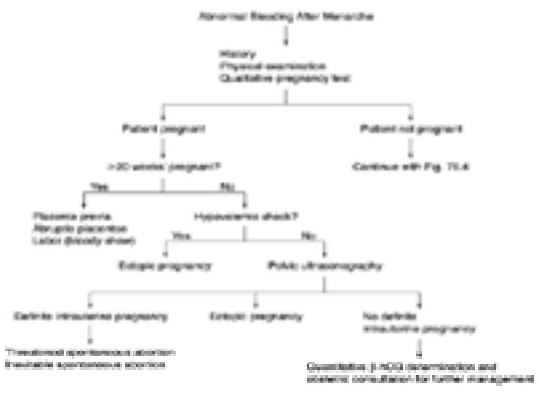

FIGURE 76.3. Diagnostic approach to abnormal uterine bleeding after menarche: pregnant patients.

BLEEDING IN LATE PREGNANCY

If the patient is 20 weeks' pregnant or more by history or abdominal examination, potential causes of bleeding that must be identified promptly are a bloody show during labor, premature separation of the placenta (abruptio placentae), and placenta previa (Fig. 76.3).

Because pelvic examination of a patient with placenta previa can provoke uncontrollable hemorrhage, the emergency care of a patient with vaginal bleeding after the 20th week of pregnancy starts with the management of potential hypovolemic shock (see Chapter 3), rather than with an examination to determine the anatomic site of bleeding. Thus, the patient's vital signs are recorded, the fetal heart rate is monitored, and a large-bore intravenous catheter is put in place. The patient with an apparently normal initial blood pressure is watched carefully nonetheless because her baseline pressure during pregnancy may have been elevated. Initial laboratory evaluation should include determinations of the hematocrit, the platelet count, the prothrombin time, and the partial thromboplastin time to screen for disseminated intravascular coagulation, which may be present in moderate and severe abruption. If the patient continues to bleed while in the ED, volume replacement is initiated while blood is typed and cross matched for use when available. If the patient is stable and the fetus is in no distress, the goal of subsequent investigation is to determine the location of the placenta and to identify the cause of the bleeding if it is not placenta previa. Obviously, an obstetrician should be consulted at the earliest opportunity regarding further ED management of the pregnant patient with second- or third-trimester bleeding.

BLEEDING WITH SHOCK

If the patient with vaginal bleeding is in the first or second trimester of pregnancy and has shock or early signs of cardiovascular instability (pallor, perspiration, vomiting), ruptured ectopic pregnancy must be ruled out. In this case, the treatment of shock and diagnostic measures should be undertaken simultaneously. Pelvic examination is performed, and obstetric consultation should be obtained rapidly. Emergency laparoscopy or laparotomy may be necessary for critically ill patients. If the patient is relatively stable, culdocentesis or transabdominal or transvaginal ultrasonography may help to clarify the diagnosis.

EARLY PREGNANCY

The patient with uterine bleeding before 20 weeks' gestation has a pregnancy that is either intrauterine but complicated or ectopic. In 1992, approximately 2% of all pregnancies in the United States were ectopic. The risk is lower among adolescents than among older women. The case-fatality rate declined dramatically between 1970 and 1986, from 35 to 4.9 deaths per 10,000 ectopic pregnancies.

Vaginal bleeding occurs in 60 to 80% of patients who have ectopic pregnancies. The bleeding is usually light. The timing of the bleeding sometimes leads the patient to consider it a normal menstrual flow, but about 75% of patients report having missed between one and three menstrual periods. Approximately 90% of patients with ectopic pregnancies experience localized or diffuse abdominal pain that may be present only briefly or for longer than a week before the diagnosis is made. The classic triad of amenorrhea, abdominal pain, and abnormal bleeding occurs in only about 70% of patients with ectopic pregnancy. On examination, the uterus is normal in size or only minimally enlarged because it does not contain the embryo.

Transvaginal or transabdominal ultrasonography is used to guide the management of an adolescent patient with vaginal bleeding and a positive qualitative pregnancy test. If sonography shows that the pregnancy is intrauterine and the fetus is viable, threatened abortion is diagnosed. The bleeding is usually light; some patients have uterine cramps. A spontaneous abortion is considered inevitable or incomplete if the fetal heartbeat is not detectable or if tissue fragments have already been expelled from the uterus. The bleeding is usually heavier, and the patient reports painful uterine contractions. Quantitative b-hCG levels can remain well above 0 for as long as 4 to 6 weeks after spontaneous and induced abortions.

Septic abortion is diagnosed if signs of infection—usually fever, disproportionately severe pelvic pain, and leukocytosis—are present during a spontaneous or induced abortion. After an induced abortion, persistent or heavy bleeding may indicate retained products of conception. In a missed spontaneous abortion, the embryo is not expelled from the uterus within 4 weeks of its death. Dark bleeding is often seen. The patient's symptoms of pregnancy may have regressed, the uterus is smaller than it should be according to her menstrual history, and disseminated intravascular coagulation may occur. Although the emergency physician needs to be able to recognize these complications of pregnancy, consultation with an obstetrician is an important component of clinical management for pregnant patients with bleeding.

Sonographic signs suggestive of ectopic pregnancy include a solid or complex adnexal mass, a pelvic mass, particulate fluid in the fallopian tube, an endometrial pseudogestational sac, and cul-de-sac fluid. If sonography fails to demonstrate either a definite intrauterine pregnancy or a clearly ectopic pregnancy, a quantitative b-hCG level should be obtained. On ultrasonographic examination, an intrauterine gestational sac should be visible with an abdominal probe when the b-hCG level is above 6000 mIU/mL and with a transvaginal probe when the b-hCG is above 2000 mIU/mL. A fetal heartbeat is detectable by approximately the fifth week of gestation (3 weeks after conception) on transvaginal ultrasonographic examination and by the sixth or seventh week of gestation on transabdominal ultrasonography. Among patients with vaginal bleeding, no definite intrauterine gestational sac on transvaginal sonography, and a b-hCG level of 2000 mIU/mL or higher, about 40% will miscarry, about 55% have ectopic pregnancies, and only about 5% have normal intrauterine pregnancies.

Serum progesterone measurement can also be helpful in predicting the outcome of pregnancy complicated by vaginal bleeding. The likelihood of fetal viability declines as the progesterone level declines. Approximately 90% of pregnant patients with vaginal bleeding but with progesterone concentrations above 20 ng/mL have normal pregnancy outcomes. However, at a progesterone level below 10 ng/mL, only about 20% of pregnancies will continue normally. Serum

progesterone measurement is not helpful in distinguishing spontaneous abortion from ectopic pregnancy.

Pregnant patients with vaginal bleeding and indeterminate results on transvaginal ultrasonography should be followed carefully, either by admission to hospital or by close outpatient follow-up with serial quantitations of b-hCG. Obstetric consultation should be obtained in developing an appropriate management plan. In a normal pregnancy, between days 5 and 42 after conception and above an initial level of 100 mIU/mL, the b-hCG level doubles approximately every 2 days. A decline in b-hCG on serial measurement or an increase of less than 66% in 48 hours will suggest a nonviable fetus, but cannot differentiate intrauterine from extrauterine pregnancy.

VAGINAL OR CERVICAL BLEEDING

On pelvic examination, only a few patients will prove to have vaginal or cervical bleeding. Patients with bleeding from significant vulvar, vaginal, or cervical lacerations should be referred to a gynecologist. The evaluation and management of victims of sexual assault are discussed in detail in Chapter 94 and Chapter 128. Hymenal tears produced by coitus rarely require any treatment beyond reassurance for the patient. Bleeding genital warts should not be treated with topical podophyllin because toxic amounts of the resin can be absorbed systemically (see Chapter 94). Malignant tumors are a rare cause of vaginal bleeding during adolescence.

Patients are unlikely to be aware of cervical friability or bleeding caused by infection. On examination, however, punctate cervical hemorrhages (a strawberry cervix) can be seen in about 3% of women with trichomonal vaginitis. Cervical bleeding after swabbing and mucopurulent discharge are common manifestations of cervicitis caused by *Chlamydia trachomatis*. Cervical lesions of herpes simplex may also cause a small amount of bleeding.

UNDIAGNOSED UTERINE BLEEDING

Most adolescents with the complaint of vaginal bleeding are not pregnant, and their bleeding is uterine in origin. Each of these patients should receive a complete blood count to screen for anemia and thrombocytopenia. Thrombocytopenia of any cause is the most common coagulation defect responsible for excessive menstrual bleeding. The history and physical examination may now lead the emergency physician to consider as more or less likely each of the several diagnoses discussed below (Fig. 76.4).

FIGURE 76.4. A diagnostic approach to abnormal uterine bleeding after menarche: nonpregnant patients.

ADNEXAL MASS

An adnexal mass in a teenager with abnormal uterine bleeding and a negative pregnancy test may be an ovarian cyst, an abscess, or rarely, a neoplasm. Laboratory investigations should be used to clarify the size, location, and nature of the mass (ultrasonography) and to estimate the likelihood of pelvic infection (leukocyte count, sedimentation rate, cervical tests for gonorrhea and chlamydial infection).

PELVIC TENDERNESS

Pelvic inflammatory disease and ovarian cysts are the likely diagnostic possibilities in a patient with abnormal uterine bleeding and pelvic pain or tenderness. Abnormal bleeding occurs in nearly one-third of patients with pelvic inflammatory disease, probably as a result of endometritis. Pelvic inflammatory disease is discussed in greater detail in Chapter 94. Rarely, an adolescent has spotty midcycle bleeding for 24 hoursor less in association with the transient decline in estrogen level that occurs at the time of ovulation. The unilateral pain of mittelschmerz may accompany this brief bleeding episode.

PAINLESS UTERINE BLEEDING

Most patients with painless abnormal bleeding have dysfunctional uterine bleeding (DUB), a consequence of anovulation. Anovulation is an especially likely diagnosis in patients who experience alternating oligomenorrhea and menometrorrhagia. The most common underlying causes of the anovulation itself are functional immaturity of the hypothalamic–pituitary axis, obesity, and polycystic ovary syndrome (see Chapter 48). The management of DUB is detailed in Chapter 94. Hypothyroidism should be considered as a possible underlying cause of dysfunctional uterine bleeding if the patient has other symptoms or signs of thyroid dysfunction.

Hormonal contraception is an important, common cause of dysfunctional uterine bleeding. Of women who use birth

control pills containing 35 µg or less of estrogen, 5 to 10% will have breakthrough intermenstrual spotting or bleeding, especially during the first 3 months of contraceptive pill use. Breakthrough bleeding is also a common side effect of progestin-only contraceptive pills, injectable medroxyprogesterone, and long-acting progestin implants. Many patients using birth control pills experience estrogen withdrawal bleeding if they forget to take one or several pills.

Less common causes of painless abnormal bleeding include gonococcal and chlamydial endometritis, pharmacologic anticoagulation, and disorders of platelet function (e.g., Glanzmann's thrombasthenia, von Willebrand's disease). Every sexually active patient should be screened for gonorrhea and chlamydial infection. Also to be kept in mind is the possibility, albeit unlikely, of a false-negative urine pregnancy test (as a result of testing too soon after conception, dilute urine, or low hCG production by a blighted or ectopic ovum). The large number of commercially available urine pregnancy tests vary in sensitivity. The ED physician should be aware of the lower limit of detection of the hCG test in use at his or her facility.

CHAPTER 77

Vaginal Discharge

JAN E. PARADISE, MD

Department of Pediatrics, Boston University School of Medicine, and Child Protection Program, Boston Medical Center, Boston, Massachusetts

Normal infants over 1 month of age and prepubertal girls do not have liquid vaginal secretions. Consequently, any vaginal discharge in a female child is abnormal. However, vaginal discharge in neonates and girls who are pubertal may be either normal or abnormal because during these times, estrogen, either maternal or endogenous, stimulates growth of the vaginal epithelium and secretion of mucus by the paracervical glands. The resulting vaginal discharge consists of desquamated epithelial cells and mucus, is not irritating, and requires no treatment. It is known as physiologic leukorrhea. A vaginal discharge that persists beyond the neonatal period, that occurs during childhood, or that is accompanied by discomfort in a pubertal patient is abnormal and needs to be investigated.

EVALUATION AND DECISION

General Considerations

Although the complaint of vaginal discharge is common among both children and adolescents, the emergency physician should recognize from the outset that this symptom is not necessarily a sensitive or a specific indicator of actual lower genital tract disease. On the one hand, as noted in the definition given previously, an asymptomatic vaginal discharge during the first several weeks of life or after the onset of puberty is a normal occurrence. This physiologic leukorrhea nevertheless may prompt an emergency department (ED) visit by a girl in early puberty concerned about the unexpected change in her body's function. On the other hand, among prepubertal girls, the complaint of vaginal discharge, irritation, itching, or dysuria can indicate a urologic, gastrointestinal (GI), dermatologic, or gynecologic disorder. Thus, the emergency physician must routinely review GI and dermatologic, as well as genitourinary, symptoms when evaluating a girl with the complaint of vaginal discharge. In addition, every child with genital complaints (and her parents) should be asked directly about the possibility that she has experienced sexual contact (see Chapter 128). Although physicians are sometimes reluctant to raise this question, many parents will have considered it already, and some will have asked their daughters before the visit to the doctor.

The physical examination and cultures of any vaginal discharge visible on examination are the emergency physician's best guides to proper management of an infant or child with the complaint of vaginal discharge. For examination of the external genitalia, infants and children should be placed in the frog-leg position either on the parent's lap or on an examining table (see Fig. 94.2A). The genital mucosa of infants and children is normally reddish rather than dull pink, because the epithelium is relatively thin in the absence of estrogenic stimulation. This appearance of the introitus should not be mistaken for inflammation. Children should be examined next in the knee–chest position to check for the presence of a foreign body (see Fig. 94.2B). If the examiner sees a vaginal discharge when the child is in either position, a specimen should be collected for culture after the child has returned to the supine position. The use of a soft plastic medicine dropper or a bladder catheter attached to a 3-mL syringe with butterfly tubing is a fairly comfortable method for aspirating vaginal secretions. If a girl's secretions are minimal, the dropper or catheter can be used instead to instill and then withdraw nonbacteriostatic saline washings for culture. Alternatively, the physician can obtain secretions with a cotton-tipped swab moistened with nonbacteriostatic saline solution, but this method is usually less comfortable for the patient.

If a postpubertal girl with vaginal discharge or other lower genital tract complaints has never had sexual intercourse, a speculum examination is not necessary for her evaluation. Either the frog-leg or the lithotomy position may be used for inspection of the girl's external genitalia and for the collection of specimens for microscopic examination, culture, or both.

Standard speculum and bimanual pelvic examinations are integral components of the evaluation of sexually active adolescents with vaginitis. Because these patients have high rates of sexually transmitted infections, the examiner should routinely obtain vaginal specimens for microscopy and cervical specimens for the diagnosis of *Chlamydia trachomatis* and *Neisseria gonorrhoeae.* In addition, the emergency physician must be alert for signs of pelvic inflammatory disease and pregnancy.

The patient's age and hormonal status should be considered first in the differential diagnosis of vaginal discharge (Fig. 77.1). For a more detailed discussion of the specific vaginal infections mentioned in this section, the reader is referred to Chapter 94.

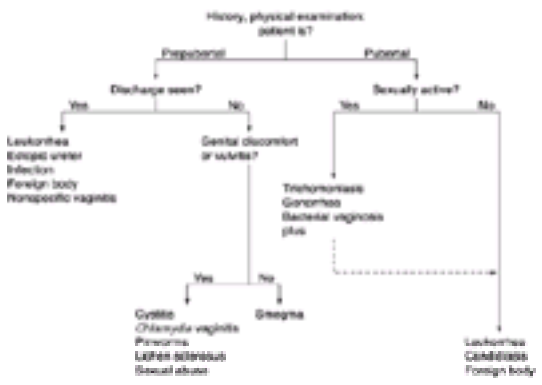

FIGURE 77.1. A diagnostic approach for vaginal discharge.

Infancy and Childhood

Physiologic leukorrhea is a normal vaginal discharge common among female infants during the first 2 to 3 weeks of life. It is clear or white, slippery when fresh, and sticky when dried. Some neonates have associated withdrawal bleeding when maternal estrogenic stimulation of the uterine endometrium wanes. Trichomonal vaginitis should be suspected if an infant's discharge persists beyond the neonatal period. Occasionally, a baby whose mother has trichomonal vaginitis acquires this infection during delivery. Infected infants may be irritable and have a whitish or yellowish thin discharge. Uncommonly, infants have purulent discharge associated with a congenital malformation of the genitourinary tract (e.g., ectopic ureter). A malformation should be suspected if an infant's discharge is accompanied by signs of systemic infection (fever, vomiting, or poor appetite) or if a child with chronic discharge also has had recurrent urinary tract infections (UTIs).

Among older infants and children, a visible vaginal discharge is most likely to indicate a bacterial infection. Cultures for *N. gonorrhoeae* and for other pathogens must therefore be obtained. Children with vaginitis should never be treated with antibiotics on the basis of the character of the discharge, microscopy, or Gram stain. Definitive diagnosis by culture is necessary to guide antibiotic selection and to address the medicolegal or public health questions raised when gonorrhea or *Shigella* is diagnosed.

Gonococcal infection typically produces a whitish to greenish purulent discharge. Bloody discharge occurs in half the cases of *Shigella* vaginitis and is common in vaginitis caused by group A b-hemolytic streptococci. Trichomonal vaginitis occurs virtually exclusively in infants less than 6 months of age and in postpubertal children. Chlamydial infections are nearly always asymptomatic but can produce dysuria, genital discomfort, or a scant mucoid vaginal discharge. Diagnostic tests for *C. trachomatis* vaginal infection should be reserved for children with histories of sexual abuse and for those whose bacterial cultures already have proved negative because the prevalence of infection is low in unselected populations and because false-positive antigen-detection tests are relatively common. As in adults, diabetes mellitus, broad-spectrum antibiotics, and immunodeficiency are risk factors for the development of candidal vaginitis in children.

An intermittently bloody, foul-smelling vaginal discharge is the classic complaint of the patient with a vaginal foreign body. Small wads of toilet paper, the most common foreign bodies, are usually easy to see just inside the vaginal vault on knee–chest examination. The emergency physician must have a high index of suspicion for this diagnosis if the child's vagina cannot be inspected satisfactorily while in the knee–chest position, because intravaginal toilet paper cannot be palpated rectally. Rigid foreign bodies—pencil erasers, pins, beads, nuts—are more likely to be palpable during rectal examination but are uncommon. Gentle vaginal lavage with saline solution can be used to flush out bits of toilet paper. Small round objects sometimes can be removed if the examiner places a finger in the rectum and then applies gentle outward pressure. However, if the object is large or sharp or if simpler maneuvers fail, visualization and removal of a foreign body under conscious sedation or general anesthesia may be required.

If examination of the patient discloses vulvar inflammation, excoriation, or hypopigmentation but little or no vaginal discharge, lichen sclerosus and other dermatologic disorders should be considered in the differential diagnosis. Lichen sclerosus is a chronic, idiopathic dermatitis characterized by atrophy, telangiectasia, and hypopigmentation of the perineal skin, often in a figure-of-eight pattern (see Fig. 76.2). Because severe cases can resemble genital trauma, the physician should take care not to confuse the two. Perineal excoriation or inflammation secondary to pinworm infestation, varicella, or any generalized dermatitis also can be misinterpreted as primary vulvovaginal disease.

Some girls with complaints of vaginal discharge or discomfort will have no abnormality on genital examination. In these cases, diagnostic possibilities include poor perineal hygiene, smegma, masturbatory behavior, sexual abuse, *Chlamydia* vaginitis, and UTI. Girls with poor perineal hygiene will respond well to frequent sitz baths. Genital smegma occurs in girls, as well as in boys, and sometimes is mistaken by parents for a pathologic discharge. It consists of desquamated epithelial cells; is thick, yellow or white, and sticky; and is characteristically located in the interlabial folds and around the clitoral prepuce. Somatic genital discomfort is the presenting complaint of a small number of children who have been sexually abused but are not injured or infected. The task of differentiating abused children from those who display age-appropriate masturbation or genital curiosity can be difficult and often requires consultation with a specialist in child mental health or sexual abuse assessment. The possibility of UTI also should be pursued in girls with genital symptoms but normal physical examinations.

Children with vaginal discharge that cannot be ascribed to any of the conditions just discussed generally are considered to have nonspecific vaginitis. This condition has been attributed to poor perineal hygiene and mechanical or chemical irritants. Accordingly, frequent sitz baths, careful wiping anteroposteriorly after defecation, and the avoidance of

presumed irritants (e.g., ballet tights, bubble bath, sand) are recommended for its treatment. These measures will produce improvement in most patients with nonspecific vaginitis but should not be recommended until after examination has been performed and appropriate cultures obtained.

Adolescence

With the onset of puberty, girls' rising estrogen level promotes the discharge of vaginal mucus and cells. This physiologic leukorrhea persists throughout the reproductive years but is most likely to arouse the concern of girls who are starting puberty and are therefore unaccustomed to its presence. On microscopic examination, the discharge shows only abundant epithelial cells. Culture of a specimen is unnecessary. Postpubertal girls with genital itching are most likely to have candidal vaginitis, even in the absence of any predisposing factor. The associated cheesy discharge may be so scanty that it goes unmentioned by the patient and unnoticed by the clinician. Among postmenarchal patients, birth control pills, broad-spectrum antibiotics, diabetes mellitus, and pregnancy are associated with an increased likelihood of symptomatic vulvovaginal candidiasis. Physical irritants, either mechanical or chemical, should be considered in the differential diagnosis for patients with nonspecific examinations and only polymorphonucleocytes or no abnormality on microscopic examination of the vaginal discharge. Although it is much more common among sexually active adolescents, bacterial vaginosis (see below) occurs occasionally in teenagers who have never had sexual intercourse. A forgotten tampon, the most common intravaginal foreign body, is a rare cause of vaginitis in adolescents.

In girls who have had sexual intercourse, bacterial vaginosis (known previously as nonspecific vaginitis, *Gardnerella* vaginitis, *Haemophilus vaginalis* vaginitis, and *Corynebacterium* vaginitis), trichomoniasis, and gonorrhea are the most likely causes of an abnormal vaginal discharge. Bacterial vaginosis is a clinical syndrome characterized by increased, malodorous vaginal discharge with a pH above 4.5, clue cells but few neutrophils seen on microscopy, and the release of an aminelike odor when potassium hydroxide is added to the discharge. The syndrome is thought to reflect overgrowth of anaerobes and *G. vaginalis* and a relative paucity of lactobacilli in the vaginal ecosystem; it is probably the most common cause of symptomatic vaginal discharge among sexually active adolescents who visit urban EDs. Trichomonal vaginitis is characterized by an increased volume of vaginal discharge associated in some cases with mild pruritus. The discharge is frothy in about 25% of cases. Gonococcal cervicitis or endometritis can produce a noticeable vaginal discharge, but most infected adolescent girls have no lower genital tract symptoms. A pathologic discharge in a girl with gonococcal cervicitis is most likely to be caused by concomitant trichomoniasis or bacterial vaginosis.

Three maneuvers—measurement of the pH of vaginal discharge and microscopic examination of the discharge suspended in 0.5 mL or less of saline solution and in 10% potassium hydroxide—are needed to provide a diagnosis for adolescent patients with vaginitis. To avoid contamination by cervical discharge, specimens should be obtained by swabbing the lateral vaginal wall. Indicator paper should be applied directly to undiluted discharge to measure pH because blood, seminal fluid, lubricating jelly, and saline can falsely elevate the measurement.

Bacterial vaginosis may be diagnosed when three of four conditions are present (Amsel criteria): 1) a homogeneous, whitish discharge; 2) vaginal pH above 4.5; 3) a fishy odor liberated when potassium hydroxide is added to the discharge; and 4) clue cells. Clue cells are squamous epithelial cells with indistinct borders obscured by granular bacteria, best seen at 400 magnification. On Gram stain, long Gram-positive rods (lactobacilli) are scarce, and short Gram-negative and Gram-variable coccobacilli (*Gardnerella, Prevotella, Mobiluncus* species) are abundant. Trichomoniasis is easily diagnosed if motile flagellates are seen on microscopic examination (see Fig. 94.7). However, because microscopy is negative in 20 to 50% of infected women, a rapid DNA probe test or a culture for *Trichomonas* can be helpful for diagnosing patients with suggestive symptoms or signs but negative wet preps. Fungal hyphae are not visible microscopically in over half of patients with symptomatic candidiasis (see Fig. 94.8). It is therefore reasonable to recommend empirical antifungal treatment for patients with vulvovaginal pruritus or burning and a vaginal pH less than 5 if a mechanical or physical irritant cannot be identified and if no alternative diagnosis is identified on microscopy.

A follow-up plan should be outlined clearly for every adolescent patient seen in the ED with a newly diagnosed sexually transmitted infection to identify treatment failures and reinfections, to ascertain whether the patient's sexual partner was treated, to explore the patient's need for contraception, and to carry out other preventive health measures, including Papanicolaou screening and acquired immunodeficiency syndrome (AIDS) counseling.

CHAPTER 78

Vomiting

***MOLLY W. STEVENS, MD and *†FRED M. HENRETIG, MD**

**†Department of Pediatrics, The University of Pennsylvania School of Medicine, and †Division of Emergency Medicine, †Section of Clinical Toxicology, The Children's Hospital of Philadelphia, †The Poison Control Center, Philadelphia, Pennsylvania*

Vomiting is defined as the forceful, coordinated act of expelling gastric contents through the mouth. Vomiting may be caused by number of problems in diverse organ systems. Although it often represents a transient response to a self-limited infectious, chemical, or psychologic insult, it also may portend serious infections, metabolic disturbances, or diseases in gastrointestinal (GI), neurologic, or other major organ systems. Thus, an orderly approach to diagnosis is crucial.

Vomiting is a highly complex act, involving coordinated closure of gastric pylorus and glottis; relaxation of stomach, cardioesophageal junction, and esophagus; and vigorous diaphragmatic and abdominal wall muscular contraction. A series of interconnected coordinating centers in the medulla have been identified, with varying responsiveness to afferent signals from diverse areas of the body, including nocireceptors, chemoreceptors, and mechanoreceptors in the pelvic and abdominal viscera and peritoneum, genitourinary system, pharynx, labyrinth, and heart. The chemoreceptor trigger zone (CTZ) in the floor of the fourth ventricle contains chemoreceptors that monitor both blood and cerebrospinal fluid and is probably the key center initiating the emetic response to drugs (especially cytotoxic chemotherapeutic agents) and metabolic aberrations. Recent therapeutic advances arise from an evolving understanding of neurotransmitter activity in these centers. Blocking serotonin (5-hydroxytryptamine) in the CTZ and in vagal nuclei using receptor antagonists (ondansetron hydrochloride or granisetron) has proven to be successful in preventing emesis associated with many chemotherapeutic and radiotherapeutic cancer treatments, as well as emetogenic poisonings.

A related complaint, also often heard in the emergency department (ED), is that of young infants who “spit up.” This refers to the nonforceful reflux of milk into the mouth, which often accompanies eructation. Such nonforceful regurgitation of gastric or esophageal contents is most often physiologic and of little consequence, although it occasionally represents a significant disturbance in esophageal function.

It is convenient to attempt to organize the many diverse causes of regurgitation and vomiting into age-related categories (Table 78.1). Although overlap is considerable, the most common and serious entities tend to fall into such groupings.

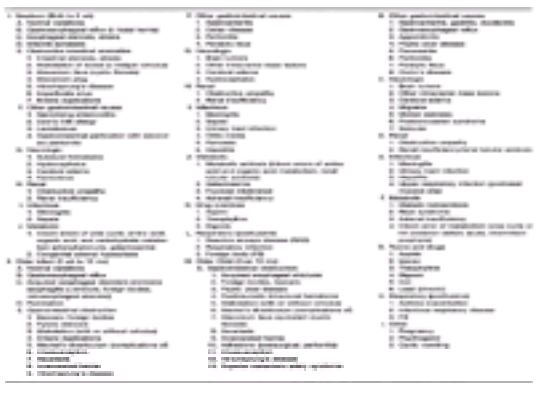

Table 78.1. Vomiting and Regurgitation: Principal Causes by Usual Age of Onset and Etiology

EVALUATION AND DECISION

General Approach

A brief perusal of the long list of causes for vomiting in Table 78.1 serves to emphasize the need for an orderly approach to the differential diagnosis of this symptom. The approach advocated here focuses on three key clinical features: child's *age*, evidence of *obstruction*, and signs or symptoms of *extra-abdominal organ system disease.* Other important points to

consider include *appearance* of the vomitus, *overall degree of illness* (including the presence and severity of dehydration or electrolyte imbalance), and *associated GI symptoms*.

HISTORY

The history should focus on the key elements already listed. The patient's age often is critical because certain important entities (especially those that cause intestinal obstruction) are seen exclusively in neonates, older infants, or children beyond the first year of life. Evidence of obstruction, including symptoms of abdominal pain, obstipation, nausea, and increasing abdominal girth, are sought in addition to vomiting. Other associated GI symptoms may include diarrhea, anorexia, flatulence, and frequent eructation with reflux. The suspicion of significant extra-abdominal organ system disease is raised by neurologic symptoms such as severe headache, stiff neck, blurred vision or diplopia, clumsiness, personality or school performance change, or persistent lethargy or irritability; by genitourinary symptoms such as flank pain, dysuria, urgency and frequency, or amenorrhea; by common infectious complaints such as fever, sore throat, or rash; or by respiratory complaints such as cough, increased work of breathing, or chest pain (Table 78.2 and Table 78.3).

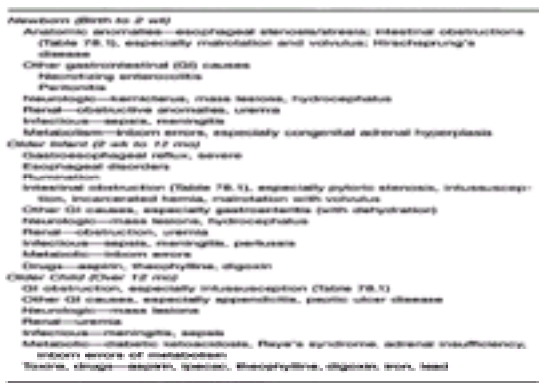

Table 78.2. Life-Threatening Causes of Vomiting

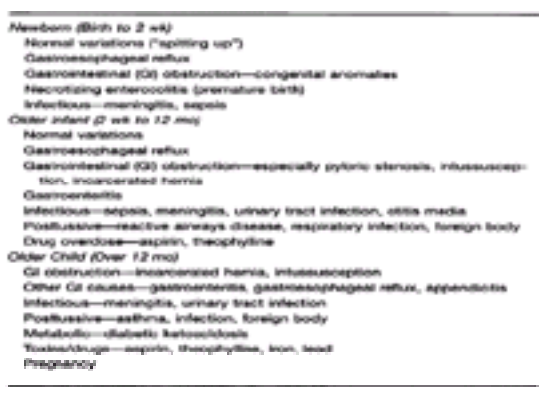

Table 78.3. Common Causes of Vomiting

The appearance of the vomitus (by history and inspection when a specimen is available) often is helpful in establishing the site of pathology. Undigested food or milk should suggest reflux from the esophagus or stomach caused by lesions such as esophageal atresia (in the neonate), gastroesophageal (GE) reflux, or pyloric stenosis. Bilious vomitus suggests obstruction distal to the ampulla of Vater, although it occasionally is seen with prolonged vomiting of any cause when the pylorus is relaxed. Fecal material in the vomitus is seen with obstruction of the lower bowel. Hematemesis usually reflects a bleeding site in the upper GI tract; its evaluation is detailed in Chapter 30.

PHYSICAL EXAMINATION

The physical examination is directed first toward evaluating the overall degree of toxicity. Does the baby look septic? Is there the inconsolable irritability of meningitis? Are there signs of life-threatening dehydration or concern for symptomatic hypoglycemia? Does the child exhibit the bent-over posture, apprehensive look, and pained avoidance of unnecessary movement typical of peritoneal irritation in appendicitis? Next, attention is aimed at the abdomen. Are there signs of obstruction such as ill-defined tenderness, distension, high-pitched bowel sounds (or absent sounds in ileus), or visible peristalsis? A complete physical examination must include a search for signs of neurologic, infectious, toxic/metabolic, and genitourinary causes, as well as an evaluation of hydration status (see Chapter 18).

The diverse nature of causes for vomiting makes a “routine” laboratory or radiologic screen impossible. The history and physical examination must guide the approach in individual patients. Some well-defined clinical pictures demand urgent radiologic workup. For example, abdominal pain and bilious vomiting in a child requires supine and upright plain films and a limited upper GI series for evaluation of congenital obstructive anomalies such as malrotation; or a child with paroxysms of colicky abdominal pain and grossly bloody stools requires immediate flat and upright abdominal films and usually a contrast (air or barium) enema for the likely diagnosis and reduction of intussusception. Other situations require no imaging studies (e.g., a typical case of viral gastroenteritis or a classic history for pyloric stenosis with definite palpation of the pyloric tumor). In many cases, body fluid cultures or serum chemical analyses are essential for making a diagnosis (e.g., meningitis, aspirin toxicity, Reye syndrome, pregnancy) or for guiding management (e.g., degree of metabolic derangement in pyloric stenosis, diabetic ketoacidosis). For most straightforward, common illnesses (e.g.,

gastroenteritis, cold with posttussive emesis), laboratory investigation is unwarranted.

APPROACH TO CHILDREN BY AGE GROUPS

With these introductory concepts in mind, we can approach the differential diagnosis of the principal causes of vomiting on an age-related basis. An algorithm for such an approach that uses the key clinical features previously outlined is illustrated in Figure 78.1.

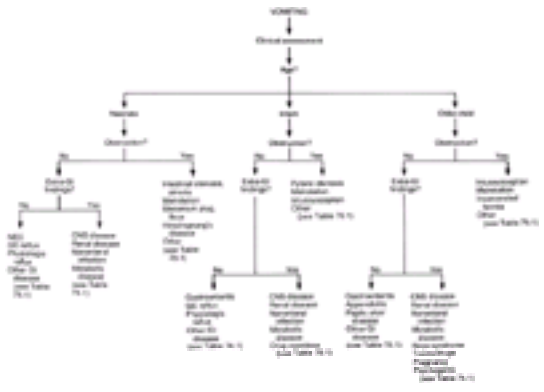

FIGURE 78.1. Differential diagnosis of vomiting. *GI,* gastrointestinal; *NEC,* necrotizing enterocolitis; *GE,* gastroesophageal; *CNS,* central nervous system.

Neonates

A careful history should focus on the perinatal events, onset and duration of vomiting, nature of the vomitus, associated GI symptoms, and the presence of symptoms referable to other organ systems. Newborn babies with the onset of vomiting in the first days of life always should be suspect for one of the common *congenital GI anomalies* that cause obstruction, such as esophageal or intestinal atresia or web, malrotation, meconium ileus, or Hirschsprung's disease. If the vomiting is bilious, bright yellow, or green, an urgent surgical consultation is required. In most cases, a serious and possibly life-threatening mechanical obstruction may be the cause of bilious vomiting. All patients in whom the possibility of GI obstruction is entertained must have immediate flat and upright abdominal films. Other clinical features, such as toxicity, dehydration, and lethargy, usually attest to the length of time of the obstruction and its severity. Except for the later presentations of malrotation, most neonates with a congenital basis for their bowel obstruction will present during their initial nursery stay. Therefore, it is uncommon to see such babies for the first time in the ED. Neonates or infants with malrotation and volvulus may present with abdominal pain (crying, drawing up their knees, poor feeding), with evidence of obstruction (bilious emesis), or an acute abdomen (abdominal distension or rigidity). The diagnosis of malrotation is confirmed by the abnormal radiographic location of the duodenal–jejunal junction (upper GI series) and/or the cecum (contrast enema).

Other serious causes of neonatal vomiting that may present to the ED include *infection*, such as meningitis, sepsis, pyelonephritis, or necrotizing enterocolitis (it should be noted that such serious infections are often not accompanied by fever in the neonate); *increased intracranial pressure* (ICP) related to cerebral edema, subdural hematoma, or hydrocephalus; *metabolic acidosis* or *hyperammonemia* caused by the rare inborn errors of amino acid and organic acid metabolism; and *renal insufficiency* or *obstruction*. Such infants usually appear ill, with associated lethargy and irritability; sometimes fever, a full fontanel, a diminished urinary stream, an abdominal mass, or respiratory signs will suggest the correct cause. Obviously, any ill neonate with vomiting, even in the absence of obstruction, also requires hospitalization and prompt evaluation for sepsis and neurologic, renal, and metabolic disease.

Commonly, however, a young infant in the first 2 to 4 weeks of life who appears entirely well is brought to the ED with the complaint of persistent vomiting. The birth history and perinatal course are unremarkable. The baby has gained weight appropriately (usually 5 to 7 oz/week after the first week of life), is vigorous, and has an entirely normal physical examination. Usually, a close description of the “vomiting” (or even better, a trial feeding in the ED) reveals the problem to be *physiologic regurgitation* or *reflux*; so-called spitting up. This is a common (nearly 20% of infants reflux) and insignificant problem, probably representing some normal variation in the developmental maturation of the lower esophageal sphincter (LES). These infants do not exhibit forceful abdominal contractions but rather reflux milk effortlessly into their mouths, which dribbles out, usually when prone, and often with a burp. The degree of reflux may be increased by improper feeding techniques such as failure to burp the baby, using nipples with holes that are too small, bottle propping, or overfeeding. Observation of a feeding trial and emphasis on good technique suffices for initial management of such babies. Like all newborns, they should be referred for ongoing pediatric care. Most babies outgrow such regurgitation by 6 to 9 months of age, and 95% have resolution of symptoms by 12 months.

Other infants who regurgitate easily may not be managed so easily. Their course may have more significant symptoms of pain, arching, and high volume and frequency of regurgitation, or it may be complicated by distal esophagitis or gastritis, failure to thrive, esophageal–peptic strictures, pulmonary disease, or rarely, apnea or near–sudden infant death syndrome (SIDS) event. Such infants are diagnosed as having *gastroesophageal reflux disease* (GERD), a more severe or pathologic degree of LES dysfunction that is much less common (1:500). Several imaging and physiologic studies may be used to confirm the diagnosis and to correlate a patient's signs and symptoms with episodes of reflux. A 24-hour intraesophageal pH probe is the most sensitive diagnostic test for GE reflux. Based on the patient's history, evaluation of delayed gastric emptying can be done by GE scintiscan, or by an upper GI series to rule out an anatomic cause for the delay. Endoscopy is used to assess suspected complications (esophagitis or stricture); esophageal manometry is primarily a research tool in this disease. Infants with GE reflux should be followed closely by a pediatrician. In

uncomplicated GE reflux, reassurance, postural management, and dietary measures are usually adequate. For more severe symptoms or with complications, additional medical management includes the use of prokinetic agents (cisapride or metoclopramide) and acid blockade (ranitidine or cimetidine). Omeprazole, a proton pump inhibitor, has been useful for resistant or severe esophagitis, but its safety and dosing in young children has not been well established. GERD that is resistant to vigorous medical therapy (continues to cause serious complications) may be considered for surgical fundoplication (see Chapter 93 and Chapter 118).

Older Infant

Infants who present with vomiting after the first few weeks of life may still have intestinal obstruction, but the underlying causes are somewhat different than in the neonate. The important lesions responsible for mechanical obstructions in this age group include congenital hypertrophic pyloric stenosis (HPS), malrotation, intussusception, incarcerated hernia, enteric duplications, and complications of Meckel's diverticulum. Occasionally, other anomalies that might be expected to present in the neonate, such as Hirschsprung's disease, will appear only after several weeks or months of life. In all cases, these conditions have physical findings suggestive of intestinal obstruction and often are specific for the level of obstruction. Having a high index of suspicion for both common and uncommon forms of intestinal obstruction is important to making a timely diagnosis.

The typical infant with *pyloric stenosis* (see Chapter 118) appears in the ED at 4 to 6 weeks of age (95% present by 3 months; rarely after 20 weeks) with a chief compliant of projectile vomiting during or shortly after a feeding. The vomiting in pyloric stenosis is typically crescendo in nature, with increasing frequency and severity over days to weeks. By contrast, vomiting caused by GE reflux tends to be relatively consistent over time; in malrotation, vomiting is sudden in onset and can be episodic. The vomitus is nonbilious, reflecting obstruction at the pylorus, and usually is voluminous, nearly the entire content of the feeding. The infant may become constipated if vomiting has been of sufficient duration. On examination, an olive-sized mass may be palpated (most easily after vomiting has occurred) in the right upper quadrant to the right of the midline and just above the umbilicus. Peristaltic waves may be visualized, moving from left upper to right upper quadrants, again indicating obstruction at the pylorus. Unless the infant is significantly dehydrated, the child usually is vigorous and active, although irritable because of hunger. These infants often develop hypochloremic, hypokalemic metabolic alkalosis, which should be corrected before surgery (see Chapter 86).

The diagnosis of pyloric stenosis is clinical, based on the classic history of projectile, nonbilious emesis, and examination with hyperperistalsis and palpation of a pyloric mass or “olive.” Imaging studies (ultrasound (US) or upper GI series) are not necessary if the history and examination are conclusive. In recent years, however, earlier presentations have resulted in a greater number of infants evaluated before the development of the diagnostic clinical hallmarks, and consequently an increased reliance on imaging studies to confirm the diagnosis. Early diagnosis has been beneficial with a decrease in the proportion of patients with alkalosis, shortened hospital stay, and decreased morbidity. US has become the diagnostic modality of choice with characteristic findings in HPS of a thickened pyloric wall (greater than 3 mm) with a lengthened canal (greater than 15 mm). However, some centers have found upper GI series to be more cost effective because of greater operator experience with the procedure and therefore fewer repeat studies, and the ability to provide information on other origins of nonbilious vomiting. Endoscopy has recently been recommended as an adjunct test for complicated cases in which clinical examination, US, and/or upper GI series were inconclusive. Surgical pylorotomy, the standard treatment for HPS, is scheduled as soon as dehydration and metabolic derangements (if present) have been corrected. Medical management with intravenous or oral atropine has been successful in a recent re-investigation. Still, a larger, well-controlled trial and cost analysis would be necessary before its use is recommended in place of surgical correction.

Between 2 months and about 5 to 6 years of age, the most common cause of obstruction is *intussusception* (see Chapter 118). Most children develop this disorder between 3 months and 2 years of age; the average was 16 months old in a recent large series. Early symptoms usually include paroxysms of colicky abdominal pain and vomiting, suggesting a GI illness. Initially, the infant may appear relatively well between attacks, but some children will fall asleep or seem prostrate at these times. Initially, there may be a normal stool, then occult positive, but usually within 6 to 12 hours, dark maroon blood is passed per rectum; this blood often is mixed with mucus, earning the label of “currant jelly” stool. However, some infants with intussusception may present primarily with lethargy and decreased responsiveness, without striking GI symptoms (so-called neurologic or painless intussusception). Examination of the abdomen usually reveals a somewhat tender, sausage-shaped mass on the right side. The mass may be more easily appreciated by bimanual rectal and abdominal examination, and a test for occult blood may be positive in the absence of gross blood.

Recommendations for the diagnosis and treatment of suspected intussusception include supine and right-side up decubitus radiographs (decubitus to look for free air or mass at the hepatic flexure region; supine for signs of obstruction such as abnormal air–fluid levels, paucity of gas, or mass effect). US sometimes is used instead of radiographs if experienced personnel are available. Reduction is attempted by contrast (air or liquid) enema if perforation (free air on radiograph or peritonitis) or shock is not evident. Recent success rates for reduction in pediatric centers using air or liquid contrast enemas have improved to the range of 80 to 90%, with some centers reporting their increased success with repeated attempts after short intervals (45 to 60 minutes). Open reduction with laparotomy is reserved for patients with perforation or shock at initial diagnosis or when enema reduction is unsuccessful.

Other important causes of obstruction in the older infant include incarcerated inguinal hernia, volvulus, Hirschsprung's disease, or complications related to Meckel's diverticulum. The presence of an incarcerated hernia will be apparent on examination. Volvulus of the bowel is virtually always associated with bilious vomiting. A good clue to diagnosis of Hirschsprung's disease is asking, “Has your child ever had a normal (unstimulated) bowel movement?” (see Chapter 14 and Chapter 118). The obstructive complications of Meckel's diverticulum include intussusception and volvulus and have similar presentations of these types of obstruction related to other causes.

The principal nonobstructive causes of vomiting in the older infant include GI, neurologic, renal, infectious, and metabolic disorders. Nonobstructive GI disturbances are probably the most common cause for vomiting in this age group. *Viral gastroenteritis*, although usually appearing predominantly as diarrhea associated with vomiting, often begins with a

prodromal phase of vomiting alone (see Chapter 84). Physical findings usually are limited to ill-defined and inconsistent abdominal pain and signs of a variable degree of dehydration. Vomiting in older infants also is caused at times by persistent GE reflux, as well as by abdominal disorders uncommon in infancy, such as peptic ulcer disease or appendicitis. Occasionally, vomiting is seen in paralytic ileus related to infection (pneumonia, peritonitis) or electrolyte disorders.

Neurologic causes of vomiting in infancy also include *mass lesions* such as tumor, abscess, and intracranial hematoma (see Chapter 83), as well as *meningitis* and *encephalitis*. There may be evidence of increased ICP: increasing head circumference, bulging fontanel, and split sutures (papilledema is rarely noted during infancy). However, some brainstem tumors cause protracted vomiting by direct effect on the vomiting center without an accompanying increased ICP. Again, it is to be emphasized that meningismus rarely is seen with meningitis in infancy and that signs of increased ICP occur late (see Chapter 84). Early findings include fever, vomiting, lethargy, and irritability, especially the paradoxic irritability of increased crying with parental fondling.

Infections outside the GI and neurologic systems may cause vomiting in infants and, occasionally, in older children. The more important such infections are *otitis media* (OM), *urinary tract infection* (UTI), *respiratory infections*, and *viral hepatitis*. Positive physical findings on otoscopic examination are seen in OM, along with mild irritability, and often, fever (see Chapter 84). UTIs may be surprisingly devoid of localizing signs and symptoms in preschool children (see Chapter 122); nonspecific GI complaints, including vomiting and abdominal pain, fever, irritability, and anorexia, may be the only presenting symptoms. Urinalysis and culture provide the specific diagnosis. Vomiting also is a common event after the paroxysms of coughing seen in infants with pertussis (see Chapter 84). It is a common symptom in the prodromal phase of infectious hepatitis, usually preceding the onset of jaundice (see Chapter 93). Abnormal liver function tests substantiate this latter diagnosis.

Renal and *metabolic disorders* also cause vomiting in the older infant. Renal failure, renal tubular acidosis, or rarely, diabetic ketoacidosis may be seen in this age group. Hypoadrenalism, hepatic failure, Reye syndrome, and inborn errors of metabolism such as galactosemia and fructose intolerance also may present in infancy and may have vomiting as a prominent symptom in an ill-appearing infant.

Occasionally, parental overzealous use of over-the-counter or prescribed drugs in infants will lead to *intoxication.* Drugs that often produce vomiting in excessive doses include aspirin, theophylline, and digoxin; all of these intoxications are easily verified by associated signs and symptoms and specific drug levels. The problem of accidental ingestion is discussed later.

An additional rare cause of regurgitation or vomiting in infants, with onset usually at 6 to 12 months of age, is *rumination* (see Chapter 131). This severe psychiatric disorder of infancy, related to abnormal maternal–infant relationship, may progress to severe failure to thrive and to death. These infants seem to self-induce the reflux, often by gagging themselves, and often appear to partially rechew and reswallow their vomitus.

Older Child

Many of the causes of intestinal obstruction and other important GI diseases described in neonates and older infants, such as volvulus associated with malrotation, Hirschsprung's disease, a meconium ileus “equivalent” in the child with cystic fibrosis, and an incarcerated hernia, occasionally may first appear in the older child. Older children with malrotation and/or volvulus will often have a previous episodic history of vomiting or intermittent colicky abdominal pain. In addition, older children often are subjected to blunt abdominal trauma; persistent vomiting after such injury may reflect obstruction related to a duodenal intramural hematoma or ileus secondary to pancreatitis. Gastroenteritis, as in infants, continues to be the most common cause of vomiting in the older child seen in the ED. Two entities that usually occur in older children, appendicitis and peptic ulcers, are discussed here, although they occur rarely in infancy as well.

Appendicitis (see Chapter 118) in a preadolescent child classically begins with periumbilical, crampy abdominal pain and anorexia, often followed by vomiting. Then the pain shifts to the right lower quadrant and fever may develop. Younger children may deviate from this pattern by exhibiting less specific symptoms early in their illness and a more rapid progression to perforation and generalized peritonitis. As peritoneal irritation becomes well established, the child attempts to minimize any motion to the abdomen. Physical examination usually reveals localized involuntary right lower quadrant guarding and tenderness that, when mild, may be easier to elicit by asking the child to cough or to hop on one foot. In addition, there may be rebound and referred rebound tenderness along with a tender fullness high on the right during rectal examination. Atypical positions of the appendix (e.g., retrocecal, retroileal, pelvic) will be reflected in atypical areas of maximal tenderness, as well as in confusing symptoms such as diarrhea or dysuria (caused by appendiceal inflammation adjacent to colon or ureter/bladder). Pertinent laboratory findings often include leukocytosis with a left shift in the differential count, but a normal white blood cell (WBC) count in an afebrile patient does not rule out appendicitis. The urinalysis usually is normal. Occasionally, in an atypical patient, abdominal radiographs may be helpful in showing a right lower quadrant fecalith, localized obstruction, a mass effect with a paucity of gas in the right lower quadrant, or lumbar spine scoliosis. Appendicitis is a clinical diagnosis, but when the differential diagnosis is difficult or in early or equivocal cases, imaging studies are helpful. US has become the modality of choice in most centers for children with suspected appendicitis. US can be particularly helpful in distinguishing tubo-ovarian pathology or renal pathology from appendicitis. Computed tomography (CT) scan is widely becoming the imaging study of choice in adults; recent studies show excellent sensitivity of right lower quadrant CT with rectal contrast. In children, its use has currently been limited to patients with equivocal US studies or if an abdominal abscess is suspected. Its use has been suggested for patients with an unclear diagnosis who would be admitted to the hospital for observation, with the goal of decreasing therapeutic delays or of averting unnecessary admissions or surgeries.

Vomiting as a symptom of *peptic ulcer disease* in children usually is seen in association with abdominal pain (see Chapter 93). In young children, the pain often is nonspecific and not easily related to meals. In adolescents, the pattern becomes more classically related to food or antacids. There may be hematemesis and/or melena. The abdominal

examination may be normal or reveal mild to moderate epigastric tenderness. A strong clinical suspicion of peptic ulcer disease should be confirmed with an upper GI series or endoscopy. Other inflammatory lesions of the upper GI tract (gastritis, duodenitis, and Crohn's disease) can also cause persistent vomiting.

Genitourinary causes of vomiting in the older child include UTI and obstructive urologic disease. An important additional concern in adolescent girls is early *pregnancy* (see Chapter 48). It is common for such patients to visit the ED with the chief complaint of persistent vomiting (not necessarily only in the morning) for several weeks, and often sexual activity and/or amenorrhea is initially denied. Physical findings at this stage of pregnancy may be subtle. Thus, prolonged vomiting in a postmenarchal girl should be pursued with the appropriate urine or serum gonadotropin assays (see Chapter 48 and Chapter 130).

The important extra-GI infectious diseases of the older child that cause vomiting have been discussed for the most part under the neonatal and infantile headings of this chapter. Serious infections localize symptoms more readily in this older age group. Meningitis usually is accompanied by meningismus after the age of 2 years. Lower urinary infections tend to present with dysuria, frequency, and urgency as children approach school age, and pyelonephritis with fever and lower back pain or tenderness. The toddler or school-age child also may vomit with pharyngeal irritation (pharyngitis, postnasal mucous drip) or have posttussive emesis with persistent or severe cough caused by asthma, respiratory infection, or respiratory foreign body.

Neurologic disease that causes vomiting in the older child again represents (primarily) lesions that cause increased ICP or direct irritation of the medullary vomiting center; they usually lead to papilledema and/or abnormal neurologic findings on examination. One important exception is childhood *migraine* (see Chapter 83). Preadolescent children do not usually present with the classic migraine picture with aura, hemicranial headache, and scotomas. More often, they complain of rare but severe, poorly localized headaches accompanied by nausea and vomiting and followed by sleep. The physical examination between attacks usually is normal. Another common but minor form of vomiting on a neurologic basis (caused by labyrinthine stimulation) would be the propensity to motion sickness.

Metabolic aberrations, including hepatic, renal, and adrenal failure, all may cause vomiting in the older child (as well as during infancy). *Ketoacidosis* presenting for the first time in an as yet undiagnosed diabetic occurs more commonly in older children, especially at school entrance age and later as adolescence begins (see Chapter 97). Vomiting may be the chief complaint of such children, although careful questioning usually uncovers a preceding 3- to 4-week history of polyuria, polyphagia, polydipsia, and at times, weight loss. A fruity breath odor, dehydration, hyperpnea, and varying degrees of altered sensorium typically are present, and a urinalysis and serum glucose determination confirm the diagnosis of diabetic ketoacidosis.

The other important, but increasingly uncommon, cause of vomiting is *Reye syndrome* (see Chapter 93). Although it may occur at any age, it tends to be seen more commonly in toddlers and school-age children. Typically, these children have had a preceding viral illness within the past 2 weeks (especially varicella and influenza in the United States) from which they have just recovered, or they are recovering at the time of presentation. Generally, about 24 hours of severe, recurrent vomiting is followed immediately by progression through the varying stages of encephalopathy. Physical examination at the time of vomiting, before the onset of encephalopathy, may be normal or show only hepatomegaly. Thus, it is crucial to consider Reye or a Reye-like syndrome in the differential diagnosis and to pursue laboratory evidence of hepatic dysfunction in any child with persistent vomiting in association with recent flulike syndromes or varicella or with persistent vomiting with even the mildest change in sensorium toward obtundation and/or delirium. Abnormal laboratory data in Reye syndrome include elevated serum transaminase and ammonia, prolonged prothrombin time, and often, hypoglycemia; bilirubin usually is normal, making other forms of severe liver disease unlikely. Recent research has emphasized that the differential in cases meeting the criteria for Reye syndrome include Reye-like syndromes: inherited metabolic disorders and viral and toxic diseases. After emerging as a discrete diagnosis in the 1960s, there has been a dramatic global decline in cases of Reye syndrome since the late 1970s. Differing experiences internationally, as well as the increased differential diagnostic capabilities in distinguishing Reye-like syndromes, have rekindled the debate over the etiologic association of aspirin in Reye syndrome and the role of its decreased use in the declining frequency of cases. The substitution of acetaminophen for aspirin for antipyresis in childhood viral illnesses will most likely continue in this country until these issues are clarified.

In the discussion regarding older infants, mention was made of occasional inadvertent drug overdose by parents, causing intoxication-related vomiting. In children 1 to 4 years of age, *accidental ingestion* is a common problem. Acute poisonings that cause vomiting as a prominent symptom include aspirin, theophylline, digoxin, and iron sulfate (see Chapter 88). Chronic *lead poisoning* also occurs in this pica-prone age group. Early symptoms of lead intoxication are vomiting, colicky abdominal pain, anorexia, constipation, and irritability. Tragically, many such youngsters have been diagnosed as having nonspecific gastroenteritis syndromes initially, only to return days to weeks later with frank encephalopathy and, ultimately, severe neurologic sequelae. The history of pica and lead paint exposure (peeling paint chips, especially in homes dating back to the 1940s and 1950s) should be sought in every toddler with persistent vomiting. The diagnosis of plumbism can be confirmed with elevated blood levels of lead and erythrocyte protoporphyrins (see Chapter 88).

Finally, the school-age child or adolescent may vomit on a *psychologic* basis. Acutely, brief episodes of vomiting may occur with any emotionally disturbing event. Children with school phobia or other significant psychiatric problems may vomit persistently. Adolescents are at risk for self-induced vomiting in the context of the anorexia nervosa and bulimia syndromes (see Chapter 129 and Chapter 130). Before the physician attributes the vomiting to a psychologic cause, however, a careful history, general examination, and complete neurologic examination are necessary to minimize the likelihood of missing any organic origin. An assessment of disturbed family dynamics, history of emotional disorders, or evidence of depression and/or anxiety during the ED interview may corroborate the suspicion of vomiting on a psychologic basis and may warrant a psychiatric referral.

CHAPTER 79

Weakness/Flaccid Paralysis

JOANNE M. DECKER, MD

Department of Pediatrics, The University of Pennsylvania School of Medicine, and Division of Emergency Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

A large number of diagnostic considerations exist for the previously well child who presents to the emergency department (ED) complaining of recent onset of weakness or diminished muscle strength (Table 79.1). The initial diagnostic approach may vary considerably, depending on specific clinical and historical features. This chapter limits the discussion to the assessment of the child with acute or subacute onset of weakness and associated flaccid paresis or paralysis on neurologic examination. This chapter does not discuss weakness or inability to move an extremity secondary to pain from trauma (i.e., fracture) or infection (i.e., septic joint) or the child with generalized malaise. Although occasionally children will have weakness on a psychogenic basis, such patients can be distinguished from those with flaccid paralysis on the basis of neurologic examination.

Upper Motor Neuron Disease	Lower Motor Neuron, Neuromuscular Junction, and Muscle Disease
Cerebral Cortex	*Anterior Horn Cell*
Cerebrovascular accident	Poliomyelitis
Hemorrhage	Hopkins' syndrome
Emboli	Werdnig-Hoffman disease
Spinal Cord	*Peripheral Nerve Disease*
Trauma, hemorrhage	Guillain-Barré syndrome
Infection	Heavy metal poisoning
Epidural abscess	Fish toxins
Transverse myelitis	Porphyria
Malignancy	*Neuromuscular Junction*
Disc herniation	Organophosphates
Tethered cord	Tick paralysis
	Botulism
	Myasthenia gravis
	Muscle Disease
	Inflammatory myopathy
	Periodic paralysis
	Rhabdomyolysis
	Muscular dystrophies

Table 79.1. Differential Diagnosis Table

Motor weakness is defined as a decreased ability or inability to move one or several extremities voluntarily against gravity. It may present acutely, subacutely, or intermittently with easy fatigability. It is a reflection of a disease process that may involve the motor neuron unit at any or all of its points. Upper motor disease affects structures extending from the cerebral cortex to, but not including, the anterior horn cell. It is generally characterized by increased deep tendon reflexes and spasticity; however, early in the clinical course there may be flaccid paralysis. Lower motor neuron disease may involve the anterior horn cell, the peripheral axons, the neuromuscular junction (NMJ), or the muscle fibers. In general, it is associated with absent or diminished deep tendon reflexes. Although flaccid paralysis or profound weakness in children is an unusual finding in general, relatively common causes are listed in Table 79.2, and serious life- or limb-threatening causes are listed in Table 79.3.

Infant botulism
Guillain-Barré syndrome
Viral myositis

Table 79.2. Common Causes of Weakness

Cerebrovascular accident	Guillain-Barré syndrome
Spinal cord compression	Infant botulism
Organophosphate or heavy metal poisoning	Rhabdomyolysis
Tick paralysis	

Table 79.3. Life-Threatening Causes of Weakness

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of acute weakness can be categorized by the different parts of the nervous system that are affected. Upper motor neuron disease involves either the cerebral cortex or the spinal cord. The cerebral cortex can be damaged by a cerebrovascular accident (CVA), leading to sudden weakness, usually unilateral. Although CVAs are not as common in children as in adults, various predisposing factors can occur in the pediatric population. Children with sickle cell disease have increased risk for cerebral infarction during a vaso-occlusive crisis. Cerebrovascular disease associated with the rare metabolic disorder homocystinuria may result in CVA. Hypercoagulable states such as found in pregnancy, malignancy, or severe dehydration can lead to venous thrombosis. Embolic causes are to be considered in patients with congenital heart disease, mitral valve prolapse, or a history of rheumatic fever. An intracranial hemorrhage may occur after a relatively minor trauma in a child with hemophilia or spontaneously from a previously undiagnosed tumor or arteriovenous malformation (AVM). Finally, cocaine and amphetamine use have been associated with cerebral infarction in previously healthy patients.

Many processes can damage or compress the spinal cord, leading to weakness or paralysis. Trauma, with or without associated vertebral fracture or dislocation, can lead to spinal cord contusion or transection. The trauma often is severe (i.e., motor vehicle accident, football injury); however, it may be mild, particularly in children with Down syndrome or juvenile rheumatoid arthritis (JRA), in whom there may be an associated cervical vertebral instability. Neck or back trauma can also cause an epidural hematoma, which compresses the spinal cord as it expands. This is of particular concern in patients with hemophilia or other underlying coagulopathy.

Infectious causes of spinal cord compression include epidural abscess and transverse myelitis. An epidural abscess may develop from hematogenous dissemination of staphylococci or arise from direct spread from an adjacent carbuncle or vertebral osteomyelitis. In transverse myelitis (see Chapter 83), areas of inflammation and infarction in the spinal cord result in a clinical picture of flaccid paralysis in both legs, along with rectal and bladder incontinence. Often, cerebrospinal fluid (CSF) protein is elevated and pleocytosis is evident. Although the exact relationship between antecedent viral illnesses and transverse myelitis is not well understood, a history of fever, malaise, and myalgia for several days before the onset of paralysis often occurs.

Other causes of spinal cord compression include hemorrhage from trauma or an AVM, malignancy in the form of a spinal or paraspinal tumor or metastasis, disc herniation, or a tethered cord.

Werdnig-Hoffman disease is a disease of the anterior horn cells that presents with gradual weakness of the proximal muscles. There are three types, with onset of symptoms ranging from birth to 2 years of age. Lower cranial nerve involvement occurs early, leading to feeding difficulties and changes in the quality of the cry. The disease is gradually progressive, with deterioration of muscle strength and eventual respiratory insufficiency.

If peripheral axons are the site of the disease process, motor and sensory functions are both impaired with distal changes usually noted first. In children, one of the more common causes of acute peripheral neuropathy is Guillain-Barré syndrome (GBS) (see Chapter 83). It generally presents as ascending symmetric weakness over days to weeks, usually beginning in the legs and progressing proximally. More than half of the patients will have had an upper respiratory or gastrointestinal infection in the 4 weeks before the onset of the weakness. Many causative agents have been implicated including *Mycoplasma pneumoniae,* influenza virus, adenovirus, varicella, measles, mumps, Epstein-Barr virus, and cytomegalovirus. *Campylobacter jejuni* has been shown to be associated with a more severe form of the disease. A large majority of children report pain in the first week of the illness, with subsequent weakness developing in the painful muscles. Children, if old enough, may also describe paresthesias or numbness, often in a stocking-glove distribution.

The diagnosis of GBS is generally made based on history and clinical presentation. It can be supported, if necessary, by a lumbar puncture showing increased protein concentration in the CSF with no pleocytosis. In fact, the cell count is generally less than 10 lymphocytes/mm^3 and always less than 50 lymphocytes/mm^3. Electrodiagnostic studies can be done as well, if the diagnosis is still in question, and will show a characteristic multifocal demyelination pattern. Factors that make the diagnosis of GBS less likely include fever at the time of presentation, age less than 1 year, sharp sensory level, or persistence of bowel or bladder symptoms. In a young child, when sensory symptoms cannot be described by the patient and sensory examination is limited, GBS is more difficult to diagnose. Other more likely causes in infants with weakness include the anterior horn cell diseases and infantile botulism, discussed in the following.

Heavy metal poisoning from lead, arsenic, or thallium can also cause peripheral nerve damage. Lead poisoning is associated with anemia, abdominal pain, constipation, and often encephalopathy in children (see Chapter 88). Thallium

ingestion may cause ptosis, alopecia, and vomiting in addition to weakness.

Fish toxins can also cause peripheral neuropathy (see Chapter 88). Ciguatera is an illness caused by a toxin from fish that are found generally in the South Pacific, but occasionally near the lower Atlantic states. Nausea and vomiting begin 4 to 36 hours after ingestion of the fish, followed by paresthesias and weakness, and typically reversal of hot/cold sensation. Ingestion of shellfish contaminated during a “red tide” has been associated with paralysis as well. Initial nausea and vomiting are followed rapidly by paresthesias, cranial nerve involvement, and weakness. Supportive care is indicated for both until the paralysis reverses.

Finally, acute intermittent porphyria is a rare autosomal-dominant cause of peripheral neuropathy and paralysis. It is often associated with abdominal pain. Peripheral motor weakness is present and often is more evident in proximal muscles. Central nervous system involvement may be manifested by altered sensorium and hallucinations, and there may be sensory involvement as well. Acute attacks can be precipitated by drugs such as barbiturates, sulfonamides, griseofulvin, estrogens, and alcohol. Detection of increased porphyrin precursors in the urine, as well as familial history, help make the diagnosis.

Diseases involving the NMJ can be recognized by their association with cranial nerve findings and autonomic processes. Importantly, sensation is *not* affected. Organophosphate exposure is a classic example of NMJ dysfunction. Organophosphates, which are used as insecticides, inhibit cholinesterase activity, thereby allowing acetylcholine to remain bound to its postsynaptic receptor. Acetylcholine receptors are found in the brain, at the motor end plate, and in muscarinic receptors in the autonomic nervous system. Thus, in addition to muscle fasciculations, muscle cramps, and weakness, patients exposed to organophosphates may have symptoms of altered mental status and cholinergic stimulation (see Chapter 88).

Tick paralysis is caused by another toxin that is presumed to affect the NMJ, produced by the dog tick *Dermacentor variabilis* and the Rocky Mountain wood tick *Dermacentor andersoni*, as well as several other species of ticks found in the United States. Because exposure to the tick often precedes the paralysis by 5 to 10 days, travel history is important. The paralysis is typically ascending, and progresses rapidly over 12 to 36 hours to the bulbar area. Although 50% of patients may complain of paresthesias, the sensory examination is usually normal. Tick paralysis, although not commonly encountered, should be considered in the differential diagnosis of acute weakness, particularly in spring and summer months of the endemic areas, when ticks are most active in the warm environment.

A third agent that involves the neuromuscular junction is the toxin of *Clostridium botulinum.* It produces paralysis by preventing release of acetylcholine at the myoneural junction. It can be found in improperly home-canned foods or any incompletely reheated or unheated food. It also is found in the soils of some areas of the United States, particularly in eastern Pennsylvania and California. If contaminated food is the source of the toxin, within 24 to 48 hours of exposure, patients will experience nausea and vomiting, followed by diplopia, photophobia, and then dysphagia and dysarthria from sequential involvement of cranial nerves. Skeletal muscle paralysis follows without any sensory involvement. In wound botulism, a wound is contaminated with soil containing the spores of the clostridium. It presents in a similar manner except that no gastrointestinal symptoms are associated.

In infant botulism, the GI tract of the infant is colonized by *C. botulinum.* It has been linked to ingestion of honey, which has a high rate of contamination by the spores. Because the spores are also found in soils, they may gain access to the baby from dust at a nearby construction site, or soil tracked into the home. Although it is generally seen in infants younger than 9 months of age, peak incidence is between 2 and 3 months. It commonly presents with a history of constipation, lethargy, and feeding difficulties. On physical examination, hypotonia, general muscle weakness, pooling of oral secretions, and a decreased gag reflex are present, and dilated pupils respond poorly to light. Sensory examination is normal. Deep tendon reflexes may be normal or diminished early, and are generally diminished or absent late in the disease.

Finally, myasthenia gravis is a disease process involving the transmission of acetylcholine across the synaptic membrane to its receptors. It is recognized by easy fatigability of muscles and worsening weakness over the course of a day. Sensory examination and deep tendon reflexes are normal. Ptosis is often the most easily recognized symptom.

When the muscle itself is the target of the disease, proximal weakness is often noted first, and sensory function is normal. An example of muscle diseases is the group of inflammatory myopathies in which the muscles are often tender. In dermatomyositis or polymyositis, skin and joint manifestations and proximal weakness are usually present. The characteristic rash in dermatomyositis is an erythema of the upper eyelid area, spreading to a malar distribution. Erythema over the extensor surfaces of joints is often present also. Deep tendon reflexes diminish as weakness progresses and muscles atrophy. In viral myositis, a febrile respiratory illness is associated with significant muscle tenderness and weakness. Deep tendon reflexes are generally present, and sensory examination is normal. Serum creatine kinase is elevated in all of the inflammatory myopathies. Another muscle disease involves periodic attacks of paralysis associated with either decreased or increased serum potassium. The hypokalemic form may be associated with an autosomal-dominant familial disorder, hyperthyroidism, hyperaldosteronism, chronic renal disease, ingestion of large amounts of licorice, or chronic vomiting or diarrhea. The familial form often presents in adolescence with sudden paralysis that may involve all the extremities, usually after a large carbohydrate meal or during rest after strenuous exercise. Sensory examination is normal. Autosomal-dominant familial hyperkalemic paralysis usually is less severe. Improvement of paralysis should ensue after intravenous correction of the potassium imbalance.

Rhabdomyolysis from excessive physical exertion, prolonged seizures, stimulant-drug overdose, or genetic disorders may result in acute weakness. Muscles are generally tender, myoglobin is evident in the urine, and serum creatine phosphokinase (CPK) and AST are elevated.

Finally, the muscular dystrophies, although usually thought of as more slowly progressive, can present to an emergency physician as a recently noticed weakness by the patient or their family. The forms that present in childhood involve the

proximal muscles and are primarily X-linked and thus are seen in boys 3 to 15 years of age. They often present first with gait disturbances, including toe walking, waddling, or frequent falling. The children may have trouble getting up from the floor and may demonstrate the Gower sign C, a pushing off the floor with the hands to assist the weak pelvic and thigh muscles. Muscles are generally not tender. Deep tendon reflexes are present early, but disappear later. Sensory examination is normal, and serum creatine kinase is elevated.

EVALUATION AND DECISION

Information most helpful in the critical assessment of the child with sudden paralysis can be discovered in a detailed history, with particular attention to trauma, toxic exposures, prodromal illness, and family history. The physical examination should note the distribution of paralysis—symmetric versus asymmetric, proximal versus distal—as well as associated cranial nerve weaknesses; facial, ocular, or bulbar, deep tendon reflexes, and sensory changes. These clinical features guide the diagnostic approach, as outlined in Figure 79.1.

FIGURE 79.1. Approach to the child with weakness or flaccid paralysis. *SCIWORA,* spinal cord injury without obvious radiographic abnormality; *CT,* computed tomography; *CVA,* cerebrovascular accident; *MRI,* magnetic resonance imaging; *AVM,* arteriovenous malformation; *CPK,* creatine phosphokinase.

The first important historical question is whether the patient had neck or back trauma preceding the weakness. If so, the patient should be immobilized, and spinal radiographs should be taken immediately. Cord transections often result in initially flaccid paralysis and sensory loss below the level of the lesion, along with bladder and rectal incontinence. Deep tendon reflexes may be absent early but will become increased over time. If a patient has these symptoms after trauma, radiographs can confirm a fracture or dislocation. However, a patient with persistent symptoms should remain immobilized until further imaging studies are done because negative radiographs do not completely obviate spinal injury (see Chapter 106).

Once it has been confirmed that the patient has had no trauma, a complete history should be taken. A history of acute weakness associated with abdominal pain or vomiting suggests a possible toxin exposure such as botulism or fish poisoning. Information should be elicited relating to ingestion of potentially contaminated foods and the possibility of other symptomatic exposed individuals. Treatment in either case is supportive, with particular attention to respiratory function. Gastric decontamination and antitoxin may be used if necessary. Gastrointestinal symptoms may also be associated with heavy metal ingestion, either intentional or accidental. Finally, porphyria should be considered as a possible cause of weakness and abdominal pain. A familial history or recent ingestion of a known precipitant and urine studies for porphyrin precursors will help confirm the diagnosis.

A history of constipation for several days before the onset of weakness in a child less than 1 year of age highly suggests infantile botulism. Parents often also report several days of lethargy and feeding difficulties as well. Ingestion of honey or proximity to an endemic area would further support the diagnosis.

Before proceeding with the physical examination, the physician should be sure that the patient has not had an organophosphate exposure. Generally, this is given in the history or easily recognized by the strong garliclike smell on the patient and the readily apparent cholinergic symptoms. Health care personnel caring for such a patient should be careful to protect themselves from exposure by protective clothing and eyewear until the patient is decontaminated.

Upon beginning a thorough physical examination, the patient's respiratory and cardiovascular status should be assessed. Although rare, some diseases cause rapidly progressive weakness and may quickly involve the respiratory muscles or gag reflex. Resuscitation and stabilization should be done before further diagnostic evaluation.

One of the main goals of the physical examination in a patient with acute weakness is to locate the site of the disease process. Acute hemiplegia, with or without facial involvement or mental status changes, should direct the physician to an intracranial process such as a cerebral infarction or hemorrhage. Any child suspected of having a CVA should be stabilized and have a computed tomography (CT) scan of the head done promptly. Rarely, seizures or complicated migraines can be associated with hemiplegia, but usually the possibility of an intracranial event must be eliminated first.

When evaluating a patient with a complaint of weakness, a thorough motor examination will help define and locate the disease process. The physician should assess not only active motor strength but also resistance to gravity. Muscle groups should be inspected for increased or decreased tone, atrophy, and fasciculations. Deep tendon reflexes should be classified as normal, increased, diminished, or absent. A careful sensory examination should be done, both to light touch and to pain, as well as vibratory and position sense. It should be determined whether a spinal level of sensory loss is detectable. The patient's back should be examined for swelling, erythema, loss of normal lordosis, point tenderness,

rigidity, or splinting. Cranial nerves should be carefully assessed, looking specifically for ophthalmoplegia, facial weakness, or bulbar weakness as evidenced by dysphagia, dysarthria, or decreased gag.

Initially, the physician should determine whether the patient has signs and symptoms consistent with an acute or subacute spinal cord compression. A history of back trauma or back pain should be investigated, including eliciting the onset, location, and radiation, if any, of the pain. Other important historical questions pertaining to cord compression include bowel or bladder dysfunction, paresthesias, and abnormal gait. Motor examination would reveal profound weakness or paralysis, with distal more than proximal muscle groups affected. In spinal cord compression, patients may have diminished reflexes early in the course, progressing to increased reflexes later. Often, a spinal sensory level corresponding to the level of loss of motor function is detectable. There may be bladder retention or urinary or fecal incontinence.

Although spinal cord compression may have many etiologies that present similarly, some factors may be helpful in making a diagnosis. Acute onset of symptoms with associated fever and back pain suggests an epidural abscess or transverse myelitis. A patient with an epidural abscess may have point tenderness over the affected area in addition to the paralysis and bowel and bladder dysfunction. In transverse myelitis, prominent sensory loss occurs for pain and temperature, usually with a definable spinal sensory level corresponding to the level of back pain. Acute onset of symptoms without fever may indicate a spontaneous hemorrhage from an AVM. A more subacute presentation may suggest a spinal or paraspinal tumor. Disk herniation is less common in children but may be associated with trauma or symptoms of sciatica. Evidence of spinal dysraphism, such as a hair tuft, dermal sinus, or lipoma, may be a clue to a tethered cord, which also usually presents with a more gradual onset of weakness. Initial evaluation of any patient with signs and symptoms suggesting spinal cord compression should include spinal radiographs, usually followed by magnetic resonance imaging (MRI). Spinal cord compression is an emergency and may require high-dose methylprednisolone to decrease swelling and protect the spinal cord (see Chapter 125).

Assessment of deep tendon reflexes is the next important step in differentiating causes of weakness. Diseases of the NMJ, such as myasthenia gravis, should have normal reflexes. Myasthenia may also be recognized by the involvement of cranial nerves producing dysphagia, facial weakness, and ophthalmoplegia. Rarely, early in their course, other disease processes may present with weakness and normal deep tendon reflexes. However, they can be differentiated from myasthenia gravis by other factors, as explained in the following.

Decreased or absent reflexes, when not caused by early spinal cord compression, are a sign of disease in the anterior horn cell, peripheral nerve, or muscle. The physician can use the sensory examination to further distinguish these. If there is abnormal sensation on examination or subjective reporting of paresthesias, the disease is in the peripheral nerves. The most common cause for an acute or subacute onset of ascending flaccid paralysis, with diminished or absent deep tendon reflexes and associated sensory symptoms, is GBS (see Chapter 83). On physical examination, there may be demonstrable sensory loss, as well as loss of position and vibratory sense. Motor weakness, most often asymmetric and distal, is clinically apparent, although 10 to 20% of patients may have descending paralysis or proximal-greater-than-distal weakness. The combination of lower extremity weakness and sensory changes often cause the child to have an abnormal gait, which is often the presenting symptom. Deep tendon reflexes are diminished or absent in the weak muscles, although they may be preserved in less-affected muscles early in the course of the illness. Associated cranial nerve involvement is seen in 30 to 40% of patients, usually manifested by facial weakness or ocular paresis. Pupillary response is not affected, and rarely are the lower cranial nerves involved. Occasionally, children have autonomic symptoms, including arrhythmias and blood pressure lability. These can become severe and, in some cases, life-threatening. Because up to 20% of children will require assisted ventilation for respiratory paralysis, children with GBS should be admitted to the hospital and observed carefully for progression of weakness. In some cases, plasmapheresis or intravenous immunoglobulin administration may be indicated.

Tick paralysis can present similarly to GBS. Any patient with acute onset of ascending paralysis associated with dysesthesias or cranial nerve palsies should be carefully examined for ticks, particularly in the scalp and hairline. Removal of the tick results in dramatic and complete improvement.

In a patient with decreased or absent deep tendon reflexes but normal sensory examination, the disease process is either in the anterior horn cells or in the muscles. Examples of anterior horn cell disease include spinal muscular atrophy (Werdnig-Hoffman disease), enteroviral infection such as polio, and Hopkins' syndrome. In Werdnig-Hoffman disease, the infants have no associated pupillary or ocular motility dysfunction but are noted to have tongue fasciculations and a decreased gag reflex. Proximal muscles are weak, and deep tendon reflexes are diminished or absent. Sensory examination is normal.

Polio and Hopkins' syndrome both present with a unilateral, asymmetric paralysis. Polio is associated with fever, irritability, and often meningeal signs. There may be an antecedent history of exposure in an unimmunized person or oral vaccine administration in a young infant. Hopkins' syndrome is associated with a preceding asthma exacerbation, but the patient usually has no other symptoms at the time of presentation of the weakness.

Although infant botulism is a disease process of the NMJ and reflexes should be preserved, it may be confused with anterior horn disease because reflexes may in general be difficult to elicit or appreciate in a young infant. It will otherwise present similarly, with progressive weakness and normal sensory examination. Infant botulism may be distinguished by a history of constipation and the presence of dilated pupils poorly reactive to light.

Disease processes involving the muscle present with weakness, decreased reflexes, and a normal sensory examination. These include hypokalemia, hyperkalemia, rhabdomyolysis, inflammatory myopathies, and muscular dystrophies. These can be distinguished from anterior horn cell diseases by history, physical examination, and laboratory evidence of abnormal serum potassium, elevated CPK, or urine myoglobin.

In summary, when presented with a patient with a history of sudden or progressive weakness, the emergency physician

must carefully sort through the history of the weakness for evidence of trauma or toxins, as well as any associated symptoms. The physical examination is important in characterizing the nature, location, and symmetry of the weakness, as well as determining whether there are any accompanying sensory losses. Deep tendon reflexes must be checked carefully, and cranial nerve examination is also important. The history and physical together, as always, can determine the cause of the weakness in most cases. Select diagnostic studies, including imaging modalities, lumbar puncture, and serum and urine laboratory tests, may further clarify the diagnosis. Because of the life-threatening nature of many of the causes of weakness, most patients after ED evaluation and management will require inpatient hospital treatment.

CHAPTER 80

Wheezing

BRUCE ROSENTHAL, MD

Division of Pediatric Emergency Medicine, Mercy Hospital, Pittsburgh, Pennsylvania

Wheezes are continuous whistling or musical adventitial sounds that are the hallmark of lower airway obstruction. This chapter presents an organized approach to the diagnosis of conditions associated with wheezing in children beyond the newborn period. Emphasis is given to those conditions most likely to be encountered by the emergency department (ED) provider.

PATHOPHYSIOLOGY

Obstruction to air flow is the common denominator in all conditions that produce wheezing. Wheezing usually results from obstruction of the intrathoracic lower airways (bronchi and bronchioles) and only rarely by narrowing of the trachea or major bronchi. Obstruction of the lower airway passages may be anatomic or physiologic and is the result of one or more of several mechanisms: 1) extrinsic airway compression, 2) intrinsic airway narrowing, or 3) intraluminal airway blockage. Table 80.1 provides a simplified pathophysiologic classification of conditions that cause wheezing in children.

Extrinsic Airway Compression
Congenital structural anomalies
Cystic malformations of the lung
Vascular ring
Cardiovascular enlargement
Mediastinal tumors
Teratoma, neuroblastoma, thymoma, ganglioneuroma, pheochromocytoma
Enlarged mediastinal lymph nodes
Tuberculosis, sarcoidosis, leukemia, lymphoma
Intrinsic Airway Narrowing
Structural anomalies
Tracheobronchomalacia/stenosis
Bronchopulmonary dysplasia
α_1-Antitrypsin deficiency
Bronchospasm
Anaphylaxis
Organophosphate poisoning
Inflammation
Asthma
Bronchiolitis
Smoke inhalation
Bronchiectasis
Pulmonary hemosiderosis
Pulmonary aspiration
Gastroesophageal reflux
Swallowing disorders
Tracheoesophageal fistula
Intraluminal Airway Obstruction
Foreign body aspiration
Miscellaneous Causes
Congestive heart failure
Immune deficiency
Cystic fibrosis
Immotile cilia syndrome

Table 80.1. Causes of Wheezing in Childhood

DIFFERENTIAL DIAGNOSIS

Table 80.2 outlines the relative prevalence of those conditions associated with wheezing in children with which the emergency physician should be most familiar, and Table 80.3 lists the life-threatening causes of wheezing.

Disease Prevalence	<1 yr	>1 yr
Common	Bronchiolitis Asthma	Asthma
Less common	Pulmonary aspiration Gastroesophageal reflux Swallowing disorder Foreign body Bronchopulmonary dysplasia Cystic fibrosis	Foreign body aspiration Anaphylaxis
Uncommon	Congenital heart disease Defective host defenses Immune deficiency Immotile cilia syndrome Congenital structural anomalies Tracheobronchomalacia Vascular ring Lobar emphysema Cystic abnormalities Tracheoesophageal fistula	Defective host defenses Mediastinal tumors or enlarged lymph nodes Parasitic infection Pulmonary hemosiderosis α1-Antitrypsin deficiency

Table 80.2. Clinical Classification of Wheezing: Age at Diagnosis and Disease Prevalence

Asthma (severe)	Mediastinal tumor
Bronchiolitis (severe)	Congestive heart failure
Foreign body	

Table 80.3. Life-Threatening Causes of Wheezing

Most Common Conditions

Bronchiolitis is an acute viral infection of the lower respiratory tract caused predominantly by respiratory syncytial virus (RSV). Occurring in epidemics between late fall and early spring, this condition primarily affects infants 2 to 6 months of age but may occur in children as old as 2 to 3 years of age. Rhinorrhea and a low-grade fever typically accompany a prominent staccattolike cough and a variable degree of respiratory distress. The concurrence of respiratory symptoms in other family members is common.

Asthma is a chronic inflammatory disorder of the airways, characterized clinically by *recurrent* episodes of coughing and/or wheezing. Acute exacerbations of asthma are usually triggered by respiratory infections, allergens, and irritants such as cigarette smoke. Patients with asthma have a higher incidence of associated atopic disease, which includes allergic rhinitis and conjunctivitis and atopic dermatitis. Immediate family members are also more likely to be affected by asthma and atopic disease.

Less Common Conditions

Pulmonary aspiration is a less common cause of wheezing that occurs in several fairly characteristic clinical circumstances. Recurrent aspiration of oropharyngeal foodstuffs or gastric contents is usually seen in patients with severe developmental delay and a variety of neuromuscular diseases. Disordered swallowing and esophageal motility, and gastroesophageal reflux typically contribute in varying degrees to the recurrent aspiration that occurs in these patients. Repeated aspiration is also seen in children with structural anomalies of the laryngeal complex or an H-type tracheoesophageal fistula. Patients with chronic recurrent aspiration may develop wheezing and respiratory distress in the absence of a well-defined episode of choking or severe coughing because many such patients have depressed cough reflexes or experience “microaspiration.” Fever often accompanies pulmonary aspiration, reflecting associated chemical inflammation or infection of the tracheobronchial tree.

In otherwise healthy children, the abrupt onset of respiratory distress, associated with an episode of coughing, choking, or gagging, suggests the pulmonary inhalation of a foreign object (see Chapter 29). Foreign body aspiration is typically seen in toddlers, although older infants may aspirate solid food particles or small objects placed within their reach. The aspiration of a small object or food substance may be unwitnessed and go unrecognized for weeks or months until persistent lower respiratory symptoms trigger a search for an underlying cause. In these circumstances, persistent cough, wheezing, and sometimes recurrent fever is associated with an area of consolidation and/or collapse on radiograph; these symptoms fail to resolve despite seemingly appropriate medical therapy for presumed asthma and/or pneumonia.

Wheezing attributable to anaphylaxis is also of sudden onset and usually is accompanied by one or more other clinical findings that include urticaria, angioedema, stridor, and hypotension. When wheezing is the only finding, anaphylaxis may be suspected when the onset of respiratory difficulty is associated closely with Hymenoptera envenomation or food ingestion. Wheezing typically responds promptly to epinephrine administration or to bronchodilator therapy.

Infants and young children with a history of prematurity, oxygen therapy, and ventilatory support for a variety of conditions occurring in the newborn period may have wheezing caused by bronchopulmonary dysplasia (BPD). This condition is the childhood equivalent of chronic obstructive lung disease and represents a pathophysiologic continuum that includes varying degrees of structural damage and airway inflammation. Although gradual improvement in lung

function occurs during infancy and early childhood, bronchial hyperactivity and recurrent episodes of wheezing may persist until later in childhood. Cor pulmonale may exist in patients with severe pulmonary function impairment. Other coexisting problems associated with prematurity such as brain damage and esophageal reflux may complicate the respiratory pathophysiology in patients with BPD.

Uncommon Conditions

Cardiovascular abnormalities are one of many uncommon causes of wheezing in children. Small airway edema in the setting of congestive heart failure or airway impingement by enlarged cardiovascular structures are the usual pathophysiologic mechanisms. Most such cardiac conditions are associated with other abnormal physical findings, including cyanosis, murmurs, abnormal pulses, poor perfusion, or signs consistent with congestive heart failure. A congenital vascular ring may cause wheezing secondary to extrinsic airway compression. Abnormal cardiac physical findings are generally absent in patients with a vascular ring, although concomitant esophageal compression may result in dysphagia. A right-sided aortic arch is associated with this anomaly.

Children with various defects in host defense mechanisms often present with recurrent wheezing and bacterial pulmonary infections. In addition to respiratory tract involvement, patients with cystic fibrosis (see Chapter 96) will often exhibit steatorrhea and growth failure because of pancreatic insufficiency and malabsorption. Children with cell-mediated or humoral immune deficiency syndromes can have opportunistic infections or repeated extrapulmonary infections, including meningitis, otitis media, otitis externa, furunculosis, and mucocutaneous candidiasis. Similarly, patients with the immotile cilia syndrome develop repeated sinusitis and otitis media, often in association with situs inversus viscerum and bronchiectasis (Kartagener's syndrome).

Other uncommon causes of wheezing include extrinsic tracheobronchial compression by an enlarged lymph node or tumor (see Chapter 100). Mediastinal or hilar lymph node enlargement most often is the result of leukemia, lymphoma, sarcoidosis, or a mycobacterial or fungal infection. Mediastinal tumors most likely to produce pulmonary symptomatology include neuroblastoma, pheochromocytoma, ganglioneuroma, thymoma, and teratoma.

Congenital structural anomalies of the respiratory tract, including bronchogenic cysts, intrinsic stenosis, and webs, are among the rarest causes of wheezing in children. Respiratory symptoms typically begin in the neonatal period or early infancy. The predominant clinical features will be determined by the site of abnormality within the tracheobronchial tree. Stridor and a croupy cough are typical of laryngotracheal constriction, whereas wheezing and recurrent pneumonia are more characteristic of bronchial narrowing. Respiratory findings generally worsen with intercurrent respiratory infection and may accentuate with crying and activity.

EVALUATION AND DECISION

Initial Considerations

Table 80.4 presents a capsule summary of the clinical features associated with the more prevalent causes of wheezing in childhood.

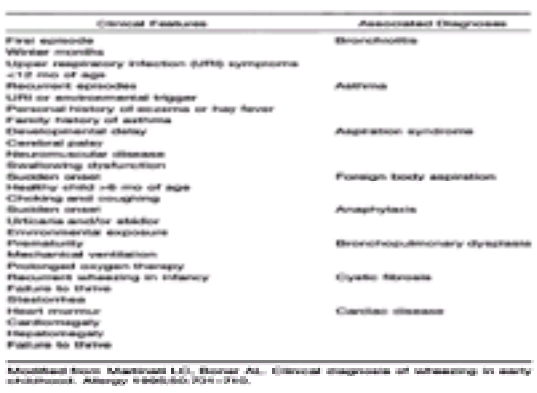

Table 80.4. Clinical Features and Associated Diagnoses

History

Thorough history taking is the key to arriving at an accurate diagnosis in a child with wheezing. In particular, consideration of the age at onset, course and pattern of illness, and associated clinical features, provides a useful framework for approaching a differential diagnosis (Fig. 80.1 and Fig. 80.2).

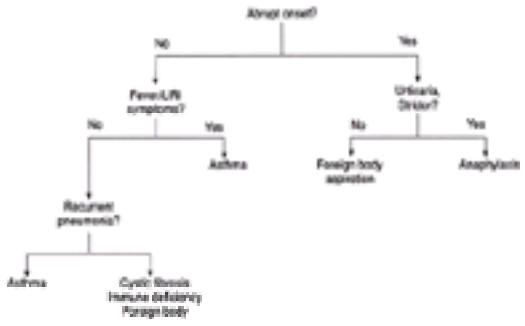

FIGURE 80.1. Approach to wheezing in children under 1 year of age. *URI,* upper respiratory infection.

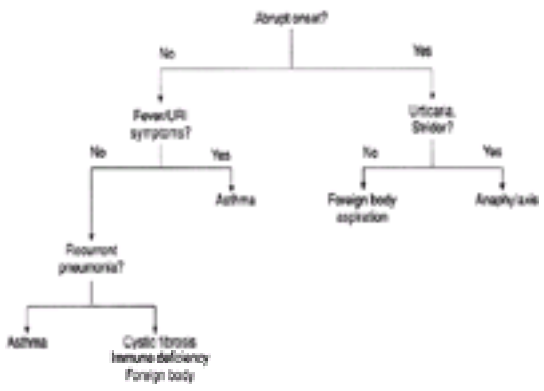

FIGURE 80.2. Approach to wheezing in children 1 year old or older. *URI,* upper respiratory infection.

The onset of wheezing in the neonatal period is associated with congenital structural airway anomalies, although a history of prematurity and mechanical ventilation is more suggestive of BPD. The *first episode* of wheezing in an otherwise healthy infant in association with cold symptoms indicates bronchiolitis. *Recurrent episodes* of wheezing precipitated by colds and a variety of other triggers is the hallmark of asthma. On the other hand, *recurrent wheezing beginning in infancy,* or *"difficult to control asthma,"* at any age should lead to a consideration of cystic fibrosis, gastroesophageal reflux, recurrent pulmonary aspiration or a retained airway foreign body, or immune deficiency. *Persistent wheezing* at any age suggests mechanical airway obstruction from a variety of causes, including congenital airway narrowing, pulmonary foreign body, and compression by a mediastinal tumor. The *sudden onset* of wheezing is characteristic of pulmonary aspiration or anaphylaxis.

As indicated previously, the diagnosis of a chronic wheezing disorder, such as asthma, relies on the identification of recurrent episodes of obstructive lower airway disease. Unfortunately, limitations of parental recall combined with the misdiagnosis of previous bronchospastic episodes as infectious illnesses sometimes make it a challenge to reconstruct an accurate history. In particular, subtle manifestations of asthma are often misinterpreted as episodes of bronchitis, pneumonia, or bronchiolitis. Accordingly, it is often useful to ask if the child has ever had any of these or other "breathing problems" or has ever been treated with a "breathing medicine."

Cough as a salient feature in patients with obstructive lower airway disease cannot be overemphasized. In fact, in many patients with asthma, recurrent cough may be the predominant presenting clinical feature and wheezing may be absent despite careful lung auscultation ("cough variant asthma"). Further inquiry might reveal that a patient usually experiences severe or persistent bouts of coughing in association with colds or that coughing is the cause of recurrent nighttime awakening.

As outlined in Table 80.4, the review of systems may provide additional clues to a variety of disorders. Similarly, the family medical history can contribute significant support for the diagnosis of a number of conditions, particularly asthma and rare inherited disorders such as cystic fibrosis.

Physical Examination

Wheezing must be distinguished from other causes of "noisy breathing" in children, which including the stridor of upper airway obstruction (see Chapter 72), the stertor of nasal congestion, and audible rhonchi. Because of the dynamic flexibility of airway structures, these clinical features of airway obstruction vary in accordance with the respiratory phase. Accordingly, upper airway collapse and stridor are worse on inspiration, whereas lower airway narrowing and wheezing are accentuated on expiration. Moreover, sounds originating in the upper airway passages (e.g., stridor, stertor) are transmitted with uniform quality and intensity across both lung fields. By contrast, wheezes tend to be polyphonic in pitch and distributed somewhat unevenly in intensity and location, despite the fact that most disorders causing lower airway obstruction affect both lungs simultaneously. This auscultatory asymmetry reflects the variation in airway narrowing that typically occurs from one lung segment to another. Conversely, wheezes consistently limited to a single lung field suggest a localized obstructive process, such as a foreign body or an extrinsic mass lesion.

The intensity of wheezes and their pitch and duration are a function of the degree of airway narrowing and the velocity of air flow at the site(s) of obstruction. In patients with minimal airway obstruction, wheezing may be difficult to detect. When such instances are suspected, forced exhalation may reveal low-pitched wheezes limited to the end of expiration. Subtle

wheezes can be accentuated further by combining forced exhalation with simultaneous manual compression applied by the examiner in the anteroposterior dimension of the chest (so-called squeezing the wheeze).

As airway narrowing and minute ventilation increase, wheezes becomes louder and higher pitched. However, as airway obstruction becomes progressively more severe, air flow and wheezes will diminish proportionately. A “quiet chest” in the face of significant respiratory distress may indicate respiratory failure. Conversely, in patients with reversible bronchospasm, air exchange and wheezes are often noted to increase in response to bronchodilator therapy.

As mentioned earlier, the clinical evaluation of a patient with obstructive lower airway disease will invariably reveal a prominent cough. To the experienced clinician or parent, this cough usually will be perceived as having a characteristic whistling or “wheezy” quality that is distinct from the “rhoncorous” cough of bronchitis or the “seal-like” cough of croup. Physical examination of the wheezing child may also reveal inspiratory and expiratory crackles, which are far more often attributable to subsegmental atelectasis than to an associated pneumonia and parenchymal consolidation.

Key “extrapulmonary” physical findings associated with the more prevalent causes of wheezing in childhood are included in Table 80.4.

Diagnostic Tests

Only a limited number of diagnostic modalities are needed to support the ED evaluation of the wheezing child. Many other necessary investigations can be performed as part of a subsequent inpatient or outpatient workup. The chest radiograph is the most important test obtained in the ED. Even so, its value is limited in helping establish a definitive diagnosis in a wheezing child. Rather, the chest radiograph assists in identifying disease complications such as pneumonia, atelectasis, pneumothorax, or pneumomediastinum. Among the few conditions that can be conclusively identified on the basis of plain film findings are heart disease, mediastinal masses, and some foreign bodies of the airway and esophagus.

Varying degrees of hyperaeration, bronchiolar thickening, and subsegmental atelectasis are the most common radiograph findings in patients with bronchiolitis or asthma. Pulmonary infiltrates may reflect the primary viral disease process in bronchiolitis or the complication of airway obstruction in asthma. When either disorder is suspected, a chest radiograph usually can be avoided if the patient is afebrile and little to no respiratory distress is present. The available data do not support the utility of obtaining a chest radiograph for all patients with their first episode of wheezing.

When bronchiolitis is a suspected cause of wheezing, occasionally it is helpful to identify respiratory syncytial virus in nasopharyngeal secretions by performing a rapid immunoassay while the patient is in the ED. The diagnosis of asthma can be supported by demonstrating improvement in peak flow measurements after bronchodilator treatment. Other patients with asthma may benefit from formal pulmonary function evaluation or bronchial challenge testing performed at a later time.

Patients suspected of having aspirated oropharyngeal or gastric contents should have plain radiographs taken of the chest. Nonspecific findings consistent with lower airway obstruction generally proceed the appearance of infiltrates. The location of the latter depends on the position of the patient at the time of the aspiration event. Patients thought to have recurring episodes of pulmonary aspiration subsequently should have further testing to identify swallowing dysfunction, gastroesophageal reflux, or actual tracheobronchial soiling. Such tests might include a barium esophagram, esophageal pH monitoring, esophageal endoscopy and biopsy, or radionuclide scintigraphy (“milk” scan). Fiberoptic bronchoscopy may be required to diagnose patients with a tracheoesophageal fistula.

An immediate and aggressive workup is always justified in patients suspected of having an airway foreign body (see Chapter 29) on the basis of acute and sudden symptomatology. In this setting, chest radiographs are usually normal, although occasionally they can demonstrate a radiopaque object, the faint outlines of a radiolucent foreign body, segmental atelectasis, or a focal area of hyperinflation. Patients with a persistent lower airway foreign body are more likely to show focal collapse and consolidation that is evident on standard chest roentgenograms. Bilateral decubitus views, inspiratory and expiratory radiographs, or airway fluoroscopy may be used to provide additional diagnostic information. Bronchoscopy is the procedure of choice both from a diagnostic and therapeutic perspective when a foreign body is strongly suspected.

The diagnosis of BPD is established on the basis of chronic respiratory symptoms superimposed on a background of neonatal lung disease. Nevertheless, a chest radiograph characteristically shows hyperexpansion and streaky or patchy infiltrates, punctuated by areas of alternating local hyperaeration and atelectasis.

Newborn screening now should identify most children with cystic fibrosis. Nevertheless, infants with recurrent wheezing and those with failure to thrive associated with chronic diarrhea should be referred for sweat chloride testing.

A patient suspected of having congenital or acquired heart disease should have an electrocardiogram (ECG) and a chest radiograph performed in the ED. Definitive diagnosis generally requires echocardiography or cardiac catheterization. A barium swallow is usually sufficient to diagnose the presence of a vascular ring, although angiography is necessary for exact anatomic definition.

Approach

The evaluation of a wheezing child begins with an immediate assessment of the degree of respiratory distress and consideration of the need for general supportive measures. Patients with suspected respiratory failure should be managed aggressively, as outlined in Chapter 5 and Chapter 68. Clinical features suggestive of respiratory failure include severe respiratory distress, agitation or lethargy, dusky mucous membranes, signs of autonomic excess (tachycardia, diaphoresis, peripheral vasoconstriction), poor air movement on lung auscultation, and oxyhemoglobin

saturation of less than 90%. Blood gas analysis will aid in the determination of respiratory failure.

Supplemental oxygen should be offered promptly to any patient with respiratory distress and adjusted to maintain a hemoglobin saturation of 95% or greater. Patients suspected of having reversible bronchospasm should be given a bronchodilator, such as albuterol, by inhalation while further evaluation and management is proceeding according to the priorities established earlier in this chapter.

Expeditious management is essential in patients with poor baseline pulmonary functions because they can develop respiratory failure quickly. Such patients include children with significant BPD and advanced cases of progressive chronic lung disorders such as cystic fibrosis. Moreover, careful titration of inspired oxygen concentration is important in patients with chronic respiratory insufficiency to avoid respiratory drive suppression.

Infant Less Than 1 Year Old

An algorithm for elucidating the cause of wheezing in the child less than 1 year old is presented in Figure 80.1. The abrupt onset of wheezing, often immediately preceded by an episode of choking, gagging, or vomiting, is highly suggestive of pulmonary aspiration; foreign body aspiration should be considered in the previously healthy older infant, whereas gastroesophageal reflux with aspiration of gastric contents is a more likely cause in early infancy. However, most young infants who present with a first episode of wheezing have bronchiolitis. In this illness, fever and upper respiratory symptoms usually accompany wheezing and respiratory distress during the winter months. A similar complex of physical findings in an older infant with a history of bronchiolitis or wheezing and clear improvement after bronchodilator administration is characteristic of asthma.

The remaining disorders often are found in infants who have overt evidence of chronic or severe underlying illness and who typically present with recurrent or persistent episodes of wheezing and respiratory distress. Neurologic disability predisposes a child to gastroesophageal reflux or a swallowing disorder and recurrent pulmonary aspiration. A report of prematurity and/or respiratory difficulty at birth may be a clue to BPD. Recurrent pneumonia, failure to thrive, and steatorrhea are characteristic of infants with cystic fibrosis, whereas pneumonia in association with repeated extrapulmonary infection is suggestive of an immune deficiency. A heart murmur and other clinical findings consistent with congestive heart failure are indicative of congenital heart disease and pulmonary edema. Wheezing accompanied by stridor commonly indicates the coexistence of viral croup but may reflect intrinsic congenital airway narrowing, such as tracheobronchomalacia or extrinsic compression by a mediastinal structure. In the absence of any of the clinical clues listed, the first episode of wheezing in an otherwise healthy child, especially when it occurs during the winter months, is likely to represent bronchiolitis.

Child 1 Year Old or Older

Figure 80.2 outlines an algorithmic approach to the more common causes of wheezing in the child who is 1 year old or older. The sudden onset of respiratory distress and wheezing associated with an episode of choking and coughing is likely to indicate foreign body aspiration, particularly in a toddler who has been eating or playing with a small object. An abrupt onset of wheezing also may accompany stridor, urticaria, and hypotension in the older child with an anaphylactic reaction. However, most first or recurrent episodes of wheezing represent asthma. Typically, such episodes are precipitated by a concurrent upper respiratory infection, and the patient may show responsiveness to bronchodilator administration.

Wheezing and recurrent pneumonia in multiple pulmonary segments are characteristic of patients with defects in host defense mechanisms, such as cystic fibrosis, an immune deficiency syndrome, or the immotile cilia syndrome. Children in this age group who present with these disorders usually have a history of lower respiratory illness that began in infancy, as well as other signs and symptoms suggestive of chronic disease. Repeated pneumonia in the same pulmonary segment in an otherwise healthy child that begins in late infancy or in early childhood is likely to represent a previously unrecognized bronchial foreign body. In the absence of any of the clinical clues previously listed, the first episode of wheezing in an otherwise healthy child is likely to represent asthma.

It is imperative that *all* patients with wheezing receive outpatient follow-up with their primary care provider or, in some instances, with a specialist. With few exceptions, follow-up evaluation should take place within a few days to a week of the ED visit.

CHAPTER 81

Weight Loss

JANE M. LAVELLE, MD

Department of Pediatrics, The University of Pennsylvania School of Medicine, and Department of Pediatrics, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Weight loss occasionally prompts a visit to the emergency department (ED). More commonly, it is an important physical examination finding in a patient presenting with another complaint. Acute weight loss is most commonly caused by a negative fluid balance occurring in the face of illness and can be life-threatening. These problems have special importance to the emergency physician. Chronic weight loss may result from a number of medical and nonmedical causes leading to inadequate nutrition. Any complaint of weight loss, or documented weight loss, is a significant finding that demands careful evaluation and follow-up.

PATHOPHYSIOLOGY

The health of infants and children depends on a balanced intake of fluid and nutrients that serve as building blocks for new tissue. The major determinants of body weight are water and the organic fuels, carbohydrates, protein, and fat. Weight loss occurs when the daily balance of one of these becomes negative (Fig. 81.1). Overall, during childhood, the major cause of weight loss is protein-energy intake inadequate to meet the energy demands of cell metabolism and tissue synthesis. Causes include decreased calorie intake, normal calorie intake with increased metabolic requirement, and normal calorie intake in the face of malabsorption or impaired use. During acute illness, fluid loss in excess of intake, in the presence of protein-calorie malnutrition, is the most common cause. Water losses occur primarily through the gastrointestinal (GI) tract but also through the urine and skin. Fever, infection, trauma, and thermal injury all cause a dramatic increase in metabolism that is rarely balanced with intake. During chronic illness, a cyclic pattern of adequate intake alternating with starvation results in gradual weight loss over time.

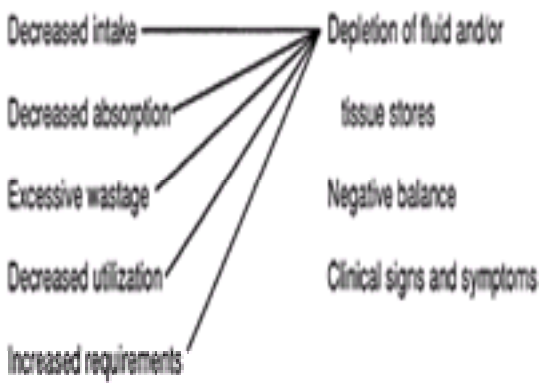

FIGURE 81.1. Pathophysiology.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of weight loss is extensive and can be thought of in major categories, including inadequate fluid and/or caloric intake, decreased absorption, excessive wastage, and increased catabolism or abnormal caloric use (Table 81.1). The single most common cause of acute weight loss in all age groups is dehydration that occurs in conjunction with an acute infectious illness. In the infant and toddler with chronic weight loss or lack of appropriate weight gain, failure to thrive (FTT) or undernutrition is usually identified in the first 3 years of life and is estimated to occur in 10% of children. This is a complex disorder resulting from physical and/or psychosocial problems. In the older patient with chronic weight loss, an underlying medical or psychiatric illness is more likely than in the infant (Table 81.2). In some instances, the exact diagnosis is not made at the time of the ED visit, but a workup may be initiated and an appropriate

referral made.

Table 81.1. Differential Diagnosis of Weight Loss

	Infants	Older Children/Adolescents
Acute	Gastroenteritis	Gastroenteritis
	Acute infectious illness	Acute infectious illness
	Pyloric stenosis	
	Gastroesophageal reflux	
Chronic	Failure to thrive	Inflammatory bowel disease
		Eating disorders
		Affective disorders

Table 81.2. Common Causes of Weight Loss

A few life-threatening diseases associated with weight loss must be separated out from conditions that carry no immediate risk (Table 81.3). Severe dehydration in the presence of gastroenteritis or other acute illness may be catastrophic in any age group (see Chapter 18). In young infants, several disease states need to be considered. The salt-losing form of congenital adrenal hyperplasia (CAH) presents with anorexia, vomiting, dehydration, and progressive weight loss. In female infants, virilization of the external genitalia provides a clue to the diagnosis; however, this is lacking in male infants. The characteristic electrolyte abnormality of hyponatremia and hyperkalemia and the rapidity of onset of the patient's illness support the diagnosis of CAH (see Chapter 97). Inborn errors of metabolism cause a wide variety of symptoms, but poor feeding, anorexia, vomiting, weight loss, and lethargy are always present (see Chapter 98).

Infants	Older Children/Adolescents
Gastroenteritis, secondary dehydration	Gastroenteritis, secondary dehydration
Inborn errors of metabolism	Diabetes mellitus
Congenital adrenal hyperplasia	Addison's disease
Congenital immune deficiencies	
Acquired immunodeficiency	
Congenital heart disease	
Pyloric stenosis	

Table 81.3. Potential Life-Threatening Causes of Weight Loss

Those presenting in the first weeks of life are severe and fatal if the correct diagnosis is not made. These disorders may masquerade as (or be complicated by) sepsis, hypoglycemia, hypocalcemia, or GI obstruction, but an inborn error must always be considered in neonates presenting with weight loss. Clinical deterioration in a previously normal baby, history of previous fetal death, or consanguinity increases suspicion. Infants and young children with congenital immune deficiency syndromes have a significant component of weight loss and wasting, in addition to repeated infections, seborrheic dermatitis, alopecia, chronic diarrhea, and hyperplastic joints. Infants with acquired immunodeficiency often lose weight before diagnosis. Both groups of children are at risk for life-threatening infections. Congenital heart diseases and pulmonary diseases are also associated with poor growth and may require acute intervention.

In older children, a few diseases associated with weight loss are acutely life-threatening and include adrenal crisis, diabetes mellitus with ketoacidosis, and severe dehydration. Older children and adolescents with Addison's disease have gradual onset of fatigue and weakness, anorexia, weight loss, and low blood pressure. If the diagnosis is not made, adrenal crisis may supervene, leading to circulatory failure, which may be rapidly fatal. Evidence of hyperpigmentation (particularly around the genitalia, nipples, axilla, and umbilicus) provides a clue to the diagnosis. Ketoacidosis is the initial manifestation in many children with diabetes; these children often give a history of weight loss in the presence of

polyphagia, polydipsia, and polyuria.

EVALUATION AND DECISION

General Approach

Consideration of the child's age and the severity and duration of the weight loss along with the presence of other systemic symptoms and specific physical examination findings help narrow the extensive differential diagnosis. Many diagnoses are exclusive to specific age groups. For the emergency physician, severity is an important consideration because sudden losses are more suggestive of life-threatening disorders that require prompt recognition and treatment.

Acute weight loss (occurring in less than 2 weeks) is most often caused by anorexia, poor fluid and calorie intake, increased losses, and increased metabolic need in association with an intercurrent illness. Weight loss is a sensitive indicator for dehydration and commonly occurs in the presence of any significant febrile illness. In this setting, the history includes an estimation of intake, losses, and increased need for fluids and calories. The types of losses pinpoint the location of GI pathology. The presence of other symptoms consistent with an acute infectious process substantiates the cause. Circulatory compromise suggests severe depletion (see Chapter 3 and Chapter 18) or adrenal crisis (see Chapter 97).

Chronic weight loss (occurring over more than 2 weeks) results from a combination of factors, including anorexia, poor utilization or malabsorption, and increased requirements, as well as health consequences imposed by the underlying disease state. When considering the cause of chronic weight loss, broad categories exist, including loss 1) secondary to a medical cause (underlying infection, absorptive defect, inflammatory or neoplastic disease); 2) related to a psychosocial or psychiatric cause; or 3) resulting as a consequence of both problems. A complete review of systems, in search of fever, night sweats, arthritis, abdominal pain and/or diarrhea, dermatitis, and other constitutional symptoms, helps the physician reach the diagnosis. A detailed dietary and feeding history (including frequency, types, and amounts of foods ingested) is invaluable. The attitude of the child and family toward food and eating habits should be explored. An estimation of caloric intake is attempted from a record of intake the day preceding the interview. Formula preparation and juice consumption are important historical pieces for babies. Gross overestimation of intake often indicates a psychosocial cause for the poor growth because of an inexperienced parent, poor parental–child interaction, and/or multiple caretakers. A search for a cause of family stress or dysfunction, economic problems, and available resources is essential. The presence or absence of symptoms of depression (poor school performance, disturbed sleep, loss of appetite, and apathy) is also important.

A complete and careful physical examination with attention to vital signs, state of hydration, and findings suggestive of specific disease states (e.g., murmur and/or cyanosis, lymphadenopathy, dermatitis, hyperpigmentation, abdominal mass and/or tenderness, arthritis, neurologic abnormalities) provides useful clues. Nutritional inspection includes an evaluation of body fat, muscle mass, hair, skin, and nails. Physical signs associated with specific vitamin deficiencies are nonspecific and occur late in the course of malnutrition. Dysmorphic features should be noted and a thorough neurologic examination performed. Infants should be observed nursing or being bottle fed, with attention to any gagging, choking, reflux, or respiratory distress.

Measurements of weight, recumbent length in babies younger than 2 years, standing height in children older than 2 years, and head circumferences are necessary components of the physical examination. Normal growth is present when sequential measurements consistently lie within the 5th to 95th percentile on standard growth charts from the National Center for Health Statistics. Values on standard growth curves for children 0 to 36 months are obtained from recumbent length measurements; standing height measurements may be as much as 2 cm shorter. Use of growth charts to evaluate the child's weight and height relative to each other and previous values is important. In infants and toddlers with proportionately low measurements of all parameters, head circumference, weight and height, congenital defects ranging from metabolic/genetic disorders to prenatal or perinatal asphyxia represent the differential diagnosis. This group of children may never achieve normal growth even in the face of nutritional interventions. Infants/toddlers with normal head circumference and mild or proportionate weight reduction to height include those with constitutional growth delay, genetic dwarfism, or endocrine disorders. The final category represents the majority of infants and toddlers. Children in this group have normal head circumference and low weight out of proportion to height. Inadequate nutrition is the cause. Anthropometric measurements may be helpful in sorting out adequacy of growth of children consistently less than 5% after the ED evaluation. Looking at growth parameters over time is extremely helpful, although usually unavailable in the ED; a consistent fall in a downward direction requires a diligent search for an underlying chronic illness.

The severity of malnutrition can be defined further by using the actual weight expressed as a percentage of the ideal weight for the patient's actual height. Mild protein-energy malnutrition exists when the actual weight is 85 to 90% of the ideal body weight for actual height, moderate when this is 75 to 85%, and categorized as severe when this falls below 75%. The degree of malnutrition is important when considering the refeeding regimen and decision making regarding the patient's disposition.

Growth curves have been created for special groups of children who exhibit different growth patterns than the general population. The growth of premature infants can be evaluated based on their corrected age or on special growth graphs created by Babson. The premature infant normally attains “catch-up” growth during the first 2 years of life (after which normal growth curves can be used). Another standard growth curve has been created for the evaluation of growth during the adolescent age that includes the patient's sexual maturity rating. These graphs account for the variability in the timing of the adolescent growth spurt, and deviation from the standard growth curves should be interpreted with caution. No routine screening panel of laboratory tests is indicated in patients with undernutrition. Rather, they should be done as indicated by the history and physical examination. Considerations include complete blood count, erythrocyte protoporphyrin or ferritin, electrolytes, glucose, blood urea nitrogen (BUN), creatinine, serum protein profile, urinalysis, and stool examination (Table 81.4).

Primary	Secondary
Complete blood count	Bone age, chest radiograph
Erythrocyte protoporphirin (or ferritin)	Thyroid function tests
	Immunologic studies
Serum glucose, electrolytes	Chromosomes
BUN, creatinine	Urine for ketones/reducing substances
Serum proteins	Plasma ammonia
Urinalysis, urine culture	Plasma lactate
Stool hemoccult, clinitest	Serum/urine amino acids
Calcium, phosphate	Urine organic acids
Liver function tests	EEG/head imaging
Sedimentation rate	Sweat test
Tuberculin test	Lactose breath test
	Stool for trypsin
	Stool for fat
	B_{12}
	UGI/colonoscopy

EEG, electroencephalogram; UGI, upper gastrointestinal radiographic study.

Table 81.4. Possible Laboratory Test

Infants

Infants should regain their birth weight by 10 to 14 days of age. Average daily weight gain in the first 6 months of life is 20 g and decreases to 15 g in the second half of the first year. During the first 2 months of life, head circumference increases by 0.5 cm per week, and from 2 to 6 months by 0.25 cm per week. When evaluating the infant with weight loss or inadequate weight gain, the physician should include in the history perinatal events and the onset and character of the symptoms. The presence of vomiting and acute weight loss in an otherwise well baby with a good appetite suggests gastroesophageal reflux or pyloric stenosis (Fig. 81.2). Poor sucking or swallowing and delayed development indicates neurologic or neuromuscular disease. Vomiting and anorexia, altered mental status, seizures, and characteristic body fluid odors (see Chapter 98) point to metabolic disease. Renal insufficiency or tubular disease or liver disease also may cause anorexia and vomiting and thus poor growth. Frequent infections, dermatitis, and diarrhea are associated with immune deficiency syndromes. The infant who tires or becomes diaphoretic with feedings may have congenital heart or pulmonary disease. The presence of malodorous, loose stools suggests primary malabsorption or cystic fibrosis. Blood-streaked, water-loss stools may be related to milk protein allergy or infectious (especially bacterial) enteritis.

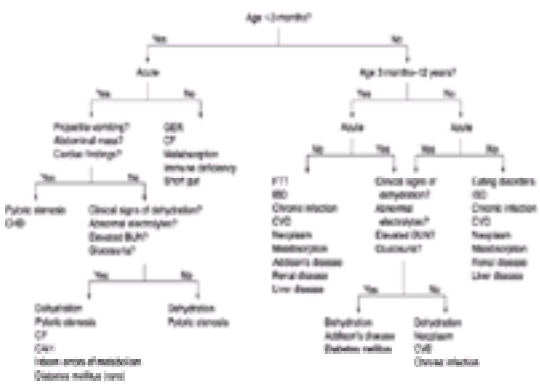

FIGURE 81.2. An approach to the evaluation of weight loss. *BUN,* blood urea nitrogen; *CHD,* congenital heart disease; *CF,* cystic fibrosis; *CAH,* congenital adrenal hyperplasia; *CVD,* collagen vascular disease; *IBD,* inflammatory bowel disease; *FTT,* failure to thrive; *GER,* gastroesophageal reflux.

The physical examination includes measurement of length, weight, and head circumference. When all three parameters are abnormal, a neurologic, genetic, or metabolic cause is suspect. When length and weight are subnormal but proportional, skeletal dysplasias, endocrinopathies, or constitutional short stature are likely. When only weight is below normal, an acute illness, dehydration, or deprivation is probably the culprit; the infant should be evaluated for signs of dehydration, cardiac or pulmonary disease, and neurologic abnormalities. As noted previously, observation of a feeding infant may offer some relevant clues. The evaluation of an infant with suspected failure to thrive as a result of child abuse is discussed in Chapter 128.

Older Children

In approaching children older than 3 to 5 years, the same principles are used (Fig. 81.2). Average weight gain until puberty is 2 kg per year and average growth is 5 cm (2 inches) per year. A careful history, physical examination, and growth assessment identify the child with growth failure that requires further investigation. The most common causes of chronic weight loss in this age group are diabetes mellitus (DM) and inflammatory bowel disease (IBD). Therefore, important historical points include a history of increased appetite, polyuria, and polydipsia. With regard to IBD, colicky abdominal pain, diarrhea, and other symptoms such as arthritis or rash are pertinent. However, weight loss may be the sole manifestation. In this age group, mental health disorders are an important consideration. The incidence of diagnosed depression in children continues to increase because of both improved recognition and a rising incidence in our society.

Adolescents

Growth failure in adolescents may be the harbinger of chronic illness. The history and physical examination again help in uncovering the pathology. Consideration of underlying inflammatory, chronic infectious, or neoplastic disease is

important (Fig. 81.2).

Eating disorders often emerge during adolescence. As in FTT, the diagnosis is made with a careful dietary history and physical examination. These patients exhibit an intense fear of fatness, a relentless pursuit for thinness, a preoccupation with food, and a distorted body image. A limited laboratory evaluation that excludes diseases that may mimic anorexia and bulimia is indicated (see Chapter 130). In cases complicated by severe malnutrition (weight loss over 20% of ideal body weight), metabolic derangements, dehydration, or acute psychosis, patients with eating disorders are cared for initially in the hospital.

Laboratory Tests

The potential list of tests to aid in the evaluation of weight loss is extensive (Table 81.4). Decisions to obtain diagnostic tests should be made individually after a thorough history and examination is completed. A complete blood count serves many purposes and may uncover macrocytosis caused by hypothyroidism or malabsorption of folate or B_{12}; microcytosis caused by iron deficiency, chronic blood loss, or chronic infection; polycythemia related to chronic heart or lung disease; neutropenia indicative of Schwachmann syndrome; elevated neutrophil count secondary to infection; abnormal cell counts or morphologies caused by underlying neoplasm; or thrombocytosis caused by chronic infection or underlying malignancy. Electrolytes may confirm the presence of significant dehydration, and hyponatremia in the presence of hyperkalemia suggests the diagnosis of adrenal insufficiency. Alterations in serum proteins may reflect aberrant absorption, decreased synthesis, or chronic infection. The urinalysis evaluates tubular function and may reveal glucosuria or disaccharide intolerance or galactosemia, as well as infection and renal tubular acidosis. The stool should be checked for the presence of blood, infectious agents, and reducing substances. With the results from this battery of tests, in conjunction with the physical examination and history, a diagnosis or appropriate referral can be made.

SUMMARY

Weight loss is a complaint that requires careful evaluation. With an acute episode of weight loss, many patients seen in the ED will have fluid loss and mild protein energy malnutrition related to an intercurrent illness with anorexia, increased metabolic need, or increased losses. Most of these children will return to baseline spontaneously when their illness resolves. Chronic weight loss or growth failure is indicative of less common diseases, and those for which the differential diagnosis is extensive. In small children, the most common cause is psychosocial growth failure. In older children and adolescents, an organic cause becomes more likely.

Disposition

As always, the general appearance of the infant or child determines the timing and the scope of the evaluation. Hospitalization is indicated in any child who is suspected to have sustained trauma or been abused and may be indicated in those with physical findings consistent with severe malnutrition such as weight 60% less than ideal body weight, hypothermia, bradycardia, or hypotension. Children with mild to moderate protein calorie malnutrition can be referred back to their pediatrician for outpatient management. Nutrition is a central component of well-being in the growing child, and malnutrition carries significant morbidity and mortality. Thus, persons who care for children need to have a sense of normal growth and must develop an approach for the evaluation and treatment of growth failure.

CHAPTER 82

Cardiac Emergencies

[*]MICHAEL H. GEWITZ, MD AND [†]VICTORIA L. VETTER, MD

[*]*Department of Pediatrics, New York Medical College, Director of Pediatrics, and Pediatric Cardiology, Children's Hospital at Westchester Medical Center, Valhalla, New York;*
[†]*Department of Pediatrics, The University of Pennsylvania School of Medicine, and Division of Cardiology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania*

Cardiac problems in infancy and childhood are not rare, often are complex, and always have important implications for the general health of the child. This chapter provides information regarding the evaluation and management of the more common emergencies that arise from the presence of cardiovascular disease in children. For the health care professional not well-versed in childhood cardiac disease, a brief overview is provided as background for the specific problems discussed in detail.

OVERVIEW

As with other pediatric disorders, cardiac diseases in childhood can be congenital or acquired. Major and minor structural diseases of the heart for the most part result from derangements of embryologic development and thus are present in some form at birth. However, the clinical manifestations of such problems may be delayed for days, months, or even years. In contrast, many other disorders of cardiac physiology result from problems superimposed on inherently normal cardiac structures. These problems often are acute in their development when a relatively sudden change from normal cardiac physiology occurs, leading quickly to the development of symptoms. It should be remembered, however, that acquired cardiac diseases also can be associated with prolonged latent periods. For example, the most prevalent form of acquired heart disease in the United States, coronary artery disease, probably has its beginnings in childhood in numerous instances, although its appearance as a clinical entity occurs much later. Examples of forms of congenital and acquired pediatric cardiac problems are reviewed in Table 82.1.

Congenital	**Example**
Disorders of septal or valvar development	Pulmonary, aortic valve stenosis Mitral or tricuspid atresia Ventricular septal defect Atrial septal defect
Disorders of venous or arterial connection	Transposition of the great vessels Anomalies of pulmonary venous return
Disorders of conduction system development	Congenital AV block Persistent bypass tract syndromes (preexcitation)
Acquired	**Example**
Disorders of cardiac muscular function	Cardiomyopathy associated with cancer therapies Acute myocarditis Acute pericarditis
Disorders of valvar function	Acute rheumatic fever Bacterial endocarditis
Disorders of cardiac rhythm	Drug-induced arrhythmias Postsurgical heart block

AV, atrioventricular.

Table 82.1. Examples of Acquired and Congenital Forms of Pediatric Heart Disease

The incidence rate of congenital heart disease has been fairly constant over the past few decades and is estimated to be approximately 8 to 10 cases per 1000 live births (0.8 to 1%). This includes all forms of defects and all ranges of severity but does not include the most common isolated congenital cardiac lesion, bicuspid aortic valve, which occurs in an additional 1 to 2% of people. The prevalence figures for congenital heart disease (CHD) are continually increasing, however, as more and better treatment modalities become available to sustain critically ill patients and because many of these patients are beginning to have offspring of their own. Recently, studies have found the incidence of congenital cardiac problems in children of parents with CHD to range from 5 to 15%. (The disorders seen as part of the spectrum of CHD are extremely variable; comprehensive texts are available for more detailed reviews.)

Age at presentation can vary significantly, depending on the type of congenital cardiac lesion and its severity in terms of effect on cardiac performance. Not all congenital heart defects are clinically apparent at birth. Severe obstruction to pulmonary or systemic flows may be masked in the first few days of life by persistence of a patent ductus arteriosus, whereas the presence of an important ventricular septal defect may not become evident until 4 to 6 weeks of age. This wide disparity in age at presentation is related to the physiologic interactions of the systemic and pulmonary vasculature, as well as to the anatomic specifics of any particular lesion. Table 82.2 presents examples of typical presenting ages for the more common forms of CHD. Although it is not important for the emergency practitioner to be versed specifically in all possible defects, knowledge of the anatomic and physiologic possibilities is important so that the practitioner's awareness of potential problems can lead to appropriate triage and initiation of care. One useful approach is to categorize lesions by the presence or absence of arterial desaturation; thus, there are cyanotic and acyanotic forms of CHD. Table 82.3 reviews some of the congenital lesions that segregate into these two groups.

First 2 Weeks	*6 Weeks to 6 Months*
Left ventricular outflow obstruction	VSD
Coarctation of aorta	AV canal malformations
Severe aortic stenosis	Coronary artery anomalies
Left heart hypoplasia	Truncus arteriosus
Cyanotic lesions	*Over 6 Months*
Transposition of great vessels	VSD
Total anomalous pulmonary venous return	Atrial septal defect
Atrioventricular (AV) canal malformations	Isolated valvar lesions (e.g., pulmonic stenosis, mitral insufficiency)
Truncus arteriosus	Small PDA
First Month	Partial anomalous pulmonary venous return
Coarctation of aorta	Coarctation of aorta
Ventricular septal defect (VSD)	
Patent ductus arteriosus (PDA)	
Truncus arteriosus	
Complex lesions with multiple anomalies (e.g., double-outlet right ventricle)	

[a]There is considerable overlap regarding any particular lesion and the specific clinical setting. This list is representative and illustrative, not all-inclusive.

Table 82.2. Age of Presentation of Congenital Heart Disease[a]

Acyanotic Lesions	*Cyanotic Lesions*
Secundum atrial septal defect	Tetralogy of Fallot
Ventricular septal defect	d-Transposition of the great vessels
Patent ductus arteriosus	Tricuspid atresia variants
Aortic stenosis/regurgitation	Total anomalous pulmonary venous return
Coarctation of the aorta	Truncus arteriosus
Pulmonic stenosis—valvar	Pulmonary atrioventricular fistula
Peripheral pulmonary stenosis	Complete atrioventricular canal defect
Mitral stenosis/regurgitation	Ebstein's anomaly of the tricuspid valve
Partial anomalous pulmonary venous return	Pulmonary atresia with septal defect
Congenitally corrected transposition of the great vessels	Single ventricle states

Table 82.3. Exemplitive Congenital Heart Lesions

Even without recalling specific lesions, however, only a few key principles of cyanosis must be understood (Table 82.4) to be able to consider the possibilities when faced with a particular patient. For example, a patient with anemia may have cyanotic CHD yet not be visibly desaturated; or a patient may have a significant level of pulmonary valve stenosis with significant obstruction to pulmonary blood flow but not appear cyanotic. Conversely, a patient may not have a loud cardiac murmur or any murmur at all and still have a serious cyanotic cardiac lesion (see Chapter 33).

In the presence of normal hemoglobin moieties and normal cardiac output, right-to-left shunting must be present to produce cyanosis; this can be intrapulmonary, intracardiac, or both.
Obstruction to pulmonary blood flow alone does not produce cyanosis.
A critical mass of reduced hemoglobin must be present to allow visual estimation of cyanosis.
Right-to-left shunts are not usually associated with heart murmurs.
The presence of visible cyanosis depends on the interrelationship of pulmonary and systemic blood flows and hemoglobin concentration.

Table 82.4. Useful Rules of Cyanotic Congenital Heart Disease

In diagnosing children with possible CHD, therefore, it is usually not necessary to remember long lists of complex lesions. An appreciation of what is anatomically possible and what is physiologically rational, however, usually leads to the ability to discern what is clinically likely in any particular situation.

The next sections deal with specific examples of the melding of these anatomic and physiologic concerns in emergency

situations that involve cardiovascular diseases in children.

CONGESTIVE HEART FAILURE

Background

Heart failure is best described as a syndrome in which the heart cannot maintain a level of tissue perfusion adequate to meet metabolic needs. During childhood, these needs also include growth and development. This section offers an outline of the primary etiologic and physiologic factors that underlie the clinical presentation of the child in congestive heart failure (CHF) and that influence management decisions.

Etiologic Considerations

Although the primary cause of CHF in infants and children is CHD, a panoply of conditions can be associated with the presentation of CHF in the presence of normal underlying cardiac structure. Table 82.5 lists the more common clinical entities associated with CHF, including primary cardiac disease and conditions in which the heart is affected secondarily. In general, the principal physiologic problems that lead to impaired myocardial performance include 1) excessive pressure loads such as with left-sided heart obstructions; 2) excessive volume loads, such as with large left-to-right shunts, valvar regurgitation, and severe anemia; 3) primary inotropic depression such as with myocarditis, endocrinologic disorders, or coronary perfusion irregularities; and 4) rhythm abnormalities such as supraventricular tachycardia (SVT) or severe forms of heart block.

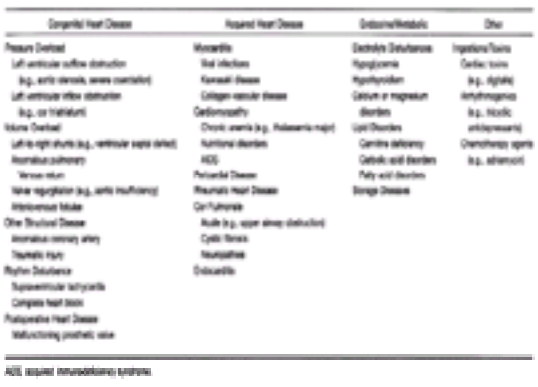

Table 82.5. Etiologic Considerations for Congestive Heart Failure

The history is critical in determining the cause of CHF and should not be glossed over in the rush to treat. Knowledge of preexisting cardiac disease obviously is important. A history of known hematologic disorders such as thalassemia or sickle cell anemia also should be sought. Because heart failure can develop as a consequence of pressure overload of the right side of the heart secondary to pulmonary vasoconstriction and hypoxia, a history of respiratory tract difficulties or breathing pattern irregularities also should be reviewed carefully. A knowledge of other systemic conditions is likewise crucial. For example, several recent studies have indicated that human immunodeficiency virus (HIV) infection can affect cardiac performance seriously on an acute and chronic basis. Late stages of HIV infection often are complicated by cardiomyopathy and CHF. Careful clinical assessment that looks for signs of cardiac involvement should be part of the evaluation of children with HIV who present with hypotension or who have respiratory problems not responsive to direct pulmonary management. As another example, a history for Kawasaki disease should be sought in patients with new-onset CHF that appears to be related to inflammatory myocardial disease, even if other classic signs are not overtly present.

In the presence of appropriate physical findings and historical information, the diagnosis of CHF usually is evident in the older child. The principal problem of diagnosis centers on the infant, in whom differentiation between CHF and primary respiratory tract disease can be difficult. Auscultation of cardiac murmurs is helpful, of course, but such murmurs may not always be audible, particularly in severe failure with low output. Parenchymal lung disease may result in systemic desaturation to the same degree as CHF with associated pulmonary congestion and ventilation-perfusion imbalance. Palpation of the liver edge below the costal margin in an infant may be related to hyperexpansion of the lungs and not to systemic venous congestion. Conversely, respiratory tract signs such as wheezing and retractions may be part of the clinical picture of heart failure in the absence of primary lung disease. The chest radiograph often fails to distinguish clearly between cardiac and pulmonary disease because pulmonary markings often mimic infiltrative patterns. Generally, however, evidence of cardiac enlargement on the radiograph is a useful differential point. Other noninvasive methods, such as echocardiography, also can help establish the diagnosis of cardiac disease.

Pathophysiology

There are four primary determinants of normal cardiac function, each of which may relate to the development of heart failure. The first is preload, the volume at end-diastole that must be ejected by the left ventricle, that closely reflects the intravascular volume status of the child in general, and that directly affects cardiac performance through the Frank-Starling relationship. The second, afterload, is the opposing force to ventricular ejection and relates to the tension that must be developed by the myocardium to eject a given preload. The third determinant, contractility, can be viewed as an intrinsic property of cardiac muscle that permits alterations in cardiac shape necessary for ejection and is determined by fundamental properties of cardiac ultrastructure. The fourth and last determinant, heart rate (HR), is related to intrinsic electrophysiologic capabilities of the specialized cardiac conduction system and to supervening neurologic input. It is

directly related to cardiac output (CO) through the classic relationship:

$$\mathrm{CO} = \mathrm{HR} \times \mathrm{SV}\ (\textbf{stroke volume})$$

Compensatory Responses

To understand the basis for the clinical findings commonly associated with CHF, the physician must direct attention to the physiologic responses to inadequate cardiac function. These include mechanical effects, such as ventricular hypertrophy and ventricular dilation; neurohumoral effects, principally those that involve the adrenergic nervous system; biochemical effects at the cardiac cellular level that alter myocardial energy metabolism and the excitation–contraction coupling process; and hematologic effects that involve oxygen transport. In addition, pulmonary responses, including increased respiratory frequency and altered respiratory patterns, also make up an important part of the clinical picture of CHF.

Clinical Manifestations

The clinical manifestations of CHF are directly related to the compensatory mechanisms already described:

1. Cardiac enlargement usually is the result of ventricular dilation. Although it often may be possible to detect cardiac enlargement by displacement of the cardiac impulse, the chest radiograph remains the most readily available method for assessing ventricular dilation (Fig. 82.1 and Fig. 82.2). Care must be taken to distinguish the normal cardiothymic silhouette from true cardiomegaly in an infant (Fig. 82.2). The other preeminent finding related to mechanical compensatory responses is ventricular hypertrophy, which is easily distinguishable on the electrocardiogram (ECG) (Fig. 82.3). As a compensatory mechanism, hypertrophy occurs before dilation in pressure overload situations, whereas dilation may occur first in volume overload of the heart. As a rule, the cardiac size can be a reliable guide to the overall fluid volume status of the infant or child.

FIGURE 82.1. Chest radiograph of older child with congestive heart failure. Note cardiac enlargement and evidence of pulmonary venous congestion.

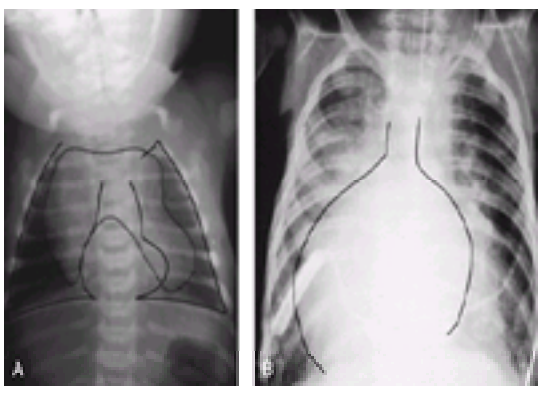

FIGURE 82.2. A. Normal cardiothymic shadow. Thymus is demarcated by speckled line and overlies a portion of the heart shadow. **B.** True cardiomegaly in an infant associated with pulmonary edema. Entire area enclosed in outline is cardiac shadow.

FIGURE 82.3. Electrocardiogram demonstrating left ventricular hypertrophy. Note increased R-wave voltage in left precordial leads and abnormal T-wave changes.

2. Tachycardia is easily detected clinically and, if necessary, confirmed by ECG. A rate of more than 160 beats per minute (bpm) in an infant or 100 bpm in the older child may be a signal for increased adrenergic tone and catecholamine release that is part of the neurohumoral response to diminished cardiac output.
3. Abnormalities of cardiac auscultation also are commonly present. The protodiastolic gallop, or third heart sound (S_3), is a sign of decreased ventricular compliance and increased resistance to filling. Less often, the fourth heart sound, or atrial gallop (S_4), can be heard in children. It should be noted that these auscultatory events can be normal findings in children, and thus, the entire clinical picture must be evaluated before defining their significance in any particular situation.
4. Respiratory responses, notably tachypnea, usually are present as part of the total picture of CHF. Often, rales, rhonchi, and wheezing may be heard and should not be confused as signs of pulmonary parenchymal disease rather than heart failure. In contrast, it is not unusual, particularly in infants, for rales to be absent despite the presence of tachypnea or wheezing because considerable alveolar fluid accumulation is necessary for the development of rales. Thus, the presence of rales usually implies severe failure in an infant, whereas pulmonary interstitial fluid collection, which occurs at an earlier stage, may be represented by tachypnea and wheezing alone. In older children, dyspnea with activity and orthopnea also may be present. A chronic cough also can be a sign of pulmonary congestion associated with CHF and not primary lung disease. Associated with these findings are chest retractions that reflect the large negative intrathoracic pressures needed to ventilate stiff, fluid-filled lungs.
5. Growth failure and undernutrition may be important clinical correlates of chronic CHF. These reflect not only diminished cellular substrate availability as a result of inadequate tissue perfusion but also increased caloric expenditure associated with heightened oxygen consumption and increased work of breathing. Feeding difficulties, which may be associated with the respiratory patterns previously noted, aggravate caloric balance even further.
6. Cool, moist extremities and a generalized pallor also may be present as a result of peripheral vasoconstriction secondary to catecholamine release and the need to maintain blood pressure (BP) in the face of reduced CO.
7. Central and peripheral fluid accumulation with elevated systemic venous pressure also accompanies CHF, reflecting impaired cardiac emptying, as well as impaired sodium and protein balance. Hepatomegaly, jugular venous distension, and peripheral edema represent the clinical manifestations of this aspect of the problem. Peripheral edema, it should be noted, is an unusual finding in young infants. Pulsus alternans, a beat-to-beat variability in the strength of the pulse, also is a clinical sign of cardiac mechanical decompensation.

The child with overt CHF who is seen in the emergency department (ED) may present with nearly all the aforementioned signs and symptoms. If the child is severely ill, pallor will be evident, tachypnea prominent, and intercostal retractions visible. The liver is enlarged and palpable well below the right costal margin; a spleen tip also may be palpable. The pulses are weak and thready, and the skin may be moist and cool to the touch. Auscultation of the chest reveals rales, rhonchi, and sometimes, wheezes. Tachycardia is present, and auscultation of the heart sounds often elicits a gallop rhythm. Murmurs may be strikingly absent unless preexisting heart disease is present. A child with this spectrum of findings deserves immediate attention. Acute heart failure in a child usually implies an unstable situation with possible rapid deterioration.

Laboratory Findings

Usually, a clinical diagnosis of CHF can be made without extensive radiographs or laboratory tests. However, certain objective changes may corroborate the clinical findings:

1. As noted, a chest radiograph shows an increased cardiothoracic ratio, as well as pulmonary congestion. Kerley B lines or platelike atelectasis at the lung bases, which reflect dilated pulmonary lymphatics, may be present. Pleural effusions are common.
2. The ECG is a nonspecific indicator of cardiac decompensation. The precordial voltages decrease in certain conditions associated with CHF, such as myocarditis, but may be normal or increased in other situations despite overt CHF. The ECG is helpful also for establishing the cause of the CHF, such as cardiac arrhythmia or myocardial ischemia.
3. Echocardiography or radionuclide studies can be helpful in evaluating the child with CHF. The differentiation of an enlarged cardiac silhouette secondary to impaired cardiac performance with ventricular chamber enlargement rather than pericardial fluid accumulation can best be made by ultrasound examination. In addition, functional indices can be obtained as an objective measure of cardiac performance and response to therapy.
4. Blood gas abnormalities may be present. Prolonged tissue hypoperfusion can result in metabolic acidosis of a significant degree, and the pulmonary abnormalities already noted may result in hypoxia.
5. Other abnormalities that may be present include electrolyte changes (hyponatremia and hypochloremia) and a reduction in hematocrit, based on dilutional factors. The sedimentation rate (ESR) usually is lowered in active CHF. In addition, in infants with CHF, serum glucose and calcium should be monitored because deficiencies in either may be responsible in large measure for the impaired cardiac function. In situations of suspected perfusion abnormalities or inflammatory myocardial diseases, cardiac enzymes—creatine phosphokinase (CPK) in particular—may be elevated.

Management

For the patient who requires emergency treatment of CHF, initial medical therapy includes several therapeutic measures as outlined in Table 82.6. First, supplemental oxygen should be given through a humidified system. In children, a tight-fitting mask or nasal cannula may not be effective because too much energy is expended fighting such apparatuses. Second, elevation of head and shoulders is helpful in the face of pulmonary edema, with maintenance of the lower extremities in a dependent position to increase peripheral pooling and thus diminish pulmonary blood volume. A “cardiac chair” or appropriate modification of an infant seat establishes this posture in the small baby. Third, morphine sulfate (0.05 to 0.1 mg/kg subcutaneously) can be helpful in the face of agitation and air hunger associated with pulmonary edema. Fourth, positive-pressure respiration by endotracheal intubation is sometimes indicated for severe situations,

particularly if arterial blood gas analysis shows respiratory decompensation (Pa CO_2 50 mm Hg). In infants, the use of controlled mechanical ventilation to improve respiratory status greatly enhances survival. Fifth, bicarbonate therapy sometimes is indicated to correct metabolic acidosis that arises from diminished tissue perfusion. It should be remembered that administration of sodium bicarbonate during respiratory decompensation is hazardous because further PaCO_2 elevation can occur. In addition, bicarbonate given by rapid infusion can promote cerebral edema and rapidly affect serum osmolarity with deleterious effects. Also, an excessive sodium load can result from injudicious use of bicarbonate. Thus, only for severe acidosis (pH less than 7.2) should bicarbonate be considered and, even then, only if respiratory function is satisfactory (see Chapter 95). Last, an intravenous (IV) infusion should be started to aid in the administration of drugs and the strict monitoring and administration of fluids.

Define cause, if possible, through history and physical examination.	Perform arterial blood gas determination.
Elevate head and chest.	Achieve rhythm control.
Ensure adequacy of ventilation.	Treat pulmonary edema (e.g., diuretics, morphine sulfate).
Administer oxygen.	Provide inotropic support (digitalis or catecholamines).
Initiate cardiorespiratory monitoring, including frequent blood pressure measurement.	Consider afterload reduction.
Achieve venous access and obtain laboratory studies (e.g., complete blood count, electrolytes).	

Table 82.6. Emergency Management of Congestive Heart Failure

Blood products in the form of packed cells should be administered if the child is severely anemic. Antibiotics should be reserved for unequivocal evidence of infection or for situations in which circumstantial evidence is strongly suggestive and appropriate cultures have been drawn. The use of corticosteroids may be indicated at times, particularly for heart failure precipitated by rheumatic heart disease. However, decisions of this type should be made with cardiac consultation. Treatment of arrhythmias that result in CHF is discussed subsequently under Cardiac Arrhythmias.

Although newer inotropic agents have become available, the mainstay of the medical management of CHF is still digitalis, or other well-tested inotropic agents, to improve contractility and diuretics to manipulate ventricular preload and intrapulmonary fluid. Recently, pharmacologic adjustments of afterload have become an important part of CHF treatment. Regardless of the specific therapy, frequent reexamination and reevaluation are mandatory.

Digitalis

The drugs of choice for improving the inotropic condition of the heart, unless the CO is severely compromised and the child is acutely ill, are the digitalis glycosides. Several investigations have helped improve our understanding of the mechanisms of action of these agents and how to adjust their administration to specific clinical situations. Although the use of digitalis in infants was reported more than 35 years ago, until recently, dosing regimens have been strictly empiric in their derivations. The use of a radioimmunoassay to determine serum digitalis levels has helped define a dosing format. In infants and children, debate exists about the true therapeutic concentration range. As noted in Table 82.7, the principal clinical value of digitalis pharmacokinetic studies thus far has been to verify that the same unit dose per kilogram of body weight is not necessarily best for children of all ages and that premature infants, in particular, require close adjustment of dose, based on body weight.

I. Usual Doses (IM or oral)		
	Weight (g)	Dose (TDD)*
Premature infants	500–1000	20 µg/kg or 0.02 mg/kg
	1000–1500	20–30 µg/kg or 0.02–0.03 mg/kg
	1500–2000	30 µg/kg or 0.03 mg/kg
	2000–2500	30–40 µg/kg or 0.03–0.04 mg/kg
Term to 12 yr		40–60 µg/kg or 0.04–0.06 mg/kg (no dose greater than 1.5 mg TDD)
II. Alterations in Usual Doses		
Lower if renal function is impaired		
Lower in presence of poor myocardial function (cardiomyopathy, myocarditis)		
Lower in presence of metabolic imbalance (electrolyte abnormalities, hypoxia, acidosis)		
IV dose is 75% of oral or IM dose		

*TDD, Total digitalizing doses. Digitalizing regimen usually given as initial dose = one-half of TDD, second dose = one-fourth of TDD, at 8–12 hr; third dose = final one-fourth TDD at 8–12 hr after second dose. Maintenance is then started as one-eighth TDD every 12 hr. (Note: Parenteral preparation contains 100 µg/mL and oral, 50 µg/mL.)

Table 82.7. Digitalization with Digoxin

The mechanism by which digitalis improves cardiac performance centers on the regulation of the ionic movements that are part of the contractile process. In particular, inhibition of adenosine triphosphatase (ATPase) by digitalis interferes with the sodium pump mechanism, allowing intracellular accumulation of sodium and, consequently, increasing the level of available calcium for contraction. The associated effect of intracellular potassium depletion may be related to the development of toxicity from digitalis preparations.

The result of digitalis administration for CHF is an increase in the force of cardiac contraction and thus an improvement in emptying of the ventricle. Intracardiac filling pressures are reduced, CO rises, cardiac size decreases, and HR slows.

Eventually, use of the compensatory mechanisms (p. 662) to maintain CO is mitigated.

Several important points must be remembered when prescribing digitalis glycosides, regardless of the specific one selected or the route of administration. Diligent care must be used in relaying the prescribing information to avoid errors that may have fatal consequences. Calculations of the total digitalizing dose should be double-checked and clearly recorded. The microgram dosage should be unequivocally clear, and the corresponding volume to be administered also should be written down. If possible, the prescription should be checked by other medical personnel. Decimal errors are inexcusable but all too common.

The route of administration also has a significant bearing on the dosage prescribed. Parenteral digoxin preparations contain 100 µg/mL, and oral preparations contain 50 µg/mL. In the emergency setting, parenteral administration often is the preferred route. If given IV, the calculated oral dose is reduced by 25%, and the child should be monitored for sudden changes in HR or rhythm. Tissue perfusion levels should be assessed as satisfactory before intramuscular (IM) administration is contemplated because poor absorption from an IM dose (which can be painful) may undercut the therapeutic response.

Digoxin is administered at the dosages described in Table 82.7 (maximum 1.5 mg). The total digitalizing dose is given over 24 hours (one-half initially, then one-quarter in 8 to 12 hours, and one-quarter in another 8 to 12 hours). The daily maintenance dosage is one-quarter of the total digitalizing dose divided into twice daily doses.

Poisoning from digitalis ingestion may be the precipitating cause for emergency evaluation and for the development of CHF. Various systemic manifestations may be associated with overdosage, including nausea, vomiting, weakness, and worsening of preexisting heart failure. The ECG manifestations of digitalis excess are reviewed subsequently under Irregular Heart Rates. Care should be taken to clarify the ECG distinctions between “digitalis toxicity” and the more benign “digitalis effect.” In general, it is safest to assume that the appearance of a new major conduction disturbance in a child who takes a digitalis preparation is related to the drug.

Treatment of digitalis toxicity involves cessation of the drug. Potassium supplementation may be helpful, specifically when potassium depletion has occurred because of dietary factors or diuretic therapy. Potassium should not be given to a patient with digitalis-related atrioventricular (AV) block (see Cardiac Arrhythmias). Diphenylhydantoin is particularly useful in disorders of impulse formation related to digitalis therapy (e.g., premature ventricular contractions [PVC]). In instances of severe heart block, pacing may be required. The presence of digitalis is not an absolute contraindication for cardioversion, and in certain instances, cardioversion may be required to convert even a digitalis-induced rhythm disturbance. On occasion, calcium ethylene diamine tetracetic acid (EDTA) (30 mg/kg slow IV over 2 hours) may be used as an adjunct to the previously mentioned forms of therapy. Careful monitoring is required, however, because hypocalcemia may be induced and because EDTA may negate the therapeutic effects of digoxin, resulting in worsening CHF.

The availability of digoxin antibodies is an important adjunct in the treatment of digoxin toxicity. “Digibind” and other such drugs use the Fab fragment of antibody to digoxin to lower serum concentrations rapidly. Although it usually is necessary to combine vigorous antiarrhythmic therapy (see next section) with digoxin antibody treatment, this form of therapy can provide dramatic improvement in as little as 30 minutes. It must be cautioned, however, that Fab treatment in patients receiving chronic digoxin therapy for CHF may exacerbate CO problems by essentially “withdrawing” the drug. Dosage of Fab generally is equimolar to the estimated amount of digoxin in a patient's body. The onset of action is relatively rapid, with some clinical response noted in as little as 30 minutes after completion of infusion. Complete reversal of a toxicity can occur in 3 to 4 hours. However, close supervision of the patient is needed because with the administration of digoxin antibody, rapid occurrence of hypokalemia can occur. In patients with atrial fibrillation, a rapid ventricular response may occur to exacerbate problems, and occasionally a patient may experience hypersensitivity if sheep protein allergy is present. The elimination of digoxin antibody fragments may take up to several days or longer, especially if renal insufficiency is present, and may interfere with subsequent serum digoxin levels done by radioimmunoassay. Thus, other techniques for assessment of digoxin levels may be needed to follow-up patients at risk.

To use digoxin antibodies, it is assumed that the digoxin body burden approximates the nanogram per milliliter digoxin level. Thus, 1.0 ng/mL digoxin level reflects a burden of 1 mg digoxin. Each vial of purified digoxin-specific Fab fragments binds at least 0.4 mg of digoxin. Thus, for a digoxin level of 5 ng/mL, for example, 12.5 vials of Fab fragments will be required. No specific pediatric dose has been derived, and the relationship of digoxin level to body burden may not be as close as these values indicate. Thus, this dosage may not be entirely accurate for infants and small children.

Other Inotropic Agents

In situations of severely compromised CO, isoproterenol or dopamine, both a-receptor agonists, has been used successfully in infants and children. Dobutamine, an analog of dopamine, also has been found to be useful in such circumstances, particularly when impaired myocardial perfusion is part of the underlying problem.

Isoproterenol (Isuprel) has vigorous inotropic effects, as well as significant chronotropic effects. As noted under Cardiac Arrhythmias, for persistent bradycardia, isoproterenol is the drug of choice. Cardiac rhythm effects may limit the use of isoproterenol, however, because induction of tachyarrhythmias is a known consequence of its administration. In addition, hypotension may occur. The starting dose is 0.1 µg/kg per minute by continuous infusion (see Table 82.12).

Dopamine has achieved a wide degree of popularity because of its ability, at low dosages (“dopaminergic effects”), to augment renal blood flow directly, in addition to improving cardiac output. Furthermore, the chronotropic activity of the drug is somewhat lower than isoproterenol, and there is less of a tendency to produce hypotension. Several studies have established the efficacy and safety of dopamine in infants and children. The drug is available in 5-mL ampules that contain 200 mg of dopamine; this must be diluted in 250 to 500 mL of a neutral or acidic solution (usually 5 to 10% dextrose or saline). Dopamine must not be administered through the same IV solution as sodium bicarbonate because

alkali will deactivate the drug. Initial doses in pediatrics range from 2 to 5 µg/kg per minute given by continual infusion. For severe systemic hypotension, 5 to 10 µg/kg per minute may be used as the starting dose. The response should be relatively prompt, with an increase in HR and BP followed by improvement in urine output. Increasing the infusion rate may be necessary, but at higher dosages (15 µg/kg per minute), the beneficial effects of dopamine on renal blood flow are mitigated, and at 20 µg/kg per minute, adrenergic effects predominate and renal blood flow may be reduced. Adverse effects from dopamine include nausea and vomiting and changes in cardiac rhythm, particularly in patients with preexisting arrhythmias and especially at higher infusion ranges (greater than 10 µg/kg per minute). Dopamine also may elevate pulmonary vascular resistance and should be used with caution, if at all, in patients with pulmonary vascular obstructive disease. Monoamine oxidase inhibitors may potentiate the effect of agents such as dopamine.

These agents should be administered under close supervision, optimally with monitoring of arterial pressure, central venous and/or pulmonary wedge pressure, HR, and urinary output.

Dobutamine recently has achieved an increased level of popularity because of its relatively rapid response after initiation of infusion and because of the achievement of favorable hemodynamic effects with less myocardial oxygen debt burden than occurs with dopamine. Fewer chronotropic and arrhythmogenic effects appear to result from dobutamine, and it may have a more direct effect on enhancement of coronary flow. Therefore, dobutamine may have particular efficacy when impaired myocardial perfusion is suspected, as in heart failure from inflammatory myocardial disease or abnormalities that involve the coronary arteries. Dobutamine is administered in similar fashion to dopamine with initial dosages that range from 2.5 to 5.0 µg/kg per minute. Higher dosages may be used, but complicating adrenergic effects, in particular potentiation of rhythm disorders, begin to predominate when high dosages (15 to 20 µg/kg per minute) are used. As with dopamine, dobutamine can be used in concert with other agents, such as afterload reduction drugs.

Concern about the efficacy of dobutamine in the young infant (less than 1 year old) remains. In such infants, dobutamine may improve CO but not result in BP elevation. Thus, in severe hypotension in the young infant associated with septic shock, for instance, dobutamine may be more appropriate as an adjunct, and not as a primary inotrope.

Diuretics

Alterations in renal perfusion and salt and water balance are well known correlates of CHF. Reduced renal blood flow can result in increased circulation volume and increased sodium and water reabsorption (through associated secondary hyperaldosteronism). Thus, diuretics play a critical role in the management of the child with CHF.

The so-called loop diuretics are used most commonly for the acute treatment of CHF. Furosemide (Lasix) is the most popular of these, but ethacrynic acid (Edecrin) also may be used. Through effects on sodium and chloride transport in the loop of Henle, interference with urinary concentrating capability is achieved and diuresis is achieved. An initial dose of 1 mg/kg IV usually results in adequate urine flow within 1 to 2 hours of administration. If 3 to 5 mL/kg per hour urine flow is not achieved, a subsequent dose (at an increment of 1 mg/kg) can be given and repeated at hourly intervals, to a maximum of 3 to 5 mg/kg. Close observation for changes in serum electrolytes, especially potassium, is important because IV digitalis may be given concurrently.

Thiazide diuretics are much less commonly used to treat acute CHF and are now reserved for more chronic situations (as oral agents). Nevertheless, agents such as hydrochlorothiazide or chlorothiazide, working at the tubular level, produce good diuretic effects.

Other classes of diuretics have become available and may be particularly useful in refractory conditions or in cases in which traditional diuretics are already in use. Of these agents, metolazone (Zaroxolyn) has been administered most often. It is for oral use; thus, onset of action is delayed. Particularly intense potassium depletion can result from metolazone, and patients who take this drug should be evaluated for potassium loss whenever they present in the ED.

Spironolactone is considered an adjunctive form of diuretic therapy in most situations and is not a first-line drug because its diuretic effect may not occur for 2 to 3 days. Aldosterone antagonism makes it suitable for use as an additional agent when potassium loss is a problem.

With the proper use of digitalis and diuretic therapy, improvement can be achieved in most children with CHF. Failure to improve an exacerbation of CHF in children already taking these medications requires scrutiny for any of the following: 1) persistent arrhythmia; 2) untreated or unrecognized infection; 3) anemia, especially in the infant with CHF; 4) inadequate or excessive digitalis dose, particularly in the patient with inflammatory myocardial disease; or 5) electrolyte disturbance, such as hypokalemia, which may be worsened with diuretics. If these entities can be ruled out, more intensive treatment is indicated to improve CO.

Other Noncatecholamine Agents

Among recent additions to the pharmacologic tools readily available to treat acute CHF are the bipyridine derivatives amrinone and milrinone. These drugs have the combined effects of inotropic support and peripheral vasodilation. Although the exact mechanism of action is unclear, they are known to be inhibitors of myocardial cyclic adenosine monophosphate (cAMP) phosphodiesterase activity, thereby enhancing intracellular levels of myocardial cAMP. There is also a direct vascular smooth muscle relaxant action. In an ideal sense, amrinone and its class of therapeutic agents could represent a major therapeutic breakthrough because the inotropic effects of these drugs may be additive to other agents, especially to digitalis. However, pediatric experience has been tempered by the profound vasodilatory effects of the drug and the need for careful invasive monitoring when it is used. Adequate filling volumes must be maintained to ensure adequate systemic perfusion. Occasionally, hypersensitivity reactions have occurred with amrinone. Fever and thrombocytopenia are also known side effects, and potassium levels should be followed closely, especially if diuretics are used in conjunction with this drug. Finally, chemical interaction with glucose (dextrose) solutions can occur, and the drug should not be diluted with these fluids. In the patient with CHF in whom standard digoxin and/or catecholamine therapy

does not provide improved peripheral perfusion status, use of amrinone (IV) should be considered. Infusion rates range from 5 to 10 µg/kg per minute with a bolus dosage to start therapy of 0.50 to 2.0 mg/kg given initially over 2 to 5 minutes.

Vasodilators

The management of CHF also includes manipulation of loading conditions, following on the physiologic principles defined earlier in this chapter. Both afterload and preload interventions can be useful. Agents with effects on cardiac loading have been shown to be efficacious in adults with chronic ischemic forms of cardiac dysfunction and are appropriate for infants and children with heart failure unresponsive to more conventional treatment regimens. In heart failure with reduced CO, systemic vascular resistance often is elevated by compensatory mechanisms used to maintain BP. Preload reserve is used through cardiac dilation to increase stroke volume, but this is accomplished at the expense of a decreased ability of the myocardium to shorten as needed to overcome the increase in afterload. Thus, there is a "mismatch" of afterload and preload reserve in heart failure. Vasodilators that work primarily on arteriolar smooth muscle cause afterload reduction while venodilation works on preload by lowering cardiac filling volumes. Some of these agents have mixed effects (Table 82.8). In the vasodilator group, the nitrates, particularly Nitroprusside, have been most actively used in the acute-care setting. Sodium nitroprusside has both arteriolar and venous actions, a prompt onset of action, and usually a short duration of effect. In the patient with impaired renal function, however, caution must be exercised in its use because the byproduct, thiocyanate, can accumulate with neurologic, endocrinologic, and other toxicity. Other drugs used include a-receptor blockers and angiotensin-converting enzyme (ACE) inhibitors, although these are more commonly used in the long-term care setting via the oral route. Calcium channel blockers appear to be most useful for diastolic dysfunction conditions. These situations involve heart failure developing in the face of myocardial hypertrophy and/or normal end systolic volume, such as in hypertrophic cardiomyopathy. The negative inotropic effects of these agents require their use only with careful cardiac monitoring. It is important for the emergency physician to be aware of the chronic use of these drugs in patients who may present with an exacerbation of heart failure because continuation of such therapy in the acute-care setting may be required. Afterload reduction therapy, when used IV, usually requires extensive monitoring because failure to maintain adequate cardiac filling can have serious negative results. Emergency use of afterload reduction should be limited to those well versed in cardiopulmonary physiology, and maintenance of such treatment should be carried out in an intensive care environment.

Agent	Class	Action	Dosage
Nitroprusside	Nitrate	Mixed dilator	1–10 µg/kg/min IV (maximum: 125–10 µg/kg/min)
Nitroglycerin	Nitrate	Venodilator	2–10 µg/kg/min
Hydralazine[a]	Smooth muscle inhibitor	Arteriolar dilator	0.1–0.5 mg/kg/dose q6h or 0.2–1 mg/kg single dose IV
Prazosin	α Blockade	Mixed dilator	0.01–0.05 mg/kg/dose by mouth q8–12hr
Captopril	ACE inhibitor	Mixed	0.1–0.5 mg/kg/dose by mouth q8hr
Enalapril	ACE inhibitor	Mixed	5 or 12 hr (maximum: 5 mg/kg/day)[b]
Diltiazem	Ca^{2+} channel blocker	Arteriolar dilator	0.2–0.5 mg/kg/dose by mouth or sublingual q8hr
Nifedipine	Ca^{2+} channel blocker arteriolar		0.25–1 mg/kg

ACE, angiotensin-converting enzyme; Mixed, both arterial and venous vasoactivity.
[a]Precise mechanism not identified; may inhibit calcium activity.
[b]If Enalapril is available for an every 8-hr regimen (enalaprilat), 0.01–0.05 mg/kg/dose.

Table 82.8. Afterload Reducing Agents Used in Congestive Heart Failure

NEWBORN WITH OBSTRUCTED SYSTEMIC OR PULMONARY BLOOD FLOW

Background

For the baby with cyanotic CHD or with obstruction to systemic blood flow, emergency intervention is crucial, indeed life-sparing, and usually must be delivered before permanent long-term therapy can be undertaken. The emergency physician must be able to recognize when such a life-threatening circumstance is present and must be able to initiate therapy even before a precise diagnosis can be accomplished. Although this is most often a problem for the neonatologist or other physician caring for an infant during the first few days of life, these babies also are brought to EDs after having been at home. Still others may need the help of emergency medical personnel as they are transported to cardiac centers for definitive care. Therapy in these critical infants depends on manipulation of the ductus arteriosus.

Pathophysiology

In fetal life, the ductus arteriosus is the principal conduit allowing the preponderance of right ventricular output to bypass the nonventilating fetal lungs (Fig. 82.4). This pathway thus allows fetal circulatory viability even in the face of extreme disorders of functional cardiac development (Fig. 82.5 and Fig. 82.6). In the case of impaired systemic blood flow, the fetus and later the neonate, survives because the ductus allows right ventricular output to reach the systemic circulation. This right-to-left shunt mitigates the effects of even complete aortic and/or mitral atresia. In situations of obstructed pulmonary blood flow, the ductus serves as a conduit for systemic (left ventricular) output to reach the pulmonary circulation. This left-to-right shunt becomes crucial once the newborn becomes dependent on his or her own pulmonary circulation for oxygenation after delivery. Typical conditions that are "ductal dependent" are listed in Table 82.9.

Ductal-Dependent Pulmonary Blood Flow	*Ductal-Dependent Systemic Blood Flow*
Pulmonary atresia with intact ventricular septum	Coarctation of the aorta
Tricuspid atresia	Aorta arch interruption
Critical pulmonary stenosis	Hypoplastic left heart syndrome (aortic atresia)

Clinical Manifestations

Any newborn with sudden onset of either collapsed systemic circulation or intense cyanosis should be considered at risk for the presence of a ductal dependent state. In these babies, closure of the ductus unmasks the underlying circulatory insufficiency resulting in the clinical picture of either severe hypoxemia or shock or both. These infants may be as old as 1 or 2 weeks, although usually this catastrophe becomes apparent within the first days of life. However, there are times when the process of ductal closure leading to the presentation can be delayed even longer than 2 weeks.

The mechanisms responsible for ductus closure have been defined over the past several years. Although a prolonged discussion is not relevant in this context, it is important for the emergency physician to understand that these factors center on the balance of dilator and constructor hormones, namely prostaglandins, and that manipulation of this hormonal system can yield prompt and substantial results. Of course, treatment of heart failure and impaired oxygenation involve more than just ductus manipulation as outlined elsewhere in this text.

Management

Based on the previous principles, prostaglandin E_1 (PGE_1) has become the standard medical intervention used in this urgent situation. PGE_1 provides relatively rapid stabilization until more permanent measures can be undertaken. There are few, if any, concerns that would contraindicate the use of PGE_1 when any of the conditions noted above are suspected. Dosage is by infusion at 0.05 to 0.10 µg/kg per minute, after an initial bolus of 0.10 µg/kg. The specific site of infusion is not critical as long as patency of access can be continuously verified. Side effects can be important and, unless prepared for, can be life-threatening. These include bradycardia, apnea, hypotension, and seizures. Rash and hyperthermia also can develop. Therefore, when PGE_1 therapy is initiated, the ability to support respiration and blood pressure should be secured. Intubation may be required and should always be considered if a prolonged transport is planned. It has become evident over the past two decades that manipulation of the ductus by PGE_1 administration has been one of the most important advances in the early treatment of even the most severe forms of CHD.

CARDIAC ARRHYTHMIAS

General Considerations

Background

Disturbances in cardiac rhythm are relatively common in infants, children, and adolescents. An apparent increase in the incidence of cardiac arrhythmias in children can be explained by the extensive use of ECG monitoring equipment in children's hospitals, advances in cardiac surgery that have resulted in the survival of children with complex CHD, new techniques to investigate rhythm disturbances, and an increased awareness on the part of pediatricians and pediatric cardiologists of the manifestations of abnormal cardiac rhythms in children.

Pathophysiology

The electrical impulse that initiates and coordinates the mechanical activity of the heart is propagated in an orderly manner through the normal heart. This electrical activity is initiated in the sinoatrial (sinus) node located at the junction of the superior vena cava and right atrium (Fig. 82.7). Activity then spreads through the atria to the AV node located in the lower part of the right atrium near the coronary sinus and just above the septal leaflet of the tricuspid valve. The impulse continues to the bundle of His, which then divides into the right and left bundle branches in the ventricle. The bundle branches then divide into the Purkinje fibers of the ventricular myocardium, and the entire ventricle is thus depolarized.

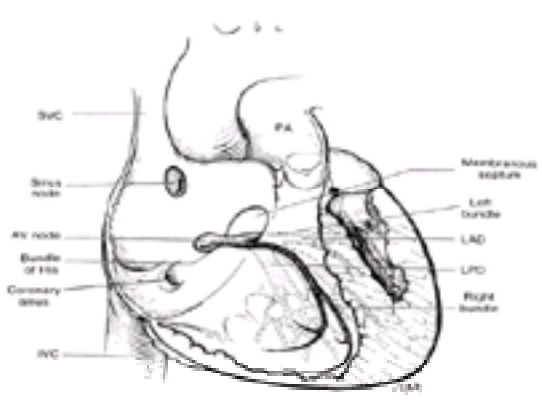

FIGURE 82.7. Schematic representation of the intracardiac conduction system. *IVC,* inferior vena cava; *LAD,* left anterior division; *LPD,* left posterior division; *PA,* pulmonary artery; *SVC,* superior vena cava.

Arrhythmias in children are caused by disturbances in impulse formation or conduction or both. In many children with rhythm disturbances, no cause is recognizable. However, certain children have a propensity to develop arrhythmias. Some types of CHD have a relatively high incidence of associated cardiac arrhythmias. These include corrected transposition of the great vessels, Ebstein's anomaly of the tricuspid valve, congenital mitral stenosis, and the asplenia-polysplenia syndromes. Other children may have congenital complete heart block, Wolff-Parkinson-White (WPW) syndrome, or the long Q-T syndrome. Postsurgical arrhythmias are commonly seen in children after repair of d-transposition of the great vessels, tetralogy of Fallot, endocardial cushion defects, large atrial septal defects, and the

Fontan procedure. Acquired heart diseases with rhythm disturbances may include cardiomyopathies, rheumatic carditis or rheumatic heart disease, Kawasaki disease, viral myocarditis, cardiac tumors, and hemochromatosis.

Systemic diseases or abnormalities associated with cardiac arrhythmias include electrolyte disturbances, neuromuscular disorders (muscular dystrophy, Friedreich's ataxia), endocrine disorders (hyperthyroidism or hypothyroidism), inherited disorders of metabolism (glycogen storage disease, Pompe's disease), mitochondrial disorders (acyl Co-A dehydrogenase deficiency, Kearns-Sayre syndrome), collagen diseases (systemic lupus erythematosus [SLE]), pulmonary diseases (bronchopulmonary dysplasia, cystic fibrosis), hematologic disorders (anemia, thalassemia major), neoplasms, renal diseases (uremia), infectious diseases, and central nervous system (CNS) diseases (increased intracranial pressure [ICP], encephalitides). Drugs and toxic substances (digitalis, general anesthesia, theophylline, sympathomimetic drugs, epinephrine, tricyclic antidepressants) also can lead to abnormalities of cardiac rhythm.

Clinical Manifestations

Many children are not aware of or are unable to express awareness of an abnormal cardiac rhythm. Thus, the physician must suspect the diagnosis from the secondary manifestations. Arrhythmias may surface in the following ways:

1. Symptoms of CHF (see previous section)
2. Symptoms related to decreased cerebral blood flow (syncope, dizziness, irritability, and inappropriate behavior)
3. Symptoms related to decreased coronary blood flow (anginal chest pain)
4. Perception of the rhythm disturbance by the child (palpitations, skipped beats)

Management

Management of the child with a cardiac arrhythmia requires recognition of the manifestations of these disorders, diagnosis of the type of rhythm disturbance, understanding of the mechanism of the abnormality, knowledge of appropriate therapy (pharmacologic or other intervention), judgment about the appropriate timing and urgency of therapy, and understanding of potential side effects of the therapy. Once an abnormality in cardiac rhythm is suspected or found, the precise diagnosis must be made to institute appropriate treatment. This generally depends on evaluation of the ECG. The resting ECG used to evaluate cardiac arrhythmias should include a long rhythm strip in addition to a complete 12- or 15-lead ECG. Lead II often is used for the rhythm strip, but a V_1 lead or another lead in which P waves are prominent may be more helpful. The rhythm on the ECG should be evaluated for rate, regularity, mechanism, and origin of the disturbance.

Cardiac arrhythmias become emergencies when they produce hemodynamic alterations that result in a decreased CO or have the potential to do so. To treat cardiac arrhythmias effectively, one must be able to identify specific arrhythmias, recognize signs and symptoms of cardiac decompensation, and understand which arrhythmias are likely to produce rapid cardiac decompensation. Most infants and children who have symptomatic arrhythmias will require cardiac consultation and admission to the hospital for treatment and observation and continuous ECG monitoring (telemetry or bedside with arrhythmia analysis is preferred). Table 82.10 represents an overview of the emergent management of arrhythmias.

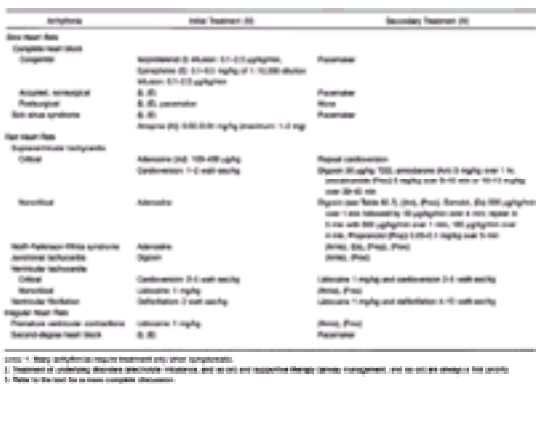

Table 82.10. Emergent Management of Arrhythmias in Children

The cardiac arrhythmias discussed in this section are classified according to their presentation to the physician: slow HRs, rapid HRs, and irregular HRs. Slow HRs that are most commonly seen in the ED include complete (or third-degree) heart block, second-degree heart block, sinus or junctional bradycardia, and the sick sinus syndrome. SVT and ventricular tachycardia (VT) cause a rapid HR. Irregular rhythms usually are caused by premature ventricular or atrial contractions and second-degree heart block.

To determine whether a HR is abnormally fast or slow, one must know the normal range of rates for children of various ages. Results of 24-hour continuous ECG monitoring studies are redefining the normal ranges. Table 82.11 illustrates ranges of rates accepted as normal.

Age	Heart Rate (bpm)
Newborn	80–180
1 wk–3 mo	80–180
3 mo–2 yr	80–160
2 yr–10 yr	65–130
10 yr–adult	55–90

Table 82.11. Normal Heart Rate Ranges

Slow Heart Rates

Complete Heart Block

Complete (third-degree) AV heart block is the most common cause of significant bradycardia in infants and children. Complete heart block, which may be congenital or acquired, results from a complete failure of conduction from atria to ventricles. The atrial rate is usually faster than the ventricular rate, which usually is 40 to 80 bpm. A typical ECG is shown in Figure 82.8.

FIGURE 82.8. Example of complete heart block. Note absence of any regular P-R interval. Ventricular rate 62 bpm, atrial rate approximately 95 to 115 bpm.

Congenital Heart Block

Congenital heart block may be idiopathic, associated with specific types of congenital heart defects such as l-corrected transposition of the great arteries or left atrial isomerism/polysplenia syndromes (heterotaxy), or associated with collagen disease in the mother associated with the presence of anti-Ro (SS-A) and anti La (SS-B). Congenital heart block is being diagnosed more often in utero with the use of fetal monitoring and fetal echocardiography, but it may not be recognized for weeks or months after birth.

All infants with congenital heart block have bradycardia. Although some remain asymptomatic, others develop CHF and, occasionally, cardiovascular collapse and sudden death. An ECG will differentiate sinus bradycardia from complete heart block. Sinus bradycardia should respond to the usual resuscitative measures: ventilation and oxygenation, treatment of acidosis, and catecholamine support of HR and BP. The infant with complete heart block who has severe CHF or who is in shock may also require intubation for adequate ventilation, oxygenation, and treatment of acidosis. If no improvement is obtained with these measures, infusion of isoproterenol or epinephrine may increase the HR slightly, allowing time for the placement of a temporary pacemaker (Table 82.12). A hydropic infant may require emergency phlebotomy, as well as a potent diuretic such as furosemide (1 mg/kg IV). Distressed infants with congenital heart block generally have HRs below 50 bpm. If an infant is distressed with a rate greater than 50 bpm, one should suspect significant CHD or some other associated problem such as infection or sepsis in addition to the heart block. The infant in extremis from a slow HR may require immediate temporary pacing in the ED. This may be accomplished by the transcutaneous route or by the transthoracic route. The transcutaneous route, which was first introduced by Zoll in 1952, has recently been reintroduced. This technique involves the use of pacing electrodes placed on the anterior and posterior chest attached to an external current source. Temporary transthoracic pacing is available in most cardioverter defibrillator units. This technique may be used successfully in critical situations to increase the HR but should be replaced as soon as possible with another type of pacemaker because third-degree burns have been noted under the pacing electrodes after short periods in infants. Special wires available for transthoracic pacing can be placed by the subxiphoid route in infants and children. The procedure uses techniques similar to those used for pericardiocentesis. A pacing wire is inserted through a needle that subsequently is removed once the wire is inside the heart. This type of pacing should be replaced by a transvenous pacemaker once the patient is stable. If time allows, placement of a temporary transvenous pacemaker either through the umbilical vein or femoral vein (see Procedures in Section VII) under direct fluoroscopic observation in a cardiac catheterization laboratory is preferred. Temporary transvenous pacing is reserved for infants with signs of CHF, most commonly seen with HRs under 50 bpm or with slightly higher rates in association with a structural congenital heart defect. However, an infant with an HR of 45 bpm should not be paced solely on the basis of HR but should be observed

for signs of CHF such as tachypnea, poor feeding, or hepatomegaly. The width of the QRS on the ECG does not always correlate with the need for a pacemaker, although wider QRS rhythms often are associated with lower escape rates. Only a small percentage of infants with congenital heart block require pacing, and many of these escape the need for pacemakers until they are older.

Drug	Route	Dose
Epinephrine	IV	0.01–0.05 mg/kg (0.1 mL/kg of 1:10,000 solution or 0.01 mL/kg of 1:1,000 solution)
	Infusion	0.1–2.0 μg/kg/min
Isoproterenol	Infusion	0.1–2.0 μg/kg/min

Table 82.12. Treatment of Heart Block

The older child with congenital complete heart block may also present with symptoms associated with CHF. More commonly, dizziness, presyncope, syncope, exercise limitation, or fatigue are the presenting complaints in the older child. At times, the appearance of a ventricular arrhythmia is the presenting sign of difficulty in these patients.

Acquired Nonsurgical Heart Block

Acquired nonsurgical heart block may be idiopathic or associated with congenital heart defects, infectious diseases such as myocarditis (viral or Lyme) or endocarditis, inflammatory processes (lupus, rheumatic fever), Kawasaki disease, muscle diseases, cardiac tumors, or cardiac sclerosis. The emergency treatment for congenital or acquired nonsurgical heart block is similar. Subsequent implantation of a permanent pacemaker is based on the symptoms, CHF, or decreased CO and signs such as low HRs and pauses in rhythm. Resolution of congenital heart block may occur in some inflammatory processes. A single typical Stokes-Adams or syncopal attack not related to neurologic or endocrinologic factors is considered an indication for pacemaker insertion because these attacks may be fatal. The patient with acquired heart block who presents with a syncopal episode requires a temporary transvenous pacemaker. This should be left in place during induction of anesthesia for permanent pacemaker implantation because serious arrhythmias have been noted to occur at this time if adequate CO is not maintained by pacing.

Pharmacologic therapy plays a role if adequate ventilation, oxygenation, and treatment of acidosis does not produce a normalization of the CO as reflected by the BP and peripheral perfusion. The initial drug to be used should be isoproterenol (Table 82.12) because it is most effective in increasing the HR. Adequate intravascular volume should be maintained during isoproterenol infusion because its vasodilatory effect may result in lowered BP. Epinephrine may be tried in place of, or in addition to, isoproterenol if bradycardia persists.

Temporary transvenous pacing may be required during the acute phase of an infectious process, even when permanent pacing is not needed, as in myocarditis. The presence of CHF is an additional indication for pacing.

Postsurgical Complete Heart Block

Postsurgical heart block is less common today than in the early days of surgery for congenital heart defects, with a current incidence of less than 1%. Improved knowledge of the location of the conduction system, as well as the implementation of intraoperative mapping techniques, has helped decrease this serious postsurgical complication. Postsurgical complete heart block may be transient or permanent heart block. Transient complete heart block generally resolves within 8 days. Permanent complete heart block generally presents immediately after surgery but may not occur until many years after surgery. All patients with postsurgical permanent complete heart block should have implantation of permanent pacemakers. Emergency treatment of symptomatic postsurgical complete heart block includes pharmacologic support and temporary pacemaker placement until a permanent pacemaker can be placed.

Sinus Bradycardia

Sinus bradycardia is a HR below the normal range for age (Table 82.11). An ECG is necessary to rule out second-degree or complete heart block; P waves with a normal P-R interval must precede each QRS complex in sinus bradycardia. Sinus bradycardia is commonly associated with sinus arrhythmias. It often occurs in the athletic child or in the adolescent as a normal variant, especially during sleep. Other causes of sinus bradycardia include hypothyroidism, increased ICP, and drugs such as propranolol or digoxin. Therapy of the underlying disorder is indicated, but in symptomatic patients atropine may be useful as a temporizing measure (Table 82.13). Isoproterenol or epinephrine also may be given in this emergency setting (Table 82.12).

Test	Expected Normal Response
Atropine (0.02–0.04 mg/kg)	HR >90 bpm
	>25–50% increase in HR
Isoproterenol (1–3 μg/min)	>25% increase in HR
Exercise	95% of expected normal rate
Electrophysiology study	Normal CSNRT (<550 msec)
	Normal SACT (45–105 msec)
24-hr ambulatory monitor	Normal low rate for age
	Pauses <3 sec

CSNRT, Corrected sinus node recovery time; *HR*, heart rate; *SACT*, sinoatrial conduction time.

Table 82.13. Evaluation of Sick Sinus Syndrome

Sick Sinus Syndrome

Sick sinus syndrome is a condition in which sinus node function is depressed and may present with a sinus bradycardia or a slow junctional rhythm often in association with alternating episodes of tachycardia. Syncopal episodes may occur. This abnormal cardiac rhythm may be seen in children who have undergone atrial surgery for closure of an atrial septal defect, particularly of the sinus venosus type, the Mustard procedure for correction d-transposition of the great arteries, Fontan repair for single ventricle complexes, or in association with a viral myocarditis, or as an idiopathic occurrence. Table 82.13 outlines the evaluation of the child with a suspected sick sinus syndrome. Evaluation will generally be performed by a pediatric cardiologist.

The urgency of the clinical picture determines the treatment of the child with sick sinus syndrome. The asymptomatic patient with a slow HR can be referred for consultation with a cardiologist. The child with CHF or inadequate perfusion from bradycardia or tachycardia requires therapy directed at the specific arrhythmia and admission to the hospital. Isoproterenol or epinephrine infusions (Table 82.12) may increase the HR temporarily in a child with bradycardia but, in this situation, also may precipitate tachyarrhythmias; thus, these drugs should be administered cautiously under continuous monitoring. Symptomatic slow rhythms may require temporary or permanent cardiac pacing.

Pacemakers

Pacemakers are being used more often in infants and children for the treatment of congenital or acquired (usually postsurgical) complete heart block or sick sinus syndrome. In addition, some patients with tachyarrhythmias or with the long Q-T syndrome are being treated with pacemakers. Therefore, it has become important for the emergency physician to recognize the normal and abnormal function of a pacemaker.

Pacemakers have become complex. They may be single-chamber or dual-chamber units. The pacemaker may sense in a chamber, pace in a chamber, be inhibited by a chamber's activity, or perform all functions. Newer pacemakers are rate responsive and sense external factors such as motion or minute ventilation, with subsequent increases in HR.

In pediatrics, the most common pacemaker in the very young is still the pacemaker that senses and paces the ventricle. Motion-sensing, rate-responsive pacers are less useful in young infants than in older children. Rate-responsive and dual-chamber pacemakers that pace or sense in the atrium and the ventricle are being used commonly in children old enough to have two endocardial or epicardial wires placed. Examples of normal function, failure to capture, and failure to sense are shown in Figure 82.9.

FIGURE 82.9. A. Electrocardiogram showing pacemaker that paces atrium and after 150 msec paces ventricle. Note pacemaker stimulus artifact before the P wave and the QRS complex. **B.** Electrocardiogram showing pacemaker that senses atrium and paces ventricle after a 150-msec delay. Note pacemaker stimulus artifact only precedes the QRS complex. **C.** Electrocardiogram showing ventricular pacing at 100 bpm with normal capture. Note pacemaker stimulus artifact preceding the QRS. **D.** Electrocardiogram showing ventricular pacing at 85 bpm with intermittent failure of capture. Note several pacemaker stimulus artifacts are not followed by a QRS complex, indicating failure of capture. **E.** Electrocardiogram showing ventricular pacing at 90 bpm, showing normal sensing of patient's intrinsic rhythm. **F.** Electrocardiogram showing ventricular pacing at 100 bpm, showing inappropriate sensing and failure to stimulate the heart secondary to wire fracture.

When a pacemaker malfunction is suspected, the specific problem should be identified if possible. A chest radiograph should be obtained to look for wire fractures or lead displacement. Most pacemaker programs now have computerized programmable analysis systems to help identify the problem. An ECG lead that shows the largest possible pacemaker stimulus artifact should be chosen with multiple leads providing more information. A pacemaker stimulus that falls outside the cardiac refractory period and fails to result in a ventricular depolarization indicates a failure of capture. In the currently available pacemakers, the output of the pacemaker may be reprogrammed externally, often resulting in normal capture. As the battery generator is depleted, the rate on most pacemakers decreases to a predetermined end-of-battery life indicator, which reveals impending battery failure.

An abnormally long pause or an earlier-than-expected paced complex indicates a sensing failure, either inappropriate sensing of another electrical signal (e.g., T wave sensing instead of QRS) or failure to sense the QRS. Sensing errors can be identified and external reprogramming accomplished.

Any patient with evidence of pacemaker malfunction should be admitted to the hospital if the problem cannot be resolved in the ED. A consultation with a pediatric cardiologist is generally required to troubleshoot and correct pacemaker problems. The patient with pacemaker malfunction who has symptomatic bradycardia should be managed with the regimens previously discussed Table 82.11.

The procedure for inserting a temporary pacemaker is described in Section VII.

Fast Heart Rates

Supraventricular Tachycardia

Background

Paroxysmal SVT, previously called paroxysmal atrial tachycardia (PAT), is the most common significant arrhythmia seen in pediatric practice. Paroxysmal SVT describes a group of arrhythmias with similar ECG features but different mechanisms. These mechanisms have been clarified by the use of specialized intracardiac pacing and recording techniques known as the electrophysiologic study and have been shown to originate in the sinus node, atrium, and approaches to the AV node or in junctional conduction tissue or to be associated with reentry using atrioventricular accessory pathway.

A typical ECG seen in a pediatric patient with SVT is shown in Figure 82.10. Note the rapid rate and the narrow QRS complex. The P waves are different from the usual sinus P wave but may be obscured by the ST segment and not be visible at all. The rate of tachycardia in infants ranges from 220 to 320 bpm. Older children have tachycardia rates that range from 150 to 250 bpm. Supraventricular tachycardia with aberrancy has an ECG with a wide QRS complex and may resemble VT.

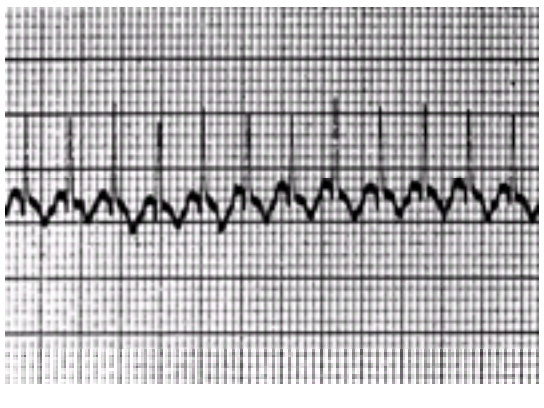

FIGURE 82.10. Supraventricular tachycardia, rate 300 bpm.

The infant with SVT is most commonly less than 4 months of age and is more likely to be male (male:female ratio is 3:2). Although 50% of cases in infants have been classified as idiopathic, 24% have associated conditions such as infection, fever, or drug exposure (most commonly cold medications containing sympathomimetic amines), 23% have CHD (Ebstein's anomaly or corrected transposition are most common), and 22% have WPW syndrome. Those classified as idiopathic generally are considered to have concealed accessory pathways or other reentrant circuits. Older children with SVT are more likely to have WPW, concealed bypass tracts, or CHD.

Pathophysiology

Electrophysiologic catheterization techniques have provided much information about the mechanisms of SVT and have established that SVT actually is several arrhythmias, including 1) those caused by reentry within the sinoatrial node, atrium, AV nodal approaches, and accessory pathways, including the WPW syndrome; and 2) those caused by enhanced automaticity of specialized atrial fibers. The supraventricular arrhythmias most commonly seen in pediatric patients include AV nodal reentrant SVT (usually younger than 5 years of age), WPW with SVT, concealed bypass tracts with SVT, atrial flutter or atrial fibrillation, and ectopic atrial tachycardia.

The concept of AV nodal reentry as a mechanism for SVT was first proposed by Mines in 1913, and the presence of dual

pathways in the AV node was shown subsequently by Moe and colleagues. Recently, programmed stimulation has demonstrated the role of reentry in SVT. By convention, the dual pathways have been labeled a and b. The a pathway is slower conducting but has a shorter refractory period than the faster conducting b pathway. The application of this concept to human SVT is shown in Figure 82.11. During sinus rhythm, the atrial impulse traverses the faster conducting b pathway to produce a single QRS complex. The impulse travels simultaneously down the a (slow) pathway, reaching the His bundle shortly after it has been depolarized and rendered refractory by the impulse that was conducted down the b pathway. In response to an atrial premature depolarization, the impulse is blocked in the b pathway as a result of its longer refractory period and proceeds slowly down the a pathway. If conduction down the a pathway is slow enough to allow the previously refractory b pathway time to recover, a single atrial echo results. An earlier atrial premature depolarization (Fig. 82.11) also blocks in the b pathway, conducts slowly down the a pathway and arrives later to conduct retrograde through the b pathway back to the a pathway with antegrade conduction producing a sustained AV nodal reentrant tachycardia.

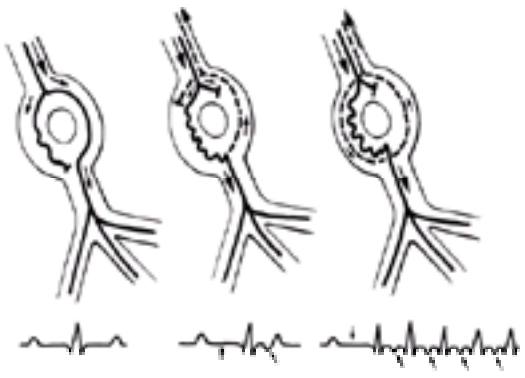

FIGURE 82.11. Schematic representation of conduction pathway and corresponding ECG in the development of AV nodal reentry. See text for full discussion. *LBB,* left bundle branch; *RBB,* right bundle branch.

If conduction delay and refractoriness in both pathways are appropriate, a continuously circulating wavefront of electrical activity ensues, resulting in a reentrant tachycardia. The conditions for reentry may be found in the sinus node, atrium, AV node and accessory pathways, and the Purkinje fibers of the ventricles. The most common form of SVT in pediatrics is caused by sustained reentry within the AV nodal approaches or a bypass tract (accessory pathway).

The rate of SVT appears to reflect the conduction properties of the AV node and bypass tract when involved. Patients whose AV nodes or bypass tracts conduct slowly, either spontaneously or from the effects of drugs like digitalis or propranolol, have slower rates during SVT.

SVT is the usual clinical problem that affects patients with the WPW syndrome. The arrhythmia has all the characteristics of reentry but the reentrant circuit involves an extra AV accessory pathway. WPW complexes, which consist of a short P-R interval and a widened QRS complex with a slurred upstroke (delta wave), generally are not seen during the tachycardia, but only after conversion to normal sinus rhythm as shown in Figure 82.12. The WPW complex represents the presence of a bypass tract connecting atria and ventricles. The short P-R interval and delta wave characteristic of the WPW syndrome are produced by conduction over the accessory pathway, which has different electrophysiologic properties from the normal AV conduction system. The ventricular complex is a fusion beat with a variable contribution from conduction through the accessory pathway and the AV node. The greater the contribution from the accessory pathway, the larger the delta wave and more bizarre the QRS.

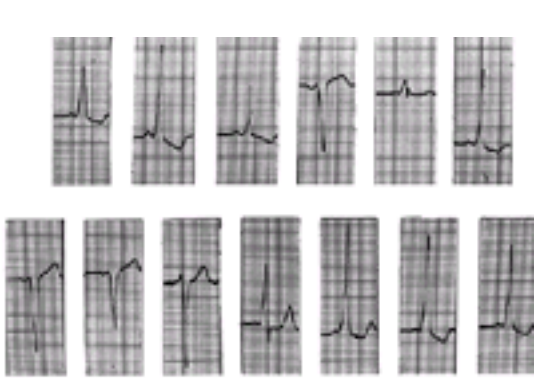

FIGURE 82.12. Electrocardiogram in Wolff-Parkinson-White (WPW) syndrome. Note wide QRS, presence of delta wave (slurred upstroke of R), and short P-R interval.

Episodes of SVT in WPW syndrome usually are initiated by a premature atrial depolarization that blocks antegrade conduction in the accessory pathway and travels to the ventricles over the normal AV conducting system. The impulse, on reaching the ventricular insertion of the bypass tract, can travel retrograde up the bypass tract to the atrium and reenter the AV node to start a “circus movement” or reentrant type of tachycardia.

Therefore, reentrant SVT in WPW syndrome is analogous to AV nodal reentrant SVT with the bypass tract functioning like a b pathway (fast conduction, long refractory period) and the AV nodal-His-Purkinje system functioning like an a

pathway (slow conduction, short refractory period). Because antegrade conduction during SVT occurs over the usual AV conducting system, the QRS complexes will be normal. In rare cases, the route of reentry may be reversed, and the bypass tract forms the antegrade limb. In these cases, the QRS complexes will be wide and bizarre, and the arrhythmia may simulate VT.

A concealed bypass tract indicates that the bypass tract is used only as the retrograde limb of the reentrant circuit during SVT but is not used for antegrade conduction during normal resting rhythm. Thus, the resting ECG appears normal.

Because the ventricle must be depolarized before retrograde conduction up the bypass tract, atrial activation must always follow ventricular activation; therefore, the P wave follows inscription of the QRS complex. The P-R interval is usually less than 50% of the R-R interval. In AV nodal reentrant SVT, the P wave may or may not be visible but, if visible, is generally closely related to the preceding QRS complex.

The identification of the mechanism of the tachycardia in SVT is helpful from a therapeutic point of view so that a medication known to act specifically on the AV node, on the accessory pathway, or on the atrial tissue may be chosen. In addition, if the tachycardia can be initiated reproducibly in the electrophysiology laboratory, the efficacy of a specific drug can be tested in the laboratory rather than empirically chosen.

Clinical Manifestations

The clinical findings in the patient with SVT depend on the duration of the arrhythmia and the presence or absence of an underlying heart defect or myocardial dysfunction. In the patient with no congenital heart defect or myocardial dysfunction, CHF usually appears only after 24 hours of a rapid rate. However, when the patient is first seen in the ED, the precise onset of the SVT is rarely certain. Likewise, the presence of associated heart defects generally is unknown. Therefore, all patients must be treated with some degree of urgency.

The infant with SVT may present with only a fast rate or have varying degrees of CHF (poor feeding, irritability, respiratory distress) or shock. The infant may be acidotic and appear to be septic.

The child older than 5 or 6 years of age will usually complain of some symptom such as chest pain or a rapid heartbeat. The child may also present with signs of CHF but is unlikely to be quite as ill when first seen as the infant or young child, unless a congenital heart defect or primary myocardial disease is present.

Management

Because the mechanisms of SVT are now identifiable, treatment can be chosen for the specific forms of the disease. However, the main principle of treatment in any cardiac arrhythmia is that the type of therapy is determined by the urgency of the situation. Thus, a different mode of treatment is chosen for the patient with tachycardia in shock than for the asymptomatic patient who has only a fast HR (Table 82.14).

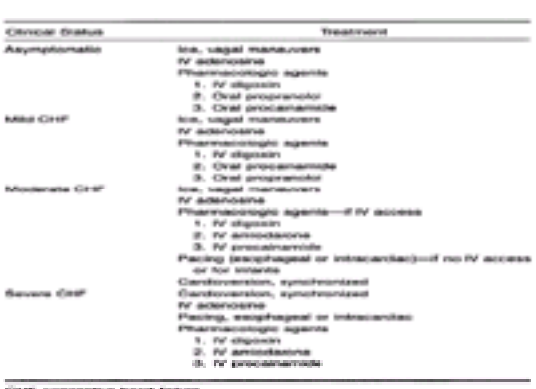

Table 82.14. Treatment of Supraventricular Tachycardia

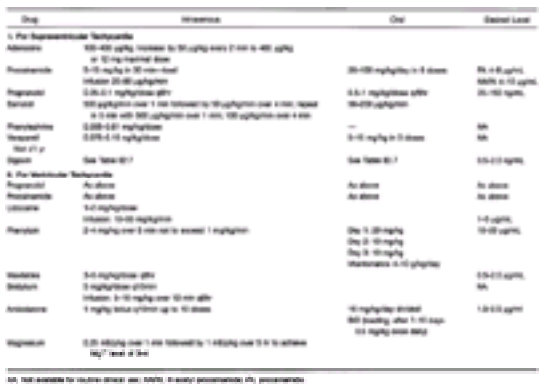
When the SVT is caused by reentry using the AV node (AV nodal reentry), or AV reentry using a bypass tract, any intervention that interrupts the critical relationship of conduction and refractoriness in the AV node can interrupt the tachycardia. The patient's response to the drugs or maneuvers is not always predictable. The methods used most often are those that slow AV nodal conduction. In adult patients, carotid sinus pressure or the Valsalva maneuver often can terminate the tachycardia by increasing vagal tone, slowing conduction and prolonging refractoriness within the AV node. Although these maneuvers often are ineffective in children, the occasional successful attempt justifies their initial use. Ice water or ice bags applied to the face have been used to recruit the diving reflex and stop the SVT. This technique should be reserved for children who are monitored, with particular caution used in applying these techniques in young infants because significant sinus slowing may occur.

A rapid pharmacologic treatment now available is adenosine. It has a rapid onset of action, usually within 10 seconds, and a short half-life, with side effects lasting less than a minute and rarely being serious. Adenosine may be used in acutely ill patients but should not delay immediate cardioversion in severely compromised patients. Appropriate doses are shown in Table 82.15.



Drug	Intravenous	Oral	Desired Level
I. For Supraventricular Tachycardia			
Adenosine	100–400 µg/kg, increase by 50 µg/kg every 2 min to 400 µg/kg or 12 mg maximal dose		
Procainamide	5–15 mg/kg in 30 min—load Infusion 20–80 µg/kg/min	20–100 mg/kg/day in 4 doses	4–8 µg/mL NAPA in 10 µg/mL
Propranolol	0.25–0.1 mg/kg/dose q6h	0.5–1 mg/kg/dose q6h	25–100 ng/mL
Esmolol	500 µg/kg/min over 1 min followed by 50 µg/kg/min over 4 min; repeat in 5 min with 500 µg/kg/min over 1 min, 100 µg/kg/min over 4 min	50–200 µg/kg/min	
Phenylephrine	0.005–0.01 mg/kg/dose	—	NA
Verapamil Not <1 y	0.075–0.15 mg/kg/dose	3–10 mg/kg in 3 doses	NA
Digoxin	See Table 82.7	See Table 82.7	0.5–2.0 ng/mL
II. For Ventricular Tachycardia			
Propranolol	As above	As above	As above
Procainamide	As above	As above	As above
Lidocaine	1–2 mg/kg/dose Infusion: 10–50 mg/kg/min		1–5 µg/mL
Phenytoin	2–4 mg/kg over 5 min not to exceed 1 mg/kg/min	Day 1: 20 mg/kg Day 2: 10 mg/kg Day 3: 10 mg/kg Maintenance: 4–10 g/kg/day	10–20 µg/mL
Mexiletine	5–6 mg/kg/dose q6h		0.5–2.0 µg/mL
Bretylium	5 mg/kg/dose q12h Infusion: 5–10 mg/kg over 10 min q6h		NA
Amiodarone	5 mg/kg bolus q12h/d up to 10 doses	10 mg/kg/day divided Still loading, after 1–10 days: 5–10 mg/kg once daily	1.0–3.0 µg/ml
Magnesium	0.25–50 mEq/kg over 1 min followed by 1 mEq/kg over 3 h to achieve Mg2+ level of 3 mg		

NA, Not available for routine clinical use; NAPA, N-acetyl procainamide; PA, procainamide.

Table 82.15. Antiarrhythmic Agents

Any patient with SVT who presents with shock, acidosis, or severe hemodynamic compromise should be treated immediately. If adenosine is not effective, synchronized direct current (DC) cardioversion at a dosage of 1 to 2 watt-sec/kg should be used and doubled until effective or until a dosage of 10 watt-sec/kg is reached. If ventricular fibrillation should occur, repeat cardioversion generally converts the patient to normal sinus rhythm. The patient should be given a sedative or short-acting anesthetic, and preparations should be made for airway support and ventilation if needed. The underlying acidosis should be treated and adequate ventilation and oxygenation provided because cardioversion may not be successful in the presence of hypoxia or acid-base imbalance. The presence of digoxin in the patient should not prevent the use of cardioversion when needed. Evidence of digoxin toxicity such as ventricular arrhythmia may be treated with lidocaine. Once the patient's rhythm has been converted, the chosen chronic treatment should be initiated immediately.

Children who have only mild to moderate failure may be treated medically, as described earlier, with adenosine if vagal maneuvers fail because most of these patients will convert rapidly after pharmacologic treatment. Agents, other than digitalis, useful for the treatment of SVT are reviewed in Table 82.15. The preferred medical treatment of AV nodal reentrant SVT in children is digoxin, which works by prolonging AV nodal conduction and refractoriness in both the fast (b) and slow (a) pathways. When refractoriness of the fast pathway is prolonged greater than conduction down the slow pathway, SVT cannot be initiated.

The usual digitalizing dose appropriate for age is used (Table 82.7). The route (IV or IM) depends on the status of the patient. IV digoxin should be used in the presence of CHF when perfusion is decreased. As noted earlier, the IV dose should be calculated to be 75% of the oral or IM dose. The interval of time that precedes the second and third doses of the total digitalizing dose should be determined by the patient's status. These additional doses may be required after only 2 to 4 hours. If the tachycardia persists after three doses, one to two additional doses may be given.

Propranolol, which prolongs AV nodal conduction and refractoriness in both a and b pathways, should be used with caution in the ill child because it may depress cardiac function even more. In instances in which cardiac function is preserved, a slow IV dose may be given. The dosage is 0.1 mg/kg IV. A shorter acting b blocker, esmolol, may be preferred. The doses are shown in Table 82.15. Digoxin seems to be slightly more effective than propranolol in treating SVT. Raising the blood pressure with a-adrenergic agents such as phenylephrine can terminate the SVT by stimulating the vagus through the baroreceptor reflexes (Table 82.15). Termination of AV nodal reentrant SVT by these agents and by vagal maneuvers almost always occurs by gradual slowing and then antegrade block in the slow (a) pathway. In most instances, the tachycardia is terminated by a so-called nonconducted atrial echo.

Procainamide may be used under the guidance of a cardiologist to terminate AV reentrant SVT by blocking retrograde conduction in the fast (b) pathway (Table 82.15). SVT can be converted in the catheterization laboratory by rapid atrial pacing. An electrode catheter is placed in the high right atrium. Rapid atrial pacing (faster than the SVT rate) often interrupts the reentrant cycle and results in normal sinus rhythm. Even when normal sinus rhythm cannot be achieved, a slower rate may be obtained if 2:1 AV nodal block is produced by rapid atrial pacing.

A less invasive method of esophageal overdrive pacing to terminate SVT in infants and children can be used. A small bipolar electrode catheter is passed by the nasogastric route and positioned in the esophagus behind the left atrium. As with intracardiac methods, esophageal rapid atrial pacing at a rate faster than the SVT can capture the atrium and interrupt a reentrant circuit, terminating the SVT.

The treatment of SVT in WPW syndrome or in a concealed bypass tract is similar to the treatment of AV nodal reentrant SVT because the AV node participates in one limb of the reentrant circuit. Propranolol is an exceptionally effective drug because it slows AV nodal conduction and prolongs refractoriness while having no significant effects on the accessory pathway. Digoxin, with similar effects on the AV node, must be used cautiously in patients with WPW syndrome because it can shorten the refractory period of the bypass tract and enhance conduction in the accessory pathway. In a patient with an associated atrial tachyarrhythmia such as atrial flutter or atrial fibrillation, digoxin may predispose to a rapid ventricular response or ventricular fibrillation secondary to rapid conduction of the atrial impulse down the bypass tract. A high percentage of adults with WPW syndrome and SVT also have atrial fibrillation, but the incidence of this association is lower in children. Class IA or IC agents such as procainamide or flecainide are often effective in this type of SVT because they act on the accessory pathway to slow conduction and prolong refractoriness and thus interrupt the retrograde limb of the reentrant circuit.

Although verapamil has been an effective treatment of SVT in adults, serious problems, including hypotension, cardiovascular collapse, and death, have occurred with its use in pediatric patients. This is especially true for patients less than 1 year of age and those in CHF. Therefore, verapamil generally should be avoided in patients less than 3 years

old. Even in older patients, other regimens should be tried first. When used, a dose of 0.075 to 0.15 mg/kg is effective. It is important to give the drug slowly, over at least 2 minutes, while monitoring the child's ECG and BP closely. IV calcium (10% CaCl at a dose of 10 mg/kg) and isoproterenol should be available immediately and should be drawn up in the appropriate dose before verapamil is given. Some recent studies suggest that pretreatment with calcium may prevent the severe hypotension, but this is not the case universally. Verapamil should not be used in patients who have received IV b blockers and should be used with extreme caution in patients who use any other antiarrhythmic agent.

As soon as the patient converts from SVT, an ECG in sinus rhythm should be obtained. This allows diagnosis of the presence of the WPW syndrome or other abnormalities that might direct chronic therapy to be identified. In general, digoxin is not advised in the presence of WPW syndrome unless one knows that the accessory pathway refractory period is relatively long and is unaffected by the digoxin; this drug might shorten the accessory pathway refractory period and promote rapid ventricular conduction of supraventricular impulses to the ventricle. This is particularly problematic in the presence of atrial flutter or fibrillation and WPW syndrome. In the absence of associated atrial arrhythmias and the presence of CHF, digoxin may be used temporarily in these patients until cardiac function improves. The patient may be switched from digoxin to a b blocker at that time.

Infants with SVT should receive maintenance treatment for the first year of life, even if there are no recurrences. This type of therapy should be instituted in the hospital on continuous ECG monitoring to observe for adverse side effects of the antiarrhythmic agent. Studies have shown that only 20 to 30% of patients will have recurrences if the medicines are continued for this period. Treatment is also advised for infants who convert spontaneously from documented episodes of SVT because these children are predisposed to recurrences. Older children or infants, who are difficult to control and have multiple recurrences that often require combinations of digoxin and propranolol or digoxin and procainamide, must be managed individually and should not have their medicines routinely discontinued after 1 year. Children with SVT should not be treated for upper respiratory tract infections with sympathomimetic amines. Instead, if needed, pure antihistamines, such as those listed in Table 82.16 should be used.

Chlorpheniramine Maleate (Chlor-Trimeton—Schering) (Teldin—SKF)	For Coughs: Robitussin
Brompheniramine Maleate (Dimetal—Robbins)	Robitussin DM
Tripolidine HCl (Actidil—Burroughs Wellcome)	Robitussin with codeine—need a prescription
Promethazine HCl (Phenergan—Wyeth)—need a prescription	Phenergan with codeine—need a prescription
Diphenhydramine (Benadryl—Park Davis)	Terpin Hydrate with codeine—need a prescription
	Claritin (Loratadine—Schering)
	Zyrtec (Cetirizine HCl—Pfizer)
	Allegra (Exofenadine—Hoechst)

Table 82.16. Preferable Agents for Treatment of Upper Respiratory Infection in Children with Supraventricular Tachycardia

Atrial Flutter and Atrial Fibrillation

Atrial flutter and fibrillation occur uncommonly in children. Atrial flutter consists of rapid, regular atrial excitation at rates of 280 to 480 bpm (Fig. 82.13). The ventricular response depends on AV nodal conduction that may allow 1:1, 2:1, 3:1, or 4:1 conduction. The typical ECG reveals saw-toothed flutter waves best seen in leads 2 and V_1. Atrial flutter is most commonly seen in children with CHD, especially postoperatively after Mustard repair for d-transposition of the great arteries or the Fontan repair, but it also can occur idiopathically or congenitally.

FIGURE 82.13. A. Atrial flutter. Sawtooth baseline is apparent. Regular QRS with ventricular rate of 250. **B.** Atrial fibrillation. Irregularly irregular QRS with course erratic baseline undulations representing fibrillatory waves.

Atrial fibrillation consists of totally disorganized rapid atrial activity (at a rate of 400 to 700 bpm) with a variable ventricular rate secondary to varying AV block. Atrial fibrillation is seen most commonly in adolescents with long-standing rheumatic or congenital mitral disease or in patients with hyperthyroidism.

Children with atrial fibrillation or flutter raise the same therapeutic problems as those with SVT. If cardiac compromise

does not necessitate immediate cardioversion, the initial treatment is digoxin. Adenosine increases the AV block and therefore may help diagnostically, but it usually will not correct the atrial flutter or fibrillation to sinus rhythm. In the child who is stable and has a normal BP and adequate perfusion, the physician should allow 24 hours for a response to digoxin before adding a second drug such as procainamide. Failure to achieve a normal rhythm after an additional 24 to 48 hours calls for cardioversion. Therapeutic drug levels for these agents, which should be obtained in a steady state of drug administration, are listed in Table 82.15.

Automatic Atrial or Junctional Tachycardia

Automatic atrial or junctional tachycardias may be difficult to control and often are associated with inflammatory states such as myocarditis. Digoxin (at relatively low dosages initially to avoid ventricular arrhythmias in a sensitive myocardium), IV procainamide, and IV amiodarone have been effective (Table 82.15). Once the abnormal rhythm has converted, chronic therapy must be initiated, otherwise, the arrhythmia is likely to recur. Chronic drugs for these arrhythmias include digoxin, b blockers, procainamide, flecainide, amiodarone, and sotalol.

Ventricular Tachycardia

VT is defined as three or more consecutive PVCs (Fig. 82.14). The HR usually is 150 to 200 bpm but may be slower or more rapid. These contractions may be hemodynamically inefficient and result in syncope and death. The cause may be electrolyte imbalance, metabolic disturbances, cardiac tumors, drugs, cardiac catheterization or surgery, CHD, cardiomyopathies, acquired heart disease, right ventricular dysplasia, prolonged Q-T syndrome, or idiopathic.

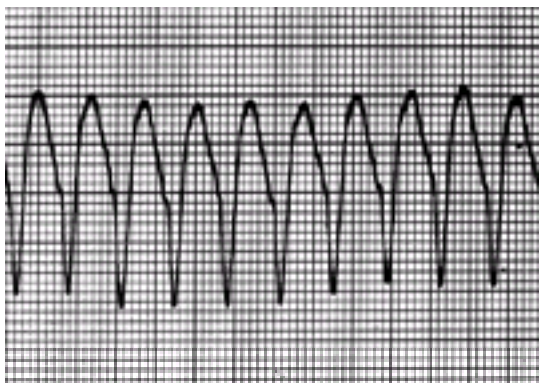


FIGURE 82.14. Ventricular tachycardia. Wide QRS with rate of approximately 250 bpm; sinusoidal pattern.

VT is being seen more commonly in children who can be divided into three groups: 1) patients with identifiable noncardiac causes (electrolyte imbalance, toxins, drug overdoses, or drug toxicity), 2) patients with no known underlying heart disease and no extracardiac disturbances (may have small Purkinje cell tumors or foci in the right ventricular outflow tract or left ventricle septum), and 3) patients with either congenital or acquired heart disease.

In children with identifiable extracardiac abnormalities (group 1), the underlying disturbance is treated. Children with no known cardiac or extracardiac causes for VT (group 2) require treatment if they have a sustained, rapid arrhythmia. As with SVT patients, the urgency of treatment depends on the clinical status. In cases of shock, impending cardiac decompensation, or cardiac failure, synchronized DC cardioversion at 2 to 5 watt-sec/kg up to 10 watt-sec/kg should be used. IV lidocaine at 1 to 2 mg/kg also may be effective (Table 82.15); a continuous infusion of lidocaine at 10 to 50 µg/kg per minute may be required. Other effective drugs include intravenous amiodarone at 5 mg/kg over the first hour, followed by a 5 to 10 µg/kg per minute IV infusion or intravenous procainamide at 10 to 15 mg/kg given over 30 to 45 minutes, followed by a 20 to 80 µg/kg per minute IV infusion. Those with Purkinje cell tumors or ectopic foci may be amenable to catheter radiofrequency ablation or surgical ablation in selected cases.

Rapid ventricular pacing may be used for overdrive suppression for conversion to normal rhythm if pharmacologic therapy fails or is contraindicated. Chronic treatment with nadolol, propranolol, mexiletine, amiodarone, procainamide, sotalol, or propafenone has been effective for long-term control of this arrhythmia.

No data exist that determine whether asymptomatic patients with normal hearts and idiopathic slow VT should be treated with antiarrhythmic agents. Certainly, the patient should not be made more toxic by the therapy than by the arrhythmia. Treatment should be determined by hemodynamic status and potential problems that might occur from the arrhythmia.

Patients with CHD (group 3) and VT raise a different issue. Often, these patients have some degree of hemodynamic compromise associated with ventricular dysfunction and do not tolerate the VT at all. The emergent and chronic treatment is similar to that outlined previously but may be required even more urgently. All patients with CHD and sustained VT over 150 bpm require therapy because sudden death occurs in up to 30% of patients with CHD who have VT. Some patients in this group with slower VT or nonsustained VT may require treatment, especially if hemodynamic abnormalities exist.

The congenital long Q-T syndrome is a special case. Sudden death occurs in 73% of patients who are not treated. The sudden death is secondary to ventricular tachyarrhythmias (torsades de pointes) of the type that often degenerates to ventricular fibrillation. Any patient who presents with VT, especially of the polymorphic or torsades de pointes type, should have corrected Q-T intervals determined in sinus rhythm. A genetic basis for long Q-T syndrome has now been described. A complete family history may reveal the occurrence of sudden death in young relatives, or a family history of syncope associated with exercise or emotional stress. A family history of hearing deficit may be elicited. Emergent

treatment of these patients includes lidocaine and synchronized DC cardioversion when needed. If the VT is polymorphic, nonsynchronized cardioversion or defibrillation is indicated. In addition, temporary atrial or ventricular pacing at a rate 10 to 20% faster than the underlying sinus rate may be needed to control the arrhythmia, especially in patients with underlying bradycardia, a common association. Intravenous propranolol, phenytoin, and magnesium have been used successfully in these patients. The class I agents that prolong the Q-T interval in normal patients should be avoided in patients with these long Q-T intervals. In fact, a number of drugs that may produce this form of VT are shown in Table 82.17. This type of drug effect is believed to be related to QTc prolongation with associated ventricular arrhythmias and bradycardia at times. Temporary pacing and removal of the offending agent are effective therapies. In acquired long Q-T with ventricular arrhythmias, especially if bradycardia is a prominent factor, an isoproterenol infusion may be therapeutic.

Antiarrhythmic Agents	*Psychotropic Drugs*
Quinidine	Tricyclic Antidepressant
Procainamide	Amitriptyline
Flecainide	Phenothiazines
Encainide	Haloperidol
Disopyramide	Risperidone
Amiodarone	Pimozide
Sotalol	Lithium carbonate
Antihistamines	Sertraline hydrochloride
Terfenadine	Nefazodone hydrochloride
Astemizole	Fluvoxamine maleate
Diphenhydramine	*Other*
Antibiotics/Antifungal Agents	Cisapride
Erythromycin	Probucol
Trimethoprim	Anthracyclines
Sulfamethoxazole	Organophosphates
Pentamidine	Epinephrine
Ketoconazole	Diuretics
Fluconazole	Potassium loss
Itraconazole	
Clarithromycin	
Azithromycin	

Table 82.17. Pharmacologic Agents That Prolong Q-T Intervals

Ventricular Fibrillation

Ventricular fibrillation consists of chaotic irregular ventricular contractions with cessation of circulation. Electrical defibrillation with correction of precipitating factors (acidosis, electrolyte imbalance, hypoxia) may result in conversion to normal sinus rhythm. The treatment of cardiac arrest is discussed in Chapter 1.

Irregular Heart Rates

Premature Depolarizations

Background

The primary irregular rhythm that may require attention is the PVC. PVCs are seen as premature, wide, bizarre-shaped QRS complexes. Generally, the T wave is opposite in direction to the main deflection of the QRS. A compensatory pause usually follows the premature beat, and P waves may reveal AV dissociation or retrograde conduction or may be absent. When a rhythmic pattern of PVCs is established, the designation of bigeminy, trigeminy, or quadrigeminy is made, depending on whether that beat followed every second, third, or fourth sinus beat. Nonsustained VT consists of three PVCs or more that last for 10 seconds or less.

Pathophysiology

PVCs often occur without identifiable cause in children and have been considered benign. However, PVCs are seen in children with CHD and CHF, viral myocarditis, Lyme myocarditis, cardiomyopathies, cardiac tumors, hemochromatosis, or electrolyte imbalance. They also are seen in association with various forms of drug administration, including general anesthesia, digoxin, sympathomimetic amines, and phenothiazine tranquilizers. PVCs may be precursors of VT or fibrillation.

Clinical Manifestations

Children who present with PVCs are often asymptomatic and unaware of their arrhythmia, especially if they are younger than 5 years of age. If the PVC is appreciated, the child may complain of a “skipped” or “hard” beat, a fluttering or pounding in the chest, difficulty breathing, or chest pain. If the PVCs are frequent and/or associated with heart disease (congenital or acquired), the child may note dizziness or a rapid heartbeat. Frequent PVCs in the presence of compromised cardiac function may worsen the CO and produce signs and symptoms of CHF.

Management

The only PVCs that require treatment are those that cause or are likely to cause hemodynamic compromise. This generally is seen in the context of frequent PVCs in a patient with abnormal cardiac function as evidenced by cardiomegaly on chest radiograph, abnormal cardiac function or dilated chamber sizes on echocardiography, or abnormal exercise responses on exercise stress testing. Symptoms of dizziness, chest pain, or presyncope may accompany PVCs in patients with abnormal cardiac function. Such patients may be found to have myocarditis, cardiomyopathy or a congenital heart defect (preoperative or postoperative), and abnormal underlying cardiac function. The treatment may include lidocaine, mexiletine, procainamide, propranolol, or amiodarone (Table 82.15) as outlined in the section on VT. Although digoxin is not generally considered for patients with PVCs or VT, patients with poor myocardial function, as evidenced by the clinical findings of CHF and echocardiographic evidence of abnormal

myocardial function, may benefit from digitalization.

Rapid nonsustained VT, usually with rates over 150 bpm, may require treatment even in the presence of a normal heart because of the tendency for symptoms to develop, especially if the abnormal rhythm is present more than 40% of the time.

Isolated multiform or coupled PVCs or nonsustained VT (rate 150 bpm or less) in an asymptomatic patient with a normal heart may not require treatment, but this decision must be individualized after consultation with a cardiologist. Rarely is emergency treatment of this type of patient required, and investigations that use 24-hour continuous ECG monitors, exercise stress testing, echocardiography, and/or the electrophysiologic catheterization studies may be used to determine the appropriate management. It sometimes is helpful to observe the patient's response to activity. If the PVCs abate completely with sinus tachycardia (140 to 150 bpm), they are likely to be benign in terms of clinical significance and need for therapy, although this is not universally true.

Isolated PVCs in an asymptomatic patient in the presence of a structurally and functionally normal heart do not require treatment. Continuous 24-hour ambulatory monitoring should be performed to rule out the presence of undetected VT or complex ventricular arrhythmias. Restriction of caffeine and other stimulants should be recommended in all patients with ventricular arrhythmias.

Premature atrial contractions (PACs) or PVCs generally do not require treatment. Patients with frequent PACs or PVCs should be evaluated appropriately to rule out myocarditis. Continuous 24-hour ambulatory monitoring should be performed to rule out the occurrence of SVT. Elimination of caffeine or other stimulants such as theophylline, pseudoephedrine, and other sympathomimetic amines may decrease the frequency of PACs. Unless the PACs are demonstrated to initiate episodes of SVT, no treatment is indicated. Variations of normal rhythms commonly seen in children and that do not require treatment include sinus arrhythmia and wandering atrial pacemakers as long as rates remain in the normal ranges.

First-Degree and Second-Degree Heart Block

First-degree heart block reflects slowed conduction from the sinus node to the ventricle and is manifested by a prolonged P-R interval. It is seen with digoxin and other antiarrhythmic drugs; certain types of CHD (primum and secundum atrial septal defects); and inflammatory diseases such as rheumatic, viral, or Lyme myocarditis.

Second-degree heart block results in the failure of some impulses to traverse the AV node. The Wenckebach phenomenon, a form of second-degree heart block, is a result of progressive slowing of AV conduction and is seen as progressively prolonged P-R interval and eventual dropped beat. Other forms of second-degree heart block include high grade 2:1, 3:1, and 4:1 block.

Children with first-degree and second-degree heart block rarely are symptomatic unless the associated HR is low enough to decrease the CO. In such instances, signs and symptoms of CHF may be present.

Both first-degree and second-degree heart block may be associated with digitalis toxicity, requiring the digitalis dose be adjusted downward or temporarily held if second-degree AV block is present. Otherwise, first-degree heart block does not need therapy. Second-degree heart block is treated only if it produces a HR sufficiently slow to interfere with cardiac output. In this instance, the management is the same as that outlined for complete heart block (p. 672).

Arrhythmias Associated with Electrolyte Abnormalities

Alterations in electrolyte concentrations may influence cardiac rate, rhythm, and automaticity and may lead to arrhythmias. Potassium and calcium abnormalities are the most common electrolyte alterations that produce arrhythmias, but abnormalities in magnesium and acid-base balance are also important. Commonly, a combination of ionic alterations is responsible for arrhythmias. Any patient with significant arrhythmias should be evaluated for an electrolyte disturbance. The ECG changes may be characteristic and lead to suspicion of a specific electrolyte abnormality. Normal ECG intervals (P-R, QRS, QTc) are listed in Table 82.18.

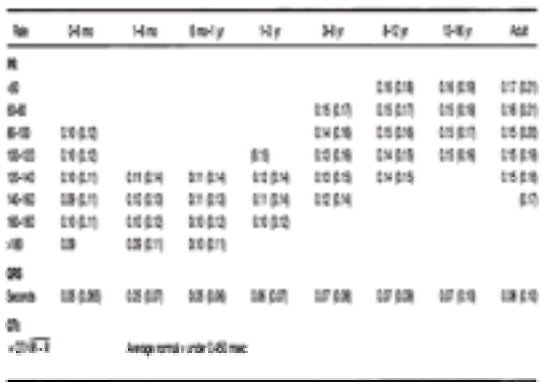

Table 82.18. P-R Interval and QRS Duration Related to Rate and Age (and Upper Limits of Normal)

Hyperkalemia

Hyperkalemia is common in hospitalized children and produces recognizable ECG alterations. Peaked T waves are seen at a serum concentration of 5 to 6 mEq/L, and the QRS widens with a concentration exceeding 6 mEq/L. The Q-T interval increases with the increasing QRS duration. As P wave amplitude decreases, P wave duration increases, and the P-R interval increases above 7 mEq/L. Above 8 to 9 mEq/L, P waves disappear, the ventricular rate becomes irregular, and severe bradycardia with sinus arrest, block, or idioventricular rhythms occur, often with a sinusoidal wave pattern. Ventricular fibrillation or asystole occurs at serum concentrations greater than 12 to 14 mEq/L. Low serum calcium enhances the myocardial toxicity of hyperkalemia. Likewise, acidosis potentiates hyperkalemia by producing potassium ion efflux from cells.

Hypokalemia

Serum potassium concentrations of less than 2.7 mEq/L generally produce typical ECG changes in ventricular repolarization. These changes include a U-wave amplitude greater than 1 mm, seen best in leads V_2 and V_3, and ST-segment depression greater than 0.5 mm. The Q-T interval lengthens and the T wave flattens with progressive hypokalemia. The P-R interval may be prolonged, and intraventricular conduction may be delayed with widening of the QRS complex. With significant hypokalemia, P-wave and QRS amplitude may increase. Other arrhythmias that have been associated with hypokalemia include ectopic atrial and ventricular complexes, ectopic atrial tachycardia with block, AV dissociation, second-degree AV block, ventricular bigeminy, VT, and ventricular fibrillation.

Patients taking digoxin who become hypokalemic are especially susceptible to arrhythmias because of the synergistic effects of digoxin and hypokalemia on automaticity and conduction.

Hypocalcemia

Hypocalcemia produces characteristic ECG changes that consist of Q-T interval prolongation secondary to ST-segment prolongation (Fig. 82.15) and occasionally, reversal of the T wave. The ECG changes correlate with ionized calcium because the degree of Q-T prolongation generally is proportional to the degree of hypocalcemia. Abnormal rhythms, although uncommon, have been reported and include SVT, 2:1 AV block, complete heart block, and torsades de pointes VT. The effects of calcium and potassium on myocardial cells are antagonistic.

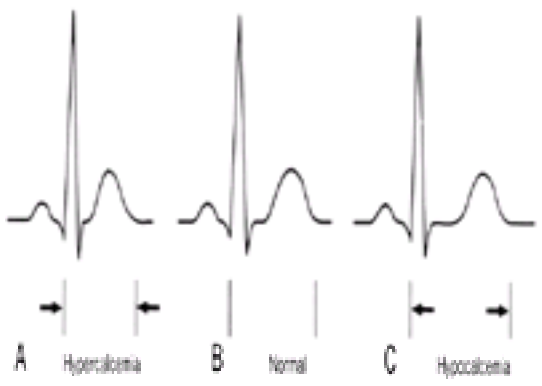

FIGURE 82.15. Electrolyte effects on ECG Q-T interval. Note prolongation with hypocalcemia, shortening with hypercalcemia.

Hypercalcemia

Hypercalcemia, with levels above 12 mg/dL, produces a shortened Q-T interval (Fig. 82.13), a shortened ST segment, and normal or prominent U waves. Severe hypercalcemia causes P-R interval prolongation, QRS prolongation, and occasionally, second-degree and third-degree heart block. Elevated serum calcium decreases the effect of hyperkalemia and potentiates digoxin toxicity. Thus, calcium should be administered cautiously to patients taking digoxin and the HR should be monitored.

Hypomagnesemia

Low magnesium levels often are associated with hypokalemia and hypocalcemia. The ECG abnormalities seen may be those associated with any or all of these aberrations and include prolongation of the corrected Q-T interval. Ectopic beats and T-wave changes are commonly noted. Torsades de pointes VT and ventricular fibrillation have been reported.

Hypermagnesemia

Hypermagnesemia of 3 to 5 mEq/L or higher may be associated with a delay in AV and intraventricular conduction.

Treatment of these electrolyte abnormalities is discussed in Chapter 86.

PERICARDIAL DISEASE

Background

Few medical situations exist in which a simple, quickly performed medical procedure can result in immediate, lifesaving

results. Among these is pericardiocentesis for cardiac tamponade. The technical aspects of pericardiocentesis are discussed elsewhere (see Procedures in Section VII). This section addresses etiologic concerns, clinical findings, and other initial management measures that must be taken to evaluate and treat satisfactorily the child with pericardial disease.

Three forms of illness can affect the pericardium. Pericarditis, usually not a true medical emergency, is a nonspecific term that denotes inflammatory disease. Pericardial effusion, a condition that requires close evaluation but does not necessarily require emergency treatment, implies fluid accumulation within the pericardial space. Cardiac tamponade, a true medical emergency that requires immediate attention, connotes a situation in which impairment of ventricular filling has resulted from pericardial fluid accumulation or from constriction of the heart by an abnormally thickened pericardium, resulting in impairment of CO.

Table 82.19 reviews some of the principal causes of pericarditis in childhood. When considering the cause of pericardial disease and its clinical correlates, it is important to remember that the pericardium is in continuity with the surrounding intrathoracic structures. Thus, conditions that affect the pleura, the mediastinal structures, or the diaphragm may affect the pericardium as well.

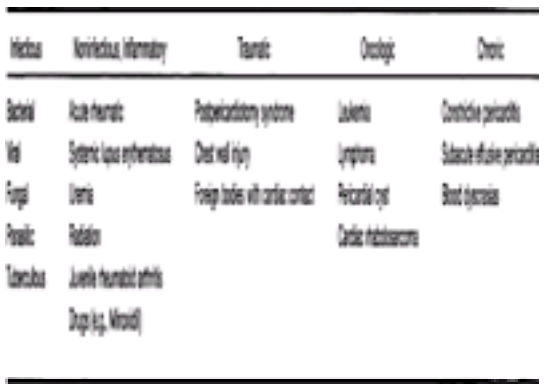

Table 82.19. Causes of Diseases of the Pericardium

Infectious diseases remain the most likely cause of pericarditis in childhood. Although a viral etiology often is presumed to be causative, in only about 20 to 30% of the time is an actual viral pathogen confirmed. Coxsackievirus (group B) and enteric cytopathogenic human orphan (ECHO) viruses are paramount, but other agents, including rubella, Epstein-Barr virus, adenovirus, influenza virus, and mumps virus, have all been associated with pericardial inflammation and pericardial effusion. Rarely do viral diseases result in cardiac tamponade.

Purulent pericarditis is often a medical emergency, however, because of associated cardiac tamponade and because of important sequelae that may be mitigated by early effective treatment. Although it is a disease seen at all pediatric ages, approximately 30% of the cases involve children younger than 6 years of age. *Staphylococcus aureus, Haemophilus influenzae, Neisseria meningitidis, Streptococcus pneumoniae,* and other streptococci are the principal bacterial agents responsible for childhood pyogenic pericarditis, although other pathogens have been recovered occasionally. Other organisms also may cause pericardial infection and chief among these is *Mycobacterium tuberculosis.* In patients from underdeveloped countries, in fact, *M. tuberculosis* may be equally as common as *S. aureus* as a cause of pericardial infection and must not be overlooked. Associated infections, such as respiratory tract disease, osteomyelitis, and pyogenic arthritis, may be present and may be clinically helpful in identifying the specific organism involved. For example, reviews have noted that many cases of staphylococcal pericarditis were associated with infections distant to the pericardium, such as osteomyelitis, whereas most cases of *H. influenzae* pericarditis were associated with respiratory tract infection. Meningococcemia is associated with pericardial involvement in about 5% of cases.

In childhood, noninfectious pericardial disease also can be significant. The postpericardiotomy syndrome is nearly always associated with pericardial inflammation and must be thought of in the postoperative cardiac patient who develops a pericardial effusion, fever, leukocytosis, and a high ESR from after the first week until several weeks after surgery. This syndrome may occur in as many as 15 to 20% of children who undergo open heart surgery. Other important causes of pericardial inflammation include collagen vascular disease and oncologic diseases, especially mediastinal lymphoma.

Pathophysiology

As noted earlier, pericardial inflammation is not usually life-threatening. Of concern for the physician who evaluates a child in an emergency situation are the hemodynamic sequelae of either fluid accumulation in the pericardial space and scarring and thickening of the pericardium, leading to restriction of cardiac filling. Usually, a small amount of intrapericardial fluid (less than 30 to 50 mL) exists in an equilibrium state between secretion into the pericardial space and reabsorption. With a sudden accumulation of fluid or with a more gradual increase of large amounts of fluid within the pericardial sac, interference with ventricular filling occurs, leading to decreased stroke volume and to falling BP. Cardiac filling may be compromised through several interrelated mechanisms, including increased ventricular end diastolic pressure, a decreased gradient for venous return, premature AV valve closure, and shortened diastolic time. The clinical manifestation of these physiologic aberrations, known as cardiac tamponade, is directly related to the severity of these abnormalities and to compensatory mechanisms evoked to overcome them.

Clinical Manifestations

A history of onset of respiratory difficulties after resolution of an upper respiratory illness may indicate pericardial disease in some instances. Chest pain, usually a benign symptom in childhood, is common with pericardial inflammation. This pain varies, depending on position. Occasionally, abdominal pain may be the presenting symptom.

The child with significant pericardial effusion may show clinical signs similar to several of those noted in the preceding section on CHF. Tachypnea secondary to raised pulmonary venous pressures and decreased pulmonary compliance usually is present. This may be associated with intercostal retractions. Reduced CO may result in peripheral vasoconstriction, manifested by cool extremities, pallor, or decreased systemic BP. Elevated systemic venous pressures cause neck vein distension, hepatomegaly, and on occasion in a more chronic picture, protein loss through either the GI tract or the urine. Tachycardia is a universal finding and is representative of an effective compensatory mechanism, but only up to a point. This compensation is limited because diastolic filling times become further shortened by the increased HR.

The cardiac auscultatory findings directly relate to the degree of pericardial fluid accumulation. A friction rub—the scratching, harsh sound commonly heard throughout the cardiac cycle—often is not audible in the presence of significant amounts of intrapericardial fluid and may become apparent only after pericardiocentesis. The heart sounds usually are distant, or muffled, and the apical impulse is weak. In general, the presence of a quiet precordium in the face of these previously noted respiratory and circulatory changes should alert the examiner to the possibility of pericardial disease with effusion.

The sine qua non of cardiac tamponade is pulsus paradoxus. The finding of a paradoxical pulse greater than 20 mm Hg is unequivocal evidence of circulatory compromise. In addition, most investigators assume that as little as 10 mm Hg is suggestive of hemodynamic impairment.

The physiologic mechanisms that underlie pulsus paradoxus can be viewed as exaggerated examples of the integrated functioning of the cardiopulmonary unit. Normally, a small fall (under 10 mm Hg) in systolic BP is noted with inspiration as a result of several factors. As negative intrathoracic pressure is generated by the inspiratory effort, the gradient for systemic venous return increases, favoring right-sided heart filling. At the same time, diaphragmatic descent exerts a traction effect on the heart, limiting filling and ejection. In addition, there may be some decrease in pulmonary venous return because the gradient from pulmonary veins to left atrium probably is reduced. Thus, left-sided heart output and systemic BP are reduced. The pericardium itself is an additional variable factor. In general, because it envelops the heart, the pericardium tends to retard expansion of ventricular volume, normally only to a limited degree. Thus, in normal respiration, the pericardium exerts an additional volume-reducing effect on the left ventricle. In pericardial disease states, as the pericardium itself becomes more rigid or as fluid in the pericardial space increases and intrapericardial pressure rises, the restriction to left ventricular output becomes greater and the consequent decline in systemic BP becomes steeper.

The best method of detecting pulsus paradoxus is to measure BP first in the usual way at expiration and then to inflate the cuff a second time to a few millimeters of mercury above the systolic BP and allow the cuff to deflate slowly. As the pressure falls, the Korotkoff sounds disappear with each inspiration. At the point at which they cease to disappear, becoming equal to that auscultated during expiration, the measured BP is recorded. The difference between the initial maximum systolic BP and the final measurement is the pulsus paradoxus.

It should be noted that pulsus paradoxus is not a finding unique to cardiac tamponade. It is a common finding in respiratory tract disease (asthma) and also may be present in CHF without pericardial effusion.

Laboratory Findings

Laboratory findings vary according to the underlying causes of pericardial disease. Although cardiac tamponade is a clinical diagnosis, certain laboratory tools can be extremely helpful in clarifying the situation.

The ECG shows diminished precordial voltage in most instances of significant intrapericardial fluid accumulation (Fig. 82.16). With pericarditis, an associated current of injury pattern that reflects myocardial involvement, seen as elevations in the ST segments, also may be present. Diffuse T-wave inversions also are common. The heart size is increased on chest radiograph (Fig. 82.17) with pericardial effusion but can be entirely normal if there is no significant amount of intrapericardial fluid. The lung fields may be clear, but one should look for associated bronchopneumonia or pleural effusions that may be helpful for diagnostic considerations. In some situations, as with constrictive pericarditis, the heart size may be relatively small. If the patient has had previous chest radiographs, a sudden increase in heart size always should arouse the suspicion of pericardial effusion.

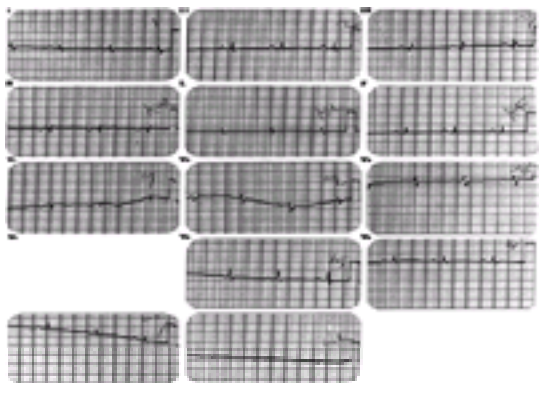

FIGURE 82.16. Electrocardiogram in pericardial effusion. Generalized low voltage present. ST-T wave flattening is

present.

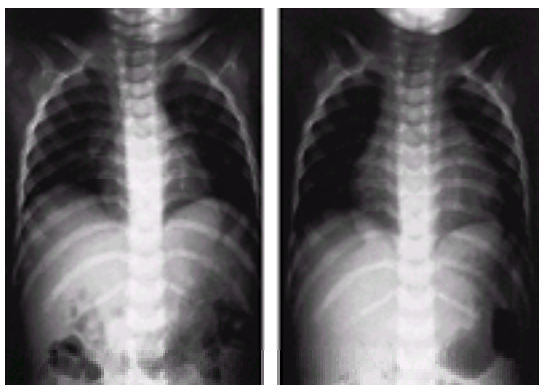

FIGURE 82.17. Radiographs from an infant 4 days before and at the time of the diagnosis of purulent pericarditis. Note the increasing heart size and the “water-bottle” silhouette.

Echocardiography has become the diagnostic procedure of choice for determining the presence and amount of intrapericardial fluid. An echo-free space between the epicardium and the pericardium can be readily identified (Fig. 82.18), with a negligible incidence of false-positive diagnoses in experienced hands. Quantitation is not exact, but evidence of anterior and posterior fluid accumulation suggests a large collection. Either single crystal M-mode echocardiography or two-dimensional real-time echocardiographic studies can be used, although the latter are preferred. In addition, serial evaluation of the pericardial space is easily accomplished by using echocardiography and is helpful for observing the effects of treatment and for evaluating indications for further therapeutic maneuvers after initial drainage measures.

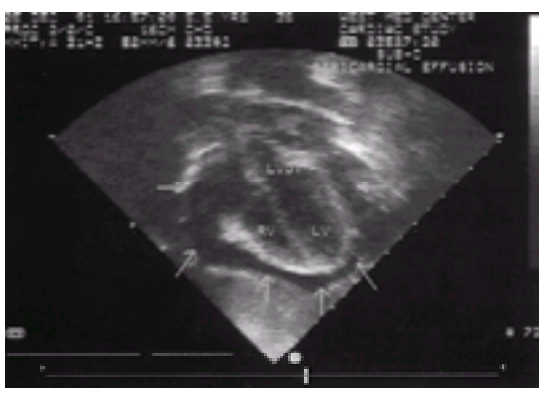

FIGURE 82.18. M-mode echocardiogram in pericardial effusion. Note absence of echoes (clear area) between epicardium and pericardium, representing intrapericardial fluid. *ECG,* electrocardiogram; *ENDO,* endocardium; *EPI,* epicardium; *LV,* left ventricle; *PE,* pericardial effusion; *PERI,* pericardium; *RV,* right ventricle.

When infectious pericardial disease is suspected, as with the evaluation of any other potentially life-threatening infection, a complete bacteriologic evaluation should be initiated before antibiotic therapy is begun.

Management

For pericarditis without evidence of pericardial effusion, emergency invasive treatment usually is not indicated. Symptomatic therapy for pain should be prescribed, and bed rest in the hospital is advisable. The patient should be followed closely for the development of complications such as myocarditis, pericardial effusion, and cardiac tamponade. Diagnostic evaluation to identify the cause should be initiated.

For pericardial effusion, a more definitive approach is needed. Careful evaluation of vital signs and frequent attention to development of pulsus paradoxus are mandatory. Cardiology consultation should be obtained, and the patient should be admitted for evaluation. Diagnostic pericardiocentesis often is required in the de novo presentation, particularly without evidence of other forms of systemic disease; it always is required with the suspicion of a purulent pericardial process. Antibiotic therapy alone is not adequate for treatment of purulent pericarditis. Usually, in the presence of purulent pericarditis, an open drainage procedure is indicated. It is contingent on the emergency physician to ensure cardiovascular stability in the presence of pericardial effusion because tamponade can develop rapidly once maximum pericardial distensibility has been reached (Table 82.20).

1. Ensure adequacy of ventilation and cardiac output
2. Administer oxygen
3. Initiate cardiorespiratory monitoring
4. Obtain laboratory studies (simultaneously with step 5)
Complete blood count, platelet count, electrolytes, blood urea nitrogen, creatinine, glucose, arterial blood gas, blood culture, chest radiograph, electrocardiography, echocardiography
5. Achieve venous access
6. Pericardiocentesis (see Section VII)
Send specimen for laboratory studies: cultures, CIE, viral titers, antinuclear antibody, Gram stain, cytology, cell count and differential, chemical profile
7. Administer antibiotics[a]
Oxacillin (150 mg/kg/day) or nafcillin or methicillin and Chloramphenicol (100 mg/kg/day)
Aminoglycoside (immunocompromised patient)

[a]Select antimicrobials to cover *S. aureus* and *H. influenzae* at least until specific infection is isolated.

Table 82.20. Purulent Pericarditis: Immediate Management

The management of cardiac tamponade requires intense medical vigilance. Although it may be possible in relatively mild or highly selected situations to manage the effusion conservatively, it generally is necessary to remove the fluid. A full discussion of the techniques used for pericardiocentesis in the emergency situation is available in Section VII of this book. This can be a lifesaving technique and, when done successfully, shows clearly the fruitful outcome of appropriate, decisive evaluation and treatment procedures.

INFECTIVE ENDOCARDITIS

Background

One of the persistently complex problems of pediatric cardiovascular medicine has been the evaluation and management of the child with infective endocarditis. Although long-term treatment issues generally are not within the province of emergency medical care, it is critically important for the emergency physician to be aware of the clinical context in which bacterial endocarditis is a consideration. It is also incumbent on the emergency physician to initiate therapy in certain instances, and it is always crucial to avoid unnecessary clouding of the diagnosis.

Etiologic Factors

The clinical picture of infective endocarditis has been evolving steadily over the past 10 to 20 years. Although the most common setting for this problem is the child with preexisting CHD, variability exists in terms of the types of associated lesions (Fig. 82.19), and it is of concern that a substantial proportion of cases develop in children with no history of cardiac abnormality. These children may be among the most ill, presenting with their illness as part of an acute bacterial endocarditis picture.

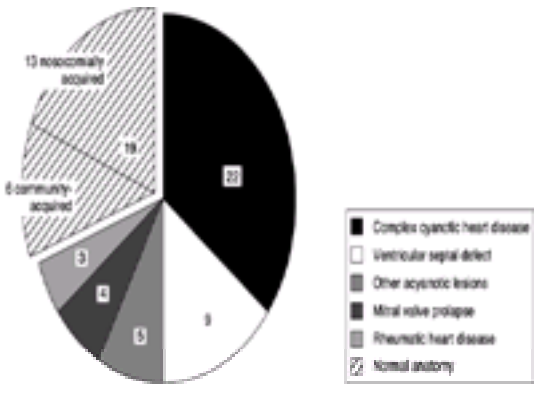

FIGURE 82.19. Distribution of underlying cardiovascular findings in endocarditis in a series of 62 children. (Reprinted with permission from Saiman L, Prince A, Gersony WM. Pediatric endocarditis in the modern era. J Pediatr 1993;122:847–853.)

Certain factors appear to predispose a child to the development of endocarditis. It is widely believed that among these are dental and surgical procedures. Dental procedures even without periodontal disease can yield significant bacteremia. Unfortunately, many ordinary daily events are associated with at least transient bacteremia (Table 82.21). It is small wonder, in fact, that more cases of endocarditis are not evident if bacteremia of oral cavity origin were a singular factor. Conversely, invasive procedures specifically involving the heart, such as cardiac catheterization, in patients with even the highest risk are rarely associated with endocarditis development. Recently, the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease of the American Heart Association undertook a major review of the guidelines for endocarditis prevention. This review identified the procedures likely to predispose to endocarditis development (Table 82.22) and stratified the cardiac conditions with the highest likelihood of susceptibility regarding their risk potential for endocarditis development (Table 82.23). These findings were based on several emerging trends: 1) children with even the most severe congenital cardiac malformations increasingly survive complicated surgical procedures performed at younger and younger ages, thereby increasing the pool of susceptible children at risk; 2) children who develop endocarditis are more likely to overcome the episode than in the past because of improved clinical and microbiologic technologies and a broadened selection of antimicrobials; 3) the advent of chronic parenteral access catheters for nutritional and pharmacologic therapies of premature neonates and of older children with chronic illnesses, such as oncologic diseases or metabolic and neuromuscular disorders, has created a widening population of susceptible children

with structurally normal hearts; 4) mitral valve prolapse has emerged as a not uncommon finding even in children and reports of endocarditis in this setting have resulted in controversy regarding what distinguishes a truly abnormal valve from the normal variability that enhanced imaging techniques have enabled us to identify as part of the growth and development process.

Procedures	Bacteremia (%)
Tooth extractions (no gingivitis)	34
Tooth extractions (gingivitis)	70–75
Endocontic procedures	4
Chewing mint candy	20
Brushing teeth	40
Oral irrigation device	27–50
Massage of nfected tonsl	23
Urethral surgery	57
Massage of nfected prostate	67
Barium enema	11
Bronchoscopy	15
Sigmoidoscopy	5–10

Table 82.21. Transient Bacteremia and Various Procedures or Conditions

Table 82.22. Procedures and Endocarditis Prophylaxis

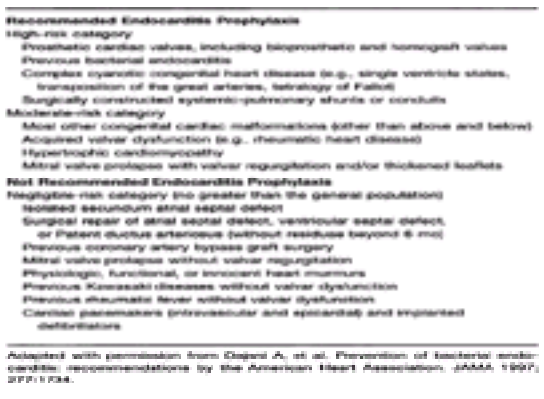

Table 82.23. Cardiac Conditions Associated with Endocarditis

Despite some changes in the specifics of the clinical epidemiology of endocarditis, certain physiologic conditions appear to be consistently most important. Diseases characterized by a highly turbulent stream of blood or a high velocity of flow are particularly prone to this complication. Such lesions include ventricular septal defect, aortic valve stenosis, and mitral valve regurgitation. Children with postoperative systemic-to-pulmonary shunts also are in this category. In contrast, secundum atrial septal defect is a lesion with a negligible risk for endocarditis because the shunt flow is of low velocity. It is presumed that in “high velocity–narrow orifice” conditions, damage to cardiac surfaces occurs, resulting in a nidus for platelet disposition and vegetation formation.

Microbiology

Causative organisms include bacteria and fungi and are often related to the initiating event. Thus, although streptococci in general are the most common causative agents, viridans streptococci are the typical isolates following oral procedures. Staphylococci also are common etiologic agents, especially in children with structurally normal hearts or, ironically, in those with postoperative CHD, such as prosthetic valves. Other bacteria are much less likely to be present in childhood endocarditis. These include Gram-negative organisms, present in immunocompromised children and sick neonates, *Enterococci*, *Pneumococci*, and *Haemophilus* species. These data are reviewed in Table 82.24.

Organism	Frequency (%)
Streptococci	
Viridans	50
Pneumococci	8
β-Hemolytic	5
Enterococci	5
Staphylococci	
S. aureus	25
S. epidermidis	8
Gram-negative bacilli	8
Fungi	8
Culture-negative endocarditis	20

Table 82.24. Agents Associated with Pediatric Infective Endocarditis

Clinical Manifestations

Confirmation of a positive diagnosis depends on the recovery of organisms obtained by blood culture. To arrive at that point, however, a high degree of suspicion must be maintained. Often, early signs and symptoms can be subtle and persist for considerable time before the diagnosis is made. With viridans streptococcal endocarditis, this is a common situation. As a rule, persistence of fever in any child with CHD should prompt the clinician to consider the possibility of endocarditis.

In the clinical context of CHD, certain conditions should prompt a careful evaluation for the presence of endocarditis. These include 1) unexplained fever or a protracted febrile course in a presumed “viral” syndrome, 2) pneumonia, 3) the development of a new neurologic deficit, 4) the onset of hematuria, and 5) signs of systemic or cutaneous embolization.

The classic findings of fever, a change in the cardiac examination, splenomegaly, and evidence of emboli usually are present in severe cases but may require serial examinations. Emboli may be discovered by careful funduscopic examination, by observing for conjunctival lesions, or by meticulous scrutiny of the nailbeds, palms of the hands, soles of the feet, and other skin surfaces. Microscopic hematuria should be recognized as an important sign of endocarditis in the appropriate clinical context. Scrapings of cutaneous emboli may be helpful for rapid identification of infecting organisms.

Complications

The morbidity from infective endocarditis has decreased considerably in recent years. Currently, most series cite a fatality rate of 15 to 20%. Although this is still a high percentage, especially for pediatric illness, it should be remembered that more than 50% mortality was the norm in the 1950s and that the disease was nearly always fatal in the preantiobiotic era.

Other complications occur in as many as 40 to 60% of cases. Systemic or pulmonary emboli, depending on the intracardiac site of the vegetation, are a major source of concern and indicate prompt initiation of treatment. Major neurologic sequelae can arise from focal embolization to the CNS; thus, the presentation of a new neurologic deficit in a child with heart disease can be another clinical clue to the diagnosis of endocarditis. Myocarditis, myocardial abscesses, valvar obstructions associated with large vegetations, and ruptured sinus of Valsalva are other important complications that can be manifested by the appearance of CHF.

Acute bacterial endocarditis, or the development of an acute situation such as new aortic insufficiency, should be considered a true medical emergency. Often, early reparative surgery is required to save the child's life in this situation. These children are critically ill, and CHF is a grave sign in the context of suspected endocarditis. Characteristic heart murmurs may be absent in this setting, and their absence should not be taken as a cause for optimism. Other indications for surgery include the development of a cardiac arrhythmia (heart block), continued embolization, and continued positive blood cultures after initiation of appropriate therapy. Hemodynamic changes can transpire quickly, demanding frequent examinations even while the child awaits hospital admission or transfer from the ED.

Management

Treatment of infective endocarditis should be started as early as possible after appropriate evaluation is completed. Blood cultures must be drawn regardless of the presence or absence of classic clinical findings. To facilitate the diagnosis, the physician, particularly one who evaluates a child with heart disease with unexplained fever, must obtain blood for appropriate cultures at an early stage. In most of cases of endocarditis, the causative organism will be recovered from the initial two blood cultures. Particular emphasis should be placed on avoiding contamination of the sample site. Growth of spurious organisms can be misleading and dangerously time-consuming because bacteria on the skin can be implicated in endocarditis. It is not mandatory to obtain cultures at the time of fever spikes because bacteremia is fairly constant in the untreated patient. Early consultation should be sought from a cardiologist because specialized procedures such as echocardiography may help pinpoint the diagnosis rapidly, even in relatively difficult situations (Fig. 82.20).

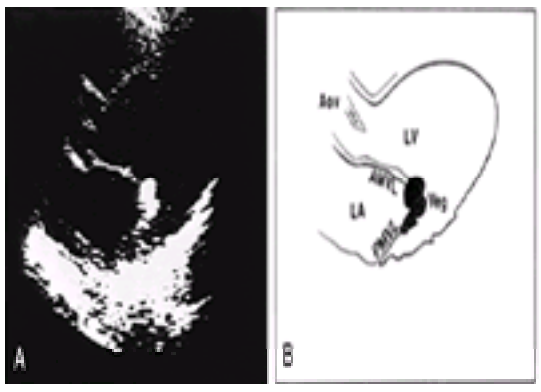

FIGURE 82.20. A. Long axis parasternal two-dimensional echocardiogram in patient with mitral valve pneumococcal endocarditis. **B.** Schematic view of **(A).** *AMVL,* anterior mitral valve leaflet; *Aov,* aortic valve; *LA,* left atrium; *LV,* left ventricle; *PMVL,* posterior mitral valve leaflet; *Veg,* vegetation.

In every instance, the diagnosis of infectious endocarditis implies long-term antibiotic therapy; thus, most management issues arise after the patient has left the emergency area. In general, antibiotic therapy should be instituted as soon as the diagnosis is made. If the patient is critically ill, it may be necessary to initiate therapy even before the results of cultures have returned. Certainly, stabilization of the patient with heart failure, initiation of the diagnostic workup, and mobilization of the relevant medical personnel are the responsibilities of the emergency physician in dealing with the child with suspected endocarditis. If the situation requires the initiation of therapy without definition of the microbial agent, many experts recommend the combination of an aminoglycoside, such as gentamicin (5 to 7.5 mg/kg per day) and a penicillinase-resistant penicillin such as oxacillin (150 mg/kg per day). Others advocate the use of ampicillin (200 mg/kg per day) and gentamicin for the initial therapy in this particular situation. Cephalosporins such as cefuroxime may also play a role in this context.

Much mention has been made of the value of antimicrobial prophylaxis in mitigating the development of infectious endocarditis, although it should be noted that the precise population benefits of prophylaxis never have been fully substantiated. Nevertheless, it remains incumbent on the physician who sees a child with heart disease in the ED to ensure that prophylaxis has been implemented if warranted. Prevention guidelines have been recently modified by the American Heart Association (Table 82.25). As a rule, such measures are practical only in the face of a well-defined, predisposing event. The usual child with heart disease who presents with a routine febrile illness does not require prophylactic antibiotics. Unnecessarily hasty administration of antibiotics when not indicated can be harmful because obfuscation of the ultimate diagnosis may result in damaging delay.

Situation	Agent	Regimen
For Dental, Oral, Respiratory Tract, or Esophageal Procedures		
Standard general prophylaxis	Amoxicillin	Adults: 2.0 g; Children: 50 mg/kg PO; 1 hr preprocedure (maximum: 2.0 g)
Unable to take oral medications	Ampicillin	Adults: 2.0 g IM or IV; Children: 50 mg/kg IV or IM within 30 min of procedure
Allergic to penicillins	Clindamycin	Adults: 600 mg; Children: 20 mg/kg PO; 1 hr preprocedure
	Cephalexin or Cefadroxil	Adults: 2.0 g; Children: 50 mg/kg PO; 1 hr preprocedure
	Azithromycin or Clarithromycin	Adults: 500 mg; Children: 15 mg/kg PO; 1 hr preprocedure
Allergic to penicillin and unable to take oral medication	Clindamycin	Adults: 600 mg; Children: 20 mg/kg IV within 30 min of procedure
	Cefazolin	Adults: 1.0 g; Children: 25 mg/kg IV or IM within 30 min of procedure
For Genitourinary/Gastrointestinal (nonesophageal) Procedures		
High-risk patients	Ampicillin plus Gentamicin	Ampicillin 50 mg/kg IM or IV (max 2.0 g) plus gentamicin 1.5 mg/kg within 30 min of procedure; 6 hr later, ampicillin 25 mg/kg IV or IM or amoxicillin 25 mg/kg PO
High-risk allergic to ampicillin and amoxicillin	Vancomycin plus Gentamicin	Vancomycin 20 mg/kg IV over 1–2 hr plus gentamicin 1.5 mg/kg complete treatment within 30 min of procedure
Moderate-risk patients allergic to Amp/Amox	Vancomycin	Vancomycin 20 mg/kg IV over 1–2 hr—complete treatment within 30 min of procedure

Total children's doses should never exceed adult doses.
Second dose of vancomycin or gentamicin not recommended.

Table 82.25. Endocarditis Prophylaxis Regimens

If systemic antibiotics are contemplated for other infectious indications, in most cases a blood count and a blood culture should be drawn before antibiotic therapy begins. In particular, these measures should be taken for the child with heart disease and a major infection, such as pneumonia or cellulitis, even if no clinical evidence of endocarditis is immediately apparent. It is not mandatory to admit the child with heart disease and an intercurrent febrile illness to the hospital on every occasion, and the previously noted laboratory studies may be helpful in making such a decision. Clinical judgment remains the best immediate guide for hospitalization. Although a high degree of suspicion for the possibility of endocarditis is mandatory, the emergency physician should resist the temptation to administer antibiotics indiscriminately to the child with heart disease.

HYPOXEMIC ATTACKS

Background

Children with cyanotic CHD in which pulmonary blood flow is reduced, such as tetralogy of Fallot, may experience periodic episodes of intense hypoxemia. Emergency attention usually is sought for these episodes at the nearest medical location. Therefore, the emergency physician who cares for children should have a good understanding of the associated physiologic and management principles.

Pathophysiology

The reasons for the acute nature of these episodes have never been defined. Initial thoughts that “cyanotic spells” were caused by spasmodic contraction of the portion of right ventricular outflow tract known as the “infundibulum” cannot provide the entire explanation because children with pulmonary atresia in whom no subpulmonic infundibulum has developed also can experience hypercyanotic attacks. Additional theoretic concerns have focused on 1) sudden changes in systemic vascular resistance and in venous return to the heart, which consequently affect the intracardiac right-to-left shunt; 2) alterations in sensitivity of the respiratory center; 3) significant changes in HR; or 4) some combination of all these factors. A schematic cycle of postulated mechanisms is noted in Figure 82.21.

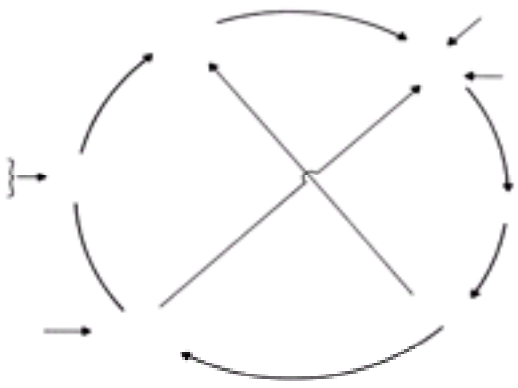

FIGURE 82.21. Schema of interrelated events in the genesis of hypoxemic spells. See text for discussion. (Reprinted with permission from Anthony CL, et al. Pediatric Cardiology, Medical Outline Series. Garden City, NY: Medical Examination Publishing, 1979:193.)

Any number of precipitant events related to these physiologic factors can be associated with the development of cyanotic spells. Often, they are morning events, noted shortly after awakening. This may be related to the sudden changes in CO that occur after arousal from a long sleep. Other likely times for the appearance of hypercyanosis include periods of dehydration, during invasive medical procedures, or other significant stresses.

Clinical Findings

The diagnosis of a hypoxemic spell usually is self-evident. Aside from the obvious cyanosis and the history of heart disease, there also may be a preceding history of squatting with exertion or of other positional vagaries that parents may recall. It is not necessary for the child to have been overtly cyanotic before the onset of a spell because such episodes can occur in children with little or no preexisting cyanosis. During a spell, the child may be irritable and crying or may be lethargic and even unconscious. Hyperpnea is a feature of the syndrome and should be distinguished from tachypnea or other abnormal respiratory patterns that may signal other medical problems associated with cyanosis. During a spell, there may be a notable absence or lessening of a previously heard heart murmur because pulmonary blood flow through the stenotic right ventricular outflow tract is reduced considerably. Laboratory investigations, such as arterial blood gas analysis, ordinarily should be avoided in the initial evaluation. If the attack is prolonged and associated with deepening sensorium changes, assessment of acid-base balance and ventilatory status may be indicated. Monitoring with peripheral oxygen saturation meters (transcutaneous) may be helpful to chart responses to therapy.

Management

The child with hypoxemic spells requires immediate attention. Appropriate positioning, oxygen, and administration of morphine are the standard initial therapeutic measures, and these usually result in prompt abatement of the attack (Table 82.26).

Knee-chest position	IV fluids
Oxygen administration	Vasoconstrictors
Evaluate and treat cardiac arrhythmia	Phenylephrine 0.10 mg/kg bolus, IM or subcutaneous; 2–10 µg/kg/min infusion IV
Morphine sulfate (subcutaneous) (0.1–2 mg/kg)	Methoxamine 0.10 mg/kg IV
Propranolol IV (0.2 mg/kg over 5 min)	Bicarbonate (2–3 mEq/kg, IV; ensure adequate ventilation)

Table 82.26. Acute Management of Hypoxemic Spells

Traditionally, subcutaneous morphine has been used in the treatment of cyanotic spells. Relatively large doses are given (0.1 to 0.2 mg/kg), although the precise mechanism of action is unknown. Morphine probably does not act to inhibit catecholamine action at the cardiac level but may abort the cycle of hyperpnea and vasomotor changes by depressing the respiratory center. A theoretic negative effect of morphine is its tendency to lower systemic vascular resistance.

Oxygen should be administered because Pa_{O_2} levels may be low and some benefit in terms of oxygen saturation may be obtained from even relatively small increments in dissolved oxygen. In the face of significant reduction of pulmonary blood flow, however, as occurs with a “spell,” oxygen may not have a dramatic effect.

The child should be placed in a knee–chest position and calmed, if possible. If the attack persists, additional therapeutic steps are needed. Sodium bicarbonate may be indicated; the dosage depends on arterial pH. Propranolol also has been recognized as efficacious in this situation, and an IV dose of 0.2 mg/kg over 4 to 5 minutes may yield relatively prompt improvement. Whether propranolol primarily affects the infundibular contraction, the hyperpneic ventilatory response, systemic vasomotor tone, or all of these is unclear. It should be remembered that propranolol may exacerbate bronchospasm if the patient has a coincident history of asthma.

IV fluids should be administered during the severe spell in maintenance doses at least because pulmonary blood flow and right ventricular output depend on volume. Functionally, right ventricular outflow obstruction may be heightened in the face of depleted intravascular volume.

Vasopressors have been advocated as alternates or adjuncts in treating hypoxemic spells. Phenylephrine can be given as a dilute IV solution of 10 mg/100 mL and infused at 2 to 10 µg/kg per minute. HR should be monitored and frequent BP assessment carried out if this type of agent is used. Methoxamine (10 mg/ 100 mL) or metaraminol (50 mg/100 mL) also may be used. By increasing systemic vascular resistance, these drugs reduce intracardiac right-to-left shunting favorably and thus improve systemic oxygenation. Digitalis, epinephrine, or norepinephrine should not be used, however, in this setting.

If any underlying condition exists, such as a cardiac rhythm disturbance, prompt correction according to the principles noted under Cardiac Arrhythmias may alleviate this situation quickly. Cardiac consultation is advisable as soon as feasible to make extended management decisions, even if the spell has abated with the measures already mentioned. In most situations, if the spell has required more than oxygen and positional adjustment to abate, hospitalization is indicated. Usually, although relieved with therapy, spells indicate appropriate surgery for the cardiac defect.

ACUTE RHEUMATIC FEVER

Background

Although the large numbers of patients with rheumatic fever seen in the past in the United States have dissipated because of improved diagnosis and treatment of streptococcal infections, the disease still occurs and, recently, has had resurgence. Also, rheumatic fever remains one of the most common causes of cardiovascular morbidity in children from other countries. The most common age of attack in the United States is 5 to 15 years, and winter and spring seasonal peaks are still typical.

Pathophysiology

It has been established clearly that streptococcal infection is a necessary precedent for the development of rheumatic fever. In particular, a history of infection by this organism of the upper respiratory tract should be sought in any suspected case. The precise mechanistic relationship between antecedent streptococcal infection and rheumatic fever, however, remains ill defined. Many serologic types of group A streptococci can be associated with acute rheumatic fever, so the antigenic factors involved are common to various strains of the organism. The particular host factors that determine who succumbs to acute rheumatic fever and who does not, despite identical infections, are also poorly defined. A clear-cut familial pattern has never been identified, although familial susceptibility appears to be a factor. The more common theoretic considerations that relate streptococcal infection and acute rheumatic fever are 1) an immunologic (autoimmune) response that involves host reaction to infection with a target organ being the heart, specifically, endocardial tissue; 2) a persistence of organism despite therapy, with localization to cardiac tissue; and 3) a direct reaction to the organism such as cardiotoxicity from streptolysin O produced by the organism. Thus far, no evidence of direct cardiac infection has developed, making experimental evaluation difficult.

Clinical Manifestations

The diagnosis of rheumatic fever requires a high index of suspicion. The time-honored Jones criteria (Table 82.27), if unequivocally present, usually establish the diagnosis, but the situation may not be always so clear-cut.

Major	Elevated acute phase reactants
Carditis	Erythrocyte sedimentation rate
Arthritis	C-reactive protein
Subcutaneous nodules	Prolonged P-R interval
Erythema marginatum	Supporting evidence of antecedent
Chorea	group A streptococcal infections
Minor	Positive throat culture of rapid
Clinical findings	streptococcal antibody titer
Arthralgia	Elevated or rising streptococcal
Fever	antibody titer
Laboratory findings	

Adapted from Jones TD. The diagnosis of rheumatic fever. JAMA. 1944; 126: 481., as modified in Guidelines for the diagnosis of rheumatic fever. JAMA 1992; 268:2069.

Table 82.27. Rheumatic Fever Manifestations

A complete, careful physical examination is the mandatory first procedure. Special attention should be given to eliciting joint pathology and cutaneous findings whose presence may facilitate the diagnosis in difficult cases. All the major Jones criteria are derived through clinical examination that usually needs to be repeated at frequent intervals. Among the major criteria, carditis can be overdiagnosed easily. Misinterpretation of normal (“innocent”) murmurs, whose auscultation is heightened in the presence of fever or other causes of increased cardiac output, can lead to overdiagnosis. The presence of an apical systolic murmur (characteristic of mitral insufficiency) or of a basal diastolic decrescendo murmur (typical of aortic insufficiency) is an important sign of carditis. The presence of a pericardial effusion, CHF, or pericarditis also strongly suggests the carditis component of acute rheumatic fever, even in the absence of valvar murmurs. Care must be taken to exclude other causes for cardiac findings, such as deteriorating CHD, which may result in cardiac decompensation not related to a rheumatic process. If possible, the examining physician should attempt to document a change in previous clinical findings in children with preexisting heart disease (or previous rheumatic fever episodes). Although regurgitant lesions, such as aortic or mitral insufficiency, are common components of the acute manifestations of rheumatic fever, stenotic lesions, such as aortic or mitral stenosis, usually are not seen with a first attack of acute rheumatic fever.

Polyarthritis is the most commonly found major criterion. It should be remembered that this is true joint inflammation, not arthralgia. Tenderness, motion restriction, heat, redness, and swelling are the typical signs. In contrast to other forms of collagen disease, joint involvement in rheumatic fever usually is migratory and multiple and tends to localize to the larger joints of the extremities. It may be necessary to avoid rapid use of anti-inflammatory agents in patients with suspected acute rheumatic fever to clarify the diagnosis of migratory polyarthritis.

The cutaneous criteria are erythema marginatum and subcutaneous nodules. These findings are not as common as arthritis and carditis and are rarely present as the only major criteria. Nodules usually occur in situations of recurrent rheumatic fever or chronicity. They are found over extensor surfaces of joints, such as elbows or knees; are firm and decidedly nontender; and are movable on palpation. Erythema marginatum characteristically appears on the trunk and proximal extremities and is an extremely evanescent finding. The application of heat may accentuate its appearance. This rash is notable for its fine, lacy appearance with central blanching and a serpiginous pattern. It is not pruritic and is usually distinguished easily from drug rashes or other viral exanthems.

Chorea is the fifth of the major criteria defined by Jones. It is a relatively rare finding limited to children older than 3 years of age and most often occurs some time after the initial streptococcal infection, making accurate diagnosis difficult. Chorea is typified by involuntary purposeless movement of the extremities and facial grimacing. Notable emotional lability is also a part of the picture. The ED diagnosis of acute rheumatic fever rarely depends on chorea as the principal manifestation. The physician should be aware, however, of the possibility of the diagnosis in a child who presents with this finding and should arrange for appropriate further evaluation of the cause of the chorea.

The “minor criteria” defined by Jones are nonspecific indices of inflammatory disease and, often, are sources of overdiagnosis of acute rheumatic fever. The fever associated with acute rheumatic fever is notable for its lack of associated chills or rigor. It typically is low grade, and fevers of greater than 40°C (104°F) or a history of a febrile seizure should point to other illnesses. The wildly fluctuating fever of juvenile rheumatoid arthritis (“quotidian” pattern) usually is not a part of the rheumatic fever picture. Elevation of the ESR or C-reactive protein should be present in acute rheumatic fever, but severe CHF may lower the ESR. A prolonged P-R interval is common in acute rheumatic fever but also is an extremely nonspecific finding. It does not necessarily correlate with the presence of organic murmurs and can be found in other inflammatory cardiac diseases or as a result of certain drugs. Overemphasis of the significance of P-R prolongation is a common cause of improper diagnosis.

It must be emphasized that the modified Jones criteria include evidence of recent streptococcal infection in the history. Culture documentation is helpful, but serologic evidence may be the most rewarding and diagnostic data. The widespread use of the multiple antibody test (Streptozyme) has made serologic confirmation of recent streptococcal infection much easier. The antistreptolysin O test (ASO) is still a commonly used single serologic test and is well standardized. Levels above 250 Todd units in older children and above 333 in younger children are present in active rheumatic fever. As many as 20% of otherwise normal children can have elevated ASO titers, and depending on the time course of the illness, other antibody determinations may be required.

The differential diagnosis of acute rheumatic fever includes many diseases that fall under the classification of “collagen vascular” as well as other types of diseases. The Jones criteria themselves can include a spectrum of illnesses such as juvenile rheumatoid arthritis, serum sickness, systemic lupus, and even bacterial endocarditis or septic arthritis. Viral processes, such as myocarditis or pericarditis, also must be excluded, as well as intracardiac lesions such as left atrial myxoma.

Careful application of the Jones criteria plus documentation of a streptococcal infection of recent onset should enable the physician to diagnose acute rheumatic fever most of the time. Caution must be exercised in arriving at the diagnosis because initiation of therapy may suppress findings critical to the diagnosis. Thus, decisions to treat must be tempered with the understanding that it is vital to collect as much definition of the disease process as possible.

As noted earlier, acute-phase reactants such as the ESR and C-reactive protein are elevated in acute rheumatic fever. A complete blood count should be drawn to screen for anemia or an elevated white blood cell count. Leukocytosis not only is a manifestation of infection but may be considered an acute-phase reactant as well. Throat cultures (at least two) should be obtained before penicillin therapy is started. In addition, the streptococcal screen previously described should be obtained. Blood cultures often are drawn, with appropriate concern, to rule out subacute bacterial endocarditis, a problem that can present in an identical fashion to acute rheumatic fever.

A chest radiograph to assess heart size can be helpful for gauging the severity of carditis, as well as for objectively

verifying its presence. An ECG should be taken to ensure that a rapid pulse rate is the result of sinus tachycardia and to enable measurement of P-R interval. If pericardial disease or intracardiac myxoma needs to be ruled out, an echocardiogram can provide highly sensitive information. These latter procedures usually are completed, of course, after cardiac consultation has been requested. The appropriate laboratory procedures to help rule out other forms of collagen-vascular disease are described in Chapter 101.

Management

Acute rheumatic fever requires admission to the hospital and long-term management. That is, a prolonged treatment course is indicated once the diagnosis is made. Most considerations in caring for a child with acute rheumatic fever are not made in the ED. It should be restated that a rush to treat with anti-inflammatory drugs (aspirin or steroids) in a poorly documented case may obscure the ultimate diagnosis and may delay further therapy, thereby compromising more than helping the patient.

Principles of management include 1) treatment of the active streptococcal infection, 2) rest, 3) anti-inflammatory agents, and 4) treatment of chorea. All patients with acute rheumatic fever should receive a course of penicillin to eradicate any streptococci. Intramuscular benzathine penicillin in appropriate dosage for age and weight (see Chapter 84) is preferable. Bed rest may be helpful for as long as evidence of active inflammation is present. It should be initiated at diagnosis and is best done during the initial period in a hospital setting. Anti-inflammatory drugs (salicylates or steroids) may be indicated, but the tendency to begin such therapy before confirmation of the diagnosis, as outlined already, should be resisted. If arthritis without carditis is present, aspirin usually is sufficient (see Chapter 96). Treatment of carditis may include steroids in selected cases, but that decision should be undertaken only after the child is hospitalized and a cardiologist has been consulted. Treatment of chorea is also a long-term management issue, with agents such as diazepam or haloperidol currently favored (see Chapter 129). Recent evidence suggests a role for steroids in the treatment of chorea and for the presence of carditis.

Occasionally, the child with acute rheumatic fever may present with significant cardiac compromise that involves CHF associated with a large degree of valvar regurgitation or pericardial effusion that results in cardiac tamponade. Initially, the heart failure or tamponade should be managed as outlined in the previous sections, and then consideration should be given to the rheumatic process.

A most important aspect of management of the patient with rheumatic fever is prevention of recurrent attacks. It has been documented clearly that penicillin can be effective in this setting, with minimal patient risk. The most reliable prophylaxis is the IM route, with injections of 1.2 million units of benzathine penicillin G every 28 days being the preferred treatment. Oral penicillin (200,000 units twice daily) is an alternative prophylactic regimen. Sulfonamides may be used, as well as erythromycin, in patients sensitive to penicillin. Recommended dosages for the sulfonamides are 0.5 to 1.0 g/day, depending on weight, and 250 mg twice daily for erythromycin. Although current recommendations about the duration of prophylaxis are under scrutiny, most centers continue to use antibiotics for a minimum of 10 to 15 years after the initial diagnosis, and some use them for life. Increasing age may lessen susceptibility to streptococcal disease, but reliable evidence is lacking to substantiate this impression conclusively. The physician who evaluates a child with known rheumatic heart disease for any reason should review the prophylaxis status of the child at every occasion.

CHAPTER 83

Neurologic Emergencies

MARC H. GORELICK, MD, MSCE

Division of Pediatric Emergency Medicine, A. I. duPont Hospital for Children, Wilmington, Delaware, and Department of Pediatrics, Jefferson Medical College, Philadelphia, Pennsylvania

Signs and symptoms of neurologic dysfunction in children either are produced by primary nervous system disorders or are secondary to systemic disease. The differential diagnosis of many such neurologic findings can be found in the first section of this book. This chapter focuses on the management of conditions primarily involving the various parts of the nervous system, including the brain, spinal cord, and peripheral nerves. The illnesses are classified by their most prominent clinical manifestations: seizures, altered mental status, headache, weakness, disorders of balance, abnormal movements, and cranial nerve dysfunction.

SEIZURES (SEE ALSO CHAPTER 70)

Seizures are among the more common neurologic symptoms that lead to an emergency department (ED) visit. Epidemiologic studies indicate that from 3 to 6% of children will have at least one seizure in the first 16 years of life; most of these are simple febrile seizures, discussed in the following section. Fortunately, recurrent seizures or other signs of neurologic dysfunction occur in only a small number of these children. However, the first seizure is always frightening and produces anxiety.

A *seizure* is defined as a transient, involuntary alteration of consciousness, behavior, motor activity, sensation, and/or autonomic function caused by an excessive rate and hypersynchrony of discharges from a group of cerebral neurons. The term *convulsion* is often used to describe a seizure with prominent motor manifestations. Epilepsy, or seizure disorder, is a condition of susceptibility to recurrent seizures.

Most seizures are brief, lasting less than 10 to 15 minutes. *Status epilepticus* refers to seizures that are continuous for 30 minutes or longer or to repetitive seizures between which the patient does not regain consciousness.

Pathophysiology

The basic pathophysiologic abnormality common to all seizures and convulsions is the hypersynchrony of neuronal discharges. Many precipitating factors, including metabolic, anatomic, and infectious abnormalities (see Chapter 70), may produce seizures. Seizures that result from an identified precipitant are called symptomatic, or provoked, seizures, whereas those with no precipitating factor are called idiopathic or cryptogenic. Febrile seizures (seizures occurring in association with a febrile illness, without evidence of intracranial infection or other identified cause) are a particular type of provoked seizure seen in children between the ages of 6 months and 6 years. The exact cause of febrile seizures remains elusive. Elevated body temperature lowers the seizure threshold, and the immature brain appears to have a particular susceptibility to seizures in response to fever. It is unclear whether height of fever or rate of temperature rise is more important in inducing febrile seizures, but individual predisposition plays an important role.

During a seizure, cerebral blood flow, oxygen and glucose consumption, and carbon dioxide and lactic acid production increase. If the patient remains well-ventilated, the increase in cerebral blood flow is sufficient to meet the increased

metabolic requirements of the brain. Brief seizures rarely produce lasting deleterious effects on the brain; however, prolonged and serial seizures, especially status epilepticus, may be associated with permanent neuronal destruction.

Clinical Manifestations

When the physician is faced with a child with an acute paroxysmal event, the first step is to distinguish seizures from other nonepileptic phenomena. If the event is indeed a seizure, it may be classified according to type. Finally, a specific causative factor should be sought. The extent of the emergency evaluation is determined by the clinical scenario; some of the diagnostic assessment may be deferred. Of course, when a child is actively seizing, the first priority is to provide necessary resuscitation measures and control the seizures (see Chapter 70 and the following).

Nonepileptic Paroxysmal Events

Paroxysmal events other than seizures that involve changes in consciousness or motor activity are common during childhood and may mimic epilepsy (Table 83.1). Breath-holding spells occur in children 6 months to 4 years of age. Breath-holding spells take two forms: cyanotic and pallid. In the cyanotic form, the infant begins crying vigorously, often in response to an inciting event, then holds his or her breath and becomes cyanotic. After approximately 30 to 60 seconds, the child becomes rigid. As the spell ends, the child becomes limp and may have a transient loss of consciousness and twitching or jerking of the extremities, but quickly returns to full alertness. A pallid breath-holding spell may follow a seemingly insignificant trauma. The child may start to cry, but then turns pale and collapses. There is a brief period of apnea and limpness, followed by rapid recovery. In both types of breath-holding spells, the typical history and lack of postictal drowsiness help determine the diagnosis. Breath-holding spells may be recurrent but disappear spontaneously before school age.

Breath-holding spells	Acute dystonia
Syncope	Gastroesophageal reflux
Migraine	Night terrors
Jitteriness	Sleep paralysis
Benign myoclonus	Narcolepsy
Shuddering attacks	Pseudoseizures
Tics	

Table 83.1. Nonepileptic Events That May Mimic Seizures

Syncope is a brief, sudden loss of consciousness and muscle tone. There are numerous causes of syncope, many of which can be detected on the basis of historical information, physical examination, and simple laboratory tests (see Chapter 73). A syncopal episode can usually be distinguished from a seizure based on the description. The child is typically upright before the event and often senses a feeling of light-headedness or nausea. The child then becomes pale and slumps to the ground. The loss of consciousness is brief, and recovery is rapid. On awakening, the child is noted to have signs of increased vagal tone, such as pallor, clammy skin, dilated pupils, and relative bradycardia. Patients with narcolepsy also experience sudden alterations in alertness, with sleep occurring suddenly and uncontrollably during the daytime. In about half of the patients, narcolepsy is associated with cataplexy, a sudden loss of muscle tone brought on by a sudden emotional outburst. Narcolepsy is far less common than syncope; both occur more often in adolescents than in younger children.

Single episodes of staring, involuntary movements, or eye deviation have been found to occur commonly in the first months of life, although they rarely lead to the parent seeking medical attention. In some children, however, these episodes occur frequently. Children with benign shuddering attacks have episodes of staring and rapid tremors involving primarily the arms and head, sometimes associated with tonic posturing. The episode lasts only a few seconds, and afterward the child resumes normal activity. Acute dystonia, usually seen as a side effect of certain medications, can mimic a tonic seizure. The child having a dystonic reaction, however, does not lose consciousness and has no postictal drowsiness.

Several paroxysmal events are associated with sleep. Night terrors (see Chapter 131) usually begin in the preschool years. The sleeping child wakes suddenly, is confused and disoriented, and appears frightened, often screaming and showing signs of increased autonomic activity (tachycardia, tachypnea, sweating, dilated pupils). Such episodes typically last only a few minutes, and the child does not usually recall the event. Benign myoclonus is characterized by self-limited episodes of sudden jerking of the extremities, usually upon falling asleep. There is no alteration of consciousness. In sleep paralysis, there is a transient inability to move during the transition between sleeping and waking, also with no change in level of consciousness.

Pseudoseizures are occasionally seen, often in patients with an underlying seizure disorder or with a relative with epilepsy. Some features suggestive of pseudoseizures are suggestibility, lack of coordination of movements, moaning or talking during the “seizure,” lack of continence, autonomic changes, postictal drowsiness, and poor response to treatment with anticonvulsant agents.

The most important diagnostic test in distinguishing nonepileptic events from seizures is a careful history, including a detailed description of the event from the person who witnessed it. In atypical or unclear cases, referral for

electroencephalogram (EEG) or video EEG monitoring may help in establishing the diagnosis.

Types of Seizures

Clinically, seizures may be divided into partial and generalized seizures (Table 83.2). Generalized tonic-clonic seizures (previously called grand mal seizures) are the type most often seen in acute pediatric care. The onset of generalized tonic-clonic seizures usually is abrupt, although 20 to 30% of children may experience a sensory or motor aura. If sitting or standing, the child falls to the ground. The face becomes pale, the pupils dilate, the eyes deviate upward or to one side, and the muscles contract. As the increased tone of the thoracic and abdominal muscles forces air through the glottis, a grunt or cry may be heard. Incontinence of urine or stool is common. After this brief tonic phase (10 to 30 seconds), clonic movements occur. The child is unresponsive during the seizure and remains so, postictally, for a variable period. After the seizure, there may be weakness or paralysis of one or more areas of the body (Todd's paralysis). In atonic, or akinetic, seizures (drop attacks), there is abrupt loss of muscle tone and consciousness. Myoclonic seizures are characterized by a sudden dropping of the head and flexion of the arms (“jackknifing”); however, extensor posturing also may occur. The episodes occur quickly and frequently, as often as several hundred times daily.

Generalized	Partial (Focal)
Absence (petit mal)	Simple (no impaired consciousness)
Typical	Motor
Atypical	Sensory
Tonic-clonic (grand mal)	Autonomic
Clonic	Psychic
Tonic	Complex (impaired consciousness)
Myoclonic	Partial seizures becoming partially generalized
Akinetic/atonic (drop attacks)	

Table 83.2. Seizure Types

Absence (petit mal) seizures are generalized seizures marked by sudden and brief loss of awareness, usually lasting 5 to 30 seconds. With typical absence seizures, there is no loss of posture or tone and no postictal confusion. There may be a minor motor component such as eyelid blinking.

The child with simple partial (focal) seizures has unimpaired consciousness. Motor signs are most common in children, although sensory, autonomic, and psychic manifestations are possible. The motor activity usually involves the hands or face and spreads in a fixed pattern determined by the anatomic origin of the nerve fibers that innervate the various muscle groups. Focal seizures may become secondarily generalized, in which case there will be alteration of consciousness. Complex partial seizures, also called psychomotor or temporal lobe seizures, exhibit a diverse set of clinical features, including alterations of perception, thought, and sensation. In children, they are usually marked by repetitive and complex movements with impaired consciousness and postictal drowsiness.

Establishing an Underlying Cause

The first steps in the evaluation of seizures are a thorough history and a physical examination, the results of which are helpful in determining the direction of the search for a specific cause. Important historical items to elicit include fever, trauma, underlying illnesses, current medications, and possible toxic ingestions. A complete neurologic assessment to evaluate for signs of increased intracranial pressure (ICP), focal deficits, or signs of meningeal irritation is also essential.

An important distinction is whether the seizure is associated with fever. Simple febrile seizures are those that are single, brief (less than 15 minutes), and generalized. Approximately 20% of febrile seizures are complex, meaning they are focal, are prolonged (more than 15 minutes), or occur multiple times during the same illness. In children older than 12 months of age with a typical simple febrile seizure and no evidence of meningeal signs, no further evaluation of the seizure is generally required. Clinically unsuspected meningitis is exceedingly rare in such children. In one study of 503 children with meningitis, none presented with an isolated febrile seizure; conversely, two other studies of 803 children found meningitis in none of the children with a febrile seizure but no other clinical findings of meningitis. Lumbar puncture (LP) is mandatory if meningitis is suspected on the basis of physical findings. An LP should be strongly considered in children younger than 12 months of age, in whom signs of meningitis may be subtle, or when the febrile seizure is complex. In addition, LP should be considered for children with prolonged fever before the seizure, particularly those who have sought medical care in the previous 48 hours and who have been found to be at higher risk. Other laboratory tests discussed in the next paragraph have been found to have little yield in the child with a typical febrile seizure and are unnecessary. Other diagnostic tests to determine the source of the fever are determined by other features such as the height of fever and child's age because the frequency of specific infections such as occult bacteremia is not increased in children who have experienced a febrile seizure.

For the child who presents with a first-time, nonfebrile seizure, laboratory or radiologic evaluation to search for a specific treatable cause of the seizure may be indicated. There is little utility in extensive, routine workups; rather, ancillary test selection should be guided by the results of the history and physical examination. Because hypoglycemia may be clinically difficult to detect, a rapid glucose test should be performed on all children. In young infants, children with prolonged seizures, and those with a suggestive history or physical examination, determination of serum sodium and calcium is also indicated. Other laboratory tests that may be indicated, depending on the clinical picture, include serum magnesium, hepatic transanimases, ammonia, and serum or urine toxicology tests. LP is rarely emergently necessary in

the afebrile child without meningeal signs, although it should be considered in neonates even without fever.

In children with a known seizure disorder, subtherapeutic anticonvulsant levels are the most common reason for recurrent seizures. The name and dosage of anticonvulsant medications used should be elicited, as well as the time of the last dose given, any missed doses, the last change in dosage, and recent levels if known. Intercurrent illness may also play a role because the metabolism of some medications is affected by systemic illness. Such children should have blood drawn for measurement of anticonvulsant levels. Although many drugs have a therapeutic range (Table 83.3), individual patients may require levels outside that range for adequate seizure control; conversely, dose-dependent toxic effects may be observed in some children even at typically therapeutic levels.

Drug	Seizure Type	Daily Dose (mg/kg)	Oral Dosage Forms	Serum Half-Life (h)	Therapeutic (Blood Levels (µg/mL)
Carbamazepine (Tegretol)	Generalized motor, partial, complex partial	10–30	Tablets: 100, 200 mg Suspension: 100 mg/5 mL	8–24	4–12
Phenytoin (Dilantin)	Generalized motor, partial, complex partial	3–10	Capsule: 100 mg Chewable tab: 50 mg Suspension: 125 mg/5 mL	10–30	10–20
Phenobarbital	Generalized motor, partial, complex partial	3–4	Tablets: 15, 30, 60, 100 mg Elixir: 20 mg/5 mL	24–96	15–40
Primidone (Mysoline)	Generalized motor, partial, complex partial	10–25	Tablets: 50, 250 mg Suspension: 50 mg/5 mL	12	5–12 (plus measure phenobarbital level)
Valproate (Depakote)	Absence, myoclonic, partial complex, generalized motor	20–40	Tablets: 125, 250 mg Sprinkles: 125 mg Syrup: 250 mg/5 mL	8–18	50–100
Ethosuximide (Zarontin)	Absence	20–40	Capsule: 250 mg Syrup: 250 mg/5 mL	30–60	40–100
Lamotrigine (Lamictal)	Partial, atonic, myoclonic, mixed types	10–15	Tablets: 25, 100, 150 mg	24	Not known
Clonazepam (Klonopin)	Atonic, myoclonic, generalized motor	0.03–0.1	Tablets: 0.5, 1, 2 mg	18–50	0.020–0.080 (20–80 ng/mL)

Table 83.3. Commonly Used Anticonvulsant Agents

Computed tomography (CT) and magnetic resonance imaging (MRI) allow detailed visualization of the gross anatomy of intracranial structures by a noninvasive technique. Presently, CT is more available on an emergent basis in most institutions. It also is a shorter procedure, and patient monitoring is usually easier. CT (or MRI, if available) is indicated in the emergency evaluation of prolonged or focal seizures, when focal deficits are present, when there is a history of trauma, when the child has a ventriculoperitoneal shunt, or when there are associated signs of increased ICP. For other children, an imaging study may be useful in identifying structural anomalies and determining prognosis, but such studies may be deferred to a follow-up visit. Cranial imaging is not indicated in the evaluation of simple febrile seizures.

EEG is also helpful in the evaluation of children with nonfebrile seizures. It is rarely beneficial in acute management, but children with nonfebrile seizures should be referred for outpatient testing.

Management

Resuscitation and Supportive Care

The administration of nasal oxygen and maintenance of an adequate airway are vital parts of the initial management of the unconscious, actively convulsing child (see Chapter 70). Trismus often occurs in generalized seizures but is transient. If the teeth are tightly clenched, even the placement of the airway should be deferred until it can be inserted without undue trauma during a phase of relaxation. Seizure-associated hypoventilation and apnea are common with prolonged seizures, often as a side effect of anticonvulsant medications, and providers caring for such children should be prepared to offer assisted ventilation. Intravenous access should be established promptly; however, because of the potential for increased ICP, fluid therapy should be used judiciously until a more thorough evaluation is performed. The child with active convulsions should be protected from trauma. There is no benefit to placing objects in the child's mouth to prevent tongue biting.

Stopping the Seizure

It is unusual for the child with a brief seizure to arrive in the ED actively convulsing because, by definition, such seizures last less than 15 minutes. Therefore, the actively convulsing child usually is already in a prolonged or serial seizure state, and pharmacologic intervention to terminate the seizure is required (Fig. 83.1).

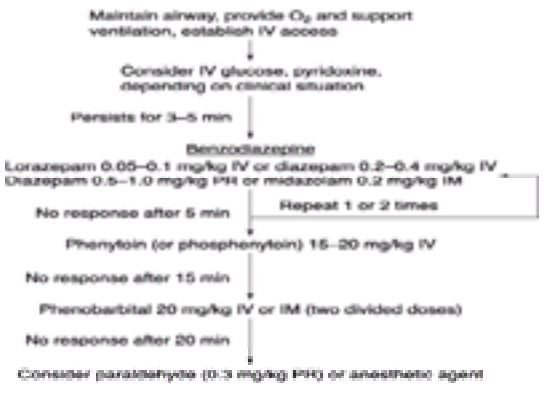

FIGURE 83.1. Treatment of status epilepticus. O_2, oxygen; *IV,* intravenous; *PR,* per rectum; *IM,* intramuscular.

Intravenous access is established, and blood is drawn for diagnostic studies. If hypoglycemia is documented by rapid glucose assay or if rapid determination is unavailable, intravenous glucose is given in a dose of 2 to 4 mL/kg of 25% dextrose in water. In neonates or in children with suspected isoniazid toxicity, pyridoxine 100 mg intravenously (IV) may be administered.

In most situations, benzodiazepines are the first drug of choice for acute seizures because of their rapidity of action. Lorazepam (Ativan) is the preferred agent. Given in a dose of 0.05 to 0.1 mg/kg IV (maximum 4 mg/dose), it has an onset of action of 2 to 5 minutes, and the duration of anticonvulsant effect is 12 to 24 hours. The dose may be repeated after 5 to 10 minutes. An alternative is diazepam (Valium), 0.2 to 0.4 mg/kg IV (maximum 10 mg/dose), which has a similarly rapid onset of action but a much shorter duration of anticonvulsant activity, usually less than 30 minutes. Thus, if diazepam is used, another agent for longer-term control, such as phenytoin, is needed to prevent seizure recurrence. If IV or intraosseous access cannot be established, diazepam may be administered rectally in a dose of 0.5 to 1.0 mg/kg, instilling the IV formulation with a syringe. Intramuscular midazolam (Versed) has also been shown to be effective in a dose of 0.2 mg/kg (maximum 7 mg). Midazolam may also be given intravenously.

All of the benzodiazepines can cause sedation and respiratory depression. Equipment for establishing an airway and supporting respiration must be available, especially if repeated doses are used. Sedation and respiratory depression may persist for hours, particularly with diazepam. Hypotension is uncommon but may be a problem with multiple doses or when barbiturates are administered concomitantly.

If the seizures have not been controlled within 15 minutes with benzodiazepines, phenytoin (Dilantin) should be given. Phenytoin is administered IV, at a loading dose of 15 to 20 mg/kg. In patients known to be taking phenytoin chronically, a smaller dose of 5 to 10 mg/kg should be used initially unless the serum level is known to be very low. Each 1 mg/kg of phenytoin administered raises the serum level by approximately 1 mg/mL. Phenytoin is highly lipid soluble and reaches therapeutic levels in the brain within 10 to 20 minutes, with a duration of action of 12 to 24 hours. Because rapid IV infusion may lead to hypotension and cardiac arrhythmias, the maximum rate of administration is 50 mg/minute, and cardiac monitoring is required. Local reactions such as thrombophlebitis are also common. Fosphenytoin (Cerebyx) is a recently developed prodrug of phenytoin, which is rapidly metabolized to the active form. It offers several advantages over phenytoin, including more rapid administration (150 mg/minute) and fewer local and systemic side effects. Fosphenytoin may also be given intramuscularly, unlike phenytoin. The dose of the two drugs is identical; fosphenytoin doses are expressed as phenytoin equivalents. Although pediatric data are sparse, the pharmacokinetics and safety profile of fosphenytoin appears to be similar to that seen in adult patients. Unlike other anticonvulsant medications, phenytoin does not cause sedation or respiratory depression.

Phenobarbital is the next agent to be added if phenytoin is not effective or contraindicated (e.g., allergy, known therapeutic level). The loading dose of phenobarbital is 20 mg/kg, usually given in two divided doses. The drug is given intravenously over 5 to 10 minutes, or intramuscularly in the absence of IV access. Onset of action is usually within 15 to 20 minutes and lasts more than 24 hours. Phenobarbital, like other barbiturates, may cause significant sedation and hypotension.

Patients with status epilepticus that lasts more than 60 minutes present a special problem. Further management should be done in conjunction with a neurologist and with EEG monitoring when possible. Continuous infusion of benzodiazepines may be used. Paraldehyde is often effective but is difficult to handle because of its foul odor, reactivity with rubber and plastic (necessitating the use of glass syringes), and lack of water solubility. A dose of 0.3 mg/kg diluted 1:1 in oil may be given rectally. Other agents potentially useful in the management of refractory status epilepticus include pentobarbital and general anesthetics such as isoflurane, etomidate, and propofol.

With prolonged seizures, the duration of postictal drowsiness and confusion may also be protracted. However, the child who fails to arouse within 15 to 30 minutes after cessation of seizures should be evaluated carefully to rule out nonconvulsive status epilepticus. Children with status epilepticus, even if successfully treated in the ED, should be admitted to the hospital for monitoring and observation.

Rarely, a child may enter the ED in absence status. In this case, the child may be sitting in a confused or dreamy state. Such attacks may last for hours or even days. The drug of choice in the treatment of absence status is lorazepam or diazepam at the dosages already outlined.

At times, a child may enter the ED with continual focal seizure activity (with or without clouding of consciousness), a condition known as epilepsia partialis continua. The treatment for partial seizures is less urgent than that for generalized seizures, and such seizures are often intractable to anticonvulsant medication. In such cases, phenytoin or fosphenytoin in a dose of 18 to 20 mg/kg can be infused slowly. All such patients should be admitted to the hospital for further observation and evaluation. Other pharmacologic attempts to control these focal seizures should be performed in the hospital.

Initiating Anticonvulsant Medication

Nonfebrile Seizures The decision to initiate long-term prophylactic therapy with anticonvulsant medications is based on a consideration of a number of factors, including the patient's age, type of seizure, risk of recurrence, coexisting medical conditions, and family factors. The consequences of further seizures must be balanced against the potential side effects of the anticonvulsant agents. Treatment is seldom started after a single, uncomplicated nonfebrile seizure because most such patients will not experience a seizure recurrence. On the other hand, a patient who has had two or more such seizures should generally receive anticonvulsant therapy. When possible, it is preferable for long-term treatment decisions to be made in conjunction with the provider who will be responsible for ongoing follow-up of the patient, either a neurologist or the child's primary care physician. Sometimes, it may be necessary to begin prophylactic treatment in the

ED, pending a more complete outpatient evaluation.

A number of drugs are effective in preventing seizures (Table 83.3). Some are better for certain types of seizures, and all have different profiles of adverse effects. The following principles should guide selection of an anticonvulsant medication:

1. Choose a drug that is effective for the particular type of seizure. When more than one agent is available, choose the least toxic one. Initial therapy should be with a single agent.
2. Start at the low end of the dosage range.
3. Arrange for a serum level of the drug to be measured, when appropriate. This is done after a steady state is anticipated, usually five times the half-life of the drug.
4. If a child is already taking an anticonvulsant medication and has an adequate level, consider adding another agent.

Carbamazepine (Tegretol) Carbamazepine is effective against generalized tonic-clonic seizures as well as simple and complex partial seizures. The effective serum concentrations of carbamazepine range between 4 and 12 µg/mL, but with this drug, there is a variable correlation among clinical efficacy, toxicity, and the serum concentration. Recommended maintenance dosages range between 10 and 30 mg/kg per day, divided into three daily doses. The administration of a total maintenance dose to a previously untreated patient often results in drowsiness, blurred vision, and at times, severe lethargy, so this drug should be initiated by gradual increases in dosage (10 mg/kg per day to start, increased by 5 mg/kg per day every 3 to 4 days) until a full maintenance level is reached. Unlike several other agents, it is not available in an IV form. Concomitantly administered medications that may lead to toxic carbamazepine levels include macrolide antibiotics (e.g., erythromycin), isoniazid, cimetidine, verapamil, and diltiazem.

Carbamazepine may cause hepatic and hematologic toxicity but causes little, if any, cognitive dysfunction in most patients. Therefore, it often is the drug of choice for children with generalized seizures.

Phenobarbital Phenobarbital is another broad-spectrum anticonvulsant useful for generalized tonic-clonic and partial (simple and complex) seizures. It remains a commonly used initial drug, primarily because of its low cost and low toxicity. The effective serum concentration ranges between 15 and 40 µg/mL. This serum level usually can be maintained with a dosage of 3 to 6 mg/kg per day in children and 1 to 2 mg/kg per day in adolescents, administered in divided doses twice daily. A loading dosage of approximately twice the maintenance dosage (6 to 10 mg/kg per day in children and 2 to 4 mg/kg per day in adolescents) for 2 to 3 days brings the serum concentration to the therapeutic range within 48 to 72 hours. Such loading dosages usually are associated with considerable transient drowsiness. There is a wide margin between the anticonvulsant and soporific effects of phenobarbital, and drowsiness rarely persists at the recommended dosages. Decreased attention, hyperactivity, and alterations of mood occur in 30 to 50% of children maintained on phenobarbital. These behavioral changes are the most commonly encountered side effects and often are sufficiently undesirable to force the change to another drug. Possible associated long-term cognitive effects also makes phenobarbital problematic, and many clinicians do not consider it a first-line drug.

Primidone (Mysoline) Primidone has a similar effectiveness and side effect profile to phenobarbital, one of its main metabolites. The maintenance dosage is 10 to 25 mg/kg per day, given in two to four divided doses. The therapeutic serum level is 5 to 12 µg/mL; the serum level of phenobarbital should also be monitored when using primidone.

Phenytoin (Dilantin) Phenytoin is another agent effective in the treatment of several seizure types, including generalized motor seizures and both simple and partial complex seizures. The effective serum concentration of phenytoin is between 10 and 20 mg/mL. The usual maintenance dosage is 7 to 10 µg/kg per day in children weighing less than 20 kg, 5 to 7 mg/kg per day in children weighing between 20 and 40 kg, and 5 mg/kg per day in children weighing more than 40 kg, given in once or twice daily doses. However, there is considerable variation in metabolism among patients. Saturation of biotransforming enzyme systems often occurs between serum levels of 10 and 20 µg/mL, so small changes in a dose in this range may lead to relatively large changes in serum levels.

Loading dosages of four times the daily dosage (maximum 20 mg/kg per day) on the first day and two times the daily dosage for the next 2 days will bring serum levels into the therapeutic range within 24 hours; side effects rarely occur with this loading dosage. Gingival hyperplasia is a common side effect and may be seen with phenytoin concentrations in the therapeutic range; this cosmetic side effect and the drug's tendency to cause hirsutism and coarsening of facial features often limit long-term use, especially in girls. Drowsiness, ataxia, nystagmus, and seizures are dose-dependent toxic effects rarely seen with levels in the therapeutic range. Other adverse effects include drug rashes (Stevens-Johnson syndrome) and hematologic and hepatic side effects. Several medications may cause increased phenytoin levels: cimetidine, estrogens, chlorpromazine, chloramphenicol, and isoniazid.

Valproate (Depakote) Valproate is highly effective in the treatment of generalized epilepsy, including especially absence and myoclonic seizures, as well as simple and complex partial seizures. Doses of 20 to 40 mg/kg usually result in therapeutic levels of 50 to 100 µg/mL. However, serum drug levels may not be highly predictive of efficacy or toxicity. The primary side effects include gastrointestinal upset and drowsiness; hepatic, renal, pancreatic, and hematologic dysfunction are also seen. Children younger than 2 years old are at particular risk of idiosyncratic fatal hepatotoxicity. Therefore, valproate is rarely the initial drug of choice for young children with generalized seizures.

Clonazepam (Klonopin) Clonazepam is used to control myoclonic and atonic seizures. The usual dosage is 0.05 to 0.2 mg/kg per day, given in two to four divided doses. The therapeutic range is 0.02 to 0.08 µg/mL (10 to 80 ng/mL). Patients taking clonazepam may experience drowsiness, ataxia, and drooling.

Ethosuximide (Zarontin) Ethosuximide is indicated for the management of absence seizures. It is given at a dosage of 20 to 40 mg/kg per day divided into twice daily doses, with a usual therapeutic level of 40 to 100 µg/mL. Side effects include headache, nausea, and vomiting; erythema multiforme and a lupuslike syndrome have also been reported.

Lamotrigine (Lamictal) Lamotrigine is a new agent available for treatment of partial seizures, atonic and myoclonic

seizures, and intractable mixed seizures (Lennox-Gastaut syndrome). The usual dosage is 10 to 15 mg/kg per day, which is reduced to 5 mg/kg per day when given in conjunction with valproate. Drowsiness, vomiting, and drug rash (including Stevens-Johnson syndrome) are reported side effects.

Other Agents Several new agents are newly available in the United States or currently under investigation. These include vigabatrin (Sabril), gabapentin (Neurontin), and felbamate (Felbatol). Because of the risk of severe hepatotoxicity, felbamate is restricted to use in children with intractable seizures refractory to other treatment.

Febrile Seizures. For children with febrile seizures, the issue of chronic prophylactic medication is more controversial. Presumptive antipyretic therapy for a nonspecific illness does not appear to reduce the risk of seizure recurrence, although it may give the parent a sense of “doing something.” Phenobarbital was widely used in the past for children with recurrent febrile seizures, but this practice is much less common now because of concerns about adverse cognitive and behavioral effects of the medication. To be effective, phenobarbital must be given continuously. Other commonly used anticonvulsant agents such as phenytoin and carbamazepine appear to be ineffective. More recently, some clinicians have used diazepam, administered intermittently during febrile illnesses (0.33 mg/kg every 8 hours), to prevent febrile seizures. One controlled trial showed this treatment to be effective, albeit with a high incidence of side effects; in addition, other studies have failed to confirm the effectiveness of this approach, largely as a result of poor compliance or inadequate recognition of fever. With little evidence that febrile seizures (even febrile status epilepticus) cause permanent neurologic damage or that their control results in a lower incidence of subsequent epilepsy, there is little need to treat most patients. In carefully considered individual cases, long-term continuous therapy with phenobarbital or intermittent therapy with diazepam may be considered. This should usually be done in conjunction with the child's primary care provider.

Disposition Hospital admission is generally required for children who have had a prolonged seizure requiring acute treatment with anticonvulsant medication. Other children, even those with a first-time seizure, can generally be followed as outpatients if they appear well after the seizure, follow-up can be ensured, and the parents are comfortable with home management. Seizure first-aid should be explained to the family before discharge.

After a simple febrile seizure, hospitalization is seldom necessary, and children may be followed by their primary physician. Some useful information can be given to parents after a first febrile seizure. First, they should be informed of the benign nature of the convulsions and the lack of evidence that they cause any type of neurologic injury. Approximately one-third of children with a first febrile seizure will have another one. Of recurrences, 75% occur within 1 year, and they are uncommon beyond 2 years; fewer than 10% of children with febrile seizures have more than three. The recurrence rate is lower if the seizures begin after the first year of life, and the risk is also reduced in children with higher temperature and longer duration of fever before the initial febrile seizure. For example, the recurrence risk is about 35% when the first seizure occurs at a temperature of 38.5°C (101.3°F), compared with a risk of 13% with a temperature of 40°C (104°F). Having a complex first febrile seizure (even febrile status epilepticus) does not increase the risk of recurrence, nor does it increase the chance that a recurrent seizure, if it occurs, will be complex.

Many parents worry that febrile seizures will lead to future epilepsy. A child who has had a febrile seizure but no other risk factors for epilepsy may have a slightly increased risk of future nonfebrile seizures, but the magnitude of this increase is still extremely small: 1 to 2% lifetime risk versus a 0.5 to 1% lifetime risk in the general population. Several risk factors that increase the likelihood of a child experiencing future nonfebrile seizures have been identified. These risk factors include a family history of epilepsy, a complex febrile seizure, and the presence of an underlying neurologic or developmental abnormality. Importantly, even with two or more of these risk factors, the risk of epilepsy is only 10%. Thus, for most children with no risk factors, the parents may be reassured that future epilepsy, although possible, is extremely unlikely. Furthermore, there is no association between febrile seizures and any type of developmental or learning disabilities.

DISORDERS THAT PRESENT WITH ENCEPHALOPATHY (SEE CHAPTER 13)

Encephalopathy is an imprecise term that implies diffuse brain dysfunction with or without alterations in the level of consciousness. The emergency physician often must decide whether the child's degree of irritability, uncooperativeness, and lethargy is proportionate to the degree of systemic illness; whether it is caused by fear; or whether it represents cortical dysfunction. Encephalopathy may be a sign of numerous systemic disorders, or it may result from certain primary disorders of the central nervous system (CNS), discussed next.

Encephalitis

Background

Encephalitis is an inflammation of the brain parenchyma. When there is an associated leptomeningeal involvement (as often occurs), the term *meningoencephalitis* may be applied, whereas *encephalomyelitis* implies involvement of the spinal cord as well. CNS dysfunction is caused by direct invasion of brain by a pathogen, most often a virus, or is secondary to immunologic mechanisms, as in postinfectious encephalomyelitis.

Viral encephalitides are caused by a wide variety of viruses that lead to clinically similar illnesses (Table 83.4). Mumps was the most common cause of meningoencephalitis before the introduction of vaccination, with up to 50% of patients with mumps parotitis having cerebrospinal fluid (CSF) pleocytosis. Classically, the illness occurs several days to 2 weeks after the onset of parotitis but may precede the onset of systemic illness or occur without parotitis and tends to be mild. Measles encephalitis is less common since the advent of widespread live immunization. The onset usually occurs during the prodromal period or after the rash has appeared. Ataxia is the most common neurologic abnormality, and sequelae occur in up to 30% of cases. Varicella encephalitis occurs 2 to 9 days after the onset of the rash; severe infections are uncommon, except in the immunosuppressed host.

Arboviruses	Varicella-zoster
Eastern equine encephalitis	Epstein-Barr
Western equine encephalitis	Cytomegalovirus
St. Louis encephalitis	Mumps
Japanese encephalitis	Measles
California (LaCrosse) encephalitis	Enteroviruses
Herpesviruses	Rabies
Herpes simplex	

Table 83.4. Agents of Viral Encephalitis

The arthropodborne encephalitides--including St. Louis, Western equine, Eastern equine, and California encephalitis--occur in sporadic and epidemic forms, often in late summer or early fall, and tend to cluster in localized geographic areas. Sequelae may be severe and mortality high, especially in eastern equine encephalitis.

Herpes simplex virus (HSV) is a common cause of sporadic encephalitis. Disease in neonates is usually caused by HSV type 2, acquired from perinatal transmission. In previously healthy older children and adults, encephalitis usually results from infection with HSV type 1 and may be a complication of acute primary infection or reactivated latent infection. Recognition of herpes encephalitis is important because specific antiviral therapy reduces the substantial morbidity and mortality of this disease.

Infection with rabies virus, although rare in the United States, is an important cause of encephalitis worldwide. Nonviral pathogens, including *Mycoplasma pneumoniae,* Lyme disease, and rickettsiae, may also cause encephalitis.

Postinfectious encephalitis may follow infection with numerous viruses, including measles, varicella, influenza, and Epstein-Barr virus. The CNS involvement may be confined to a specific area, as in acute cerebellar ataxia after varicella infection, or may be widespread. The latter condition is often designated acute disseminated encephalomyelitis. A particularly virulent form with high mortality is known as acute hemorrhagic leukoencephalitis. A clinical syndrome of encephalopathy after immunization, particularly with whole-cell pertussis vaccine, is also described, although more recent epidemiologic evidence has called into question the association with pertussis immunization.

Pathophysiology

Viral encephalitis usually follows a viremia, although direct spread can occur less commonly via peripheral nerves or the nasal mucosa. Upon reaching the CNS, viral replication in neural cells interferes with cellular function and may lead to cell death. Cerebral edema may result from capillary leakage, with subsequent increased ICP. The degree and extent of neuronal dysfunction depends in part on the pathogen involved and also on host factors, especially immunocompetence. In general, the incidence of overt neurologic findings and sequelae is higher in children younger than 1 year of age.

Postinfectious encephalitis is presumed to be an immune-mediated phenomenon, involving the white matter of the CNS. Demyelination, the pathologic hallmark of the disease, may be focal or widespread.

Clinical Manifestations

The clinical picture of viral encephalitis ranges from a mild febrile illness associated with headache to a severe, fulminant presentation with coma, seizures, and death. The onset of encephalitis may be abrupt or insidious. Typical features consist of fever, headache, vomiting, and signs of meningeal irritation. Altered consciousness, ataxia, and seizures are also seen. Focal neurologic deficits occur in certain types of encephalitis, particularly HSV. Flaccid paralysis may be seen in cases of encephalomyelitis, and rarely, respiratory or cardiac dysfunction results from brainstem involvement. Rash or mucous membrane lesions are often seen with the exanthematous viruses such as measles and varicella; however, cutaneous findings are uncommon with HSV encephalitis.

Laboratory assessment often is nonspecific. The peripheral blood count usually shows a mild polymorphonuclear or mononuclear leukocytosis. With viral encephalitides, CSF pleocytosis is variable and, if present, usually is fewer than 500 cells/mm^3. These cells may be predominantly polymorphonuclear early in the course of the illness; however, a mononuclear predominance is common later. Red blood cells are present in the CSF in approximately 50% of children with herpes encephalitis. Spinal fluid protein and glucose usually are normal with viral encephalitis, but the protein may be greatly elevated in postinfectious encephalomyelitis.

Virus isolation from the CSF may be difficult but should be attempted, as should viral isolation from other body sites, including the nasopharynx, skin lesions, urine, and feces. Serologic evidence for viral infection based on acute and convalescent IgG titers, although useful later, gives little help in making an immediate diagnosis. Infection with arboviruses may be established more rapidly by detecting virus-specific IgM in CSF or serum.

Diagnosis of herpes simplex poses a special problem because early diagnosis is important in instituting effective therapy. When available, polymerase chain reaction (PCR) testing of CSF yields rapid evidence of viral nucleic acid and is highly sensitive and specific. Imaging studies, although less sensitive, may also be useful. Either CT or MRI may demonstrate focal parenchymal involvement or edema of the temporal lobes (Fig. 83.2). MRI is more sensitive than CT, although both may be normal in the early stages of disease. Similarly, EEG may demonstrate focal slowing or epileptiform discharges

localized to the temporal lobes, but absence of such findings does not rule out herpes encephalitis.

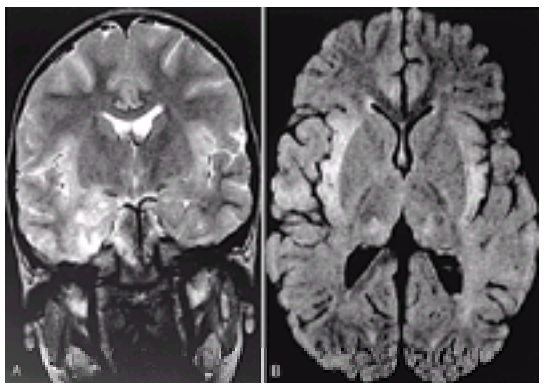

FIGURE 83.2. Coronal **(A)** and axial **(B)** T_2-weighted magnetic resonance images showing multifocal areas of abnormal signal in the medial aspects of both temporal lobes *(large arrow)* and left posterior parietal lobe *(small arrow)* in a patient with herpes simplex encephalitis.

Management

Presently, the treatment of nonherpes viral encephalitis is primarily supportive. Children with very mild manifestations may be followed at home, but those with more significant illness should be hospitalized for observation and monitoring of neurologic status, treatment of increased ICP if present, and fluid restriction and monitoring of urine output and serum sodium because of the risk for inappropriate antidiuretic hormone (ADH) secretion.

Herpes simplex encephalitis causes death or neurologic sequelae in more than 70% of patients. Treatment with acyclovir (30 to 60 mg/kg per day divided three times daily for 14 to 21 days) has resulted in a decrease in mortality and some improvement in morbidity. It must be used early in the disease to achieve maximum benefit. Thus, acyclovir should be considered in all patients suspected of having herpes encephalitis on the basis of clinical or epidemiologic grounds (e.g., history of exposure, oral vesicles, focal neurologic or radiographic findings); because clinical features and laboratory tests are not perfectly sensitive, initial presumptive treatment may be indicated even in the absence of corroborating evidence.

Hemorrhagic Shock and Encephalopathy Syndrome

Hemorrhagic shock and encephalopathy syndrome (HSES), first described in 1983, is a syndrome of catastrophic illness that affects infants less than 1 year of age. It is characterized by the sudden onset of coma, seizures, and shock in a previously healthy infant. Despite the fact that many reported infants with HSES had recent or intercurrent viral illness, no causal link has been established, and the cause and underlying pathophysiology of HSES are unknown. The clinical features are similar to those seen in severe bacterial sepsis, although cultures are by definition negative in children with HSES. The syndrome also resembles heat stroke, leading to speculation that an abnormality of thermal regulation may be responsible.

No standardized diagnostic criteria for HSES exist. Besides the encephalopathy, seizures, and shock, other consistent features of HSES include high fever at the onset, disseminated intravascular coagulation and hemorrhage, and metabolic acidosis. Affected children have a number of characteristic laboratory abnormalities consistent with multiple organ system dysfunction, including elevation of blood urea nitrogen (BUN), creatinine, hepatic transaminases, and creatine phosphokinase (CPK), anemia, thrombocytopenia, and coagulopathy. The laboratory abnormalities peak in the first 48 hours. Brain CT reveals only cerebral edema in the first few days, followed by development of encephalomalacia in severely ill individuals.

Treatment of infants with HSES consists of intensive supportive care. The prognosis is poor, with 50 to 80% mortality and severe neurologic morbidity in most survivors. With increased recognition of the syndrome, however, there have been reports of less severely ill patients with improved outcome.

DISORDERS THAT PRESENT WITH HEADACHE

Headaches of varying character, severity, and origin affect patients of all ages. Much of the CNS, including the brain parenchyma, is devoid of pain sensors. However, headache may result from compression, inflammation, or distortion of a number of pain-sensitive cranial structures, including the proximal portions of the large cerebral arteries, the arteries of the dura and scalp, the intracranial venous sinuses, the dura, the facial sinuses, orbits, teeth, scalp, muscles, and cervical roots of the spinal cord. A full discussion of the differential diagnosis of headache is given in Chapter 56.

Migraine

Background

Migraine—recurrent headaches separated by long, symptom-free intervals—is probably the most common specific cause of episodic headaches in children. In epidemiologic studies, prevalence estimates for migraine in children range from 3 to 10%. A number of forms of migraine are recognized. Migraine is considered “classic” when the headache is well localized and preceded by an aura and considered “common” when it is not. The common form of migraine predominates in

children. Basilar migraine is a migraine variant that involves the posterior cerebral circulation in which brainstem symptoms, possibly including transient loss of consciousness, predominate. Cluster headaches, which are unilateral, occur in runs and are associated with autonomic changes. They represent a rare migraine variant in childhood. Cyclic vomiting, a syndrome of recurrent, discrete attacks of abdominal pain, nausea, vomiting, and pallor, is also believed to be a migraine variant, sometimes called abdominal migraine.

Pathophysiology

The pathogenesis of migraine is not fully delineated, but the headache is thought to be secondary to paroxysmal vascular instability that results in intracranial vasoconstriction followed by vasodilation. These vascular changes often occur sequentially, resulting in premonitory motor, visual, or sensory symptoms (the vasoconstrictive phase), and then headache (the vasodilation phase). The biochemical basis of this instability may be caused by depression of serotonergic brainstem neurons, although many neuronal transmitter abnormalities have been described.

Clinical Manifestations

Prolonged (up to 24 to 48 hours), moderate to severe headache is characteristic of migraine. The headaches may be pulsating and unilateral but assume this pattern less often in children than in adults. Migraine is commonly associated with nausea, vomiting, abdominal pain, and photophobia or phonophobia. Auras occur in less than half of children who experience migraines. During the headaches, analgesics are relatively ineffective, and children seek a quiet, dimly lit area to rest or sleep. Occasionally, the attacks awaken the children from sleep. The physical examination usually shows no focal neurologic deficits, although hemiplegia and ophthalmoplegia may occur in complicated migraine. Unless these episodes have occurred previously, their presence warrants further neurologic evaluation, usually in the form of CT or MRI scanning.

A family history of migraine is helpful in diagnosis, and a disproportionate number of children who experience migraines have episodes of motion sickness, dizziness, vertigo, or frank paroxysmal events. Common trigger factors for migraine in children include emotional stress, lighting changes, and minor head trauma. Particularly in adolescents, it is useful to screen for depression or other psychosocial stressors that may warrant separate treatment. Foods, such as lunch meats, which contain nitrates, and cheeses, which contain tyramine, are less common but important triggers.

The diagnosis of migraine is based almost exclusively on the history and is supported by the absence of abnormalities on examination. There are no diagnostic laboratory tests or imaging studies. Given an accurate history, differentiation from tension headaches, sinusitis, and headaches secondary to intracranial lesions usually is possible; studies such as EEG, CT, and MRI are rarely indicated. Of children who experience migraines, 20 to 90% have been reported to have nonspecific EEG abnormalities, but the EEG usually is not helpful in diagnosis.

Management

A number of agents are available for the treatment of acute migraine (Table 83.5). For many children, mild oral analgesics such as acetaminophen or ibuprofen combined with bed rest may provide sufficient relief and should be considered the first-line agents of choice. Ketorolac (Toradol), a nonsteroidal anti-inflammatory agent for parenteral use, may be used when nausea or vomiting limits oral intake. A short course of a narcotic analgesic such as codeine may occasionally be needed if nonnarcotic agents have failed, especially if the headache prevents sleep.

Drug	Usual Dose
Analgesics	
Acetaminophen	10–15 mg/kg/dose PO or PR q4hr
Ibuprofen	5–10 mg/kg/dose PO q6h
Ketorolac (Toradol)	30 mg initial dose, then 15–30 mg/dose (0.5 mg/kg) IV or IM, or 10 mg/dose PO, q6–6hr
Codeine	0.5–1 mg/kg/dose PO q4–6hr
Antiemetics	
Metoclopramide (Reglan)	0.5–2 mg/kg/dose PO or IV q6–6hr
Prochlorperazine (Compazine)	0.1 mg/kg/dose PO or IM q6hr
Promethazine (Phenergan)	0.25–1.0 mg/kg/dose PO, PR, IV, or IM q4–6hr
Specific Antimigraine Agents	
Dihydroergotamine	0.5–1.0 mg/dose IV or IM, may repeat after 1 hr
Sumatriptan (Imitrex)	6 mg SC or 100 mg PO

(PO, orally; PR, per rectum; IV, intravenously; IM, intramuscularly; SC, subcutaneously.

Table 83.5. Agents for Acute Treatment of Migraine

When nausea and vomiting are severe, antiemetic medications such as metoclopramide (Reglan), prochlorperazine (Compazine), and promethazine (Phenergan) are useful. In addition to their antiemetic effect, these agents often provide some relief of the headache as well and may permit the use of other oral medications. All of these agents have the potential to produce dystonic reactions.

Ergot preparations act primarily as cerebral vasoconstrictors and are specifically indicated for aborting acute migraine attacks. Ergotamine tartrate is administered orally or sublingually, but it must be used early in the headache to be effective, preferably at the outset of the prodrome. Because most young children cannot identify an aura, their use is limited before adolescence. Common side effects of ergot preparations include nausea, vomiting, cramps, and distal paresthesias, all of which may intensify the symptoms of migraine. Chronic ergotism and dependence may occur with repeated use. Dihydroergotamine (DHE) is an injectable ergot derivative with fewer side effects. Ergotamine preparations with additional drugs such as phenobarbital and caffeine are available; however, there is little evidence to show that they

are more efficacious than ergots alone.

For acute migraine, DHE can be given to older children and adolescents in an initial dose of 0.5 mg IM or IV (no milligram-per-kilogram dose has been established). The initial dose of DHE may be repeated in 1 hour if necessary. One study in adults reported that 3 mg administered intranasally is also effective. Antiemetics may be useful to control the nausea and vomiting that often occur after DHE administration.

Sumatriptan succinate (Imitrex) is a serotonergic agent available for either oral or subcutaneous administration. Its effectiveness in relieving symptoms of acute migraine has been demonstrated in adults, but similar evidence is lacking in children. The dose for children 12 years and older is 6 mg subcutaneously or 100 mg orally. Sumatriptan is generally well tolerated; side effects include irritation at the injection site, flushing, tachycardia, disorientation, and chest tightness that lasts for several minutes after parenteral administration. Sumatriptan should not be used concomitantly with ergotamines. A reasonable approach is to use sumatriptan after a trial of analgesics in an older child, although older children or adolescents with recurrent migraine and a history of successful treatment with sumatriptan in the past may benefit from earlier use of this agent.

If migraines are frequent and severe, prophylactic treatment is possible. Many drugs have been used, but because they require close, serial examination and have no effect on the acute attack, they should not be started in the ED. Among the medications used for chronic suppressive therapy are propranolol, tricyclic antidepressants, cyproheptadine (Periactin), valproic acid, and calcium channel blockers.

Idiopathic Intracranial Hypertension (Pseudotumor Cerebri)

Background and Pathophysiology

Idiopathic intracranial hypertension (IIH), also called pseudotumor cerebri, is a poorly understood condition of increased ICP. It may occur at any age during childhood but is more common in adolescents, especially in obese individuals. Females are more commonly affected. A number of other conditions have been reported in association with IIH; these include infections (otitis media, mastoiditis), endocrinologic conditions (hyperthyroidism, Addison's disease), medications (steroid withdrawal, tetracycline, hypervitaminosis A), and mild head trauma. However, a causal relationship remains unproved, and in most cases of IIH, no cause is identified. The mechanism of increased ICP in IIH remains unknown, although several hypotheses have been postulated, including vasogenic brain edema and impaired reabsorption of CSF by the arachnoid villi.

Clinical Manifestations

Headache, of variable severity and duration, is the most common presenting symptom. It is typically worse in the morning. Nausea, vomiting, dizziness, and double or blurred vision also occur. If the process is long-standing, decreased visual acuity or visual field deficits can result. Infants often have nonspecific symptoms of lethargy or irritability. Papilledema is seen in virtually all cases. Other neurologic symptoms and signs are often absent; however, cranial nerve palsies, particularly affecting the sixth cranial nerve, may be seen.

Diagnosis should be considered when a child with a prolonged history of headache is found to have evidence of papilledema without other neurologic findings. Pseudotumor cerebri is a diagnosis of exclusion, and mass lesions and infectious processes must be ruled out. Because posterior fossa tumors and obstructive or nonobstructive hydrocephalus may mimic pseudotumor early in the course of disease, CT or MRI should be obtained in all children with this constellation of findings. In cases of IIH, the ventricles will appear normal or small. If no mass lesion is present, an LP should be performed with a manometer to measure opening pressure. The patient must be recumbent with legs extended to ensure an accurate reading of the opening pressure. Children with pseudotumor have elevated opening pressure (greater than 200 mm H_2O), but normal CSF cell count, protein, and glucose. In children with intermittent symptoms, the opening pressure may be normal when the headache is waning, even though papilledema may persist for several weeks.

Management

Removal of sufficient CSF to normalize ICP usually leads to relief of symptoms. Treatment may then be started with acetazolamide (Diamox) to decrease CSF production (60 mg/kg per day divided four times daily). Although recommended by some authorities, corticosteroids have not been proven to be effective in the management of this condition. However, in cases of IIH following withdrawal of steroid therapy, a course of prednisone or dexamethasone may be beneficial. Patients with mild symptoms and good response to LP may be discharged to home with close follow-up arranged. Children with severe or persistent symptoms or those with visual changes may require hospital admission. Intracranial hypertension may be recurrent or chronic, and long-term monitoring, particularly of visual function, is important.

DISORDERS OF MOTOR FUNCTION (SEE CHAPTER 79)

Every level of the neural axis is involved in the performance of motor tasks. Anatomic localization usually is possible after evaluation of the distribution and character of the deficit (Table 83.6). Paresis refers to partial or complete weakness of a part of the body. Various clinical designations are used to describe some patterns of weakness: paraplegia (or paraparesis), affecting the lower half of the body; quadriplegia, affecting all limbs; and hemiplegia, referring to weakness of one side of the body. Paraplegia most often results from spinal cord involvement, whereas hemiparesis is most often a sign of cortical disease. Some of the common conditions affecting various levels of the neuromotor system that may present with acute motor dysfunction are discussed next.

	Tone	Distribution	Reflexes	Babinski	Other
Upper motor neuron	Increased (may be decreased acutely)	Pattern (e.g., hemiparesis, paraparesis) Distal > proximal	Increased (may be decreased acutely)	Extensor	Cognitive dysfunction possible
Anterior horn cell	Decreased	Variable, asymmetric	Decreased to absent	Flexor	Fasciculations; no sensory involvement
Peripheral nerve	Decreased	Nerve distribution	Decreased to absent	Flexor	Sensory involvement
Neuromuscular junction	Normal	Fluctuating	Usually normal	Flexor	–
Muscle	Decreased	Proximal > distal	Decreased	Flexor	Tenderness; signs of inflammation possible

Table 83.6. Localizing Level of Neuromotor Dysfunction

Stroke/Cerebrovascular Accident

Background

Stroke is defined as a syndrome of acute onset of focal neurologic deficit that persists for more than 24 hours. Stroke is relatively rare in children but may complicate a number of other pediatric medical conditions. For example, among children with sickle cell disease, the incidence of stroke has been reported to be 6 to 9%. Others at risk are those with various forms of cardiac disease, which is one of the most common causes of stroke in children. Table 83.7 lists some of the common causes of stroke, as well as some more uncommon conditions in which stroke is a prominent clinical feature.

Vascular	Drugs
Arteriovenous malformation	Cocaine
Aneurysm	Amphetamines
Moyamoya disease	Oral contraceptives
Fibromuscular dysplasia	Ergot poisoning
Cardiac	Metabolic
Valvular heart disease (including endocarditis)	Homocystinuria
Right-to-left shunts	Fabry's disease
Atrial tumors	Mitochondrial encephalopathies (MELAS syndrome)
Arrhythmia	Organic acidemias
Cardiomyopathy	Hyperlipidemias
Infectious	Hematologic
Meningitis (especially tuberculous)	Sickle cell disease
Mycotic aneurysm	Coagulopathies (e.g., hemophilia)
Mastoiditis, otitis media, or sinusitis leading to venous sinus thrombosis	Anticoagulant deficiency (protein C, protein S, antithrombin III)
Trauma	Polycythemia
Intracranial hemorrhage	Acute myelogenous leukemia
Cervical trauma with vertebral artery injury	Systemic lupus erythematosus
Intracranial trauma with carotid injury	Neurocutaneous Syndromes
Brain tumor	Neurofibromatosis
	Tuberous sclerosis
	Sturge-Weber syndrome

Table 83.7. Causes of Stroke in Children

Pathophysiology

Generally, stroke is classified as either primarily ischemic (including embolic phenomena) or hemorrhagic. In ischemic stroke, there is focal reduction in cerebral blood flow, with hypoxic damage to brain parenchymaleading to neuronal injury and death. Further damage ensues from reperfusion of ischemic areas. More recently, attention has focused on secondary factors that play an important part in determining the extent of damage after acute ischemia; these include excess accumulation of excitatory amino acids and generation of free radicals.

Clinical Manifestations

The presentation of stroke in children is highly variable, influenced by the portion of the cerebral vasculature affected as well as the child's age. Hemiparesis is most often observed, with facial weakness typically ipsilateral to weakness in the rest of the body. Involvement of the anterior cerebral artery leads primarily to lower extremity weakness, whereas compromise of the middle cerebral artery circulation produces hemiplegia with upper limb predominance, hemianopsia, and possibly dysphasia. Less commonly, the posterior circulation is affected, which results in vertigo, ataxia, and nystagmus, as well as hemiparesis and hemianopsia. Older children often have concomitant headache, whereas children less than 4 years of age are more likely to have associated seizures. The child with a stroke may also have a diminished level of consciousness.

Investigations in a child with acute hemiparesis should be directed at confirming the diagnosis of stroke and attempting to identify an underlying cause if none is known. Imaging studies are useful. Cranial CT without contrast is the study of choice for identifying acute hemorrhage. However, CT may be normal in the first 12 to 24 hours after an ischemic stroke; MRI, in contrast, may show changes as early as 6 hours after infarction. A usual approach is to obtain a noncontrast CT, followed by MRI if no hemorrhage is seen.

In a child without a known predisposing condition, ancillary tests may be revealing of the cause of the stroke. Studies worth considering in such patients, depending on the clinical picture, are listed in Table 83.8. In one large series of 129 children with ischemic stroke, no cause was found in 35%.

Brain Imaging	Erythrocyte sedimentation rate
Computed tomography (noncontrast)	Hemoglobin electrophoresis
Magnetic resonance imaging	Protein C and S quantification
Angiography (standard or magnetic resonance)	Antithrombin III level
Cardiac	*Chemistry*
Electrocardiogram	Blood urea nitrogen
Echocardiogram	Cholesterol and triglycerides
Hemetologic	Hepatic transaminases
Complete blood count	Serum amino acids
Prothrombin and partial thromboplastin times	Urine organic acids
Fibrinogen	Toxicology screen
	Lactate
	Lumbar Puncture

Table 83.8. Studies to Consider in the Evaluation of the Child with Acute Stroke

Management

Initial treatment after an acute stroke is focused on stabilization and supportive care, including control of any seizures. Several aspects require special attention. Although evident hypotension should be treated with volume expansion, administration of free water should be restricted because of the potential for edema formation. Hypertension, if present, must be treated cautiously, and the blood pressure lowered gradually. Both hypoglycemia and hyperglycemia can exacerbate ischemic stroke, so careful monitoring of serum glucose is important. Fever, which can occur in children with stroke, may also contribute to ischemic damage and should be controlled with antipyretics.

Further therapy is determined by the type of stoke. With hemorrhagic stroke, neurosurgical intervention may be required to evacuate a hematoma or excise a bleeding arteriovenous malformation (AVM). Catheter-directed embolization may also be possible in cases of AVM. Children with sickle cell disease and stroke should have acute transfusion to decrease the level of hemoglobin S to less than 30%. Thrombolytic and anticoagulant therapies have been shown to be effective in adults with ischemic stroke but remain untested in children. Similarly, novel therapies such as calcium channel blockers and free radical scavengers have not been studied in pediatric patients; their use remains experimental.

Overall, prognosis for children with stroke is better than that in adults. However, regardless of treatment, long-term morbidity of stroke in children is high, with more than 75% of affected children experiencing sequelae such as hemiparesis, seizures, and learning difficulties.

Spinal Cord Dysfunction

Background

Dysfunction of the spinal cord may result from any of a variety of disorders, either intrinsic or extrinsic to the spinal cord, with a great deal of overlap in their clinical presentation. Transverse myelitis is an intramedullary disorder, involving both halves of the cord over a variable length, with involvement of motor and sensory tracts. It occurs in children and adults, although it is rare in the first year of life. Transverse myelitis is believed to be a localized form of acute disseminated encephalomyelitis, discussed previously. Like the latter disorder, transverse myelitis may occur after a number of infections; among those commonly reported are Epstein-Barr virus, cytomegalovirus, measles, mumps, *Campylobacter jejuni,* and *M. pneumoniae.* Transverse myelitis may also result from systemic autoimmune disorders such as lupus erythematosus or scleroderma. In some older children and adolescents, transverse myelitis is a first manifestation of multiple sclerosis.

Acute spinal cord compression in children usually is caused by trauma, infection, or cancer. Spinal trauma may lead to contusion or concussion of the cord with hemorrhage, edema, and local mass effect, or to development of a spinal epidural hematoma. Parenchymal injury usually presents acutely, but an epidural hematoma may develop over several days after the antecedent trauma. Epidural abscess is the most common infectious cause of spinal cord compression. It is usually caused by hematogenous spread of bacteria, with *Staphylococcus aureus* being the most common pathogen. Neoplastic causes include both primary intraspinal tumors (ependymoma and astrocytoma) and extrinsic lesions such as neuroblastoma or lymphoma.

Pathophysiology

Transverse myelitis is believed to be caused by an autoimmune process, with demyelinating lesions found in the spinothalamic and pyramidal tracts and posterior columns of the spinal cord. During the course of the illness, the initial area or areas of spinal cord inflammation may extend rostrally and caudally to involve an extensive portion of the spinal cord.

Mass lesions may cause damage by direct compression of spinal cord tissues or, secondarily, by interference with the tenuous arterial (or, less commonly, venous) blood flow to the spine with resultant spinal infarction.

Clinical Manifestations

Spinal cord dysfunction from any cause is characterized by paraplegia below the level of involvement, hyporeflexia, and sensory symptoms such as bandlike pain at the level of compression, and sensory loss or paraesthesias below the area of damage. If the lower spinal cord is involved (the conus), there usually is early loss of bowel and bladder control. Compression of the cauda equina usually results in asymmetric symptoms, radicular pain, and focal lower extremity

motor and sensory abnormalities.

Transverse myelitis may affect any level of the spinal cord, but thoracic involvement is most common. Initial symptoms include lower extremity paresthesia, local back pain, unilateral or bilateral lower extremity weakness, and urinary retention. A preceding respiratory or gastrointestinal illness is usually reported, and at the time of diagnosis, fever and meningismus are sometimes seen in children. Characteristically, the insidious onset of paresthesia or weakness of the lower extremities progresses over days or, rarely, weeks, and then is replaced by the abrupt occurrence of static paraplegia or quadriplegia and, in the cooperative child, a detectable sensory level. In other children, the course of progression may be less than 12 hours. The sensory loss generally involves all modalities, although a spinothalamic deficit (pain) may occur without posterior column dysfunction (vibration). The weakness usually is symmetric but may be asymmetric. After a variable interval, initial flaccidity may be replaced by spasticity. Sphincter disturbance of the bowel and bladder occurs in most patients, bladder distension being the most common initial sign of damage.

Traumatic and infectious spinal lesions are usually accompanied by relatively acute onset of local back pain, which is exacerbated by direct percussion of the area. Pain may precede other symptoms for days. With tumors, however, there may be weakness in the absence of pain. Patients with epidural abscess often have systemic signs of infections such as fever, headache, vomiting, and perhaps neck stiffness. Bony tenderness in such a patient may indicate vertebral osteomyelitis or discitis, which can also present with weakness, although usually less severe than is seen with actual spinal cord involvement.

Prompt diagnosis of spinal cord lesions requires a high level of expectation. Detailed neurologic examination is essential, with particular attention to quality of deep tendon reflexes, any asymmetry of reflexes or strength, evaluation for a sensory level, and assessment of anal tone and cremasteric reflexes (in males). Note also any point percussion tenderness.

Diagnosis is confirmed by emergency neuroimaging, with precautions to immobilize the patient as much as possible. Plain spine films are useful initially in trauma. MRI of the spine is the procedure of choice to detect compressive mass lesions, but if not immediately available, plain or CT myelography is an alternative. In transverse myelitis, the cord may be widened at the level of involvement. This is easier to detect with MRI, which in some cases may also reveal evidence of focal intramedullary demyelination.

LP alone should not be performed if a diagnosis of spinal cord compression is entertained. If no mass lesion is noted and transverse myelitis is a diagnostic possibility, LP may be useful, showing a normal or slightly elevated opening pressure and a mild pleocytosis in the CSF in nearly 50% of patients at the time of presentation. The CSF protein is often elevated and may demonstrate oligoclonal bands or increased myelin basic protein, but the glucose usually is normal.

Management

Treatment of children with spinal injury from trauma begins with splinting and immobilization of the spine. If trauma is likely, high-dose methylprednisolone, if given within 8 hours of injury at an IV dose of 30 mg/kg followed by infusion at 5.4 mg/kg per hour for 23 hours, improves the quality of neurologic outcome. Neurosurgical consultation should be obtained as soon as possible; however, early surgical attempts to decompress the swollen spine (laminectomy or midline myelotomy) have proven ineffective and, possibly, detrimental.

In cases of possible epidural abscess or tumor-related mass, IV dexamethasone at a loading dose of 2 mg/kg (up to a maximum of 100 mg) should be given, followed by 1 to 2 mg/kg per day IV in four divided doses over the next 24 hours. In patients with a presumed infectious cause and those with cancer of unknown origin, surgical decompression is indicated on an emergent basis to alleviate pressure and pinpoint diagnosis. Further treatment depends on the organism or exact tumor type found.

Treatment of transverse myelitis is supportive, and some degree of recovery occurs in approximately 80% of cases. All children with this syndrome should be hospitalized. Although systemic corticosteroids are often recommended for treatment of transverse myelitis, there is little evidence of their efficacy. Treatment with intraspinal steroids or emergency laminectomy has also not been shown to improve outcome. High-dose dexamethasone as described previously may be begun until cord compression by a mass lesion is ruled out.

Acute Polyneuritis

Background and Pathophysiology

Acute polyneuritis, also called Guillain-Barré syndrome, is characterized by symmetric ascending paralysis. Pathologically, the hallmark of this disease is primary demyelination of motor and sensory nerves, believed to be secondary to autoimmune mechanisms. It occurs in children in all age groups but is uncommon before 3 years of age. An antecedent respiratory or gastrointestinal infection or immunization precedes the onset of illness by 1 to 2 weeks in more than 75% of childhood cases.

Clinical Manifestations

Weakness, commonly with an insidious inset, is the usual presenting complaint. Paresthesias or other sensory abnormalities such as pain or numbness are prominent in up to 50% of cases, particularly in older children. The paresthesias and paralysis usually are symmetric and ascending, although variations may occur. Early in the course of illness, distal weakness is more prominent than proximal weakness. Deep tendon reflexes are depressed or absent at the time of diagnosis. Affected children often have an ataxic gait.

Cranial nerve abnormalities occur during the illness in 30 to 40% of cases and may be the predominant finding,

especially in the Miller-Fisher variant of this syndrome, which is characterized by oculomotor palsies, ataxia, and areflexia without motor weakness of the extremities. The most common cranial nerve deficit is seventh (facial) nerve palsy, followed in decreasing frequency by impairment of cranial nerves IX, X, and XI and oculomotor abnormalities. Autonomic dysfunction occurs commonly and results in blood pressure lability, postural hypotension, and cardiac abnormalities; it is a disproportionate cause of morbidity and mortality. Urinary retention, if it occurs, is usually seen late in the illness. As the paralysis ascends, muscles of breathing may become involved, leading to respiratory embarrassment.

The primary aid in diagnosis is LP, which demonstrates an elevated protein, normal glucose, and fewer than 10 white blood cells/mm^3—the so-called albuminocytologic disassociation. The protein elevation occurs in almost all cases but may be delayed for weeks, usually peaking in the second or third week of illness. Electrophysiologic evidence for Guillain-Barré syndrome is the presence of nerve conduction velocity delay, which usually is not demonstrable until the second or third week of illness. Emergency electromyography (EMG) and nerve conduction velocity testing are not indicated.

Management

Because of the potential for progression to life-threatening respiratory compromise, the child with Guillain-Barré syndrome should be hospitalized and observed closely. Impending respiratory distress must be anticipated, and routine respiratory monitoring should be aided by specific measures of respiratory function, particularly measurement of negative inspiratory force. Because autonomic dysfunction is common, blood pressure must be monitored closely and abnormalities treated vigorously.

Acute polyneuritis is generally self-limiting, with more than 90% of children in most series having complete or near complete recovery. In mild cases, in which children retain the ability to ambulate, only supportive care is required. However, immunomodulatory therapy may be of benefit in more severely affected children. Plasmapheresis and intravenous immunoglobulin have both been used. Although well-controlled, blinded studies of these treatments in children are lacking, the available data suggest both are effective in reducing the duration and severity of illness in those most severely affected, especially when begun early in the course of the disease. Corticosteroids have not been shown to be beneficial in acute Guillain-Barré syndrome.

Myasthenia Gravis

Background and Pathophysiology

In myasthenia gravis, antibodies directed against acetylcholine receptor protein of the postsynaptic neuromuscular junction cause intermittent failure of neuromuscular transmission and fluctuating weakness. Myasthenia manifests by fluctuating weakness of cranial and skeletal musculature, exacerbated by exertion. More commonly a disease seen in adults, myasthenia gravis occurs in children in three major forms: transient neonatal, infantile, and juvenile (most common).

Clinical Manifestations

The juvenile form of myasthenia clinically mimics the adult disease. The mean age of onset is 8 years, with a female predominance of approximately 4:1. The onset of symptoms may be insidious or acute. Most cases affect the cranial nerves, and any cranial nerve can be involved in combination or isolation. Bilateral ptosis is the most common cranial nerve deficit, followed in incidence by oculomotor impairment. Generalized truncal and limb weakness is present at onset in up to half of cases and eventually develops in most children with myasthenia. The diagnosis should be suspected if there is a history of worsening weakness during continual activity or if fatigability of muscle strength is demonstrable. Illnesses confused with myasthenia include the muscular dystrophies, congenital myopathies, inflammatory myopathies, acute and chronic polyneuropathies, and in the infant, botulism.

The Tensilon test is the backbone of diagnosis. In this procedure, the anticholinesterase drug edrophonium (Tensilon), which has a 30-second onset and approximately a 5-minute duration of action, is given slowly by IV at a dosage of 0.2 mg/kg, up to a maximum dose of 10 mg. Atropine should be immediately available to treat potential severe cholinergic reactions (e.g., bradycardia). Initially, one-tenth of the total dose is given, and if no hypersensitivity or severe reactions are noted, the remainder of the dose is administered. Because edrophonium is short-lived, interpretation of the response requires close monitoring of a muscle or muscle group in which improvement can be seen clearly, such as the eyelid elevators. In small children, this often is impossible and longer-acting anticholinesterases such as neostigmine (0.125 mg in an infant and 0.04 mg/kg in an older child) can be used. EMG provides electrophysiologic evidence for myasthenia gravis, with a decremental response to repetitive nerve stimulation, but may be negative when the disease is confined to the cranial nerves.

Management

Although myasthenia gravis is potentially life-threatening, specific management usually can be delayed until after diagnosis is made. If there is evidence of respiratory compromise, ventilatory support is mandatory. Treatment is begun with the use of cholinesterase inhibitors to prolong the availability of acetylcholine at the neuromuscular junction. Presently, the anticholinesterase of choice is pyridostigmine (Mestinon) at a starting dosage of 1 mg/kg by mouth every 4 hours, adjusted according to the clinical response. Other agents, such as corticosteroids or antimetabolites, may be beneficial in selected cases. If there is any concern about respiratory compromise or if severe weakness is present, the child should be hospitalized immediately.

Myasthenia has a fluctuating, unpredictable course that can be exacerbated by intercurrent illness and by certain drugs, particularly the aminoglycoside antibiotics. In a known myasthenic, rapid worsening and respiratory compromise

(myasthenic crises) may be difficult to differentiate from deterioration secondary to overdose of anticholinesterases (cholinergic crises) because the muscarinic side effects of the anticholinesterases, such as nausea, vomiting, cramps, and muscle fasciculations, may be absent. At times, differentiation can be made by giving 1 to 2 mg of IV edrophonium after ensuring respiratory sufficiency. This should result in rapid improvement in the patient with a myasthenic crisis. This procedure may be falsely positive, however, and if the diagnosis is unclear, the patient should be withdrawn from all anticholinesterases and, if necessary, maintained on mechanical respiration for 48 to 72 hours. Cholinergic crises require the immediate withdrawal of all anticholinesterases. Myasthenic crises respond variably to additional anticholinesterases, and plasmapheresis or steroid therapy may be particularly useful in this situation. Both myasthenic and cholinergic crises mandate admission to the hospital.

Botulism

Background and Pathophysiology

Infantile botulism is a cause of acute weakness in previously well infants less than 6 months old. The illness is secondary to intestinal colonization by *Clostridium botulinum,* which produces a neurotoxin that impairs acetylcholine release from the nerve terminal. Spores of *C. botulinum* are of ubiquitous origin, found in soil and agricultural products. Honey has been found to be a particularly significant reservoir. Although infant botulism occurs throughout the United States, the incidence is highest in certain areas; approximately half the cases have been reported from California, Utah, and Pennsylvania. The various host factors that predispose certain infants to intestinal colonization are poorly understood.

Clinical Manifestations

The initial symptom of botulism usually is constipation, followed insidiously by lethargy and feeding difficulties. Physical findings at the time of presentation are hypoactive deep tendon reflexes, decreased suck and gag, poorly reactive pupils, bilateral ptosis, oculomotor palsies, and facial weakness. Differential diagnosis includes all the potential causes of lethargy and poor feeding in infancy, and infants are often misdiagnosed initially. Laboratory studies, including the leukocyte count and LP, are normal. The diagnosis is confirmed by identification of *C. botulinum* toxin (usually type A or B) in the feces or isolation of the organism in stool culture, which is less sensitive. EMG may supply immediate information. Characteristic EMG findings are brief, small-amplitude action potentials; posttetanic facilitation; and normal nerve conduction velocity.

Management

Management of infant botulism is strictly supportive. Affected infants require hospitalization to observe for respiratory compromise. In one large series of 57 patients, 77% required endotracheal intubation because of loss of protective airway reflexes, and 68% received mechanical ventilation for some period. Nasogastric or nasojejunal feedings are usually needed as well. The use of cathartics or other laxatives to reduce the amount of *C. botulinum* present in the intestine has not proved beneficial. Botulinum antitoxin has resulted in anaphylactic reaction in infants and is not recommended. Antibiotics such as penicillin, although widely used, have not been shown to eradicate the organism from the bowel or result in clinical improvement.

Periodic Paralysis

Background and Pathophysiology

Familial periodic paralysis is a rare illness, inherited in an autosomal-dominant fashion that results in episodes of severe weakness associated with an abnormality of circulating potassium during attacks. Two major forms of illness—hyperkalemic and hypokalemic—are recognized. (A third type, normokalemic, has been described but most likely represents a rare variant of the hyperkalemic variety.) Other disorders that can produce weakness and electrolyte abnormalities, such as use of corticosteroids or diuretics, thyrotoxicosis, hyperaldosteronism, and renal insufficiency, may mimic the periodic paralyses. The serum potassium abnormalities in familial periodic paralysis are thought to be epiphenomena of yet undelineated muscle membrane abnormalities.

Clinical Manifestations

Many of the clinical features are common to the various forms of periodic paralysis. Characteristically, a previously well patient develops a flaccid weakness in his or her trunk and upper thighs, and the weakness gradually involves the remainder of the skeletal muscles. Deep tendon reflexes are diminished. The attacks last from hours to days, and between the attacks, muscular strength usually is normal, although a minority of patients have residual muscular weakness.

Hypokalemic periodic paralysis, the most common type, occurs primarily in young adults. Trigger factors include vigorous exercise, heavy carbohydrate meals, alcohol, and the cold. During an attack, potassium levels are usually 2 to 2.5 mEq/L, and electrophysiologic examination demonstrates unstimulatable muscles. The hyperkalemic form usually begins in the first decade of life, and attacks occur predominantly during the period of rest after vigorous exercise or after fasting. The episodes are more common than in hypokalemic paralysis, but often last less than a few hours. Myotonia usually is associated with the illness. During the attack, plasma potassium is moderately elevated, although it is often in the upper normal range. In both forms of periodic paralysis, electrocardiogram (ECG) changes consistent with the serum potassium abnormality may be noted, and cardiac arrhythmias may rarely arise.

Management

Emergency treatment of hypokalemic periodic paralysis includes oral, or rarely IV, potassium. Prophylactically, patients should avoid precipitants such as vigorous exercise or large carbohydrate loads. Recurrences may be prevented with

spironolactone or acetazolamide.

Attacks of hyperkalemic periodic paralysis are often brief enough that acute treatment is unnecessary. In severe attacks, IV calcium gluconate may be helpful. Acetazolamide, thiazide diuretics, and albuterol have been used for prevention of recurrences.

DISORDERS OF BALANCE (SEE CHAPTER 11)

Acute Cerebellar Ataxia

Background and Pathophysiology

Acute cerebellar ataxia, characterized by the acute onset of unsteadiness in a previously well child, is the most common cause of ataxia in young children. It is seen primarily between the ages of 1 and 4 years but can occur at any time during childhood. The exact cause of the illness is unclear; however, it is believed to be a parainfectious or postinfectious demyelinating phenomenon and likely represents a localized form of postinfectious encephalitis. Acute cerebellar ataxia occurs most commonly after primary varicella. Other infections implicated include infectious mononucleosis, enteroviruses, herpes simplex, influenza, *Mycoplasma,* and Q fever. Ataxia is usually seen 5 to 10 days after the onset of illness, although symptoms may be delayed for up to 3 weeks, and there are some reports of cerebellar ataxia preceding the rash of chickenpox.

Clinical Manifestations

The child develops acute truncal unsteadiness with a variable degree of distal motor difficulty, such as tremor and dysmetria. Dysarthria and nystagmus are variably present. Some children have nausea and vomiting, presumably caused by vertigo. Headache is rare.

When acute ataxia follows varicella in a child with no other neurologic findings, the diagnosis may be made on clinical grounds. In atypical cases, CT or MRI may be necessary to rule out a cerebellar mass. LP is not usually necessary in typical cases; if performed, it reveals a mild CSF pleocytosis in approximately half of the cases.

Management

Treatment is supportive. Resolution of symptoms is complete in most children within 2 weeks of onset, but mild residual neurologic deficits have been reported in 10 to 30% of cases. Varicella-associated cases appear to have the most benign prognosis.

Benign Paroxysmal Vertigo

Benign paroxysmal vertigo is an illness that affects children primarily between 1 and 4 years or age, although it can occur any time during the first decade. It manifests with acute episodes of dizziness and imbalance, lasting seconds to minutes. Between episodes, the child is asymptomatic. During the spell, the child characteristically becomes frightened and pale but does not lose consciousness. He or she may have associated nausea, vomiting, or visual disturbance. The physical examination is usually normal except for nystagmus, which may be present. Although the cause of this illness is unknown, it is thought to be a migraine variant. Many children go on to develop more typical migraine headaches later, and there is often a family history of migraine disease. As the name suggests, the course of benign paroxysmal vertigo is self-limiting and benign, and treatment is supportive.

MOVEMENT DISORDERS

Involuntary movements are components of many CNS disorders and tend to be complex. A classification into specific subtypes, based on the character, predominant anatomic localization, rhythmicity, and frequency, is arbitrary but useful in deducing the cause of the disorder (Table 83.9). Movements such as chorea, athetosis, dystonia, ballismus, and certain types of tremors suggest dysfunction of the extrapyramidal nervous system. Involuntary movements also are caused by damage to the cerebellum or its outflow tract, especially static (on maintaining fixed position) and intention tremors. Myoclonus may occur secondary to cerebral cortex, brainstem, or spinal cord disease. Tics, another form of involuntary movement, may be extremely difficult to distinguish from chorea and are best differentiated by their stereotypic character. They probably represent the most common involuntary movement disorder but are not true neurologic emergencies. Many illnesses may present with involuntary movements and are diagnosed by associated neurologic findings.

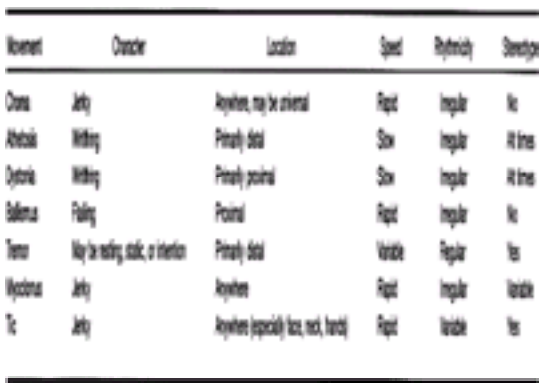

Table 83.9. Categorization of Movement Disorders

Acute Dystonia

Dystonia is marked by involuntary, sustained muscle contractions, typically of the neck and trunk, that cause twisting movements and abnormal postures. In generalized dystonia, the head is usually deviated to the side, and there is grimacing of the face. Acute dystonia in children is nearly always the result of exposure to an antidopaminergic agent such as a neuroleptic, antiemetic, or metoclopramide. Chronic dystonias are rare but may be seen as an isolated disorder or as a manifestation of cerebral palsy. Dystonia must be differentiated from torticollis, an abnormal tilt of the head and neck usually resulting from irritation or spasm of the sternocleidomastoid muscle. Another clinically similar condition is Sandifer's syndrome, which describes intermittent arching of the back and neck observed in infants with gastroesophageal reflux.

Acute dystonia resulting from exposure to antidopaminergic drugs is treated with diphenhydramine (1 mg/kg per dose IV, PO, or IM) or benztropine (Cogentin) (1 to 2 mg/dose IM). Because the half-life of many of the precipitating agents is fairly long, treatment should be continued for 24 to 48 hours.

Sydenham's Chorea

Background

Sydenham's chorea, the most common form of acquired chorea seen in children, occurs primarily between the ages of 3 and 13 years. Marked by involuntary movements, coordination difficulties, and emotional lability, its onset may be abrupt or insidious. Sydenham's chorea is thought to be a poststreptococcal disease and may occur months after the primary bacterial infection. It is one of the major diagnostic criteria for rheumatic fever (see Chapter 82).

Clinical Manifestations

The involuntary movements may be subtle at first and exacerbated by stress. Initially, the movements classically affect the face and distal portion of the upper extremities and consist of rapid, involuntary random jerks. This results in the milkmaid hand, in which the child's hand cannot maintain a uniform strength while grasping the examiner's hand. The involuntary movements disappear during sleep. There usually is associated muscular hypotonia and marked coordination difficulties, and speech is often jerky. Hemichorea, in which the abnormal movements are predominantly unilateral, occurs in some cases. The deep tendon reflexes are normal, although occasionally, the patellar reflex is said to be “hung up.” There is no evidence for upper motor neuron disease.

Serologic evidence for preceding streptococcal infection is absent in up to 25% of cases, and only one-third of patients have associated manifestations of rheumatic fever at the time of diagnosis. In the absence of such confirmatory evidence of a poststreptococcal cause, other disorders that may present with chorea must be considered in the differential diagnosis. These include atypical seizures, drug intoxication, choreoathetoid cerebral palsy, familial choreas, chorea gravidarum, collagen vascular disease, Wilson's disease, and Lyme disease.

Management

Initially, all patients should have a hematologic profile, sedimentation rate, and serologic test for streptococcal infection. An ECG also should be performed to look for evidence of rheumatic carditis (e.g., prolonged P-R interval). If there is a question concerning diagnosis, further tests, such as CT, MRI, LP, and serologic evaluation for collagen vascular disease, might be helpful, but they are not usually necessary on an urgent basis.

The success of any treatment is hard to evaluate because the course is so unpredictable. Haloperidol (0.5 to 1 mg twice daily) has been reported to result in improvement within 2 to 3 days. Because patients with Sydenham's chorea have an increased incidence of rheumatic carditis, prophylactic penicillin should be used, unless another specific cause is determined for the chorea.

DISORDERS OF CRANIAL NERVE FUNCTION

Optic Neuritis

Background

Optic neuritis is an acute inflammation or demyelination of the optic nerve characterized by an impairment of vision, progressing over hours or days and associated with tenderness of the eyeball exacerbated by eye movement. The disease is primarily unilateral, but an increased incidence of bilateral involvement is found in children. Optic neuritis in children is most commonly presumed to be on an autoimmune basis following a viral disease, including the childhood exanthems. At times, a contiguous sinusitis may cause the illness. Of patients with unilateral optic neuritis, 20% will develop multiple sclerosis at a later date, but there is little reason to make this diagnosis before the development of other symptoms of neurologic dysfunction.

Clinical Findings

On examination, decreased visual acuity and decreased color vision are associated with a relative afferent pupillary deficit to light and a central scotoma in the affected eye. The relative afferent pupil defect is demonstrated by the swinging flashlight maneuver, during which the pupil of the affected eye constricts briskly when light is shone into the

contralateral eye (the consensual light reflex) and dilates when light is immediately shone into the affected eye. With bilateral disease, the change in pupillary reflexes may not be apparent. Funduscopic examination discloses a hyperemic, swollen optic disc; in the rare cases of retrobulbar optic neuritis, funduscopic examination is normal.

Optic neuritis must be distinguished from papilledema secondary to increased ICP. Papilledema is almost always bilateral and associated with normal vision and normal pupil reactivity until late in the disease. In cases of bilateral optic neuritis, differentiation may be impossible because funduscopic findings are identical in the two illnesses. If any doubt of increased ICP persists, the patient should undergo evaluation by CT or MRI of the brain and, if normal, CSF analysis. In optic neuritis, the opening pressure is normal, but there may be a mild lymphocytic pleocytosis or elevated CSF protein.

Management

The course of the illness is variable, with most patients recovering to normal or near normal vision over 4 to 5 weeks. Treatment with high-dose systemic corticosteroids, such as prednisone 2 mg/kg per day orally for 7 to 10 days has not been shown to improve the ultimate prognosis but may result in a slightly faster resolution of symptoms.

Facial Nerve Palsy

Background

Weakness in the distribution of the seventh cranial (facial) nerve may be produced by either central (upper motor neuron) or peripheral (lower motor neuron) dysfunction. Peripheral disease is most common in children, particularly when the facial weakness is an isolated finding. Bell's palsy refers to peripheral facial nerve weakness with no identifiable underlying cause. It is believed to be secondary to edema of the facial nerve as it passes through the facial canal within the temporal bone. There is often a history or preceding upper respiratory infection, and in at least a subset of patients, there is evidence of reactivation of infection with Epstein-Barr virus or HSV. Facial palsy may also a manifestation of early disseminated Lyme disease. It usually occurs in isolation, although there may be other signs of CNS disease. Although in general most cases of facial nerve palsy in children are of the idiopathic (or viral reactivation) type, in endemic areas, Lyme disease may be the most common cause.

Clinical Manifestations

Facial weakness may be partial or complete. On the affected side, there is flattening of the nasolabial fold at rest, and the child has difficulty closing the eye or raising the corner of the mouth to smile. In many cases, pain localized to the ear precedes the paralysis. With upper motor neuron involvement, there will be some residual capacity to furrow the brow because of crossed innervation, whereas the entire face is involved with peripheral disease. There may be bilateral involvement in Lyme disease, in contrast to Bell's palsy, which is always unilateral.

In children with facial nerve palsy caused by Lyme disease, other manifestations, such as erythema migrans, are rarely seen (27% in one series). Thus, even in the absence of other findings, serologic evidence for systemic Lyme infection should be sought in all children with isolated seventh nerve paresis in endemic areas. An LP should be performed if there is other evidence of meningoencephalitis such as headache; however, the need for LP in a child at risk for Lyme disease with isolated facial nerve palsy is controversial. Other associated neurologic abnormality, specifically in the other cranial nerves, necessitates further evaluation, including CT or MRI.

Management

Treatment for facial nerve palsy not associated with Lyme disease is somewhat controversial, but steroids may be beneficial when started early in the course of the disease. Some authors have recommended a course of prednisone (2 mg/kg per day in two divided doses) over 7 to 10 days if the patient is seen within the first 24 to 48 hours days of disease. A recent study suggests that acyclovir may be of benefit. Regardless of treatment, complete recovery is seen in 60 to 80% of children, beginning during the second to third week of illness. Those with partial paralysis generally have a better prognosis. During recovery period, special care should be taken to protect the cornea by the instillation of bland ointments (e.g., Lacrilube). The child should be referred for reexamination to ensure a recovery during the expected time period.

Children with clinical or serologic evidence of Lyme-associated facial nerve palsy should be treated with oral antibiotics (amoxicillin, tetracycline, or erythromycin) for 21 to 28 days. The effectiveness of steroids in such patients has not been evaluated. Parenteral antibiotic treatment is recommended for children who also have evidence of meningitis.

CHAPTER 84

Infectious Disease Emergencies

GARY R. FLEISHER, MD

Department of Pediatrics, Harvard Medical School, and Division of Emergency Medicine, Children's Hospital, Boston, Massachusetts

Although not as dramatic as multiple trauma or cardiac arrhythmias, infection precipitates more emergency department (ED) encounters than either of these other two conditions. Fever is the single most common chief complaint among children seen in the ED at most children's hospitals. Only a small fraction of patients with infections die; however, such diseases, being so much more common than noninfectious conditions with high fatality rates, account for a large percentage of deaths in the ED. Russo et al. reviewed the charts of children dead on arrival and found that infection ranked second only to trauma as a cause of mortality.

The approach to the febrile child is outlined in Chapter 28. In the current chapter, infections are divided anatomically as follows: generalized (bacterial), central nervous system (CNS), upper respiratory, lower respiratory, gastrointestinal (GI), bone and soft tissue, and genitourinary. Systemic nonbacterial illnesses, including the childhood exanthems, and several miscellaneous syndromes are dealt with as a group at the end of this chapter. Infections of the heart are discussed in Chapter 82, and encephalitis is covered as a neurologic emergency (see Chapter 83); human immunodeficiency virus (HIV), a disease of growing importance in children, is discussed in Chapter 85.

For each anatomic area, the relative frequency of disease caused by various pathogens is discussed and an approach is given for establishing a specific cause. A more extensive description is provided for the serious and/or treatable conditions, often clustering similar or less significant pathogens. The recommendations for management are derived from published literature. In certain areas, particularly as regards the indications for admission, scant information exists. Thus, it has been necessary at times to offer, as guidelines, the protocols that the author has found successful in clinical practice in the ED, even though they may not have been subjected to vigorous clinical trials.

INFECTIOUS SYNDROMES

Bacteremia and Sepsis

Bacteremia refers to the presence of bacteria in the blood stream. When bacteremia occurs in a young child and produces relatively few signs or symptoms, other than fever, the patient is considered to have the syndrome of occult bacteremia. The presence or absence of toxicity differentiates occult bacteremia, which is relatively asymptomatic, from sepsis, which is accompanied by findings of serious systemic illness. Because these infections represent a continuum, whereby some children with occult bacteremia proceed to develop the manifestations of sepsis, a separation into distinct diagnostic categories is not always possible. Bacterial infections in the bloodstream may occur in isolation (primary) or in association with focal disease (secondary). This section focuses on primary infections.

Bacteremia

Background

Streptococcus pneumoniae causes 90% of primary occult bacteremias. Less commonly encountered pathogens include *Salmonella*, *Neisseria meningitidis*, group A streptococcus, group B streptococcus, *Haemophilus influenzae* (Hib), and rarely, others. Table 84.1 summarizes the bacteria isolated in prospective studies of bacteremia. Since the introduction of a conjugated vaccine against Hib to be administered to children in the first 6 months of life, the isolation of this organism has declined almost to zero.

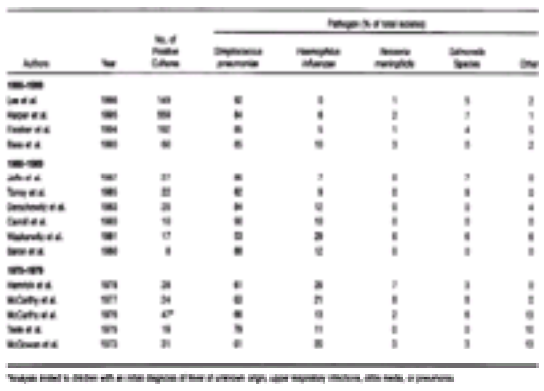

Table 84.1. Organisms Recovered from the Blood of Children with Unsuspected Bacteremia[a]

Occult bacteremia occurs with predictable regularity among febrile children younger than 2 to 3 years of age but perhaps not as often in the first 3 months of life, except in association with *Salmonella* gastroenteritis or urinary tract infections (UTIs). Before the advent of the conjugated vaccine against Hib, McGowan et al. recovered pathogens from 22 of 551 (4%) outpatient children with an elevated temperature. In this series, blood cultures were positive in 1 of 74 (1%) infants 6 months of age or younger, 11 of 116 (9.5%) children 7 to 12 months old, 5 of 131 (3.8%) of those 13 to 24 months old, and 5 of 225 (2.2%) of those more than 24 months of age. In a report of patients from the post–*H. influenzae* type b era, Lee and Harper noted a rate of bacteremia of 1.57% overall and 1.45% *for S. pneumoniae*; the peak incidence occurred in children 6 to 12 months of age. Dershewitz et al. noted similar rates of bacteremia (1.9 to 5.9%) in three groups of children, drawn from varying socioeconomic backgrounds. The introduction of a conjugated vaccine against *S. pneumoniae* will most likely occur within the next decade and would be expected to significantly reduce the incidence of bacteremia.

Pathophysiology

There appears to be a continuum of disease, starting with colonization and progressing through occult bacteremia, that may have three outcomes: 1) spontaneous resolution, 2) sepsis, or 3) focal infection. Clearly, pathogens such as *N. meningitidis* and *H. influenzae* have a greater tendency than *S. pneumoniae* to produce sepsis or invasive disease. Other than the specific organism, factors have not yet been completely defined that determine which children become colonized, which colonized children become bacteremic, and which bacteremic children improve without therapy.

Clearly, exposure to carriers plays an essential role in the process, accounting for the increased incidence of asymptomatic carriage and disease among household contacts of patients with infections caused by *N. meningitidis* or *H. influenzae.* A concurrent viral infection may increase the likelihood of bacteremia in a colonized of a child by disrupting the normal mucosal barrier. Bactericidal antibody in the serum has been shown to protect carriers against meningococcal disease; however, some persons without such antibodies do not progress beyond colonization. Among 492 military recruits studied by Goldschneider et al., 54 lacked bactericidal antibody to meningococcus group C. Of these 54 men, 24 acquired the organism in the nasopharynx, and 11 showed a bactericidal antibody response. Five of those without such a response developed meningococcal meningitis.

Clinical Manifestations

By definition, occult bacteremia causes few symptoms and signs. The complaints are usually those of malaise or an upper respiratory infection (URI). Fever, without evidence of a source, may be the only physical finding, or the patient may have a minor focus of infection, such as otitis media (OM).

McCarthy et al. attempted to define the history and observation variables useful in assessing febrile children. Observation of behavior (playfulness, alertness, and consolability) had the strongest correlation with the overall assessment; however, 9 of 21 children subsequently shown to have serious illnesses were not initially categorized as being moderately or severely ill. A subsequent study by Baker et al. found that this observational scale did not predict serious illness accurately in young infants, and Teach et al. noted a similar lack of success in older children with occult bacteremia. Waskerwitz et al. reported that physician assessment for bacteremia had limited utility with a sensitivity of 47%, a specificity of 83%, and a positive predictive value of 14%.

Children 3 to 24 months of age, who appear well with a fever at or above 39°C (102.2°F), have a 1.5 to 2% incidence of occult bacteremia compared with less than 0.5% for the group with low-grade fever (38° to 38.9°C [100.4° to 102°F]), but further elevations of the temperature above the 39°C (102.2°F) mark only minimally increase the likelihood of bacteremia. Torrey et al. tested whether the initial overall assessment of the response to an antipyretic drug administered in the ED could distinguish febrile children with bacteremia from those with viral infections. Neither the initial assessment nor the magnitude of the decrease in temperature was predictive for the presence or absence of organisms in the bloodstream. Additional studies have confirmed that the response to antipyresis does not correlate with the presence of bacterial infection.

The white blood cell (WBC) count is usually elevated in children with bacteremia, particularly with *S. pneumoniae.* For all pathogens, Jaffe and Fleisher found the sensitivity of the WBC count among children 3 to 36 months of age with a temperature greater than 39°C (102.2°F) to be 92% at 10,000/mm^3 or more, 65% at 15,000/mm^3 or more, and 38% at 20,000/mm^3 or more. Limiting their analysis to pneumococcal bacteremia among a similar group of highly febrile infants and toddlers, Kuppermann et al. reported that 8.2% of highly febrile infants and toddlers with a WBC count of 20,000/mm^3 or more had occult pneumococcal bacteremia. Lee and Harper demonstrated that the risk of bacteremia was greater among the more highly febrile patients with leukocytosis (Table 84.2) and noted an incidence in the range of 10%

among those with significant elevations.

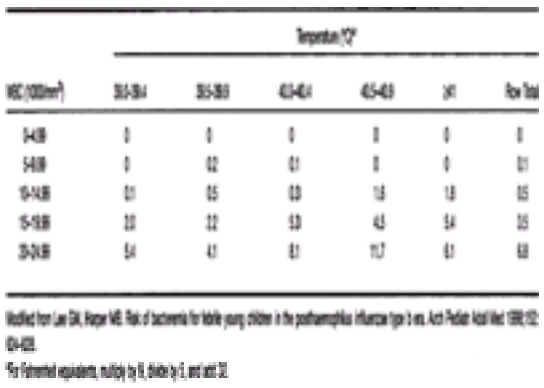

Table 84.2. Proportion of Patients with Bacteremia, Depending on White Blood Cell (WBC) Count and Temperature, 1993–1996

A shift to the left in the differential count and signs of toxicity on the peripheral smear are seen more often in bacteremic children than in those with viral infections, but neither serves to reliably distinguish the two groups. Although both the erythrocyte sedimentation rate (ESR) and the C-reactive protein (CRP) are usually elevated in patients with bacteremia, these tests provide only minimal additional information.

Management

A discussion on the management of bacteremia must address three issues: 1) evaluation for bacteremia in the febrile child with a seemingly trivial febrile illness, 2) treatment of the child with suspected bacteremia but no signs of sepsis or focal disease, and 3) therapy of proven bacteremia. Although controversy plagues all of these areas, the information accumulated over the last decade clearly shows some limitations to clinical judgment and points to the not uncommon occurrence of serious complications from bacteremia.

The likelihood of bacteremia in the child between 3 and 24 months of age with a fever of 39°C (102.2°F) or higher, coupled with the difficulties of clinical assessments in these youngsters, makes obtaining a WBC count, differential, and blood culture useful in many cases but rarely mandatory. With lower fevers in these young children or with highly elevated temperatures in children older than 24 months of age, the physician can rely more firmly on clinical judgment. In addition, children fully immunized against Hib have a reduced risk of bacteremia from this organism, once the most common cause of pediatric meningitis following occult bacteremia. In the patient who is believed to be more irritable or toxic than the usual child with a fever—but not so ill as to require an admission to the hospital—a WBC count and blood culture provides some guidance. In addition, patients who have a lumbar puncture performed in the ED as part of an evaluation for febrile seizures or suspected meningitis should have cultures of their blood. In these situations, the finding of a WBC count of 15,000 to 20,000/mm^3 or more strongly suggests a role for presumptive antibiotic therapy.

The role of presumptive antibiotic therapy for patients at risk for occult bacteremia remains controversial. Several pioneering but uncontrolled studies suggested a decreased incidence of focal bacterial sequelae after treatment with oral antibiotics, such as amoxicillin, but a subsequent randomized and blinded trial by Jaffe et al. did not confirm this observation in a limited sample of patients. Carroll et al. reported that intramuscular penicillin reduced focal complications from bacteremia; however, only 10 children had organisms recovered and a priori penicillin lacks effectiveness against *H. influenzae* and *Salmonella* species. A multicenter comparison of intramuscular ceftriaxone (50 mg/kg as a single dose) and oral amoxicillin (60 mg/kg per day given every 8 hours) described the complete elimination of bacteremia and a significant reduction in definite focal infections with ceftriaxone, a finding confirmed in subsequent, larger retrospective studies and by meta-analysis.

The decision about whether to treat children who are at risk for occult bacteremia hinges in large part on the balance between unnecessary administration of therapy to many children with no organisms in the bloodstream and prevention of serious complications in the few with bacteremia. Because diagnosis based on clinical and laboratory findings at the time of the visit has limited accuracy, physicians must choose between two alternatives, neither of which is completely satisfactory. Presumptive treatment is particularly appropriate for patients 3 to 24 months of age with a fever 39°C (102.2°F) or higher who are at higher-than-average risk (e.g., more irritable or lethargic than the usual child with a fever; WBC count of 15,000 to 20,000/mm^3 or more). For this group, intramuscular ceftriaxone (50 mg/kg) has been demonstrated to be effective. In managing highly febrile, young children not thought to be at higher risk, observation at home and/or oral antibiotic drugs, such as amoxicillin (50 to 75 mg/kg per day for two days) represent the major choices of treatment. If a conjugated vaccine against *S. pneumoniae,* currently under evaluation, proves effective and is introduced for general use, there will most likely be no role for presumptive antibiotic therapy, except in unusual circumstances.

The management of patients with proven bacteremia hinges on the identity of the pathogen. If penicillin-sensitive *S. pneumoniae* is isolated, the clinical findings at repeat examination determine the subsequent treatment. Children without fever or evidence of a serious infection (e.g., meningitis, pneumonia, cellulitis) should receive oral penicillin 50,000 units/kg per day or amoxicillin 50 mg/kg per day for 10 days; those with fever (38.5°C [101.2°F] or higher), clinical toxicity, or a serious focal infection merit initial intravenous (IV) antibiotic therapy. Children returning after a blood culture has grown other pathogens (*H. influenzae, N. meningitidis*, penicillin-resistant *S. pneumoniae*) are managed most prudently with IV antibiotics in the hospital because even those who remain well and afebrile appear to have some potential for persistent bacteremia and/or the continued evolution of focal infections. A few recent studies have

suggested, however, that selected afebrile and well-appearing children with a prior blood culture yielding penicillin-resistant *S. pneumoniae, N. meningitidis,* or *H. influenzae* may be managed with outpatient therapy, such as ceftriaxone (50 mg/kg), pending the results of repeat cultures.

Sepsis

Background

In sepsis, bacteremia exists in association with signs of serious systemic illness. The etiology of sepsis varies with age in the otherwise healthy child.

During the first 2 months of life, group B streptococcus and *Escherichia coli* are the most common isolates with sepsis. The group B streptococci cause more than 10,000 cases of neonatal disease yearly in the United States. At Yale, Gladstone et al. reviewed a decade of neonatal sepsis, from 1979 to 1988, and compared the findings to earlier reports from the same institution. Among 270 infants with sepsis, they isolated group B streptococcus from 64, *E. coli* from 46, *Klebsiella pneumoniae* from 18, and *H. influenzae* from 8. Analysis of the trend showed a steady level of infection for the group B streptococcus, compared with the prior decade, and a slight decrease in incidence for *E. coli.* Although some reports have suggested a downward trend in early onset group B streptococcus sepsis following the introduction of strategies for prophylaxis based on maternal screening, Pena et al. observed a steady incidence in late onset disease in Boston from 1982 to 1996.

N. meningitidis and *S. pneumoniae* infect the newborn only occasionally, but at a later age they emerge as the most common causes of sepsis in children. In a 12-year review, before the advent of the conjugated vaccine against Hib, Jacobs et al. studied 42 cases of “apparent meningococcemia” and found 30 infections with *N. meningitidis* and 12 with *H. influenzae.* Pneumococcal sepsis occurs more commonly in children with an absent or dysfunctional spleen. Group A streptococcus, *Staphylococcus aureus,* and *Salmonella* are recovered from the bloodstream relatively rarely, unless specific focal infections are present or, in the case of *Salmonella,* the patient has typhoid fever.

Sepsis occurs less often than bacteremia; however, large numbers of children with meningococcemia are occasionally seen in epidemics. Approximately 1,500 cases of meningococcal sepsis are reported yearly in the United States, most affecting children. The usual annual incidence has been estimated at 1 per 100,000 population, although in one epidemic, the attack rate was 838 per 100,000 children.

Certain conditions impose an increased susceptibility to sepsis on children. These include neoplasia, immunodeficiency syndromes, immunosuppressive therapy, asplenia, and sickle cell disease. The hemoglobinopathies pose a particularly urgent problem because of their relative frequency and the fact that overwhelming sepsis may occur in the young before the initial clinical manifestation of the underlying hematologic disease. Among 326 consecutive children with sickle cell hemoglobinopathies seen at The Children's Hospital of Philadelphia in a single year, the temperature was 38°C (100.4°F) or higher in 154, and four of those with fever had positive blood cultures. Two of the four were septic and the other two were bacteremic, but in the latter the immediate institution of antibiotic therapy may have prevented the rapid evolution of systemic toxicity.

Pathophysiology

As discussed under occult bacteremia, the first step toward sepsis occurs with colonization of the host by potentially pathogenic bacteria. The site of colonization is usually the pharynx in older children but may be the umbilicus or bowel in the neonate. Among immunosuppressed children, organisms that reside in the GI tract often invade the bloodstream.

After entry into the bloodstream, bacteria increase in number. As some of the organisms are lysed, toxic products, such as endotoxin, are released into the circulation. These products interact with host proteins and bind to receptors on cells of the immune system, as well as endothelia. Activation of the host cells follows, releasing a series of inflammatory mediators into the circulation. The initial cascade includes tumor necrosis factor (TNF), interleukin-1, and interleukin-6. Subsequently, additional interleukins and prostaglandins assume an important role.

Not every child with bacteremia develops the clinical manifestations of sepsis. The intrinsic virulence of the pathogen determines, in part, whether the bacteremia resolves spontaneously. *N. meningitidis* bacteremia results in sepsis or a focal infection in 50 to 75% of children, whereas *Salmonella* almost always remains asymptomatic. Host factors also assume an important role in clearing circulating bacteria. The young child, particularly younger than 2 years old, has a greater tendency to become seriously ill.

Clinical Manifestations

The duration of the history in a child with sepsis varies. Even though some children are febrile for several days during a preceding bacteremia, others develop a sudden dramatic illness. The interval between the initial fever and death may be less than 12 hours in fulminant meningococcemia (Fig. 84.1). The child progresses with continued sepsis from malaise to profound lethargy and, finally, to obtundation. Although fever is the cardinal sign of infection, children younger than 2 to 3 months of age may remain afebrile with sepsis; hypothermia is common in the first month of life.

FIGURE 84.1. Sepsis secondary to infection with *N. meningitidis.* Note diffuse purpuric lesions in this critically ill child.

A marked tachycardia occurs early in the course of the disease, at times exceeding 200 beats per minute (bpm) in the first 3 months of life, 175 bpm between 4 months and 2 years of age, and 150 bpm in the older child. Hypotension and tachypnea are present. The skin is cold and poorly perfused; in addition, petechiae and purpura may appear, particularly with *N. meningitidis.*

The hemoglobin and hematocrit are usually normal, falling occasionally from hemolysis as seen with disseminated intravascular coagulation (DIC). Although leukocytosis usually accompanies sepsis, an overwhelming infection occasionally produces neutropenia. The WBC count is rarely normal, and the differential is almost always shifted to the left; metamyelocytes and band forms often make their way into the peripheral blood. As the infection progresses, the platelet count decreases. It is distinctly unusual to have evidence of cutaneous hemorrhage from sepsis without thrombocytopenia. Similarly, the prothrombin time (PT), partial thromboplastin time (PTT), and fibrin degradation products rise with the ongoing consumption of the clotting factors. The electrolytes reflect a metabolic acidosis, and occasionally, mild hyponatremia occurs; the blood urea nitrogen (BUN) is usually normal but may rise in the face of preceding dehydration. A Gram stain of a petechial scraping shows the etiologic agent in one-third of cases. In the infant, hypoglycemia may occur.

Management

Although the initial therapy for sepsis is directed at the preservation of vital functions, every effort must be made to obtain the appropriate diagnostic studies (Table 84.3). Blood should be drawn for culture, complete blood count (CBC), platelet count, PT, PTT, electrolytes, BUN, arterial blood gas (ABG) analysis, serum aspartate aminotransferase (AST, formerly SGOT), and serum alanine aminotransferase (ALT, formerly SGPT) in conjunction with the immediate insertion of an intravenous catheter.

1. Ensure adequate ventilation and cardiac function.
2. Obtain laboratory studies (simultaneously with step 3): CBC, platelet count, PT, PTT, electrolytes, BUN, creatinine, glucose, arterial blood gas, blood culture, fibrin degradation products, AST, ALT.
3. Initiate hemodynamic monitoring and support: peripheral venous access; urinary catheter; central venous and arterial catheters (as indicated); cardiorespiratory monitors; normal saline, starting at 20 mL/kg.
4. Administer drugs and other therapeutic agents:
   Antibiotics: <2 months: ampicillin (50 mg/kg) and gentamicin (2.5 mg/kg)
   >2 months: ceftriaxone (50 mg/kg) or cefotaxime (50 mg/kg) or both ampicillin (50 mg/kg) and chloramphenicol (25 mg/kg)
   Sodium bicarbonate (pH <7.0) 1–2 mEq/kg
   Glucose (serum glucose <50 mg/dL) 0.25–1 g/kg
   Packed red blood cells (Hgb <10 g/dL) 10 mL/kg
   Platelet concentrates (platelet count: <50,000/mm^3) 0.2 unit/kg
   Fresh-frozen plasma (elevated PT/PTT) 10 mL/kg

CBC, complete blood count; PT, prothrombin time; PTT, partial thromboplastin time; BUN, blood urea nitrogen.

Table 84.3. Immediate Management of Sepsis

As initial therapy, normal saline, with or without 5% dextrose, is given at 20 mL/kg per hour or more rapidly, depending on the response. The unstable patient may require central venous, arterial, and urinary catheters. Deterioration often occurs after antibiotic administration because of sudden lysis of organisms, resulting in massive endotoxemia and release of cytokines, particularly TNF. Thus, appropriate venous and arterial access should ideally be in place before or concurrent with the administration of antimicrobial drugs. The initial laboratory studies, the response to the bolus of saline, and the measurements of the intravascular status determine the type and quantity of the subsequent fluids and the need for vasopressors (see Chapter 3).

For children younger than 2 months of age, ampicillin (200 mg/kg per day) and gentamicin (7.5 mg/kg per day) are administered; cefotaxime (150 mg/kg per day) may be used in place of gentamicin for the newborn. Dosages need to be decreased for premature infants in the first month of life and term infants in the first week (Table 84.4A and Table 84.4B). Cefotaxime (200 mg/kg per day) or ceftriaxone (100 mg/kg per day) alone provides effective monotherapy for the child older than 2 months of age. Vancomycin (40 mg/kg per day) may be added for patients who are critically ill or at particular risk of infection with penicillin-resistant *S. pneumoniae,* as in the case, for example, of a patient with sickle cell anemia who is taking daily prophylactic penicillin. In the presence of a focus of infection likely to be staphylococcal, oxacillin (150 mg/kg per day) can be used together with cefotaxime; alternatively, the combination of clavulanic acid and ampicillin (200 mg/kg per day) may be administered. Chloramphenicol (75 to 100 mg/kg per day) or meropenem (60–120 mg/kg per day) should be kept in mind for children with allergies to penicillins and cephalosporins. Corticosteroid therapy

is not recommended for sepsis.

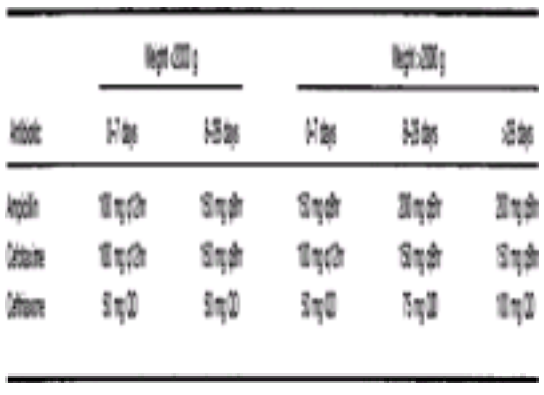

Table 84.4A. Intravenous Antibiotic Dosing for Newborn Infants Based on Age and Weight (Total Daily Dose [mg/kg/day] and Dosing Interval)

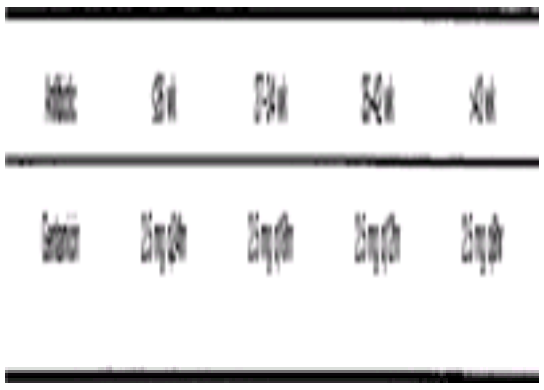

Table 84.4B. Intravenous Antibiotic Dosing for Newborn Infants Based on Gestational Age (mg/kg/dose)

Blood components are given as indicated by the results of the initial hematologic studies. If the hemoglobin is lower than 10 g/dL, packed red cells are administered at 10 mL/kg. Thrombocytopenia (less than 50,000/mm ^{3}) is corrected with platelet concentrates at 0.2 units/kg and decreased clotting factors with fresh-frozen plasma 10 mL/kg. For the child with hypoglycemia (glucose less than 50 mg/dL), glucose should be given at a dose of 0.25 to 1 g/kg in the form of a 25% solution. Heparin plays no role in the initial emergency care of the child with sepsis but may be useful subsequently to treat severe thrombotic episodes. Specific inhibitors of endotoxin and cytokines, such as bacterial polysaccharide inhibiting protein (BPI) are under investigation but have not been demonstrated to be effective as of yet.

Central Nervous System Infections

Three important infectious syndromes involve the CNS: meningitis, encephalitis, and brain abscess. Because encephalitis and brain abscess usually confront the emergency physician as problems in the differential diagnosis of various neurologic manifestations, they are discussed as neurologic emergencies in Chapter 83.

Meningitis, an inflammation of the membranes lining the CNS, results from an infection or irritation on a noninfectious basis. Inflammation of the meninges produces a pleocytosis in the cerebrospinal fluid (CSF), allowing, in most cases, for the diagnosis of meningitis by examination of this readily accessible material. However, organisms may occasionally infect the meninges without eliciting a cellular reaction, either because sufficient time has not elapsed for a leukocyte response or because the pathogen is of low virulence.

In the ED setting, most cases of meningitis result from an infection of the CNS. Table 84.5 lists those organisms that are the more common invaders of the meninges. The most important initial task that confronts the emergency physician is the identification of children with bacterial meningitis, a life-threatening infection amenable to therapy if diagnosed sufficiently early in the course. The sine qua non for the definitive diagnosis of meningitis is examination of the CSF. Routine studies performed on this fluid should include cell count with differential, glucose, protein, Gram stain, and bacterial culture. In selected cases, additional studies, such as latex agglutination; acid fast stain; India ink preparation; serologic testing for Lyme disease and/or syphilis; cryptococcal antigen; polymerase chain reaction (PCR) for herpes; and cultures for anaerobic bacteria, mycoplasma, mycobacteria, and fungi, are indicated. Values of various parameters of the CSF are presented for healthy persons and for those with viral and bacterial meningitis (Table 84.6).

Viruses	*Haemophilus influenzae*
Enteroviruses	*Salmonella* species
Herpes simplex	*Listeria monocytogenes*
Lymphocytic choriomeningitis	*Mycobacterium tuberculosis*
Mumps	Spirochetes—Lyme, syphilis
Other	Fungi
Mycoplasma	*Candida albicans*
Bacteria	*Cryptococcus neoformans*
Streptococcus pneumoniae	Parasites
Neisseria meningitidis	Cysticercosis
Escherichia coli	Amoebae
Group B streptococcus	

Table 84.5. Organisms That Cause Meningitis

	Neonate	Child	Bacterial Meningitis	Viral Meningitis
WBC (per mm^3)	<30	<10	200–20,000	10–1,000
Protein (mg/dL)	<170	<40	>100	40–100
Glucose (mg/dL)	>30	>40	<30	>30

Table 84.6. Usual Ranges for CSF WBC Count, Protein, and Glucose in Normal Infants and Children and in Those with Viral or Bacterial Meningitis

The CSF ordinarily contains no red blood cells. The presence of blood indicates either contamination from a traumatic lumbar puncture or hemorrhage in the CNS. If the density of the red cells is constant from the first to the last tube collected and the cells are crenated, the likelihood of CNS hemorrhage is greater. Certain infectious agents, such as herpes simplex virus, may produce a hemorrhagic meningoencephalitis.

More than 9 WBCs in the CSF from a child and 29 from a neonate indicate inflammation of the meninges. However, a specimen is sometimes obtained early in the course of meningitis before an inflammatory reaction has been invoked. Thus, a child with fewer than 10 cells in the CSF will occasionally later develop the physical and laboratory manifestations of meningitis.

In viral infections of the CNS, the WBC count in the CSF usually ranges from 10 to 1,000/mm^3. Occasionally, a WBC count as high as 2,500/mm^3 may be seen. A predominance of mononuclear cells is usually present, although early in the course of the illness, neutrophils may be in the majority. Bacterial meningitis evokes an intense infiltration of leukocytes, with a marked predominance of neutrophils. The cell count is usually in the range of 1,000 to 20,000/mm^3 but may be even higher.

The CSF glucose is normally one-half to two-thirds of the serum glucose. Equilibration between the serum and CSF glucose levels has been estimated to require at least 30 minutes. Thus, a rapid decrease in the serum glucose may obscure a wide variance from the CSF level, whereas a sudden elevation may lead to a falsely large discrepancy. Because the stress of a lumbar puncture produces hyperglycemia, a serum glucose for comparison with the CSF level should be obtained before this procedure is attempted. In viral meningitis, the CSF glucose, usually in the normal range, may be as low as 30 mg/dL. The glucose in bacterial meningitis often falls below 30 mg/dL. Hypoglycorrhachia accompanying an elevated protein level and a mild mononuclear pleocytosis should arouse a suspicion of tuberculous meningitis.

A normal CSF protein is less than 40 mg/dL in the child and 170 mg/dL in a neonate. Although the protein is minimally elevated in viral meningitis, the level in bacterial meningitis is generally 100 mg/dL or greater.

Additional studies, such as latex agglutination, may be helpful in distinguishing bacterial from viral meningitis.

Bacterial Meningitis

Background

Although almost any bacteria can cause meningitis, more than 90% of the cases in immunocompetent children result from infections with five organisms *: S. pneumoniae, N. meningitidis, E. coli,* group B streptococcus, and *H. influenzae.* The most common organism varies with the age of the child (Fig. 84.2). In the first month of life, *E. coli* and group B streptococcus are usually isolated; *Listeria monocytogenes*, a Gram-positive rod, accounts for 1 to 3% of the cases. Between 30 and 60 days of age, group B streptococcus continues to be recovered frequently, followed by *S. pneumoniae* and *N. meningitidis; H. influenzae* occurs rarely. After the first 2 months of life, *S. pneumoniae* and *N. meningitidis* cause the majority of meningeal infections; *H. influenzae* remains a consideration primarily among children not immunized with

conjugated Hib vaccine or those recently arrived from a third world country. *Salmonella,* an uncommon etiologic agent in the United States, should be suspected in the first few months of life if meningitis occurs in association with gastroenteritis.

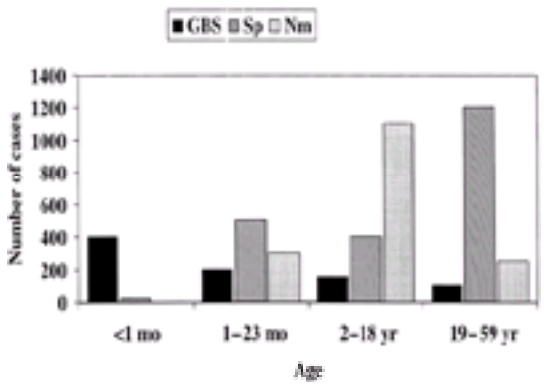

FIGURE 84.2. Projected cases of meningitis by age and organism, excluding *E. coli. GBS,* group B streptococcus; *Nm, Neisseria meningitidis; Sp, Streptococcus pneumoniae.* (Modified from Schuchat, et al. N Engl J Med 1997;337:970–976.)

Meningitis was formerly among the most common life-threatening infections of children, but the incidence of this disease has declined significantly since the introduction of conjugated vaccine against Hib. Schuchat et al. performed an active population-based surveillance of meningitis (excluding disease caused by Gram-negative enteric rods) during 1995 from all the acute-care hospitals in four states with a population of more than 10 million and described the attack rates for the various pathogens, by age (Table 84.7). Based on their findings, they projected the total number of cases of bacterial meningitis during 1995 in the United States, as shown in Figure 84.2, of particular note estimating that only 948 cases occurred in children from 1 to 23 months of age. A conjugated vaccine against *S. pneumoniae* will most likely be introduced within the next decade and would be expected to significantly reduce the incidence of meningitis.

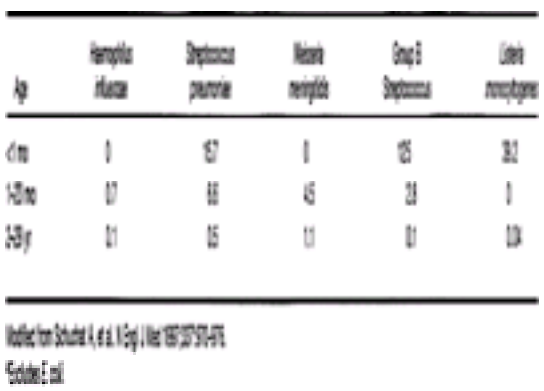

Table 84.7. Age-Specific Incidence (per 100,000) in 1995 of Bacterial Meningitis in the United States during 1995 [a]

Pathophysiology

Microorganisms gain access to the CNS through two potential pathways. Most commonly in children, a preceding bacteremia leads to hematogenous seeding of the meninges. Alternatively, direct extension may occur from a purulent parameningeal focus.

Colonization of the nasopharynx sets the stage for the subsequent development of meningitis in most bacterial CNS infections in the older child. In the infant, who is susceptible to infection with Gram-negative enteric organisms, the bowel is often the source of the pathogen. This is also the case beyond the neonatal period with less common bacteria such as *Salmonella.* A small percentage of the children colonized with a potential pathogen will develop bacteremia, but most will clear the pathogens from their bloodstream spontaneously; more than 80% of cases of bacteremia with *S. pneumoniae* resolve without leading to local infection. Although meningitis is more common after the recovery of *N. meningitidis* from the blood, most such children also escape CNS infection. Splenectomized persons, or those who have infarcted spleens on the basis of inherited hemoglobinopathies, cannot limit the spread of bacteremia as successfully as those who are immunologically intact.

Although a less common predecessor to meningitis, purulent collections contiguous to the CNS may also produce such infections. Sinusitis is the most common offender. Organisms also may invade the meninges on occasion directly from the middle ear. However, meningitis following OM usually results from bacteremia, unless a congenital or posttraumatic fistula in the temporal bone provides access to the CSF.

Clinical Manifestations

The signs and symptoms of meningitis vary with the child's age (Table 84.8). Particularly in the first 3 months of life, the clinician must maintain a high index of suspicion for this disease. In addition, it should be kept in mind that partial

treatment with antibiotics may obscure the typical findings.

		Signs	
Age	Symptom	Early	Late
0–3 mo	Paradoxical irritability	Lethargy	Bulging fontanelle
	Altered sleep pattern	Irritability	Shock
	Vomiting	Fever (±)	
	Lethargy	Hypothermia (<1 mo)	
4–24 mo	Irritability	Fever	Nuchal rigidity
	Altered sleep pattern	Irritability	Coma
	Lethargy		Shock
>24 mo	Headache	Fever	Coma
	Neck pain	Nuchal rigidity	Shock
	Lethargy	Irritability	

Table 84.8. Signs and Symptoms of Meningitis

Before 3 months of age, the history is that of irritability, an altered sleep pattern, vomiting, and decreased oral intake. In particular, paradoxical irritability points to the diagnosis of meningitis. Irritability in the infant without inflammation of the meninges is generally alleviated by maternal fondling; however, in the child with meningitis, any handling, even directed toward soothing the infant, may increase irritability by its effect on the inflamed meninges. The amount of time spent sleeping may either increase because of obtundation or decrease from irritability. Bulging of the fontanel, an almost certain sign of meningitis in the febrile, ill-appearing infant, is a late finding. Vomiting is often a prominent feature of the presentation of infants with meningitis, but when emesis occurs in isolation, particularly in the absence of fever, it more likely points to pyloric stenosis or other disorders of the GI tract.

As the child passes beyond the age of 3 months, the symptoms gradually becomes more specific for involvement of the CNS. A change in the level of activity is almost always noticeable. However, it is only in the child older than 2 years of age that meningitis manifests reliably with complaints of headache and neck stiffness.

The physical examination in the young infant rarely provides specific corroboration, even when the history suggests meningitis. Fever is often absent in these children, despite the presence of bacterial infection. Any child younger than 2 to 3 months of age who is brought to the ED with a documented temperature of 38.0° to 38.5°C (100.4° to 101.2°F) or higher should be considered at particular risk for meningitis. The physical signs are sufficiently elusive that many experts caution that one should not rely exclusively on the examination to rule out meningeal infection. In several studies, 5 to 10% of these young infants had meningitis despite being judged clinically well by experienced pediatric residents.

After 3 months of age, increasing, but not absolute, reliance can be placed on the physical findings; fever is almost inevitably noted. Specific evidence of meningeal irritation often is present, including nuchal rigidity (Fig. 84.3) and, less often, Kernig and Brudzinski signs. When a lumbar puncture fails to confirm the diagnosis of meningitis despite the presence of meningeal signs, other conditions must be pursued that can mimic the findings on physical examination. Conditions capable of producing meningismus (irritation of the meninges without pleocytosis in the CSF) include severe pharyngitis, retropharyngeal abscess, cervical adenitis, arthritis or osteomyelitis of the cervical spine, upper lobe pneumonia, subarachnoid hemorrhage, pyelonephritis, and tetanus.

FIGURE 84.3. Child with meningitis who demonstrates ill appearance and nuchal rigidity. **A.** Patient lying supine with neck in neutral position. **B.** Pain grimace and resistance (lifting of shoulders) upon attempted flexion of the neck.

At times, meningitis manifests initially as a convulsion. In the infant less than 6 months of age with a first time seizure, a lumbar puncture is mandatory to discern the presence of CNS infection, unless there are specific contraindications or an alternative diagnosis is readily apparent. The occurrence of a seizure in a febrile child older than 6 months of age presents more of a dilemma for the clinician. Febrile seizures are common, affecting 5% of children, and underlie most of these episodes. However, it may be difficult to distinguish a simple febrile seizure in an ill-appearing child with a high fever from early meningitis because of the vague symptoms and lack of definitive physical findings in the first 2 years of life. In addition, the occurrence of a convulsion may obscure such meningeal signs as nuchal rigidity, which may be masked by the hypotonia of the postictal period. Opinion varies regarding whether a febrile seizure can be distinguished clinically from a seizure secondary to meningitis. In one study reported from the era before widespread administration of the conjugated vaccine against Hib, 20% of children thought to have a first febrile seizure on the basis of the history and

physical examination eventually were determined to have meningitis. However, other investigators have reported more success in making such a clinical differentiation. Because of the difficulty of establishing a clinical diagnosis in the young child, a lumbar puncture should be strongly considered in every child less than 12 months of age with a first febrile seizure. In the older child or in the case of a recurrent febrile seizure, the experienced clinician may choose to be guided by the physical findings and the evolution of the illness over the ensuing 12 to 24 hours.

The child with meningitis often has a complicated course beginning in the ED or even preceding arrival at the hospital (Table 84.9). Shock, seizures, and hyponatremia strike at any age, whereas apnea and hypoglycemia predominantly affect infants less than 3 months of age. Although sterile subdural effusions and, rarely, empyemas usually occur later in the disease, they merit consideration in the infant with signs of herniation and a bulging fontanel.

Early	Late
Apnea	Hyponatremia
Shock	Subdural empyema
Hypoglycemia	Seizures
Hyponatremia	
Seizures	

Table 84.9. Short-term Complications of Meningitis

Management

Bacterial meningitis is a medical emergency that requires the immediate institution of therapy (Table 84.10). If the disease is diagnosed and treated promptly, mortality dwindles to less than 5%. Antibiotics should be given by IV at the completion of the lumbar puncture. Although several studies have shown the average elapsed time between arrival in the ED and delivery of antibiotics averages 2 to 3 hours, every effort should be made to reduce this interval to enhance the theoretic advantages of early therapy. If meningitis is suspected but attempts to obtain CSF are unsuccessful, this failure should not delay the antibiotic administration. It is safer to treat a child presumptively with a sterile pleocytosis than to handle the complications of progressive CNS infection. Similarly, inability to achieve venous access should not retard the initiation of drug therapy. The intramuscular route provides a suitable, temporary alternative.

1. Ensure adequate ventilation and cardiac function.
2. Obtain laboratory studies (simultaneously with step 3):
Cerebrospinal fluid: cell count, glucose, protein, Gram stain, culture, latex agglutination (as indicated)
Blood: complete blood count, platelet count, prothrombin time, partial thromboplastin time, electrolytes, blood urea nitrogen, creatinine, glucose, arterial blood gas, blood culture
3. Initiate hemodynamic monitoring and support.
Achieve venous access; use cardiorespiratory monitors.
4. Administer drugs.
Treat septic shock, if present.
Consider dexamethasone (0.15 mg/kg) before or shortly after antibiotic administration.
Antibiotics: <1 month: ampicillin (50 kg) and cefotaxime (50 mg/kg); >1 month: vancomycin (15/mg) and either ceftriaxone (50 mg/kg) or cefotaxime (75 mg/kg)*
Glucose (if serum glucose <50 mg/dL) 0.25–1 g/kg
Treat acidosis and coagulopathy, if present.

*Chloramphenicol (25 mg/kg) or meropenem (25 mg/kg) may be used in place of cephalosporins for children allergic to those agents.

Table 84.10. Immediate Management of Bacterial Meningitis

The child's age determines the spectrum of microorganisms causing meningitis and the selection of antibiotic therapy (Table 84.10). In the first 30 days of life, the most likely organisms include the Gram-negative enteric rods, such as *E. coli,* and group B streptococcus. The enteric pathogens are almost always sensitive to the aminoglycoside antibiotics; however, recent studies have shown that a third-generation cephalosporin, such as cefotaxime, may be more effective. Penicillin or ampicillin effectively treats the group B streptococcus. Ampicillin and a third-generation cephalosporin (cefotaxime) or an aminoglycoside (gentamicin) thus provide coverage for the most common pathogens in the first month of life. The spectrum of these antibiotics also includes less common organisms in the neonate, such as *S. pneumoniae, N. meningitidis,* and *L. monocytogenes. Salmonella* is a somewhat unusual cause of meningitis in the United States but may be isolated in 1 to 2% of such infections. Increasingly, this organism is resistant to ampicillin. Thus, the isolation or strongly suspected presence of *Salmonella* from the GI tract dictates the inclusion of a cephalosporin (cefotaxime or ceftriaxone). Alternatives for the penicillin-allergic child with *Salmonella* infecting the meninges include chloramphenicol and meropenem.

Between 30 and 60 days of age, group B streptococcus remains the predominant pathogen, but the Gram-negative enteric bacilli decrease in frequency. *S. pneumoniae* and *N. meningitidis* occur sporadically, as does *H. influenzae,* because these children are too young to be immunized against Hib. The usual antibiotic combination is vancomycin to cover penicillin-resistant pneumococci, with either ceftriaxone or cefotaxime (Table 84.10)

After the first 2 months, the predominant pathogens that cause meningitis are *S. pneumoniae* and *N. meningitidis. H.*

influenzae, formerly responsible for most CNS infections in children, has become exceedingly rare. As for the child between 30 and 60 days of age, initial antibiotic therapy includes vancomycin and either ceftriaxone or cefotaxime (Table 84.10). Chloramphenicol is an option for patients with a solid history of a serious reaction to penicillin.

In addition to the antibiotic administration aimed at the eradication of the offending organism, supportive therapy for complications (Table 84.9 and Table 84.10) is an essential ingredient in the care of the child with meningitis. Recommended laboratory studies on every patient include a CBC, electrolytes, BUN, PT and PTT, glucose, and blood culture. A rapid assessment should be made about the adequacy of ventilation. The CNS edema that accompanies inflammation of the meninges may produce obtundation and hypoventilation. Apneic episodes can occur in the infant. Thus, oxygen, intubation, and assisted ventilation all may be required. Bacteremia, which usually accompanies meningitis, may lead to septic shock. This condition demands vigorous fluid resuscitation with normal saline. The response to an initial bolus of 20 mL/kg saline determines the need for further therapy such as the use of cardiotonic agents (see Chapter 3). The urgency to provide adequate perfusion to the vital organs by expanding the intravascular volume takes precedence over concerns about edema in the CNS.

Hyponatremia often accompanies meningitis, resulting from water retention because of inappropriate secretion of antidiuretic hormone (SIADH). Occasionally, the oral administration of hypotonic solutions by the parents during the preceding prodromal illness may produce fluid overload and a low serum sodium (Na). If the child is believed to have seizures on the basis of hyponatremia, the physician may give 3% NaCl (see Chapter 86) at a dosage of 10 to 12 mL/kg over 1 hour.

After the correction of dehydration or shock, the rate of fluid administration to the child with meningitis should be at 75 to 100% of maintenance requirements (see Chapter 86). Generally, D5/0.2% NaCl is used for this purpose. Failure of the serum Na to rise in the hyponatremic child mandates further restriction on hydration.

Hypoglycemia occurs as a reaction to septicemia and stress. It is a more common concomitant of meningitis in the first 3 months of life. If the blood glucose is less than 50 mg/dL, 25% glucose should be given at a dosage of 0.25 to 1 g/kg. This must be followed by an infusion of 5% glucose and monitoring of the response. Occasionally, 10% glucose will be necessary to maintain an acceptable serum level.

Seizures occur in 25% of children with bacterial meningitis and, occasionally, in those with viral infections. One should always be suspicious of derangement of the glucose or sodium as a cause of convulsive activity. However, most seizures are caused by irritation of the brain from the infectious process. They are controlled in the usual fashion with diazepam or lorazepam, phenytoin, and phenobarbital (see Chapter 70 and Chapter 83).

Subdural effusion and, less often, empyema occur in 20 to 40% of children with meningitis but usually appear later in the course and remain asymptomatic. In the rare case of an infant with herniation caused by a subdural collection, percutaneous drainage relieves the pressure on the brain and produces significant improvement.

Some studies have suggested that dexamethasone at a dosage of 0.15 mg/kg per dose given every 6 hours to children older than 2 months of age mitigates the sequelae of bacterial meningitis, particularly sensorineural hearing loss. The mechanism of action has been postulated to involve inhibition of cytokine production in the CSF. Although many clinicians choose to administer dexamethasone to patients beyond the first 2 months of life in whom the diagnosis of bacterial meningitis appears highly likely, contradictory evidence exists in the literature and expert panels have withheld a definitive endorsement. If the decision is made in favor of administration, the drug should be given before antibiotic administration when possible. If dexamethasone is not administered before the initiation of antibiotic therapy, it may be given subsequently but appears to lose its theoretic benefit after an interval or more than 4 hours.

Aseptic Meningitis

Background

The aseptic meningitis syndrome is defined here as an inflammation of the meninges that occurs in the absence of bacterial growth on routine culture media. A child whose initial CSF findings suggest an aseptic meningitis may rarely turn out to have a purulent infection because bacteria do not always elicit a marked polymorphonuclear leukocytosis early in the course of the disease. In addition, bacteria with unusual growth requirements, inhibited by subtherapeutic concentrations of antibiotics, or sequestered in pockets adjacent to but not directly communicating with the CSF, all may produce an aseptic meningitis syndrome.

Both infectious and noninfectious diseases cause the aseptic meningitis syndrome (Table 84.11). By far, the most common cause is viral meningitis; however, the clinician should be alert to unusual pathogens in patients who are immunocompromised or who show atypical clinical features. Despite underreporting, the Centers for Disease Control and Prevention (CDC) notes about 5000 cases annually in the United States.

Infectious	Parasites
Viruses	Trichinosis
Early or partially treated	Toxoplasmosis
bacterial meningitis	Cysticercosis
Parameningeal infection	Malaria
Unusual bacteria	*Naegleria*
Leptospirosis	*Noninfectious*
Syphilis	Neoplasm
Tuberculosis	Hemorrhage
Ehrlichia canis	Hypersensitivity reactions
Borrelia burgdorferi (Lyme)	Heavy metal poisoning
Mycoplasma	Collagen vascular disease
Rickettsia	Sarcoidosis
Fungi	Kawasaki disease (? infectious)
Cryptococcus	
Candida	

Table 84.11. Aseptic Meningitis Syndrome

Aseptic meningitis occurs throughout the year. Because the incidence of enteroviral infections, which are responsible for a large number of the cases, peaks in the summer in temperate regions, outbreaks of aseptic meningitis are more often seen in the warm months.

Pathophysiology

The multiple causes of aseptic meningitis syndrome produce inflammation of the meninges by different mechanisms. Even among the viral infections, the pathogenesis varies considerably. Some viruses lead to an immune reaction in the CNS, whereas others invade the neural tissue directly. Access to the meninges is usually hematogenous but may be achieved by ascension along peripheral nerves.

Clinical Manifestations

The signs and symptoms of aseptic meningitis resemble those of bacterial infections of the CNS but are not usually as severe. The infant shows only lethargy and irritability, whereas the older child complains of a headache and stiff neck. Vomiting may occur and may be persistent. There is often a history of a concomitant upper respiratory or GI viral illness. Fever usually occurs but often hovers around 38.5°C (101.2°F). The infant may appear toxic, but the older child may remain remarkably well. Nuchal rigidity in a patient who is alert and conversant suggests aseptic, rather than bacterial, meningitis. Shining a flashlight in the eyes often elicits photophobia. The fontanel of the infant generally maintains a normal configuration but may bulge rarely. Aside from occasional positive Kernig and Brudzinski signs, the neurologic examination often shows no abnormalities. An altered level of consciousness or focal neurologic deficit points to meningoencephalitis rather than aseptic meningitis (see Chapter 83).

Management

In addition to the routine CSF studies, children with aseptic meningitis usually require a CBC, electrolytes, and a BUN. Most patients need no further tests, but in atypical situations, consideration should always be given to nonviral causes that may mandate additional diagnostic steps or specific therapy. If tuberculosis is suspected based on family contacts, a low CSF glucose, or pulmonary findings, a Mantoux test and chest radiograph are useful for confirmation. In endemic areas, particularly in association with erythema migrans, serologic studies for Lyme disease and antibiotic therapy may be indicated. A computed tomography (CT) scan provides essential information about patients with symptoms or signs of a parameningeal infection or CNS tumors and hemorrhages. Immunosuppressed patients develop infections with a wide variety of unusual bacteria, fungi, and parasites that can be identified in many cases with appropriate examination and culture of the CSF (India ink and acid-fast stains, cryptococcal antigen testing, fungal and mycobacterial cultures). When examining infants, the physician must remain alert to the possibility of a herpetic infection and consider obtaining a PCR for herpes simplex virus.

Therapy for the common viral infections does not currently extend beyond supportive care. Dehydration from prolonged emesis may necessitate IV fluid administration. After any deficit has been corrected, the rate should be set to provide 75 to 100% of the daily maintenance requirement to avoid overhydration and the possible aggravation of cerebral edema in the child who develops an encephalitic component.

Because the CSF findings in aseptic meningitis occasionally overlap those in bacterial infections, hospital admission is usually warranted until the CSF culture results are available. However, the experienced clinician may choose to follow the older child as an outpatient if the family is reliable and nonviral causes (e.g., tuberculosis, cryptococcosis) have been excluded. Generally, to qualify for discharge with aseptic meningitis, a patient must have all CSF parameters pointing away from bacterial infection: less than 500 cells mm^3, less than 50% polymorphonuclear leukocytes, protein less than 100 mg/dL, and glucose greater than 30 mg/dL.

Upper Respiratory Tract Infections

Infections in children involve the upper respiratory tract more often than any other region of the body. Included in this category are nasopharyngitis (common cold), stomatitis, pharyngitis, sinusitis, otitis, peritonsillar abscess, retropharyngeal and lateral pharyngeal abscesses, laryngotracheobronchitis (croup), and epiglottitis. Because the most common causative organism varies between sites, infection in this area demands a specific anatomic diagnosis if the physician is to proceed with the appropriate diagnostic evaluation and therapy.

Nasopharyngitis

Nasopharyngitis (URI), or the common cold, is a viral illness of the upper respiratory tract in children. The most commonly isolated organisms are the rhinoviruses and coronaviruses. Prospective family studies have shown that five or six episodes occur yearly during childhood. The illness is characterized by a fever of less than 39°C (102.2°F) and coryza. There may be a mild conjunctivitis and infection of the pharynx. Although the tympanic membranes may show a slightly dull appearance and decreased mobility, the characteristic features of acute purulent OM (erythema, loss of the landmarks, and bulging) are absent. Therapy is limited to a recommendation for rest, adequate hydration, saline nose drops, and antipyretic agents. Neither antibiotics nor antihistamine decongestant combinations prevent secondary

bacterial infections, such as acute purulent OM.

Stomatitis

Stomatitis, an injection of the mouth, is caused by herpes simplex and the coxsackieviruses at any age and by *Candida albicans* (“thrush”) in the infant (see Chapter 121 and Chapter 124) or in the immunosuppressed child. Viral infections cause vesicular lesions initially (Fig. 84.4) and ulcerations and plaques subsequently. Some coxsackieviruses may involve the hands and feet (Fig. 84.5A) as well as the mouth (coxsackievirus hand–foot–mouth syndrome), and herpetic stomatitis may be complicated by spread of infection to the digits, which is called herpetic whitlow (Fig. 84.5B). For otherwise healthy patients, treatment is limited to systemic antipyretic and analgesic drugs and the local application of topical analgesics, such as 2% viscous Xylocaine or the combination of Kaopectate and diphenhydramine. Oral acyclovir hastens the resolution of herpetic lesions in immunosuppressed patients.

FIGURE 84.4. Lesions of herpetic stomatitis.

FIGURE 84.5. A. Vesicles in coxsackievirus hand–foot–mouth syndrome. **B.** Herpetic whitlow.

C. albicans produces white plaques on the mucosa that bleed if scraped. Nystatin 200,000 units four times daily leads to a prompt resolution of this condition. Although either oral ketoconazole or fluconazole are effective treatments, neither is indicated routinely for the immunocompetent host.

Pharyngitis

Pharyngitis (see Chapter 71) is an infection of the throat (including the tonsils). In the immunocompetent child, several viruses, perhaps *Mycoplasma pneumoniae* and *Chlamydia trachomatis,* and only a few bacteria cause pharyngitis. Common viral isolates include the adenoviruses, influenza viruses, enteroviruses (including coxsackievirus), parainfluenza viruses, and the Epstein-Barr virus (EBV). Although many bacteria have been reported as possible causes of pharyngitis, only three organisms have well-defined roles: group A streptococcus, *Corynebacterium diphtheriae,* and *N. gonorrhoeae.*

Pharyngitis is a common infection in children. Moffet et al. reported that 128 of 230 visits to an infirmary by youngsters of school age at a children's home were for pharyngeal infections. Group A streptococcus causes almost 50% of such infections between 5 and 15 years of age but is uncommon in the first 3 years of life. In one study of 50 children less than 3 years old with exudative pharyngitis, only 7 had illness from streptococci.

For practical purposes, isolated pharyngitis can be considered as streptococcal (bacterial) or nonstreptococcal (viral). Because the symptoms of the two types overlap, the physician can reliably distinguish the more important streptococcal infections only with the aid of the laboratory. However, certain clinical features favor a bacterial cause. Such infections more often have an abrupt onset with fever and sore throat; cough and coryza are uncommon. Examination of the pharynx shows an erythematous mucosa, often with exudate (Fig. 84.6) and petechiae on the posterior palate. In addition, the cervical lymph nodes often become enlarged and tender.

FIGURE 84.6. Examination of the pharynx in a child with streptococcal infection shows enlarged, erythematous tonsils with exudate.

Although unusual, complications may occur with bacterial pharyngitis; both suppurative and nonsuppurative sequelae can result from streptococcal infections. The latter category includes acute rheumatic fever and glomerulonephritis. Viral pharyngitis resolves spontaneously in 2 to 5 days with the exception of EBV, as discussed under Infectious Mononucleosis.

In the ED, a tonsillar swab for antigen detection by latex agglutination or preferably optical immunoassay, if available, should be obtained from children with pharyngeal inflammation and those who complain of sore throat, unless the diagnosis of a generalized viral syndrome can be confidently established on clinical grounds. If the test for antigen is positive, the infection is presumably caused by group A streptococcus and the child is treated with penicillin. Although a single injection of benzathine penicillin (600,000 units if less than 28 kg and 1.2 million units if 28 kg or more) obviates all problems with compliance, oral phenoxymethyl penicillin (250 mg/dose for children and 500 mg/dose for adolescents, given two to three times per day) provides an acceptable alternative, if prescribed for 10 days. Amoxicillin may be used in place of penicillin but offers no advantage. Erythromycin (40 mg/kg per day) is used for penicillin-allergic children; azithromycin for 5 days (10 mg/kg on the first day and 5 mg/kg on subsequent days) represents a more expensive alternative. Shorter courses of therapy, particularly with oral cephalosporins, have been shown to be effective in limited studies but cannot be enthusiastically recommended at present because of the small number of patients treated in various investigations and a lack of data on the prevention of complications. Antipyretic agents, fluids, and adequate rest should be recommended. In children with pharyngitis suggestive of streptococcal disease for which antigen detection is negative or unavailable, a throat culture is indicated. While awaiting the results of cultures, one may choose to treat presumptively children with severe pharyngitis characteristic of streptococcal disease and those unable to reliably return for follow-up. Because antibiotics shorten the course of streptococcal pharyngitis minimally, there is no reason to give these drugs hastily before confirming a bacterial cause. Institution of a liquid diet and acetaminophen provide some symptomatic relief.

Otitis Media

Background

OM refers to inflammation within the middle ear. The disease can be further classified according to the associated clinical symptoms, specific otoscopic findings, duration, and occurrence of complications. Currently, the disease is divided into two broad categories (Table 84.12): acute otitis media (AOM) and otitis media with effusion (OME). AOM (formerly called acute purulent otitis media) is caused by an acute bacterial (or occasionally viral) infection, has a sudden onset, and usually causes symptoms. On the other hand, OME (formerly called serous otitis media) is not primarily bacterial in origin, has a more gradual onset, and often remains asymptomatic. A great deal of overlap exists between these two entities, such that clinical differentiation at a single point in time may not be possible. The bacterial flora of middle ear infections varies somewhat with age. Although Gram-negative enteric bacilli and *S. aureus* cause 15 to 20% of OM during the first month of life, *S. pneumoniae, H. influenzae,* and *Moraxella catarrhalis* predominate at all ages, even in the neonate. *S. pneumoniae* can be recovered from about 40% and *H. influenzae* and *M. catarrhalis* each from 20% of children with OM between 1 month and 10 years of age. Among older children and adolescents, *H. influenzae* decreases in frequency but remains a significant pathogen. More than 90% of the *H. influenzae* that cause OM are nontypeable, and most of the remainder are type b. Most *H. influenzae* and *M. catarrhalis* are resistant to ampicillin. Among pneumococci, the incidence of penicillin resistance varies geographically and continues to evolve; at present, on average, about 25% of these organisms exhibit a high level of resistance (mean inhibitory concentration [MIC] greater than or equal to 2 µg/mL) and another 15 to 20%, an intermediate level.

Type	Duration	Bacteriology	Tympanum	Signs and Symptoms
Acute otitis media (AOM)	Days to weeks	Isolation in 70%	Erythematous or purulent, bulging	Fever (70%), earache, pulse otalgia, irritability
Otitis media with effusion (OME)	Weeks to months	Occasional isolation	Dull, retracted, fluid level	Asymptomatic, decreased hearing, fullness

Table 84.12. Classification of Otitis Media

AOM concerns the emergency physician to a far greater extent than OME. It is the most common bacterial infection in children, affecting an estimated 9 million children annually. Howie and Ploussard found at least one episode of OM in two-thirds of 2-year-old children in their practice, and one in seven children had more than six episodes. Teele et al. reported an average of 0.4 to 1.2 episodes of OM annually among children from birth to age 7 years.

OM is more common in the winter in temperate climates. This is presumably related to the higher incidence of URIs during the colder months.

Pathophysiology

Any discussion of the pathophysiology of OM provokes great controversy among pediatricians and otolaryngologists alike. However, it appears that abnormal function of the eustachian tube contributes to the development of OM in most cases. Possible mechanisms for obstruction of the eustachian tube include hypertrophied nasopharyngeal lymphoid tissue or intrinsic abnormalities of the various components of this structure. Whatever the cause, blockage impairs ventilation of the middle ear, leading to an accumulation of fluid behind the tympanic membrane. This effusion then provides a fertile environment for the proliferation of bacteria from the heavily colonized nasopharynx.

Clinical Manifestations

Studies by Howie, Paradise, Klein, and others have shown the variable spectrum of OM. An infection in the middle ear may produce no symptoms, being detected only on examination, or it may cause obvious localizing pain. In the young child, the initial manifestation is often not otologic but rather fever, irritability, or diarrhea. Children beyond the age of 3 years generally, but not invariably, complain of pain in the ear. Less common symptoms include vertigo and hearing impairment.

Fever, occurring in 25 to 35% of children with AOM, serves only to arouse suspicion of infection in the middle ear. The diagnosis rests in the usual clinical settings on the accurate interpretation of the otoscopic findings, a skill gained only by experience with the pneumatic otoscope (Fig. 84.7). If cerumen obscures the tympanic membrane, a sufficient quantity must be cleared to allow adequate visualization. Either a blunt curette or an apparatus for irrigation adequately removes such material in most cases.

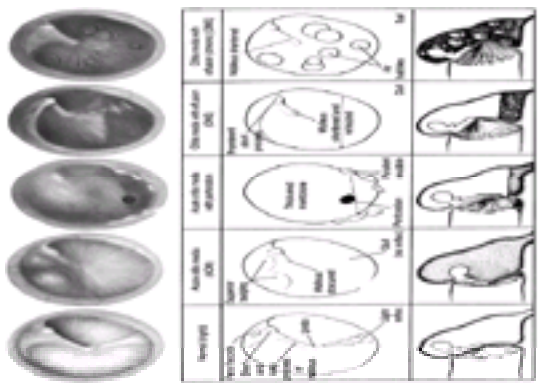

FIGURE 84.7. Appearance of the tympanic membrane in different types of otitis media.

The tympanic membrane in AOM typically bulges out at the examiner as a result of the positive pressure generated by the production of purulent material in the middle ear cavity. Although the drum is sometimes red, it more often appears yellow because of the exudate behind it. A convex contour of the drum secondary to an effusion in the child suspected of having AOM is sufficient to make this diagnosis, regardless of the color of the tympanum. The diffuse injection of the normal tympanum, which is often exaggerated by crying, should not be confused with the intense erythema of infection.

Difficulty arises in differentiating AOM from OME and in diagnosing “early” AOM, particularly in the child with a preexisting middle ear effusion. The tympanic membrane has decreased mobility in both AOM and OME; however, it is usually retracted in the latter condition. During the course of a single examination, the physician may be unable to differentiate with any certainty; in such cases, it is safest to assume a bacterial cause.

The WBC count, if obtained, usually falls within the normal range or shows a mild leukocytosis. Occasionally, a young child may have a count of 20,000 to 30,000/mm^3. Tympanocentesis, when performed as part of a research protocol yields an organism in 60 to 70% of cases. Blood cultures drawn selectively, most often from highly febrile children in the first 2 years of life, show growth of a pathogen in about 3% of cases.

Acute complications have occurred occasionally in AOM subsequent to the advent of effective antibiotics. Local suppuration may involve the mastoids and rarely leads to meningitis or brain abscess. Perforations generally heal spontaneously (see Chapter 121). A child with OM in the first year or two of life may develop dehydration from vomiting

and diarrhea associated with the infection.

Management

Uncomplicated OM in the child older than 1 month should be treated with oral antibiotic therapy on an outpatient basis. Amoxicillin (80 mg/kg per day in three divided doses) is the drug of choice in the United States. The most reasonable alternatives include 1) amoxicillin fortified with clavulanic acid in a 7:1 formulation, 45 mg/kg per day of amoxicillin in two divided doses; 2) cefuroxime axetil, or loracarbef, 30 mg/kg per day in two divided doses; and 3) ceftriaxone, 50 mg/kg intramuscularly as a single dose. Cephalosporins can be used in children with a history of penicillin allergy. Intramuscular ceftriaxone has an advantage in children with persistent vomiting and perhaps in those at high risk of occult bacteremia and also obviates the issue of compliance in high-risk social situations. Whether the course of therapy must be 10 days (except for single-dose ceftriaxone) or can be shortened is controversial. Most authorities believe that antibiotics administered for 5 days are sufficient in children older than 2 years but prefer the longer course in infants. Antihistamines and decongestants have not hastened the resolution of AOM in published studies and are thus not indicated currently.

If AOM persists during therapy with amoxicillin or recurs within 2 days of its discontinuance, ampicillin-resistant organisms emerge as likely causes of the infection. All of the alternatives to amoxicillin represent reasonable agents for a second course and no compelling data favor any particular regimen. Failure of such a second course of antibiotics to eradicate the infection necessitates a third trial of antibiotic therapy and merits consideration of a tympanocentesis for culture.

The management of OM in the first month of life has provoked controversy because of 1) the occurrence of Gram-negative enteric bacilli and *S. aureus* in middle ear infections in these children and 2) the decreased ability of the neonate to resist infection (Fig. 84.8). If a child younger than 1 month of age presents with fever or irritability and is found to have OM, admission for IV antibiotic therapy provides the safest course pending the outcome of cultures of the blood, urine, and CSF. Afebrile infants in the first month of life may be treated as outpatients with the usual oral antibiotics used for older patients and with careful follow-up.

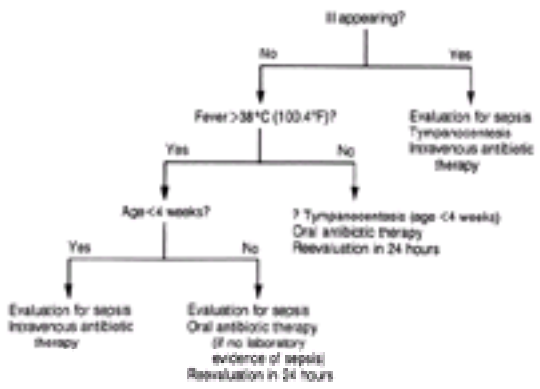

FIGURE 84.8. Diagnostic approach for the management of acute otitis media in the infant during the first month of life.

Infants between 4 and 12 weeks of age with OM can be managed as outpatients because *S. pneumoniae, H. influenzae,* and *M. catarrhalis* are the predominant organisms. However, other sources of infection, including meningitis, must be excluded in the febrile child before attributing the source of a temperature elevation to OM alone.

Otitis Externa

Otitis externa (OE), or swimmer's ear, is an infection of the auditory canal and external surface of the tympanic membrane that spares the middle ear. Multiple organisms, particularly *Pseudomonas aeruginosa,* play a role in this disease. There is usually a history of recent swimming, but occasional cases are seen in children whose only submersion occurs during normal bathing. The first symptom is itching of the ear canal. The child complains subsequently of an earache that may be unilateral or bilateral, and purulent material often drains from the ear. Fever is never present unless cellulitis or another illness is associated. Unlike AOM, pulling on the ear lobe to straighten the canal in preparation for otoscopic examination elicits marked tenderness. A cheesy white or gray–green exudate fills the canal in more than 50% of patients, often obscuring the tympanum.

OE is at times confused with AOM. Although both may cause earache (see Chapter 55), the signs and symptoms usually make an exact diagnosis possible. Occasionally, the physician cannot distinguish OE from AOM with perforation and must treat for both disorders.

Treatment consists of removing the inflammatory debris from the ear canal, eliminating pathogenic bacteria, providing symptomatic relief, and controlling predisposing factors. Usually, dry-mopping of the canal with a cotton-tipped wire applicator cleanses the canal adequately; occasionally, gentle suction is also necessary. The patient should be given commercially available otic drops and a mild analgesic, such as aspirin or acetaminophen. Acetic acid solutions (Otic-Domeboro or Vosol), the combination antibiotic–corticosteroid preparations (Cortisporin, Lidosporin), 4 drops instilled four times daily, or ofloxacin otic, 5 drops instilled twice daily, are effective. In cases with known or suspected perforations, suspensions (but not solutions) are preferred. For the occasional case of a patient with an edematous canal and thick exudate, a wick of cotton or gauze should be inserted 10 to 12 mm into the canal after cleansing to facilitate entry of the medications. All patients should be instructed to avoid swimming until cured.

Children who return without improvement after initial therapy should be examined to be certain that they have OE. If this

diagnosis is confirmed, the canal should be cleansed again and an alternate medication prescribed. The occurrence of a local cellulitis or adenitis requires the addition of an antistaphylococcal antibiotic, such as dicloxacillin (50 mg/kg per day) or cephalexin (100 mg/kg per day). Failure to respond to a second course of therapy or severe local inflammation (necrotizing OE) is an indication for referral to a specialist.

Sinusitis

Background

Sinusitis is an inflammation of the paranasal sinuses: maxillary, ethmoid, frontal, or sphenoid. The ethmoid and maxillary sinuses are present at birth, but the frontal and sphenoid do not become aerated until 4 or 7 years of age. Either an acute or a chronic infection may occur, each characterized by a different but overlapping group of symptoms. Acute sinusitis may occur in children. Among 2613 patients seen in an office practice, Breese et al. made this diagnosis in only 6 (0.23%).

Wald et al. studied the bacteriology of sinusitis in children using cultures of material obtained by antral puncture. They recovered 47 organisms from 30 children: 17, *S. pneumoniae;* 11, nontypeable *H. influenzae;* 9, *M. catarrhalis;* 2, *Streptococcus viridans;* 7, group A streptococcus; and 1, *Moraxella* species. Hamory et al. found a similar spectrum of pathogens in adults with maxillary sinusitis. Although anaerobic organisms and *S. aureus* have been reported occasionally, they do not play a role in most of these infections seen in children. *H. influenzae* type b formerly caused ethmoiditis and periorbital cellulitis but now occurs rarely.

Pathophysiology

Infection of the sinuses arises in a fashion similar to that described for AOM. Organisms ascend from the nasopharynx and cause disease if the mucosal barrier of the sinus or the normal pattern of drainage has been altered.

Clinical Manifestations

The presentation of acute sinusitis varies in some respects with the child's age. Usually, the infection follows a viral URI. Two features that distinguish sinusitis from a viral URI include persistent (longer than 10 days) and/or severe (temperature greater than 39°C [102.2°F] beyond 3 days) symptoms. Cough occurs in 75% of the patients. Unlike adolescents, young children do not often complain of a headache or facial pain. A fever is noted in about half of children with sinusitis. Nasal discharge occurs in almost all of these infections and is often the symptom that prompts a visit. The area of the face that overlies the sinus swells in 10 to 20% of the patients with maxillary disease, and periorbital or orbital edema and cellulitis even more commonly accompany ethmoiditis.

The child with chronic sinusitis complains only of chronic cough and rhinorrhea. Fever, headache, and facial pain are unusual. Often, abnormal findings are not seen on examination.

The WBC count, performed only occasionally, is normal in 60 to 80% of children with sinusitis. In 10 to 30% of these infections, transillumination of the sinuses shows a discrepancy between the two sides. The sinus radiograph is abnormal in almost every child with sinusitis (Fig. 84.9); there may be an air–fluid level, complete opacification, or mucosal thickening (greater than 4 mm). Of 60 sinuses in 30 children evaluated radiographically by Wald et al., 4 were normal, 38 showed complete opacification, 15 showed mucosal thickening, and 3 showed an air–fluid level. Hamory et al. obtained radiographs on 43 patients with 58 episodes of sinusitis. Eighteen had an air-fluid level, 18 had opacification, 12 had mucosal thickening, and 10 had no abnormalities. A CT scan is more sensitive for diagnosis than plain radiograph but is not needed in routine cases.

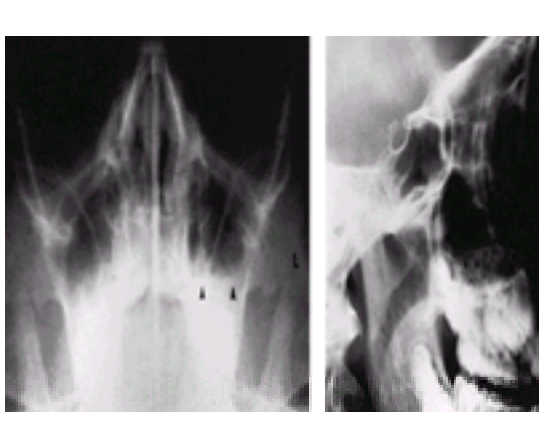

FIGURE 84.9. Anteroposterior **(A)** and lateral **(B)** radiographs show an air–fluid level in the left maxillary sinus *(arrowheads)* and mucoperiosteal thickening on the right side.

Although sinusitis usually responds to oral antibiotic therapy, serious complications occasionally result from the local spread of the suppuration. These include orbital infection, brain abscess, epidural or subdural empyema, and cavernous sinus thrombosis. Proptosis and paralysis of the extraocular muscles point to the accumulation of purulent material within the orbit. After intracranial extension, the child appears toxic and usually has a detectable neurologic deficit.

Management

Children suspected of having acute sinusitis with severe symptoms or an uncertain clinical picture should have a radiograph evaluation of their sinuses. Among this group of patients clinically believed to be at risk for an infection, any abnormality (air–fluid level, opacification, or mucosal thickening) suffices to confirm the diagnosis. Afebrile children with chronic sinusitis diagnosed on the basis of persistent nasal discharge need no laboratory or radiographic evaluation. Possible indications for antral puncture and aspiration of the sinus include 1) associated life-threatening infection, 2) immunocompromise, 3) persistent illness despite therapy, and 4) unusually severe disease. Amoxicillin (40 to 50 mg/kg per day) effectively treats the common pathogens, *S. pneumoniae* and *H. influenzae,* in most cases. Current recommendations call for antibiotic therapy for 10 days, although shorter courses of treatment are under investigation. Alternative drugs for penicillin-allergic children and those with recurrent disease are the same as for OM. Children with acute sinusitis require admission if they appear ill, have facial swelling and tenderness, or develop any complications.

Peritonsillar Abscess

A peritonsillar abscess, or “quinsy,” results from the accumulation of purulent material within the tonsillar fossa. Adolescents develop this condition more often than younger children. Group A streptococcus, various anaerobic organisms, and occasionally *S. aureus* are isolated from these lesions, which are unusual in children, in comparison to uncomplicated tonsillitis.

The complaints of trismus and difficulty in speaking separate a peritonsillar abscess from the far more common pharyngitis. The voice sounds muffled, and the child drools profusely. Both tonsils may swell, but the enlargement of one is more pronounced. Usually, the abscessed tonsil becomes sufficiently large to push the uvula to the opposite side of the pharynx, and the examiner can palpate a fluctuant mass intraorally. The WBC count is often elevated.

All children with a peritonsillar abscess should have the lesion drained in the ED or after admission to the hospital and receive treatment with antibiotics. Penicillin (100,000 units/kg per day) is usually sufficient, but the results of the culture and Gram stain of material from the infected tonsil will determine the final choice of therapy because *S. aureus* is occasionally recovered. In the unusual case of a child with respiratory compromise, aspiration of the abscess can be lifesaving. This is accomplished by using an 18-gauge needle mounted on a 10-mL syringe (see Chapter 121).

Cervical Lymphadenitis

Background

Cervical lymphadenitis is a bacterial infection of the lymph nodes in the neck. This condition must be distinguished from lymphadenopathy, an enlargement of one or more lymph nodes that occurs with viral infections or as a reaction to bacterial disease in structures that drain to the nodes.

S. aureus causes lymphadenitis in most children with an identifiable pathogen. Of 74 children with this condition, Barton and Feigin isolated *S. aureus* from 27 (36%) and group A streptococcus from 19 (26%). Other organisms that may rarely play a role include mycobacteria, *Bartonella henselae* (cat-scratch disease [CSD]), anaerobic bacteria, *Yersinia pestis* (plague), Gram-negative bacilli, *H. influenzae, Francisella tularensis,* Actinomyces, and Nocardia.

Pathophysiology

The causative organisms in cervical adenitis initially colonize the nares or pharynx or less commonly are inoculated transcutaneously. Dental abscesses may also be a source of pathogens. Whether or not they produce a local infection, the bacteria can spread to the lymph nodes in the neck. If not contained by the immune system, they proliferate within the node and evoke an inflammatory response.

Clinical Manifestations

The child with cervical lymphadenitis is usually noted to have swelling in the neck. If sufficiently old, he or she will complain of pain. Fever occurs only occasionally, more often in children less than 1 year old. The infected node may vary in size from 2 cm to more than 10 cm. Initially, it has a firm consistency, but fluctuance (Fig. 84.10) develops in about 25%. The skin overlying the node becomes erythematous, and edema may surround it.

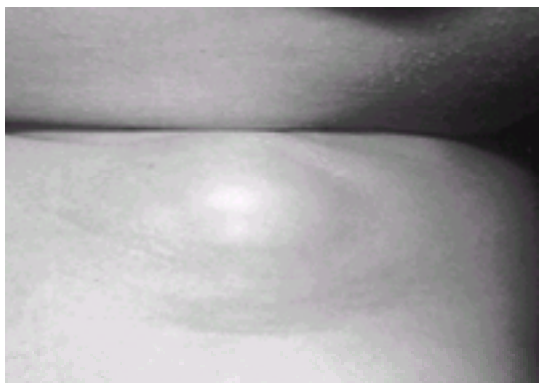

FIGURE 84.10. Lymphadenitis in the inferior cervical chain. The node appears fluctuant.

The WBC count is usually normal but may be elevated in the younger, febrile child. Aspiration of the node often identifies the organism by both Gram stain and culture, even if fluctuance is not appreciated. Children with infections from *M. tuberculosis* usually react to the standard purified protein derivative (PPD-S) skin test and have changes compatible with tuberculosis seen on chest radiograph.

Complications of bacterial adenitis are unusual. Organisms such as *S. aureus* and group A streptococcus can spread locally if unchecked. A sinus tract develops in some children infected with atypical mycobacteria. Recurrence of the infection occurs in conditions such as chronic granulomatous disease.

Management

Figure 84.11 outlines the management of the child with cervical lymphadenitis. Children with cervical adenitis who are otherwise healthy should receive an antibiotic effective against *S. aureus* and the group A streptococcus. Agents such as dicloxacillin (50 mg/kg per day) and cephalexin (50 mg/kg per day) have activity against both organisms. In more severe infections, oxacillin (150 mg/kg per day in four divided doses) can be administered intravenously. If the node is fluctuant, aspiration provides useful etiologic information and speeds the rate of resolution. All children with lymphadenitis should have a PPD skin test and should be followed until the infection subsides.

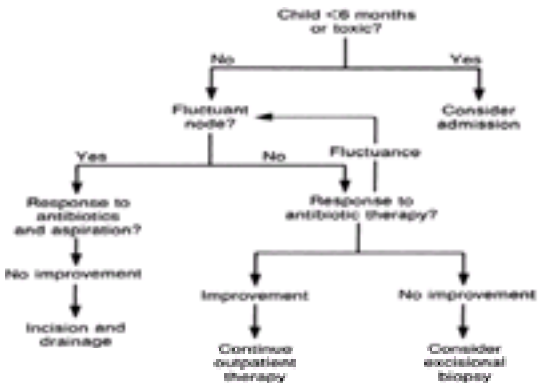

FIGURE 84.11. Diagnostic approach for the management of the child with presumed bacterial lymphadenitis.

Children less than 3 months of age and those who appear toxic or who have developed a draining sinus are best managed in the hospital. A failure to improve with oral antibiotic therapy or a positive skin test for tuberculosis necessitates subsequent hospitalization.

Retropharyngeal and Lateral Pharyngeal Abscess

A retropharyngeal abscess fills the potential space between the anterior border of the cervical vertebrae and the posterior wall of the esophagus. The usual pathogens are group A streptococcus, anaerobic organisms, and occasionally *S. aureus.* These uncommon infections occur most often in children less than 4 years of age. A lateral pharyngeal abscess occurs in the deep soft tissue space of the neck but not in the midline and is less common than a retropharyngeal infection.

The child with a retropharyngeal abscess presents with a clinical picture similar to that seen with epiglottitis, but the onset is less abrupt. Fever and a toxic appearance are common. As purulent material collects, the fluctuant mass obstructs the larynx and esophagus, leading to stridor and drooling. The abscess may cause meningismus; thus, this diagnosis should be considered in the child with nuchal rigidity but no pleocytosis in the CSF.

Although a retropharyngeal infection can rarely be seen as a midline swelling on examination of the pharynx, it is usually difficult to observe this finding in the uncooperative child. If the diagnosis is suspected and the airway is not threatened, a lateral neck radiograph or CT scan should be obtained. The radiograph shows an increase in the width of the soft tissues anterior to the vertebrae and, on occasion, an air–fluid level. Ordinarily, the width of this space is less than half that of the adjacent vertebral body if the examination is done with the neck properly extended.

A lateral pharyngeal abscess causes virtually identical symptoms to an infection in the retropharyngeal area. One important difference is that a lateral pharyngeal abscess, which is not well visualized by radiograph, requires a CT scan for diagnosis.

A retropharyngeal or lateral pharyngeal abscess poses a risk to the patency of the airway. All children with this infection should have careful monitoring in the ED and then be hospitalized in consultation with an otolaryngologist. Unless the airway is in immediate jeopardy, IV access should be secured and treatment given with either clindamycin (30 mg/kg per day in four divided doses) or a combination of penicillin (100,000 units/kg per day) and cefazolin (100 mg/kg per day), both in four divided doses. In the event of respiratory compromise, intubation or, less commonly, tracheotomy becomes necessary. Most patients require drainage, either transcutaneously with ultrasound guidance or at surgery, but a few reports indicate that high-dose antibiotics may suffice, particularly when the CT scan shows cellulitis or only a small collection of pus.

Laryngotracheobronchitis (Croup)

Background

Croup, or laryngotracheobronchitis, is a viral infection that involves the larynx and may extend into the trachea and bronchi. It is a common infection, with thousands of cases of croup to every 1 of epiglottitis among children who present to the ED. Although most children with croup are treated as outpatients, some develop more pronounced respiratory distress and require hospitalization. Hoekelman reported that 3 (1.2%) of 246 healthy term infants in a pediatric practice developed croup during their first year of life. This infection is the most common cause for stridor in the febrile child (see Chapter 72).

Parainfluenza virus can be recovered from about 60% of children with croup. Additional causes of the disease are influenza, adenoviruses, measles, and respiratory syncytial virus (RSV). Bacteria play no role.

Croup occurs more commonly in the winter months. Children between the ages of 6 months and 3 years are most commonly affected. The diagnosis of croup in a child older than 3 years should arouse the suspicion of an underlying anatomic abnormality.

Pathophysiology

The viral pathogens that eventually produce croup invade the epithelium of the pharynx initially. Spread occurs downward to the larynx and occasionally further along the respiratory tract. The infection causes endothelial damage, production of mucus, loss of ciliary function, and edema. Erythema and swelling of the vocal cords and the subglottic larynx are present. A fibrinous exudate partially occludes the lumen of the trachea.

Clinical Manifestations

Croup begins insidiously with the onset of fever and coryza. During the next 1 to 2 days, the infection spreads farther along the airway, producing signs of upper respiratory obstruction. Inspiratory stridor develops at this stage of the illness, and a barking cough is heard. The child may be unable to maintain adequate oral intake.

Although the severity of croup varies, most children appear mildly to moderately ill in contrast to the toxic patients with epiglottitis or retropharyngeal abscess. The fever usually ranges from 38° to 39°C (100.4° to 102.2°F). Tachycardia and tachypnea are evident, but the respirations rarely exceed 40 breaths/minute. Suprasternal and subcostal retractions often accompany croup. On auscultation of the chest, the examiner may hear either stridor alone in mild disease or rhonchi and wheezes with more extensive involvement of the respiratory epithelium. Cyanosis occurs only in the minority of children with severe croup.

Ancillary studies are indicated only occasionally. The WBC count is generally normal; lymphocytosis may occur as with other viral infections. The lateral and anteroposterior neck radiographs show subglottic narrowing (“steeple” sign) from soft-tissue edema in severe disease. However, most of the radiographic studies of the airway are normal or disclose only ballooning of the hypopharynx. Rather than confirm the diagnosis of croup, radiograph examination more often excludes other illness such as epiglottitis or retropharyngeal abscess. The ABG demonstrates neither hypoxia nor hypercarbia unless respiratory fatigue ensues.

Both dehydration and upper airway obstruction may complicate croup. Because of the respiratory distress and the toxicity associated with a febrile illness, the ability to maintain normal hydration will decrease in some children. Dehydration then occurs in the face of increased fluid losses through the pulmonary and cutaneous routes.

Occasionally, a child with croup develops significant upper airway obstruction. Signs suggestive of impending respiratory failure include 1) hypotonicity, 2) noticeable retractions, 3) decreased or absent inspiratory breath sounds, 4) depressed level of consciousness, 5) tachycardia out of proportion to the fever, and 6) cyanosis. Although an ABG is not needed in the evaluation of children with mild croup, this study plays a role in deciding on the therapy in more severe cases. *Respiratory failure* is defined as a partial pressure of arterial carbon dioxide (Pa CO_2) of 60 mm Hg or higher or a partial pressure of arterial oxygen (PaO_2) of less than 50 mm Hg in 100% oxygen. However, significant respiratory compromise is present in croup when the PaCO_2 rises over 45 mm Hg and the PaO_2 falls below 70 mm Hg in room air.

Management

Croup is usually apparent from the history and physical examination. Soft-tissue radiographs of the neck are needed only if the diagnosis is uncertain. Although visualization of the posterior pharynx/epiglottis is not advised routinely when epiglottitis is suspected, this examination may be performed to confirm the absence of tonsillar infection or an obviously enlarged epiglottis in cases in which one is confident that the diagnosis is croup.

Many children with croup are never taken to seek medical attention. Of those who come to the ED, most can be managed as outpatients. Clear indications for admission are dehydration and/or significant respiratory compromise. If any of the signs of respiratory failure are noted, hospitalization becomes necessary. Use of a scoring system may be helpful in deciding on disposition (Table 84.13). Neck radiographs and an ABG may be obtained in cases in which the clinical picture is not decisive. In addition, the physician should consider the social milieu of the family. Hospitalization provides the safest course for the child when the parents are unreliable caretakers or transportation to the ED for a reevaluation presents an obstacle to further treatment.

Score	Degree	Management
4	Mild	Outpatient—mist therapy
5–6	Mild to moderate	Outpatient if child improves in emergency department after mist, is older than 6 months, and has a reliable family
7–8	Moderate	Admitted—racemic epinephrine
≥9	Severe	Admitted—racemic epinephrine, oxygen, intensive care unit

Modified from Taussig LM, et al. Treatment of laryngotracheobronchitis (croup): use of intermittent positive-pressure breathing and racemic epinephrine. Am J Dis Child 1973;125:799.

[a]Any one category with a score of 3 should be considered as a severe disease.

Table 84.13. Scoring System for Assessing Severity of Croup

Mist therapy lessens the severity of croup. Water droplets penetrate to the area of inflammation in the larynx and provide moisture to the mucosa. Because the viral origin of this disease has been well established, antibiotics play no role.

Racemic epinephrine, or more recently in the United States L-epinephrine, is indicated for children with moderate to severe croup who will be hospitalized or for whom admission is being considered. The dose is 0.25 mL of racemic epinephrine, mixed with 3 to 5 mL of saline, delivered by nebulization. If a response is noted and discharge to home is contemplated, the child should be observed in the ED for at least 2 hours to be certain that the respiratory symptoms do not rebound.

Corticosteroids have long been mentioned as potential aids to the treatment of croup, but the early controlled studies on these agents failed to substantiate the early anecdotal successes. Subsequently, Leipzig et al. found dexamethasone effective in a controlled study in 1979, and a meta-analysis of the literature in 1989 supported the use of corticosteroids for hospitalized patents. More recently, controlled trials by Klassen, Schuh, and others have demonstrated that nebulized budesonide decreases the severity of illness in patients with mild to moderate croup. Budesonide has been shown to be slightly less effective than dexamethasone and to provide a slight additive effect. A single report has suggested that the response to budesonide may be equal to that of racemic epinephrine.

Until more data become available, treatment regimens will remain in flux. A reasonable approach for the present is to tailor therapy to the severity of illness. In rare cases with inadequate gas exchange, management of the airway, at times with endotracheal intubation, takes precedence; tracheal edema may make passage of a tube with the usual diameter impossible, and the physician should be prepared with one a size smaller. Patients in the ED who have concerning upper airway obstruction and a high likelihood of hospitalization will benefit from prompt administration of both racemic epinephrine by nebulization and intramuscular dexamethasone at 0.6 mg/kg. For children with moderately severe croup, when hospitalization is being considered, the response to an initial trial of mist and either intramuscular dexamethasone or nebulized budesonide can be assessed. If the response is adequate, the physician could add either a second steroid (e.g., budesonide if dexamethasone was already administered) or racemic epinephrine. Finally, most patients who are mildly ill require only instructions for home care.

Epiglottitis

Background

Epiglottitis is a life-threatening bacterial infection of the epiglottis and the surrounding structures. Recent authors have suggested that supraglottitis would be a more appropriate appellation. Rarely, thermal injury to the epiglottis may cause swelling and clinical findings similar to those seen with infection.

Before the advent of a vaccine against Hib, epiglottitis occurred with regularity in children, accounting for 1 of every 1000 pediatric admissions in the United States. It is now a rare disease in children.

Occasional cases are caused by the group A streptococcus. Although more common in the winter months, epiglottitis may occur throughout the year. The peak incidence during an era of greater prevalence fell between the ages of 3 and 7 years; however, infants and adults with epiglottitis have been well described.

Pathophysiology

The pharynx of normal children is often colonized with potentially pathogenic microorganisms such as *H. influenzae* and *S. pneumoniae.* Occasionally, these bacteria penetrate the mucosal barrier and invade the bloodstream. During the course of bacteremia, focal infection may occur at several sites, including the epiglottis and surrounding structures. Infection causes inflammatory edema, beginning on the lingual surface of the epiglottis, where the submucosa is loosely attached. The swelling progresses rapidly to involve the aryepiglottic folds, the arytenoids, and finally, the entire supraglottic larynx. Tightly bound epithelium on the vocal cords halts the spread at this level. The tremendous reduction in the caliber of the airway results in turbulent air flow on inspiration, appearing clinically as stridor.

Two possible mechanisms may explain the sudden respiratory arrest that can sometimes complicate this disease. The swollen epiglottis may be drawn into the glottis, acting like a plug to obstruct the flow of air, but this seems unlikely because the edematous, inflamed tissues of the supraglottic region become relatively tense. More likely, aspiration of oropharyngeal secretions occludes an already narrowed laryngeal inlet.

Clinical Manifestations

Epiglottitis has an abrupt onset. The duration of illness before presentation is often as short as 6 hours and rarely exceeds 24 hours. Among the 21 children reported by Greenberg and Schisgall, an average of 17 hours elapsed between the first symptom and hospital admission. The parents first note the onset of fever. Shortly thereafter, the child develops stridor and labored respirations. As the disease progresses, the supraglottic edema interferes with the ability to swallow secretions; thus, drooling is a complaint in 60 to 70% of cases. Of the children with epiglottitis, 50% complain of a sore throat. Aphonia, hoarseness, and cough are uncommon. Although both croup and epiglottitis manifest with stridor in a febrile child, the examiner can usually differentiate these two illnesses on the basis of the clinical features (Table 84.14).

	Epiglottitis	Croup
Anatomy	Supraglottic	Subglottic
Etiology	Bacterial: *H. influenzae*	Viral: parainfluenza
Age range	3–7 yr, adults	0.5–3 yr
Onset	6–24 hr	24–72 hr
Toxicity	Marked	Mild to moderate
Drooling	Frequent	Absent
Cough	Unusual	Frequent
Hoarseness	Unusual	Frequent
White blood cell count	Leukocytosis	Normal

Table 84.14. Epiglottitis and Croup: A Comparison

The anxious appearance of most children with epiglottitis strikes the examiner immediately (Fig. 84.12). To maximize air entry, these children assume a sitting position with their jaws thrust forward. Cyanosis may occur in the later stages of the illness. The temperature, almost always elevated, often reaches a level of 40°C (104°F). Tachycardia is a constant feature. Although the patients are universally tachypneic, the respiratory rate rarely exceeds 40 breaths/minute. Stridor can be heard without a stethoscope, but auscultation of the lungs reveals no other adventitious sounds. Marked retractions are seen, predominantly involving the suprasternal and subcostal musculature.

FIGURE 84.12. A 3-year-old girl with epiglottitis has an anxious appearance, assumes the “sniffing” position **(B)**, and prefers to remain sitting **(A).**

As discussed under Management, rigorous attempts to visualize the epiglottis are hazardous and should be avoided in the child with suspected epiglottitis. However, the examiner may view the pharynx without the use of a tongue depressor. The mucosa is seen to be erythematous, and pooled secretions are present in about half the children. Occasionally, a swollen, cherry red epiglottis (Fig. 84.13) protrudes above the base of the tongue and is visible without instrumentation.

FIGURE 84.13. A swollen, erythematous epiglottis after endotracheal intubation of a child with epiglottitis.

Collection of laboratory specimens is usually delayed until the airway has been secured. The WBC count is elevated in most children with epiglottitis. As in other diseases that result from bacteremia with *H. influenzae,* a leukocytosis in the range of 15,000 to 25,000/mm^3 and a shift to the left occur in response to the infection. Culture of the blood yields a pathogen in 80 to 90% of cases, and of the epiglottis, following the placement of an airway, in about 50% of cases.

A lateral neck radiograph is pathognomonic of epiglottitis. There are three characteristic features: 1) a swollen epiglottis, 2) thickened aryepiglottic folds, and 3) obliteration of the vallecula (Fig. 84.14). The normal epiglottis has a thin, curved silhouette that has been likened to a bent finger, convex on one side and concave on the other. As a result of inflammatory edema from infection, it swells and assumes a configuration that is convex on both sides. This has been called the “thumb sign.” The airway below the level of the vocal cords appears normal on the lateral neck radiograph of a child with epiglottitis.

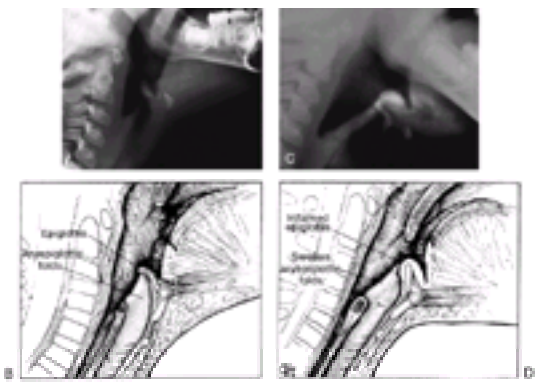

FIGURE 84.14. Appearance of the lateral neck region in a normal child (**A** and **B**) and a child with epiglottitis (**C** and **D**).

The most serious complication of epiglottitis is sudden respiratory obstruction. This may occur unpredictably at any point in the illness, before seeking medical attention, in the ED, or after hospitalization. Although a child with minimal respiratory distress may occasionally have a total obstruction, marked retractions and labored breathing should serve as a warning of an impending airway catastrophe. An additional complication of this illness is extraepiglottic spread of the infection. During the course of the bacteremia, seeding may involve the meninges, lungs, pericardium, synovial membranes, and soft tissues. Thus, the initial examination should attempt to elicit signs of infection at these additional sites.

Management

When a child is suspected of having epiglottitis, the thrust of the management plan is to make a definitive diagnosis and institute therapy before the onset of airway obstruction. The major pitfall in this process is the vigorous examination of the posterior pharynx without having considered the possibility of supraglottic infection. Such manipulation rarely may initiate laryngeal obstruction in a small number of children with epiglottitis.

The initial steps in management are based on the degree of respiratory distress and the likelihood of epiglottitis, as judged from the clinical features (Fig. 84.15). Some children with epiglottitis have total or nearly total airway obstruction as the initial presentation of their disease. In this situation, treatment precedes any diagnostic evaluation and steps to maintain an adequate exchange of air are taken (see Chapter 1 and Chapter 5).

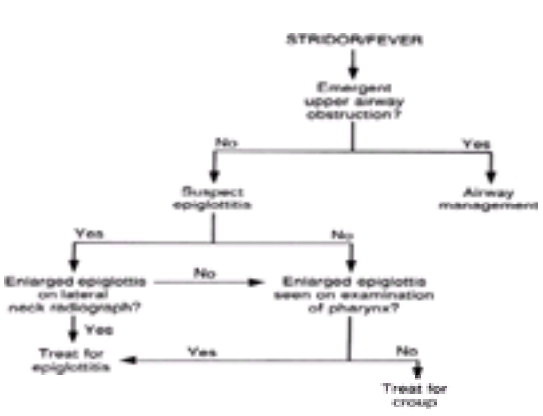

FIGURE 84.15. Diagnostic approach to the child with suspected epiglottitis.

The majority of children, however, manifest lesser degrees of stridor and respiratory compromise with fever. The clinician must decide whether the constellation of historical and physical features points to croup or epiglottitis. In most children with stridor, the history will favor croup, which is the more common of the two diseases. The child will not appear toxic or show signs of air hunger. In such situations, a lateral neck radiograph is not indicated. Rather, the pharynx may be visualized directly with a tongue depressor to confirm the absence of a swollen, inflamed epiglottis.

When the findings weigh in favor of epiglottitis, however, further examination should be postponed and immediate

preparation should be made for the insertion of an artificial airway; this includes collecting the necessary equipment and summoning additional personnel as needed. Anesthesiologists and otorhinolaryngologists alike, if available, should be involved in the care of children with epiglottitis, in addition to the staff in the ED. Following the appropriate preparations, a physician should accompany the child to the radiology department for a lateral neck radiograph, or a portable radiograph may be obtained. An IV infusion using a plastic cannula may be started in the cooperative patient. However, if the child becomes agitated or the procedure lengthy, the radiograph must be obtained quickly, assuming the airway has not been compromised, rather than persisting with attempts to gain IV access. The lateral neck radiograph either confirms or disproves the clinical diagnosis. If epiglottitis is verified radiographically, a skilled physician next performs endotracheal intubation, most often in the operating suite. If intubation is not possible, a surgical approach to the airway is necessary (Table 84.15).

Ensure adequate ventilation.	Endotracheal intubation (or tracheostomy)
Gain peripheral venous access, if tolerated by child.	Defer laboratory studies until airway is secured.

Table 84.15. Immediate Management of Epiglottitis

A review of the mortality statistics in epiglottitis emphasizes the importance of an artificial airway in the management of this illness. Rapkin described a fatal outcome in 20% of the children treated with antibiotics and observation alone. In 1978, Cantrell et al. summarized 749 cases of epiglottitis. The mortality varied with the method of airway management as follows: tracheostomy, 3 deaths among 348 children (0.86%); endotracheal intubation, 2 in 216 (0.92%); no artificial airway, 13 in 214 (6.1%).

Ceftriaxone (100 mg/kg per day in one or two divided doses) and cefotaxime (200 mg/kg per day in four divided doses) serve as single-drug alternatives and are useful particularly for patients allergic to penicillins. Chloramphenicol (100 mg/kg per day in four divided doses) also provides effective therapy. Steroids have not been shown to play a role in epiglottitis.

Bacterial Tracheitis

Infections of the trachea, presumed to be bacterial, were originally described in the period 1920 to 1940. However, the existence of bacterial tracheitis (or membranous tracheitis) was not addressed again until 1979, and some experts still question whether this is a real entity or merely a bacterial colonization of the trachea in a child with viral croup. Thus, bacterial tracheitis is, at best, an unusual infection during childhood. The putative etiologic agents are *S. aureus* and *H. influenzae,* which occur rarely at this point in time. Patients may range from infants to young children.

Clinical Manifestations

Published reports indicate that the signs and symptoms of bacterial tracheitis mimic those of acute epiglottitis but with a somewhat slower onset. The fever is usually greater than 39°C (102.2°F), and the patients are stridorous. Toxicity and respiratory distress occur as a rule. On radiograph, there is tracheal narrowing, and a pseudomembrane may be visible within the tracheal lumen; the supraglottic area is normal.

Management

Children with bacterial tracheitis are often diagnosed initially as having severe viral croup or epiglottitis. Their management is as outlined for these conditions. The first priority is to secure an adequate airway. If bacterial tracheitis is suspected on the basis of a lateral neck radiograph or the findings at laryngoscopy, antibiotic therapy should be initiated with ceftriaxone (100 mg/kg per day in one or two divided doses), ampicillin–sulbactam (200 mg/kg per day of ampicillin in four divided doses), or the combination of oxacillin (150 mg/kg per day) and chloramphenicol (100 mg/kg per day) in four divided doses. Admission to an intensive care unit is essential.

Lower Respiratory Tract Infections

The most common lower respiratory tract infections in children include bronchiolitis and pneumonia, which may be caused by various bacteria or viruses, *C. trachomatis,* or *M. pneumoniae.* Approximately 1 in 50 children in the United States has pneumonia annually. In a 12-year study of approximately 125,000 patients enrolled in the Group Health Cooperative of Puget Sound, the incidence of childhood pneumonia from all causes averaged 19 per 1000 per year. Occasional episodes of pertussis and pulmonary tuberculosis are also seen. Recently described, Hantavirus pneumonia occurs in patients with exposure to rodents and is particularly severe.

Pneumonia is an inflammation of the lung tissue that may follow a noninfectious or an infectious insult. In the ED, the febrile child with an acute onset of pneumonia almost always has an infection. The causative organisms in pneumonia vary according to the age of the child (Table 84.16). Although viral agents account for 60 to 90% of pneumonia, bacteria,

particularly *S. pneumoniae,* play a major role. *M. pneumoniae* increases in frequency after puberty. Unusual causes of pneumonia in the immunocompetent child include *Legionella pneumophilia* (Legionnaires' disease), *M. tuberculosis,* Hantavirus, rickettsia (Q fever), fungi, and protozoa. Children with neoplasms, HIV, and other forms of immunocompromise show susceptibility to a variety of unusual pathogens, including *Pneumocystis carinii* (see Chapter 85 and Chapter 100).

Table 84.16. Lower Respiratory Tract Infections

Bacterial Pneumonia

Background

Bacterial pneumonia is an inflammation of the pulmonary parenchyma caused by a bacterial pathogen. In the first weeks of life, the group B streptococcus and Gram-negative bacilli cause most such infections (Table 84.16). Between 2 weeks and 2 months of age, viruses and *Chlamydia* are most common, and viruses remain the most common isolates throughout childhood. Among the bacteria, *S. pneumoniae* predominates at every age beyond the newborn period. *H. influenzae* formerly ranked second to pneumococcus in children 2 months to 3 years of age but now occurs rarely. *S. aureus* causes a severe but uncommon pneumonia in young children; 60% of these infections occur in the first year of life. Group A streptococcus is also uncommon, *N. meningitidis* has been described rarely, and anaerobic bacteria play a role primarily following aspiration.

Definitive studies on the relative frequency of the various pathogens have not been performed in a randomly selected outpatient population of children. Because an organism is not usually recovered from the blood, establishing an etiologic diagnosis requires recovery of the pathogen from either pleural fluid or the pulmonary parenchyma. However, pleural effusion accompanies only a minority of bacterial pneumonias, and a percutaneous or transtracheal aspiration of the lung, although safe, cannot be justified on children who are sufficiently well to be managed as outpatients. Thus, the data collected on hospitalized children or those with more severe infections must be extrapolated to estimate the spectrum of pathogens in uncomplicated bacterial pneumonia. Also, antigen testing may be suggestive on urine or serum specimens.

Pathophysiology

In most pneumonias, the pathophysiology remains unknown. Pathogens reach the lung, either by hematogenous dissemination or by aspiration. In *H. influenzae,* type b, pneumonia, the organism can be recovered from the bloodstream in 90% of children, often 1 to 2 days before the appearance of the infiltrate. This suggests that bacteremia precedes the pulmonary infection. However, bacteremia is found in only 5 to 10% of pulmonary infections with *S. pneumoniae* at the time of diagnosis. Thus, aspiration must play a greater role in the pathogenesis of infections with this organism, or else the preceding bacteremia resolves before the development of pneumonia.

Following invasion of the pulmonary tissue by bacteria, an acute inflammatory reaction ensues. There is an exudation of fluid and polymorphonuclear leukocytes, followed by the deposition of fibrin. Several days later, macrophages appear in the alveoli. The accumulation of fluid in a lobe of the lung leads to the characteristic lobar consolidation seen on the chest radiograph.

Clinical Manifestations

Bacterial pneumonia generally has an abrupt onset with fever, often accompanied by chills. A cough is a common but nonspecific complaint. The young child reacts to bacterial infection in the chest with lethargy and/or a decreased appetite. Occasionally, pleuritic involvement produces pain with respiratory effort.

The observation of the child at rest before the examination often provides the key to the diagnosis of pneumonia. Tachypnea out of proportion to the fever is rarely the only sign, particularly in the first year of life. The infant who breathes at a normal rate, however, seldom has a bacterial infection of the lung. A hasty effort at auscultation that disturbs the quiet infant obscures this finding.

Fever is almost universally present, ranging from 38.5° to 41°C (101.2° to 105.8°F). Grunting respirations in a young child should arouse a strong suspicion of pneumonia. Localized findings, more often seen in the child older than 1 year, include inspiratory rales, decreased breath sounds (sometimes the only abnormality), and less often, dullness to percussion. Gastric dilation may accompany pneumonia; occasionally, the abdominal findings in pulmonary infections mimic appendicitis. With upper lobe pneumonia, the pain may radiate to the neck, causing meningismus; the diagnosis of

pneumonia must therefore be considered in the child with nuchal rigidity and normal CSF.

In the ED, a chest radiograph often assists in the management of a child suspected of having bacterial pneumonia. Although a patient who is dehydrated with pneumonia occasionally may not have an infiltrate, the radiographic evaluation confirms or denies the diagnosis of bacterial pneumonia in most cases. This is important in a clinical setting not conducive to continuity of care. In addition, the radiograph may provide information on the disease process. A lobar consolidation is assumed to be of bacterial origin, needing treatment with antibiotics (Fig. 84.16), whereas a minimal, diffuse interstitial infiltrate in a previously healthy toddler suggests a viral infection that can be managed with symptomatic therapy or, in an adolescent, *M. pneumoniae,* calling for treatment with erythromycin or another macrolide. Bilateral involvement, pleural effusion, and pneumatoceles point to more severe disease.

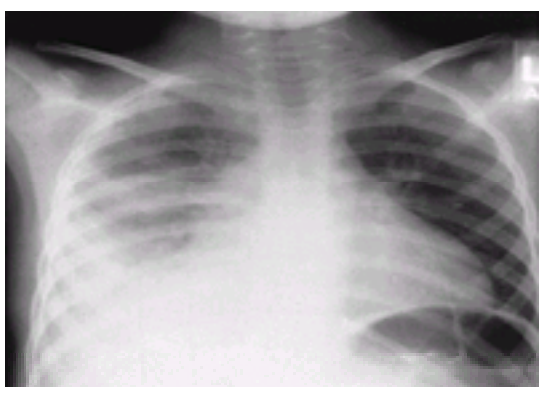

FIGURE 84.16. Radiograph showing lobar consolidation and pleural effusion in a child with bacterial pneumonia.

Further laboratory studies are obtained only on specific indications. A WBC count may be helpful in differentiating viral from bacterial disease or in assessing the likelihood of bacteremia in the young child; the count often exceeds 15,000/mm^3 and occasionally rises above 30,000/mm^3 with bacterial invasion of the pulmonary parenchyma or the bloodstream. Levels of CRP correlate with the bacteremia and lobar infiltrates more closely than the WBC count; however, this test is less readily available than the WBC count.

The most common complication of pneumonia is dehydration, particularly in young children. Electrolytes and a BUN are useful in assessing the degree of fluid loss in a child who appears ill or exhibits dry skin and/or mucosa. Rarely, extensive pulmonary involvement compromises ventilation, leading to respiratory failure. ABGs are indicated for any child with significant respiratory distress or an oxygen saturation below 90%. A pleural effusion accumulates in most infections with *S. aureus* and *H. influenzae,* less often with *S. pneumoniae.* Bacteremia may result in additional foci of infection, including meningitis, pericarditis, epiglottitis, and septic arthritis.

Management

Most healthy children with pneumonia respond to outpatient antibiotic therapy. Because most of the infections are caused by *S. pneumoniae,* amoxicillin (50 mg/kg per day given orally in three divided doses) has been the mainstay of therapy. Ceftriaxone (50 mg/kg) may be administered intramuscularly at the time of diagnosis, especially if there is any concern about oral intake during the first 24 hours. Alternatively, macrolides, including erythromycin (40 mg/kg per day in four divided doses) or azithromycin (10 mg/kg as a single dose on the first day and 5 mg/kg as a single dose on days 2 to 5), may be used in penicillin-allergic children or when mycoplasmal infection is suspected on the basis of age or radiographic findings.

Supportive therapy includes antipyretics and adequate hydration. Antitussives have no place in the treatment of pneumonia. Every child should return within 24 to 48 hours for a second evaluation; patients who do not clinically improve and become afebrile should be evaluated carefully for admission to the hospital.

Any child who appears to be toxic (on the basis of the physician's clinical judgment) or is immunocompromised should be hospitalized. Firmer, but not unarguable, indications for admission are listed in Table 84.17. The child less than 1 year of age does not tolerate bacterial pneumonia as well as those who are older. In addition, potentially serious infections with *S. aureus* and *H. influenzae* occur more often in the first year of life. The radiographic detection of a pleural effusion or pneumatocele also suggests a pathogen other than *S. pneumoniae.* Effusions should be cultured by thoracentesis (see Procedures, Section VII), which requires subsequent observation of the child in the hospital. Although a persistent elevation of the temperature is well described in children with pneumococcal pneumonia that subsequently respond to penicillin, failure of the fever to defervesce within 24 to 48 hours after the administration of antibiotics suggests a greater likelihood of more virulent pathogens.

Age <1 year (lobar infiltrate)	Failure to respond to antibiotic therapy within
Respiratory compromise	24–48 hours
Pleural effusion	Dehydration
Pneumatocele	

Table 84.17. Indications for Admission

Viral Pneumonia

Background

A number of viruses are able to infect the lungs of children and adolescents. Respiratory syncytial and parainfluenza viruses are the most common isolates, particularly in the first year of life. Other viruses, including influenza, adenoviruses, enteroviruses, rhinoviruses, measles, varicella, rubella, herpes simplex, cytomegalovirus, EBV, and hantaviruses, can cause pneumonia. Pulmonary disease complicates upper airway infections with influenza, varicella, and EBV more often in the adolescent. The annual incidence of viral pneumonia peaks in the first 5 years of life at 40 per 1000, and then declines with advancing age.

Pathophysiology

Most viruses that cause pneumonia initially invade the epithelium of the upper respiratory tract and spread locally to the lungs. The infection evokes an inflammatory response that consists primarily of mononuclear cells. After infection, the epithelial cells slough into the airway and obstruct the bronchi, producing the hyperinflation characteristically seen on chest radiograph.

A few viruses may reach the lungs by hematogenous dissemination. These include measles, varicella, rubella, cytomegalovirus, herpes simplex, and EBV.

Clinical Manifestations

Viral pneumonia generally has its onset over a 2- to 4-day period, being more gradual than with bacterial infection. Cough, coryza, and low-grade fever commonly occur. Particularly with RSV infections in the first 3 months of life, an apneic spell may be the first sign to draw attention to the illness.

Fever in viral pneumonia is usually lower than 39°C (102.2°F). As with bacterial infections, tachypnea in the undisturbed child may be the only physical finding. Rales are often audible diffusely throughout the chest, and wheezing may also be present. With more severe disease, the child shows signs of respiratory failure: grunting, cyanosis, and changes in mental status.

The WBC count varies widely in viral pneumonia. Although leukocytosis over 15,000/mm ^{3} may occur in some cases, such elevated counts should arouse suspicion of bacterial disease.

The radiographic examination provides useful clues to the type of pathogen that causes a pneumonia but can never confirm a viral infection or rule out a bacterial cause. Most typically, the radiograph in a child with viral pneumonia shows bilateral air trapping and peribronchial thickening. A diffuse increase in the interstitial markings is also commonly seen. However, the findings can vary from barely detectable increases in volume to segmental infiltrates. Decubitus films occasionally detect small effusions. Because of the limitations in obtaining reliable cultures for bacteria, it is safest to presume a bacterial cause in the child with clinical evidence of pneumonia and a lobar infiltrate, a pleural effusion, a temperature over 39°C (102.2°F), or signs of clinical toxicity. Particularly in a dehydrated child, the chest radiograph may fail to show a lobar consolidation early in the course of a bacterial pneumonia.

Most viral pneumonias resolve without specific therapy. Potential complications include dehydration, apnea, and local progression of the infection. Apnea may occur in the first 3 months of life.

Management

The physician must attempt to make an etiologic diagnosis in pneumonia on the basis of the clinical and radiographic findings without the benefit of definitive laboratory tests. A WBC count should be obtained if there is uncertainty about the likely cause. In such cases, a leukocytosis over 15,000/mm ^{3} would weigh against a viral infection.

If a viral pneumonia is strongly suspected, no specific therapy need be given. An example of such a situation would be a well-hydrated 5-year-old child with a gradual onset of cough, a temperature of 38°C (100.4°F), scattered bilateral rales, WBC count of 8000/mm^3 with predominantly lymphocytes, and the finding of hyperaeration on chest radiograph. Treatment in this case could be limited to antipyresis and hydration with a follow-up visit in 24 hours. Because the infant less than 3 months of age may become apneic during the course of viral pneumonia, these young children may benefit

from observation in the hospital.

Mycoplasmal Pneumonia

Background

M. pneumoniae is one of the most common causes of pneumonia among children older than 5 years. In younger children, infections with this organism are often limited to the upper respiratory tract or, occasionally, to the bronchial tree, although one study has implicated this organism as a common cause of pneumonia in children as young as 18 months. By the end of adolescence, 90% of the population has antibodies to *M. pneumoniae.*

Pathophysiology

The initial infection with M*. pneumoniae* occurs on the surface of the respiratory epithelium. Destruction of these cells causes them to slough into the lumen of the bronchi. The infection evokes an inflammatory response, primarily by mononuclear leukocytes.

Clinical Manifestations

Pneumonia caused by *M. pneumoniae* usually begins insidiously with fever and malaise. After 3 to 5 days, the child develops a nonproductive cough, hoarseness, sore throat, and in one-quarter of cases, chest pain. Fever is almost invariably present and may reach a level of 40°C (104°F). Children seldom develop much respiratory distress, with the exception of those who are less than 5 years old or also have sickle cell anemia or an immunodeficiency. Rales are heard in 75% of these infections, often bilaterally. The pharynx may appear inflamed, and some investigators have noted ear infections, particularly bullous myringitis, in association with pneumonia caused by *M. pneumoniae.* In 10% of patients, a maculopapular or, less often, a vesicular rash occurs; rarely, erythema multiforme, urticaria, or petechiae are seen.

The total WBC count is often normal in infections with this pathogen. A cold agglutinin titer of 32 or higher is found in most patients with lobar infiltrates from an *M. pneumoniae* infection but may also occur, although less often, with viral and bacterial illnesses. The organism may be recovered by culture, and specific diagnosis is possible with measurement of antibody titers in acute and convalescent sera; however, these procedures require 1 to 3 weeks and are not readily available. The radiographic findings show considerable variation. Between 10 and 25% of children will have lobar consolidation. Scattered segmental infiltrates, interstitial disease, and combinations of all these patterns may be seen. Pleural effusions occur in 5% of cases.

Numerous complications are described in association with *M. pneumoniae* infections, but they occur rarely. These include hemolytic anemia, arthritis, encephalitis, meningitis, and neuropathy.

Management

The diagnosis of mycoplasmal pneumonia is presumptively based on the clinical and radiographic findings and, in some cases, on the cold agglutinin titer. An older child or adolescent with the gradual onset of a mild bilateral pneumonia should be treated for this infection. On the other hand, a lobar infiltrate in a 5-year-old child usually is assumed to be of bacterial origin regardless of the level of the cold agglutinins. The results of cultures and specific serologic assays entail too great a delay to be useful to the clinician in the ED. Erythromycin (40 mg/kg per day) provides effective therapy for *M. pneumoniae* infections. The response is more pronounced in the older child with a lobar disease than in the younger child with a diffuse infiltrate.

Chlamydial Pneumonia

Background

Three species of *Chlamydia* cause pneumonia: *Chlamydia psittaci, Chlamydia trachomatis,* and *Chlamydia pneumoniae* (TWAR). Psittacosis, a severe pneumonia caused by *C. psittaci,* is rare but should be suspected in patients with unusual avian exposures. *C. trachomatis* is the most commonly recovered pathogen from children with afebrile pneumonias between 4 and 12 weeks of age. Identified as a new species in 1989, *C. pneumoniae* causes pneumonia primarily in children older than 5 years. In a study from Seattle, the attack rate for this agent was approximately 0.5 to 1 case per 1000 children (5 to 14 years old) per year, compared with 4 to 5 cases per 1000 for *M. pneumoniae*.

Pathophysiology

Among infants born to pregnant women with vaginal colonization by *C. trachomatis,* one-third to one-half acquire the organism. These infants are at risk for the subsequent development of pneumonitis. *C. pneumoniae* spread within families, day-care centers, and schools. Pathologic examination in chlamydial pneumonitis shows a mononuclear consolidation with occasional eosinophils and neutrophils and marked necrotic changes in the bronchioles.

Clinical Manifestations

Infancy. Infants with chlamydial pneumonia usually have a staccato cough that may resemble the paroxysms seen in pertussis but is usually less prolonged. In 50% of cases, conjunctivitis precedes the onset of respiratory symptoms. Pneumonia with this organism only rarely produces a fever. Mild retractions, hyperresonance, and diffuse rales are noted on examination of the chest. Hyperaeration of the lungs depresses the liver, allowing the edge to be palpated 1 to 2 mm

below the right costal margin.

Although the WBC count is usually in the normal range, the eosinophil count rises slightly (400/mm ^{3}, or 5 to 10%) in 75% of these patients. Elevated immunoglobulin levels, although nonspecific, often occur with chlamydial infections, but seldom with viral illnesses. Mild hypoxemia is common. The chest radiograph shows hyperaeration of the lungs and a diffuse increase in the interstitial markings. Lobar consolidations and pleural diffusions are not seen.

Although usually a mild illness, chlamydial pneumonia may be complicated by the occurrence of mucous plugging of the bronchi, apnea, and severe impairment of oxygenation. It is impossible to predict which infants with an initially mild course will have a stormy one.

Childhood. The spectrum of infection ranges from asymptomatic to severe. Adolescents are more likely to have signs of pneumonia than children, who may have clinical findings confined to the upper respiratory tract. Pneumonia is often preceded by sore throat and hoarseness, usually with a brief fever. By the time pneumonia has developed, the fever often resolves. Patients usually have a cough and scattered rales on auscultation. As for the clinical syndrome, the chest radiograph picture resembles that seen with *M. pneumoniae,* consisting of subsegmental lesions rather than lobar consolidation. Leukocytosis is not seen. No specific diagnostic testing is routinely available.

Management

Because of the difficulty in making a definitive etiologic diagnosis and the potential for complications, most young infants with presumed chlamydial pneumonia should be admitted to the hospital. Erythromycin (40 mg/kg per day) may shorten the course and should be given. *C. pneumoniae* infections in older children respond to therapy with macrolide antibiotics, including erythromycin (40 mg/kg per day) or azithromycin (10 mg/kg on day 1 and 5 mg/kg on days 2 through 5).

Bronchiolitis

Background

Bronchiolitis is a pulmonary infection of young children characterized by wheezing. RSV causes most of these illnesses, but other viruses, particularly parainfluenza, are isolated occasionally. In addition, *M. pneumoniae* has been reported as a rare cause of bronchiolitis.

The epidemiology of bronchiolitis primarily follows the pattern of its principal pathogen, RSV. Most of these infections occur in the winter and affect children between 2 and 8 months of age. Although some authorities do not accept the diagnosis of bronchiolitis after the age of 1 year, others believe that the disease occurs until the second birthday.

Pathophysiology

RSV, the most common cause of bronchiolitis, invades the epithelial cells of the nasopharynx and spreads to the mucosa of the lower respiratory tract by cell-to-cell transfer. The infection causes death of the cells that line the bronchi, which then slough into the lumen. The production of mucus increases, and mononuclear cells infiltrate the area. Clumps of necrotic epithelium and mucus initially decrease the diameter of the bronchi, causing turbulent air flow, particularly on expiration when the luminal diameter normally decreases. Eventually, plugging of the bronchi produces hyperinflation and atelectasis.

Clinical Manifestations

Bronchiolitis begins as a URI with cough and coryza. Over 2 to 5 days, signs of respiratory distress appear. The parents can often hear the child wheezing.

Fever occurs in two-thirds of children with bronchiolitis. They often appear ill on overall assessment. The respiratory rate climbs to at least 40 breaths/ minute and may reach 80 to 100 breaths/minute. Nasal flaring and retractions of the intercostal and supraclavicular muscles are noted and increase as the disease progresses. In bronchiolitis and other lower respiratory tract infections, the intercostal retractions are more pronounced than the supraclavicular, the opposite of the findings in croup and epiglottitis. Wheezes and a prolonged expiratory phase are heard in all children with bronchiolitis, at times without a stethoscope; rales are usually minimal. As the ventilatory muscles fatigue, the child will have grunting respirations; only in the most severe cases does cyanosis occur.

The total WBC count in bronchiolitis is normal. Usually, the chest radiograph shows only hyperaerated lungs, but there may occasionally be areas of atelectasis. If respiratory failure supervenes, the Pa O_2 decreases and carbon dioxide is retained.

The complications of bronchiolitis include dehydration, respiratory failure, and rarely, bacterial superinfection. Pneumothorax and pneumomediastinum are rarely seen. The increased respiratory effort in bronchiolitis may prevent an infant from maintaining an adequate oral intake. Careful attention should be paid to the details of fluid balance when taking a history. Of infants with bronchiolitis, 10 to 20% develop significant respiratory compromise. Cyanosis (or an oxygen saturation less than 91%), decreased inspiratory breath sounds, and lethargy on examination point to ventilatory failure. Bacterial superinfection is uncommon in the early stages of the illness, occurring occasionally in hospitalized infants. However, lobar consolidation seen on the chest radiograph suggests a potential bacterial pneumonia, although atelectatic patches may be confused with infiltrates.

Management

In the management of children with suspected bronchiolitis in the ED, a chest radiograph should be considered, both to look for findings compatible with this diagnosis and to help exclude other entities such as lobar pneumonia or a foreign body. Pulse oximetry provides an estimate of the degree of hypoxia. A WBC count, ABG, and/or electrolytes are obtained only if the diagnosis is uncertain or the clinical picture suggests that complications have occurred.

Children with bronchiolitis may benefit from nebulized bronchodilators. Although conflicting reports have been published, at least two studies have described an improvement in clinical status and oxygen saturation following albuterol delivered by nebulization and one group of investigators has found aerosolized epinephrine to be superior. For the child with moderate to severe distress, treatments can be administered every 20 minutes, starting at 0.1 to 0.3 of a 0.5% solution of albuterol or using 3 mL of 1:1000 epinephrine. Patients who show a favorable response to nebulized therapy are candidates to receive further nebulized treatments. Oral albuterol solution at a dosage of 0.1 mg/kg per dose, given every 6 hours, has limited efficacy.

Corticosteroids are not indicated for the treatment of patients with bronchiolitis. In general, it is difficult to differentiate asthma from bronchiolitis during the first 2 years of life; thus, corticosteroids may be given occasionally to some children who may have bronchiolitis or asthma, in accordance with the guidelines for the latter disease.

For the patient who does not respond to nebulized albuterol or has only mild distress, bronchodilators should not be prescribed. Therapy is limited to antipyretics and the encouragement of adequate oral intake, and the infant should be examined again after 24 to 48 hours. Dehydration secondary bacterial infection and significant respiratory distress necessitate admission to the hospital. Although not validated in infants with bronchiolitis, a score of 4 or more on the asthma scale (see Chapter 92) suggests significant respiratory compromise. An oxygen saturation less than 93% or an arterial PaO_2 less than 70 mm Hg in room air also suggests a need for hospitalization. In addition, children with underlying cardiac or pulmonary disease usually require admission. Ribavirin has proved somewhat useful in ameliorating the course of bronchiolitis, when administered by continuous aerosol for 3 to 5 days to severely ill children who are hospitalized. This agent is recommended primarily for patients with underlying cardiac or pulmonary conditions.

Pertussis

Background

Pertussis, or whooping cough, is an infection of the respiratory tract caused by *Bordetella pertussis.* Occasionally, a similar clinical syndrome is caused by *Bordetella parapertussis,* the adenoviruses, or *Chlamydia.* Young children most often contract pertussis, but the incidence in adolescents has increased recently. Although vaccination has contributed to the significant decrease in the frequency of this disease, several thousand cases occur yearly in the United States among unvaccinated children and to a lesser degree among those who have received vaccine, particularly of the whole cell variety.

Pathophysiology

Following inhalation, *B. pertussis* organisms attach to the epithelial cells of the respiratory tract. Multiplication of the bacteria leads to infiltration of the mucosa with polymorphonuclear leukocytes and lymphocytes. Inflammatory debris in the lumen of the bronchi and peribronchial lymphoid hyperplasia obstruct the smaller airways, causing atelectasis.

Clinical Manifestations

Although pertussis can be divided into three stages for discussion, a clinically distinct syndrome does not evolve until the disease has progressed to the second stage. Initially, the symptoms mimic a viral URI. This first stage (catarrhal), characterized by a mild cough, conjunctivitis, and coryza, lasts for 1 to 2 weeks. An increasingly severe cough heralds the onset of the second stage (paroxysmal), which continues for 2 to 4 weeks. After a prolonged spasm of coughing, the sudden inflow of air produces the characteristic whoop. Vomiting often occurs after such an episode. When not coughing, the child has a remarkably normal physical examination, except for an occasional subconjunctival hemorrhage. During the third stage (convalescent), the intensity of the cough wanes.

The WBC count in children usually reaches a level of 20,000 to 50,000/mm^3 with a marked lymphocytosis, but such changes are not often seen in infants less than 3 to 6 months old. Although a chest radiograph occasionally shows the characteristic “shaggy” right heart border, more often the lung fields appear clear. *B. pertussis* can be identified by fluorescent antibody staining of mucus obtained from the nasopharynx or, less commonly, recovered by culture of this material.

The fatality rate for pertussis is approximately 1% for patients in the first month of life and 0.3% for those between age 2 and 12 months. Complications often occur during a bout of pertussis. The most immediately life-threatening complication is complete obstruction of the airway by a mucous plug, leading to respiratory arrest. Although secondary bacterial pneumonia has a more insidious onset, it occurs in 25% of children with pertussis and accounts for 90% of the fatalities from pertussis. Seizures are seen in 3% of patients, and encephalitis in 1%. Sudden increases in intrathoracic pressure can cause intracranial hemorrhages, rupture of the diaphragm, and rectal prolapse.

Management

Except for occasional situations in which fluorescent antibody testing is immediately available, the diagnosis of pertussis rests on clinical grounds. Children with an unmistakable paroxysmal cough followed by a whoop should be assumed to have the disease. When the clinical picture is unclear, a WBC count and chest radiograph may be useful. The radiograph helps eliminate other causes of a severe cough (e.g., foreign body, bacterial pneumonia, cystic fibrosis,

tuberculosis), and the WBC count provides confirmatory evidence if a leukocytosis with marked lymphocytosis is found. Because of the grave risk of complications, all children less than 6 months of age diagnosed firmly as having pertussis should be observed in the hospital. Older children who show signs of respiratory compromise, such as cyanosis during paroxysms of coughing, or who develop complications also require admission. Treatment includes erythromycin (40 mg/kg per day for 14 days), maintenance of adequate hydration, and a level of respiratory support appropriate to the severity of the disease. Clarithromycin and azithromycin are alternative choices. Household and other close contacts require chemoprophylaxis with erythromycin (40 mg/kg per day for 14 days). Children younger than 7 years who are unimmunized or have received fewer than four doses of pertussis vaccine should have their pertussis immunization initiated or continued as soon as possible after exposure. Children who are fully immunized for age but have received only three doses require a fourth dose. Those who have had four doses need a booster unless the last dose has been within 3 years or they are more than 6 years old. DTP_a is preferred.

Tuberculosis

Background

In the United States, tuberculosis is caused almost exclusively by *M. tuberculosis* and occurs in childhood in several clinical forms. Although currently an unusual infection in developed countries, the incidence has increased recently and the disease should be kept in mind as an occasional, treatable cause of morbidity and mortality. At particular risk are children in urban, low-income areas and recent immigrants from underdeveloped countries. In addition, the emergency physician must be concerned about tuberculosis when either the patient or close contacts are infected with HIV (see Chapter 85).

Pathophysiology

Tubercle bacilli enter the body through the respiratory tract, producing an initial focus in the lungs. This lesion usually remains subclinical but may progress locally, resulting in a primary tuberculous pneumonia. During the primary infection, the organisms can disseminate hematogenously. Such spread may remain quiescent or, in a young child, may lead to miliary tuberculosis. Seeding of various organs occurs and may produce focal infections, a particularly serious concern with meningeal involvement.

Usually, the immune system limits the initial infection. However, reactivation of these foci may cause disease years later at any site involved during dissemination. Pulmonary lesions reactivate to produce tuberculous pneumonia in adults and adolescents much more often than in children.

Clinical Findings

Most infections by *M. tuberculosis* in children never cause any significant symptoms. Among the many possible clinical presentations, three stand out as particular concerns to the emergency physician: primary pneumonia, miliary tuberculosis, and meningitis. Pneumonia is by far the most common. Of note, these infections may develop despite prior vaccination against tuberculosis with bacillus Calmette-Guerin vaccine (BCG).

The onset of primary tuberculosis pneumonia resembles that of bacterial infections of the lungs. It begins with fever and tachypnea; rales and an area of dullness are found on examination of the chest. The WBC count may be elevated with a shift to the left, and the chest radiograph shows a lobar consolidation, often accompanied by hilar adenopathy and less often by pleural effusion or cavitation. Although the primary pneumonia often resolves spontaneously, the child occasionally follows a downhill course caused by local progression. In addition to the epidemiologic risks described, clinical findings that should arouse a suspicion of tuberculous pneumonia in the child otherwise thought to have a bacterial infection of the lung include pleural effusion, cavitation, toxicity, and a failure to respond to antibiotic therapy.

Miliary tuberculosis begins with an abrupt rise in temperature but a paucity of other physical findings; it may mimic sepsis. Subsequently, respiratory symptoms and enlargement of the liver, spleen, and superficial lymph nodes occur. The WBC count is usually in the range of 15,000/mm^3. Although the chest radiograph initially shows no lesions, a diffuse mottling of the lung fields appears 1 to 3 weeks after the fever. Miliary tuberculosis is a consideration in a child with a persistent fever and hepatosplenomegaly.

Tuberculous meningitis comes on insidiously with a low-grade fever, apathy, and in 50% of patients, vomiting. After 1 to 2 weeks of nonspecific illness, neurologic signs appear, including drowsiness and nuchal rigidity; if untreated, the child lapses into coma. The CSF shows a mononuclear pleocytosis, an elevated protein concentration, and eventually, a low glucose level.

Management

A child suspected of having pneumonic, meningeal, or miliary tuberculosis should be admitted to the hospital for evaluation and possible chemotherapy. Among inner-city populations, where the risk of tuberculosis is greatest, the routine placement of a tine or Mantoux test in children with lobar pneumonia should be considered. The Mantoux test must be interpreted in accordance with the child's age and the presence of risk factors (Table 84.18) Current treatment for tuberculosis consists of two to four or more drugs (isoniazid, rifampin, pyrazinamide, ethambutol, streptomycin, capreomycin, ciprofloxacin, cycloserine, ethionamide, kanamycin, ofloxacin, para-aminosalicylic acid) for a minimum of 6 months.

Induration ≥5 mm
Children in close contact with known or suspected cases of active tuberculosis, if adequate and timely treatment cannot be verified
Children suspected to have tuberculosis based on a consistent chest radiograph or clinical findings
Children immunosuppressed on the basis of therapy or disease
Induration ≥10 mm
Children <4 years of age
Children with chronic illness including lymphoma, diabetes mellitus, renal failure, and malnutrition
Children born in or traveling to regions of the world with a high prevalence of tuberculosis or exposed to adults likely to be infected
Induration ≥15 mm
Children ≥4 years of age without any risk factors

Modified from Committee on Infectious Diseases, 1997 RedBook. Elk Grove Village, IL: American Academy of Pediatrics, 1997.
[a]Applies regardless of previous BCG vaccination.

Hantavirus

The Hantavirus pulmonary syndrome was described in 1994 among 17 adults, of whom 13 died with severe pneumonia and hypotension. In a subsequent series, 8 of 100 patients were 16 years old or younger. Rodents serve as the reservoir for the hantaviruses, of which several varieties infect humans. The syndrome begins with fever, cough, and myalgias, followed shortly thereafter by tachypnea, tachycardia, dyspnea, and finally, hypotension. A marked leukocytosis is common along with thrombocytopenia and elevated clotting studies. The initial chest radiograph shows an interstitial more often than an alveolar infiltrate, with changes starting or becoming bilateral in the majority of cases. Pleural effusions occur in about one-quarter of the patients. The diagnosis should be considered when a severe pneumonia occurs in combination with systemic deterioration and can be confirmed subsequently by specific viral serology. Treatment is supportive.

Gastrointestinal Infections

Gastroenteritis is an inflammation of the alimentary tract that, in its acute form, is overwhelmingly infectious in origin. Viruses are the organisms most commonly found in children with diarrhea in the United States and can be isolated from 30 to 40% of patients. In 10 to 15% of patients, bacteria are recovered, including *Salmonella, Shigella, Campylobacter, Yersinia,* and pathogenic *E. coli; Aeromonas hydrophila* and *Vibrio* species, such as *Plesiomonas shigelloides,* are occasional pathogens. *Clostridium difficile,* which elaborates a toxin, may cause colitis, particularly after the use of antibiotics. Parasitic infestations rarely lead to diarrhea in the developed countries. *Giardia lamblia* and *Cryptosporidium* should be considered, particularly in outbreaks in day-care centers, and *Entamoeba histolytica*, among immigrants or travelers from tropical areas; cryptosporidiosis also affects patients with HIV. Current diagnostic techniques are unable to identify an etiologic agent in most of the remaining episodes.

In the United States, GI infections rank second in frequency to respiratory tract infections during childhood. An estimated 30,000,000 children with gastroenteritis receive treatment at home each year, 3,000,000 visit a physician, and 200,000 require hospitalization. Approximately 12% of all hospitalization of children 1 month through 4 years of age include diarrhea among one of the top three positions on the list of discharge diagnoses. Almost 400 children die annually in the United States from infections of the GI tract.

Viral hepatitis is covered in Chapter 93. Bacterial infections of the liver, almost exclusively abscesses, are rare in otherwise healthy children; more commonly, they complicate an immunosuppressive disease or therapy, or they affect the neonate.

Because calculi in the bile ducts rarely occur during childhood, cholecystitis occurs much less often in children than in adults. Occasionally, episodes are seen in adolescents or children predisposed to stone formation, as in the chronic hemolytic anemias. Less commonly, salmonellosis or leptospirosis produces acalculous cholecystitis.

In childhood, peritonitis almost invariably reflects an intra-abdominal catastrophe that requires surgical intervention. However, the accumulation of ascitic fluid in children with diseases such as nephrosis and cirrhosis allows the development of a primary infection of the peritoneum.

Viral Gastroenteritis

Background

Viral gastroenteritis occurs primarily in two forms caused by different pathogens. The Norwalk virus produces an illness characterized by an explosive onset and vomiting, more severe than the diarrhea that accompanies it. The symptoms are self-limiting, resolving in 2 to 3 days. It occurs in epidemics, most often in the winter, and affects predominantly school-age children. Rotavirus, however, produces a prolonged diarrheal illness of varying severity. It occurs more often in young children, although older family members may be affected. Other viruses, including enteroviruses, coronaviruses, and adenoviruses, may play a role in gastroenteritis.

Viral gastroenteritis is common. Among U.S. families, it trails only the common cold in frequency. Rotaviruses are the most commonly isolated pathogens, particularly among children who develop dehydration. Viral infections of the GI tract cause considerable loss of time from school and occasionally require treatment in the hospital.

Pathophysiology

Rotaviruses invade the intestinal epithelial cells, where they can be visualized by electron microscopy. The histology of the mucosal layer is disturbed during the active infection and for 3 to 8 weeks afterward. Functional abnormalities accompany the morphologic changes, including depressions of disaccharidase levels. Although Norwalk virus may invade the mucosal lining of the intestine, it has not been detected intracellularly. Histologic changes occur and persist for 2 weeks, and disaccharidase levels decline during the infection.

Clinical Findings

Children with viral gastroenteritis are usually brought to the ED with a complaint of diarrhea and/or vomiting. The numbers of stools may vary from 2 or 3 to 15 or 20 daily. Most commonly there are 6 to 8 bowel movements in a 24-hour period; the stools range from semisolid in consistency to watery. Although hematochezia may occasionally occur in viral infections, the presence of blood in the stool should suggest a bacterial gastroenteritis. Vomiting may accompany diarrhea or be the sole manifestation of a viral gastroenteritis. The daily frequency of emesis varies in the same range as for diarrhea. After forceful emesis, streaks of blood may be present in the vomitus. Many children with viral gastroenteritis beyond the age of 2 or 3 years complain of crampy abdominal pain. In more severe illnesses, the parent may relate a history of decreased oral intake and oliguria.

Children with viral gastroenteritis are usually febrile. However, in the child older than 3 years, a temperature over 39°C (102.2°F) may suggest a bacterial enteritis. Tachycardia, hypotension, and lethargy may reflect dehydration in severe episodes. Whereas the respiratory rate is usually normal, tachypnea occurs when acidosis and/or dehydration are present. The abdomen is soft and nondistended in most cases. Although the child may perceive palpation as uncomfortable, this maneuver does not elicit localized or rebound tenderness. Auscultation reveals hyperactive bowel sounds. The skin turgor is decreased and the mucous membranes are dry only in severe gastroenteritis with dehydration (see Chapter 18, Chapter 19, and Chapter 86).

No laboratory studies are indicated in the uncomplicated case of gastroenteritis. The CBC, electrolytes, and BUN usually fall within the normal range. If oral intake fails to keep pace with the efflux of fluids from the alimentary tract, dehydration occurs. The sodium, usually normal, may drop as low as 110 mEq/L or rise to 170 mEq/L, and the bicarbonate is invariably low. With mild dehydration, the serum bicarbonate hovers just below the normal level at 18 to 20 mEq/L; however, values of 10 to 12 mEq/L are usually found in the face of prolonged diarrhea. The BUN reflects the state of hydration and the adequacy at the recent intake of protein. It may climb as high as 100 mg/dL in children who lose more than 10% of their body weight. In a child who has been maintained on clear liquids, however, the BUN will not accurately indicate the degree of dehydration because urea rises as a breakdown product during protein metabolism. Although the hemoglobin and WBC count are usually normal in the child with viral gastroenteritis, hemoconcentration may occur with dehydration.

Management

Uncomplicated viral gastroenteritis usually remits in 2 to 5 days and does not require treatment in the hospital. All children should be weighed, preferably without clothing, to provide a baseline for follow-up. The vomiting will generally respond to a brief cessation of oral intake. After 2 to 4 hours of abstinence, the diet should be resumed gradually. The diarrhea may persist for several days, but hydration can usually be maintained orally after the vomiting has subsided.

Current recommendations for oral therapy emphasize the use of appropriately balanced glucose and electrolyte solutions, as well as the early reintroduction of feedings. Generally, rehydration is initiated, particularly in infants less than 1 year old, with a solution that contains 75 to 90 mEq/L sodium in a ratio with glucose of 1:1 (e.g., Rehydralyte). Older children often tolerate juices and sodas. Some studies have advocated the use of glucose polymers (e.g., Ricelyte) instead of glucose as a means to reduce diarrhea, but significant advantages have yet to be demonstrated for these products. Preparation at home of fluids that contain salt notoriously leads to errors, and this procedure is to be condemned. Similarly, the physician should avoid the use of boiled skim milk, a hypertonic solution that may produce hypernatremia.

Antiemetics and antidiarrheal medications provide minimal, if any, relief to the child. In addition, many of these medications carry significant risks. Kaopectate has been shown to increase stool losses of water and electrolytes. Although the combination of diphenoxylate and atropine (Lomotil) may be successful in adults, toxic reactions in children limit its usefulness. Trimethobenzamide (Tigan) appears to be ineffective as an antiemetic in children. Although the phenothiazine compounds reduce emesis, they occasionally produce adverse side effects, such as extrapyramidal reactions or oculogyric crises that limit their usefulness. Loperamide (0.5 mg/kg per day) has been shown to reduce the severity of diarrhea in conjunction with oral rehydration therapy but is indicated only for unusually severe or prolonged cases of gastroenteritis after excluding a cause that would respond to specific therapy. Although a few studies have suggested a small benefit from bismuth subsalicylate (Pepto-Bismol), this agent is not recommended for routine cases.

Dehydration is the only significant complication of viral gastroenteritis. If the physician suspects that a child has developed more than 5 to 10% dehydration, electrolytes and a BUN should be obtained. These tests establish the degree of acidosis and the presence of hyponatremia or hypernatremia.

Most children with gastroenteritis tolerate oral rehydration. In underdeveloped countries, even patients with severe dehydration are often managed successfully in most cases by using the oral route. However, in the ED, treatment for children with moderate to severe dehydration is usually initiated intravenously. As a rule, all patients with dehydration estimated to be greater than 10%, and many cases falling in the range of 5 to 10%, require IV fluids.

When IV therapy is chosen, a bolus of fluid, such as 10 to 20 mL/kg normal saline, may be administered over 1 hour, or

more rapidly if needed (see Chapter 3). If rehydration is achieved and the child is capable of subsequent oral intake, treatment may be continued at home (as in the milder cases).

Children who are more than 5% dehydrated or have alterations in the serum sodium (less than 130 mEq/L or more than 145 mEq/L) may require hospitalization. IV therapy should be started in the ED, particularly if there is evidence of vascular instability (see Chapter 3, Chapter 18, Chapter 19, and Chapter 86).

Bacterial Gastroenteritis

Background

Five pathogens commonly produce gastroenteritis: *Salmonella, Shigella, Yersinia, Campylobacter,* and pathogenic *E. coli.* Together, these organisms cause 10 to 15% of the diarrheal illnesses seen in children coming to the ED (Fig. 84.17). In underdeveloped countries and occasionally in the United States, *Vibrio* species must also be considered. In addition, *A. hydrophila* has been associated occasionally with diarrheal illnesses in children. *C. difficile* causes a toxin-associated colitis, particularly in patients who receive antibiotics.

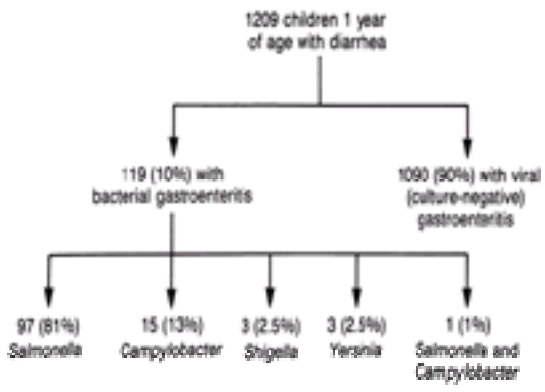

FIGURE 84.17. Etiology of gastroenteritis among consecutively cultured infants less than 1 year of age in an urban emergency department. (Reprinted with permission from Torrey S, Fleisher G, Jaffe D. Incidence of *Salmonella* bacteremia in infants with *Salmonella* gastroenteritis. J Pediatr 1986;108:718.)

Salmonella, Shigella, Yersinia, Gram-negative bacilli in the *Enterobacteriaceae* family, and *Campylobacter* do not normally inhabit the alimentary tract. Thus, recovery of one of these organisms suffices for the diagnosis of gastroenteritis. *E. coli,* however, is part of the normal bowel flora, only occasionally assuming a pathogenic role. Serotyping is useful for detecting *E. coli* O157, a cause of hemolytic uremic syndrome, but identification of other disease-producing strains is not readily available to the clinician.

Pathophysiology

Salmonella species gain access to the small intestine following ingestion. Gastric acid is usually lethal to the organism, but large numbers of bacteria may overcome this defense mechanism. Studies have shown that 10^5 virulent organisms will induce disease in 30% of healthy adults and 10^9 in 95%. Patients with gastrectomies are more susceptible to *Salmonella* infection than those with an intact stomach. *Salmonella* can penetrate the epithelial layer to the level of the lamina propria and evoke a leukocyte response. Generally, the infection extends no further, but bacteremia may occur, especially in young children. Several species, notably *S. choleraesuis* and *S. typhi,* readily enter the circulation through the lymphatics. *Salmonella* produce diarrhea by multiple mechanisms. Several toxins have been identified; in addition, prostaglandins that stimulate the active secretion of fluids and electrolytes may be released.

Certain *Shigella* attach to binding sites on the surface of the intestinal mucosal cells. The organisms penetrate the cells and proliferate within them. Intraepithelial multiplication destroys the cell and produces mucosal ulcerations. Invasion of the epithelium evokes an intense inflammatory response. At the base of the ulcerated lesions, erosion of blood vessels may lead to bleeding. Other *Shigella* elaborate exotoxins that can produce diarrhea. These toxins result in increased secretion of fluid and electrolytes by the intestinal mucosa.

Although the pathophysiology of infection from *Yersinia enterocolitica* has not been completely elucidated, clues are available from animal models and occasional pathologic specimens. The organisms are thought to produce terminal ileitis; inflammatory changes and ulcerations have been visualized with endoscopy. The infection elicits a neutrophilic response, particularly around the Peyer's patches. It then extends to the mesenteric lymph nodes, which are destroyed by microabscess formation and may enlarge considerably. Occasionally, further dissemination occurs with involvement of the liver and spleen. Although an enterotoxin has been identified in cultures of *Y. enterocolitica* maintained at 26° to 30°C (78.8° to 86°F), production in vivo has not been established.

The pathogenesis of *Campylobacter* enteritis remains unknown. Attempts to demonstrate toxin production have not met with success, and the organism has been shown to lack invasive properties. At autopsy, extensive hemorrhagic ulcerations of the bowel have been described.

E. coli may produce diarrhea on the basis of several characteristics. Pathogenic strains have been classified as enteropathogenic, enterotoxic, enteroinvasive, enteroaggregative, enteroadherent, and enterohemorrhagic. The risk of

developing hemolytic uremic syndrome after infection with *E. coli* O157 is estimated to be 10 to 15% in children.

Clinical Manifestations

Signs and Symptoms. A careful epidemiologic history often provides a clue to the diagnosis of *Salmonella* infections. Foodborne outbreaks often occur in the summer. After an incubation period of 8 to 48 hours, the child experiences crampy abdominal pain and nausea. The stools are watery and may contain blood, but this is not the rule. Fever is noted in most children. Unless protracted diarrhea has led to clinically apparent dehydration, the physical examination is unremarkable. Abdominal tenderness and distension are usual findings. The leukocyte count is usually 10,000 to 15,000/mm^3. Methylene blue staining of the stool may show the presence of polymorphonuclear leukocytes, but not in sheets as seen with *Shigella.* A single rectal swab leads to isolation of *Salmonella* from more than 90% of children with this infection.

Shigella may cause an asymptomatic infection, mild gastroenteritis, or bacillary dysentery. Mild illnesses are more common. Children affected in this way complain of frequent watery stools but few constitutional symptoms. The temperature remains normal in many cases, and the physical examination is unremarkable.

Bacillary dysentery begins suddenly with fever and abdominal pain. Diarrhea begins shortly thereafter. The stools, which may average 10 to 12 daily, contain mucus and blood, and tenesmus is common. Children with this form of shigellosis have a fever, often in the range of 39° to 40°C (102.2° to 104°F). Palpation of the abdomen often elicits diffuse tenderness but no evidence of peritoneal irritation.

Occasionally, a *Shigella* infection may produce CNS irritation because of the release of toxin before the onset of diarrhea. Thus, shigellosis must be considered in the differential diagnosis of meningismus in the absence of a pleocytosis in the CSF. A seizure may actually be the first manifestation of the illness.

Certain laboratory abnormalities strongly suggest *Shigella* as the cause of gastroenteritis. The leukocyte count often shows many band forms that exceed the mature neutrophils in number. Poh described this phenomenon in 85% of 123 children between the ages of 2 months and 8 years with shigellosis. The total WBC count may show a leukopenia or a leukocytosis but most commonly hovers in the normal range. Because *Shigella* invades the intestinal mucosa, this infection elicits a profound inflammatory response. The exudation of white cells leads to the finding of sheets of neutrophils in the stool after methylene blue staining. A single rectal swab suffices for the isolation of *Shigella* from most children with this illness.

Children with gastroenteritis caused by *Y. enterocolitica* usually have an abrupt onset of diarrhea. The stools are often watery and may contain blood, but vomiting generally remains inconsequential. Patients with this illness often complain of severe abdominal pain, sometimes before the onset of diarrhea. Delorme et al. noted this symptom in 6 of the 35 children studied, half of whom were 1 to 5 years old. In an epidemic in a school in New York State, 37 of 38 patients had abdominal pain; the potential severity of the abdominal pain in this disease is illustrated by the fact that 16 patients in this outbreak mistakenly underwent an appendectomy.

GI infection with *Y. enterocolitica* usually elicits a febrile response. The mean temperature in the young adolescents reported by Black et al. was 38.7°C (101.6°F), with a range of 37.2° to 40°C (99° to 104°F); it exceeded 37.8°C (100°F) in more than 95% of patients. Younger children appear to develop a fever less often. The abdominal examination is usually benign, but palpation produces marked tenderness in the subset of patients with mesenteric adenitis. Arthritis and skin rashes occur in 5 to 10% of patients with this disease.

The mean WBC count in children with yersiniosis is usually normal, although leukocytosis with a shift to the left occurs occasionally. The electrolytes and BUN are normal except in the face of dehydration. Examination of stool stained with methylene blue reveals polymorphonuclear neutrophils. The organism can be recovered from stool culture but requires enrichment techniques. Although a single specimen is diagnostic in 70 to 80% of illnesses, a second sample should be obtained in the face of a previous negative culture when the clinical suspicion of disease remains strong.

Campylobacter enteritis is characterized by the abrupt onset of fever and abdominal pain, followed shortly by diarrhea. The temperature often remains normal in children less than 3 months old, but ranges up to 40°C (104°F) in the older child. Vomiting occurs uncommonly and resolves rapidly. Two-thirds of children complain of abdominal pain, which may be severe. The number of stools varies from 2 to 20 daily; they are watery and contain blood in at least 50% of cases. Karmali and Fleming found frank blood in the stools of 95% of their patients. The physical examination is generally unremarkable. Although the abdominal pain occasionally simulates appendicitis, palpation of the abdomen elicits minimal tenderness. Signs of dehydration are found only rarely.

The WBC count in *Campylobacter* enteritis usually remains below 12,000/mm^3, the highest being 22,500/mm^3 in one study; on occasion, there may be a shift to the left. The electrolytes and BUN are usually normal. Maki et al. found fecal leukocytes in four of five patients with enteritis caused by *Campylobacter.* The organism is not often isolated from the blood but can be recovered easily from the stool by using appropriate media. When available, phase contrast microscopy can demonstrate the organism in fresh stool specimens.

The clinical picture of diarrhea caused by *E. coli* varies. This organism is suspected most often in the setting of a specific outbreak.

In general, features suggestive of a bacterial rather than a viral gastroenteritis include 1) more than 10 stools per day or diarrhea lasting for more than 4 days, 2) blood in the stool, 3) fever of 39.5°C (103°F) or higher, 4) clinical toxicity, and 5) polymorphonuclear leukocytes in the stool. The presence of these findings enhances the likelihood that a bacterial pathogen is involved, although a viral gastroenteritis is not necessarily ruled out.

Complications. The complications of *Salmonella* gastroenteritis include dehydration and spread of infection beyond the confines of the GI tract. During bacteremia, focal infections, including meningitis, osteomyelitis, and endocarditis, may develop. However, most episodes of bacteremia terminate spontaneously. Dehydration is diagnosed on the basis of the clinical findings: dry mucous membranes, decreased skin turgor, tachycardia, and hypotension. Although the electrolytes are most often normal, both hyponatremia and hypernatremia may occur.

Bacteremia is most common in young children. In a study by Hyams et al., 25% of hospitalized patients with *Salmonella* gastroenteritis had the organism recovered from their blood. However, Torrey et al. noted an incidence of only 6% in an ambulatory population. Although a high fever usually accompanies spread to the circulation, the physical examination is often devoid of any signs of serious illness. In addition, infants in the first 3 months of life often remain afebrile in the face of bacteremia. The WBC count is greater than 15,000/mm^3 in 80%–90% with bacteremia, and culture of the blood leads to recovery of the organism.

Enteric fever also occurs from the dissemination of certain serotypes of *Salmonella;* if *S. typhi* is isolated, the illness is called typhoid fever. The disease is characterized by chills and fever, often rising in a steplike pattern to 40°C (104°F). Diarrhea does not necessarily precede or coexist with the systemic illness. A relative bradycardia in relation to the height of the temperature is a hallmark of enteric fever. Splenomegaly and a macular rash, or rose spots, are detectable in 20 to 30% of patients. Leukopenia characterizes the hematologic picture. Both blood and stool cultures may be negative. The diagnosis may rest on a fourfold rise in the agglutinin titers.

Invasion of the bloodstream may lead to various focal diseases. Meningitis most commonly affects the youngest children. The features are identical to those observed in CNS infections with other purulent organisms. Children with sickle cell hemoglobinopathies have a peculiar predilection for bone and joint involvement. Endocarditis is less commonly seen.

The complications of shigellosis include dehydration, bacteremia, seizures, and colonic perforation. Dehydration often accompanies dysenteric infections and is diagnosed on the basis of the usual clinical findings. Bacteremia and perforation are both rare, occurring in fewer than 1% of GI infections.

Most episodes of gastroenteritis with *Yersinia* are self-limiting, resolving before dehydration develops. Appendicitis occasionally results from obstruction of the appendiceal lumen by swollen lymphoid tissue. The incidence is unknown, but 5 of 38 patients in the New York State epidemic underwent removal of appendices that were suppurative. Bacteremia and focal infection follow gastroenteritis almost exclusively in the compromised host, particularly in association with thalassemia.

Campylobacter infections occasionally lead to dehydration, but less often than is seen with the other bacterial pathogens in the GI tract. Rarely, bacteremic or focal infections occur.

Management

Salmonella gastroenteritis is usually a self-limiting illness. In most cases, the disease is not sufficiently distinct or severe enough to suggest to the clinician the need for a diagnostic evaluation. However, life-threatening complications occur with predictable regularity in infants less than 6 months of age and in children with sickle cell hemoglobinopathies.

The treatment of *Salmonella* gastroenteritis should be directed toward the maintenance of adequate hydration. As with viral infections, limitation of the diet to electrolyte solutions (“clear liquids”) suffices in most children. Antibiotic therapy neither ameliorates the course of the gastroenteritis nor eradicates the organism from the intestinal tract in the immunocompetent host. In fact, several studies have suggested prolonged carriage after the administration of antibiotics.

The indications for admission of a child with diarrhea suspected or proved to be caused by *Salmonella* species are 1) dehydration, 2) focal infection or bacteremia/sepsis, 3) age less than 3 months or temperature over 39°C (102.2°F) in a child under 12 months old (unless blood culture is known to be sterile), and 4) sickle cell anemia. If bacteremia is suspected, IV therapy with cefotaxime (200 mg/kg per day in four divided doses) or ceftriaxone (100 mg/kg per day in two divided doses) should be initiated. Chloramphenicol (75 to 100 mg/kg per day in four divided doses) or, in adolescents, one of the fluoroquinolones (ciprofloxacin, ofloxacin) provides an alternative for cephalosporin-allergic patients. When oral therapy is indicated, TMP-SMZ (8 mg/kg per day of trimethoprim in two divided doses) is the drug of choice.

Shigellosis stands alone as the only form of bacterial gastroenteritis for which antibiotics have proved efficacious. Antimicrobial therapy shortens the course of the illness and the duration of excretion of the organisms in the stool. Treatment alleviates the symptoms and signs of the gastroenteritis and limits transmission of the disease. TMP-SMZ (8 mg of trimethoprim and 40 mg of sulfamethoxazole per kilogram per day) is the initial drug of choice while the results of sensitivity tests are pending. Fluoroquinolones and ceftriaxone are alternatives.

Supportive therapy is an important aspect of the management of shigellosis. The initial oral intake should be limited to solutions with physiologic concentrations of glucose and electrolytes. As the diarrhea begins to abate, solid foods can be added. Dietary manipulation leads to resolution of the disease in some children before the isolation of the organism. Antibiotic therapy may be omitted in such cases, unless there is a particular concern about spread in a closed population.

As with other varieties of infectious gastroenteritis, most medications designed to provide symptomatic relief from diarrhea have no demonstrated efficacy. In particular, paregoric or combinations of diphenoxylate and atropine (Lomotil) are contraindicated. Dupont et al. showed that diarrhea persisted longer in infected volunteers treated with antibiotics and diphenoxylate/atropine than with those who received only antibiotics.

Most episodes of shigellosis can be handled on an outpatient basis. Indications for admission include 1) age 6 months or

younger, 2) dehydration, and 3) bacteremia (rare). Before the definitive diagnosis of shigellosis, particularly with significant bleeding, hospitalization may be required because of a concern about noninfectious entities such as a Meckel's diverticulum.

Most children with yersiniosis can be treated as outpatients. Initially, the diet should be limited to electrolyte solutions (clear liquids). Although *Y. enterocolitica* is usually sensitive in vitro to tetracycline, chloramphenicol, colistin, gentamicin, and kanamycin, current studies have demonstrated no benefit from antibiotic therapy of uncomplicated gastroenteritis. However, persistent diarrhea may respond to antimicrobial treatment. Suspected or proven sepsis merits IV administration of antibiotics such as gentamicin (5 to 7.5 mg/kg per day in three divided doses, beyond the neonatal period). The indications for admission include dehydration, severe abdominal pain suggesting appendicitis, and underlying diseases such as thalassemia.

Campylobacter enteritis is a self-limited but prolonged illness; diarrhea persists for more than 1 week in one-third of children. These organisms exhibit almost universal sensitivity to erythromycin, which can be given orally at a dosage of 40 mg/kg per day; ciprofloxacin is an alternative for adolescents. However, antimicrobial therapy has not proved to decrease the duration of diarrhea.

Antibiotic-Associated Colitis

Background

Children who take antibiotics often develop diarrhea, which varies from mild to severe. For most of the mild cases, no specific diagnosis is established. A small subset of patients, usually with more severe illnesses, have pseudomembranous colitis, caused by *C. difficile.* Although antibiotics are the most important precipitating factor for pseudomembranous colitis, the disease was recognized in the preantibiotic era and still occurs occasionally in the absence of prior antibiotic therapy. Almost every antibiotic has been reported to be associated with pseudomembranous colitis. Clindamycin, lincomycin, and the broad-spectrum b-lactam agents in particular predispose to overgrowth of *C. difficile,* but because these drugs are rarely used for children on an outpatient basis, widely prescribed medications, such as amoxicillin, are implicated more often in the pediatric age group.

Pathophysiology

C. difficile, the etiologic agent in pseudomembranous colitis, is a Gram-positive anaerobic bacillus that may be part of the normal intestinal flora, particularly during the first year of life. Even a short course of antibiotics may lead to overgrowth of this organism. Colitis results from toxin production by *C. difficile* within the intestinal lumen; the two major toxins are known as A and B. These toxins attack the membranes or microfilaments of cells and produce hemorrhage, necrosis, and inflammation.

Clinical Manifestations

Colitis with *C. difficile* varies widely in severity. Typically, profuse watery or mucoid diarrhea begins after several days of antibiotic therapy. Many older children complain of crampy abdominal pain. On examination, the usual findings include fever and diffuse abdominal tenderness. Often, the WBC count rises above 15,000/mm ^{3}. The stool may be guaiac-positive or frankly bloody; leukocytes are found on smears from approximately 50% of patients. An etiologic diagnosis requires the identification of *C. difficile* toxin in the stool; recovery of the organism on culture is suggestive but not sufficient.

If *C. difficile* colitis goes unrecognized and untreated, complications, including toxic megacolon, perforation, and peritonitis, may develop. Case fatality rates as high as 10 to 20% were described before the introduction of specific treatments.

Management

The treatment for children with colitis caused by *C. difficile* depends on the severity of the disease. Mild cases respond to cessation of antibiotics and supportive therapy with fluids and electrolytes. In particular, children seen with a small amount of diarrhea on oral antibiotics for a minor infection, in whom the suspicion of pseudomembranous colitis is low, do not need an extensive diagnostic investigation or institution of specific antimicrobial therapy.

Patients with more severe or persistent antibiotic-associated diarrhea should be evaluated for *C. difficile* with a test for toxin in the stool. Oral metronidazole (30 mg/kg/day in four divided doses) or vancomycin (40 mg/kg per day in four divided doses) are used most commonly. Although used with some success in the past, cholestyramine does not have the same efficacy as oral antibiotics, but it may be used for patients who fail treatment with vancomycin and metronidazole. Antidiarrheal agents should be avoided. When possible, the precipitating antibiotic should be discontinued, but cessation is not essential once specific therapy has been initiated. In general, children who are sufficiently ill to require treatment with vancomycin should be observed in the hospital.

Gastritis

Background

Gastritis is an inflammation of the lining of the stomach. Most cases are noninfectious; however, *Helicobacter pylori* is a Gram-negative rod that is capable of surviving in the acid milieu of the stomach to produce disease. Infection rates are low in young children but increase in adolescence. Chronic infection with this organism is associated with peptic ulcer

and gastric carcinoma.

Clinical Manifestations

Gastritis caused by *H. pylori* manifests in older children and adolescents with persistent epigastric pain, nausea, and vomiting. Often, the stool will test positive for blood. More severe cases are characterized by hematemesis. In younger children and infants unable to verbalize or localize pain reliably, irritability may be the primary manifestation.

H. pylori can be diagnosed by culture of gastric tissue obtained at biopsy, breath testing, and serology. Only serology has applicability in the setting of the ED. Sensitivity of the serologic assay has been reported to range from 70 to 95%, with greater accuracy being observed in older children.

Management

In most cases, the clinician cannot diagnose *H. pylori* infection in the ED with sufficient certainty to warrant the initiation of treatment with antibiotics. Effective two-drug regimens include clarithromycin–omeprazole, amoxicillin–bismuth, and amoxicillin–omeprazole for 2 to 4 weeks. A 1-week course of omeprazole (20 mg twice daily), clarithromycin (250 mg twice daily), and metronidazole (500 mg twice daily) proved effective in a group of 35 children 10 to 19 years of age.

Skin, Soft-Tissue, and Bone Infections

Infections of the skin, soft tissues, and bones include impetigo, cutaneous abscesses, lymphadenitis, cellulitis, fasciitis, pyomyositis, septic arthritis, and osteomyelitis. Chapter 117 deals with cutaneous abscesses. Among the others, impetigo and cellulitis are both common complaints in the ED. Although children with bone and joint infections are seen only occasionally, the differential diagnosis of several common complaints (e.g., fever, limp) often includes these conditions. Thus, the emergency physician who deals with children should be familiar with such infections, particularly because a delay in the institution of therapy can result in appreciable morbidity. Fasciitis has emerged as an important infection in children, particularly as a complication of varicella. In contrast, pyomyositis is rare in the United States, occurring more commonly in tropical regions.

Impetigo

Background

Impetigo is a bacterial infection of the skin confined to the epidermis. A deeper variety of impetigo, ecthyma, involves the dermis as well. Pustules larger than 1 cm in diameter (Fig. 84.18) characterize bullous impetigo. Impetigo is a common infection in children, particularly during the summer months. It occurs in epidemics during the warm weather in confined populations of children.

FIGURE 84.18. Bullous impetigo.

Any strain of group A streptococcus, including nephritogenic varieties, can infect the skin and cause impetigo. In recent years, *S. aureus,* the primary agent in bullous impetigo, has become a common cause of nonbullous impetigo as well.

Pathophysiology

The intact epidermis forms a relatively impervious barrier to bacteria. However, a breach in the integument, even if too small to be noticed by the patient or parents, may allow the entry of pathogens and the development of impetigo. In streptococcal infections, toxins, such as streptolysins, elaborated by the organism, promote local spread of the process. Different toxins produced by *S. aureus* lead to the accumulation of purulent material and the evolution of bullae.

Clinical Manifestations

Impetigo is more common in young children, particularly those less than 6 years of age. Typically, a parent will bring a child to the ED complaining of sores on the body. No systemic ailments, such as fever or malaise, are associated. Physical examination shows a healthy child with a normal temperature. The lesions usually ooze serous fluid but may be bullous or crusted as well (Fig. 84.18). Surrounding erythema is minimal, and the regional lymph nodes often do not enlarge noticeably.

Laboratory studies are not routinely obtained in children with impetigo. Cultures, performed only if there is any doubt about the diagnosis, will yield group A streptococci and *S. aureus* in most cases. The WBC count is normal.

The complications of impetigo include spread of the infection locally and remote nonsuppurative disease. Occasionally, impetigo may progress to cellulitis. If the lesions are caused by nephritogenic streptococci, glomerulonephritis may develop 7 to 14 days later. The attack rate for glomerulonephritis has been as high as 1% in certain epidemics, but the incidence is far less in the usual clinical setting.

Management

A single course of antibiotic therapy cures impetigo in 95% of children. Erythromycin (40 mg/kg per day in four divided doses) provides effective oral treatment for the usual pathogens. For nonbullous disease, intramuscular benzathine penicillin (30,000 to 50,000 units/kg) is a reasonable single-dose alternative, if compliance is a concern; patients who fail to improve with this regimen should receive erythromycin for presumed *S. aureus.* Other acceptable oral drugs include dicloxacillin (50 mg/kg per day) or cephalexin (50 mg/kg per day). Mupirocin applied locally is able to eradicate most cases of impetigo, particularly if the disease is limited in distribution. Combination topical and systemic therapy is unnecessary. Vigorous scrubbing does not hasten the resolution, and routine cleanliness is sufficient. Even when systemic antibiotic therapy eliminates the infection, the incidence of glomerulonephritis has not been demonstrated to decrease.

Lymphadenitis

Lymph nodes in any region of the body may become infected. Regardless of the site of involvement, the same considerations apply as discussed under cervical lymphadenitis. *S. aureus* and group A streptococcus are the most common pathogens. The finding of inguinal or axillary adenitis should prompt a meticulous search for a portal of entry for bacteria on the extremities. Locating an impetiginous lesion or other breech in the integument provides reassurance that the lymph node enlargement is caused by infection rather than by neoplasm. History should be requested regarding a cat scratch or bite as a possible etiologic focus. Particularly in the adolescent, inguinal adenitis suggests a need to look for sexually transmitted pathogens. CSD is another important consideration. The child with lymphadenitis should be treated with antibiotic therapy and drainage, if fluctuation occurs. Dicloxacillin (50 mg/kg per day) and cephalexin (50 mg/kg per day) are both effective against the usual pathogens.

Cellulitis

Background

Cellulitis is an infection of the skin and subcutaneous tissues. Any anatomic area may be involved, but the body can be divided, for etiologic considerations, into two regions: 1) the face and 2) the scalp, neck, trunk, and extremities.

Facial cellulitis includes buccal, periorbital, and less often, orbital lesions. Before the introduction of a vaccine against Hib, *H. influenzae* type b caused 50% of these infections. At present, the organisms involved most commonly are *S. aureus,* group A streptococcus, and *S. pneumoniae.* Bacteremia is present in 90% of the cases of disease caused by *S. pneumoniae* and *H. influenzae.*

S. aureus causes most nonfacial cellulitis and has been reported to be recovered from 70% of extremity lesions with an identifiable origin, either as the sole pathogen or in combination with group A streptococcus. Nonfacial cellulitis rarely results from infection *with H. influenzae,* although when this organism is involved, as with facial lesions, it usually invades the bloodstream.

Cellulitis occasionally occurs among immunosuppressed patients. In these cases, unusual organisms, including *P. aeruginosa*, Gram-negative enteric rods, and anaerobic bacteria, must be considered. Even when initial examination suggests minimal inflammation, an extensive infection may exist, because neutropenia often masks the depth of the lesion.

Cellulitis is a common infection that is more often seen in temperate climates when the weather is warm. Precise statistics on the incidence of cellulitis are not available; however, in one study during the summer months, this infection accounted for approximately 1 of every 500 visits to the ED of a children's hospital.

Pathogenesis

Cellulitis follows either hematogenous dissemination of a pathogenic organism or local invasion. Surgical or traumatic wounds may serve as a portal of entry for bacteria. This is the route by which *S. aureus* and group A streptococcus usually gain access to the subcutaneous tissue. Toxins produced by the organisms allow for local spread. Alternatively, invasion of the bloodstream may precede the appearance of cellulitis. The periorbital and facial lesions seen occasionally with *H. influenzae* and *S. pneumoniae* follow a bacteremia, and these organisms often are recovered from the blood. *S. aureus* and group A streptococcus are less often spread by this mechanism.

Clinical Manifestations

The child with cellulitis develops a local inflammatory response (Fig. 84.19) at the site of infection with erythema, edema, warmth, pain, and limitation of motion. There may be a history of a prior wound or insect bite. Facial infections are more common during the first 5 years of life. Fever is unusual, except in bacteremic infections or when the lesions are extensive. Only 10 to 20% of children with cellulitis manifest a fever. The lesion itself is erythematous and tender but not

fluctuant; red streaks may radiate proximally along the course of the lymphatic drainage. The regional lymph nodes usually enlarge in response to the infection.

FIGURE 84.19. Infant with buccal cellulitis caused by *H. influenzae*.

With cellulitis caused by *S. aureus* or group A streptococcus, the WBC count is normal in most children. More extensive lesions or bacteremia, seen only occasionally, evoke a leukocytosis. A culture obtained from the central area of the cellulitis will yield a pathogen in 50% of cases, but cultures of the blood usually remain sterile.

Bacteremia accompanies cellulitis caused by *H. influenzae* or *S. pneumoniae;* these organisms are isolated from the blood in 90% of infected patients. The WBC count is greater than 15,000/m ^{3} as a rule, usually with a shift to the left.

The complications of cellulitis, although uncommon, include local and metastatic spread of infection. The organisms may invade deeper tissues, producing septic arthritis or osteomyelitis. During the course of bacteremia with *H. influenzae, S. pneumoniae,* or rarely other organisms, there may be involvement of the meninges, pericardium, epiglottis, or synovial membranes. Multifocal areas of cellulitis should arouse a suspicion of hematogenous dissemination. Occasionally, cellulitis provides a clue to an infection that originates in deeper anatomic structures. As an example, a lesion on the abdominal wall, may be a sign of peritonitis.

Management

Most children with nonfacial cellulitis can receive antibiotic therapy as outpatients, as long as bacteremic disease is unlikely (Fig. 84.20). Because *S. aureus* and group A streptococcus are most commonly isolated, treatment should be directed at these organisms. Acceptable alternatives include a semisynthetic penicillin, such as dicloxacillin (50 mg/kg per day), cephalexin (50 mg/kg per day), or amoxicillin–clavulanic acid (50 mg/kg per day of amoxicillin); *S. aureus* is generally resistant to penicillin and ampicillin. A CBC, blood culture, and aspirate culture are not necessary in afebrile patients.

FIGURE 84.20. Diagnostic approach for the management of the child with soft-tissue swelling and possible cellulitis. *WBC,* white blood cell.

If a child with a nonfacial cellulitis has a high fever (39°C [102.2°F] or higher), the likelihood of a bacteremic infection or lymphangitic spread increases. A WBC count and culture of the blood should be obtained, along with consideration of a culture from the lesion. In cases in which the WBC count is below 15,000/mm ^{3}, antibiotic therapy is given as described for afebrile children, and the patient is asked to return the following day. A leukocytosis in association with a temperature of 39°C (102.2°F) or higher points toward IV treatment, usually on an inpatient basis, with oxacillin (150 mg/kg per day in four divided doses) or cephazolin (100 mg/kg per day in three divided doses). For children not immunized against Hib, consider therapy with cefotaxime (200 mg/kg per day in four divided doses) ceftriaxone (100 mg/kg per day in a single dose), or ampicillin–clavulanic acid (200 mg/kg per day of ampicillin in four divided doses). Children allergic to penicillins and cephalosporins can be given clindamycin (40 mg/kg per day in four divided doses) alone or with chloramphenicol (75 to 100 mg/kg per day in four divided doses) when *H. influenzae* type b is a concern.

Children with facial cellulitis and fever are particularly likely to be bacteremic, in most cases with *S. pneumoniae* or, less commonly, *H. influenzae* type b, and are at risk for local complications. Thus, they should receive IV therapy as listed previously. Those who are afebrile may be managed as outpatients if they do not have risk factors for bacteremic

disease—age less than 3 years, spontaneous cellulitis without a preceding wound, and violaceous discoloration (Fig. 84.20).

Fasciitis

Background

Fasciitis is a deep soft-tissue infection. Unlike cellulitis, it involves the fascial and muscle layers as well as the skin and subcutaneous tissues, but it does not extend per se to the bones or joints. Terms used to refer to this condition include *necrotizing fasciitis, acute streptococcal hemolytic gangrene, Meleney synergistic gangrene,* and *necrotizing erysipelas.* In recent years, the most common cause, by far, has been group A streptococcus; other etiologic agents include *S. aureus* and anaerobic organisms. Although some cases of fasciitis arise spontaneously, most occur as a complication of varicella.

Clinical Manifestations

As occurs with cellulitis, the child with fasciitis develops a local inflammatory response at the site of infection, characterized by erythema, edema, warmth, pain, and limitation of motion.

Fever occurs in almost every case, often exceeding 39°C (102.2°F). In contrast to the usual patient with cellulitis, those with fasciitis almost always appear toxic with a marked tachycardia and, occasionally, hypotension. The local lesion is often described by the family as progressing rapidly and generally exhibits noticeable induration and erythema. Particularly in the presence of varicelliform lesions, the physician should maintain a high index of suspicion for fasciitis, as opposed to cellulitis, in children with extensive local disease, high fever, and any degree of prostration. The WBC count generally reflects a leukocytosis, and blood cultures yield an organism in most cases.

Management

A confirmed case of necrotizing cellulitis should be considered an emergency. The first priorities include supportive therapy for signs of sepsis and initiation of antibiotics, followed promptly by surgical consultation. Appropriate antimicrobial therapy includes penicillin (500,000 units/kg per day in four divided doses) and clindamycin (40 mg/kg per day in four divided doses, intravenously. In a large number of cases, the surgical consultant will elect to incise and/or debride the lesions.

Omphalitis

Background

Omphalitis is an infection of the umbilical cord and surrounding tissues. Although formerly an important cause of neonatal mortality, the disease is now rare in developed countries because of advances in antisepsis and local care of the umbilical cord stump. When infection occurs, the usual pathogens *are S. pyogenes* (group A streptococcus) and *S. aureus*; group B streptococcus, and Gram-negative enteric rods may also be isolated. Children are at risk during the first 2 weeks of life.

Pathophysiology

After ligation at delivery, the umbilical stump undergoes necrosis as a result of interruption of its blood supply. Bacterial colonization follows soon after birth. In rare cases, because of colonization by virulent bacteria or ill-defined host factors, colonizing organisms may invade the umbilical cord stump and surrounding tissues. The initial infection is cellulitis, but peritonitis, liver abscess, and/or sepsis may ensue in short order.

Clinical Findings

Omphalitis is characterized first by drainage and later by erythema around the umbilical cord stump. Late in the course of infection, infants manifest the signs of sepsis, including lethargy, irritability, and hypothermia or hyperthermia. Laboratory studies are normal early in the course.

Because a small amount of drainage and patchy erythema can occur in the absence of infection, the diagnosis of omphalitis may be difficult. There are no definite clinical criteria for early infections, and laboratory tests are not helpful. The findings suggestive of omphalitis are 1) purulent, foul-smelling drainage from the umbilical cord with any erythema of the anterior abdomen, or 2) any drainage with erythema that completely encircles the umbilicus. Induration and erythema of the anterior abdomen wall are definite indicators of infection.

Management

Infants who appear toxic, have induration and erythema of the abdominal wall, or show signs clearly suggestive of omphalitis (purulence and patchy erythema or light drainage plus circumferential erythema) should be presumed to have a significant infection and require IV antibiotic agents. Appropriate therapy is oxacillin (150 mg/kg per day in four divided doses) and gentamicin (7.5 mg/kg per day in three divided doses for term infants). In some cases, minimal drainage or erythema may be present, but the findings are not sufficient for the diagnosis of omphalitis. The parents of these infants should be instructed to swab the cord after each diaper change and to observe the child for any changes in activity or feeding. Reexamination in 24 hours is advisable if the problem has not resolved.

Neonatal Mastitis

Background

Mastitis is an infection of the breast tissue that affects prepubertal children only during the first 2 to 5 weeks of life. In most cases, *S. aureus* is the offending organism, although 5 to 10% of the infections are caused by Gram-negative enteric bacteria. Girls are affected twice as commonly as boys.

Pathophysiology

Maternal hormones cross the placenta during gestation and stimulate hypertrophy of neonatal breast buds in both males and females. Usually, the enlargement subsides within 2 weeks. In occasional cases, bacteria are able to invade the hypertrophied glandular tissue, leading to abscess formation. Manipulation of the breast to excrete “witch's milk” may be a predisposing factor.

Clinical Manifestations

The primary finding in neonatal mastitis is a warm, erythematous, enlarged breast bud (Fig. 84.21). With disease progression, purulent drainage from the nipple may occur and there is tenderness to palpation. Only 25% of infants are febrile or appear ill.

FIGURE 84.21. A 2-week-old infant with mastitis, characterized by erythema and induration.

Mastitis in the infant must be distinguished from physiologic hypertrophy, which resolves spontaneously. The normal breast bud that enlarges in response to stimulation by maternal hormones is neither red nor tender; if any drainage is present, the material is milky white, rather than yellow, and does not contain polymorphonuclear leukocytes or bacteria on Gram stain.

Culture of the purulent drainage yields the pathogen in most cases, but the blood is usually sterile. Because these infections are well localized, the WBC count is usually in the normal range.

Management

Occasionally, an infant will appear septic and require appropriate supportive therapy, as described earlier in this chapter. For the remainder, IV antibiotics should be initiated, pending the results of cultures. Oxacillin (150 mg/kg per day in four divided doses) and gentamicin (7.5 mg/kg per day in three divided doses) provide appropriate coverage for the expected pathogens. Surgical consultation for possible incision and drainage is advisable in the case of local fluctuance.

Septic Arthritis

Background

Septic arthritis is an infection within a joint space. The incidence of this infection is unknown; however, Nelson reported that 20 children were admitted yearly between 1966 and 1970 to two large pediatric services in Dallas. As opposed to adults, children who develop septic arthritis are generally otherwise healthy. Boys are affected twice as often as girls.

The bacterial cause of septic arthritis varies with age. During the first 2 months of life, group B streptococcus and *S. aureus* predominate. Gram-negative enteric bacilli, *Candida* species, and *N. gonorrhoeae* are seen sporadically.

Between 3 months and 3 years of age, *S. aureus* emerges as the single most common pathogen, being isolated from 80 to 90% of children with septic arthritis. The incidence of disease caused by *H. influenzae* has declined significantly since the introduction of the conjugated vaccine, but this organism remains a concern in children in this age range who have not been immunized against this pathogen. Group A streptococcus and *S. pneumoniae* cause occasional cases.

The incidence of gonococcal arthritis in teenagers has varied in different reports, depending on the prevalence of sexual activity in the population studied. In most studies, *N. gonorrhoeae* has been the most common cause of septic arthritis among adolescents, trailed closely by *S. aureus.*

Many other organisms occasionally invade the joint space, some only in special circumstances. *P. aeruginosa* shows a peculiar predilection for septic arthritis of the foot after puncture wounds. In the child with sickle cell anemia, *Salmonella* species often cause septic arthritis. The Gram-negative bacilli are almost never recovered from previously healthy children but are seen in immunosuppressed patients. *M. tuberculosis* is a rare causative agent but may be isolated at any age.

Pathophysiology

Septic arthritis generally results from the hematogenous dissemination of an organism, into either the joint or the bony metaphysis. Rarely, a pathogen gains access to the joint by direct inoculation or spread from a contiguous site of infection. Although many children give a history of recent trauma, the role played by injury remains unknown. In gonococcal arthritis, the initial site of infection may be the genitals, pharynx, or rectum. Dissemination from the cervix follows menstruation when shedding of the organism is highest.

Bacteria in the joint space evoke an inflammatory response with an infiltration of neutrophils. The accumulation of purulent material distends the joint capsule, producing the physical and radiographic findings.

Clinical Features

Infection within a joint produces pain and limitation of motion. Thus, the site of the arthritis determines the specific complaint. Ninety percent of children have a monoarticular arthritis that involves the lower extremity (hip, knee, and ankle). Thus, limp (see Chapter 43) is the most common initial manifestation. If a joint in the arm is involved, mobility of the upper extremity will be decreased (see Chapter 36).

With infections in deeper joints, the pain may radiate to contiguous anatomic structures. Children with a septic hip often complain of an ache at the knee, and sacroiliac arthritis may mimic appendicitis, pelvic neoplasm, or UTIs. Although the duration of symptoms in septic arthritis is less than 3 days in more than 50% of children with these conditions, the delay in diagnosis may reach 3 to 4 weeks with sacroiliac arthritis.

The findings are often vague in the first 6 months of life. Pyoarthritis may cause paradoxical irritability and an increase in crying on being fondled, as seen with meningitis. The infant with a septic hip usually lies quietly, holding the leg abducted and externally rotated.

Of children with septic arthritis, 60 to 70% have a temperature of 38.5°C (101.2°F) or higher. The absence of fever occurs most commonly in the adolescent with a gonococcal infection or in the neonate. Infants with infections caused by *H. influenzae,* rare since the advent of the conjugated vaccine, almost invariably have a high fever. An erythematous swelling may surround a superficial joint that is infected. Although a temperature difference exists between the affected and unaffected sites, it can be difficult to discern in the febrile child. Inflammation within the joint distends the capsule and produces pain with movement. If a child allows the physician to manipulate an extremity through a full range of motion, septic arthritis is unlikely.

The ESR and CRP are the most consistently abnormal laboratory study. Molteni observed an elevated ESR in 32 of 37 (86%) children with septic arthritis; the median value was 50 mm. The peripheral WBC count usually varies from less than 5,000 to more than 20,000/mm^3. Although a leukocytosis with a shift to the left commonly occurs, as many as 20% of children will have a WBC count less than 10,000/mm^3. If septic arthritis is diagnosed early, a radiograph of the joint will not show any pathologic changes. The first radiographic alteration to be noted is edema of the adjacent soft tissues, which is not pathognomonic of inflammation in the joint. Later, distension of the capsule becomes visible, and bony destruction may be seen late in the course of the infection.

The thickness of the tissues that surround the hip joint makes the detection of an effusion difficult by physical examination. A radiograph of the hip should always be obtained if infection in this joint is possible. Early in the course, the tendon of the obturator internus is displaced as the muscle passes over the distended hip capsule. Continued accumulation of an inflammatory exudate forces the femoral head laterally and upward, disrupting the arc formed by the femoral head and the pelvis (Shenton's line). The hip may actually dislocate with intra-articular infection in the young infant, but this is an unusual radiographic finding in older children. Ultrasound examination is useful for the detection of a small effusion not apparent on radiograph.

No constellation of laboratory and radiographic results can rule out the diagnosis of septic arthritis; an analysis of the joint fluid is mandatory if the index of suspicion is high (see Procedures, Section VII). Infection causes an infiltration of polymorphonuclear leukocytes into the joint space. Although intraarticular WBC counts greater than 100,000/mm^3 are traditionally associated with infection, a lesser cellular response is often noted. Nelson found a WBC count in the joint fluid below 25,000/mm^3 in 9 (34%) of 31 children with proven bacterial arthritis. The joint fluid glucose is reduced to less than 40 mg/dL in only 25 to 50% of patients, but the Gram stain of the synovial fluid shows organisms in 75%. Because inflammatory exudates have bacteriostatic properties, cultures of joint fluid yield an organism in only 60% of cases. A pathogen is recovered from the bloodstream in 40% of children with septic arthritis, more commonly if *H. influenzae* or *S. pneumoniae* is the cause of the disease.

The complications of septic arthritis include both local and distant spread of the infection. Osteomyelitis often accompanies joint infections in the first year of life because of the location of the metaphysis within the joint capsule. During the process of hematogenous dissemination, bacteria may invade sites other than the joint. Simultaneous infections may occur in the meninges, pericardium, or the soft tissues; these are particularly common with *H. influenzae.*

Management

Septic arthritis demands prompt management; in particular, infection in the hip joint should be considered an emergency. Pressure generated by purulent material within the joint space can compromise the vascular supply of the femoral head, leading to necrosis and eventual loss of normal ambulation.

The initial treatment is aimed at relieving the pressure within the joint and controlling the infection. At the time of the diagnostic aspiration, as much purulent fluid as possible should be removed. Immediate surgical intervention is needed for hip infections.

All children with septic arthritis require admission to the hospital for IV antibiotic therapy. The initial choice of antimicrobials depends on the child's age and the Gram stain. If no organisms are apparent on examination of the joint fluid, presumptive antibiotic therapy is begun as follows: 1) 2 months of age or younger—oxacillin 150 mg/kg per day in four divided doses and gentamicin 7.5 mg/kg per day in three divided doses; 2) older than 2 months to less than three 3 years of age—cefotaxime 200 mg/kg per day in four divided doses, ampicillin–clavulanic acid 200 mg/kg per day of ampicillin in four divided doses or, for the penicillin-allergic patient, clindamycin 40 mg/kg per day in four divided doses and chloramphenicol 75 to 100 mg/kg per day in four divided doses; 3) 3–12 years of age—oxacillin 150 mg/kg per day up to a maximum of 6 g/day; 4) adolescents—ceftriaxone 100 mg/kg per day. Ceftriaxone (100 mg/kg/day once daily) may be used as a single agent for children older than 2 months; as further experience confirms the virtual disappearance of *H. influenzae,* oxacillin (150 mg/kg per day in four divided doses) will probably prove sufficient as monotherapy during childhood.

Osteomyelitis

Background

Osteomyelitis is an infection of the bone; a variant, discitis, affects the intervertebral disc space. Bremmer and Neligman estimated that 1 in 5000 children less than 13 years old develop osteomyelitis. Approximately 10 children with bone infections were admitted yearly to the pediatric service at Parkland Memorial Hospital in Dallas between 1959 and 1973.

S. aureus causes osteomyelitis in most cases regardless of age. During the neonatal period, group B streptococcus is the second most common isolate; *N. gonorrhoeae* and Gram-negative enteric bacilli are also found. Group A streptococcus causes 5 to 10% of osteomyelitis in children. Other pathogens are recovered rarely, including *S. pneumoniae, H. influenzae, Y. enterocolitica, Brucella* species, anaerobic organisms, *M. tuberculosis,* and *Actinomyces* species.

P. aeruginosa may infect the bones of the foot after a puncture wound. In children with sickle cell hemoglobinopathies, *Salmonella* species account for almost half the cases of osteomyelitis. Unusual pathogens may be recovered from immunocompromised children.

Pathophysiology

In most children with osteomyelitis, bacteria reach the bone through the bloodstream. Occasional infections follow the direct inoculation of pathogens or spread from a contiguous focus. During hematogenous dissemination, organisms lodge in the sinusoidal vessels of the metaphysis at the site of sludging or thrombosis. Bacterial proliferation evokes an inflammatory exudate. Within the confined space of the bone, the pressure generated by the accumulation of purulent material can necrose the cortex and elevate or rupture the periosteum. If the metaphysis is contained within the joint capsule, septic arthritis may ensue.

Clinical Features

Osteomyelitis causes bone pain as the infection progresses. The site of the osteomyelitis determines the presentation of the disease. In 90% of cases, a single bone is involved. The femur and tibia are the most common bones infected, making limp (see Chapter 43) a common presentation. In a study of 100 consecutive children with a limp seen at the ED of The Children's Hospital of Philadelphia, osteomyelitis was diagnosed in 2%.

Osteomyelitis affects the bones of the upper extremity in 25% of cases. These children complain of pain on motion of their upper extremities (see Chapter 36).

The multiplicity of bones that may be involved leads to a wide spectrum of chief complaints. Vertebral osteomyelitis manifests as backache, torticollis, or stiff neck, and involvement of the mandible causes painful mastication. Infection of the pelvis is particularly elusive and may masquerade as appendicitis, neoplasm, or UTI. Infants with osteomyelitis localize the symptoms less well than older children. Initially, irritability may be the only complaint.

Fever exceeds 38.5°C (101.2°F) in 70 to 80% of children with osteomyelitis. The infant with a long bone infection often manifests pseudoparalysis, an unwillingness to move the extremity. Movement may also be decreased in the older child, but to a lesser degree. Point tenderness is seen almost always in osteomyelitis; however, it is found in other conditions such as trauma, may be difficult to discern in the struggling infant, and does not always occur early in the course of the infection. Percussion of a bone at a point remote from the site of an osteomyelitis may elicit pain in the area of infection.

When purulent material ruptures through the cortex, diffuse local erythema and edema appear. This finding occurs often in infants, but late in the course, and is confined primarily to children in the first 3 years of life (before the cortex thickens sufficiently to contain the inflammatory exudate). Weissburg et al. noted swelling of the extremity in 14 of 17 patients with

osteomyelitis less than 1 month old.

The ESR or CRP provides a useful screening test for osteomyelitis because bony infection almost always leads to an elevation. Nelson found an ESR less than 15 mm/hour in only 4 of 88 children with osteomyelitis, and the mean value was 70 mm/hour. Although the WBC count may reach a level of 20,000/mm^3, it falls within the normal range in two-thirds of cases. Cultures from the blood yield an organism in 50% and from the bone in 70% of children with osteomyelitis.

If osteomyelitis is suspected, radiographs of the affected area should always be obtained, even though they are often normal early in the course. The first change, noted after 3 to 4 days, is deep soft-tissue swelling seen as a subtle shift of the lucent deep-muscle plane away from the bone. Within 3 to 10 days, the muscles swell and obliterate the lucent planes that usually separate them radiographically. Visualization of osseous destruction requires the loss of 40% of the bony matrix in an area at least 1 cm in diameter. This amount of demineralization occurs only after 10 to 12 days of infection. At this stage, lytic lesions and periosteal elevation are apparent on the radiograph (Fig. 84.22).

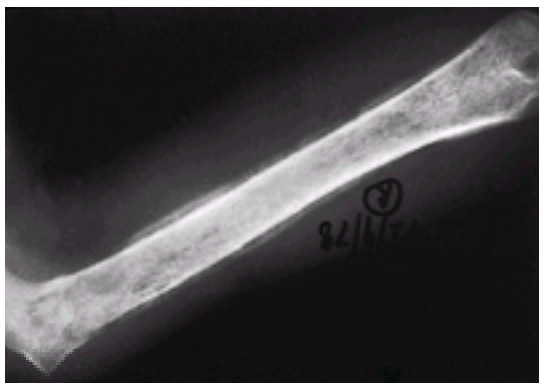

FIGURE 84.22. Radiograph showing lytic lesions and periosteal elevation with osteomyelitis.

Radionuclide scanning provides a useful diagnostic tool for the clinician. Uptake of compounds such as technetium is seen at sites of increased metabolic activity, which occurs in an infection before sufficient bony destruction has occurred to be seen on conventional radiographs. If scintigraphy is available, the patient strongly suspected to have osteomyelitis despite a normal radiograph should have this study. However, the absence of increased uptake does not preclude bony infection. Some patients will have decreased uptake because the accumulation of purulent material lessens the flow of blood to the site; occasionally, in children, the scan may be entirely normal early in the course. When scintigraphy is not diagnostic and clinical suspicion persists, magnetic resonance imaging is useful.

The complications of osteomyelitis include the spread of infection, either locally or to remote sites, chronic infection, and irreparable bony destruction.

Management

All children strongly suspected or known to have osteomyelitis require admission to the hospital for IV antibiotic therapy. Those with a low likelihood of bony infection can be reevaluated in 12 to 24 hours and can have a technetium scan at that time, if the clinical findings are not definitive. The emergency physician should withhold antibiotics until the orthopedic surgeon has been contacted about culturing the bone at the site of infection. Infants should subsequently receive oxacillin, 150 mg/kg per day in 4 divided doses, and gentamicin, 7.5 mg/kg per day in 3 divided doses; older children can be treated with oxacillin alone.

Genitourinary Infections

UTIs in the child are discussed in this section and in Chapter 54. Of the sexually transmitted genital infections, the four most important diseases in the United States are gonorrhea, syphilis, herpes, and *Chlamydia.* When any sexually transmitted disease is diagnosed, concomitant infection with HIV should be considered (see Chapter 85). These diseases are discussed subsequently in this chapter and in Chapter 94.

Urethritis/Cervicitis

Background

Urethritis may have an infectious or noninfectious cause (see Chapter 54). Among the infectious causes, *C. trachomatis* and *N. gonorrhoeae* predominate, with *C. trachomatis* being the single most common cause of urethritis in the United States. In males, approximately 50% of nongonococcal urethritis results from infection with this organism, and 20% of patients with gonococcal urethritis have a concurrent infection with *C. trachomatis.* In addition, most cases of postgonococcal urethritis are caused by this pathogen. In females, *C. trachomatis* causes the dysuria-pyuria syndrome, mucopurulent cervicitis, and pelvic inflammatory disease.

Chlamydial infections are common in adolescents. Although uncommon in prepubertal children, such infections should be considered in the setting of sexual child abuse, particularly in association with rectogenital gonorrhea.

Clinical Manifestations

Urethritis causes dysuria and discharge in the male. Persistent discharge in a young boy or adolescent treated for gonorrhea, in particular, should alert the clinician to infection with *C. trachomatis.*

Mucopurulent cervicitis caused by *C. trachomatis* in the adolescent girl is characterized by an erythematous friable cervix and the accumulation of purulent yellow endocervical secretions. Gram stain of the discharge shows more than 10 polymorphonuclear leukocytes per microscopic field under ×1000 magnification. This organism also causes the "sterile" dysuria-pyuria syndrome; females with this condition complain of dysuria, at times described as originating external to the urethra at the level of the labia, and have pyuria in the face of a negative urine culture. In prepubertal girls, *C. trachomatis* is a cause of vaginitis, usually with scant or no discharge.

Regardless of the clinical findings, chlamydial infection should be suspected with any sexual contact because most infections are asymptomatic.

An etiologic diagnosis in urethritis/cervicitis relies on the clinical syndrome, Gram stain of any discharge, and specific identification of the organism, either by antigen/DNA detection or culture. In general, culture is preferred for prepubertal children.

Management

If an etiologic diagnosis is not possible based on the clinical findings and the results of Gram stain, treatment should be given for both *N. gonorrhoeae* and *C. trachomatis.* Infections with *C. trachomatis* in adolescents and children older than 8 years are treated with doxycycline (100 mg twice daily) or a single dose of azithromycin (1 g). Children less than 8 years of age may be given azithromycin (20 mg/kg as a single dose) or erythromycin (40 mg/kg per day in four divided doses for 10 days) and should have a "test-of-cure" culture after this course of therapy.

Urinary Tract Infection

Background

Infections occur along the urinary tract from the tip of the urethra to the renal parenchyma. Clinical syndromes that may accompany infections include urethritis, cystitis, and pyelonephritis. *Bacteriuria* refers to the presence of bacteria in the urine, arising from any site in the urinary tract, with or without causing symptoms. Significant bacteriuria describes the presence of bacteria in sufficient quantity such that infection is more likely than contamination. Significant bacteriuria may be asymptomatic and the clinical syndromes mentioned above may occur in the absence of infection. Urethritis has been discussed previously. Because cystitis and pyelonephritis may coexist or be difficult to distinguish clinically and share a similar etiology, they are discussed together, using the generic term *urinary tract infection.* Urethritis is covered in a previous section.

The predominant pathogen isolated in UTIs is *E. coli,* which is recovered in 90% of cases. Next in frequency are other members of the *Enterobacteriaceae* family, including *Enterobacter* and *Klebsiella.* Among the Gram-positive organisms, enterococci are seen at all ages, staphylococcal species occur most often in adolescents, and group B streptococci are recovered primarily in infants and during pregnancy. *P. aeruginosa, Candida albicans,* and a number of other bacteria and fungi infect patients with immunocompromise, anatomic obstruction, or indwelling catheters. Cystitis may be caused, in addition, by adenoviruses.

The frequency of infections of the urinary tract varies by age, sex, and race. Overall, infections occur commonly in neonates, decrease in frequency during childhood, and then rise in incidence after puberty in sexually active females. Males are more commonly infected than females in the first 6 months of life, in part because of a higher incidence of congenital urinary tract anomalies, but they rarely acquire infections beyond this period. Females have a rather high incidence of symptomatic infection between 6 months and 2 years of age and of asymptomatic bacteriuria throughout childhood. In several studies, as many as 15% of febrile white girls between 6 months and 2 years of age had positive urine cultures, a rate fivefold greater than seen in African-American females and males of any race. Among males, circumcision decreases the likelihood of UTIs.

Pathophysiology

Bacteria may invade the urinary tract by ascension or hematogenously. In most cases, the organisms colonize the urethral area and ascend to the bladder. The higher incidence of UTI in girls is often attributed to the shorter female urethra. Hematogenous spread to the kidney may occur at times in neonates but rarely thereafter.

Those organisms that cause UTIs have certain distinct properties. In comparison to other Gram-negative rods, the few strains of *E. coli* that are most commonly recovered from the urine share recognized virulence factors, including increased adherence to uroepithelial cells and higher quantities of K antigen.

Children with UTIs have a higher incidence of genitourinary anomalies than the general population, although in most infections, no anatomic or functional abnormalities are identified. Lesions that obstruct the flow of urine and/or predispose to incomplete emptying of the bladder contribute to an increased risk of infection. Additional host factors that play a role include an alkaline urinary pH and glucosuria.

Clinical Manifestations

The manifestations of UTIs vary with age, being particularly nonspecific in infancy. During the neonatal appearance, a septic appearance (see Chapter 69) or fever is often the only finding. UTIs in infants may also cause vomiting, diarrhea,

irritability, and reportedly, meningismus.

Beyond 2 to 3 years of age, symptoms more often point to the urinary tract. For all practical purposes, strict differentiation between upper and lower tract disease is not feasible for the clinician in most cases, and children who are febrile (38.5°C [101.2°F]) should be assumed to have pyelonephritis. On the other hand, some patients will have typical syndromes that localize disease to the upper or lower tract. Typically, children with cystitis appear relatively well and complain of dysuria and suprapubic pain. On examination, they have a lower-grade fever and tenderness on the suprapubic area. In contrast, patients with pyelonephritis may be toxic and usually have additional symptoms, including vomiting and flank pain. The physician is often able to elicit tenderness to percussion in the costovertebral area, either unilaterally or bilaterally.

The mainstays of diagnosis are the urinalysis and culture of the urine, both of which require the clinician to make an interpretation that is influenced by the method of collection and processing, as well as the clinical syndrome exhibited by the patient.

Urine is analyzed directly using both a chemical reagent strip (dipstick) and microscopy, looking most specifically, in regard to infection, for the presence of leukocyte esterase, nitrites, WBCs, and bacteria. Either spun or unspun urine may be studied through the microscope, with or without the aid of a Gram stain. Spinning should be done in accordance with a standardized protocol. When a clean urine specimen is centrifuged at 2000 rpm for 5 minutes and examined under high power (×40), each leukocyte (per high power field [hpf]) represents 5 to 10 cells/mm^3, with 10 to 50 WBC/mm^3 (5 to 10/hpf) being the upper limit of normal. One organism per high power field seen on Gram stain of a spun specimen correlates with a colony count of 10^5 organisms or more.

In interpreting a urine culture in children, the physician must keep in mind that the guidelines for positivity were developed based on data in adults and that the significance of colony counts applies most explicitly to voided specimens. Given these caveats, it is generally accepted that a colony count of greater than 10^5 on a single sample indicates a probability of infection of 80%, increasing to 90% when repeated once and 95% when done a third time. Colony counts between 10^4 and 10^5 of single organisms are somewhat suggestive of infection and merit another culture. On a catheterized specimen, a result of $^3 10^4$ organisms points to infection. The criterion for a suprapubic aspirate is greater than 10^3.

In general, a single negative finding on one parameter of the urinalysis does not exclude a UTI. Taken together, however, negative testing for both leukocyte esterase and nitrates by dipstick alone, or even more so in combination with a microscopic examination that shows the absence of pyuria, makes the diagnosis of a UTI (as opposed to asymptomatic bacteriuria) in a male infant older than 6 months of age or a female older than 2 years, highly unlikely. A schema for the use of urinalysis and urine culture is presented in Figure 84.23. As illustrated for older children who are somewhat older but not yet toilet-trained, in the absence of a high likelihood of UTI a priori, the urinalysis may be collected using a bag. However, if the urinalysis is positive, a specimen for culture should preferably be obtained by catheterization or suprapubic aspiration.

FIGURE 84.23. Diagnostic approach to infants and children with fever, symptoms specifically suggestive of urinary tract infection, and/or non-specific symptoms and signs compatible with urinary tract infection. Use of urinalysis and culture in the diagnosis of UTI **(A)** in children age 2 years or younger and **(B)** in those older than 2 years. [a]UA obtained by catheterization or suprapubic aspiration. [b]UA (only) may be obtained using a urine collection bag.

Bacteremia accompanies UTIs primarily during the first 6 to 12 months of life. In the young infant, bacteremia may be present in the absence of fever and should be suspected in any children during the first year of life with a temperature 39°C (102.2°F) or higher. Indications for a CBC and blood culture with a suspected UTI include 1) signs of clinical toxicity (extreme tachycardia, low blood pressure, shaking chills); 2) age younger than 3 months; and 3) age 3 months to 1 year and temperature greater than 39°C (102.2°F). Only children with dehydration require measurement of electrolytes. When a diagnosis of pyelonephritis, as opposed to cystitis, is being entertained, consideration should be given to ascertaining the BUN and creatinine in the serum.

Management

When the diagnosis of UTI has been established, as a result of earlier urine culture, or is presumed, based on the clinical syndrome and findings on urinalysis, antibiotic therapy is indicated. If available, the results of susceptibility testing should guide the selection of antimicrobial agent. In all other cases, an antibiotic is chosen to cover the most likely pathogens.

Most patients respond to oral antibiotic therapy. Indications for IV administration of antibiotics include 1) clinical toxicity;

2) age younger than 3 to 6 months; 3) vomiting, refusal to drink, or other factors making the delivery of oral medications unreliable; 4) adverse anatomic factors, such as an obstruction to urinary flow; and 5) a known positive culture for a pathogen resistant to oral agents.

For ill-appearing patients, IV ampicillin (200 mg/ kg per day in four divided doses) plus gentamicin (7.5 mg/kg per day in three divided doses, adjusted for gestation age and weight, see Table 84.4) are given. Options for oral therapy include TMP-SMZ (8 mg/kg per day of trimethoprim in two divided doses) or cefixime (8 mg/kg per day as a single dose). If the pathogen is susceptible to ampicillin, amoxicillin provides effective oral coverage.

SPECIFIC INFECTIONS

Sexually Transmitted Diseases

Gonorrhea

Background

The term *gonorrhea* is used in this chapter to describe a genital infection with *N. gonorrhoeae,* but the organism can also produce disease at other sites. The incidence of gonorrhea remains high, and almost 1 million cases are reported yearly in the United States. The highest rate of gonococcal infection is found in adolescents and young adults. When looked for, however, gonorrhea is fairly common in prepubertal youngsters. Paradise et al. studied 38 consecutive prepubertal females with vaginitis from the ED at the Children's Hospital of Philadelphia, recovering *N. gonorrhoeae* from four. The age-specific rates for gonorrhea reported in one study were 6.1 per 100,000 from 0 to 9 years old and 37.4 per 100,000 from 10 to 14 years old. Gonococcal conjunctivitis occurs most often in the first month of life, although cases have been described in older children and adults. Other forms of gonococcal infection are rare in children.

Pathophysiology

A child acquires gonorrhea by direct contact with infected secretions. The gonococci adhere to the surface of columnar epithelial cells and then penetrate through the intracellular spaces to the subepithelial tissues. They evoke an inflammatory response with polymorphonuclear leukocytes. Extension may occur through the lymphatics or the bloodstream.

Clinical Manifestations

The most common form of infection with *N. gonorrhoeae* seen among children is infection of the genitals. Prepubertal girls develop a vaginitis, rather than a cervicitis as seen in adult women, because of differences in the vaginal mucosa. Vaginal irritation, dysuria, and a discharge are the most common complaints. Boys have a urethral discharge and occasionally swelling of the penile shaft (Fig. 84.24) or urinary retention. Fever, systemic signs and symptoms, and spread to the pelvic organs in females occur rarely.

FIGURE 84.24. Penile venereal edema in a 2-year-old boy with gonococcal urethritis.

A Gram stain will show Gram-negative intracellular diplococci in most children with gonorrhea. Cultures allow definitive identification of the organism, a crucial issue from the medicolegal standpoint. Pharyngeal and rectal cultures are positive in 5 to 10% of cases in which the organism is not isolated from the genital tract.

Despite the widespread use of prophylactic solutions in the eyes of newborns, gonococcal conjunctivitis continues to appear sporadically. A thick, purulent discharge quickly replaces the initial mild erythema from chemical irritation. Gram stain of the exudate usually shows the organism, and cultures are almost always positive.

Disseminated gonorrhea (Fig. 84.25) and pelvic inflammatory disease emerge as problems in the sexually active adult. A complete discussion of these entities is found in Chapter 94.

FIGURE 84.25. Disseminated gonococcemia in an adolescent girl. A pustule is seen on the sole of her foot, and a hemorrhagic vesicopustule has formed in the web space between her fingers, which are held adjacent to her foot.

Management

All children with suspected genital gonorrhea should have cultures of the genitals, pharynx, and rectum, as well as serologic tests for syphilis and HIV. Because of the medicolegal considerations, treatment should be delayed in prepubertal children until the diagnosis is confirmed by culture, when possible. If the results of sensitivity testing are not available, ceftriaxone is used for therapy, in a dose of 125 mg intramuscularly. Alternatives for adolescents include single-dose oral therapy with cefixime (400 mg), ciprofloxacin (500 mg), or ofloxacin (400 mg). Spectinomycin is an acceptable alternative for penicillin-allergic patients in a dose of 40 mg/kg (maximum 2.0 g) intramuscularly. Because the usual mode of acquisition often involves sexual contact, a report must be made to the appropriate community department that deals with child abuse. Concomitant therapy should be provided for *C. trachomatis,* with either azithromycin (20 mg/kg, maximum 1 g) or doxycycline (in children older than 8 years).

In infants less than 1 month of age with conjunctivitis, particularly when purulent, consideration should be given to a Gram stain and culture of the ocular exudate. The finding of Gram-negative diplococci on the smear warrants treatment with ceftriaxone (50 mg/kg as a single dose) while awaiting culture results.

Therapy for adolescents with uncomplicated gonorrhea and salpingitis is discussed in Chapter 94.

Syphilis

Syphilis is an infection caused by *Treponema pallidum.* The disease is common among adults in the United States, but it is uncommonly encountered in children. However, scattered congenital infections are seen, and an incidence of 20 per 1 million has been reported in older adolescents.

Congenital syphilis usually presents with the same clinical picture as other intrauterine infections (rubella and cytomegalovirus). Characteristic features include jaundice and hepatosplenomegaly in an ill-appearing newborn. However, some infants have only a few stigmata, and the diagnosis is often overlooked in the nursery. These children may turn up in the first months of life with skin lesions, a persistent nasal discharge, and painful extremities (pseudoparalysis of Parrot). Dark-field examination of cutaneous lesions can identify the spirochetes, and the serologic test for syphilis is positive. In addition, radiographs may show lesions of the long bones. Diagnostic criteria are provided in Table 84.19.

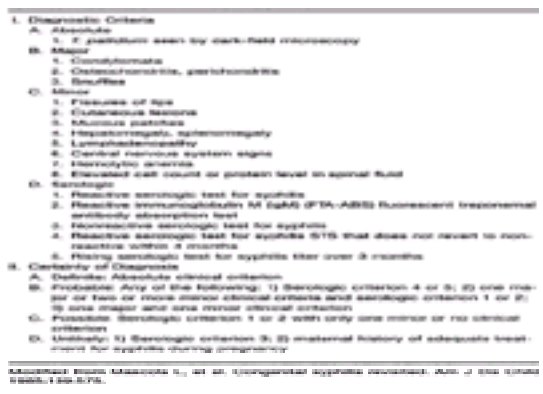

Table 84.19. Criteria for Diagnosis of Neonatal and Early Congenital Syphilis

Acquired syphilis appears in the teenager, as in the adult, in the first stage with a chancre (Fig. 84.26) and in the second stage with cutaneous or mucosal manifestations. The rash of secondary syphilis may resemble pityriasis rosea, and all sexually active patients diagnosed with this disease, particularly with involvement of the palms or soles, should have a serologic test for syphilis. Other lesions include white patches on the mucous membranes and flat-topped warts (condyloma lata) around moist areas. Such lesions shed spirochetes detectable by dark-field microscopy.

FIGURE 84.26. Chancre in an adolescent with serologically confirmed syphilis.

Congenital syphilis rarely is diagnosed in the ED, and the delay involved in confirmation moves the treatment out of the realm of the emergency physician. All such children require admission to the hospital. In acquired disease, benzathine penicillin (2.4 million units) is given intramuscularly in a single dose for early syphilis and in three doses, each separated by 1 week, for syphilis of more than 1 year's duration.

Herpes Genitalis

Herpes simplex can infect the genitals, as well as other anatomic sites. Although the most common cause of genital ulceration seen among adolescents and adults at venereal disease clinics, this entity is unusual in prepubertal children.

Genital pain is a common complaint with infections caused by herpes simplex and may precede the appearance of the lesions. Characteristically, the virus produces grouped vesicles on an erythematous base (Fig. 84.27); however, erosion of the overlying skin often leaves only painful ulcers at the time of the first visit. Particularly with a primary infection, the inguinal lymph nodes enlarge.

FIGURE 84.27. Genital herpetic lesions in a young girl who was sexually abused (Photo courtesy of Stephen Ludwig, MD)

Visual inspection often suffices for the diagnosis in the adolescent. A Tzanck smear (see Chapter 99) positive for giant cells lends further weight to the clinical impression; either immunofluorescent staining of a scraping from the base of a vesicle or a viral culture can verify the diagnosis. In children, a culture should always be obtained because the disease is rarely seen and needs medicolegal confirmation. Serologic tests for syphilis and HIV and bacterial cultures are appropriate to rule out coexisting sexually transmitted infections. Although it is occasionally spread by nonsexual contact, the physician must explore the possibility of sexual abuse when herpes genitalis occurs before puberty. Oral acyclovir therapy is indicated for primary infections; the dosage is 45–60 mg/kg per day in three divided doses.

Systemic Viral Infections

Viral Syndrome

The term *nonspecific viral syndrome* is used to refer to a generalized illness presumed clinically to be caused by a virus and characterized by malaise and, usually, fever. Numerous agents, including influenza, enteroviruses, and herpesvirus (roseola), have been implicated. Nonspecific viral syndromes and viral URIs account for most of the febrile visits made by children to the ED.

A viral syndrome begins with malaise and usually with fever, as well. The temperature varies from 37°C (98.6°F) to more than 40°C (104°F), greater elevations occurring at times in children less than 2 years old. Particularly with influenza, children who are able to verbalize their discomfort complain of diffuse aching. There may be a cough or occasional bout of emesis. Signs of mild inflammation may be seen in the upper respiratory tract.

The physician arrives at a diagnosis of a nonspecific viral syndrome by excluding other diseases on the basis of the history and physical examination. At times, a WBC count may help the physician determine whether the young child with a high fever is at risk for occult bacteremia. Treatment is limited to antipyresis with acetaminophen (15 mg/kg per dose)

or ibuprofen (10 mg/kg per dose) for patients who do not respond to acetaminophen and the maintenance of an adequate oral intake. Antibiotics will not prevent secondary bacterial infections and are not to be prescribed routinely. The parents must be instructed to seek further care if the fever persists for more than 48 hours.

Erythema Infectiosum (Fifth Disease)

Erythema infectiosum, or fifth disease, is an exanthematous illness of childhood caused by parvovirus B19. It occurs most commonly between 2 and 12 years of age. The appearance of a rash marks the onset of the disease; fever or other prodromal symptoms are uncommon. The rash involves the face initially, conferring on the child a “slapped-cheek” appearance. Maculopapular lesions erupt 24 hours later, initially on the upper portion of the extremities, and they then spread both proximally and distally. Fading of the central portion of the lesions gives a lacelike appearance to the rash. Adolescents in particular may develop arthralgia or arthritis, and patients with chronic hemolytic anemias, such as sickle cell disease, are at risk for aplastic crisis. During pregnancy, infection with parvovirus B19 causes fetal hydrops in approximately 10% of cases. There is no specific therapy in the normal host, but immunocompromised patients may benefit from intravenous gamma globulin.

Infectious Mononucleosis

Background

Infectious mononucleosis (IM) is a disease characterized by malaise, fever, pharyngitis, lymphadenopathy, and splenomegaly. In 1968, Henle and Henle showed that EBV causes this illness.

EBV infections are common, but usually asymptomatic, during the first years of life. In children, sporadic infections occur, and IM is occasionally diagnosed. By late adolescence, 50 to 90% of all people are seropositive, a higher prevalence of antibodies being found in teenagers of lower socioeconomic status. EBV infections are again common between 15 and 25 years of age in more affluent persons; half the seroconversions are accompanied by the clinical manifestations of IM.

Pathophysiology

Several studies have suggested that EBV is transmitted by intimate oral contact. The virus infects B lymphocytes that may spread to the various lymphoid tissues in the body. Sensitized T cells destroy the infected B cells and limit the production of virus; these cells are the atypical lymphocytes that appear in the circulation.

Clinical Manifestations

IM begins insidiously with fever and malaise. Three-fourths of children with this illness complain of a sore throat. Although a child may recover from IM in 7 to 10 days, the symptoms usually last for 2 to 4 weeks. This persistence of symptoms separates the patient with IM from those with pharyngitis caused by group A streptococcus or other viruses. Occasionally, the onset resembles that of infectious hepatitis.

The child with IM is febrile in 90% of cases at presentation. Enlarged lymph nodes are uniformly palpable. Although the lymphadenopathy may be limited to the cervical region, involvement of the axillary and inguinal areas occurs commonly. Pharyngitis caused by any pathogen produces an increase in the size of the anterior cervical nodes, but EBV characteristically affects the posterior cervical and submental glands as well (Fig. 84.28). In 75% of cases, the pharynx is inflamed, often with an exudate. The spleen enlarges in 60% of children and the liver in 25%. Periorbital edema and a diffuse maculopapular rash are seen occasionally.

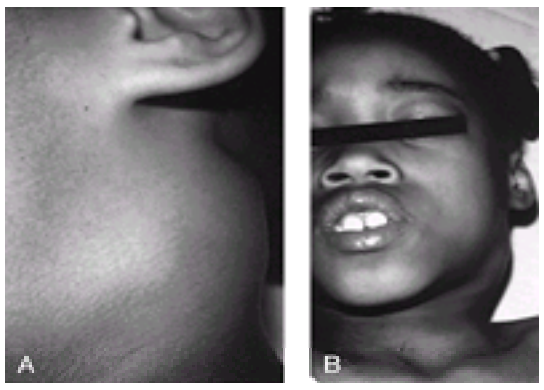

FIGURE 84.28. Posterior cervical adenopathy in a child with infectious mononucleosis. **A.** Close-up of posterior adenopathy. **B.** Anterior and posterior cervical node enlargement.

The hemoglobin and hematocrit are normal in the uncomplicated disease. Although the total WBC count does not often increase much beyond 15,000/mm^3, levels up to 30,000/mm^3 are seen in 10 to 15% of children. A higher leukocyte count casts some doubt on the diagnosis of IM. There is an absolute lymphocytosis with many atypical mononuclear cells; however, 16% of children presenting with IM in one series had fewer than 10% atypical lymphocytes, and 50% had fewer than 20% of such cells. The mainstay for the diagnosis of IM in the adult is the heterophil antibody test, but these antibodies reach levels detectable by routine assays in only 50% of children. Confirmation of a heterophil-negative case of IM requires EBV-specific serologic assays. The AST and ALT levels are elevated in most children.

The most worrisome complications of IM for the emergency physician are splenic rupture and airway obstruction. Even minor trauma can cause a rent in the capsule of the enlarged spleen seen in IM; these children manifest the usual signs of intraperitoneal hemorrhage. Occasionally, massive lymphoid hyperplasia of the tonsils occludes the airway, leading to stridor and retractions. The site of narrowing is easily visualized on examination. Less common complications include encephalitis, pneumonia, myocarditis, hemolytic anemia, and thrombocytopenia.

Management

A WBC count and heterophil antibody titer usually suffice for the confirmation of the clinical diagnosis. EBV-specific antibodies are indicated only for heterophil-negative cases.

Specific therapy is not available. Adequate rest and nutrition should be maintained, and antipyretic agents will increase the child's comfort. The treatment of a child with uncomplicated IM does not require the administration of corticosteroids, but the duration of the illness can be shortened and the patient made more comfortable by judicious use of a short course.

If complications develop, the child should be admitted to the hospital. Corticosteroids almost always shrink dramatically the enlarged tonsils of the child with airway obstruction. Prednisone is given at 2 mg/kg for the first day and tapered over 5 days. Studies with acyclovir have shown only minimal efficacy.

Measles

Background

Measles is a disease caused by a specific myxovirus and is characterized by fever, cough, coryza, conjunctivitis, and a rash. Since the large scale introduction of effective vaccines, the incidence of this disease has decreased significantly. Currently, several thousand cases still are reported each year to the CDC.

Pathophysiology

Measles virus enters the body through the upper respiratory tract, where local replication is believed to occur. A transient viremia ensues, and virus spreads to the reticuloendothelial system. A secondary viremia then follows, producing the clinical disease.

Clinical Findings

Fever and malaise herald the onset of measles. During the course of the illness, the temperature often rises to 40°C (104°F). Within 24 hours, coryza, conjunctivitis, and cough develop. Koplik's spots appear on the buccal mucosa by the third day of fever. These are seen as fine white spots on an erythematous background and have been likened to grains of sand. The rash erupts on the fourth or fifth day. The exanthem is maculopapular in appearance and begins on the face and neck. The lesions are heaviest on the upper portion of the body, often coalescing. As the rash advances down the trunk, the prodromal findings (cough, coryza, conjunctivitis) and the Koplik's spots resolve. The rash involves the extremities on its third day but has already begun to fade on the face.

A leukopenia accompanies uncomplicated measles. Specific antibodies, initially absent from the serum, reach detectable levels 2 weeks after the onset of illness.

Complications, which are unusual, fall into two categories: 1) extension of the viral infection and 2) secondary bacterial infection. The virus itself may produce inflammation of the lower respiratory mucosa, leading to laryngotracheitis, bronchitis, and/or pneumonia. Encephalitis occurs in 1 of every 1000 cases of measles; this is a debilitating illness with a mortality rate of 15%. Thrombocytopenia and corneal ulcerations are seen rarely. Lymphoid hyperplasia in the bowel can occlude the lumen of the appendix, leading to inflammation of this organ; histologic examination of surgically removed tissue confirms the diagnosis of measles on the basis of the characteristic giant cells. Acute purulent OM is the most common bacterial complication of measles, and cervical adenitis occasionally occurs. Pneumonia, although usually viral, may have a bacterial etiology.

Management

The clues gathered from the history and physical examination suffice for the diagnosis of measles by the experienced clinician. However, as the number of cases dwindles, the physician is less likely to be familiar with the disease. Often, serologic studies are required to confirm the cause, particularly among the first few children seen in sporadic outbreaks. Ordinarily, acute and convalescent titers drawn 1 to 2 weeks apart are used for a determination, but some laboratories are able to determine the serodiagnosis on a single specimen by testing for measles-specific IgM antibodies.

Measles runs a self-limited course. Bed rest and antipyretic therapy help keep the child comfortable. Antitussives, antihistamines, and topical ophthalmic preparations have no role. Prophylaxis against secondary bacterial infections with antibiotics is not warranted.

Children with uncomplicated measles or superficial secondary infections such as otitis and cervical adenitis can be treated as outpatients. Hospitalization is required when significantly severe laryngotracheobronchitis is evident, as discussed earlier in this chapter. Lower respiratory tract or CNS involvement necessitates admission to the hospital.

Measles is a preventable disease. Otherwise healthy, susceptible contacts should receive immune serum globulin, 0.25

mL/kg; the dose is increased to 0.5 mL/kg for immunocompromised patients. If within 72 hours of infection, vaccine is indicated in addition, unless the patient is less than six months of age or immunocompromised. (See Appendix D).

Roseola

Roseola infantum, or exanthem subitum, is a common, self-limiting, viral infection of infants caused in most cases by human herpesvirus-6; recently, reports indicate that human herpes virus, which occurs less often, produces a similar syndrome in slightly older children. The child, usually less than 3 years old, presents with a high fever, ranging up to 40.5°C (104.9°F), and a paucity of physical findings. There may be mild irritability but no coryza, pharyngeal infection, or conjunctivitis. After 2 to 4 days of illness, the fever drops precipitously and a rash appears. The lesions are discrete, pink maculopapules, 2 to 3 mm in diameter. They fade with pressure and do not coalesce. The exanthem appears on the trunk initially and spreads outward. Roseola resolves without complications other than an occasional febrile convulsion. The diagnosis of roseola is made on the basis of the clinical course, often in retrospect. If a WBC count is obtained, leukopenia with lymphocytosis will be seen. Treatment is limited to antipyretic agents.

Rubella

Background

Rubella is a childhood infection caused by a specific togavirus. Before the advent of vaccination, epidemics occurred every 6 to 9 years; 488,796 cases were reported to the CDC in the United States in 1964, the year of the last outbreak in this country. Presently, there are an estimated 25,000 to 50,000 cases per year. Rubella traditionally occurs in children 5 to 9 years of age, but the incidence among teenagers is increasing.

The initial site of inoculation is the upper respiratory tract, where local replication occurs. A viremia ensues, disseminating the virus to the skin.

Clinical Manifestations

Only 10% of children experience prodromal symptoms such as fever, malaise, cough, and mild conjunctivitis. However, such complaints are often voiced by the adolescent. The rash begins on the face and spreads downward, reaching the extremities by the end of the second day. The lesions are pink maculopapules that may coalesce. The lymph nodes in the postauricular, suboccipital, and posterior cervical chains enlarge and become somewhat tender. During the first 2 days of illness, the temperature usually rises, but remains under 39°C (102.2°F).

The WBC count often decreases in rubella, and a few atypical lymphocytes may appear. A fourfold rise in specific antibodies occurs after 10 to 14 days.

Complications of rubella are rare in children but include encephalitis, thrombocytopenia, and arthritis or arthralgia. Painful and/or swollen joints often occur in adolescents. Encephalitis has an incidence of 1 in 6000 cases of rubella and usually resolves spontaneously.

Management

Rubella is difficult to diagnose clinically because of its rare occurrence and the plethora of exanthems that have a similar appearance. Situations that require a definite etiologic diagnosis, such as pregnancy in an adolescent, demand serologic confirmation. Children with rubella can be managed as outpatients with antipyretic therapy. Only the rare child with encephalitis or thrombocytopenia requires admission to the hospital.

Varicella/Zoster

Background

Herpesvirus varicellae causes two clinical illnesses, varicella (chickenpox) and zoster (shingles). Varicella occurs during a primary infection and zoster occurs after a reactivation of latent virus.

Varicella is a common infection in children, usually those between 2 and 8 years of age, although the incidence is expected to drop now that an effective vaccine has been introduced. Almost 90% of susceptible household contacts of an index case develop the disease. By adolescence, serologic surveys have shown a seropositive rate of 70 to 80%. Zoster, however, affects adults predominantly. More than 60% of cases occur in persons older than 45 years.

Pathophysiology

The virus enters the body through the oropharynx and replicates locally. Viremia presumably occurs after exposure and before the onset of the exanthem. During an episode of varicella, the virus invades sensory nerve endings and ascends to the dorsal root ganglion where it becomes latent. Zoster follows reactivation of the latent virus.

Clinical Findings

Varicella. A mild prodrome that lasts 1 to 3 days often precedes the exanthem of varicella; however, the first sign of illness may be the rash. Most children develop fever, usually less than 39.5°C (103.1°F) and may complain of malaise. The fever usually has subsided within 24 hours of the appearance of the skin lesions. Recurrence of significant fever should serve as a warning sign for suspicion of complications. Lesions erupt initially on the upper trunk, neck, or face and

spread centripetally. Pruritus is universal.

The abnormal findings on physical examination are limited to the elevated temperature and the skin and mucous membrane lesions. Initially, the exanthem consists of erythematous papules that evolve into vesicles and then pustules over 6 to 8 hours (Fig. 84.29). The early vesicles have a diameter of 2 to 4 mm and a “dewdroplike” appearance. Because new lesions erupt in crops for 2 to 4 days, papules, vesicles, and pustules are usually seen together. An exanthem involves the mucosa of the oropharynx and, occasionally, the vagina. The severity of the cutaneous manifestations varies widely, and there may be from 1 to more than 1000 lesions.

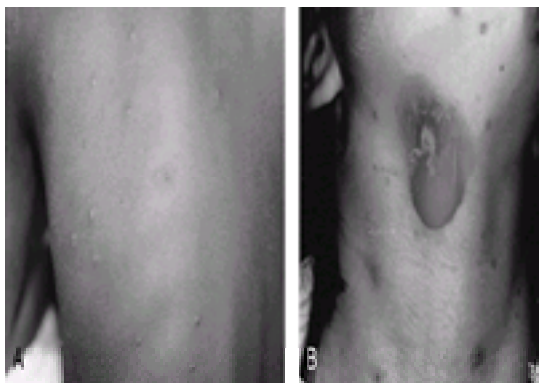

FIGURE 84.29. A. Typical lesions of varicella. **B.** Bullous varicella.

There are few laboratory derangements in varicella. The WBC count occasionally shows a leukocytosis, and the AST and ALT may be mildly elevated. In adolescents, the chest radiograph reveals an interstitial infiltrate in 5 to 10% of patients, even though there may be no respiratory symptoms.

Varicella runs a self-limited course in most cases but is occasionally a more serious illness. Fleisher et al. reviewed 96 children hospitalized with complications of this disease during a 5-year period at The Children's Hospital of Philadelphia. Of the group, 81 were immunocompetent children more than 1 month old; they experienced complications, including encephalitis (20), pneumonia (5), hepatitis (8), bacterial superinfection (22), Reye syndrome (17), unusual cutaneous manifestations (5), medication overdoses (5), exacerbation of an underlying disease (2), and dehydration (1). Simultaneous streptococcal pharyngitis can occur.

Encephalitis takes two forms: 1) a diffuse cerebritis with coma and seizures, and 2) a cerebellitis with ataxia. Both varieties may occur before, during, or after the cutaneous eruption. Because bacterial meningitis can also complicate varicella, an analysis of the CSF should be done even if viral encephalitis is suspected. There will often be a mild pleocytosis (10 to 300 cells) and a slight elevation of the protein (40 to 80 mg/dL). If the encephalopathy is thought to be related to Reye syndrome, a serum ammonia should be obtained.

Starting in approximately 1990, a number of authors reported an increasing incidence of group A streptococcal complications with varicella, including primarily sepsis and necrotizing fasciitis. The diagnosis of streptococcal sepsis should be considered in patients who appear toxic, remain febrile for 5 days or more, or develop a fever after being afebrile for more than 48 hours.

Zoster. Zoster appears suddenly in most children without any warning symptoms (pain or pruritus). The lesions are grouped vesicles on an erythematous base in a dermatomal distribution. In 15 to 20% of cases, extradermatomal cutaneous dissemination is seen. However, spread to the viscera does not occur in the immunocompetent child. If the eruption follows the ophthalmic branch of the trigeminal nerve, the cornea may be involved. The appearance of vesicles on the tip of the nose should evoke a suspicion of ocular involvement that can be best seen after fluorescein staining of the eye.

Management

Visual inspection suffices for the diagnosis of varicella; no laboratory studies are indicated. Acetaminophen is given to control the fever, and antihistaminic drugs provide some relief from the pruritus. Aspirin is contraindicated because of an association with Reye syndrome. Although some investigators have speculated about a relationship between the use of ibuprofen and the development of fasciitis, this remains unproven. Diphenhydramine (5 mg/kg per day), hydroxyzine (2 mg/kg per day), or other antihistamines may be used to decrease pruritus. The child cannot attend school for 1 week after the eruption of the first lesion.

Immunosuppressed children with varicella require hospitalization to receive IV acyclovir, which has been shown to prevent visceral dissemination; recent reports on the use of high-dose oral acyclovir in children with mild immunosuppression await further confirmation before this approach can be routinely recommended. Complications that mandate admission to the hospital for immunocompetent patients include fasciitis, Reye syndrome, pneumonia, and encephalitis, except in the mildest cases. Superficial bacterial infections such as impetigo, cellulitis (if fasciitis is thought to be unlikely), and adenitis can be treated with oral antibiotic therapy such as dicloxacillin 50 mg/kg per day, cephalexin 50 mg/kg per day, or erythromycin 40 mg/kg per day. Children with deeper bacterial infections (i.e., septic arthritis) should receive antibiotics by IV.

For immunocompetent children, oral acyclovir (80 mg/kg per day in four divided doses) given within 24 hours of the onset of the rash reduces the duration of fever and the number and duration of skin lesions. Indications for use have not been

formalized, but consideration is warranted for patients who are at some risk for a particularly severe course: infants less than 6 months old, adolescents (older than 12 years), children receiving long-term aspirin therapy or being treated with oral/inhaled steroid, patients with chronic cutaneous (e.g., atopic dermatitis) or pulmonary (e.g., cystic fibrosis) disorders, and those with fever above 40°C (104°F) and a large number of lesions noted as early as the first day of the eruption (particularly if case follows a household contact). Oral acyclovir should be considered for the pregnant adolescent, but its use remains controversial in this situation.

Zoster usually requires no specific therapy. Although famciclovir and valacyclovir are recommended for adults, they have not been shown to be efficacious in children. Antipruritic and antipyretic agents provide symptomatic relief. Immunocompromised children should be admitted to the hospital. IV acyclovir therapy benefits immunocompetent children with unusually severe disease and reduces the incidence of dissemination in immunocompromised patients. Ocular involvement merits consultation with an ophthalmologist.

Anyone likely to experience a severe episode of varicella should receive prophylaxis after a significant exposure to a patient contagious for varicella-zoster virus (household or close contact for more than 1 hour in a closed environment). Varicella-zoster immunoglobulin (VZIG), 1 vial (125 units) per 10 kg, is indicated for susceptible normal adults, pregnant women, and immunocompromised children. Newborns whose mothers have had onset of varicella within 5 days before or 2 days after delivery should receive 125 units, as soon as possible (see Appendix D).

Miscellaneous Infections

Babesiosis

Babesia species, particularly *B. microti are* protozoa, transmitted by the bite of an *Ixodes* tick, which also serves as a vector in Lyme disease. Cases of this infection have been reported with increasing frequency along both coasts and in the upper Midwest. The clinical picture of babesiosis resembles that of malaria and is characterized by anorexia, malaise, fatigue, and intermittent chills, sweats, and fevers as high as 40°C (104°F). Other than an elevated temperature, physical findings are absent or limited to mild hepatosplenomegaly. Patients with asplenia or immunocompromise are susceptible to severe, or even life-threatening, disease. Laboratory findings include hemolytic anemia with reticulocytosis, a normal or slightly decreased leukocyte count, mild thrombocytopenia, and elevated liver enzymes in half the cases. Microscopic examination of a peripheral smear confirms the presence of intracellular and extracellular ring forms, similar to those of *Plasmodium falciparum;* specific serologic assays are available as well, but the results are often delayed for several weeks and do not distinguish between acute infection and asymptomatic seropositivity. Therapy is reserved for patients with mild to moderate infections or a predisposition to severe disease. The treatment of choice is clindamycin (40 mg/kg per day in four divided doses) and quinine (30 mg/kg per day in three divided doses) intravenously.

Botulism

Background

Botulism is a paralytic illness produced by neurotoxins elaborated by *Clostridium botulinum.* The disease may result from the ingestion of preformed toxin or from the elaboration of toxin by organisms in a wound or in the GI tract. Of particular concern to the physician who cares for children is infantile botulism caused by toxin formed in the intestines. In the United States, approximately 400 cases of this disease were reported to the CDC in 1984.

During growth, *C. botulinum* releases neurotoxins that are the most potent poisons known on a weight basis. They interfere with neurotransmission at peripheral cholinergic synapses by blocking the release of acetylcholine.

Clinical Manifestations

Botulism from the ingestion of toxin causes vomiting in 50% of cases. The patients complain of weakness and a dry mouth; constipation and urinary retention may occur. Paralysis is noted within 3 days, usually affecting the cranial nerves first and then the extremities. The patients are alert and afebrile. Abnormalities of the neurologic examination include ptosis, extraocular palsies, fixed dilated pupils, symmetric weakness, and hyporeflexia. Both the ileus and urinary retention seen in this disease may lead to abdominal distension.

Infantile botulism occurs in children in the first 6 months of life who are otherwise healthy. The duration of symptoms before hospitalization ranges from 1 to 20 days. Breast-fed, Caucasian infants from middle-class families are primarily affected. Constipation is the first symptom of the disease but may not be sufficiently severe to draw attention to any underlying illness. After several days, mild lethargy, weakness, and a decreased appetite are noted. Occasionally, the onset of lethargy and weakness may be so precipitous as to resemble bacterial sepsis or meningitis.

On examination, the infant is quiet, with little discernible movement, and has a weak cry. Fever is not a part of this syndrome. The child sucks on a nipple with difficulty and may be unable to swallow. The absence of a gag reflex, profound hypotonia, and hyporeflexia in infantile botulism helps distinguish this illness from bacterial sepsis.

The WBC count is normal in botulism. Organisms may be recovered by anaerobic culture techniques from the GI tract in infantile or wound botulism, but identification of the toxins requires the specialized facilities of the public health department. Children with botulism have an electromyogram that shows a characteristic pattern of brief duration, small amplitude, overly abundant motor unit action potentials (BSAP).

Respiratory failure is a potential life-threatening complication in botulism of any variety, and ventilatory support is often required. The profound bulbar weakness in infantile botulism often prevents an adequate fluid intake; dehydration occurs

frequently.

Management

Because no test is immediately available to diagnose infantile botulism, the initial evaluation of these infants aims at excluding other causes of lethargy and weakness such as sepsis, poliomyelitis, myasthenia gravis, neuropathy, and drug ingestion. A lumbar puncture is often performed in the ED to rule out meningitis, and electrolytes and a BUN are useful to assess hydration.

The children all require admission to the hospital (Table 84.20). Monitoring of pulse and respiratory rate should start in the ED. An IV line should be started for the administration of fluids to correct dehydration and in anticipation of a possible respiratory arrest. Neither antibiotics nor antitoxin ameliorate the course of infantile botulism. Because they may potentiate the neuromuscular blockade, aminoglycoside antibiotics should be avoided when treating for possible sepsis.

Ensure adequate ventilation.	Achieve venous access and maintain
Administer oxygen, as indicated.	hydration.
Initiate cardiorespiratory monitoring.	Obtain laboratory studies.

Table 84.20. Infantile Botulism: Immediate Management

Children with foodborne and wound botulism also require admission to the hospital. Antitoxin is available from the CDC and should be administered after consultation with the staff at this agency.

Cat-Scratch Disease

CSD is an infection caused by *Bartonella henselae.* Approximately 80% of cases occur in patients less than 20 years of age. Traditionally, this disorder has been thought of primarily as an infection of regional lymph nodes (typical CSD), but the spectrum of the disease has been expanded to include infections of other organ systems by *B. henselae* (atypical CSD). In addition, this same agent causes severe infections (bacillary angiomatosis and peliosis hepatis) in patients with HIV (see Chapter 85).

More than 90% of children with typical CSD have a history of exposure to cats. The most complete form of the illness begins with a the appearance of a pustule at the site contact, 7 to 10 days after exposure. Lymphadenopathy follows within 1 to 6 weeks. The regional nodes enlarge and become mildly to moderately tender on palpation. In one-third of cases, the glands become fluctuant. The epitrochlear, axillary, inguinal, and cervical nodes are commonly affected.

Manifestations of atypical CSD include encephalitis, aseptic meningitis, neuroretinitis (blindness and stellate macular lesions of the retina), Parinaud's syndrome (conjunctivitis and preauricular adenitis), hepatitis, osteolytic lesions, and fever of unknown origin.

In typical cases with a history of exposure, particularly to a kitten, and characteristic lymph node enlargement, no specific diagnostic studies are needed. In atypical disease or with lymphadenopathy that is not characteristic, serum should be sent to a reference laboratory for an indirect fluorescent antibody test.

Various antibiotics have been reported to have some efficacy for CSD, including rifampin, TMP-SMZ, ciprofloxacin, and azithromycin. The only controlled study of patients with typical CSD found that azithromycin (10 mg/kg in a single dose on day 1, followed by 5 mg/kg once daily on days 2 through 5) shortened the duration of adenopathy. Nodes that persist and become fluctuant usually resolve after needle aspiration.

Ehrlichiosis

At least two *Ehrlichia* species cause two similar infectious illnesses: human monocytic ehrlichiosis and human granulocytic ehrlichiosis. *Ehrlichia* species are transmitted by a number of tick vectors throughout the United States. Both forms of the disease resemble Rocky Mountain spotted fever (RMSF) and are characterized by fever, chills, malaise, myalgias, and headache. Unlike RMSF, a rash occurs in only 40% of patients with human monocytic ehrlichiosis and rarely with granulocytic ehrlichiosis. The infection may spread to involve the meninges. Laboratory findings include anemia, thrombocytopenia, hyponatremia, and mildly elevated liver enzymes. Examination of the peripheral smear may show inclusions (morulae) in monocytes or granulocytes (depending on the species), but a definitive diagnosis relies on serology, which is available only from reference laboratories. The treatment of choice is doxycycline (3 mg/kg per day in two divided doses), even for children less than 8 years of age; chloramphenicol (75 to 100 mg/kg per day in four divided doses) offers an alternative.

Malaria

Malaria is a protozoal infection that occurs in humans and is caused by four species: *Plasmodium falciparum, Plasmodium vivax, Plasmodium ovale,* and *Plasmodium malariae.* Although one of the most common infections in the world, malaria is rare in the United States; about 1000 cases occur annually. However, it should be considered in recent immigrants from tropical areas and in travelers; there have been a handful of indigenously acquired cases since 1990, including transmission in the northeastern part of the country. At times, malaria may be fatal, particularly with infections from *P. falciparum.*

Pathophysiology

Plasmodia gain access to the bloodstream when a person is bitten by a female anopheline mosquito or, rarely, by transfusion or transplacentally. The sporozoites invade liver parenchymal cells that subsequently release merozoites. The merozoites enter the erythrocytes and eventually cause their destruction. Subsequent cycles of infection account for the recurrent nature of the illness.

Clinical Manifestations

Fever characterizes malarial infections. Although specific patterns may occur, chaotic elevations of the temperature are more common because of multiple broods of parasites. The typical attack starts with a chill and tachycardia. Within 1 hour, the fever rises to 40°C (104°F) or higher. A profuse diaphoresis follows and lasts for several hours. Hepatosplenomegaly is a common finding. The febrile episodes may be accompanied by hypotension and jaundice. Laboratory findings include anemia, leukocytosis, thrombocytopenia, and hyperbilirubinemia.

Complications of malaria resulting from *P. falciparum* include massive hemolysis (blackwater fever), renal failure, pulmonary edema, and cerebral dysfunction. Neurologic signs of cerebral malaria include decreased level of consciousness, behavioral changes, hallucinations, seizures, and rarely, focal signs. The CSF is usually normal.

Management

Malaria must be suspected in any febrile child recently in an endemic area and in febrile neonates born to women who are recent immigrants from such regions. Thick and thin blood smears should be done and, if positive, will confirm the diagnosis. However, these smears may be negative in some infections and are often not easily interpreted except by experienced personnel. In such circumstances, a CBC is helpful. Thrombocytopenia often occurs in children during febrile episodes; the platelet count usually falls in the range of 50,000 to 100,000/mm ^{3}.

Children with suspected or proven malaria from areas without resistant *P. falciparum* should be given chloroquine phosphate. (Updated information on the geographic prevalence of resistance is available from the CDC or the World Wide Web at www.CDC.gov.) The initial dose is 10 mg/kg of base (maximum 600 mg) followed by 5 mg/kg at 6, 24, and 48 hours. Patients unable to take oral medication require IV quinidine, beginning with a loading dose of 10 mg/kg infused over 1 hour with cardiac monitoring. Uncomplicated infections with chloroquine-resistant *P. falciparum* can be treated with oral quinine sulfate (30 mg/kg per day in three divided doses) plus oral pyrimethamine–sulfadoxine (Fansidar) (less than 1 year old, ¼ tablet; 1 to 3 years, ½ tablet; 4 to 8 years, 1 tablet; 9 to 14 years, 2 tablets; older than 14 years, 3 tablets). Fansidar should not be used in patients with known sensitivity to sulfa drugs. An alternative regimen for chloroquine-resistant *P. falciparum* is mefloquine, 15 to 25 mg/kg (maximum 1250 mg) as a single oral dose, but this drug should not be used in children who weigh less than 15 kg, in pregnant women, or in patients with epilepsy or psychiatric disorders. In life-threatening infections with known or suspected resistant organisms, quinidine should be administered by IV, as already described; this drug carries a significant risk of adverse reactions and is thus reserved for emergencies.

Parasitic Infestations of the Gastrointestinal Tract

A variety of parasites can infest the GI tract or invade the body via this route. These infestations may be asymptomatic, being detected on screening examination of the stool. In the ED, the diagnosis is usually entertained when a parent reports observing a worm (pinworm, *Enterobius vermicularis*) or in acute diarrheal diseases, particularly among patients who are immunosuppressed or recently in underdeveloped countries. Two pathogens deserve particular consideration in the United States among immunocompetent children. *Cryptosporidium parvum,* first reported as a cause of human disease in 1976 and well known as a pathogen in children with HIV, has been reported to be the responsible pathogen in 2 to 5% of cases of nonspecific, watery diarrhea and has been implicated in several large, waterborne outbreaks, one affecting an estimated 400,000 persons in Milwaukee, Wisconsin, in 1993. *Giardia lamblia* is also a waterborne parasite that can survive even in running waters and has been described as a cause of diarrhea among campers and hikers who have ingested water from streams. Both cryptosporidiosis and giardiasis merit consideration in day care settings. Table 84.21 summarizes the clinical symptoms and treatment of gastrointestinal parasites in children.

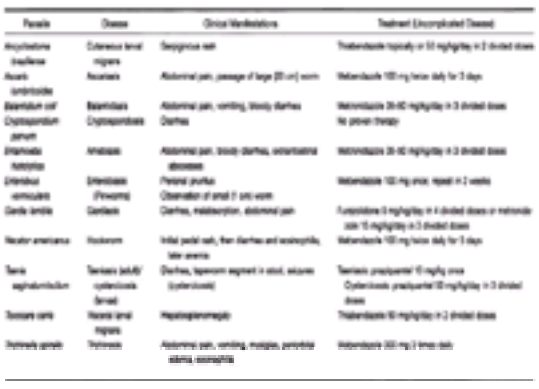

Table 84.21. Parasitic Diseases

Rabies

Rabies is a viral infection of the brain that is almost invariably fatal. Although the actual disease is rare in the United States, potential exposure in the form of animal bites commonly occurs. Dogs bite 1 million to 2 million people per year, and 75% of the victims are children.

The decision whether or not to give prophylaxis for rabies is influenced by the species of animal, the condition of the animal, the ability to study the animal, the type of exposure, and the prevalence of rabies in the region (Fig. 84.30). The incidence of rabies in the area should be available from the local health department. If a sleeping or preverbal child has had close exposure to a bat in an area where rabies is endemic in this species, prophylaxis is indicated even in the absence of a visible bite wound because of the occurrence of several pediatric cases in this circumstance. When the physician determines that prophylaxis is necessary, human rabies immune globulin (HRIG) 20 IU/kg and human diploid cell vaccine (HDCV) are used. After cleaning the wound, half the HRIG is given locally and the remainder at a distant site. Vaccine must be given in the deltoid muscle (not the thigh or buttock) in a different extremity then that used for the HRIG. (See Practical Information, Appendix D.

FIGURE 84.30. Diagnostic approach for the management of the child with a mammalian bite wound.

Rocky Mountain Spotted Fever

Background

RMSF is an infection caused by *Rickettsia rickettsii.* It is the most commonly occurring rickettsial disease in the United States. Ticks harbor the organism and transmit it to humans during blood sucking. Although the disease is named for the area of the country in which the causative agent was discovered, most cases of RMSF occur in the states along the eastern coast of the United States. The incidence of the disease peaks during the warmer months. It affects persons of all ages, but two-thirds of the victims are children and adolescents. Each year, approximately 1000 cases are reported to the CDC.

Pathophysiology

Rickettsiae are inoculated during blood sucking by a tick and replicate locally. In animal models, the organisms disseminate hematogenously and invade the endothelial lining of the small blood vessels. The infection induces an inflammatory reaction in these cells that leads to swelling, necrosis, thrombosis, and finally, occlusion of the vascular lumina. The diffuse vasculitis underlies the widespread clinical manifestations that may involve almost every organ.

Clinical Manifestations

The incubation period of RMSF ranges from 2 to 10 days but usually lasts 1 week. The initial symptoms of headache and malaise are followed by fever. The rash erupts on the third or fourth day of illness. In more than half the cases reviewed by Vianna, the exanthem appeared first on the wrists and ankles and then spread inward toward the trunk. The initial lesions are maculopapular but become hemorrhagic in the ensuing 24 to 48 hours if the disease remains unchecked (Fig. 84.31).

FIGURE 84.31. Rocky Mountain spotted fever.

The findings on examination vary with the duration of the disease. Early in the course of the illness, the child remains alert. Conjunctivitis and a rash may be the only signs. Edema begins in the periorbital regions and involves the extremities as the vasculitis progresses. Mild splenomegaly is found in one-third of cases. Vomiting is common. Although the sensorium is clear initially, obtundation and, finally, coma develop after several days of illness.

The WBC count remains normal or rises slightly with RMSF. Thrombocytopenia occurs in 75% of patients during the first stages of the disease; later, DIC may develop with a prolonged PT and PTT, as well as elevated fibrin split products. Most patients have hyponatremia but no other electrolyte abnormalities. Bradford and Hawkins noted a decrease in the serum sodium among 88% of children. Immunofluorescent staining has been used to identify rickettsiae in the endothelial cells of dermal vessels from skin biopsies but is not routinely available for diagnosis. Even when myocarditis remains clinically silent, the electrocardiogram may show signs of cardiac dysfunction. The earliest changes consist of an elevation of the ST segment; later, the P-R interval may become prolonged and arrhythmias may occur. In some cases, mild increases in the CSF cell count and protein concentration are seen.

Complications of RMSF that demand immediate attention include shock and seizures. Vascular collapse occurs from the combination of endothelial damage and inadequate hydration in the vomiting, obtunded patient. Tachycardia, hypotension, and an impaired peripheral perfusion point to a decrease in the intravascular volume. Convulsions may occur in the comatose child with RMSF. Either hyponatremia or a cerebral vasculitis may underlie the seizure activity. Occasionally, the hemorrhagic diathesis needs immediate treatment in the ED. Myocarditis and nephritis are also seen.

Management

A CBC, platelet count, electrolytes, PT, PTT, and serologic titers should be obtained on the child with suspected RMSF. These studies help pin down the diagnosis and influence the management. Because no routinely available test confirms the diagnosis of RMSF early in its course, treatment must be initiated presumptively. The mildly ill child with a fever, maculopapular exanthem, and a history of a tick bite can be treated as an outpatient. Chloramphenicol (50 mg/kg per day) is the drug of choice for patients less than 8 years of age and tetracycline (50 mg/kg per day) in older youths.

Admission is indicated when there is 1) clinical evidence of toxicity, 2) encephalitis, 3) thrombocytopenia (platelet count less than 150,000/mm^3) or derangements in the clotting studies, and 4) hyponatremia (Na less than 130 mEq/L). In the ED, an IV infusion should be started and sufficient fluids administered to maintain an adequate blood pressure as discussed under Septic Shock (see Chapter 3). Chloramphenicol (50 mg/kg per day) can be given alone if the illness is clearly felt to be RMSF; in practice, however, broader antibacterial coverage (e.g., chloramphenicol plus ampicillin or oxacillin) is often used because bacterial sepsis cannot be excluded.

Tetanus

Clinical tetanus is caused by the toxin produced by *Clostridium tetani.* The disease is rare in the United States (approximately 50 cases annually) because of widespread use of the vaccine. Neonatal tetanus from infections of the umbilicus by the organism continues to be reported occasionally. However, the more common problem for the emergency physician is the use of prophylaxis after traumatic wounds. Both tetanus toxoid (0.5 mL) and human tetanus immunoglobulin (250 units) may be indicated, depending on the wound and the immunization history (Table 84.22). Tetanus-prone wounds include punctures, crush injuries, and injuries contaminated by animal excreta or those left untreated for more than 24 hours. (See Practical Information, Appendix D.)

No. of Primary Immunizations	Years Since Last Booster	Type of Wound	Recommendation
≤2	Irrelevant	Low risk	T
		Tetanus prone	T + TIG
3	10	Low risk	T
		Tetanus prone	T
3	5–10	Low risk	No treatment
		Tetanus prone	T
3	<5	Low risk	No treatment
		Tetanus prone	No treatment

T, tetanus toxoid; TIG, human tetanus immune globulin.

Table 84.22. Guidelines for Tetanus Prophylaxis

Toxic Shock Syndrome

Background

Toxic shock syndrome (TSS) is characterized by severe, prolonged shock and is caused by a toxin produced by *S. aureus.* Todd et al. initially described this syndrome in seven children, aged 8 to 17 years, but most of the subsequently reported episodes have occurred in postpubertal females, often after a menstrual period. About 400 cases of TSS occur annually in the United States.

Colonization by a phage-group-1 toxin–producing staphylococcal strain sets the stage for the development of TSS. The enterotoxins of these organisms are pyrogenic and enhance the susceptibility to shock from endotoxins.

Clinical Manifestations

TSS begins suddenly with high fever, vomiting, and watery diarrhea. Pharyngitis, headache, and myalgias may also occur, and oliguria rapidly develops. Within 48 hours, the disease progresses to hypotensive shock. The patient has a fever, usually 39° to 41°C (102.2° to 105.8°F), a diffuse, erythematous maculopapular rash, and hyperemia of the mucous membranes. Often, marked disorientation evolves.

The WBC count is elevated, with a shift to the left. Thrombocytopenia commonly occurs, being present in more than 75% of children reported by Todd. Most patients develop DIC and have an elevated PT and PTT. Additional abnormalities in the laboratory studies may include an elevated AST, ALT, BUN, creatinine, and creatinine phosphokinase. The serum calcium and phosphate may be decreased.

Management

The initial diagnosis of TSS rests on the constellation of clinical and laboratory findings. The following laboratory tests should be obtained from all children suspected of having this syndrome: CBC, platelet count, PT, PTT, fibrin split products, electrolytes, BUN, creatinine, AST, ALT, and creatinine phosphokinase. Cultures of the blood, urine, stool, throat, and vagina serve to isolate *S. aureus* and to rule out other infectious causes of shock. A lumbar puncture often is required to exclude bacterial meningitis.

The management of TSS is the same as that for shock caused by other organisms (see Chapter 3). The physician should secure venous access with a plastic cannula and administer sufficient fluids to maintain an adequate blood pressure, beginning with 20 mL/kg of normal saline. Monitoring of the intravascular volume and urine output usually requires the placement of central venous and peripheral arterial lines and a urinary catheter.

CHAPTER 85

Human Immunodeficiency Virus Infection

MARVIN B. HARPER, MD

Department of Pediatrics, Harvard Medical School, and Divisions of Emergency Medicine and Infectious Diseases, Children's Hospital, Boston, Massachusetts

EPIDEMIOLOGY

In 1983, the first descriptions of children with acquired immunodeficiency syndrome (AIDS) appeared in the literature. Since then, it has become clear that human immunodeficiency virus (HIV), the etiologic agent for AIDS, has been present in humans for decades. HIV has since been identified and characterized, and our understanding of the clinical manifestations of HIV infection has grown. As of the end of 1997, 90% of pediatric AIDS cases reported in the United States were perinatally acquired. The number of children with perinatally acquired AIDS in the United States peaked in 1992, with the subsequent decline likely a result of the increased use of voluntary HIV testing of pregnant women and the use of antivirals to prevent perinatal transmission. As a worldwide problem, HIV infection, including infection of children, continues to grow. The World Health Organization (WHO) estimates that in 1997, approximately 590,000 children were newly HIV positive, 460,000 children died of HIV, and a cumulative 2.7 million children have died of HIV/AIDS.

AIDS in this country predominantly occurs among homosexual and bisexual men, intravenous (IV) drug users, transfusion recipients and hemophiliacs, and female heterosexual contacts of HIV-infected persons who had additional risk factors themselves such as IV drug use. Rates are highest among African-Americans and Hispanics in the Northeast region of the United States and in certain large metropolitan areas.

To decide whether HIV infection is likely, the emergency physician must consider the prevalence of HIV infection among persons with particular risk behaviors in various parts of the country. Increasingly, mothers are offered testing for HIV as a part of routine antenatal care. If so, the results of testing will identify most children at risk. If the mother was not tested, the physician must ask parents about HIV risk factors (e.g., IV drug use, crack cocaine use, intercourse with a known IV drug user, multiple sex partners). An additional risk factor is a history of blood transfusions in the parent or child between 1978 and 1985, when banked blood began to be routinely tested for HIV. It must be recognized that a high proportion (about one-third) of inner-city patients will report HIV risk behaviors; most of them will not have HIV. If the person who brings the child to the emergency department (ED) is not the parent, inquire about the parents' health and whereabouts. In high-risk areas, many children in foster care or those living with relatives have a parent who has died from an AIDS-related condition.

However, the absence of risk factors does not rule out the possibility of HIV infection. More than one-fourth of infected women cannot report a risk factor, and nearly half of HIV-positive adolescent girls acquire the infection through heterosexual contact. (Often, from the individual's perspective, a series of monogamous relationships is not interpreted as having “multiple partners.”) Because the typical incubation period in adults is about 10 years, most will not develop symptoms of HIV infection during adolescence. However, young adults who develop symptomatic infection often acquired the virus during adolescence. Often, a mother first finds out that she is infected when tested during pregnancy or when her infant is diagnosed as HIV positive. Although all mothers of infants with congenital HIV infection harbor the virus, only a small minority of their infants will be infected (about 25% of infants born to untreated HIV-positive women, or 8% of infants receiving appropriate antiviral perinatal prophylaxis).

PATHOPHYSIOLOGY

The human immunodeficiency virus is an RNA retrovirus. After gaining entrance to the body, it binds through its protein envelope, gp120, to a region of the CD4 molecule on helper T lymphocytes, monocytes, macrophages, dendritic and glial cells, and intestinal endothelial cells. Through this binding process, the virus can fuse with the cell membrane and enter the cell. There, viral RNA is transcribed to DNA by reverse transcriptase and is incorporated into the host cell DNA. The viral DNA may remain dormant for long periods but can be stimulated at any time to transcribe itself into messenger RNA, which, in turn, leads to protein synthesis, assembly, and release of virus and virus particles. How a latent infection is converted into an active one is unknown, but it is thought that the coexistence of other infections stimulates the process.

Abnormalities develop in both the cellular and humoral immune systems as HIV replication continues. Most circulating cells showing HIV infection are CD4 helper lymphocytes and with time the percentage of CD4 helper lymphocytes decreases, and the ratio of helper (CD4) to suppressor (CD8) lymphocytes reverses. In adults, the number of CD4 lymphocytes has been shown to be a useful marker for opportunistic infection; early in childhood, this is not reliably the case. High CD4 counts have been seen in association with *Pneumocystis carinii* pneumonia. The proliferation of T cells in response to antigenic stimulation is impaired, mitogenic responses may be abnormal, and delayed hypersensitivity skin tests (tetanus, *Candida*, measles-mumps-rubella [MMR]) become negative as well. Macrophages, natural killer (NK) cells, CD4 and CD8 lymphocytes, and dendritic cells all show impaired function. In addition, there is an abnormal polyclonal activation of B cells that can result in notable hypergammaglobulinemia; however, these children do not respond with appropriate antibodies to new antigens and often produce autoantibodies.

Mode of Acquisition

The likelihood of acquiring infection depends on the amount of infectious virus in the body fluid and the extent of contact with that body fluid. The amount of virus is highest in the infected individual during the initial acute infection and late in the disease during the symptomatic period when $CD4^+$ cells are depleted. The risk of perinatal acquisition increases with increasing maternal virus load and decreased maternal immunity. Infants may not develop sufficient antiviral cellular immune response to decrease the amount of virus and therefore often have high levels of viremia.

Blood and genital fluids (seminal fluid, vaginal fluid) are the most likely to transmit HIV. Other fluids such as saliva, urine, sweat, amniotic fluid, synovial fluid, feces, and tears contain no virus or only low levels of virus and are not important sources of virus transmission. The likelihood of HIV infection after a single exposure to an HIV-positive source has been estimated to be 0.01 to 1% after sexual intercourse, 0.03% with needlestick injury, 0.5 to 1% with injecting drug use, and greater than 90% with blood transfusion. Breast-feeding is associated with an increased risk of transmission of HIV to the infant. In areas such as the United States where alternatives to breast-feeding are safe, breast-feeding by known HIV-infected women is discouraged. Worldwide it now appears that breast-feeding accounts for about 12% of perinatally acquired infections with the rest occurring in and around the intrapartum period.

Detection of virus can now be accomplished by culture, quantitative HIV RNA polymerase chain reaction (PCR) techniques, and antigen testing. Quantitative HIV RNA PCR techniques allow detection of viral RNA to levels of less than 500 copies per milliliter. Plasma viremia in the acute infection is typically about 5 million per milliliter. During the asymptomatic period, it is in the tens of thousands per milliliter, although the culturable or infectious virus is substantially less (100- to 100,000-fold less).

CLINICAL FINDINGS AND MANAGEMENT

Initial Presentation of Children with HIV

Most pediatric patients are infected perinatally and develop symptoms progressively over time, and although lymphadenopathy, hepatosplenomegaly, and failure to thrive are common clinical features, any organ system can be affected (Table 85.1). Many children show signs of abnormal humoral immune function such as recurrent or persistent bacterial infection. Children lack preexisting antibodies to bacterial pathogens at the time they are infected with the HIV virus; this developmental situation makes them particularly susceptible to infection by common bacterial pathogens. Numerous studies have documented the increased incidence of bacterial infections in HIV-positive children. Some children show early defects in cellular immunity exhibited by persistent candidiasis, chronic diarrhea, or opportunistic infections. Still others may remain relatively asymptomatic for long periods (6% completely asymptomatic at 5 years).

Lymphadenopathy	Recurrent fevers
Hepatomegaly	Splenomegaly
Failure to thrive	Chronic or recurrent diarrhea
Bacteremia	Wasting syndrome
Oral thrush	Developmental delay
Chronic or recurrent parotitis	Acquired microcephaly
Opportunistic infections	Spastic paresis

Table 85.1. Signs and Symptoms of Human Immunodeficiency Virus Infection in Children

Approximately 80% of infants infected perinatally will develop clinical signs or symptoms within the first 12 months of life. However, only 20% experience a rapid progression to profound immunodeficiency. The rate of progression is likely

related to multiple host and virus-specific factors, but in perinatally acquired infection, the rate of disease progression is directly related with the severity of the disease in the mother at the time of delivery.

The initial presentation may actually represent acute HIV infection. Within days to weeks of initial exposure to HIV, a syndrome of fever, fatigue, and maculopapular truncal rash can mark acute disease. Myalgia, arthralgia, pharyngitis, lymphadenopathy, headache, nausea, vomiting, and diarrhea are common. Many also have leukopenia and thrombocytopenia. Many patients with acute HIV infection will seek care; however, few are diagnosed with acute HIV unless a specific history of HIV exposure is given because of the common occurrence of these symptoms with other viruses. The diagnosis of acute HIV infection cannot be made with standard serologic tests (enzyme-linked immunoabsorbent assays [ELISAs] or Western blot) because these tests first become positive 3 to 4 weeks after acute infection. Early detection, when indicated, is possible through the use of p24 antigen testing and plasma viral RNA testing. Follow-up testing and counseling should be arranged.

Fever

As is true for all children with fever, the evaluation of the HIV-infected child with fever requires a careful history, thorough physical examination, and often, laboratory testing. Fever in HIV-infected children can represent simple childhood viral infections, but because of the humoral immunodeficiency of these children, they also commonly suffer from acute bacterial infections. Otitis media, sinusitis, pneumonia, adenitis, bacteremia, and skin and soft-tissue infections all occur commonly. In addition, opportunistic infections must be considered. It is important to inquire about any previous opportunistic infection, or the use of prophylactic medications for the prevention of PCP, *Mycobacterium avium intracellulare* (MAI), or cytomegalovirus (CMV) because these may be markers for poor immune function. Some parents may be able to provide a recent CD4 count, but laboratory data that reflect the status of the immune system usually are not available to the emergency physician. As in any child, the general clinical appearance is an important piece of information in the evaluation of the febrile HIV-positive child. The physician should search carefully for a focus (Fig. 85.1).

FIGURE 85.1. Evaluation of the HIV-positive child with fever. *TMP-SMZ*, trimethoprim–sulfamethoxazole; *CBC*, complete blood count. (Modified from Dorfman D, Crain E, Bernstein L. Care of febrile children with HIV infection in the emergency department. Pediatr Emerg Care 1990;6:308.)

Evaluation of the Febrile, HIV-Positive Child without a Source

Experience has shown that HIV-infected children experience the usual childhood illnesses and are likely to develop the same upper respiratory infections and viral syndromes as immunocompetent children. The clinical appearance of the patient is the starting point for determining ED management (Fig. 85.1).

Evaluation of the Well-Appearing, Febrile HIV-Positive Child

The HIV-infected child who appears well and does not have an obvious source of infection presents a more difficult problem than the child with an obvious localized infection. The first step is to decide on an appropriate evaluation. Several studies have demonstrated that HIV-positive children have an increased incidence of bacteremia. They are also more susceptible to serious viral infections such as disseminated CMV. However, it appears that serious bacterial, viral, or opportunistic infections are relatively uncommon among well-appearing HIV-positive children who present to the ED with fever.

An evaluation similar to that for febrile children at risk for occult bacteremia is reasonable. However, laboratory testing should be obtained even beyond 24 months of age. Thus, even if the older child presents with a temperature of 39°C (102.2°F) or higher, a complete blood count (CBC) with differential and blood culture are recommended. Erythrocyte sedimentation rates are usually elevated in HIV-infected children and therefore are not helpful in their evaluation. If the child is still in diapers, a urine sample should be obtained for analysis and culture. Older children who are toilet-trained usually complain of dysuria or frequency if they have a urinary tract infection. If the child has any respiratory signs or symptoms, including isolated tachypnea, or if the CBC has an elevated leukocyte count with a shift to left regardless of the presence of respiratory signs, pulse oximetry and a chest radiograph should be ordered. The white blood cell (WBC) count is best evaluated in relation to baseline counts because many HIV-infected children have some degree of granulocytopenia. If it is known that the child is not leukopenic or the baseline is not available, a WBC count of 15,000/µL or greater should be considered suggestive of bacterial infection. These patients may be started on antibiotics such as amoxicillin, amoxicillin–clavulinic acid (Augmentin), or intramuscular ceftriaxone (Rocephin), pending culture results. No data support or refute this practice except for the documentation of high rates of bacteremia, predominantly

pneumococcal, as well as recurrent bacteremia in some of these patients.

If the child appears well and the evaluation has not revealed a source for the fever that requires hospitalization, the child may be sent home (if the child's caregiver can be easily contacted and has the means to return if necessary) with instructions to return if symptoms worsen or if the patient develops lethargy or will not take adequate amounts of fluids. A follow-up evaluation by telephone or by a revisit to the child's regular provider or the ED should be scheduled for the next day.

Evaluation of the Ill-Appearing, Febrile, HIV-Positive Child

The HIV-positive child who comes to the ED with fever and appears ill should be treated like other ill-appearing, febrile children because they are likely to be infected with the same types of organisms that infect immunocompetent children. A lumbar puncture is indicated for meningismus, change in mental status, or fever in children whose underlying abnormal mental status makes them difficult to assess. If a child is believed to be so unstable that lumbar puncture is not safe, it can be delayed until later. In either case, the child should be started on parenteral broad-spectrum antibiotics immediately. Ceftriaxone (100 mg/kg per day divided every 12 hours) is an appropriate choice because it covers the organisms that most commonly cause sepsis in children. Especially in young children, because of the possibility of PCP presenting with fever and ill appearance, trimethoprim–sulfamethoxasole (TMP-SMZ) (5 mg/kg per dose every 6 hours) should be added to the antibiotic regimen if there are respiratory symptoms, with or without a positive chest radiograph. Treatment for suspected PCP should not be delayed because of fear of interfering with the diagnostic workup. Fungal infections, with the exception of oral thrush, are uncommon in HIV-infected children. However, candidal sepsis must be considered in hospitalized patients who do not improve with antibiotics.

Evaluation of the HIV-Positive Child with Persistent Fever

Chronic fever is common in HIV-infected children. It can have many causes, and the evaluation of children with fever of unknown origin is often difficult and not always revealing. The major focus of such a workup in the ED is to rule out bacterial infection. A careful history and physical examination should be followed by a CBC; urinalysis; chest and sinus films; and blood, urine, and stool cultures. Recurrent otitis media is commonly seen, and some children may have recurrent parotitis or sinusitis. If no source is obvious and the basic workup is negative, more unusual infections need to be considered. Tuberculosis, although common among HIV-infected adults, is uncommon in children but may be more likely among adolescents. MAI may cause chronic fevers in HIV-infected children. It is often associated with anemia secondary to bone marrow infiltration and can be cultured from blood, stool, and bone marrow. Numerous viruses can cause chronic infections associated with fever in these children. Epstein-Barr virus (EBV) and CMV are among the more common, with CMV often presenting with chronic hepatitis and bloody diarrhea. It may also cause pneumonia and retinitis. A blood buffy coat specimen can be sent for CMV antigen detection. Most HIV-positive children with fever of unknown origin are hospitalized to facilitate the diagnostic process. The possibility that the fever is caused by one of the many drugs the child may be taking must also be considered.

Soft-Tissue Infections

Clinical Presentation

Cervical adenitis and cellulitis are common and may be accompanied by fever. Both cervical adenitis and cellulitis may be secondary to alterations in the child's immune status or may be on a mechanical basis because of superinfection of already enlarged lymph glands (in the case of cervical adenitis) or disruption of the normal skin by other lesions such as condylomata, molluscum, or vesicular and follicular eruptions. Acute bacterial adenitis in these patients is usually caused by *Staphylococcus aureus* or group A streptococci. Other less common causes, including *Bartonella*, the agent of cat-scratch disease, which can also cause bacillary angiomatosis and trench fever in these patients, should be considered.

Parotitis is a common soft-tissue infection that occurs in HIV-positive children who can have chronic enlargement of the parotid glands secondary to lymphocytic infiltration (Fig. 85.2). In these children, the parotid glands are enlarged and firm but nontender, and the overlying skin is not erythematous. With acute suppurative parotitis these children develop fever, tenderness over the parotid, and purulent drainage from Stenson's duct. *S. aureus* is the most likely offending organism.

FIGURE 85.2. Chronic parotitis in an HIV-positive child. (Courtesy of Dr. A. Rubenstein.)

Management

If the child appears well and the infection is well circumscribed and does not impinge on a critical structure such as the airway, outpatient antibiotic therapy active against *S. aureus* and *Streptococcus pyogenes* (e.g., cephalexin 60 to 80 mg/kg per day divided, four times daily) is appropriate as long as it appears that the caretaker can adhere to the regimen and the child can be reevaluated within 24 to 48 hours. In most cases, a blood culture should be obtained, particularly if the child has fever, has a history of an opportunistic infection, or does not appear well. In addition, the need for drainage (needle aspiration or surgical) must be considered. Children who are sent home must have close outpatient follow-up.

Pulmonary Infections

Just as respiratory complaints are common among immunocompetent children, so are respiratory conditions common in infants and children with HIV infection. They deserve special attention, however, because they are the most common cause of mortality in these patients. Documentation of oxygenation by pulse oximetry or arterial blood gas, blood culture for bacterial pathogens, nasopharyngeal specimens for rapid viral diagnosis, and viral culture should all be considered in any HIV-positive patient with respiratory symptoms. Chest radiographs should be obtained and can be helpful in determining the cause (Fig. 85.3). Decisions regarding sputum induction or bronchoscopy do not usually need to be made in the ED.

Pneumocystis carinii *Pneumonia*

Background

PCP is the most common serious opportunistic infection in HIV-infected children. Although PCP can occur at any age, in children it develops most commonly between the ages of 2 and 6 months and may be the first presentation of HIV infection. Moreover, the first episode is often acute in onset and may be fatal; overall, the fatality rate is about 40%.

For the most part, the results of immunologic studies are not available to the emergency physician. However, particularly relevant differences between adults and children should be noted in case the results of CD4 lymphocyte counts are known. Among adults, absolute CD4 lymphocyte counts are associated with the risk of acquiring PCP. Prophylaxis against PCP is recommended for adults with CD4 counts lower than 200 cells/µL (or previous oropharyngeal candidiasis). In young children, CD4 counts cannot be used to exclude the risk of PCP. Among HIV-infected children diagnosed with PCP, only 26% of infants 0 to 5 months of age will have a CD4 lymphocyte count of 1500 cells/µL or lower, but by 6 to 11 months of age, this is unusual, although 25% will still have CD4 counts in the range of 750 to 1499 cells/µL. For indications for PCP prophylaxis (and prophylaxis of other infections complicating HIV), see Table 85.2. When indicated, recommended prophylaxis is 150 mg TMP/m^2 per day with 750 mg SMZ/m^2 per day administered as follows: twice a day for 7 days per week; twice a day for 3 consecutive days per week; or a single daily dose for 3 consecutive days per week. For patients who do not tolerate TMP-SMZ, either Dapsone 2 mg/kg (not to exceed 100 mg) orally once per day can be given (as tolerated) or pentamidine can be given. Pentamidine is 300 mg via Respirgard II inhaler monthly for children when tolerated (usually those older than 5 years of age). Pentamidine (4 mg/kg) can also be given intravenously every 2 to 4 weeks.

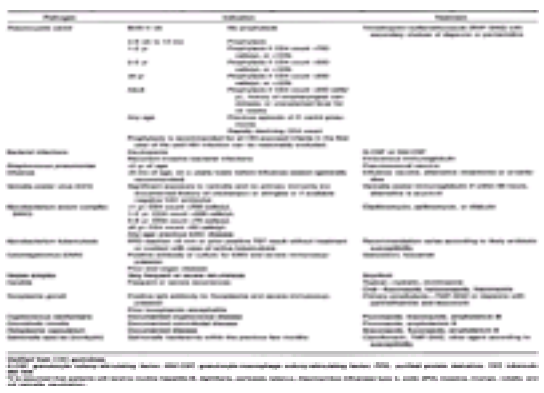

Table 85.2. Prophylaxis of Infections in Human Immunodeficiency Virus (HIV) Infected Patients[a]

Clinical Manifestations

PCP presents as an acute or subacute illness. The infant typically is febrile, with marked tachypnea, wheezing, rhonchi, and diminished breath sounds. Rales are not usually part of the PCP picture, and cough may be absent. When coughing is present, it is typically dry and nonproductive. Over hours to days, the patient develops hypoxia and increased respiratory distress.

Management

When PCP is suspected, the physician should intervene to maintain the airway as necessary, obtain an arterial blood gas or room air pulse oximetry, and provide supplemental oxygen. A chest radiograph and a serum lactate dehydrogenase (LDH) should be ordered. The patient typically has a high (greater than 30 mm Hg) alveolar-arterial (A-a) oxygen gradient and low oxygen saturation, and generally there is marked (greater than 500 IU) elevation of the serum LDH. Radiographic findings typically consist of a diffuse interstitial ("ground glass") pattern, but in infants, there may be patchy infiltrates or complete opacification of the lung fields. Occasionally, however, there may be clear lung fields with hyperinflation suggestive of bronchiolitis, and in 5 to 10% of patients with PCP, the chest radiograph appears normal.

It is often difficult to make the diagnosis of PCP in the ED. If PCP is suspected on the basis of the history, physical examination, or the results of the laboratory investigation, it is appropriate to start IV TMP-SMZ at a dosage of 20 mg/kg per day of TMP divided into 4 doses daily. The child should be hospitalized for close observation and further diagnostic evaluation should it be needed. In general, patients with PCP do not respond rapidly to antibiotic therapy. Patients intolerant of TMP-SMZ can be treated with pentamidine (4 mg/kg per day as a single daily dose) or atovaquone, but these should be considered second-line agents. The addition of corticosteroid therapy in children with severe PCP improves survival and their use is generally recommended. Patients suspected of having PCP should undergo bronchoalveolar lavage (BAL). Results of BAL will remain positive 3 to 4 days after the initiation of TMP-SMZ therapy. Therefore, if PCP is suspected, appropriate therapy should be started immediately and not be withheld pending lavage.

Bacterial Pneumonia

Background and Clinical Manifestations

The HIV-positive child with bacterial pneumonia is most often infected with the usual organisms: *Streptococcus pneumoniae, Hemophilus influenzae,* group A streptococcus, and *Moraxella catarrhalis.* Hospitalized children or those with indwelling devices may be infected with Gram-negative enteric organisms or *S. aureus.* In addition, these children often present with coinfection by respiratory viruses.

Management

A chest radiograph should be part of the evaluation of the HIV-positive child with fever of unknown origin or with respiratory signs or symptoms. The radiograph can help distinguish bacterial pneumonia (Fig. 85.3) from PCP or pulmonary lymphoid hyperplasia (PLH), and in fact, a chest radiograph compatible with bacterial pneumonia in an otherwise well-appearing child suggests that outpatient therapy may be possible if other criteria are met (Table 85.3).

Age >6 months
Able to tolerate oral fluids and medication
Absence of signs of respiratory distress (e.g., flaring or retractions)
Respiratory rate
<45 respirations/minute if age <2 years
<30 respirations/minute if age >2 years
Oxygen saturation ≥93%
Has not already worsened while receiving oral antibiotic
Close clinical follow-up available and patient able to return
Pneumocystis carinii pneumonia should be considered unlikely

Table 85.3. General Guidelines for Outpatient Therapy of Human Immunodeficiency Virus–Positive Children with Pneumonia

The chest radiograph in bacterial pneumonia typically reveals a lobar or segmental infiltrate, and the peripheral WBC count is often above 20,000/mm^3. However, because many of these children are leukopenic when not infected, it may be difficult in the ED to determine what constitutes leukocytosis. For example, a child whose normal WBC count is 2,000/µL may mount a WBC of 8,000 to 10,000/µL in response to a bacterial infection, but this would go unnoticed without knowledge of the child's baseline. Because it is rare to be confident that a pneumonia is not bacterial in origin, children with pulmonary signs and symptoms, especially associated with fever, are commonly given antimicrobial therapy against the common respiratory flora.

Other Pulmonary Infections

Other infections associated with respiratory signs and symptoms in HIV-positive children include viral illnesses, CMV

pneumonia, Mycobacterium tuberculosis, and MAI. Except for M. tuberculosis, which is surprisingly rare in HIV-infected children compared with adults, there has been little documentation of the frequency of the other infections. Adults have also had problems with coccidioidomycosis, blastomycosis, and histoplasmosis.

Wheezing

Background and Clinical Manifestations

Reactive airway disease is the most likely diagnosis in an HIV-positive child with wheezing, with or without fever. If the wheezing is associated with rales, however, the physician needs to consider the possibility of PCP or congestive heart failure. Congestive heart failure is rarely a presenting sign of HIV infection; instead, HIV-positive children with cardiomyopathy can develop congestive heart failure when under additional stress caused by an infection or fever. Physical examination may reveal the constellation of tachycardia, tachypnea, rales, and a palpable liver. However, these findings commonly occur in HIV-positive children without congestive heart failure.

Management

After a rapid but thorough physical examination to evaluate the degree of wheezing and air movement, the presence and location of retractions, and any other focus for fever, note whether the child responds to bronchodilator therapy. If so, reactive airway disease is the likely diagnosis, and the child can be treated accordingly. Pulse oximetry should be performed before the patient is discharged; although an oxygen saturation less than 95% is not an absolute indication for admission, a saturation of 95% or greater is reassuring. Five days of prednisone therapy (2 mg/kg per day divided into two doses, 60 mg/day maximum) can be given if it would be used for an immunocompetent child with the same clinical findings.

If the child has high fever (greater than 39°C [102.2°F]), a chest radiograph should be obtained to look for an infiltrate or evidence of PCP or congestive heart failure. The febrile child with wheezing and rales or evidence of pneumonia on chest radiograph who otherwise appears well enough for outpatient therapy may be given oral amoxicillin (60 to 80 mg/kg per day) or intramuscular (IM) ceftriaxone (50 mg/kg) in addition to bronchodilator therapy. However, no data provide clear support for this practice. These children should be reevaluated within 24 hours.

Children with clinical or radiographic evidence of PCP or congestive heart failure should be hospitalized. A first dose of IV TMP-SMZ should be given to infants suspected of having PCP, and congestive heart failure should be treated with afterload reducers and diuretics in addition to bronchodilators (see Cardiology section).

Lymphocytic Interstitial Pneumonitis

Background

Lymphocytic interstitial pneumonitis (LIP) is a condition that is relatively unique to pediatric HIV infection. It is thought to result from lymphoproliferative responses to Epstein-Barr DNA.

Clinical Manifestations

LIP is an insidious condition that causes a slowly progressive hypoxia typically in children who are older than 1 year of age. Table 85.4 contrasts the findings in LIP with those associated with PCP. Most children present to the ED with cough and mild tachypnea.

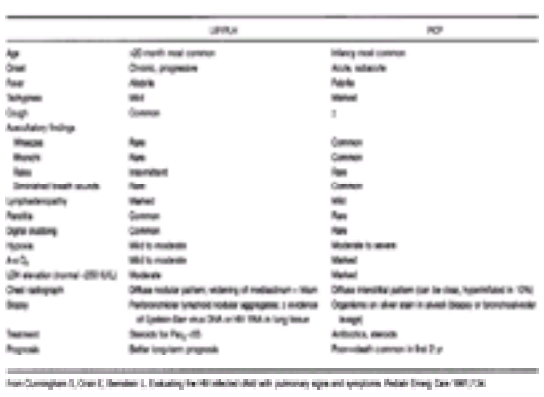

Table 85.4. Findings in Human Immunodeficiency Virus (HIV)–Positive Children with Lymphoid Interstitial Pneumonitis/Pulmonary Lymphoid Hyperplasia (LIP/PLH) vs. *P. carinii* pneumonia (PCP)

Typically, there will be marked lymphadenopathy and sometimes digital clubbing because of the chronic progressive hypoxia. Although in LIP there can be some elevation in the A-a oxygen gradient and LDH, the degree of elevation is usually less than with PCP, and it is not difficult to differentiate between the two entities.

Management

The approach to the evaluation of the HIV-infected child with respiratory signs and symptoms is outlined in Figure 85.4.

FIGURE 85.4. Evaluation of persistent respiratory signs and symptoms. *LDH*, lactate dehydrogenase; *CBC*, complete blood count; *Rx*, treatment; *PCP, Pneumocystis carinii* pneumonia. (Modified from Cunningham SJ, Crain EF, Bernstein LJ. Evaluations of the HIV-infected child with pulmonary signs and symptoms. Pediatr Emerg Care 1991;7:32–37.)

Rarely is intervention required to maintain the airway in children with LIP. Most HIV-positive children with a cough should undergo chest radiography. Chest radiography commonly reveals an interstitial nodular pattern that can be diagnostic. Occasionally, bronchiectasis develops, and these children may become superinfected with bacterial or viral pathogens and have fever. Fever is an important differentiating point in the management of HIV-positive children thought to have LIP. If the Pa_{O_2} is less than 65 mm Hg, LIP is treated with 1 to 2 mg/kg per day of prednisone to a maximum of 60 mg for 2 to 4 weeks and subsequently tapered as necessary to maintain the Pa_{O_2} above 70 mm Hg. If the patient is febrile, tuberculosis or MAI must be ruled out before beginning steroid therapy; these entities can appear similar to PLH both clinically and radiographically, but steroid therapy is contraindicated.

Gastrointestinal Tract

Chronic or recurrent oral thrush or esophageal candidiasis are common and can be treated with nystatin, clotrimazole, or fluconazole.

Diarrhea

Background

The gastrointestinal tract generally shows only subtle changes in histology in HIV infection unless there are secondary infections. In addition to the common causes of diarrhea that affect immunocompetent children, HIV-positive children are prone to parasitic *(Giardia, Microsporidium, Cryptosporidium)*, chronic viral (CMV), mycobacterial, and serious bacterial infections of the gastrointestinal tract (Table 85.5). Malnutrition is a common problem in HIV infection and, in children, requires careful monitoring of growth parameters.

Viral agents	*Shigella*
Rotavirus	*Escherichia coli*
Adenovirus	*Clostridium difficile*
Norwalk agent	*Giardia lamblia*
Cytomegalovirus	*Cryptosporidium*
Salmonella species	*Isospora*
Yersinia enterocolitica	*Microsporidia*
Campylobacter	

Table 85.5. Organisms Associated with Acute Diarrhea in Human Immunodeficiency Virus–Positive Children

Clinical Manifestations and Management

The general evaluation of the child with diarrhea is described in Chapter 19. Because diarrhea can be such a problem in HIV-infected children, the physician should seek to identify the cause. A stool test for blood, a stool smear for polymorphonuclear leukocytes, and a stool culture (for *Salmonella, Shigella, Yersinia, Campylobacter, Escherichia coli*) with consideration given to sending stool to test for parasites and *Clostridium difficile*. The child who is afebrile, appears to be well hydrated, and has no blood or leukocytes in the stool can be treated symptomatically with dietary management and close follow-up. If the child attends a day-care program and is still in diapers, the parents/guardians should be instructed to keep the child home until the illness has resolved and the culture is negative.

In febrile children with gastroenteritis, although viral causes are still most common, *Salmonella* is the primary bacterial pathogen of concern and is a major cause of bacteremia in HIV-positive children. If there is blood or more than 5 leukocytes per high-power field on examination of the stool smear but the child has normal vital signs and looks well, he or she should be treated with TMP-SMZ and reevaluated the next day. Oral ampicillin is an alternative drug, but in many

areas, 20 to 30% of *Salmonella* species are resistant to ampicillin. The child who appears dehydrated or ill should be admitted for IV hydration and parenteral antibiotic therapy.

If the patient remains symptomatic in the face of a negative stool culture and dietary management, a total of at least three stool specimens should be sent for ova and parasite evaluation and two samples tested for *C. difficile* toxin. If no cause is identified, endoscopy or colonoscopy should be considered, depending on the severity of symptoms.

Hematologic

Hematologic abnormalities are common and can be the result of HIV infection itself (occurring early or late in the illness), can be secondary to other concomitant infections (*Mycobacteria*, cytomegalovirus, parvovirus B19, fungal infections) or lymphoma, or can result from medication toxicities. Anemia is the most common, especially with zidovudine therapy; erythropoietin levels may be low, identifying patients likely to benefit from erythropoietin therapy. Nutritional deficiencies are common and may contribute to the anemia as well. Neutropenia is common and may be accentuated by medications (e.g., zidovudine, ganciclovir, TMP-SMZ) but is generally mild. If necessary, granulocyte colony–stimulating factor (G-CSF) or granulocyte-macrophage colony–stimulating factor (GM-CSF) can be given with improvement of the neutropenia. Thrombocytopenia is a typical part of the acute HIV infection and can persist or worsen over time. Improvement is often seen with antiviral therapy. If the thrombocytopenia is severe, it can generally be managed as would the non–HIV-infected patient with idiopathic thrombocytopenia (steroids, Rhogam, or gamma globulin).

Rash

Background and Clinical Manifestations

Of all the categories of dermatologic manifestations of HIV infection in children, seborrheic dermatitis and infections are by far the most common. This is in contradistinction to HIV-positive adults in whom neoplasms, particularly Kaposi's sarcoma, are seen more often. Measles can be particularly severe in HIV-positive children. The illness may be associated with the characteristic clinical signs and symptoms of generalized rash, coryza, conjunctivitis, cough, and Koplik's spots, or it may occur without the typical rash. The HIV-infected child with measles must be evaluated carefully for signs of dehydration and respiratory distress. If the child is taking liquids well and breathing comfortably, he or she may be sent home with careful instructions to return for reevaluation if status worsens. All HIV-positive children who have been exposed to measles should receive gamma globulin (0.5 mL/kg with maximum of 15 mL given intramuscularly), whether or not they have been vaccinated against measles.

Varicella can also cause severe illness in the immunocompromised host. Varicella-zoster immunoglobulin should be given to HIV-infected children after exposure to chickenpox (1 vial containing 125 U for each 10 kg of body weight with any opened vial used completely, maximal dose is 5 vials). Once clinical illness has started, these children should initially be treated with IV acyclovir (10 mg/kg every 8 hours). Children with local zoster infection may be treated with oral acyclovir (20 mg/kg per dose given every 6 hours). These children must be followed closely to ensure that the infection does not disseminate.

More than 10% of children infected with HIV will have thrombocytopenia associated with high levels of circulating immune complexes and antiplatelet antibodies that may manifest as petechiae or easy bruising. Patients with fewer than 50,000 platelets/µL should be considered for admission and treatment. Febrile or toxic-appearing HIV-positive children with petechiae must be considered to have septicemia (see Chapter 84). After a rapid assessment of the airway, breathing, and circulation, these patients should undergo a full evaluation for sepsis, including lumbar puncture, and they should receive parenteral antibiotics pending culture results.

Syphilis screening should be done for any HIV-infected child whose syphilis serology at birth is unknown because women with HIV have a high rate of coinfection with syphilis.

Neurologic Manifestations

Background

Once transmitted to the central nervous system, a neurotropic HIV strain emerges. In the early 1980s, a progressive dementia was reported in adults with AIDS. A syndrome analogous to the adult AIDS dementia complex was described in HIV-infected children in 1985 and was called AIDS encephalopathy. As it turns out, AIDS encephalopathy is common and does not require other manifestations of full-blown AIDS. More than 85% of children with HIV infection have neurologic involvement, and the possibility of HIV infection should be considered in the differential diagnosis of developmental delay or loss of milestones.

Clinical Manifestation.

These children exhibit developmental delay or developmental regression, acquired microcephaly, and pyramidal tract signs. Although growth and development are often affected by any serious illness in a child, AIDS encephalopathy may occur in patients with no signs of opportunistic infections and few signs of immunodeficiency. AIDS encephalopathy may manifest itself as a static, progressive, or indolent encephalopathy with periods of plateaus in cognitive and motor development. Static encephalopathy is defined by the presence of nonprogressive cognitive or motor deficits. Progressive encephalopathy usually begins within 2 months to 5 years after initial exposure to HIV, usually in the perinatal period. It is characterized initially by deterioration of play and progressive apathy. Developmental delay ensues, with loss of developmental milestones, including deficits in socially adaptive language and in fine and gross motor skills. As the condition progresses, there may be spastic diplegia and quadriparesis. Patients develop extrapyramidal and cerebellar signs, including rigidity, dystonic posturing, and ataxia. Seizures, although uncommon, may occur.

Another group of children present with indolent encephalopathy. These patients experience variable plateaus in their development during which there is little or no further cognitive growth. Either new milestones are not obtained or the rate of acquisition of new skills deviates from the norm and the child's initial rate of developmental progress. Many of these children may go on to develop the progressive form of AIDS encephalopathy.

Physical examination of the patient often reveals microcephaly. Younger children will be hypotonic with persistence of the Moro or tonic neck reflexes after 4 months of age. Older children may have symmetric ankle clonus and extensor plantar responses. As the condition progresses, pyramidal signs of varying severity, including a pure spastic quadriparesis with signs of pseudobulbar palsy, dysphagia, and dysarthria, are seen. Ataxia may be seen in children old enough to walk.

Managemen.

The diagnosis of AIDS encephalopathy involves obtaining a history suggestive of developmental delay or regression in an HIV-infected child. Management is more complicated when these children come to the ED with fever because it may be difficult to evaluate their mental status. In general, a lumbar puncture is necessary to rule out bacterial meningitis, unless the physician can be confident on a clinical basis that the child is behaving at baseline and that the fever is not secondary to central nervous system infection.

Other Neurologic Manifestation.

HIV-infected children are at increased risk of meningitis (including cryptococcal although less commonly than in adults, and tuberculous meningitis), encephalitis (including that caused by *Toxoplasma*), stroke and cerebral infarcts, progressive multifocal leukoencephalopathy (caused by human polyomavirus JC), and a variety of vasculopathies.

Cancers

Cancers have been seen less commonly in children than in adults. The most common malignancy of children with AIDS are non-Hodgkin's lymphomas; the second most common are leiomyomas and leiomyosarcomas in the gastrointestinal tract, and these are associated with EBV infection. Some other malignancies have also been linked to specific viral infections. Kaposi's sarcoma is associated with human herpes virus-8 infection, some peripheral lymphomas and most primary to the brain contain EBV, and anal cancers and cervical carcinomas are linked with human papilloma virus infections.

MANAGEMENT OF HUMAN IMMUNODEFICIENCY VIRUS

Overview of Anti-HIV Medications

Many effective anti-HIV medications are now available (Table 85.6). At present, these are in two general classes.

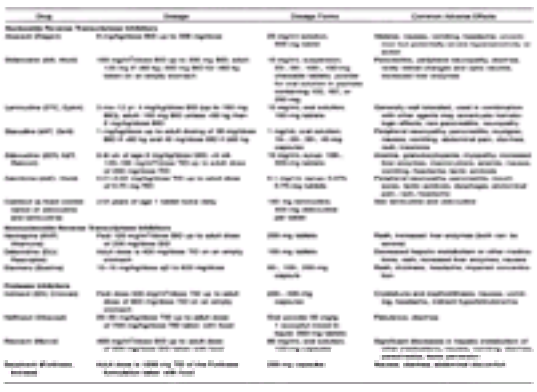

Table 85.6. Anti–Human Immunodeficiency Virus Medications

Reverse transcriptase inhibitors are nucleoside analogs that compete with the viral reverse transcriptase such as AZT (Retrovir, zidovudine), ddI (Videx, didanosine), ddC (Hivid, zalcitabine), d4T (Zerit, stavudine), abacavir (Ziagen), and 3TC (Epivir, lamivudine) or nonnucleoside reverse transcriptase inhibitors such as nevirapine (Viramune), delaviradine (Rescriptor), or etavirenz (Sustiva).

Protease inhibitors such as nelfinavir (Viracept), saquinavir (Invirase), ritonavir (Norvir), and indinavir (Crixivan) work by blocking a protease enzyme responsible for cleaving viral proteins into functional units.

Because HIV has the capacity to rapidly develop resistance to individual antiviral agents, combination therapy using three to four agents has now become the treatment standard.

Unfortunately, drug therapy is significantly limited. None of the drugs currently available has been shown to eradicate infection. The efficacy of these antivirals in various tissues that 1) may harbor virus, 2) be important in spread of virus, or 3) be important to symptomatology (e.g., lymph nodes, brain, testes, mucosal surfaces) is not always known. These drugs also commonly cause significant side effects and drug interactions that may bring patients to the ED for attention. These most commonly include rash, headache, nausea, diarrhea, pancreatitis, fatigue, anemia, granulocytopenia, peripheral neuropathy, renal stones, decreased absorption of other medications, and increased or decreased metabolism

of other medications.

Prevention of HIV Acquisition

Development of an effective and safe vaccine for the prevention of HIV is a high priority but will be unavailable for several years. Current strategies for preventing HIV infection take advantage of the finding that it may take several hours after exposure (or possibly in some cases days) for HIV infection to become established. During this time, antiviral medications can be given to prevent the transmitted virus from causing an established infection. Prevention of perinatal acquisition through the use of anti-HIV medications during the last trimester of pregnancy and the first few weeks of infancy (only AZT has been studied) has been successful in significantly reducing the risk of infection. The introduction of AZT therapy has largely been credited with the reduction in pediatric HIV cases currently seen in the United States. Unfortunately, the cost of this treatment is prohibitive in the countries where 90% of HIV infections occur. In addition, antiviral medications have significant side effects, and when considered for use to prevent transmission of HIV, the risk of drug toxicity must be weighed against the risk of HIV acquisition and the potential benefit of therapy. The risk of acquisition from exposures to HIV are listed in Table 85.7.

Exposure	Risk of Infection (per 1000)
Transfusion with positive blood unit	950
Intravenous drug use	7
Percutaneous exposure (needlestick)	3
Receptive anal intercourse	3
Receptive vaginal intercourse	1
Receptive oral sex	Low but reported
Perinatal exposure without zidovudine	250
Perinatal exposure with zidovudine	80
Breast-feeding (not single exposure)	120

Table 85.7. Approximate Risk of Human Immunodeficiency Virus Acquisition after a Single Exposure Listed by Source

Postexposure Prophylaxis

Community Exposures

Sexual contact is the most common means of transmitting HIV infection, and reducing exposure is the mainstay of public health efforts. Prophylaxis after sexual intercourse or sharing needles could potentially decrease transmission, although efficacy has not yet been demonstrated. A patient with a significant exposure to HIV, such as receptive or penetrative anal or vaginal sex, receptive oral intercourse with ejaculation, or needle sharing involving a partner who is HIV positive or who is in a known risk group should be considered for postexposure prophylaxis (PEP). At the time of this writing, no consensus guidelines have been published regarding PEP for sexual assault victims. The possibility of HIV transmission with such contacts should be discussed with the victim, the risk of transmission assessed, and PEP offered or recommended if appropriate. Risk becomes more than low risk if there is ejaculation (to risk area), multiple assailants, injuries that involve blood, evidence to suggest illicit drug use on the part of the assailant(s), and/or threats or suggestion that the assailant(s) is HIV positive. The patient who has had consensual sex with an individual known to have or to be at high risk of having HIV in which safe sex practices were not followed (or failed, e.g., broken condom) should also be offered HIV prophylaxis and risk reduction counseling.

Accidental community-acquired needlestick exposures also require attention. HIV has been detected and infectious virus has been recovered from syringes obtained from high-risk community sources. Most discarded syringes will not have any recoverable HIV, and if complete drying of the syringe has occurred, there will be no infectious HIV. Thus far, no report exists of transmission of HIV from a discarded syringe left in a public place. Therefore, the risk of transmission of HIV from an accidental needlestick from a needle/syringe found in a public place is likely low. Prophylaxis should not be routinely recommended, but because the risk is not zero, careful discussion with the family should include the need for subsequent monitoring and testing of the patient. Voluntary sharing of needles among IV drug abusers would pose a substantially higher risk because immediate use of the needle would result in a greater likelihood of infectious virus being transmitted. A prophylaxis strategy in this situation would demand the patient remove themselves from ongoing exposures, placing them at risk of acquiring HIV.

When considered appropriate (Fig. 85.5), PEP should be instituted as quickly as possible after exposure. Most would limit PEP to exposures within 72 hours of exposure (preferably less than 24 hours). Patients receiving PEP should receive first doses of medication in the ED and will need follow-up with clinicians knowledgeable about antiviral therapies and able to provide intensive emotional and behavioral counseling to help cope with the immediate event and to help them avoid situations likely to result in future exposure. The medications, which must be taken for 4 weeks, can have significant side effects.

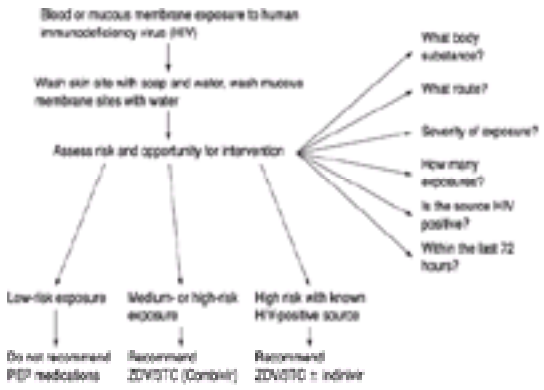

FIGURE 85.5. Postexposure prophylaxis for possible community acquired exposures to human immunodeficiency virus. When available, additional information regarding the source individual may alter recommendations. *PEP*, postexposure prophylaxis.

Health Care Worker Exposures

An increased risk for HIV infection after percutaneous exposures to HIV-infected blood is associated with the quantity of blood, as indicated by visible contamination of the device with the patient's blood, its use directly in a vein or artery, or a deep injury to the health care worker. It is likely to increase with a higher viral load in the patient's blood. Finally, the risk of acquiring HIV is decreased an estimated 80% by the prompt postexposure use of effective antiretrovirals. Each health care institution should have a system to evaluate their employees occupational exposures and offer treatment. As of December, 1997, the Centers for Disease Control and Prevention was aware of 54 health care workers that had documented seroconversion after occupational exposures and another 132 HIV-positive health care workers who are likely to have acquired infection after an occupational exposure.

DEHYDRATION

Isotonic Dehydration

Background

Isotonic dehydration reflects a loss of total body water coupled with a loss of sodium (Na) of an equal magnitude. Clinically significant dehydration occurs commonly in children. Several factors predispose infants and children to dehydration, including 1) the frequent development of acute infections with high fevers, 2) a tendency to develop vomiting and diarrhea with both nonenteral and enteral infections, and 3) the greater ratio of surface area to mass of the child.

Children may lose fluids through the gastrointestinal (GI) tract, the kidneys, and/or the skin. In the otherwise healthy child, GI losses account for most instances of dehydration, the majority of these being caused by viral or bacterial enteritis.

Pathophysiology

An understanding of dehydration in the child requires a familiarity with fluid balance in the healthy person, as well as the pathophysiology of excessive fluid losses. The daily maintenance fluid requirement is directly related to caloric expenditure. Because surface area correlates best with caloric expenditure, this parameter often serves as a guide to fluid therapy. However, the physician either must memorize estimated surface areas for children of various ages or calculate the area for each child by using a nomogram based on height and weight. Alternatively, the weight alone can rapidly provide a basis for establishing maintenance requirements. Because surface area increases at a slower rate than body mass (weight), the increment in maintenance fluids per kilogram decreases as the child grows in size. The maintenance requirement can be calculated from the following formulas:

Weight (kg)	Fluid/24 hours
<10 kg	100 mL/kg
11–20 kg	100 mL × 10 + 50 mL for each kg over 10 kg
>20 kg	100 mL × 10 + 50 mL × 10 + 20 mL for each kg over 20 kg

The maintenance requirement for electrolytes directly relates to the caloric expenditure, which also determines the requirement for water. For Na, this is 2 to 3 mEq/100 mL, and for potassium (K), 2 mEq/100 mL. As an example, a 30-kg child would have a daily maintenance requirement for fluid of 1700 mL (100 mL/kg × 10 kg + 50 mL/kg × 10 kg + 20 mL/kg × 10 kg). The requirement for Na would be 34 to 51 mEq, and for K, 34 mEq.

Isotonic dehydration is defined as a loss of total body water with the maintenance of a normal serum [Na] ranging from 130 to 145 mEq/L. The final [Na] in the extracellular fluid (ECF) is a function not only of what is lost from the body but also of the composition of replacement fluids administered at home and transcellular shifts of fluid. The initial loss of fluid from the body depletes the ECF; gradually, water shifts from the intracellular space to maintain the ECF, and this fluid is lost if dehydration persists. If dehydration is acute (the duration of the illness is fewer than 3 days), approximately 80% of the fluid loss is from the ECF and 20% is from the intracellular fluid (ICF). Additional fluid moves out of the ICF if the loss continues for 3 days or more. In such cases, the proportion of fluid lost from the two compartments is 60% from ECF and 40% from ICF. ECF contains predominantly Na at a concentration of 140 mEq/L, and ICF contains K at a concentration of 150 mEq/L.

Clinical Manifestations

A careful history taken from the parents of a child with isotonic dehydration helps establish the cause for the fluid loss and to estimate the degree of depletion. Specific inquiries must be made about the volume of the child's intake and output, focusing on GI and renal function. The physician should ask about the amount and duration of vomiting, diarrhea, and other abnormal losses, as well as about the adequacy of urine flow. In infants, the absence of tears with crying and a decrease in the number of wet diapers suggest the presence of dehydration.

The physical examination should begin with a careful weighing of the child—the most accurate clinical indicator of dehydration. The signs of dehydration become increasingly severe as the degree of dehydration progresses (see Table 18.4). With a 5% loss of body weight, the skin and mucous membranes feel dry, but there are no signs of vascular instability. Tachycardia and hypotension appear as the loss of fluid exceeds this mark, and the skin turgor shows deterioration. The development of acidosis leads to tachypnea and contributes to poor peripheral perfusion. If the child has lost more than 10% of body weight in a brief time, signs of shock, including a rapid, thready pulse; marked hypotension; and cold, clammy skin, may appear (see Chapter 3).

I. Increased Total Body Na or Increased Total Body Na Greater Than Increased Total Body Water
A. Na poisoning (accidental; Na bicarbonate therapy)
B. Hyperaldosteronism (rare in children)
II. Normal Total Body Na; "Pure" Water Loss
A. Insensible losses—respiratory and skin
B. Renal (central and nephrogenic diabetes insipidus)
C. Inadequate access to water
III. Decreased Total Body Na Less Than Decreased Total Body Water
A. Extrarenal (gastrointestinal)*
B. Renal (osmotic diuretics; glucose, mannitol, urea)
C. Obstructive uropathy
IV. Normal Total Body Na and Water with Abnormal Central Osmotic Regulation of Water Balance
A. Essential hypernatremia

Na, sodium.
*In diarrheal states, hypernatremia usually results from a combination of relatively greater water than Na losses coupled with relatively greater Na than water replacement.

Table 86.4. Causes of Hypernatremia

By definition, the [Na] falls within the normal range, 130 to 145 mEq/L, in isotonic dehydration. In mild dehydration, the serum bicarbonate is usually 15 to 20 mEq/L, but it may drop to 6 to 10 mEq/L with more severe losses. The [K] is usually normal (3.5 to 5.0 mEq/L), although transcellular shifts from acidosis may elevate the serum level (p. 821). The blood urea nitrogen (BUN) rises proportionately to the degree of fluid loss, varying from 20 to 30 mg/dL in mild dehydration to 50 to 100 mg/dL in more severe cases. However, the BUN may show less of an increase than expected from the clinical estimate of dehydration if the child's protein intake has been significantly limited in the preceding 24 to 48 hours.

Urine flow is usually scant and may even be absent, but an effort should be made to obtain a specimen. In older children with dehydration, the specific gravity rises above 1.020, often reaching 1.035. Infants, however, have a relative lack of renal concentrating ability. Even in the face of severe dehydration in the child in the first 3 months of life, the urine specific gravity may be only 1.020.

Management

In all children with significant dehydration (5% or greater), an intravenous (IV) infusion should be started and blood sent to the laboratory for measurement of electrolytes and BUN. The child with shock demands immediate fluid resuscitation and monitoring as described in Chapter 3. An initial fluid bolus of 20 mL/kg physiologic saline given rapidly in 30 to 60 minutes is the treatment of choice. With lesser degrees of dehydration, the optimal type and rate of fluid infusion are

calculated on the basis of the child's estimated ideal weight and degree of dehydration. Sufficient fluids are administered in the first 24 hours to fulfill the maintenance requirement and correct the total deficit; half the deficit is replaced in the first 8 hours.

Example

A 5-month-old infant has a 3-day history of diarrhea and a decreased oral intake. One week previously, she weighed 5.0 kg in the pediatrician's office. Now she weighs 4.5 kg and has a temperature of 37.0°C (98.6°F), pulse of 120 beats/minute, respiratory rate of 30 breaths/minute, and blood pressure (BP) of 30/40 mm Hg. The child's skin and mucosa are dry, and the skin shows “tenting” if lifted. The urine specific gravity is 1.028, and the serum electrolytes are as follows: [Na] 135 mEq/L; [K] 4.0 mEq/L; [Cl] 90 mEq/L; and HCO_3] 9.0 mEq/L. The BUN is 30 mg/dL.

This infant has lost 10% of her body weight. Because acute decreases in weight reflect fluid loss, the fluid deficit is 500 mL. Dehydration has occurred over 3 days, indicating that 60% of the loss is from the ECF and 40% from the ICF. Thus, the Na and K deficits are calculated as follows:

$$\text{Na deficit} = 135\ \text{mEq/1000 mL} \times 0.6 \times 500\ \text{mL} = 40\ \text{mEq}$$

$$\text{K deficit} = 150\ \text{mEq/1000 mL} \times 0.4 \times 500\ \text{mL} = 30\ \text{mEq}$$

The maintenance requirements for this infant are 500 mL of fluid (100 mL/kg × 5 kg), 15 mEq of Na (3 mEq/100 mL × 500 mL), and 10 mEq of K (2 mEq/100 mL × 500 mL) for each 24-hour period.

Half of the fluid and Na deficits are replaced during the first 8 hours of rehydration. Thus, the infant would receive 250 mL of deficit fluid with 20 mEq of Na. In addition to this, one-third of the maintenance requirement, or 175 mL of fluid with 5 mEq of Na, would be given during that 8-hour period, for a total of 425 mL of fluid with 25 mEq of Na.

Only half of the K deficit is corrected during each of the first 2 days, and this is done at a constant rate. Because the maintenance K for this infant is 15 mEq and the deficit is 30 mEq, the amount of K administered would be 30 mEq daily (or 10 mEq for each 8-hour period) for the first 48 hours. The solution would also need to contain an appropriate amount of bicarbonate (p. 820). A maintenance amount of bicarbonate is 2 mEq/kg per day.

Hypotonic Dehydration

The pathophysiology and clinical findings for hypotonic (hyponatremic) dehydration are discussed in the section under Disorders of Sodium Homeostasis: Hyponatremia, below. An example follows.

Example

The 5-month-old infant described under the previous section on isotonic dehydration might well have presented with more pronounced clinical manifestations of dehydration and the following serum electrolytes: [Na] 128 mEq/L; [K] 4.0 mEq/L; [Cl] 90 mEq/L; and [HCO_3^-] 9.0 mEq/L. The BUN is 30 mg/dL.

Deficits of Na and K are calculated in the same fashion as given in the previous example of isotonic dehydration. Maintenance requirements are also the same. What is different about the calculations in this example is the added Na requirement in the deficit fluids to bring the serum Na from 128 to 135 mEq/L. The calculation should be as follows:

1. $\text{Additional mEq of Na} = [135 - 128\ \text{mEq/L}]_{\text{“ideal” – “observed”}} \times \underbrace{5.0}_{\text{“healthy” body weight (kg)}} \times \underbrace{0.6}_{\text{Na space}}$
2. $\text{Additional mEq of Na} = 7.0\ \text{mEq/L} \times 5\ \text{kg} \times 0.6 = 7.0 \times 3.0\ \text{L (kg)}$
3. $\text{Additional mEq of Na} = 21\ \text{mEq}$

This extra Na is added to the previously calculated 40 mEq Na in the deficit fluids, but the rate of repair may be staged in the same fashion as for isotonic dehydration.

Hypertonic Dehydration

The background, pathophysiology, clinical manifestations, and management of hypertonic (hypernatremic) dehydration are discussed under Hypernatremia (p. 816).

ELECTROLYTE DISORDERS

Disorders of Sodium Homeostasis: Hyponatremia

Background

Hyponatremia is defined as a measured serum [Na] of less than 130 mEq/L. This common electrolyte abnormality is commonly encountered in the emergency department (ED). The multiple causes of hyponatremia are grouped into four

categories (Table 86.1).

I.	Normal Total Body Water and Na (Hyperosmolar Hyponatremia)
	A. Hyperglycemia[a]
	B. Mannitol, glycerol therapy
II.	Increased Total Body Water and Na (Edema-Forming States)
	A. Congestive heart failure
	B. Nephrosis
	C. Cirrhosis
	D. Acute renal failure
III.	Decreased Total Body Water and Na (Hypovolemic States)
	A. Gastrointestinal losses (vomiting, diarrhea, fistulas)
	B. Renal losses (diuretics, renal tubular acidosis, primary interstitial disease)
	C. Adrenal (mineralocorticoid deficiencies)
	D. Third-space losses (ascites, burns, pancreatitis, peritonitis)
IV.	Increased Total Body Water but Normal Total Body Na
	A. Syndrome of inappropriate antidiuretic hormone secretion
	B. Water intoxication
	C. Miscellaneous (reset osmostat, hypothyroidism, glucocorticoid deficiency)
V.	Pseudohyponatremia
	A. Extreme hyperlipidemia or hyperproteinemia

Na, sodium.
[a]For every 100 mg/dL rise in plasma glucose concentration above normal, there is a correspondingly decrease in plasma sodium concentration of approximately 1.6 mEq/L.

Table 86.1. Causes of Rhabdomyolysis

Pathophysiology

Basic Mechanisms

Two fundamental principles regulating Na and water balance must be reviewed. First, total body Na determines ECF volume. This is because water moves freely throughout all body compartments to restore a disturbed osmotic equilibrium, and Na is the predominant ion of the ECF space. Second, the kidney normally defends against hyponatremia by its ability to dilute the urine. Any disorder that impairs urinary dilution will lead to hyponatremia (e.g., syndrome of inappropriate antidiuretic hormone [SIADH]). Hyponatremia may result after the restoration of osmotic equilibrium in response to an absolute or relative gain of water or an absolute or relative loss of salt from the body. Total body Na can be normal, low, or even increased in the face of hyponatremia.

Applications

In the edema-forming states (Table 86.1, II), a decreased effective circulating plasma volume is sensed by the kidney as hypoperfusion. Sodium is maximally reabsorbed, the urine is concentrated (ADH is secreted in excess), and hyponatremia often ensues. Acute reduction in glomerular filtration rate (GFR) and decreased delivery of fluid to the distal tubular diluting site often result in hyponatremia in acute renal failure (ARF); this is often exacerbated by patients ingesting hypotonic fluids.

Extrarenal losses of Na and water seen with diarrhea and or vomiting lead to negative Na balance and a diminished ECF volume (Table 86.1, III). Under these hypovolemic conditions ADH is released; the activation of the volume receptors leads to increased ADH secretion even in the face of hyponatremia. Water reabsorption is maximal, the urine is concentrated, and hyponatremia results. Preservation of the ECF volume and maintaining perfusion takes precedence over avoiding hyponatremia. Renal and adrenal Na wasting may be disease or drug induced (Table 86.1, III). Structural renal disease also impairs Na and chloride reabsorption at the diluting site, leading to hyponatremia. A negative Na balance and ECF volume contraction occur in the face of inappropriately high urine Na concentrations. ADH secretion is stimulated, and renal water excretion falls. Hyponatremia occurs in states with a normal total body Na, but abnormally increased water intake or excess ADH secretion (Table 86.1, IV).

Pseudohyponatremia (Table 86.1,V) develops when significantly elevated lipid or protein concentrations expand the nonaqueous plasma volume, and the laboratory reports Na concentrations in liters of plasma and not plasma water. Extreme hyperproteinemia and/or hyperlipidemia may result in an apparently low Na concentration in the ECF by decreasing the percentage of water contained in a unit volume of plasma (normally 93%). This displacement is given by the formula:

$$\text{mL of } H_2O \text{ per 100 mL of plasma} = 91.1 - [(1.03 \times \text{total lipid in g/dL}) + (0.73 + \text{total protein in g/dL})].$$

The most common causes of hyponatremia seen in the ED are GI losses and water intoxication. The latter occurs particularly in infancy and has been increasingly reported in recent years.

Clinical Manifestations

Symptoms and signs of hyponatremia are related to the absolute level and the rate of fall of serum Na from the normal range, but they tend to be somewhat nonspecific (Table 86.2). A child may be dramatically symptomatic at a serum Na of 125 mEq/L if the Na had fallen 15 mEq/L in only 1 to 2 hours and equilibrium had not yet been restored. In contrast, another child might be totally asymptomatic at a serum Na of 120 mEq/L if the Na had fallen 20 mEq/L in 2 to 3 days and osmotic equilibrium had been reestablished. Signs and symptoms are usually seen at serum Na lower than 120 mEq/L, but specific symptoms and signs do not correlate with specific levels of serum Na. The clinical examination can help in limiting the possible diagnoses to explain the hyponatremia. It is especially critical to note the presence of edema (Table 86.1, II) and hypovolemia (Table 86.1, III).

Symptoms	Signs
Anorexia	Clouded sensorium
Nausea	Decreased tendon reflexes
Muscle cramps	Pathologic reflexes
Lethargy	Cheyne-Stokes respiration
Apathy	Hypothermia
Disorientation	Pseudobulbar palsy
Agitation	Seizures
Acute respiratory failure	

Table 86.2. Symptoms and Signs of Hyponatremia

Complications of hyponatremia that require urgent diagnosis and treatment include Cheyne-Stokes respirations and seizures. However, a clouded sensorium and pathologic reflexes are often warning signs of seizures. The laboratory studies required to initiate the assessment of most children with symptomatic hyponatremia are given in Table 86.3.

I. Blood	II. Urine
A. Electrolytes (Na, K, Cl, HCO3)	A. Urinalysis, including specific gravity
B. BUN, creatinine	B. Urine Na
C. Liver function tests	C. Urine creatinine
D. Osmolality	D. Urine osmolality

Na, sodium; K, potassium; Cl, chloride; HCO3, bicarbonate.

Table 86.3. Laboratory Evaluation of Hyponatremia

Management

Armed with a working knowledge of pathophysiology, the clinical history and examination, and the few simple laboratory tests as outlined in Table 86.3, the emergency physician should be able to diagnose rapidly the specific cause of hyponatremia in most cases. A specific diagnosis is necessary because therapies differ significantly depending on the cause of the hyponatremia. A working schema is outlined in Figure 86.1. If measurement artifacts are ruled out, one must determine whether underlying disease, such as congestive heart failure, is present. If none of these conditions are present, the presence or absence of edema will be helpful; if no edema is appreciated, one must look for evidence of third spacing as in the case of pancreatitis. In the absence of third spacing, relevant historical questions may point in the direction of dehydration. If the patient is not dehydrated but hyperkalemia is present, this may suggest congenital adrenal hyperplasia or Addison's disease. The absence of hyperkalemia may point to polydipsia or inappropriately prepared formula as a cause. If not, and the urine osmolality is greater than serum osmolality, SIADH is possible. If the urine osmolality is normal, mild dehydration, occult water intoxication, or underlying disease should be considered (Table 86.1).

FIGURE 86.1. Diagnostic approach to hyponatremia. *SIADH,* syndrome of inappropriate secretion of antidiuretic hormone.

In the patient with hyponatremia in the face of obvious contraction of ECF volume (diarrhea or vomiting), reexpansion with isotonic saline is appropriate. The volume and rate of infusion are dictated by estimates of fluid loss (i.e., weight loss) made from the history and physical examination. In shock, 20 mL/kg isotonic saline can be administered rapidly over 1 hour or more as needed and then repeated as necessary until BP and peripheral circulation return to normal. Underlying diseases, such as renal tubular acidosis (RTA) and adrenal insufficiency, can be treated most effectively by

specific replacement therapy. Diuretics, if previously given, should be discontinued promptly.

In water intoxication, restriction of daily free water administration by 25 to 50%, depending on the chronicity and severity of the hyponatremia, is the treatment of choice. In the acutely ill patient with neurologic symptoms and signs, immediate relief may be accomplished temporarily by rapidly elevating the serum Na by 10 mEq/L up to 125 mEq/L with the IV administration of 3% sodium chloride as follows: mL 3% NaCl (0.5 mEq/mL) to give = 10 mEq/L × body weight (kg) × 0.6 (ECF space). Alternatively, 10 to 12 mL/kg of 3% NaCl can be infused over 1 hour. In adults, the rapid overcorrection of hyponatremia (e.g., an increase in serum Na of more than 2 mEq/L per hour) may be dangerous, producing the crippling or even fatal osmotic demyelination syndrome. The risk of this is greatest when a rapid overcorrection is made in a case of chronic hyponatremia.

In simple water intoxication, the normal kidney responds with maximal urinary dilution, which, when coupled with restriction of water intake, rapidly restores Na concentration to normal. In SIADH, water restriction is the initial treatment of choice but is not always effective. In the edema-forming states and ARF, hyponatremia is usually mild and water restriction usually suffices. In some patients, diuretics may be necessary to treat the underlying disease. In such situations, free water excretion is increased but at the risk of inducing ECF volume contraction through increased Na excretion. Admission is recommended for any patient with symptomatic hyponatremia or hyponatremia per se (less than 130 mEq/L) when the cause is not obvious.

Disorders of Sodium Homeostasis:Hypernatremia

Background

Hypernatremia is defined as a measured serum Na concentration of greater than 145 mEq/L in the ECF. As with hyponatremia, the causes of hypernatremia can be grouped into four major categories (Table 86.4) on the basis of net changes in total body water and Na.

Pathophysiology

In hypernatremia, either an absolute or relative water deficit can occur in the face of normal, increased, or even decreased total body Na (Table 86.4). In Na poisoning, water moves into the ECF in response to an increase in Na, and the initial physical findings are usually those of obvious expansion of the ECF (Table 86.4, I). Eventually, some of this “new” ECF water is lost when the kidney excretes the extra Na.

An important cause of hypernatremia in pediatrics is the ADH-deficiency syndrome (Table 86.4, II.B), caused by partial or complete central diabetes insipidus and partial or complete nephrogenic diabetes insipidus. These patients with “pure” renal water losses never manifest signs of ECF expansion or depletion, unless they are denied free access to water or have an associated hypothalamic (e.g., third center) disturbance, in which case signs of ECF volume depletion supervene. Normally, the maximum stimulus for urinary concentration is a body weight loss of 3 to 5%; this response is blunted or absent in diabetes insipidus, and the urine is inappropriately hypotonic. Compulsive water drinking is sometimes confused with pituitary diabetes insipidus but can be easily separated. Occasionally, a child loses large quantities of water through hyperventilation or sweating in a hot, humid environment without adequate water replacement, leading to hypernatremia. Here, too, the normal renal response concentrates the urine.

When total body Na is reduced through abnormal GI fluid losses, the physical signs are those of contraction of the ECF with recent weight loss, dry mucous membranes, and once fluid losses are significant, poor skin turgor (Table 86.4, III.A). The renal response is directed toward restoring the ECF volume with maximum conservation of Na and water. Thus, the urine is concentrated and contains little Na. During an osmotic diuresis, more water than Na is lost, resulting in hypernatremia and volume depletion. Excessive solute, not reabsorbed in the proximal tubule, obligates water delivery distally and impairs free water generation. This leads to a reduced renal concentrating capacity, enhancing urinary Na and water losses (Table 86.4, III.B).

The most common cause of hypernatremia encountered in the ED is hypernatremic dehydration secondary to diarrhea.

Clinical Manifestations

Most symptoms and signs of hypernatremia result from cellular dehydration as water moves into the ECF space to lower osmolality. Brain cells are the most vulnerable to water loss, especially if the loss is acute. Symptoms and signs range from lethargy and irritability to muscle weakness, convulsions, and coma. However, if hypernatremia develops more slowly, brain cells defend their volume by manufacturing additional intracellular solute, so-called idiogenic osmoles such as the amino acid taurine, that reduces water loss to the ECF. Therefore, symptoms and signs are related not only to the level of serum Na concentration but also to its rate of rise. By the same token, therefore, rapid restoration of ECF osmolality to normal after the slow development of a hyperosmolar (e.g., hypernatremic) state does not permit brain cells to inactivate idiogenic osmoles, and cerebral edema may result. Finally, because ECF volume is defended early in the course of a dehydrating illness associated with hypernatremia, the classic physical sign of decreased skin turgor is absent until total fluid losses are severe (»10 to 15% of body weight).

The major complications of hypernatremia that require urgent diagnosis are seizures and coma. Central nervous system (CNS) signs and symptoms correlate with the degree of hypernatremia, but long-term neurologic sequelae do not, although they may be seen more often than previously thought in patients with initial serum Na values greater than 160 mEq/L.

The laboratory studies required to initiate the assessment of most children with symptomatic hypernatremia are the same as those given for hyponatremia in Table 86.3.

Management

As in the hyponatremic states, the emergency physician should be able to reach a specific category of disease or diagnosis armed with a working knowledge of pathophysiology, clinical evaluation of the status of ECF volume, and a few simple serum and urine tests.

Because emergency therapies vary considerably among the disorders noted in Table 86.4, accuracy of interpretation is important. The algorithm in Figure 86.2 provides a working schema. If there is no known underlying disease, one should probe for a history of excess sodium intake. If signs of dehydration are present, hypertonic dehydration is likely; in the absence of signs of dehydration, other conditions, such as hyperaldosteronism, should be considered.

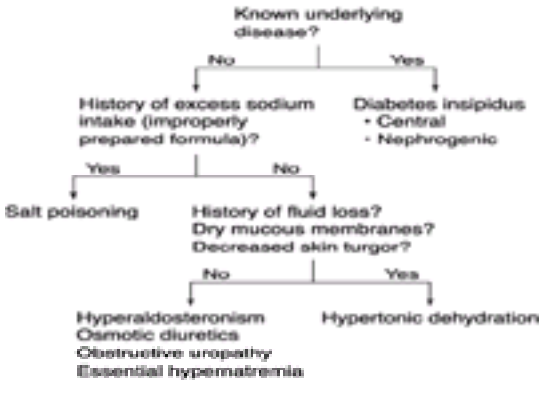

FIGURE 86.2. Diagnostic approach to hypernatremia.

In patients who are severely dehydrated and in shock, reexpansion with isotonic saline is the appropriate initial therapy (see Hyponatremia). Osmotic diuretics, if previously given, must be stopped. Replacement of water and Na losses with hypotonic electrolyte solutions is appropriate, but in the case of diarrhea, serum Na should be lowered slowly (usually no more than 10 to 15 mEq/L per 24 hours) to guard against brain edema. In hypertonic dehydration, a free-water deficit of 4 mL/kg for every 1 mEq/L of serum Na greater than 145 mEq/L should be replaced over 48 to 72 hours.

For example, a 5-month-old infant has a 3-day history of diarrhea. Last week she weighed 5.0 kg but now she weighs 4.5 kg. She has been receiving undiluted skim milk and “salt water” orally. Vital signs are normal. Electrolytes are as follows: [Na] 160 mEq/L; [Cl] 120 mEq/L; [CO_2] 10 mEq/L; and [K] 3.5 mEq/L. This patient has lost 10% of her body weight but is asymptomatic because of relative preservation of the ECF space in hypernatremia. That percentage of the total fluid deficit (i.e., 500 mL) that is to be replaced as solute-free water is calculated as follows:

$$\text{Free water (mL)} = [160 - 145\ \text{mEq/L}] \times 4\ \text{mL/kg} \times 5\ \text{kg} = 300\ \text{mL}$$

This is given slowly over 2 days to lower serum Na by approximately 10 mEq/L. The other 200 mL of the deficit are also given slowly over 2 days as solute-containing fluid. Calculation of the Na deficit (i.e., the amount of Na to put in the remaining 200 mL of volume deficit) can be made from any one of a number of general formulas based on certain fundamental assumptions about fluid and electrolyte physiology as discussed elsewhere (see Chapter 18). If one views the solute-containing fluid deficit as coming 40% from the ICF and 60% from the ECF, then deficits of Na and K are as follows:

1. ECF: $60\% \times 200\ \text{mL} \times 145\ \text{mEq/L}$, $[\text{Na}] = 17\ \text{mEq}$
2. ICF: $40\% \times 200\ \text{mL} \times 150\ \text{mEq/L}$, $[\text{K}] = 12\ \text{mEq}$

In patients with increased insensible water losses, simple free water replacement with glucose solutions is all that is required. Here, monitoring weight and serum Na concentrations are useful guides to the adequacy of therapy. Correction can usually be given over several days.

The emergency treatment of the diabetes insipidus syndromes is free water replacement, monitoring vital signs and clinical signs of dehydration, and serum Na concentration as guides to the rate and volume of replacement. There is no place for the various antidiuretic agents that promote ADH release or mimic its actions in central diabetes insipidus or for thiazide diuretics in nephrogenic diabetes insipidus as initial therapies.

Children who are victims of acute salt poisoning and who are severely symptomatic can safely have serum Na concentrations lowered rapidly, either by a combination of loop diuretics (furosemide 0.5 to 2 mg/kg every 12 hours) and glucose water administration or, rarely, peritoneal dialysis against a Na-free dialysate. The latter procedure should be carried out only in consultation with a nephrologist. Admission is recommended for any patient with symptomatic hypernatremia or severe hypernatremia per se (greater than 160 mEq/L) when the cause is not obvious.

Disorders of Potassium Homeostasis: Hypokalemia

Background

Hypokalemia is defined as a measured serum K concentration of less than 3.5 mEq/L. The three most common causes of hypokalemia seen in the pediatric ED are 1) gastric alkalosis from vomiting (e.g., pyloric stenosis), 2) chronic use of loop diuretics for conditions such as congenital heart disease and bronchopulmonary dysplasia, and 3) uncontrolled diabetic ketoacidosis (DKA). No specific environmental factors are known to result in hypokalemia. A rare genetic cause of hypokalemia that affects children is familial periodic paralysis. The causes of hypokalemia are varied. With the exception of transcellular shifts of K, most causes of hypokalemia result in increased renal K excretion, either as a primary or secondary event. The four major categories of hypokalemia are shown in Table 86.5.

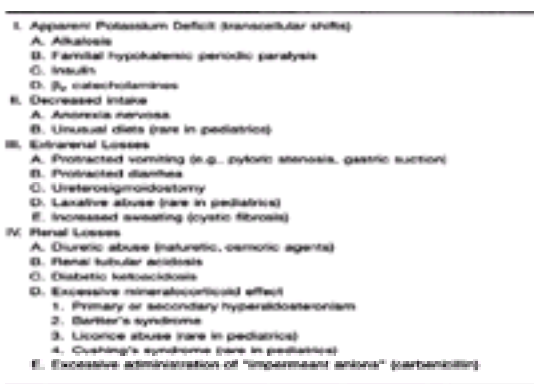

Table 86.5. Causes of Hypokalemia

Pathophysiology

Basic Mechanisms

When confronted with unexpected hypokalemia, the emergency physician is dealing with one of two pathophysiologic situations: 1) K shifts into cells in exchange for hydrogen ion (H^+), or 2) extrarenal or renal losses. Potassium shifts into cells in response to alkalosis and out of cells in response to acidosis; for every 0.1-unit rise or fall in pH, there is a reciprocal change in ECF K concentration of approximately 0.6 mEq/L. Insulin facilitates cellular uptake of K. In view of these observations and with the knowledge that K is primarily an intracellular cation, it can be appreciated that ECF K concentration does not reflect the status of total body K. Therefore, when evaluating total body K in light of disturbances in ECF K concentrations, one must know the plasma pH.

The mechanisms that govern renal K excretion are outlined in Table 86.6. Potassium is filtered at the glomerulus and reabsorbed in the proximal tubule (65%) and the ascending loop of Henle (25 to 30%). The K that appears in the urine is the result of distal tubular secretion. Hyperaldosteronism increases Na-K exchange in the distal tubule. Conditions that increase Na delivery to the distal tubule, such as volume expansion, also lead to increased K excretion.

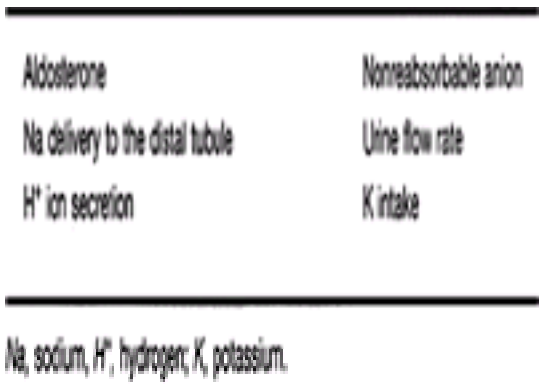

Table 86.6. Factors Governing Renal Potassium Excretion

Applications

Increased renal secretion of K is seen in 1) alkalosis, which increases distal tubular delivery of bicarbonate, 2) high cellular K concentration in response to elevated systemic pH, 3) increased urinary flow rate, and 4) increased K intake.

Potassium depletion and the resultant hypokalemia that occur with vomiting cannot result primarily from the K lost in the vomitus itself because gastric fluid concentration of K is only 5 to 10 mEq/L. Rather, renal losses account for most of the K deficit seen with vomiting. ECF volume depletion leads to secondary hyperaldosteronism, and alkalosis leads to increased bicarbonate delivery to the distal tubule. Both phenomena increase urinary losses of K. In addition, with continued volume depletion, alkalosis is maintained because the proximal tubule preferentially reabsorbs Na with bicarbonate to restore ECF volume (filtered chloride is reduced and K shifts into cells). Early in the course of vomiting, hypokalemia can be corrected merely by restoring ECF volume with isotonic saline without K supplements, providing

convincing evidence of the role of volume contraction in causing renal K wasting. Chronic diarrhea results in large K losses. Ureterosigmoidostomy can lead to K and bicarbonate secretion in exchange for Na and chloride (Cl) reabsorption, resulting in a hyperchloremic, hypokalemic acidosis. In cystic fibrosis, volume contraction can result from excessive cutaneous losses of water, Na, and Cl through increased sweating in the summer months. This may lead to renal K wasting and alkalosis.

One of the hallmarks of RTA is hypokalemia, which is paradoxical in view of the corresponding acidosis but occurs because renal K wasting results from secondary hyperaldosteronism and bicarbonaturia. The marked glycosuria of DKA increases urine flow rate and distal Na delivery, thus enhancing K excretion. Bartter's syndrome is an uncommon, poorly understood cause of hypochloremic, hypokalemic metabolic alkalosis. Hypokalemia is often profound and resistant to replacement therapy. The mechanism is probably either a primary renal chloride or K leak.

Clinical Manifestations

The cause of hypokalemia can usually be suspected as belonging to one particular diagnostic category after obtaining a careful history. For example, in familial periodic paralysis, the weakness comes on gradually over a few hours and may last 48 to 72 hours. It may be heralded by short episodes of weakness in one or more extremities. It usually occurs during periods of rest after vigorous exercise or a carbohydrate load.

Potassium depletion can result in widespread disturbances in cellular physiology and function, although symptoms are usually not seen at serum K concentrations above 3 mEq/L. The major abnormalities and their clinical consequences are listed in Table 86.7. The most important clinical manifestations of hypokalemia relate to abnormal neuromuscular function. Impulse formation and propagation and the resultant muscle contraction are impaired in both striated and smooth muscle, leading to ileus, tetany, skeletal muscle weakness, and if severe enough, paralysis and areflexia.

Muscle cell dysfunction (rhabdomyolysis)
Cardiac cell dysfunction (myocardiopathy, arrhythmias)
Neuromuscular dysfunction (weakness/paralysis, ileus, tetany, encephalopathy with underlying liver disease)
Renal (polydipsia, polyuria, concentration defect)

Table 86.7. Pathophysiological (Clinical) Consequences of Hypokalemia

Hypokalemia may cause rhabdomyolysis with myoglobinuria. Alteration of the cardiac action potential by slowing the rate of repolarization leads to conduction abnormalities and arrhythmias (see Chapter 82). However, although the signs and symptoms of hypokalemia generally parallel its rate of development and its severity, electrocardiogram (ECG) changes often fail to correlate with serum K. They are helpful if present but not reassuring if absent. In the presence of digitalis, however, hypokalemia is much more likely to produce cardiac arrhythmias.

Complications that require urgent diagnosis include acute respiratory failure from muscle paralysis, cardiac arrhythmias, and myoglobinuria, which can lead to ARF.

Laboratory and radiologic evaluations are outlined in Table 86.8. Generally, in situations of total body K depletion, a 1 mEq/L fall in serum K concentration reflects a 100 to 200 mEq K deficit. This figure may be somewhat lower in young children. The blood glucose rises in diabetes mellitus and creatinine phosphokinase with rhabdomyolysis. An increased BUN reflects contraction of ECF volume. If the electrolytes reveal a hyperchloremic hypokalemic metabolic acidosis with a normal anion gap and an alkaline urine pH, RTA should be suspected. When there is a hypochloremic metabolic alkalosis, the urine electrolytes are helpful. A urine chloride less than 10 mEq/L suggests vomiting, cystic fibrosis, or diuretic abuse as the cause of hypokalemia. A urine chloride greater than 20 mEq/L points to one of the disorders that lead to mineralocorticoid excess. When the urinary K is less than 10 mEq/L, several conclusions can be drawn. First, the K deficiency has probably been present for at least 2 weeks. Second, the kidney can be excluded as the route of K depletion. An elevated urinary K concentration, however, suggests either K wasting of short duration or a primary renal loss. In similar fashion, a urinary concentrating defect that persists in the face of a stimulus to concentrate bespeaks chronic K depletion.

Table 86.8. Laboratory Evaluation of Hypokalemia

Management

To effectively manage hypokalemia in the ED, one must delineate the source of the condition, as shown in Figure 86.3. An apparent K deficit (with normal total body K) caused by transcellular shifts may occur with alkalosis. Known underlying disease, such as cystic fibrosis and RTA, also causes hypokalemia. If the patient is acidotic, the emergency physician should consider DKA with a severe potassium deficiency, whereas alkalosis suggests conditions such as pyloric stenosis or cystic fibrosis. A normal pH indicates unusual diets (anorexia nervosa), Cushing's syndrome, or hyperaldosteronism.

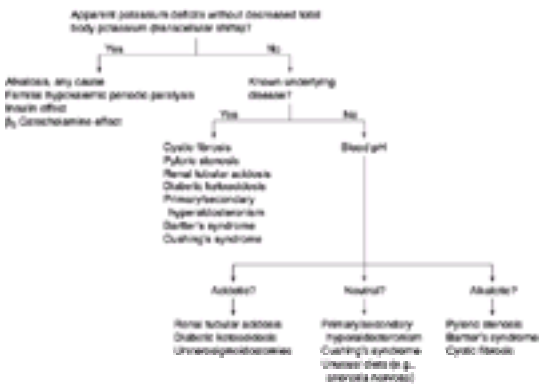

FIGURE 86.3. Diagnostic approach to hypokalemia.

When hypokalemia results from simple transcellular shifts in response to alkalosis without an accompanying K deficit, correction of the pH is all that is required. It is estimated that for every 0.1-unit change in pH, there is an average inverse change in the serum potassium of 0.6 mEq/L. In periodic paralysis, K supplementation with 2 to 6 mEq/kg per day is recommended with careful monitoring of serum K to avoid hyperkalemia as paralysis subsides. In most circumstances, K repletion should be slow (over days) and given by the oral route once urine flow is confirmed. IV loading should be avoided except under special conditions. Despite the fact that ECF K concentration does not reflect accurately total body K deficits, serum K concentration is the only practical way of assessing adequacy of replacement and avoiding unwanted complications. An estimate of the K deficit is generally obtained from the degree of hypokalemia and the blood pH, and it can be replaced over 2 to 3 days (assuming no ongoing losses) (Table 86.9). If IV replacement must be used, no more than 40 mEq/L of K should be given by peripheral vein and 80 mEq/L by central vein. In terms of the quantitative rate of repair, this should be no more than 0.2 to 0.3 mEq K/kg per hour. However, if potentially life-threatening cardiac arrhythmias or respiratory paralysis are evident, up to 1 mEq/kg per hour can be given by infusion pump with continuous ECG monitoring. Finally, the selection of the specific K salt used in repairing deficits is important. Generally, potassium chloride should be used if there is alkalosis, and potassium bicarbonate or its equivalent should be used if there is acidosis. In states of ECF volume depletion from any cause, volume replacement with isotonic saline is as important as K replacement in normalizing serum K and turning off renal K wasting.

Serum K (mg/L)	Plasma pH	K Deficit (%)
2.9	7.6	18
2.5	7.5	15
3.0	7.4	10
3.5	7.3	10

Table 86.9. Twenty-kg Child; Total Body Potassium = 40–50 mEq/kg or 800–1000 mEq

The child with symptomatic hypokalemia requires admission for therapy and monitoring (and possibly for diagnostic workup), as do most children with a serum K of less than 3.0 mEq/L.

Disorders of Potassium Homeostasis: Hyperkalemia

Background

Hyperkalemia is defined as a measured serum K concentration greater than 5.5 mEq/L. No specific environmental factors are known to result in hyperkalemia. The causes of hyperkalemia are varied. With the exception of transcellular shifts of

K, most of the common causes of hyperkalemia result from impaired renal excretion because of decreased glomerular filtration, low urine flow, or decreased tubular secretion. Occasionally, exogenous or endogenous (i.e., from cell breakdown) K loading is responsible for the observed hyperkalemia. The categories of hyperkalemia are shown in Table 86.10.

I. Pseudohyperkalemia (Hemolysis, extreme leukocytosis, or thrombocytosis)
II. Apparent K Excess (Transcellular shifts)
A. Acidosis
III. Increased Intake
A. Endogenous (rhabdomyolysis, massive hemolysis)
B. Exogenous (suicide attempt with K salts)
IV. Decreased Excretion
A. Acute or chronic renal failure (oliguria)
B. Adrenal corticoid deficiency (acute adrenal insufficiency, hyporeninemic hypoaldosteronism)
C. Use of K-sparing diuretics in renal failure or in conjunction with dietary K supplements
D. β-Blockers converting enzyme inhibitors

K, potassium.

Table 86.10. Causes of Hyperkalemia

Pathophysiology

Pseudohyperkalemia is seen when blood is drawn after prolonged application of a tourniquet but is easily diagnosed by repeating the K measurement after drawing blood without a tourniquet. It may also occur with extreme leukocytosis or extreme thrombocytosis. In these situations, the diagnosis is made by measuring the white blood cell (WBC) or platelet count or plasma K. Hyperkalemia that results from transcellular K shifts in response to acidosis can be seen with normal or decreased total body K. In the former case, simple correction of the pH is all that is required. However, hyperkalemia from acidosis usually occurs in the face of total body K deficits such as diarrheal dehydration or DKA. In such a case, it is vitally important to begin K replacement as the pH is being returned to normal, thus avoiding a sudden fall in serum K concentration as it shifts back into cells.

The pathophysiology of hyperkalemia in cases of endogenous K release from cells is straightforward. Cellular catabolism occurs in the face of negative nitrogen balance from any cause; in pediatrics, this usually results from dietary protein restriction. Injury from trauma or burns can accelerate K delivery into the ECF, but life-threatening hyperkalemia rarely ensues if renal function is intact. The most common cause of hyperkalemia encountered in the ED is probably metabolic acidosis followed by reduced renal excretion. The latter occurs commonly in ARF from any cause, especially when there is concomitant oliguria. (See Table 86.6 for factors that control urinary K excretion.) In adrenal corticoid deficiency states or in patients who receive K-sparing diuretics, distal tubular secretion of K is impaired.

Clinical Manifestations

The predominant symptoms and signs are neuromuscular. Paresthesias are followed by weakness and even flaccid paralysis. Major toxicity is reflected in the ECG. The earliest change is symmetric peaking of the T wave, then widening of the P-R interval. First-degree heart block, loss of the P wave, ventricular arrhythmias, and cardiac standstill may follow. Cardiac arrest is more commonly seen with hyperkalemia than with hypokalemia. In general, the ECG changes parallel the degree of hyperkalemia when it has developed acutely. The presence of any ECG changes associated with hyperkalemia mandates urgent diagnosis and therapy.

The laboratory evaluation of hyperkalemia is outlined in Table 86.11. Although hypokalemia may cause rhabdomyolysis, hyperkalemia is often an early and life-threatening consequence of rhabdomyolysis from other causes. An elevated BUN and creatinine point to ARF. The urinary electrolyte pattern of the untreated patient can be helpful if adrenal corticoid deficiency is suspected. In acute adrenal insufficiency, urine Na concentration is inappropriately high and urine K concentration is inappropriately low for their respective serum concentrations.

Na, sodium; K, potassium; Cl, chloride; HCO_3, bicarbonate.

Table 86.11. Laboratory Evaluation of Hyperkalemia

Management

Determining the origin of hyperkalemia is crucial before managing this life-threatening condition. Figure 86.4 provides an algorithm for ascertaining the cause. If the patient has apparent K surplus, conditions such as hemolysis or metabolic acidosis may be responsible. Conversely, if there is no evidence of K surplus, a known underlying disease such as acute adrenal insufficiency may be present. When there is no known underlying disease and the blood pH indicates acidosis, acute or chronic oliguric renal failure may offer an explanation. Alkalosis points to excessive potassium intake, rhabdomyolysis, or ingestion of K-sparing diuretics, b-blockers, or angiotensin-converting enzyme (ACE) inhibitors. A normal pH suggests a hyporeninemic state.

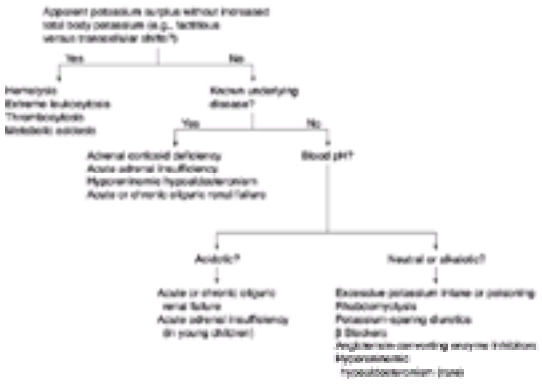

FIGURE 86.4. Diagnostic approach to hyperkalemia.

Three general techniques are used (Table 86.12) to lower serum K levels to normal: 1) reverse the membrane effects, 2) transfer K into cells, and 3) enhance renal excretion of K. If patients are asymptomatic, serum K is less than 6.5 mEq/L, and the ECG is normal or reveals only peaked T waves, all that may be required is discontinuation of K intake, removal of K-sparing diuretics if they are being used, and treatment of acidosis. Exceptions to this occur in acute oliguric renal failure and rhabdomyolysis, in which the serum K level may rise to much higher levels precipitously, and a more aggressive therapeutic approach is indicated.

Technique	Agent	Dose	Route of Administration	Onset/Duration of Action	Comment
Reversal of membrane effects	10% Calcium Gluconate	0.5 mL/kg	3-5 min IV	Min/30-60 min	ECG monitor; discontinue if pulse rate <100
Movement of K into cells	Na bicarbonate, 7.5% (1 mEq = 1 mL)	2-4 mL/kg	30-60 min	30 min/1-4 hr	May use in the absence of acidosis
	Glucose 50% plus insulin (regular)	1 unit for every 3-4 g glucose	Bolus	Bolus	Monitor blood glucose
Enhanced excretion of K	Kayexalate	1 g/kg	Can be given in 10% glucose (1 g/3-4 mL) every 4-6 hr	Hours/variable	Can be given PO or by rectum

IV, intravenous; ECG, electrocardiogram; K, potassium; Na, sodium; PO, orally

Table 86.12. Emergency Treatment of Hyperkalemia

When ECG changes are more widespread and/or serum K is greater than 7.0 mEq/L, several available therapies are designed to move K into cells acutely, including glucose and insulin combination and Na bicarbonate. The latter agent has recently been shown to be effective even in the absence of acidosis. With the onset of cardiac arrhythmias or a serum K level greater than 8.0 mEq/L, urgent therapy is needed. Under continuous ECG monitoring, IV calcium is given first to reverse potentially life- threatening arrhythmias without altering serum K. Calcium accomplishes this by restoring a more normal differential between the threshold and resting transmembrane potentials. This then may be followed by glucose and insulin and Na bicarbonate.

For more long-term control of hyperkalemia, the cation exchange resin Na polystyrene sulfonate (Kayexalate) can be administered. Finally, in patients with oliguric renal failure, peritoneal dialysis removes potassium, although the immediate fall in serum levels may reflect redistribution caused by the alkalinizing effect of dialysis and the glucose load in the dialysate itself. The dosages of drugs used to treat hyperkalemia, the recommended rates of administration, and onset of action are detailed in Table 86.12.

Any child with symptomatic hyperkalemia or a serum K level greater than 6.5 mEq/L on a nonhemolized sample deserves admission for therapy and additional workup.

Disorders of Calcium Homeostasis: Hypocalcemia

Background

Hypocalcemia beyond the neonatal period is defined as a measured total serum calcium (Ca) concentration of less than 9.0 mg/dL. There are three major categories of hypocalcemia in infants and children, as noted in Table 86.13.

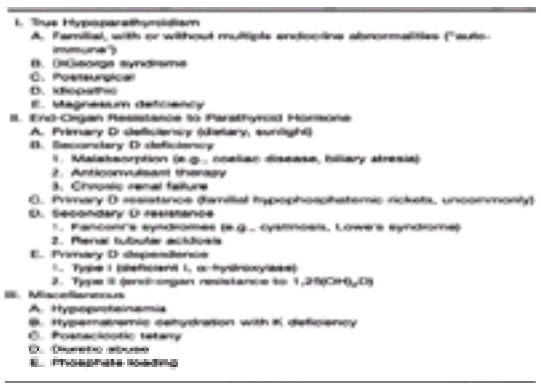

Table 86.13. Causes of Hypocalcemia

Pathophysiology

Basic Mechanisms

The skeleton contains 99% of total body Ca; the remaining 1% is distributed in intravascular, interstitial, and intracellular fluids. Most of the skeletal Ca is in a nonexchangeable pool and is unavailable for moment-to-moment regulation of Ca homeostasis. In addition, there is an as yet unclear but reciprocal relationship between serum Ca and serum inorganic phosphorus; factors that raise phosphorus result in a lowering of Ca and vice versa. The active form of vitamin D [1,25(OH)$_2$D] promotes Ca and phosphorus absorption from the gut when present in physiologic concentrations. It also enhances the parathyroid hormone (PTH)-dependent mobilization of Ca from mineralized bone and has a small but important action on the renal conservation of Ca. Thus, 1,25(OH) $_2$D is a Ca-promoting hormone that serves to raise serum Ca in response to hypocalcemia and/or increased tissue demands for Ca. PTH secretion is enhanced by hypocalcemia and suppressed by hypercalcemia. Serum Ca is raised in response to increased PTH by at least two mechanisms: 1) increased Ca resorption from bone and 2) increased renal excretion of phosphorus. Calcitonin acts in response to hypercalcemia by inhibiting bone resorption and thereby lowering Ca delivery into the ECF. The action of 1,25(OH)$_2$D and PTH is through receptor binding and stimulation of mediators such as cyclic adenosine monophosphate (cAMP). Therefore, hypocalcemia could result from an absolute deficiency of one or both of these compounds, end-organ resistance caused by a lack of receptors or abnormal receptor binding, or impaired formation or action of the mediators.

Applications

Examples of all of these potential abnormalities have now been described and are outlined in Table 86.13. The causes of hypocalcemia listed under Table 86.13, I and II are rarely encountered in the ED.

In simple or primary vitamin D deficiency, impaired Ca absorption and bone resorption cause the observed hypocalcemia, although 1,25(OH)$_2$D may be normal or even elevated in blood. The anticonvulsant agents diphenylhydantoin and phenobarbital probably induce hepatic microsomal enzymes that increase the conversion of 25(OH)D in the liver to inactive metabolites. In addition, diphenylhydantoins also interfere with intestinal calcium absorption. Hypocalcemia is uncommon in children who take anticonvulsant agents unless they are also receiving a poor Ca intake and have little sunlight exposure. When chronic renal insufficiency is moderate to severe (i.e., GFR of 50% of normal or lower), a decrease in renal mass leads to decreased production of 1,25(OH) $_2$D. In addition, decreased renal excretion of phosphorus causes hyperphosphatemia and a reciprocal fall in serum Ca. Secondary hyperparathyroidism then ensues. Dietary intake of Ca is often decreased in these patients. For all of these reasons, hypocalcemia is common and often resistant in this condition. Occasionally, hypocalcemia is seen in ARF, especially when acidosis is vigorously treated with alkali.

Hypocalcemia is not commonly seen but may occur in familial hypophosphatemic rickets. In RTA, the combination of hypercalciuria secondary to obligatory bicarbonaturia and acidosis and probable impairment in 1,25(OH) $_2$D production may lead to hypocalcemia. Hypocalcemia is often profound and refractory to therapy in the various forms of vitamin D dependence. The characteristic blood profile in this and the other abnormalities of vitamin D metabolism are outlined in Table 86.14.

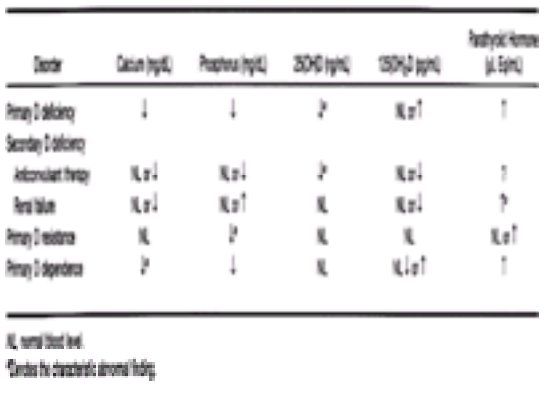

Table 86.14. Blood Profile in Disorders of Vitamin D Metabolism

Hypocalcemia that results from a lowered protein-bound fraction is commonly associated with the hypoproteinemia of nephrotic syndrome or protein-losing enteropathy, although ionized Ca is normal. The hypocalcemia is mild, usually in the range of 7.5 to 9.0 mg/dL, and rarely causes symptoms. Hypernatremic dehydration in association with a K deficit results in hypocalcemia for reasons that are unclear. Overvigorous correction of acidosis, especially in the dehydrated child, will drive Ca into bone, resulting in hypocalcemic tetany. Diuretic abuse with the potent loop blockers (ethacrynic acid, furosemide) may cause massive hypercalciuria and hypocalcemia, especially in the face of a hypochloremic alkalosis. Phosphate loading, either exogenous or endogenous (e.g., lysis of tumor cells), results in hyperphosphatemia, with a corresponding fall in serum Ca until the extra phosphorus is excreted.

Clinical Manifestations

The signs and symptoms of hypocalcemia per se are primarily neuromuscular in origin. Nonspecific findings (vomiting, muscle weakness, and irritability) are common. In addition to the characteristic tetany and positive Chvostek's and Trousseau's signs, there may be frank seizures or laryngospasm with upper airway obstruction. Rickets is characterized by thinning of the inner table of the skull (craniotabes), enlarged costochondral junctions (rachitic rosary), and thickening of the wrists and ankles. The ECG may reveal a prolonged Q-T interval.

Complications that require urgent diagnosis include frank tetany, laryngospasm, and seizures. Laboratory studies that should be included in the initial evaluation are listed in Table 86.15. The diagnosis of primary hypoparathyroidism is established by finding hypocalcemia, hyperphosphatemia, undetectable PTH, and a normal renal and skeletal (calcemic) response to exogenous PTH. Hypomagnesemia may also result in functional hypoparathyroidism. The characteristic laboratory profiles of the various vitamin D abnormalities are outlined in Table 86.14. In this latter group of diseases, symptomatic hypocalcemia is often preceded by poor linear growth and clinical rickets.

Table 86.15. Laboratory Evaluation of Hypocalcemia

Management

Specific therapy varies by diagnosis (Fig. 86.5). If there is an apparent Ca deficit (without evidence of hypocalcemia), hypoalbuminemia must be considered. When calcium deficiency is suspected, the serum phosphate must be measured. If this value is normal, entities such as anticonvulsant therapy and malabsorptive syndromes may explain the hypocalcemia. If the serum phosphate level is elevated, true hypoparathyroidism should be considered. A low serum phosphate level suggests primary vitamin D deficiency, RTA, or other conditions (Fig. 86.5).

FIGURE 86.5. Diagnostic approach to hypocalcemia.

The emergency treatment of choice for hypocalcemia from any cause other than hypomagnesemia is IV calcium. It should be given under cardiac monitoring at a starting dose of 0.5 to 1.0 mL/kg as 10% Ca gluconate administered over 3 to 5 minutes. The infusion should stop if the heart rate falls below 60 beats/minute. Once symptoms are relieved, Ca gluconate can then be added to the IV solution (100 mg of elemental Ca/kg per 24 hours) or Ca may be administered orally. When magnesium deficiency is suspected or confirmed as the cause of hypocalcemia, magnesium should be administered, usually by the intramuscular (IM) route. One gram of 50% magnesium sulfate contains 99 mg of magnesium, or roughly 8 mEq. The dose of magnesium is 0.5 mEq/kg (6 mg/kg) or 0.125 mL/kg of the 50% solution.

Children with unanticipated hypocalcemic tetany, seizures, or laryngospasm should be admitted for treatment and workup for the underlying cause of the hypocalcemia.

Disorders of Calcium Homeostasis: Hypercalcemia

Background

Hypercalcemia is defined as a measured total serum Ca concentration of greater than 11.0 mg/dL. This discussion excludes hypercalcemia in the newborn. The major causes of hypercalcemia in infants and children are outlined in Table 86.16. Hypercalcemia can result from increased Ca absorption from the gut or increased Ca resorption from bone. Hypercalcemia occasionally results from a massive increase in dietary Ca intake or a reduction in the renal excretion of Ca.

I. Primary Hyperparathyroidism (rare in pediatrics)
  A. Sporadic
  B. Familial (with or without associated endocrine abnormalities)
II. Infantile Hypercalcemia
III. Vitamin D Intoxication
IV. Immobilization
V. Malignant Disease
  A. Bony metastases (especially associated with lymphoreticular malignancy)
  B. Ectopic production of parathyroid hormone or other bone-resorbing factors
VI. Miscellaneous
  A. Sarcoidosis (rare in pediatrics)
  B. Thiazide diuretics
  C. Hypervitaminosis A

*This list is not meant to be comprehensive but includes the important causes in children.

Table 86.16. Causes of Hypercalcemia[a]

Pathophysiology

In hyperparathyroidism, increased bone resorption of Ca results in hypercalcemia, and decreased renal reabsorption of phosphorus results in hypophosphatemia. Because PTH stimulates bone turnover, alkaline phosphatase is elevated. PTH is inappropriately elevated for the level of serum Ca and confirms the diagnosis.

The vitamin D toxicity syndromes can usually be suspected from the history; hypercalcemia is the result of increased Ca absorption. If the intoxicating compound was conventional vitamin D, the hypercalcemia may be prolonged because of the storage of this compound in adipose tissue.

Immobilization hypercalcemia occurs typically in the adolescent who is growing rapidly. Acute injury or illness that requires prolonged immobilization (especially in traction) leads first to hypercalciuria and then to hypercalcemia. The presumed cause is increased bone resorption in the face of decreased or arrested bone mineralization.

Lymphoreticular malignancies in childhood may be associated with hypercalcemia from one of several mechanisms: 1) bony metastases with localized bone resorption; 2) rarely, the elaboration of a PTH-like peptide by tumor cells; and 3) release of other factors that promote bone resorption, such as prostaglandin E or osteoclast activating factor. In sarcoidosis, there is a heightened sensitivity to the Ca-absorbing effects of vitamin D, but the precise mechanism is unclear. Thiazide diuretics reduce renal Ca excretion probably by two mechanisms: 1) ECF contraction that leads to enhanced proximal tubular reabsorption of Ca with Na, and 2) increased renal tubular sensitivity to PTH-induced Ca reabsorption. Hypervitaminosis A can increase skeletal resorption of Ca, leading to hypercalcemia. Associated and characteristic findings are failure to thrive, dry skin and rash, poor hair texture, papilledema, and headache.

Clinical Manifestations

Symptoms and signs of hypercalcemia are listed in Table 86.17 and are grouped by organ system. Mild hypercalcemia (Ca 11 to 13 mg/dL) usually produces headache, irritability, and GI upset. When serum Ca rises above 14 to 15 mg/dL abruptly, a life-threatening hypercalcemic crisis may occur, consisting of severe vomiting, hypertension, polyuric dehydration, ARF, and coma. Laboratory studies that should be included in the initial evaluation are shown in Table 86.18. In any patient with unexplained hypercalcemia, an appropriate workup for hidden malignancy should be initiated once the hypercalcemia is controlled.

I. Neurologic
  A. Headache, irritability, lethargy, fatigue
  B. Weakness, seizures, coma
  C. Hyporeflexia, behavioral changes
II. Gastrointestinal
  A. Anorexia, nausea, vomiting, constipation
  B. Dehydration
III. Cardiovascular
  A. Bradycardia, hypertension, short QTc interval (electrocardiograph)
IV. Renal
  A. Polydipsia, polyuria
  B. Hypokalemia, aminoaciduria, nephrocalcinosis, nephrolithiasis
V. Dermatologic
  A. Pruritus
  B. Band keratopathy, ectopic calcification

[b]Selection of studies depends on the suspected diagnosis.

Table 86.18. Laboratory Evaluation of Hypercalcemia

Management

Treatment of hypercalcemia is facilitated by knowing the underlying cause of the derangement. Figure 86.6 provides an algorithmic approach to delineating the cause. Entities such as malignancy and sarcoidosis may result in hypercalcemia; if there is no known underlying disease and the serum phosphorus is normal, immobilization, thiazide diuretics, or hypervitaminosis A may be responsible. If the serum phosphorus level is low, primary hyperparathyroidism must be considered. If the phosphate level is elevated, vitamin D intoxication is a possibility.

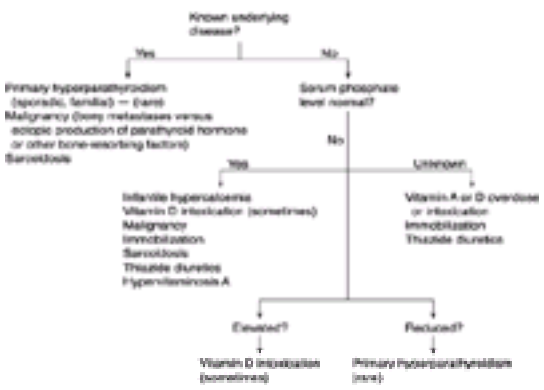

FIGURE 86.6. Diagnostic approach to hypercalcemia.

The choice of therapy depends on whether the kidneys are functioning normally. The initial emergency treatment for symptomatic hypercalcemia is designed to enhance Ca excretion by saline infusion at a rate of twice maintenance followed by bolus injections of furosemide, 1 to 2 mg/kg every 6 to 8 hours. The subsequent amount and rate of saline to be administered depends on the state of hydration and presence or absence of hypertension or preexisting cardiac disease, but in an otherwise normal patient, saline flow rates of two to three times daily maintenance would be appropriate until the serum Ca returns to normal. Treatment of a hypercalcemic crisis depends on the underlying cause, the level of serum Ca, and the severity of signs and symptoms. It always requires hospitalization in an intensive care setting. In acute oliguric renal failure, peritoneal or hemodialysis against a low Ca dialysate is usually effective, albeit slowly administered over hours. Any child in hypercalcemic crisis or with a serum Ca greater than 13 mg/dL should be admitted for therapy and diagnostic evaluation.

Disorders of Magnesium Homeostasis: Hypomagnesemia

Background

Serum magnesium (Mg) levels range from 1.5 to 2.2 mEq/L and do not vary with age. Balance studies indicate that approximately 50% of ingested Mg is absorbed in the intestine, with an average adult diet containing 200 to 700 mg/day. Normally, the kidney reabsorbs 95% of the filtered Mg, but virtual exclusion of Mg from the urine can occur in states of dietary Mg deprivation or extrarenal losses after 2 to 3 days. Diuretics and volume expanders all enhance urine Mg excretion. Mg deficiency can occur in the hospitalized child and is of particular importance in the intensive care unit, where up to 20% of patients may experience hypomagnesemia.

Pathophysiology

Hypomagnesemia is defined as a serum level less than 1.5 mEq/L. The major causes are related to GI and renal losses and are outlined in Table 86.19. GI losses account for most cases of hypomagnesemia in children. Upper GI fluids contain only 1 to 2 mEq/L Mg, but diarrheal fluid can contain up to 15 mEq/L. Renal excretion parallels urine flow, as well

as Na and Ca excretion; factors that increase Ca and/or Na excretion also enhance Mg excretion. Many drugs induce renal Mg wasting through proximal tubular cell injury.

I. Gastrointestinal Disorders
A. Acute or chronic diarrhea
B. Malabsorption states
C. After extensive bowel resection
D. Enteric fistulas
E. Prolonged nasogastric suction
II. Renal Loss
A. Osmotic diuresis (glucose, mannitol)
B. Chronic parenteral fluid therapy
C. Alcoholism
D. Hypercalcemia
E. Chronic renal disease (e.g., tubulointerstitial)
F. Drugs
1. Diuretics
2. Aminoglycosides, amphotericin B
3. Cisplatin, cyclosporin
III. Endocrine-Metabolic
A. Diabetes mellitus
B. Phosphate depletion
C. Hyperparathyroidism or hypoparathyroidism
D. Primary aldosteronism

Table 86.19. Causes of Hypomagnesemia

Clinical Manifestations

The clinical signs and symptoms of hypomagnesemia relate to signs of neuromuscular irritability, like those seen with low serum Ca. Chvostek's and Trousseau's signs may be seen along with carpopedal spasms. Ataxia, vertigo, athetoid, choreiform movements, tremors, nystagmus, and seizures are manifestations of severe deficiency. If Mg deficiency is subacute or chronic, muscle weakness and atrophy may be noted. ECG changes (prolonged P-R interval, long Q-T interval, tachyarrhythmias) may be noted.

Management

Figure 86.7 presents an approach to diagnosing the causes of hypomagnesemia and determining subsequent therapy. Known underlying disease, such as short gut syndrome and malabsorptive states, can lead to this condition. In the absence of known diseases, chronic diarrhea, enteric fistulae, and chronic diuretic use are possibilities.

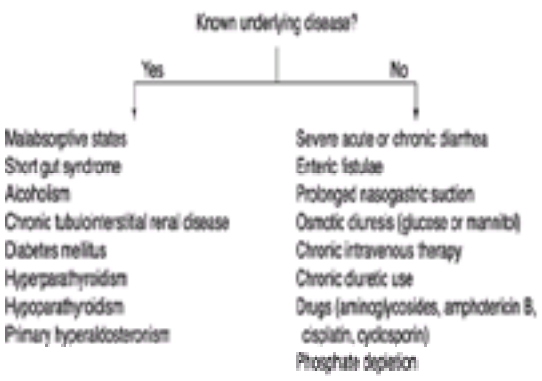

FIGURE 86.7. Diagnostic approach to hypomagnesemia.

Patients with symptoms and signs of Mg deficiency should be treated, although the magnitude of the deficiency is difficult to estimate. IM injections of $MgSO_4$ are particularly painful in children. Therefore, an IV injection or infusion is preferred in the ED, particularly in cases of seizures or cardiac arrhythmias. An initial dose of 25 to 50 mg/kg can be given either as the 10 or 50% solution (100 or 500 mg/mL), then repeated every 4 to 6 hours as necessary. Alternatively, a constant infusion of between 100 to 200 mg/kg per day may occasionally be needed to keep serum Mg normal.

Disorders of Magnesium Homeostasis: Hypermagnesemia

Background

Hypermagnesemia is uncommon in pediatrics but, as in adults, is usually related to accidental overdose. This is particularly true in patients with impaired renal function.

Pathophysiology

Blood levels exceed 2.2 mEq/L in these patients. Antacids, enemas, purgatives, or IV solutions that contain Mg usually account for the source of the intoxication.

Clinical Manifestations

Neuromuscular symptoms and signs are the earliest and most predominant presentations of hypermagnesemia and roughly parallel blood levels. BP may fall at levels greater than 5 mEq/L. Reflexes are lost early (e.g., 4 to 5 mEq/L), followed by depressed respirations and even apnea (e.g., 8 to 10 mEq/L). ECG changes include increased P-R, QRS,

and Q-T intervals (also noted at Mg levels greater than 5 mEq/L). At levels greater than 15 mEq/L, heart block may be noted. Coexisting hypocalcemia is often noted in patients with hypermagnesemia, possibly reflecting a suppressive effect of high Mg levels on PTH secretion.

Management

The first principle of therapy is to discontinue any form of Mg intake. If renal function is normal, hydration and diuresis are indicated. The signs and symptoms of acute, severe Mg intoxication may be antagonized initially by IV infusion of Ca (e.g., 0.5 mL/kg of 10% Ca gluconate). Patients with renal insufficiency and magnesium intoxication should undergo acute peritoneal dialysis or hemodialysis using a low Mg bath.

Disorders of Acid-Base Homeostasis: Metabolic Acidosis

Background

Definition

Of the four primary acid-base disorders, only metabolic acidosis is discussed in this section because it is the most commonly encountered acid-base disturbance in pediatric emergencies. *Metabolic acidosis* is defined as a net gain in H^+ ions or a net loss of bicarbonate HCO_3^- ions in the ECF. Clinically, this is reflected by a fall in plasma or serum HCO_3^- (or in some laboratories total, CO_2 or CO_2 that is approximately 95% HCO_3^-). The lower limit of normal for infants and children is 20 mEq/L.

Epidemiology

Most of the common causes of metabolic acidosis are acquired. However, certain inborn errors of metabolism may present clinically with severe metabolic acidosis in the first few months of life. An important epidemiologic consideration in all children with unexplained metabolic acidosis is accidental or intentional poisoning with any number of agents.

Etiology

The causes of metabolic acidosis are conveniently grouped into two major categories: those with a normal anion gap (also known as the “delta” or “R” fraction) and those with an increased anion gap. The anion gap is determined from the serum electrolytes by the following formula:

$$\text{Anion gap} = \underset{\text{mEq/L}}{\text{Serum [Na] mEq/L}} - \underset{\text{mEq/L}}{[Cl^- + HCO_3^-]}$$

Potassium is not included in this formula because it is present only in relatively low concentrations that vary slightly compared with the other ions. We use 16±4 mEq/L as the normal range for patients less than 2 years old. The causes of metabolic acidosis are outlined in Table 86.20. An algorithmic guide (Fig. 86.8) to the causes of metabolic acidosis is based on the value of the anion gap. If the anion gap is elevated and there is known disease, possibilities include DKA, acute or chronic renal failure, or diarrheal dehydration. If the anion gap is elevated without a history of known disease, it is valuable to check the serum lactate. If this is elevated, hypoxia and sepsis must be considered. Normal serum lactate points to conditions such as poisoning. If the anion gap is normal, renal disease such as RTA and tubulointerstitial disease are possibilities. When the anion gap is normal and there is no known underlying disease, entities such as hypernatremic dehydration, enteric fistulae, and drug must be considered.

I. Elevated Anion Gap Acidosis
   A. Diarrheal dehydration
   B. Diabetic ketoacidosis
   C. Renal failure (acute or chronic)
   D. Inborn errors of metabolism
   E. Poisons (e.g., salicylates, ethanol, ethylene glycol)
   F. Lactic acidosis (e.g., hypoxia, sepsis, idiopathic)
II. Normal Anion Gap Acidosis
   A. Hypernatremic dehydration (older children)
   B. Renal tubular acidosis
   C. Hyperalimentation
   D. Enteric fistulas (e.g., pancreatic) or enterostomies
   E. Ureterosigmoidostomy
   F. Drugs (e.g., Sulfamylon, ammonium chloride, amphotericin, acetazolamide)
   G. Early renal failure (chronic interstitial nephritis)
   H. Dilution (rapid volume expansion)

Table 86.20. Cause of Metabolic Acidosis

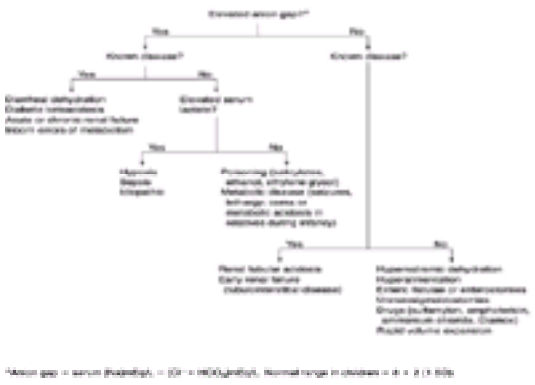

FIGURE 86.8. Diagnostic approach to metabolic acidosis (reduced serum bicarbonate for age). [a]Anion gap = serum [Na]mEq/L – [Cl^- + HCO_3]mEq/L. Normal range in children =16±4 mEq/L.

Pathophysiology

Basic Mechanisms

Metabolic acidosis results from one of three general pathophysiologic mechanisms: 1) increased H^+ ion delivery into the ECF, 2) increased HCO_3^- loss from the ECF (GI or renal), and 3) decreased renal H^+ ion excretion. The result is a fall in serum tCO_2 or HCO_3^-; the pH that is the negative logarithm of the [H^+] is usually below normal (less than 7.37) unless there is a second acid-base disturbance that drives the pH in the opposite direction.

ECF [H^+] or pH is maintained within narrow limits by a series of buffers, the most important of which is the bicarbonate buffer system. It operates in the ECF (35% of total buffering) and ICF of red blood cells (RBCs) (18% of total buffering) and provides immediate defense against life-threatening acidemia. It is an excellent and versatile buffer system for two reasons: 1) the carbonic acid-bicarbonate system represents a weak acid-strong conjugate base system that readily accepts protons of H^+ ions from nonvolatile acids in the usual range of plasma pH, and 2) the product that results from adding H^+ to this system is CO_2, which can be blown off by the lungs, thus blunting the net change in H^+ or pH.

The overall buffering mechanisms in response to metabolic acidosis are listed in Table 86.21. Of practical importance is the length of time it takes each mechanism to operate in returning pH to normal. Eventual full correction of metabolic acidosis requires renal excretion of excess H^+ ions, which takes several days to accomplish. Normally, children produce twice as much acid as adults per day (i.e., 2 to 3 mEq/kg). Because the final pH that results from metabolic acidosis is a reflection of the extent of the physiologic compensatory (i.e., adaptive) response, as well as the magnitude of the initiating disturbance, we must briefly consider this adaptive response. The compensatory response to metabolic acidosis is hyperventilation. This process produces a respiratory alkalosis, defined as a P_{CO_2} lower than normal (e.g., 40 mm Hg), which returns the pH *toward,* but *not to,* normal. This response is immediate and, for all practical purposes, is completed by the time the emergency physician sees the child with a metabolic acidosis (e.g., more than 12 to 24 hours after the onset of the inciting illness). The stimuli to hyperventilation are probably 1) through peripheral chemoreceptors that immediately sense the fall in plasma pH or rise in H^+ and, somewhat later, 2) the respiratory center that senses similar changes in the cerebrospinal fluid (CSF). These later changes do not occur immediately because P_{CO_2} diffuses across the blood-brain barrier faster than HCO_3^-, and initially the CSF pH may actually rise. A useful formula that predicts the normal adaptive response to metabolic acidosis is as follows:

1. Extracellular buffering (instantaneous)	3. Intracellular buffering (2–4 hr)
$H^+ + Buf^- \rightarrow HBuf$	Diffusion of H^+ into cells
$H^+ + HCO_3^- \rightarrow H_2CO_3$	H^+ + proteinate$^-$ → H protein
2. Respiratory buffering (10–15 min)	H^+ + hemoglobinate$^-$ →
$H^+ + HCO_3^- \rightleftharpoons H_2CO_3 \rightleftharpoons H_2O +$	H hemoglobin
$CO_2 \uparrow$	$H^+ + PO_4^- \rightarrow HPO_4^-$

Table 86.21. Buffering Mechanisms in Metabolic Acidosis

$$P_{CO_2} = 1.5 \times [HCO_3^-] + 8 \pm 2$$

If the P_{CO_2} is greater than expected from the calculations, a second acid-base disturbance, respiratory acidosis, should be suspected. In other words, the compensatory response is inadequate. If, however, there is an exaggerated compensatory response with a P_{CO_2} lower than expected from the calculations, a primary respiratory alkalosis should be suspected. Note that this formula probably does not apply to pH values less than 7.00.

Net renal acid excretion is accomplished by two mechanisms: 1) H^+ ion secretion by the renal tubule in exchange for HCO_3^- ion, and 2) H^+ ion binding to ammonia. Negligible H^+ ion is quantitatively excreted in the free state.

Applications

Elevated Anion Gap Let us first consider the causes of an elevated anion gap acidosis (Table 86.20). Diarrheal dehydration in infants and young children is the most common cause of metabolic acidosis. It tends to produce an elevated anion gap because of the early development of tissue catabolism and starvation ketosis. These result in increased H^+ ion production in association with release of increased amounts of organic anions into the ECF. DKA results in the increased production of b-hydroxybutyric acid and acetoacetic acid, both of which raise the anion gap. In severe renal failure, normally occurring anions, including phosphates, sulfates, and creatinine, accumulate. In addition, tissue catabolism ensues early in the face of oliguria and decreased caloric intake. The acidosis itself is also contributed to by decreased ammonia production by the damaged kidney.

A number of the rarely seen inborn errors of metabolism may present with severe metabolic acidosis after the institution of milk (protein) feeds. Various poisons, but especially salicylates, cause metabolic acidosis, either by their metabolic conversion to acids that are fully ionized at body pH or by liberation of endogenous acids as a consequence of interference with normal metabolic pathways. Suspicion of occult poisoning can be derived from a laboratory clue—an increased osmolal gap. The normal difference between the measured and calculated serum osmolality is 10 mOsm/L or less. The calculated osmolality equals 2[Na] + BUN over 2.8 + glucose over 18. Alcohols such as methanol or ethylene glycol are often responsible for a raised osmolal gap. Lactic acidosis is probably a more common cause of metabolic acidosis than is currently recognized in pediatrics. It most typically develops in the setting of acute circulatory and/or respiratory failure with shock, hypoxia, and poor tissue perfusion. A common predisposing event is sepsis with Gram-negative organisms. Hepatic failure, drugs and toxins, type I glycogen storage disease, and pulmonary embolus are other causes seen in children. In a significant number of patients, the cause is unknown. Primary hyperventilation produces moderate elevations in serum lactate but rarely leads to symptomatic acidosis.

Normal Anion Gap We can now turn to a consideration of the common causes of a normal anion gap acidosis (Table 86.20). In most cases, this results from a relative or absolute hyperchloremia. In hypernatremic dehydration secondary to diarrhea seen in adults and children, increased Cl^- reabsorption in the large bowel may account in part for the relative hyperchloremia. In addition, in extreme hypertonic states (i.e., serum Na greater than 165 mEq/L), Na^+ may be underestimated relative to Cl^- if electrolytes are being measured by the autoanalyzer technique. The hyperchloremia seen in both the proximal and distal forms of RTA is thought to result from a renal loss of HCO_3^- without a corresponding loss of chloride. The Na^+ deficit occasioned by the loss of $NaHCO_3$ and other Na^+ salts in turn leads to volume contraction, stimulating the renal tubular reabsorption of NaCl. Effectively, $NaHCO_3$ is replaced by NaCl in the ECF. Another clue to the diagnosis is an inappropriately alkaline urine pH (greater than 5.5) in the face of systemic acidosis.

Other more rare causes of a normal anion gap acidosis include therapy with hyperalimentation solutions, amphotericin B, and Sulfamylon.

Enteric fistulas and ureterosigmoidostomies probably produce a normal anion gap acidosis through enhanced Cl^--HCO_3^- exchange in the bowel.

Chronic interstitial nephritis with early renal failure (GFR 25 to 50% of normal) may result in a hyperchloremic acidosis. The pathophysiologic picture is one of RTA with renal bicarbonate wasting, but an additional component is reduced ammonia production and ammonium excretion.

Clinical Manifestations

The clinical manifestations of metabolic acidosis usually reflect the predisposing illness and are not unique in themselves. Nonetheless, in some patients, the presenting complaints appear to result primarily from the acid-base disturbance, in that they resolve after bicarbonate therapy. The signs and symptoms include tachypnea with or without hyperventilation, abdominal pain, vomiting, unexplained fever, and lethargy. Tachypnea and hyperpnea are characteristic of severe lactic acidosis, and coma may ensue if the pH is significantly depressed. There is often an associated but unexplained leukocytosis.

The urgency to diagnose metabolic acidosis is linked to the clinical imperative of defending the blood pH within a life-sustaining range. Factors that mandate rapid diagnosis (therapy) include 1) a severely depressed blood pH (less than 7.15 to 7.20), indicating marked acidemia; 2) a critically ill patient with multisystem disease, especially pulmonary and/or renal disease; 3) inability to treat the underlying disease effectively; and 4) the combination of hypoxia and acidemia that together can cause myocardial depression.

The laboratory studies required to diagnose and characterize metabolic acidosis are given in Table 86.22. A measurement of pH is needed to assess the potential urgency of alkali therapy, and the remainder of the arterial blood gas analysis is needed to assess the adequacy of respiratory compensation. The simultaneous measurement of blood and urine pH provides a clue to the diagnosis of RTA; this diagnosis is also suspected in the patient who has hypokalemia rather than normokalemia or hyperkalemia.

Table 86.22. Laboratory Evaluation of Metabolic Acidosis

Management

The choice of therapy is alkali, and the preferred agent is almost always $NaHCO_3$. Sodium lactate, given as lactated Ringer's solution, is an acceptable alternative, provided that liver function is normal and lactic acidosis is ruled out. Patients require treatment if the serum HCO_3^- is less than 15 mEq/L and/or the pH is less than 7.20, unless the underlying disorder is simple diarrheal dehydration. In that case, discontinuing oral intake and administering IV fluids are usually the only therapies required. The diarrhea usually stops, and the kidney corrects the acidosis.

Of equal importance to the choice of alkali therapy is the amount of bicarbonate to use and the rate of repair. The bicarbonate or buffer deficit requires some estimate of the “bicarbonate space,” which in health equals the ECF space of 20% of body weight in liters. However, recent experimental studies in dogs have suggested that the bicarbonate space is increased in severe metabolic acidosis to as much as 50% and, in lactic acidosis, even to 100%. The proposed reason for this is the movement of excess H^+ ions out of the ECF into other body compartments. Calculations of the HCO_3^- deficit therefore may be as follows:

Mild/moderate acidosis (pH 7.20 to 7.37):

$$HCO_3^- \text{ deficit in mEq} = (\text{“Normal” serum } [HCO_3^-] - \text{“Observed” serum } [HCO_3^-]) \times 20\% \text{ of total body weight in liters}$$

Severe acidosis (pH less than 7.20):

$$HCO_3^- \text{ deficit in mEq} = (\text{“Normal” serum } [HCO_3^-] - \text{“Observed” serum } [HCO_3^-]) \times 50\% \text{ of total body weight in liters}$$

If the volume of infused solution must be limited, 7.5% $NaHCO_3$ (1 mEq/mL) is used; otherwise, lesser concentrations should be used. Full correction of serum HCO_3^- should never be attempted; a reasonable goal is to increase serum HCO_3^- in increments of 5 to 10 mEq/L until a level of 15 to 18 mEq/L is achieved or a pH of 7.25 or greater. At this point, maintenance HCO_3^- therapy can be continued at roughly 2 mEq/kg per day unless the underlying cause of the acidosis has been successfully treated.

Requirements for alkali can vary because acid production may continue and/or the distribution space for bicarbonate theoretically could change. Frequent checks of serum HCO_3^- must accompany therapy. Overzealous alkali therapy is risky and can lead to a variety of complications, as outlined in Table 86.23. In some patients, such as those with uremic acidosis, chronic bicarbonate therapy may not be indicated because stabilization occurs with only mildly positive H^+ ion balance (HCO_3^- greater than 15 mEq/L), and the Na load occasioned by additional alkali therapy may aggravate preexisting hypertension or congestive heart failure. Similar reasoning would apply to patients who are hypernatremic or hyperosmolar. Any child who requires IV alkali therapy should be admitted to the hospital.

I. Hypokalemia	C. Endogenous manufacture of HCO_3^-
A. K^+ losses as part of the disease process (e.g., renal tubular acidosis, diabetic ketoacidosis)	III. Cerebrospinal Fluid Acidosis
	A. Delay in equilibrium of HCO_3^- across the blood-brain barrier
B. K^+ shifts into cells	IV. Sodium Overload
II. Alkalosis	V. Hypocalcemic Tetany
A. Overcorrection	A. Ca^{2+} binding to protein
B. Persistent hyperventilation	B. Ca^{2+} incorporation into bone

K^+, potassium; HCO_3^-, bicarbonate; Ca^{2+}, calcium.

Table 86.23. Complications of Alkali Therapy in Metabolic Acidosis

SPECIFIC RENAL SYNDROMES

Nephrotic Syndrome

Background

Definition

Nephrotic syndrome is the clinical expression for a variety of primary and secondary glomerular disorders, the hallmarks of which are 1) hypoproteinemia (serum albumin less than 3.0 g/dL); 2) heavy proteinuria, initially or at some point in the illness (more than 40 mg/m^2 per hour in a 24-hour urine); 3) edema; and less consistently 4) hyperlipidemia (predominantly triglycerides and cholesterol). *Primary nephrotic syndrome* is the term applied to diseases limited to the kidney. They are further classified according to the response to corticosteroid therapy and histology on renal biopsy. *Secondary nephrotic syndrome* is the term applied to multisystem disease in which the kidney is involved. Occasionally, nephrotic syndrome develops as a consequence of exposure to environmental agents, including heavy metals and bee venom. Table 86.24 lists the most important disorders in each category.

Syndrome and Histologic Pattern	Usual Response to Corticosteroids
I.Primary	
A. Minimal change (also lipoid nephrosis, "nil" disease)	S
B. Focal segmental sclerosis	R
C. Membranoproliferative nephritis	R
D. Membranous nephropathy	rS
E. Proliferative nephritis	S
1. Mesangial	R(?)
2. Focal	R(?)
3. Diffuse	
II. Secondary	S
A. Lupus nephritis	R
B. Sickle cell anemia	R
C. Henoch-Schönlein purpura	R
D. Hereditary nephritis	R
E. Drugs, toxins	R
F. Infections	R
G. Miscellaneous	

S, sensitive; R, resistant.

Table 86.24. Nephrotic Syndrome

Epidemiology

Nephrotic syndrome is worldwide in distribution. It tends to occur more commonly in boys than in girls. The mean age of onset tends to be earlier (younger than 6 years) in primary nephrotic syndrome than in secondary nephrotic syndrome (older than 6 years). Incidence and prevalence figures show some geographic variation: in the United States, the figures are 1.3 to 2.8 per 100,000 and 14 to 16 per 100,000 children, respectively. Although the disease is usually sporadic, a familial incidence is clearly established with a polygenic inheritance pattern. The infantile or congenital form of nephrotic syndrome is particularly common in children of Finnish extraction and is inherited as an autosomal-recessive trait.

Etiology

The causes of the primary and most of the secondary glomerular disorders associated with the nephrotic syndrome are largely unknown. By far, the most common form of nephrotic syndrome is that associated with “nil disease,” or minimal change on renal biopsy. It is also called idiopathic nephrosis of childhood and accounts for 80% of pediatric cases. There is no definite association with antecedent bacterial (e.g., streptococcal) or viral infections, although the presenting illness and episodes of clinical relapse are often associated with upper respiratory or GI infections. An immunologic basis for nephrotic syndrome has been suggested from a number of studies that have reported 1) persistently elevated serum IgM levels, 2) circulating immune complexes, 3) spontaneous remissions with natural measles infections (which are known to induce suppression of cell-mediated immunity), 4) suppression of lymphocyte proliferative responses in vitro by serum from patients with nephrotic syndrome, 5) hyperactivity of lymphocytes from patients when exposed to renal antigens in vitro, and 6) response of some patients to immunosuppressive agents. The strongest argument against an immunologic factor as a cause of nephrotic syndrome has been the failure to find immune reactants or inflammation in kidney biopsies, despite repeated studies of these patients.

The typical age of presentation of primary nephrotic syndrome is 18 months to 5 or 6 years. When nephrotic syndrome appears in the neonatal period, it likely is the congenital or Finnish type, which is steroid resistant and generally carries a fatal prognosis. Conversely, nephrotic syndrome that presents in a teenager is more likely to be associated with a primary or secondary form of underlying nephritis, and renal biopsy is generally indicated.

Pathophysiology

The hallmark of nephrotic syndrome is edema, signaling salt and water retention. Although the mechanisms of edema formation are incompletely understood, altered Na handling by the kidney always occurs. The site within the kidney may depend on the state of ECF volume. It is generally believed that the initiating factor is a large glomerular leak of proteins, predominantly albumin, leading to hypoalbuminemia. The leak is probably related to some noninflammatory immunologic or metabolic process that reduces the negative charges in the glomerular basement membrane. These charges are primarily represented by sialic acid residues that ordinarily repel albumin and other negatively charged plasma proteins. With loss of serum albumin and other plasma proteins, the intravascular oncotic pressure falls, and fluid moves out of the vascular and into the interstitial spaces, in accordance with Starling's principles. Because the liver ordinarily has a large

synthetic capacity for albumin, the persistent hypoalbuminemia noted in most nephrotics is probably not simply the result of urinary losses. Other contributing factors suggested in the literature, but not proved, are 1) decreased protein intake, 2) decreased synthesis, and 3) increased catabolism. Once plasma oncotic pressure falls, extracellular volume is reduced, which the kidney “reads” as a decreased effective circulating arterial volume. Proximal tubular sodium reabsorption is increased in response to this stimulus. The renin–angiotensin system is also stimulated, aldosterone secretion rises, and distal tubular sodium reabsorption intensifies. This secondary hyperaldosteronism perpetuates the edema-forming state. However, some patients may have normal or increased extracellular volume in the face of edema, further emphasizing the complexities of renal Na handling in this syndrome. The increased lipid turnover seen in nephrotic syndrome is characterized by elevations is serum triglycerides and cholesterol. The stimulus to this increased synthesis is unknown but is related to the degree of hypoproteinemia. Limited studies have pointed to a reduction in lipoprotein lipase and/or other circulating lipolytic factors and a selective retention of large-molecular-weight lipoproteins.

Clinical Manifestations

Presentations

The major presenting complaint is edema, which may be localized or diffuse. A typical story is that of a 2- or 3-year-old child with puffy eyes who was treated for allergies but did not improve. A rapidly changing belt, trouser, or shoe size may be indicative of rapid weight gain before edema is detectable. The rate and degree of edema formation vary from child to child and appear to be directly related to the degree of hypoalbuminemia. This, in turn, reflects the degree of albuminuria and the dietary protein intake. Pleural effusions and ascites, for example, are typically seen when serum albumin is below 1.5 g/dL. The degree of edema also depends on and varies inversely with the urine output, which is typically reduced in the full-blown case. In fact, in some patients true oliguria (less than 300 mL/m $_2$ per day) may be seen, although it almost never signifies ARF. Rarely, salt and water retention is abrupt and massive, leading to respiratory distress because of a combination of hydrothorax and ascites with elevation of the diaphragm. Ascites may also be associated with various abdominal complaints such as anorexia, nausea, and vomiting, which are thought to result from edema of the intestinal wall because they disappear with successful treatment of the edema.

Complications

The acute complications of nephrotic syndrome occur in two groups of patients: 1) those who present de novo or in relapse but not taking steroids, and 2) those who present in relapse or remission while still receiving pharmacologic doses of steroids (Table 86.25). Bacterial infections are noted with increased frequency in both groups, although they are more common in the steroid-treated children. The types of infections include cellulitis, peritonitis, sepsis, pneumonia, meningitis, and arthritis. More recently, Gram-negative organisms have been reported as often as Gram-positive organisms, the most common of which is *Streptococcus pneumoniae.* The typical signs and symptoms of infection may be masked in the steroid-treated nephrotic child, especially when the dose of steroid is high (e.g., 2 mg/kg per day prednisone). Even peritonitis may occur without local abdominal signs in the child with ascites because the accumulated fluid prevents painful contact between the inflamed visceral and parietal layers of the peritoneum.

I. Without Steroid Therapy	C. Hypercoagulability[a]
A. Bacterial infection	D. Respiratory embarrassment
B. Hypovolemia	E. Hypertension
C. Hypercoagulability (thrombo-embolic phenomena)	F. Altered behavior
D. Respiratory embarrassment	G. Steroid withdrawal (benign intracranial hypertension)
II. With Steroid Therapy	
A. Bacterial infection[a]	
B. Hypovolemia[a]	

[a]These complications occur more often after steroid therapy.

Table 86.25. Acute Complications of Nephrotic Syndrome

Symptomatic hypovolemia, which can progress to shock despite the presence of edema, results from injudicious fluid restriction, excess diuretic administration, or a combination of both. This complication should rarely happen once the patient is under medical management. The problem is not total body water or salt depletion but intravascular depletion that results from the abnormal distribution of what amounts to excess total body salt and water in the interstitial spaces. The signs and symptoms are those common to any child with hypovolemic shock.

Hypercoagulability, the tendency to form venous thromboses and thromboemboli, stems from many factors in nephrotic syndrome, including hyperlipidemia that leads to hyperviscosity, thrombocytosis, and increased levels of circulating fibrinolytic inhibitors. Renal vein, pulmonary artery, and peripheral pulmonary emboli are particularly devastating manifestations of hypercoagulability in nephrotic syndrome. The addition of steroid therapy enhances this risk by mechanisms that are unclear, although it is believed that prednisone exerts some antiheparin effect in humans. For these reasons, nephrotic children should never have femoral or other deep venipunctures unless no alternative vascular access exists.

As mentioned already, massive ascites may rarely lead to acute respiratory embarrassment, the treatment for which includes emergency paracentesis.

In steroid-treated children, acute rises in BP with symptoms of headache, blurred vision, or frank encephalopathy may

occur at any point in the clinical course. The diagnosis of hypertensive encephalopathy does not require a specific level of systolic and/or diastolic BP. Rather, it is the degree of BP change and rate of rise that cause symptoms. Acute mood changes, ranging from euphoria to depression, are associated with the introduction, sudden increase, or decrease of steroid therapy. Symptomatic complaints include irritability with a low frustration level, hyperwakefulness at night, and emotional lability with crying and withdrawal. Abrupt reductions in steroids may lead to benign intracranial hypertension characterized by headaches, vomiting, and occasional papilledema, which are not associated with arterial hypertension.

Although hyponatremia and hypocalcemia are often noted in the laboratory (see Laboratory and Radiologic Studies), they are rarely associated with acute symptoms.

Laboratory and Radiologic Studies

Laboratory studies can be grouped into three general categories: 1) those required to confirm nephrotic syndrome, 2) those designed to categorize nephrotic syndrome as primary or secondary, and 3) those designed as aids to medical management. These studies are outlined in Table 86.26.

I. Diagnostic Tests to Confirm Nephrotic Syndrome
  A. Serum proteins (albumin, globulin)
  B. Serum cholesterol
  C. Urine protein
    1. Qualitative (dipstick: albumin)
    2. Quantitative (24-hr collection)
II. Diagnostic Tests to Distinguish Primary from Secondary Nephrotic Syndrome
  A. Urinalysis (evidence of nephritis)*
  B. Screening test for sickle cell anemia
  C. Serum immunoglobulins
  D. Serum C3 complement
  E. Serum antinuclear antibody, DNA binding
  F. Hepatitis B surface antigen
III. Management Tests
  A. Complete blood count, especially hematocrit
  B. Serum Na, K, CO_2, Cl, Ca, uric acid
  C. Serum creatinine, blood urea nitrogen

Na, sodium; K, potassium; CO_2, carbon dioxide; Cl, chloride; Ca, calcium.
*Hematuria plus proteinuria generally indicates nephritis, especially if there are cellular (e.g., red blood cell) casts in the sediment.

Table 86.26. Laboratory Tests in Nephrotic Syndrome

Hypoalbuminemia is defined as a serum albumin less than 3.0 g/dL and occurs in virtually every child with nephrotic syndrome. The measurement of the urinary protein concentration varies somewhat with urinary volume but is usually 3 to 4+ (300 to 1000 mg/dL) in the untreated patient. Heavy proteinuria is the most reliable indicator of nephrotic syndrome and is defined as a 24-hour urine protein excretion of more than 40 mg/m^2 per hour, or approximately 1 g in a 30-kg child. The urinalysis occasionally shows RBCs and casts, suggesting an underlying nephritis, although this will not distinguish between causes of primary and secondary nephrotic syndrome. In most nephrotics, the urine-specific gravity is high, generally greater than 1.020.

The child with nephrotic syndrome often has an elevated hematocrit that results from intravascular dehydration. It is typical for nephrotic children to have depressed serum Na levels, usually in the range of 120 to 135 mEq/L. This rarely causes symptoms and does not require specific treatment. Hypocalcemia is also common but usually asymptomatic; the fall in Ca usually parallels that of albumin. Although the baseline uric acid is normal, many of these children later receive diuretic agents that can cause hyperuricemia. An initial elevation of the BUN in the range of 20 to 40 mg/dL is not at all uncommon and may reflect a reduction in GFR because of low plasma volume. Persistent azotemia can result from persistent reduction in GFR (an ominous prognostic sign) or, more commonly, from any combination of injudicious fluid restriction, increased catabolism caused by poor dietary intake and/or infection, and/or steroid therapy. Serum creatinine should serve to differentiate these two categories and either confirm or deny a true impairment in renal function caused by intrinsic renal damage.

Management

Acute management of nephrotic syndrome can be divided into two categories: specific and supportive. In the ED, the primary goal is usually to restore and preserve intravascular volume or to treat symptomatic edema.

Despite the presence of peripheral edema, shock is treated in the usual way, with 20 mL/kg per hour of normal saline until circulation is restored (see Chapter 3). If the child is clinically dehydrated and hemoconcentrated (hematocrit more than 50%) but not in shock, a trial of Na-deficient fluids orally at twice maintenance is preferable to an immediate start of hypotonic IV solutions (i.e., 5% dextrose in 0.25 N salt solution). Fluids should be given in small amounts (1 to 4 oz) at frequent intervals (1 to 4 hours) to avoid vomiting caused by an edematous gut. Although Na restriction is indicated for an edematous nephrotic child, water restriction is rarely indicated and only further decreases a usually low urine output. The ongoing state of intravascular hydration can be assessed by serial hematocrit tests.

If the patient is well hydrated but symptomatic from massive edema, a trial of diuretics is warranted. Symptoms include difficulty in ambulating, abdominal discomfort, skin breakdown, and respiratory distress. Furosemide, 1 to 2 mg/kg per day in two divided oral doses, can be used. If there is no response, additional diuretics that act at other sites in the tubule (thus enhancing the diuretic effect) may be added. Commonly used agents are spironolactone and hydrochlorothiazide, both starting at 1 mg/kg per day in two doses. Diuretics do not usually work, however, if the serum albumin concentration is less than 1.5 g/dL. When it appears urgent to remove some edema fluid, a combination of albumin infusions followed 30 minutes later by IV furosemide is often effective. The dose of albumin is 0.5 to 1.0 g/kg given as 25% salt-deficient albumin followed by 0.5 to 1.0 mg/kg of furosemide. Paracentesis is rarely indicated but may bring prompt relief of severe respiratory distress from massive ascites.

Prednisone is generally begun at a dosage of 2 mg/kg per day in two or three divided doses after the workup is initiated and a tuberculin test is placed. If the patient has previously been responsive to prednisone and is on either no drug or a maintenance program, a return to full therapy is indicated, provided frank relapse is obvious. If not, a quantitative 24-hour urine test should be ordered. Concurrent administration of a low-sodium antacid may reduce the risk of gastric irritation.

Antibiotics are not administered prophylactically but are used when a bacterial infection is suspected and the physician is awaiting results of appropriate cultures. This is particularly true if the patient is receiving Cytoxan or chlorambucil, as well as prednisone. Any child with active nephrotic syndrome and an unexplained fever must be considered to have a bacterial infection until proved otherwise. A blood culture is indicated, and a diagnostic paracentesis for Gram stain and culture is appropriate in the presence of obvious ascites. Penicillin has been the appropriate first choice in the past to treat *S. pneumoniae.* However, in view of reports of increased Gram-negative bacterial infections in nephrotic children, it may be necessary to broaden this initial coverage with ampicillin, one of the newer cephalosporins, and/or an aminoglycoside. In the presence of documented infection, high-dose steroid treatment should be reduced but not discontinued. Reducing the daily or alternate-day dose (if 2 mg/kg or more) by half is appropriate—but no lower than 10 to 15 mg/day. Finally, good hygiene and a balanced high-protein diet are important adjuncts to therapy.

Indications for emergency admission of a child with active nephrotic syndrome are listed in Table 86.27. As in diabetes mellitus, the admission of a newly diagnosed child is as much for patient and parental education as it is for further workup and treatment. If a patient is more than 10% dehydrated, has orthostatic hypotension, and/or has a hemoglobin greater than 16 g/dL or a hematocrit more than 50%, admission is advised for IV rehydration therapy with close observation of vital signs and urine output.

Newly diagnosed patient	Refractory edema (e.g., respiratory distress)
Severe dehydration (e.g., poor intake, persistent vomiting)	Peritonitis
Unexplained fever (e.g., suspected bacterial infection)	Renal insufficiency (e.g., elevated serum creatinine)

Table 86.27. Indications for Admission for Nephrotic Syndrome

Hypertension

Background

Definition

For the purposes of this chapter, *hypertension* (see Chapter 35) is defined as a systolic and/or diastolic BP higher than two standard deviations above the mean for age and sex. This definition implies that BP measurements have been taken carefully several times during the course of evaluation and that the child is not diagnosed as being hypertensive until the mean values from two or three such evaluations have been established over several weeks. The emergency physician is not afforded this opportunity for continued surveillance and is often dealing with symptomatic children who are severely hypertensive. Nonetheless, as with all patients who are diagnosed as being hypertensive, strict attention must be paid to the technical details of the measurement. The apparatus must calibrate to “zero,” the cuff should be one-half to two-thirds the width of the upper arm, the inflatable bladder should encircle the arm, and note should be taken of undue patient anxiety, pain, or muscle contraction, all of which can elevate the systolic and diastolic readings.

It can be useful to group children into four major age categories when defining upper limits of systolic and diastolic BPs (Table 86.28). In addition, it is useful to think of hypertension in terms of its four different presentations, each of which is discussed under Clinical Manifestations: 1) asymptomatic or minimally symptomatic hypertension, 2) malignant hypertension, 3) accelerated hypertension, and 4) hypertensive encephalopathy.

	Upper Limit (mm Hg)	
Age (yr)	Systolic	Diastolic
0–2	110	65
3–6	120	70
7–10	130	75
11–15	140	80

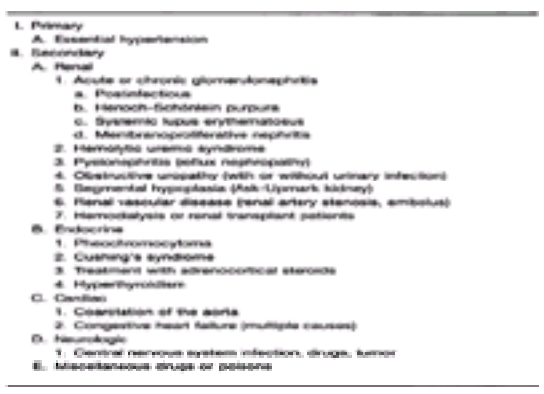
Table 86.28. Hypertension

Epidemiology

Hypertension is a major worldwide public health concern; in the United States alone, it is estimated that 40 million adults are hypertensive, or roughly twice the number reported in yearly surveys. It has only been in recent years that pediatricians have recognized hypertension as a widespread and common health problem among children. Hypertension occurs throughout childhood and shows no sexual preference. As with adults, it probably occurs more often in African-Americans than in Caucasians. There appear to be certain predisposing factors in genetically susceptible children, including dietary sodium intake, physical inactivity, and obesity. In addition, genetic studies have also shown “clustering” of hypertension in certain families with strongly positive histories. Finally, infants who have high-normal or frankly elevated BP readings tend to “track” along the same BP percentiles as they progress through childhood.

Etiology

Now that essential hypertension is acknowledged as a cause of hypertension in childhood, pediatric hypertension should be divided into primary and secondary causes (Table 86.29). Generally, the endocrinologic, cardiac, neurologic, and miscellaneous causes of hypertension produce relatively mild and asymptomatic increases in BP and affect systolic more than diastolic readings. The one exception is pheochromocytoma, a rare disease in children. Steroid-induced hypertension usually requires several weeks of pharmacologic doses to develop (e.g., 2 mg/kg per day prednisone). Occasionally, primary (essential) hypertension produces symptoms such as headaches, abdominal pain, and/or visual disturbances but rarely leads to malignant hypertension with or without encephalopathy. Most children with severe elevations of diastolic BP (e.g., higher than 95 mm Hg for those less than 10 years old; higher than 100 mm Hg for those more than 10 years old) and hypertensive crises have a secondary renal or renovascular cause for their hypertension. In several large surveys of severe diastolic hypertension reported from tertiary referral centers, the four most common causes in order of decreasing frequency were 1) chronic glomerulonephritis, 2) chronic (primary or secondary) pyelonephritis, 3) coarctation of the aorta, and 4) renal artery stenosis. The younger the child and the higher the BP, the more likely it is that an underlying cause for hypertension will be found.



I. Primary
A. Essential hypertension
II. Secondary
A. Renal
1. Acute or chronic glomerulonephritis
a. Postinfectious
b. Henoch-Schönlein purpura
c. Systemic lupus erythematosus
d. Membranoproliferative nephritis
2. Hemolytic uremic syndrome
3. Pyelonephritis (reflux nephropathy)
4. Obstructive uropathy (with or without urinary infection)
5. Segmental hypoplasia (Ask-Upmark kidney)
6. Renal vascular disease (renal artery stenosis, embolus)
7. Hemodialysis or renal transplant patients
B. Endocrine
1. Pheochromocytoma
2. Cushing's syndrome
3. Treatment with adrenocortical steroids
4. Hyperthyroidism
C. Cardiac
1. Coarctation of the aorta
2. Congestive heart failure (multiple causes)
D. Neurologic
1. Central nervous system infection, drugs, tumor
E. Miscellaneous drugs or poisons

Table 86.29. Causes of Hypertension

Pathophysiology

Measured BP results from the interaction of physiologic mechanisms that regulate vascular volume and cardiac output on the one hand and peripheral vascular tone on the other hand. Because pressure equals flow times the resistance to flow, BP equals cardiac output (CO) times total peripheral resistance (TPR), or:

$$BP = CO \times TPR$$

Factors that influence CO, either directly or through changes in vascular volume, include circulating aldosterone levels, the autonomic nervous system, renal regulation of sodium balance, and small vessel compliance (i.e., capacitance and resistance).

The distribution of the blood volume is as important as the total blood volume itself in affecting BP. Normally, volume is distributed partly in “resistance” vessels on the arterial side of the circulation. When blood volume is increased primarily in the resistance vessels, CO and BP are much more likely to rise than when the increase is primarily in the capacitance vessels. Factors that influence TPR by inducing vasoconstriction or vasodilation include activity of the autonomic nervous system, levels of circulating catecholamines, and levels of circulating angiotensin II (Fig. 86.9).

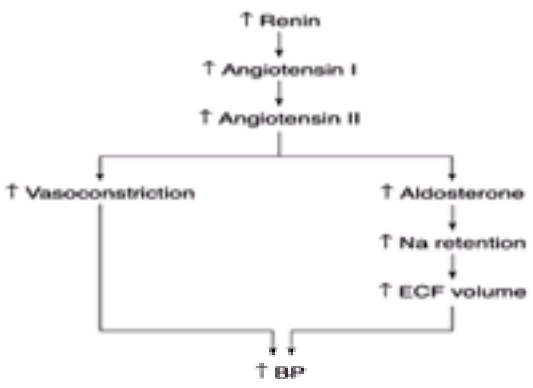


FIGURE 86.9. Mechanisms generating hypertension. *Na,* sodium; *ECF,* extracellular fluid; *BP,* blood pressure.

Obviously, hypertension occurs when an increase in CO is not matched by a physiologic and reciprocal fall in TPR, and vice versa. In clinical practice, however, hypertension is only rarely the result of a single pathophysiologic abnormality, such as activation of the renin–angiotensin system, leading to vasoconstriction and thereby to increased TPR, or excessive salt and water retention that leads to increased blood volume and CO. Rather, hypertension can be thought of as developing in two phases: 1) an initial or generating phase, which may be caused primarily by increased CO or vasoconstriction; and 2) a maintenance phase that is almost always the result of increased CO from any number of causes. Generally, the history and physical examination provide reliable guides in assessing the relative roles of CO and TPR in the acutely hypertensive child. Using this information, the emergency physician can make a rational selection of initial antihypertensive drugs.

The pathophysiology of hypertensive encephalopathy is controversial. What is generally agreed on is that autoregulation of cerebral blood flow is disrupted, leading either to overregulation with exaggerated vasospasm and ischemic injury or to underregulation with breakthrough of the circulation, increased cerebral flow, and cerebral edema.

Clinical Manifestations

As already outlined, hypertension usually presents in one of four ways (Table 86.30). First, there is the asymptomatic or mildly symptomatic child with mild to moderate elevations in BP (130 to 150 mm Hg systolic; 80 to 94 diastolic). Acute symptoms are usually nonspecific and may include headaches, abdominal pain, epistaxis, and irritability. If the hypertension is chronic, failure to thrive, irritability, personality changes, and deteriorating school performance may be prominent complaints.

Asymptomatic or mildly symptomatic	Accelerated hypertension
Malignant hypertension	Malignant hypertensive encephalopathy

Table 86.30. Clinical Presentations of Hypertension

Malignant hypertension is characterized by marked elevations in systolic and/or diastolic BP (e.g., 160 mm Hg or higher systolic for those less than 10 years of age; 170 mm Hg or higher systolic for those more than 10 years; 105 mm Hg or higher diastolic for those less than 10 years; 110 mm Hg or higher diastolic for those more than 10 years) and is often associated with spasm and tortuousity of the retinal arteries, papilledema, and hemorrhages and exudates on funduscopic examination. This condition is much more commonly seen in adults than in children. *Accelerated hypertension* is defined as an acute rise in systolic and/or diastolic BP superimposed on previously existing hypertension. In both malignant hypertension and accelerated hypertension, the patient may present with dramatic symptoms and signs such as heart murmur, congestive heart failure (CHF), lower motor neuron facial palsy, and hematuria.

Hypertensive encephalopathy is often seen in malignant hypertension and consists of a combination of symptoms and signs that often vary from patient to patient (Table 86.31). No single symptom or sign is diagnostic of this syndrome; the diagnosis is confirmed by demonstrating a rapid improvement in the symptoms and signs after the BP is lowered. Although there is no generally agreed-on level of systolic and/or diastolic BP at which encephalopathy occurs, most investigators believe that the rate of rise in the BP is as important as the actual level itself. In this, as in all forms of severe hypertension (which are almost always secondary), the presenting complaints are usually attributable to the hypertension itself and not to the underlying disease.

Nausea, vomiting
Headaches
Altered mental status (neuropsychiatric symptoms, confusion, stupor, coma)
Visual disturbances (blurry vision, decreased visual acuity, diplopia)
Seizures, stroke

Table 86.31. Malignant Hypertensive Encephalopathy

Ascertaining the cause for increased BP in the acutely hypertensive child with an abnormal neurologic examination presents a difficult challenge (Table 86.32). In general, when there is primary neurologic disease with secondary hypertension, the hypertension is usually mild and predominantly systolic. To determine whether the hypertension caused the neurologic abnormalities or vice versa, the physician must first observe the neurologic response to lowering the BP. If signs and symptoms clear rapidly, he or she is probably dealing with true hypertensive encephalopathy. In addition, primary neurologic disease can be screened for by a spinal tap (if a mass lesion is not suspected) or computed tomography (CT) scan (if a mass lesion or intracranial bleeding is suspected).

Head trauma	Brain tumor
Cerebral hemorrhage or infarction	Uremic encephalopathy
Meningitis, encephalitis	

Table 86.32. Differential Diagnosis of Hypertensive Encephalopathy

The urgency of prompt treatment of malignant hypertensive encephalopathy is attested to by the fact that fully one-third of severely hypertensive children develop neurologic abnormalities that may be sudden in onset yet may leave permanent deficits. These include cortical blindness, infarction of the optic nerve, and hemiplegia.

Finally, in patients with an acute exacerbation of long-standing hypertension, overzealous antihypertensive therapy can produce relative hypotension and, paradoxically, can lead to some of the neurologic abnormalities previously cited.

When confronted with newly diagnosed hypertension in the child, the physician should ask three important questions: 1) Is the hypertension primary or secondary? 2) Is there evidence of target organ injury? and 3) Are there associated risk factors that would worsen the prognosis if the hypertension were not treated or were treated unsuccessfully? The laboratory and radiologic workup can then be divided conveniently into three categories, as outlined in Table 86.33. The laboratory and radiology studies listed in the table are intended to be comprehensive, covering children with the full range of secondary causes of hypertension. Obviously, the emergency physician can usually establish a strong working diagnosis from the history and physical examination and selected laboratory tests.

I. Diagnosis: Primary or Secondary
A. Laboratory
1. UrinalysIs
2. Urine culture
3. Urinary catecholamines
4. Complete blood count with platelet count and blood smear
5. Serum Na, K, Cl, CO_2, Ca, P,
6. Serum blood urea nitrogen, creatinine
7. Serum C3 complement, antistreptolysin O titer, antinuclear antibody
8. Plasma renin
B. Radiology
1. Chest radiograph
2. Intravenous pyelogram
3. Voiding cystourethrogram
4. Cardiac catheterization
5. Renal ultrasound
6. Renal scan
7. Renal arteriogram
C. Other
1. Electrocardiogram
II. Tests for Target Organ Injury
A. Urinalysis
B. Chest radiograph
C. Electrocardiogram
III. Tests for Associated Risk Factors
A. Serum lipid profile (e.g., lipoprotein electrophoresis)
B. Serum uric acid

Na, sodium; K, potassium; Cl, chloride; CO_2, carbon dioxide; Ca, calcium; P, phosphorus.

Management

Acute Management of Hypertension

The spectrum of hypertension that presents to the pediatric ED ranges from mild and asymptomatic to a true hypertensive emergency (see Chapter 35). A brief but careful history and physical examination aim to classify the severity of the hypertension encountered. When the hypertension is severe, this evaluation should progress only after the ABCs (airway, breathing, and circulation) of resuscitation have been accomplished. Features of the history to be ascertained include duration of hypertension, details of its onset, and degree of compliance with any current drug therapy. The possibility of renal disease should be explored: has there been any history of urinary tract infections, failure to thrive, hematuria, edema, or umbilical artery catheterization? In addition, does the patient have a history of joint pain, swelling, palpitations, weight loss, flushing, weakness, drug ingestion, or a family history of renal disease or hypertension?

After several determinations of BP, a focused physical examination should be performed immediately. Emphasis should be placed on the neurologic examination, searching for any evidence of dysfunction. Funduscopic examination may reveal hemorrhage, papilledema, or infarcts. Any signs of CHF and discrepant upper and lower extremity BP measurements should be noted. Palpable kidneys or peripheral edema may suggest a renal origin, and an abdominal bruit, if present, suggests the possibility of renovascular hypertension. Initial laboratory studies should include a complete blood count (CBC), electrolytes, BUN, creatinine, urinalysis, chest radiograph, and ECG.

It is the presence or absence of acute end-organ dysfunction discovered in the history, physical examination, or laboratory studies and not the height of the BP that distinguishes a hypertensive urgency from a hypertensive emergency (Fig. 86.10). The division into these categories determines the site of treatment (i.e., ED, intensive care unit, routine hospital unit). The patient's clinical profile may provide clues regarding derangements in CO and/or TPR. These, along with a suspected origin, will guide the mode of therapy. Classifying the hypertensive episode as urgent or emergent governs the approach to treatment.

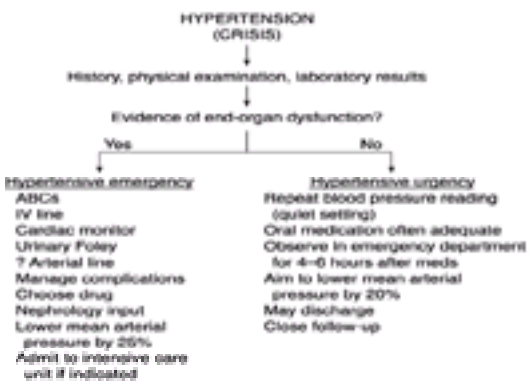

FIGURE 86.10. Diagnostic approach for management of acute hypertension. *ABCs,* airway, breathing, circulation; *IV,* intravenous.

Hypertensive Emergency

In a hypertensive emergency, an IV line should be placed immediately to allow administration of medications and fluid resuscitation if indicated. It is important to note that many patients in hypertensive crisis have volume depletion most likely caused by vomiting, diarrhea, or a diuresis of unclear origin. A cardiac monitor and urinary catheter should be used from the outset. Continuous BP monitoring must be provided, preferably by arterial catheter. Any serious complications must be managed before or as the hypertension is treated (e.g., anticonvulsants should be administered to a seizing patient along with hypertensive medications). A number of medications are available for hypertensive emergencies, and the drug(s) chosen will depend on several factors. To be considered are the patient's clinical condition, the presumed cause, whether there is a change in CO (propanolol would be contraindicated in the presence of CHF) or TPR, and whether there is end-organ involvement (nifedipine would be contraindicated in the presence of intracerebral bleeding).

In a hypertensive emergency, the goal is to lower the BP promptly but gradually. The mean arterial pressure should be lowered by 25% over several minutes to several hours, depending on the nature of the emergency. For example, a patient who is seizing or herniating must have the BP reduced immediately. This is not so for a patient who presents with headache or vomiting. Once antihypertensive therapy is begun, the patient's condition must be assessed frequently, giving special attention to the BP and neurologic status. Precipitous decreases in BP can lead to avoidable neurologic deficits. Therefore, the preferred drugs are those that allow for close monitoring of BP reduction (e.g., those given in incremental infusions). Most hypertensive emergencies can be controlled given the availability of new classes of potent antihypertensive agents and the expertise to use them. In general, physicians treat hypertensive emergencies most effectively by becoming expert in the use of a few agents. Each of the most commonly used medications offers distinct advantages and disadvantages. Each clinical situation dictates the precise mode of therapy, but some general guidelines are usually applicable.

The medications described next are recommended for use in the emergency setting (Table 86.34). Sodium nitroprusside is an arteriolar and venous vasodilator that is invariably effective. It reduces peripheral resistance and cardiac filling pressure. BP therefore decreases with little change in CO, and reflex tachycardia does not occur. It is largely metabolized to cyanide in the RBCs and cyanide reacts with thiosulfate in the liver to form thiocyanate. Sodium

nitroprusside is administered by constant infusion. Its effect is immediate and lasts only as long as the infusion is continued. Its use requires intensive observation and therefore may not be indicated in the ED. The drug requires 10 minutes to prepare and is sensitive to light. The other disadvantages are its extreme potency and the risk of thiocyanate and cyanide toxicity, which are time-dependent phenomena. Thiocyanate is excreted by the kidneys; therefore, the risk of early toxicity is increased in patients who present with renal insufficiency.

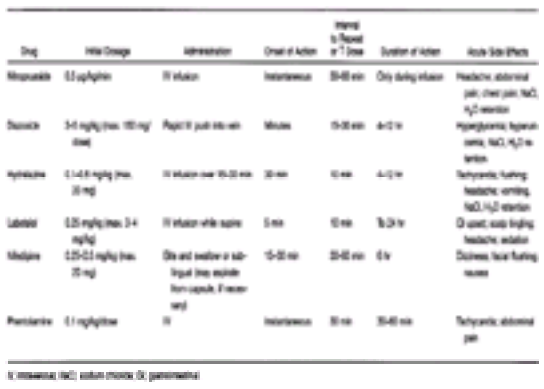

Table 86.34. Drugs Used in Hypertensive Emergencies

Diazoxide is an arteriolar vasodilator that is a potent hypotensive agent. It has little effect on capacitance vessels and no direct cardiac effect. Its onset of action is 1 to 5 minutes, and it can be administered in frequent small boluses to avoid hypotension. It may provide a long duration of BP control (8 to 12 hours). It causes marked salt and water retention, and in patients with edema, it should be followed by a diuretic agent. It also causes a reflex tachycardia and hyperglycemia.

Hydralazine is an arteriolar vasodilator that is not as potent as diazoxide and sodium nitroprusside. It is administered by IV, and the onset of action is usually within 30 minutes. Reflex tachycardia often occurs and may require the introduction of a b blocker.

Labetalol is an a_1- and nonselective b-adrenergic blocker. Blockade of the a_1 receptor results in vasodilation and is thought to be responsible for the acute antihypertensive action. The b blockade prevents reflex tachycardia. It is available in both oral and IV forms. b Blockade may result in hyperglycemia and/or hyperkalemia. Dosing is independent of renal function. It has been reported to be effective in the management of severe hypertension that results from pheochromocytoma and coarctation of the aorta and is a reasonable alternative in the treatment of hypertensive crises in patients with end-stage renal disease.

Nifedipine, a calcium channel blocker, causes direct vasodilation of the arterioles, leading to a reduction in peripheral vascular resistance. It does not affect CO. It can be administered sublingually, but biting the capsule and swallowing its contents achieves measurable blood levels more rapidly than the sublingual route. Its action begins within 15 minutes, and the peak activity occurs at 30 to 60 minutes. A mild increase in heart rate may occur. The patient may complain of headache and flushing. Its use depends on the patient's state of consciousness.

Phentolamine is a pure a-adrenergic blocker used almost exclusively for the treatment of catecholamine crisis (as seen in patients with pheochromocytoma or ingestion of sympathomimetic agents such as cocaine). It is administered as an IV bolus, and the effect is immediate. The response lasts approximately 15 minutes. Side effects include tachyarrhythmia and angina.

After antihypertensive therapy has been instituted and the patient's end-organ disease has been stabilized, the patient must be admitted to the intensive care unit for close monitoring and further hypertensive management.

Hypertensive Urgency

A *hypertensive urgency* is defined as severe hypertension without evidence of end-organ involvement. Patients with known hypertension who present in an urgent hypertensive crisis may not require hospitalization if the therapy in the ED is successful and adequate follow-up can be ensured. Often, oral antihypertensive agents will be sufficient (Table 86.35), although there are occasions when parenteral therapy is indicated.

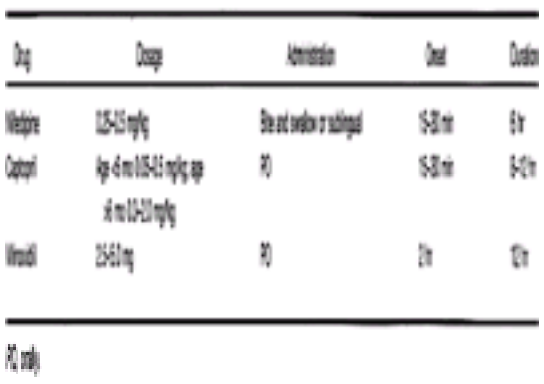

Table 86.35. Drugs Used in Hypertensive Urgencies

Nifedipine is an appropriate and effective agent for hypertensive urgencies. Its features have already been discussed. Captopril is a rapidly acting, powerful inhibitor of the ACE. It is absorbed rapidly after an oral dose and has an onset of action in 30 minutes. Its use does not result in a change in CO or heart rate. Minoxidil is a potent arteriolar dilator that can be given orally. It blocks calcium uptake through the cell membrane. Its onset of action is within 2 hours. Reflex tachycardia often occurs, along with fluid retention that requires a diuretic.

A 4- to 6-hour period of observation should follow the administration of the antihypertensive agent in the ED. This should be done to identify any untoward effects of the medication such as orthostasis. Patients should be discharged on the same medication used in the ED.

When hypertension is discovered by accident and is not the reason for the patient's visit, medical follow-up for repeated BP measurements is indicated before therapy is begun, especially if the elevation is mild (no more than 5 to 10 mm Hg above the upper limits of normal for systolic and diastolic pressures given in Table 86.28). If the BP is moderately elevated but the patient is asymptomatic, two options exist. Arrangements can be made for an outpatient workup in the future and a thiazide diuretic or a b blocker may be initiated at a low dosage. Alternatively, the patient may be admitted to begin an evaluation and therapy under hospital observation.

What follows are illustrative cases of hypertensive crises and their management.

Case 1. A 13-year-old obese African-American male has occasional bifrontal headaches and a BP of 155/95 mm Hg (mean of three readings). Funduscopic and cardiovascular examinations are normal. The family history is positive for hypertension in an obese mother and maternal grandmother, and the diet contains excessive fried food.

Comment. This story is classic for essential hypertension, and the only diagnostic studies that are required immediately are a urinalysis and urine culture, although many physicians would do a CBC and tests for creatinine and electrolytes. Studies for target organ damage and associated risk factors should be done at a later time.

Case 2. An 11-year-old girl presents with a gradual onset of headaches and weight loss and the acute onset of abdominal pain with vomiting and blurry vision. She has a history of three episodes of “cystitis” and cystoscopy with urethral dilation. Examination reveals a thin girl in obvious pain with a BP of 180/120 mm Hg (mean of three readings) and arteriolar spasm and papilledema on funduscopic examination. Urinalysis reveals clear urine with a specific gravity of 1.005, but otherwise, it is negative.

Comment. This scenario represents a hypertensive emergency: severe hypertension with target organ disease. The likely diagnosis is pyelonephritis-induced reflux nephropathy given the history of urinary tract infections, low urine specific gravity, and the level of the BP. This patient will require an IV line and the prompt reduction of her BP. The treatment choices are diazoxide, hydralazine, or nifedipine. Nitroprusside would be contraindicated if the patient was known to have severe renal insufficiency. BP and neurologic status should be monitored frequently. This patient will require admission, probably to the intensive care unit. Appropriate renal studies should be performed after stabilization and during hospitalization. A nephrology consult should be obtained.

Case 3. A 10-year-old, previously well boy has a gradual onset of aggressive, sullen behavior followed by a severe headache, decreased visual acuity, and a generalized seizure. Family and patient medical histories are negative. BP is 220/150 mm Hg (mean of three readings); there is florid papilledema with hemorrhages and exudates in the retina, cardiac enlargement, and a bruit over the left flank.

Comment. The presumptive diagnosis is hypertensive encephalopathy caused by renal artery stenosis. The patient has a hypertensive emergency. After the ABCs are monitored and stabilized, the patient will require parenteral antihypertensive therapy. Anticonvulsant drugs should be readily available in the event that the seizure activity recurs in the ED. Either diazoxide or sodium nitroprusside may be used. If the patient is known to have renal insufficiency and presents with signs or symptoms of hypertensive encephalopathy, nitroprusside should be used as a last resort and only for a brief period. The BP should be reduced over 2 to 3 hours by not more than 25% of the mean arterial pressure. This patient is a candidate for an intra-arterial catheter to measure the BP frequently and accurately. Intensive care unit admission is required. When the patient is stable, a renal scan and arteriogram should be performed.

Case 4. A 6-year-old boy presents with obvious symptoms and signs of CHF and red–brown urine. Urine output has been “low.” He had a sore throat 10 days ago. The BP is 160/110 mm Hg (mean of three readings), there is obvious CHF with peripheral edema, and the urine reveals 3+ protein, large blood, and 40 to 50 RBCs, 10 to 20 WBCs, 3 to 6 granular, and 0 to 2 RBC casts per high-power field.

Comment. This patient has acute glomerulonephritis (presumably poststreptococcal infection) with acute hypertension and oliguria leading to salt and water retention and CHF. His BP requires immediate therapy. An IV line, cardiac monitor, and urinary Foley must be placed as soon as possible. Electrolytes, BUN, and creatinine should be sent to the laboratory immediately. The preferred antihypertensive agent is hydralazine or diazoxide. He will also require diuretic therapy. After the BP has been stabilized, the patient will require admission. Appropriate serologic and urinary studies can be sent when time permits.

Acute Renal Failure

Background

Definition

ARF is an acute reduction in renal function, the hallmark of which is a decreased GFR. It may occur de novo or superimposed on preexisting renal disease. Cardinal features are solute retention, demonstrated by a rise in serum BUN and/or creatinine concentrations (i.e., azotemia) and oliguria or, more rarely, anuria. Oliguria has been variably defined in the pediatric patient as 1) urine output 300 mL/m^2 per day or less, 2) urine output 400 mL/day or less, 3) urine output 0.5 or 1 mL/kg per hour or less for an undefined period, and 4) urine output 0.5 or 1 mL/kg per hour or less for 12 to 24 hours. In the ED, precise measurements of previous urine output are rarely available, so it is convenient to use the figure 1 mL/kg per hour or less for an unspecified period. True oliguria can then be confirmed later after 24 hours of hospital observation.

Although less common in children than in adults, ARF can occur in the face of normal or near normal urine output, particularly after burns or exposure to nephrotoxins. Finally, ARF can and should also be defined anatomically in terms of the localization of the insult. Thus, azotemia and oliguria may be caused by prerenal, renal (i.e., parenchymal), or postrenal (i.e., obstructive) factors. These are important clinical distinctions to make because if recognized promptly, prerenal and postrenal causes of ARF can often be reversed with appropriate therapy.

Epidemiology

ARF is generally sporadic in nature. There are no clearly defined environmental factors that play a role in the common causes of pediatric ARF, other than various infectious agents that have been linked with hemolytic uremic syndrome (HUS). Rarely, myoglobinuric ARF is secondary to a genetic abnormality in muscle metabolism. The incidence of ARF in hospitalized children beyond the neonatal period is unknown. At The Children's Hospital of Philadelphia, approximately 5 to 10 children have ARF on admission, and 30 to 40 are seen in consultation in the hospital each year.

Etiology

As suggested in the definition of ARF, an anatomic approach to the various causes is useful (Table 86.36). Prerenal factors include 1) decreased CO that results from various hemodynamic abnormalities that cause left ventricular failure or cardiogenic shock; 2) true hypovolemia that results from excessive salt and water losses or from hemorrhage; and 3) “relative” hypovolemia that results from an altered distribution of salt and water out of the ECF space (i.e., “third-spacing”) as seen in nephrotic syndrome, cirrhosis, pancreatitis, and burns.

I. Prerenal
A. Decreased cardiac output (cardiogenic shock)
B. Decreased intravascular volume (hemorrhage, dehydration, “third-spacing”)
II. Renal
A. Primary renal parenchymal disease
1. Vascular (acute glomerulonephritis, HUS)
2. Interstitial (pyelonephritis, drug-induced)
B. Acute tubular necrosis
1. Ischemic injury (see I.B, above)
2. Nephrotoxic injury (antibiotics, uric acid)
3. Pigmenturia (myoglobinuria, hemoglobinuria)
III. Postrenal
A. Obstructive uropathy
1. Posterior urethral valves
2. Intraabdominal tumor
3. Nephrolithiasis (rare)
B. Renal vein thrombosis (rare outside of the neonatal period)

HUS, hemolytic uremic syndrome.
[a]Major pediatric causes of acute renal failure are listed in parentheses.

Table 86.36. Causes of Acute Renal Failure[a]

Primary renal (parenchymal) causes of ARF can be divided into two general categories: 1) inflammatory diseases that are usually immunologic or infectious in nature, such as acute poststreptococcal glomerulonephritis, methicillin-induced hypersensitivity interstitial nephritis, and pyelonephritis, and 2) ischemic or nephrotoxic injuries that have been grouped under the general heading of acute tubular necrosis. Of increasing pediatric interest and perhaps importance are nephrotoxins that have long been known to play an important role in adult ARF. Most prominent in this regard are drugs, including several commonly used antibiotics (aminoglycosides and cephalosporins), heavy metals (mercury, lead, cisplatinum), and diuretics (thiazides and furosemide). When administered together, the antibiotics and diuretics appear to act synergistically in their nephrotoxic effect. Uric acid may also have a direct nephrotoxic effect, and it also may cause renal tubular (luminal) obstruction.

Postrenal or obstructive factors include, most commonly, posterior urethral valves and abdominal lymphomas or rhabdomyosarcomas that cause extraureteral or extravesical compression. Rarely, a large kidney stone will obstruct the bladder outlet or the urethra.

The frequency of various causative factors in ARF differs significantly between adults and children, as seen in Table 86.37. Medical causes are much more common in children; postsurgical ARF is much more common in adults. Although the incidence of nephrotoxic ARF in children is low (Table 86.37), it reflects the data from several older published series and focuses more on the newborn and younger infant than on the older child.

Category	Approximate Incidence (%)[a]	
	Adults (N = 2476)	Children (N = 362)
Medical	24	85
Postsurgical	43	11
Toxin	10	<1
Trauma	14	?
Miscellaneous	9	4

[a]Adult data are based on two large series; pediatric data are based on six series, three of which focus on the newborn and infant less than 1 year old.

Table 86.37. Categories of Acute Renal Failure

Pathophysiology

Early concepts of the pathophysiology of parenchymal ARF in humans suggested that various predisposing factors led to a final common pathway of renal ischemia that, in turn, resulted in tubular injury. This theory gave way to the theory of "vasomotor nephropathy," which suggested that ARF could be divided into an initial phase, mediated either by ischemia or nephrotoxic injury; a maintenance phase, which resulted from increased intrarenal renin release and consequent intrarenal vasoconstriction; and a recovery phase. However, recent studies have thrown doubt on this largely hemodynamic model as satisfactory to explain oliguria and/or solute retention in all patients with ARF. In some animal models, vasoconstriction and renal ischemia may lead to a parallel decrease in renal blood flow and GFR in the initial phase of ARF, but renal blood flow spontaneously returns to normal (or is restored with vasodilators) despite a persistently low GFR with oliguria in the maintenance phase of ARF. It is more likely that parallel changes in renal blood flow and GFR explain the solute retention and oliguria of prerenal ARF rather than intrinsic ARF. What differentiates prerenal from intrinsic ARF is preservation of tubular function in the former, especially maximum urinary concentration and sodium reabsorption (see Clinical Findings), and response of azotemia and oliguria to volume replacement.

In addition to hemodynamic mediators of renal injury, nephronal and cellular mediators play important roles in the induction of ARF. Proximal tubular cell injury leads to epithelial cell death, loss of tubular integrity with fluid and solute "backleak," and the release of cellular debris that leads to tubular luminal obstruction. Cellular and metabolic alterations include production of oxygen free radicals when renal blood flow is restored, Ca influx into the cell that leads to changes in tubule cell volume, and an energy crisis within renal tubular cells caused by depletion of adenine nucleotides. Studies in several animal models have led to the conclusion that four major factors are probably operative alone or in combination in all forms of human intrinsic ARF. These are decreased renal blood flow, decreased glomerular filtration (i.e., decreased glomerular permeability, K_f, and/or glomerular surface area), tubular luminal obstruction, and tubular backleak. A summary of one proposed schema for the pathogenesis of ARF in humans is outlined in Figure 86.11. What is important to emphasize is that in most patients with ARF, more than one pathophysiologic abnormality is operating at any given time.

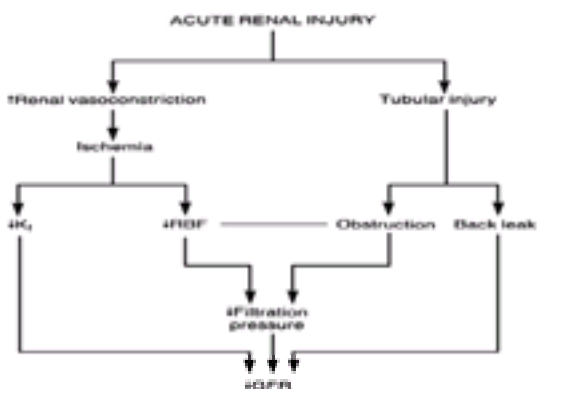

FIGURE 86.11. Acute renal failure pathogenesis. K_f, glomerular capillary ultrafiltration coefficient; *RBF*, renal blood flow; *GFR*, glomerular filtration rate. (Adapted from Hostetter JH, et al. Mechanisms of impaired glomerular filtration in acute renal failure. In: Brenner BM, Stem JH, eds. Contemporary Issues in Nephrology: Acute Renal Failure. New York: Churchill Livingstone, 1981:6.)

Clinical Manifestations

Presentation

The presentation of ARF varies and usually relates to the underlying disorder. Typical symptoms and signs are given in Table 86.38, together with the likely diagnosis. This list is by no means comprehensive but emphasizes those disorders likely to be encountered. Most children are oliguric or give a history of "decreased urination." If solute retention is severe and has persisted for days to weeks before seeking medical attention, the clinical manifestations of uremia may ensue and obscure, for the moment, the underlying diagnosis (Table 86.39). One consideration that must always be raised in a patient with suspected ARF is whether it has occurred de novo or is superimposed on preexisting chronic renal failure. Clinical clues that may lead to the latter diagnosis are failure to thrive, a history of polyuria/polydipsia, continued good urine output despite historical and physical evidence of dehydration, and physical evidence of renal rickets. Relevant

laboratory data to support the diagnosis of chronic renal disease are reviewed later in this chapter.

Symptoms	Signs	Likely Diagnosis
Nausea, vomiting	—	Gastroenteritis (ATN)
Diarrhea	Dehydration, shock	Gastroenteritis (ATN)
Hemorrhage	Shock	ATN
Fever	Petechiae, bleeding	Sepsis, DIC (ACN)
Melena	—	HUS
Sudden pallor	—	HUS
Grand mal seizures	—	HUS
Fever, chills	Flank tenderness	Pyelonephritis
Fever, skin rash	Erythema multiforme, purpura	AIN HSP nephritis
Sore throat	Hypertension	PSGN
Pyoderma	Edema	PSGN
Grand mal seizures	Congestive heart failure	PSGN
Trauma	Muscle tenderness	Myoglobinuria
Myalgia	Myoedema	Myoglobinuria
Antibiotics, diuretics	—	Nephrotoxic acute renal failure
Variable urine output	Suprapubic mass	OU

ATN, acute tubular necrosis; *DIC*, disseminated intravascular coagulation; *ACN*, acute cortical necrosis; *HUS*, hemolytic uremic syndrome; *AIN*, acute interstitial nephritis ("hypersensitivity nephritis"); *HSP* Henoch–Schönlein purpura nephritis; *PSGN*, poststreptococcal glomerulonephritis; *OU*, obstructive uropathy.

Table 86.38. Acute Renal Failure Presenting Symptoms and Signs

I. Gastrointestinal
- A. Nausea, vomiting, diarrhea
- B. Hiccoughs, fetid odor
- C. Hematemesis, melena

II. Cardiovascular
- A. Pericarditis

III. Dermatologic
- A. Pruritus
- B. Uremic "frost"

IV. Neurologic
- A. Apathy, fatigue
- B. Psychiatric disturbance
- C. Seizures
- D. Asterixis
- E. Coma
- F. Peripheral neuropathy

Table 86.39. Acute Renal Failure: Clinical Uremia

Complications

It is the immediate or, occasionally, the delayed complications of ARF, not ARF itself, that confront the emergency physician with the most important diagnostic and therapeutic challenges. The major complications in terms of frequency and threat to life are disturbances in serum tonicity and water balance; severe hyperkalemia with impending or actual cardiac arrhythmia; CHF with pulmonary edema, usually secondary to hypertension; malignant hypertensive encephalopathy with seizures; urinary tract infection with associated urinary obstruction; and metabolic seizures.

As previously discussed, serum tonicity and serum osmolality measure different phenomena. The former reflects solutes that do not traverse cell membranes, thereby regulating transcellular water movement. The latter reflects all solutes, regardless of their cell membrane permeability. ARF is an excellent example of this distinction. Because urea freely crosses all cell membranes, it raises body fluid osmolality without affecting tonicity or transcellular water movement. A child with a serum Na of 140 mEq/L, glucose of 90 mg/dL, and BUN of 100 mg/dL is hyperosmolar but isotonic. Water balance is normal. If that same child had a serum Na of 125 mEq/L, he or she would be considered isoosmolar but hypotonic and would require water restriction to forestall all swelling.

Hyperkalemia occurs in association with many causes of ARF but particularly in association with myoglobinuria and after open heart surgery. It is aggravated by hemolysis, acidosis, infection, and catabolic stress. CHF and malignant hypertensive encephalopathy typically occur in many forms of acute glomerulonephritis but especially in poststreptococcal glomerulonephritis. The risks of rapid destruction of renal parenchyma by bacterial organisms is dramatically increased in the face of obstructive uropathy. Such patients usually have systemic symptoms and signs of infection, including fever, chills, vomiting, abdominal pain, and costovertebral angle tenderness. Metabolic seizures are most often the result of uremia and not hyponatremia and/or hypocalcemia, which are often present in ARF. Hyponatremia is mild and usually develops slowly. Hypocalcemia usually does not cause tetany in the untreated patient because of coexistent metabolic acidosis.

Laboratory and Radiologic Studies

Of particular importance in differentiating the three anatomic forms of ARF are the urinalysis and the so-called urinary indices. In the critically ill patient who has not passed urine, a sterile straight catheterization of the bladder is appropriate to obtain a sample. The urinalysis is most helpful in separating glomerulonephritis from the other causes of ARF. In the typical case of acute glomerulonephritis, the dipstick shows large amounts of blood and protein, and RBCs, granular, and cellular (i.e., RBC) casts are in the spun sediment. Patients with prerenal ARF and those with acute tubular necrosis typically have little blood or protein by dipstick and an unremarkable sediment save for hyaline casts. Occasionally, the latter group will have prominent numbers of renal tubular epithelial cells and epithelial cell casts in the sediment, but this is generally unhelpful.

The major differentiation of prerenal ARF from acute tubular necrosis is by urine concentration as measured by specific gravity. Typically, the patient with prerenal ARF has a concentrated urine (specific gravity greater than 1.025), whereas the patient with acute tubular necrosis tends to have an isosthenuric urine (specific gravity 1.005 to 1.015). Hematuria by

dipstick examination without corresponding RBCs in the sediment suggests hemoglobinuria or myoglobinuria as the cause of ARF, especially if pigmented granular casts are also seen. Renal tubular and bladder epithelial cells and epithelial cell casts are commonly seen in nephrotoxic ARF or drug-induced (hypersensitivity) acute interstitial nephritis. Eosinophils on a Wright's stained urine sediment make the latter diagnosis much more likely. Marked pyuria, leukocyte casts, and a positive Gram stain of the urine all support the diagnosis of acute pyelonephritis, with or without coexistent obstruction.

Urinary indices refer to the ratios of the simultaneously measured solutes sodium, creatinine, and urea, and osmolality in “spot” samples of blood and urine. The primary purpose of these indices is to assist in differentiating prerenal ARF from acute tubular necrosis. These indices have generally replaced the BUN:creatinine ratio and “spot” urine sodium concentrations, which are too variable to reliably separate prerenal from renal ARF. They are outlined in Table 86.40.

Indices	Acute Renal Failure	
	Prerenal	Intrinsic[b]
Older Children and Adults		
U/P urea nitrogen	>8	<3
U/P creatinine	>40	<20
U/P osmolality	>500 mOsm/kg H_2O: >1.5	<350 mOsm/kg H_2O: <1.5
FE_{Na} (%)[c]	<1.0	>1.0
Neonates and Infants		
U/P urea nitrogen	Variable	Variable
U/P creatinine	Variable	Variable
U/PO osmolality	>1.0	<1.0
FE_{Na} (%)[c]	>2.5	<2.5

[a] U_x/P_x refers to simultaneously measured urine and plasma concentrations of x.
[b] Refers to classical acute tubular necrosis from various causes.
[c] Fractional excretion or filtered sodium = $(U/P)_{Na}/(U/P)_{creatinine} \times 100$.

Table 86.40. Acute Renal Failure: Urinary Indices[a]

Other diagnostic studies are outlined in Table 86.41. HUS is typically characterized by thrombocytopenia, microangiopathic hemolytic anemia with RBC fragmentation, and oliguria. However, early in the course of HUS, the only abnormal findings may be a rising BUN and falling hemoglobin, or bloody diarrhea alone, suggesting inflammatory bowel disease. The coagulation profile is often abnormal in HUS and always so in disseminated intravascular coagulation (DIC). Low C3 complement is seen in 90% of children with poststreptococcal glomerulonephritis, and elevated streptococcal serologies occur in 85 to 95% of such children, depending on the number of antibodies measured. A typical patient with poststreptococcal glomerulonephritis is presented in the section on hypertension (Case 4). Elevated antinuclear antibody titers are found in virtually all patients with lupus nephritis, albeit a rare cause of ARF. High IgE levels and absolute eosinophilia suggest acute interstitial nephritis. Elevated creatine phosphokinase (CPK) is an invariable accompaniment of rhabdomyolysis and myoglobinuria. In patients with massive hemolysis, serum haptoglobin falls to undetectable levels and elevated plasma hemoglobin may impart a pink–red color to the serum. An elevated 24-hour urine excretion of uric acid supports the diagnosis of uric acid nephropathy as the primary cause of ARF. A potentially useful screening test is the ratio of urine uric acid to creatinine on a “spot” urine specimen; if the ratio is 1.0 or greater, it supports this diagnosis. Most of the other causes of ARF result in a raised serum but not urine uric acid.

Test	Diagnosis
Blood	
Platelet count	HUS, DIC
Blood smear	HUS, DIC
Coagulation profile	HUS, DIC
Blood culture	DIC, acute pyelonephritis
Streptococcal serologies	PSGN
C3 complement	PSGN
Antinuclear antibody	Systemic lupus erythematosus-nephritis
IgE, eosinophil count	AIN
Aminoglycoside level	Nephrotoxicity
Creatine phosphokinase (CPK)	Myoglobinuria
Haptoglobin, “pink” plasma	Hemoglobinuria
Urine	
Culture	Acute pyelonephritis
Protein (24 hr)	Acute nephritis
Uric acid (24 hr or $U_{uric}/U_{creatinine}$ ratio)	Uric acid nephropathy
Radiology	
Renal ultrasound	Obstructive uropathy
Intravenous pyelogram	Obstructive uropathy, pyelonephritis
Voiding cystourethrogram (VCUG)	Underlying chronic renal disease, obstructive uropathy
Renal flow scan	Acute tubular necrosis (cortical necrosis), renal vascular insult

HUS, hemolytic uremic syndrome; DIC, disseminated intravascular coagulation (bacterial sepsis); PSGN, poststreptococcal glomerulonephritis; AIN, acute interstitial nephritis (“hypersensitivity” nephritis).

Table 86.41. Acute Renal Failure Laboratory Tests for Diagnosis

Renal ultrasound has replaced intravenous pyelogram (IVP) as the initial radiograph study of choice to differentiate postrenal (obstructive) from intrinsic renal causes of ARF. This is particularly true in critically ill patients because the ultrasound evaluation is a noninvasive procedure without the risk of IV injection of contrast. The ultrasound examination does not usually show the specific site of obstruction, but the IVP should not be performed until the patient is cardiovascularly stable and well hydrated. The IVP subsequently provides data on renal size, position, and to some extent, function. Information gained may include evidence of obstruction; pyelonephritic scarring; and small, contracted kidneys that suggest underlying chronic disease. An early but persistent nephrogram phase of the IVP, without normal concentration of the dye in the pelvocaliceal system, supports the diagnosis of acute tubular necrosis with tubular backleak. The vesicoureterogram (VCUG) is often underused in the initial evaluation of suspected causes of postrenal ARF. It is the best test to diagnose posterior urethral valves (the most common obstructive cause of ARF) and provides additional information about the presence or absence of coexistent vesicoureteral reflux. The renal scan is best used to assess blood flow to and within the kidneys. In experienced hands, the scan can also assess renal size and differentiate intrinsic renal from postrenal causes of ARF. It may be used in conjunction with ultrasound in the child whose clinical status rules out the immediate use of IVP dye. An additional advantage of the scan over IVP is that it does not require a

minimal level of estimated GFR to be performed (i.e., serum creatinine 4.0 mg/dL or greater).

Management

When confronted in the ED with a child who has ARF, the examining physician should always ask four questions about therapy: 1) Is this prerenal ARF and can parenchymal ARF be prevented by the appropriate fluid therapy? 2) Are there any life-threatening complications evident at this time that must be treated immediately? 3) Is there urinary tract infection with associated obstruction that must be relieved immediately? and 4) Are there indications for immediate peritoneal dialysis or hemodialysis? An initial set of laboratory tests provides a guide for subsequent management (Table 86.42):

Blood	Other
Hemoglobin, hematocrit	Chest radiograph
Blood urea nitrogen, creatinine	Electrocardiogram
Electrolytes (Na, K, Cl, HCO_3)	Echocardiogram
Blood gas (optional)	
Ca, P, Mg, uric acid	

Table 86.42. Acute Renal Failure: Laboratory Tests for Management

1. If prerenal ARF is suspected from the clinical history, physical examination, and urinary indices, fluid resuscitation should be used. Confirmation of this diagnosis requires a resumption of normal urine flow and a decrease in solute retention after restoration of euvolemia. An approach to fluid resuscitation is outlined in Table 86.43. A single exception to this approach might be the patient who is euvolemic or even hypervolemic but in cardiogenic shock. In the critically ill, unconscious, or uncooperative patient with an uncertain urine output, placement of an indwelling urinary catheter helps monitor urine output accurately. One clinical condition that demands the use of mannitol and furosemide is myoglobinuria or hemoglobinuria. Here the purpose of therapy is to prevent tubular obstruction by pigmented proteins after ECF volume is restored. The order of therapy in Table 86.43 is revised; 1 to 2 mg/kg of furosemide IV is given initially followed 5 to 10 minutes later by 0.5 g/kg mannitol. After urine flow is established, an infusion of 5% mannitol in one-quarter strength saline can be administered as milliliter-for-milliliter replacement of urine until the pigmenturia has resolved. Finally, as indicated in Table 86.43, failure to respond to a fluid challenge or a fluid plus diuretic challenge has one of three explanations: 1) volume losses have been underestimated, 2) there is coexistent urinary obstruction, or 3) the patient has already developed parenchymal ARF. The major risk of mannitol occurs in a parenchymal ARF because if not excreted, it will recirculate and may cause ECF volume expansion.

I. Dehydration with Shock
A. 20 mL/kg/hr of crystalloid solution[a] until vital signs stable and urine flow reestablished (0–10 mL/kg/hr)
B. Repeat hourly if necessary for 1–2 doses
C. After hour 2 or 3, if no urine flow, catheterize
D. If no urine in bladder, give furosemide, 2 mg/kg IV[b]
E. If no urine flow, treat as parenchymal ARF
II. Hemorrhage with Shock
A. 20 mL/kg/hr of plasma, or if unavailable, crystalloid solution as listed in I.A
B. Transfuse when blood available (whole fresh blood or packed red blood cells plus fresh-frozen plasma)
C. After hour 2 or 3, if no urine flow, catheterize
D. If no urine in bladder, give furosemide, 2 mg/kg IV[b]
E. If no urine flow, treat as parenchymal ARF

[a]Normal saline; 5% dextrose in normal saline; 10% dextrose in one-quarter strength sodium chloride plus one-quarter strength sodium bicarbonate (37.5 mEq/L each).
[b]Mannitol can be substituted for furosemide at a dose of 0.5 g/kg (2.5 mL/kg of a 20% solution) infused over 10–20 min. A urine flow of 6–10 mL/kg/hr should be established in the first several hours.

Table 86.43. Acute Renal Failure (ARF): Immediate Therapy of Prerenal ARF

2. Regarding life-threatening complications of ARF, the therapy of hypertensive emergencies has been discussed previously (p. 839). Hyponatremia is common but rarely symptomatic in ARF unless it is the result of ECF volume depletion. In euvolemic or clinically edematous patients, the treatment is fluid restoration and no extra sodium. Hypocalcemia is also common but rarely symptomatic in ARF and should not be treated with supplemental calcium until and unless the serum phosphorus concentration is known. Failure to take this precaution may result in raising the $Ca \times P_i$ product and risk ectopic calcification or further renal damage. Metabolic acidosis does not need correction unless the serum bicarbonate is less than 15 mEq/L, and only then with slow replacement with 1 mEq/kg per day of bicarbonate and frequent monitoring. “Overshoot” alkalosis can easily occur in the face of a rapidly changing GFR and urine flow. Also, a sudden shift of the pH toward normal or an alkaline range can convert asymptomatic hypocalcemia into frank tetany. Treatment of hyperkalemia is often the most urgent goal in ARF. Specifics of therapy for varying levels of serum K are outlined in Table 86.44.

1. Serum [K] 5.5–7.0 mEq/L (normal ECG): Kayexalate 1 g/kg PO or per rectum*
2. Serum [K] >7.5 mEq/L or >7.0 mEq/L with abnormal ECG†: Step 1. Calcium gluconate 0.5 mL/kg as 10% solution over 2–4 min with ECG monitoring; stop when pulse rate falls 20 beats/min or to <100 beats/min Step 2. Sodium bicarbonate 3.3 mL/kg of 7.5% solution Step 3. Glucose 1 mL/kg as 50% solution; hyperkalemia persists, infuse a 20–30% glucose solution with 0.5 unit regular insulin/kg; keep blood sugar <300 mg/dL
3. Serum [K] persistently >6.5 mEq/L: Dialysis

ECG, electrocardiogram.
*Kayexalate exchanges 1 mEq K for 1 mEq Na and lowers serum [K] by approximately 1 mEq/L within 4 hr. It can be administered p.o. with food or beverage, by nasogastric tube, or per rectum in 10% glucose/water (1 g in 4 ml) or in 20% sorbitol (50–100 ml). It must be retained for at least 30 min.
†Serum [K] >7.0 with a normal ECG can be treated as outlined in Step 1.

Table 86.44. Acute Renal Failure: Emergency Treatment of Hyperkalemia

3. If the clinical picture, urinalysis, and Gram stain suggest urinary tract infection, then coexistent obstructive uropathy must be ruled out rapidly. It can be suspected immediately because acute pyelonephritis in the unobstructed patient rarely causes ARF. Absence of a history of difficulty voiding or failure to palpate an enlarged bladder does not rule out obstruction, and a renal ultrasound should be obtained.
4. The indications for dialysis are outlined in Table 86.45. Generally, peritoneal dialysis is favored over hemodialysis, although the latter may be more efficient at removing certain nephrotoxins and potassium. The reasons for favoring peritoneal dialysis are its ready availability, the relatively simple technique used, and its safety in terms of preserving cardiovascular stability or minimally disturbing cardiovascular instability. It is generally not recommended in patients with generalized vasculitis, heat stroke, or recent abdominal surgery. An exciting and newer modality of acute renal replacement therapy is continuous arteriovenous hemofiltration (CAVH). It is of particular value in removing plasma water and small middle solutes in hemodynamically unstable patients. Any child with suspected or proven ARF from any cause deserves hospitalization.

Uremic syndrome
Blood urea nitrogen >100 mg/dL
Persistent hyperkalemia (serum [K] >6.5 mEq/L)
Persistent metabolic acidosis (serum [HCO_3] <10 mEq/L)
Persistent congestive heart failure
Oliguric acute renal failure secondary to hemolytic uremic syndrome or rhabdomyolysis with myoglobinuria

Table 86.45. Acute Renal Failure: Indications for Peritoneal Dialysis

Hemolytic Uremic Syndrome

Background

Definition

HUS is a multisystem disorder that affects primarily infants and young children. It is the most common cause of renal failure in young children and has an incidence of 0.3 to 10 cases per 100,000 during childhood. The definition includes renal dysfunction, nonimmune hemolytic anemia, and thrombocytopenia. Extrarenal manifestations such as neurologic injury may occur and indicate that the process is not solely limited to the renal system.

Epidemiology

Caucasian children are affected more often than African-American children, and HUS has been reported in teenagers and adults. HUS occurs worldwide, but there are several well-defined regions in which HUS is endemic (Quebec province in Canada, Buenos Aires, and surrounding environs of Argentina). Causative factors include various infectious agents, both bacterial and viral. HUS appears to occur sporadically and in epidemics, and recent work has clearly established several familial patterns to confirm the role of genetics.

Subtypes

Two principal subgroups are defined in children: diarrhea associated (D +) and non–diarrhea-associated (D–). The diarrhea-associated type includes typical cases that present with a diarrheal illness of sudden onset. It is most often associated with *Shigella*-like toxin (SLT) producing *Escherichia coli* or *Shigella dysenteriae* type 1. The incidence of diarrhea peaks in summer and early fall and affects all races and genders equally. The nondiarrheal type may include a genetic predisposition, may relapse, does not show a seasonal variation, and has an overall worse prognosis. It is not associated with SLT producing *E. coli* or *S. dysenteriae* type 1. However, *S. pneumoniae* has been implicated as a causative agent. Other causes of nondiarrheal HUS are pregnancy, malignancy, and oral contraceptives.

Pathophysiology

In diarrhea-associated HUS, the usual causative organism is an enterohemorrhagic strain of *E. coli* of the serotype O157:H7. Serotype O157:H7 produces large amounts of toxins (verotoxins or Shiga-like toxins). There are two main types of Shiga toxins, 1 and 2, which are produced by the *E. coli* O157:H7 strain. This strain is responsible for approximately three-quarters of the cases of HUS. The major reservoir for this pathogen is the intestinal tract of domestic animals. The usual route of contamination in humans is via ingestion of improperly cooked meats and unpasteurized milk. Other potential sources are vegetables, unpasteurized apple cider, and swimming pools. *Shigella* also produces a toxin that is similar structurally to the *E. coli* toxin. Various other bacteria and viruses have been implicated in the initiation of HUS, but the only proven links are *E. coli* O157:H7 and some non-O157 strains, *Shigella,* and *S. pneumoniae.* Once an individual is infected, he or she can transmit the pathogen to others.

After the verotoxin is absorbed by the intestine, it is thought to initiate glomerular endothelial cell injury, which initiates the pathogenesis of HUS. This process then leads to intravascular and intraglomerular fibrin clot formation, which is enhanced by simultaneous activation of the coagulation system, leading to vascular occlusion and sclerosis of the glomeruli. Vessel narrowing leads to mechanical damage of erythrocytes, resulting in a microangiopathic hemolytic anemia. Intrarenal platelet adhesion occurs and causes thrombocytopenia. Platelet aggregation factors appear to play an important role in this process. Endothelial cell prostacyclin, a platelet antiaggregating factor, is depleted in HUS because of toxin-induced endothelial cell damage. Renal dysfunction results from decreased glomerular filtration because blood flow is reduced through the stenotic vessels.

Clinical Manifestations

Historical features of diarrhea-associated HUS include abdominal pain and diarrhea. Fever and vomiting may also be present, but it should be noted that *E. coli* O157:H7 infection rarely results in fever. There may also be blood in the stool, and this is seen more often in *E. coli* O157:H7 infections. Within the first week after the development of these symptoms, the patient will experience an abrupt onset of pallor, listlessness, irritability, and oliguria. The onset of HUS is relatively explosive, particularly the change in skin color. Physical examination reveals a sallow complexioned, listless, dehydrated child who may have edema hypertension, petechiae, and/or hepatosplenomegaly. Neurologic manifestations may be striking in HUS; some degree of encephalopathy is present in most patients. Specific findings include obtundation, hemiparesis, seizures, and brainstem dysfunction. The initial impression may be that of a surgical abdomen, primary colitis, or intussusception when hematochezia is the predominant complaint; in these cases, a barium enema is often the first diagnostic test ordered.

Diagnosis of HUS is based on the clinical profile of hemolytic anemia, thrombocytopenia, and ARF. The anemia is severe in many cases with a hemoglobin of 5 to 9 g/dL. The reticulocyte count is mildly elevated, and the platelet count can drop as low as 20,000/mm^3. The peripheral smear shows helmet cells, burr cells, and schistocytes, confirming the microangiopathic process. The urinalysis reveals hematuria, sometimes gross, with variable degrees of proteinuria and leukocyturia. Granular and hyaline casts are often seen in the urine sediment. Chemical studies reveal azotemia, metabolic acidosis, hyperbilirubinemia, and an increased lactate dehydrogenase (LDH). Routine stool cultures will not reveal *E. coli* O157:H7. The presence of O157 antigen must be detected with a specialized antiserum directed at the antigen. The laboratory evaluation of HUS is summarized in Table 86.46. Other causes of microangiopathic hemolytic anemia and renal failure that should be considered are systemic lupus erythematosus and malignant hypertension (Table 86.47).

I. Blood	E. Electrolytes (Na, K, Cl, HCO_3)
A. Complete blood count, reticulocyte count	F. Blood urea nitrogen, creatinine
B. Platelet count	G. Liver function tests
C. Blood smear	II. Urine
D. Coagulation screen (PT, PTT)	A. Urinalysis
	III. Stool

PT, prothrombin time; *PTT*, partial thromboplastin time.
A, antigen studies for *E. coli* 0159:H7.

Table 86.46. Laboratory Evaluation of Hemolytic Uremic Syndrome

I. Sporadic	B. Type 2
Infant–young child	1. Low prostaglandin levels
Typical prodrome	2. Atypical prodrome (URI)
Good prognosis	3. Older children
II. Familial	4. Sporadic occurrence; sibs develop much later
A. Type I	5. Poor prognosis
1. Typical prodrome	C. Type 3
2. Occurs in endemic areas	1. Autosomal-dominant trait
3. Siblings develop HUS within 1–2 wk	2. Older patient
4. Good prognosis	3. Pregnancy associated
	4. High mortality

URI, upper respiratory infection.

Table 86.47. Clinical Subtypes of Hemolytic Uremic Syndrome (HUS)

Management

The cornerstone of treatment remains early recognition and supportive care. Oliguric ARF is best managed by dialysis when any one or a combination of the following complications occurs: 1) BUN more than 100 mg/dL; 2) CHF; 3) encephalopathy; and 4) hyperkalemia, particularly if associated with an arrhythmia. Peritoneal dialysis has been shown to be as effective as hemodialysis. Treatment of the intrarenal coagulation with heparin or streptokinase is discouraged. The microangiopathic process is managed with transfusions of blood and platelets as clinically indicated. There has been no efficacy demonstrated in the use of fresh-frozen plasma (FFP) or plasmapheresis in the diarrhea-associated form of HUS. However, success has been reported after infusion of FFP in patients with the nondiarrheal form of HUS.

Aggressive management of HUS yields a greater than 90% survival rate. Return to normal renal function occurs in 65 to 85% of these patients. Older patients without a diarrheal syndrome, pregnant women, and familial cases have a much worse prognosis. In addition, patients with severe hypertension and arteriolar changes on renal biopsy and those with recurrent disease fare less well over time.

Acute Glomerulonephritis

Background

Definition

Acute glomerulonephritis refers to a syndrome characterized by the sudden appearance of smoky, tea-colored, or grossly bloody urine in which heavy proteinuria and hematuria is found along with the appearance of RBC casts, as well as hyaline and granular casts. The urine is typically concentrated and acidic.

Epidemiology

The paradigm form of acute glomerulonephritis is postinfectious or poststreptococcal nephritis. Specific strains of group A, b-hemolytic streptococci stimulate an immune response that is nephritogenic in character. In the temperate climates, type 12 b-hemolytic streptococci induce the typical “strep throats” noted in these patients before the onset of the urinary abnormalities. Such children are typically school-age and male. In the southern and tropical climates, type 49 streptococci induce pyoderma as the antecedent infection, usually in younger preschool children. In certain populations, the disease appears to be endemic, and cycles of epidemic acute glomerulonephritis have been noted (Red Lake Minnesota Indians; Maracaibo, Venezuela; Trinidad). Curiously, the prognosis appears to be more favorable in the epidemic than in the sporadic form of the disease.

Etiologies

Various causes may lead to acute glomerulonephritis. These causes can be divided into conditions that affect the kidney and conditions that are more systemic in nature that may present with renal manifestations (Fig. 86.12).

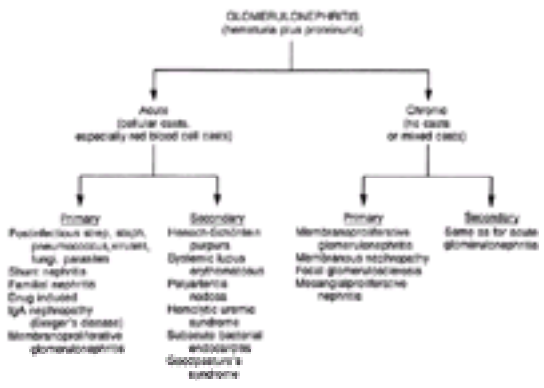

FIGURE 86.12. Categorization of glomerulonephritis.

Pathophysiology

It is believed that postinfectious acute glomerulonephritis results from the formation of soluble immune complexes either in the circulation or in situ within the kidneys in response to infection with streptococci or other agents. These complexes then deposit along the glomerular basement membrane and activate the complement system, thereby leading to the release of more inflammatory mediators and recruitment of acute inflammatory cells to the glomeruli. Localization of immune complexes is a function of their size, the activity of the reticuloendothelial system, hemodynamic factors, and the activity of glomerular mesangial cells in clearing and/or transporting these complexes. Similar pathogenetic mechanisms appear to be operative for shunt nephritis, lupus nephritis, and drug-induced nephritis. In Goodpasture's syndrome, rarely seen in children, antibodies are formed against pulmonary and glomerular basement membranes, leading to an

inflammatory reaction.

Clinical Manifestations

Generally, the diagnosis of acute glomerulonephritis is not difficult to make in the ED. The typical story is that of a 5- or 6-year-old boy who, 1 to 2 weeks after a sore throat, develops the sudden onset of brown, tea-colored, or grossly bloody urine in association with peripheral edema, particularly around the eyes, and a decreased urinary output. There may be associated cough and congestion. On physical examination, hypertension, both systolic and diastolic, is found. Some children are completely asymptomatic and present merely with abnormally colored urine. Rarely, patients may develop acute CHF or acute malignant hypertensive encephalopathy, dramatic complications of a sudden rise in BP caused by an acute reduction in GFR, with consequent retention of salt and water. These patients are particularly challenging for the emergency physician because the complications often mask the underlying disease. The history may or may not be positive for an antecedent infection. Generally, however, there is a latent period of 10 to 14 days after a sore throat and 14 to 20 days after pyoderma in poststreptococcal glomerulonephritis; 75% of children have edema and abnormally colored urine. This edema is usually firm in texture. The incidence of hypertension and oliguria varies from 25 to 33% of patients. ARF and nephrotic syndrome occur, but much less commonly.

The emergency physician must always consider an underlying chronic nephritis with an acute exacerbation when making the diagnosis of acute glomerulonephritis de novo. Underlying chronic nephritis may be suspected initially by the absence of a latent period between the antecedent infection and the onset of urinary abnormalities, an anemia disproportionate to the degree of renal glomerular insufficiency, and changes in the optic fundi of chronic hypertension. Poor linear growth is also a clue to the duration of glomerulonephritis and attendant renal insufficiency.

IgA nephropathy and membranoproliferative glomerulonephritis may be difficult to differentiate from the typical form of poststreptococcal glomerulonephritis if there is not good evidence for an antecedent strep infection. Familial nephritis is often associated with eye and hearing abnormalities. Secondary forms of glomerulonephritis are diagnosed on the basis of other systemic manifestations; these diseases are covered elsewhere in this text.

The laboratory database is outlined in Table 86.48. The findings on urinalysis are the single most important in categorizing glomerulonephritis. Proteinuria, although a function of urinary concentration, is almost always greater than 2 on the dipstick, indicating that the protein present is not merely a result of the hematuria itself. RBC casts are the hallmark of acute glomerulonephritis from any cause. Leukocyturia may also be seen. In girls, urinary tract infection can present with proteinuria and hematuria, so a urine culture should always be obtained in the initial workup. Routine electrolytes may reveal hyponatremia secondary to water retention, hyperkalemia secondary to oliguria, and of course, azotemia with a raised BUN and creatinine. In nephrotic patients, serum albumin is reduced. Hemoglobin is usually normal. Serologic studies are important in confirming a streptococcal source. Antibodies to any or all five extracellular streptococcal antigens may be measured; the more antibodies measured, the more likely abnormal results will be found. For patients who sustain strep throats, antistreptolysin O (ASO) and antihyaluronidase (AH) titers are measured. Antistreptolysin peaks at 10 to 14 days and AH at 3 to 4 weeks. For patients who sustain pyoderma, anti DNAse-B antibodies are measured. Antibiotic therapy blunts the antibody responses to these streptococcal antigens. If systemic lupus erythematosus is suspected as the cause of acute glomerulonephritis, an antinuclear antibody titer should be measured. The C3 complement is depressed in 90% of patients with poststreptococcal glomerulonephritis and in a number of other types of acute glomerulonephritis. Occasionally, group A b-hemolytic streptococci will be recovered from the throat or the skin when the patient presents with urinary abnormalities. Therefore, cultures should be routinely obtained. A chest radiograph is advised in hypertensive patients with or without signs and symptoms of CHF. Renal biopsy reveals swollen glomeruli with proliferation of the extracapillary cells; deposition of immunofluorescent-positive granules of IgG, IgM, and C3; and subepithelial electron-dense deposits. The latter two findings represent immune complexes.

I. Urine	E. Streptococcal serologies (ASO, anti-DNAse-B)
A. Urinalysis	F. C3 complement
B. Urine culture	G. Antinuclear antibody
II. Blood	III. Other
A. Complete blood count	A. Throat culture
B. Electrolytes (Na, K, Cl, HCO_3)	B. Skin culture (if pyoderma is present)
C. Blood urea nitrogen, creatinine	C. Chest radiograph
D. Total protein, albumin, and globulin	

Table 86.48. Laboratory Evaluation of Acute Glomerulonephritis

Management

The goals of the emergency physician are to recognize the diagnosis and to treat life-threatening emergencies secondary to hypertension. If CHF (p. 838) is noted, the head-up position, supplemental oxygen, and 0.5 to 1.0 mg/kg Lasix administered by IV are recommended. Hypertension may be treated with 0.25 to 0.5 mg/kg sublingual nifedipine, 2.5 to 5.0 mg/kg IV diazoxide by push, or 0.5 mg/kg hydralazine given by IV over several minutes. Nitroprusside is rarely required. Encephalopathy usually requires antihypertensive therapy only if the link between severe hypertension and the neurologic abnormalities is noted immediately.

Any child with acute glomerulonephritis who is oliguric or hypertensive should be admitted for close observation. In the mildly affected patient, discharge from the ED is reasonable if the patient is instructed to follow a low-sodium diet. A follow-up appointment with the primary physician is advised within 48 to 72 hours, and instructions are given to the family on following urine output and weight and observing for the signs and symptoms of hypertension.

Poststreptococcal glomerulonephritis carries an excellent prognosis in children; more than 80% recover spontaneously without apparent sequelae. A particularly ominous variant of acute glomerulonephritis, known as rapidly progressive glomerulonephritis, is heralded by progressive oligoanuria and azotemia, often leading to uremia. Extracapillary crescents of proliferating cells are noted in the glomeruli on renal biopsy in these patients. Persistent hypertension, edema, nephrotic-range proteinuria, azotemia, and hypocomplementemia that occur in a patient who, on first evaluation, appears to have acute glomerulonephritis may be indications of a more chronic form of the disease and are indications for renal biopsy.

Henoch-SchöAdonlein Purpura

Background and Pathogenesis

Henoch-SchöAdonlein purpura is considered one of the collagen vascular diseases in which a vasculitis of small blood vessels give rise to the triad of abdominal pain, arthritis, and purpura. Renal involvement with an acute glomerulonephritis is often present. The disease occurs in school-age children and young adults and is more common in Caucasians and males. The cause is unclear. Patients are often found to have elevated IgA levels in the blood in the acute phase, and both IgA-containing circulating immune complexes and glomerular mesangial deposition of IgA by immunofluorescence microscopy are additional markers of the disease. The IgA-containing immune complexes may also be detected in the skin lesions in these patients.

Clinical Manifestations

Antecedent upper respiratory tract infections are noted in one-third to three-quarters of patients. The abdominal pain is described as colicky but often severe. The arthritis is migratory, affecting the larger joints. Swelling may not be present around these joints. The rash is symmetric and purpuric and most noticeable over the extensor surfaces of the arms, legs, and buttocks. Other rashes, including erythema multiforme, may also be noted. Renal involvement is variable but typically occurs in the first month of illness. Asymptomatic microhematuria occurs most commonly in 80% of affected patients. Azotemia is usually transient. The older the child and the later the onset of renal involvement, especially if there is nephrotic-range proteinuria and/or renal insufficiency, the worse the prognosis. Hypertension is uncommon.

Routine laboratory studies that include CBC, electrolytes, serum proteins, and C3 complement are usually normal. The diagnosis is primarily based on clinical findings. Henoch-SchöAdonlein purpura nephritis is difficult to differentiate from IgA nephropathy in the absence of the skin rash and joint findings.

Management

There is no specific therapy for Henoch-SchöAdonlein purpura other than the use of corticosteroids used acutely to treat the severe abdominal pain or arthritis that occurs in selected patients. Signs and symptoms may wax and wane for a period of several months. Prognosis is generally excellent but depends on the severity and extent of renal involvement.

Renal Tubular Acidosis

RTA is a syndrome characterized by a persistent hyperchloremic nonanion gap metabolic acidosis. In this disorder, the renal regulation of the bicarbonate reabsorption and/or regeneration is deranged. Although RTA is rare, the emergency physician may occasionally encounter children with this abnormality; therefore, knowledge of its presentation and treatment is indicated.

A child with RTA may confront the emergency physician in one of several clinical settings: 1) an acute urinary tract infection, 2) muscle weakness and/or an adynamic ileus of the bowel secondary to profound hypokalemia, and least common, 3) acute renal colic secondary to the passage of renal calculi. RTA is divided into four types (Table 86.49).

Types	• Proximal RTA
• Distal RTA	Type 2 RTA
Type 1 or classic RTA	• Hybrid RTA
Type 4 or hyperkalemic RTA	

Table 86.49. Renal Tubular Acidosis (RTA)

Patients with all types of RTA present with a nonanion gap hyperchloremic metabolic acidosis. The GFR is almost always normal. The disorder may be primary (sporadic or familial) or secondary to various systemic disorders. Specific features facilitate the categorization of RTA types.

The physiologic characteristics of type 1 (distal) RTA are related to a reduced net rate of hydrogen ion secretion of the distal nephron. There may also be mild to moderate bicarbonate wasting. Patients with type 1 RTA are not able to lower their urine pH below 6 regardless of the severity of the acidosis. Proximal tubular functions are normal. The presentation may include acidosis, failure to thrive, hypokalemia (at times severe), nephrocalcinosis, or rickets.

Hyperkalemic, or type 4, RTA is thought to be the most common occurrence in children. This abnormality is caused by a disturbance in the renal handling of hydrogen and potassium ions. Patients with type 4 RTA are usually able to make a mildly acidic urine.

Type 2, or proximal, RTA is a defect in the reabsorption of filtered bicarbonate in the proximal tubule. This represents a derangement in the sodium-hydrogen ion exchange mechanism in this tubule segment. Distal mechanisms of acidification are intact. Many patients with this tubular disturbance manifest the problem as part of the Fanconi's syndrome. Patients with type 2 RTA have severe bicarbonate wasting when plasma bicarbonate is normal and an alkaline urine pH, but during acidotic states, the bicarbonaturia is decreased and the urine pH may be 5 to 5.5.

Once a patient is found to have a nonanion gap hyperchloremic metabolic acidosis, it is important to rule out other possible sources of the acidosis. For example, diarrhea with bicarbonate wasting and urinary tract infection with a urea-splitting organism should be considered. The arterial pH and P CO_2 should be measured several times, and all urine specimens passed should be tested for pH. A serum creatinine should be checked to confirm normal glomerular function. Several serum potassium determinations should be performed, and these may delineate the type of RTA present.

Management

The immediate treatment of RTA in the ED depends on the severity of signs and symptoms of hypokalemia (see section on Hypokalemia). Therapy of this disorder is best carried out in conjunction with a nephrologist. Administration of alkali is the treatment of choice for most types of RTA. However, overzealous IV alkali therapy should not be attempted because a rise in blood pH often lowers serum potassium and may exacerbate symptoms of weakness and/or cardiac arrhythmia.

The most commonly used alkalis are sodium bicarbonate and sodium citrate. In patients with hypokalemic RTA, a portion of the alkali can be given as $KHCO_3^-$ or K^- citrate. Plasma bicarbonate and serum potassium levels should be determined every 2 to 4 days initially. In patients with hyperkalemic RTA (type 4), furosemide is occasionally required to return the potassium to normal. Rarely, exchange resins are indicated.

Bartter's Syndrome

Bartter's syndrome was first described in 1962 and represents a constellation of renal tubular disorders characterized by profound hypokalemia, hypochloremic metabolic alkalosis, hyperreninemia with secondary hyperaldosteronism, but normal BP and renal glomerular function. The normal hypertensive response to IV angiotensin II infusion is blunted.

The pathogenesis of this disorder is controversial and probably involves a variety of tubular disturbances in K, Na, Cl, and Mg transport. The hallmark of Bartter's syndrome is urinary potassium wasting, but salt wasting is also common. Urinary prostaglandin excretion is increased, and a central role for prostaglandin overproduction is supported by the tendency of the biochemical abnormalities of this disorder to respond to the administration of prostaglandin synthetase inhibitors such as aspirin, indomethacin, and ibuprofen. In some patients, renal biopsy reveals hyperplasia of the juxtaglomerular apparatus, the site of renin production in the kidney.

The clinical presentation in infants and young children is characteristic and often reminiscent of RTA. Growth failure is severe, and episodes of severe vomiting and diarrhea that lead to dehydration often punctuate an early history of anorexia, polydipsia, and polyuria. There may be muscle weakness, aggravated by the bouts of dehydration. Such weakness is a constant complaint in older children. Unlike the more common forms of metabolic alkalosis that result from vomiting and overzealous diuretic therapy, sodium chloride therapy does not reverse the alkalosis and hypochloremia, and potassium chloride supplements rarely raise serum potassium levels to normal.

The differential diagnosis includes primary causes of hyperaldosteronism and renin-secreting tumors, in which hypotension is a prominent clinical finding, and pseudo-Bartter's syndrome is characterized by sodium, chloride, and potassium losses. Pseudo-Bartter's syndrome may be caused by cystic fibrosis with excessive sweating, diuretic abuse, chloride diarrhea, and the ingestion of a chloride-deficient formula.

The urinalysis reveals a concentrating defect but is otherwise unremarkable, save for the high concentration of electrolytes. Potassium repletion should be accomplished slowly unless there is life-threatening hypokalemia. As in severe RTA, mechanical ventilation may be necessary for extreme hypoventilation with associated respiratory acidosis. There is no role for ammonium chloride or a prostaglandin synthetase inhibitor in the emergency setting. Volume depletion should be managed in the conventional manner, with IV normal saline.

Urolithiasis

Background

Urolithiasis refers to calculi formation in the kidneys, ureters, or bladder. Once thought to be primarily an adult disease, it

is known to affect children and adolescents as well. It is important that physicians who treat pediatric patients in ED recognize those children who are at greatest risk of urolithiasis and develop an approach to its management.

Epidemiology

Urolithiasis occurs at a rate of 140 per 100,000 adults in the United States, and the incidence in children is approximately $^{1}/_{50}$ of that seen in adults. The incidence of pediatric admissions caused by urinary calculi varies from 1 per 7,600 to 1 per 1,066, depending on geographic area. It is estimated that at least an equal number of children are treated for stone disease as outpatients. Urolithiasis is endemic to specific areas of the United States, most notably portions of the southeastern states also known as the “stone belt” and southern California. Geographic location worldwide also plays a part in the cause of urinary calculi. In European children, infection-related stones comprised 75% of the diagnoses, whereas in Southeast Asia, endemic uric acid bladder stones are most common. In North America, metabolic causes account for more than 50% of diagnoses, and the stones contain calcium for the most part.

Among children, boys and girls are affected almost equally, unlike the male preponderance seen in adult stone patients. Urolithiasis is rare in African-American children, with 94% of urinary calculi occurring in Caucasians. The mean age of diagnosis is approximately 9 years.

Pathophysiology

Stone formation is a complex process that involves multiple physiochemical and anatomic factors (Fig. 86.13). Urinary crystallization is strongly related to the free concentrations of the lithogenic ions such as calcium and oxalate. The activity product is equal to the product of the concentrations of the ions in question, and it often exceeds the solubility product. Thus, urine is often supersaturated with calcium and oxalate ions at concentrations that, under laboratory conditions, would crystallize in vitro. Yet this does not happen in the urine because in most people inhibitors of nucleation are present. Such inhibitors may include urinary citrate, glycosaminoglycans, and more recently, glycoproteins such as nephrocalcin and uropontin.

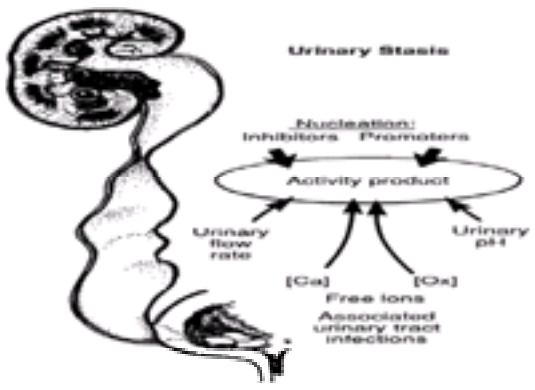

FIGURE 86.13. Pathogenesis of urinary calculi formation.

Certain factors act to promote urinary stone formation such as stasis of urine. Anatomic causes of bladder stasis may include megaureter, ureteropelvic junction (UPJ) obstruction, or a neurogenic bladder. Crystallization can be initiated on damaged urothelium or on a foreign body, and these are examples of heterogeneous nucleation. Certainly one factor in stone disease is dehydration because it raises the urinary free ion concentrations beyond a point at which even the inhibitors can prevent nucleation. Maintaining a dilute urine is the first step in preventing recurrence of nephrolithiasis.

Types of Calculi

Urinary calculi are often divided into four major categories: calcium, infection-related, cystine, and uric acid stones. Approximately 60% of urinary stones are calcium oxalate or calcium phosphate. Hypercalciuria is the most common noninfectious cause of urolithiasis in children. It generally correlates with a daily urinary calcium excretion greater than 4 mg/kg, and a random Ca:Cr ratio greater than or equal to 0.21 when the patient is on an undefined diet. Hypercalciuria usually occurs in the absence of an elevated serum calcium, and the idiopathic form is most commonly seen in children. Idiopathic hypercalciuria, even in the absence of calculus formation, has been associated with hematuria. This is attributable to calcium oxalate crystals that injure the urothelium. Some other causes of calcium urolithiasis are hyperparathyroidism; hypercalcemia; distal RTA; medications such as furosemide; and hyperoxaluria, hyperuricosuria, and hypocitraturia, and the idiopathic form that may result from increased absorption or renal leak of calcium.

Infection-induced stones are made of struvite (magnesium, ammonium, phosphate) and carbonate apatite. The bacterial enzyme urease ultimately creates an environment that favors the formation of struvite. Organisms that produce urease are *Proteus, Pseudomonas, Klebsiella, Serratia, Mycoplasma,* and *Staphylococcus.* Infection-induced stones are usually discovered before age 5 and 80% are found in boys. Typically, affected children have staghorn calculi that fill the renal calyces or pelvis. Urinary sediment will reveal pyuria, bacteriuria, and struvite crystalluria.

Cystine calculi account for approximately 4% of pediatric urolithiasis. Cystinuria is a recessively inherited disorder of amino acid transport manifested as excessive urinary excretion of cystine, arginine, lysine, and ornithine and by formation of urinary calculi. Cystine stones are usually radiopaque because of the sulfur ions present. Cystine crystals in the urine can be identified by their flat hexagonal shape.

Uric acid calculi account for 3 to 5% of pediatric urolithiasis. Most uric acid calculi result from precipitation of uric acid from supersaturated urine. Lithiasis may be idiopathic or associated with hyperuricemia, hyperuricosuria, or chronic excessive fluid losses. The most common cause of uric acid urolithiasis in children in the hyperuricemia/hyperuricosuria that results from increased purine synthesis as in patients with myeloproliferative disorders. Uric acid stones are generally multiple and are radiolucent.

Clinical Manifestations

Children with urolithiasis rarely present with the excruciating pain of stone passage as seen in adults. Pain occurs in the abdomen or flank in 50% of patients. In infants, such pain may be confused with colic, and occasionally, a diaper that is stained or shows crystals will provide a clue. Hematuria, either microscopic or macroscopic, occurs in at least 90% of children with urolithiasis. Other symptoms include urinary frequency, dysuria, and at times, urinary retention. A history of urinary tract infection is variably present. A family history of urolithiasis can be elicited in 50% of patients. Colic and hematuria episodes are most characteristic of calcium stones.

The physical examination may reveal tachycardia and an increase in BP because of pain; fever may be seen in 15% of patients. Costovertebral angle and/or flank tenderness may be present.

Management

If the history and physical examination are suggestive of urolithiasis, one should proceed to the detection of the calculus (Fig. 86.14). A urinalysis is an essential diagnostic screen for stone disease. In most affected children, there will be microscopic or macroscopic hematuria; pyuria and bacteriuria may also be found. Crystal formation, if present in the urinary sediment, is an additional supportive and often diagnostic finding. Definitive detection of a radiopaque calculus relies on an imaging study. It is estimated that 95% of urinary calculi are radiopaque and can therefore be identified on a plain abdominal radiograph. Ultrasonography is an adjunctive study that can detect upper tract calculi reliably and is also particularly useful for delineating obstructing calculi. The IVP is helpful in locating a ureteral or bladder stone and urinary obstruction.

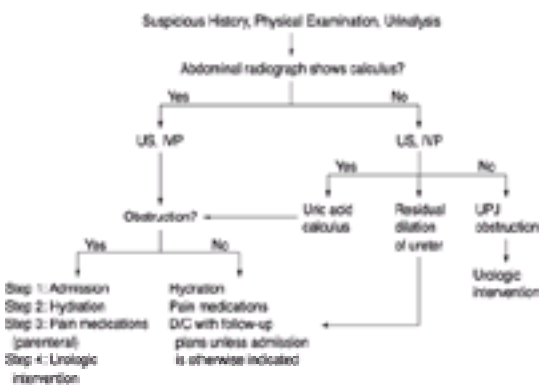

FIGURE 86.14. Diagnostic approach for evaluation for urinary calculi. *US,* ultrasound; *IVP,* intravenous pyelogram; *D/C,* discharge; *UPJ,* ureteropelvic junction.

Once a calculus has been detected in the ED, attention should be focused on the recognition and treatment of the potential acute complications that may accompany urolithiasis. Such complications include pain (at times severe), urinary tract infection, and/or urinary obstruction. If a urinary calculus is not found with the aforementioned studies but the history is suspicious of calculus disease, it is likely that the patient has already passed the stone and presently is suffering from the aftermath of stone passage (i.e., spasm and dilation of the ureter). In this scenario, one must carefully examine the urine for crystalluria and hematuria, as well as search for an increased Ca:Cr ratio.

For severe pain, relief should be provided promptly. Narcotic analgesics such as morphine sulfate or meperidine may be necessary. Nonsteroidal anti-inflammatory medicines such as ibuprofen may have an important role in pain management if the patient can tolerate oral medications. Some patients may be unable to drink, and IV hydration may be required to ensure an adequate urine flow rate. If there is no evidence of urinary obstruction or renal insufficiency, fluids should be run at twice the maintenance requirement. When an associated urinary tract infection is suspected, appropriate antimicrobials should be initiated after culture. If urinary obstruction is entertained, a sonogram should be performed urgently and a urologic consultation should be obtained. Immediate treatment of an obstruction-inducing calculus includes extracorporeal shock wave lithotripsy, percutaneous nephrostolithotomy, or open stone surgery. All urine should be strained to assist in collecting gravel or stone particles for analysis. If a patient is known to have renal insufficiency, the management of superimposed urolithiasis should be done in conjunction with a pediatric nephrologist. Numerous indications exist for the admission of patients with urolithiasis (Table 86.50). If the patient does not fit into one of these categories, outpatient management is appropriate. Because the rate of recurrence of calculi formation is high, a stone patient should be referred to a pediatric urologist or nephrologist to ensure a detailed follow-up that focuses on stone analysis and long-term management. Prevention relies heavily on consistently high fluid intake.

Urinary obstruction	Solitary kidney
Intractable pain	Renal insufficiency
Dehydration	Inability to tolerate oral fluids

Table 86.50. Urolithiasis—Indications for Admission

Chronic Renal Failure

Background

Chronic renal failure (CRF) in children is not a rare entity; studies suggest an incidence of 16 per million population in the United States. Many children who have reached end-stage renal failure (ESRF) are receiving chronic hemodialysis or, more recently, chronic ambulatory peritoneal dialysis (CAPD), often in the home. In all pediatric patients with ESRF, renal transplantation is the ultimate therapeutic goal. The causes of ESRF vary with age: for those younger than 5 years, congenital structural lesions predominate, along with obstructive uropathies; for those older than 5 years, acquired lesions are more commonly seen. A summary list of causes for ESRF is shown in Table 86.51.

I. Congenital Structural Lesions
A. Hypoplasia, dysplasia
B. Malformations (cystic diseases)
II. Obstructive Uropathies
A. Posterior urethral valves
B. Bilateral ureteropelvic junction obstruction
C. Bilateral vesicoureteral reflux with infection (e.g., reflux nephropathy)
III. Acquired Nephropathies
A. Chronic glomerulonephritis
B. Hemolytic uremic syndrome
C. Acute tubular or cortical necrosis
D. Hereditary nephritis

[a]This list is not intended to be comprehensive; it lists the most common causes of end-stage renal failure.

Table 86.51. Causes of End-Stage Renal Failure[a]

Pathophysiology and Clinical Findings

Once a critical level of renal functional deterioration occurs from any cause, eventual progression to ESRF is inevitable. This “threshold level” has not been defined, and the rate of progression varies, although it appears highest at around the time of puberty. Many factors can precipitate this deterioration: ongoing immunologic injury, urinary tract infection, hypertension, extra cellular volume depletion, urinary obstruction, and hypercalciuria with or without nephrolithiasis. Many patients are not known to have CRF when they present acutely to the ED. Clues in the history are excessive fatigue, anorexia, vomiting, short stature, skeletal pain, polyuria, and polydipsia. On physical examination, signs of anemia, a fetid breath, chronic changes of hypertension, asterixis, and peripheral neuropathy are tell-tale clues. Signs and symptoms of CRF usually begin at a GFR 20% of normal or less, and virtually always when the GFR reaches 10% of normal. Rapid falls in GFR may exacerbate the clinical picture.

Management

Disturbances in fluid electrolyte and acid-base balance, calcium and vitamin D metabolism, and cardiovascular and neurologic function predominate in ESRF and are outlined in Table 86.52. Anemia in ESRF has been managed successfully with a combination of effective dialysis and recombinant erythropoietin injections. CHF may be aided by improving the hemoglobin level and restricting or removing extra salt and water, either with diuretics or dialysis. Uremic pericarditis is less commonly seen in children than in adults and appears to correlate with the level of serum creatinine. The careful monitoring of water intake is required to avoid hyponatremia and hypernatremia because the kidneys' ability to modulate urinary water excretion is greatly reduced. Some patients may also exhibit an Na-wasting state despite the low GFR. Potassium retention is a significant risk in ESRF, particularly in patients who have not yet started dialysis. Uremia may block transcellular K transport in these patients. Accumulation of organic acids and the inability of the damaged kidney to regenerate new bicarbonate buffer explain the metabolic acidosis of ESRF. Modest doses of alkali normally correct this problem unless the patient is “Na-sensitive”; in that case, dialysis is indicated to avoid fluid overload.

I. Anemia
A. Decreased erythropoietin production
B. Hemolysis
C. Blood loss (bleeding tendency)*
II. Cardiovascular
A. Congestive heart failure*
B. Uremic pericarditis*
III. Fluid, Electrolyte, Acid-Base Balance
A. Reduced free water clearance, obligatory isothermia*
B. K balance lost when glomerular filtration rate <10 mL/min, hyperkalemia common*
C. Metabolic acidosis (increased anion gap)*
IV. Vitamin D/Ca Metabolism
A. Hypocalcemia, hyperphosphatemia*
B. Secondary hyperparathyroidism
C. Osteomalacia (aluminum bone disease)
V. Immune Function
A. Increased risk of infection*
1. Impaired host defense (white blood cell function)
VI. Neurologic Function*
A. Inability to concentrate, loss of memory
B. Headache, drowsiness, coma
C. Weakness, tremors, seizures
D. Peripheral neuropathy
E. Autoimmune dysfunction (sweating, swings in blood pressure)

*Improved with dialysis.

Table 86.52. Matabolic and Clinical Abnormalities in End-Stage Renal Failure

Renal osteodystrophy is the term used to describe the myriad changes that occur in Ca, vitamin D, and bone metabolism in ESRF. The combination of a reduced phosphate intake and/or phosphate binders, supplemental calcium (when serum phosphate has been normalized), and 1,25-dihydroxyvitamin D therapy often improves patients with renal osteodystrophy before dialysis is required. The use of antacids and dialysis baths that contain aluminum has provided a particularly devastating form of osteomalacia and dementia not amenable to the usual therapies.

The uremic state clearly impairs WBC function; neutrophil chemotaxis and mononuclear cell chemotaxis are reduced, increasing susceptibility to infection.

The neurologic disturbances noted in ESRF are what usually define the “uremic state.” Clinical manifestations are diverse but often respond dramatically and rapidly to efficient dialysis. Of particular note is the dialysis disequilibrium syndrome, characterized by headache, nausea and vomiting, visual disturbances, disorientation, wide swings in BP, and seizures. This condition is less common in children than in adults but occurs when initial dialysis (usually hemodialysis) lowers a significantly elevated BUN (150 mg/dL or greater) too rapidly, allowing water to move into brain cells and cause cerebral edema. Rapid infusion of mannitol is often effective in reversing these signs and symptoms.

Rhabdomyolysis

Background

Rhabdomyolysis represents a disruption of the skeletal muscle leading to leaking of intracellular contents. It is uncommon in pediatrics, affecting adolescents more commonly than children. A number of disorders, including trauma, intoxications, seizures, infections, endocrinopathies, and metabolic defects, may lead to significant injury of skeletal muscle (Table 86.53). Influenza infections are perhaps the most common precipitating event overall. Of particular note in otherwise healthy adolescents is exertional rhabdomyolysis, which may develop after strenuous exercise.

Trauma	Amphetamines
Extensive muscle injury	Aspirin
Crush injury	Neuroleptic agents
Compartment syndrome	Monoamine oxidase inhibitors
Strenuous exertion	Succinylcholine
Infections	Envenomations
Influenza	Endocrinopathies
Sepsis	Hyperthyroidism
Toxic shock syndrome	Hypothyroidism
Rocky Mountain spotted fever	Diabetic ketoacidosis
Tetanus	Inherited disorders of muscle enzymes
Hyperthermia	Miscellaneous
Prolonged seizure	Polymyositis
Toxins/medications	
Ethanol	
Cocaine	

Table 86.53. Causes of Rhabdomyolysis

Pathophysiology

Regardless of the specific insult, the final common pathway in rhabdomyolysis is injury to skeletal muscle leading to myolysis. As the muscle cells break down, they release their intracellular contents, including myoglobin, CPK, glutamic oxaloacetic transaminase, lactate dehydrogenase, potassium, and phosphate, into the plasma. The circulating myoglobin is subsequently excreted in the urine.

Clinical Manifestations

The classic triad of complaints in rhabdomyolysis consists of myalgias, weakness, and dark urine. In mild cases, particularly early in the course, myalgias may be the predominant manifestation, with or without mild weakness. The emergency physician should inquire about preceding viral infections, exercise, environmental conditions, injuries, bite wounds, ingestions, and medication use. Important considerations in the medical history include seizures, thyroid disorders, and diabetes.

On examination, findings specific to rhabdomyolysis include tenderness of the muscles to palpation, decreased strength, and less commonly, edema. The vital signs may be revealing of the cause in the case of hyperthermia. In some cases, trauma may be apparent, as in the form of a crush injury; however, patients with muscle injury secondary to vigorous exercise may manifest no local signs or minimal tenderness and edema.

The most reliable test for rhabdomyolysis is elevation of the CPK level to at least five times the upper limit of normal. The release of CPK occurs rapidly after injury to the muscle, peaks at 24 to 36 hours, and persists for several days. Levels as high as 50,000 to 100,000 units/mL are not unusual. The urine from patients with rhabdomyolysis may appear dark and test positive for blood with a reagent strip, but RBCs are not increased on microscopy. Other laboratory abnormalities include hyperphosphatemia, hypocalcemia, acidosis, hyperuricemia, and elevations of BUN and creatinine.

The major potential complication of rhabdomyolysis is ARF, resulting at least in part from myoglobin casts obstructing renal tubules. Renal failure manifests with oliguria or anuria and worsens the biochemical profile of the patient by increasing the plasma levels of hydrogen ions, phosphate, potassium, BUN, and creatinine.

Management

In addition to general supportive care of critically ill patients, when possible, steps should be taken to eliminate the inciting event. As an example, anticonvulsants are administered to interrupt status epilepticus and cooling is indicated for the patient with hyperthermia. Initial measurement of muscle enzymes and electrolytes is appropriate, and vital signs should be monitored. Therapy is directed at restoring vascular volume, when compromised, and facilitating blood flow to the kidneys in an effort to preserve renal function. Management begins with the delivery of a 20 mL/kg bolus of normal saline. In more severe cases, diuresis is achieved either with mannitol (1 g/kg) or furosemide (1 mg/kg). Depending on their severity, acidosis and electrolyte disorders may need specific treatment; occasionally, dialysis is required. Patients with significant rhabdomyolysis, as defined by markedly elevated levels of CPK and/or myoglobinuria, require admission to the hospital.

CHAPTER 87

Hematologic Emergencies

ALAN R. COHEN, MD

Department of Pediatrics, The University of Pennsylvania School of Medicine, and Division of Hematology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Hematologic emergencies arise in children who have been previously well, who have known blood diseases, or who have systemic diseases. Although the particular setting in which a serious blood abnormality occurs affects some facets of emergency care, the initial measures of support, diagnosis, and treatment are based on general principles that often cross the boundaries between the usual categories of blood disorders. This chapter emphasizes these principles as they apply to disorders of red cells, white cells, platelets, and coagulation. The initial evaluation and treatment of life-threatening disorders are described in detail. When controversy exists regarding specific management problems, alternative approaches are presented.

DISORDERS OF RED BLOOD CELLS

Severe anemia is a pediatric emergency that requires rapid evaluation and treatment to prevent hypoxia, congestive heart failure, and death. The classification of causes of anemia according to 1) blood loss, 2) increased red cell destruction, and 3) decreased red cell production is familiar to most physicians and provides an excellent starting point for the evaluation of the anemic child. In Chapter 59, these categories are used for the differential diagnosis of hematologic causes of pallor and for the appropriate selection of initial laboratory studies. In the section that follows, the same classification is applied to the emergency management of specific hematologic disorders.

Blood Loss

Trauma is the leading cause of major hemorrhage in children. Every emergency physician must be prepared to act quickly and systematically when confronted with an actively bleeding child. The initial approach often requires the joint effort of a team of doctors and nurses to accomplish numerous tasks simultaneously. Within the first few minutes, the nature of the accident, an estimate of blood loss, and the presence of major current or chronic illnesses, including bleeding disorders, should be determined. The adequacy of the airway must be ensured. Vital signs should be measured frequently to detect early signs of hypovolemic shock. All clothing should be removed, and the child should be examined for sites of bleeding other than those found on initial inspection. Intravenous (IV) access should be established, preferably in a large vein, and blood samples should be drawn for a complete blood count (CBC) (including platelet count), screening coagulation studies (prothrombin time and partial thromboplastin time), and the cross-matching of donor blood. A spun hematocrit should be measured immediately in the emergency department (ED) if a CBC cannot be obtained quickly. If bleeding is brisk and sustained or if there is any suggestion of hypovolemic shock, volume expanders should be infused. Both colloid preparations, such as 5% albumin, and crystalloids, such as saline or Ringer's lactate, are effective for the maintenance of intravascular volume, but the latter solutions may be more readily available and should be used initially.

After immediate stabilization has been completed and external hemorrhage has been slowed or stopped, the child should be evaluated for internal hemorrhage. This evaluation is especially important when the nature of the trauma is unclear or when multiple areas of the body may have been involved, as in automobile or bicycle accidents. The importance of

locating internal hemorrhage is underscored by the occurrence of hypovolemic shock and death in the child whose skin lacerations were sutured but whose ruptured spleen went undetected. Suspicion of internal bleeding should be raised in the presence of a continuously falling hematocrit or continuing signs of hypovolemic shock despite control of external bleeding and the replacement of seemingly adequate volume. Respiratory compromise, a protuberant abdomen, or changing sensorium may be further clues to the presence of internal hemorrhage. Further studies, including radiographs of the chest and abdomen, peritoneal lavage, and computed axial tomography (CAT) of the head or abdomen, should be instituted when appropriate.

Gastrointestinal (GI) bleeding and other forms of nontraumatic hemorrhage can also be life-threatening. In some cases, the severity of bleeding is accentuated by the combination of an anatomic lesion and a related bleeding disorder, such as esophageal varices with a coagulopathy caused by liver failure. Unexplained severe anemia requires a careful search for bleeding in the GI tract, retroperitoneal space, or elsewhere.

The approach to blood transfusion (Table 87.1) can be divided into three levels of intervention, depending on the clinical findings and the laboratory data:

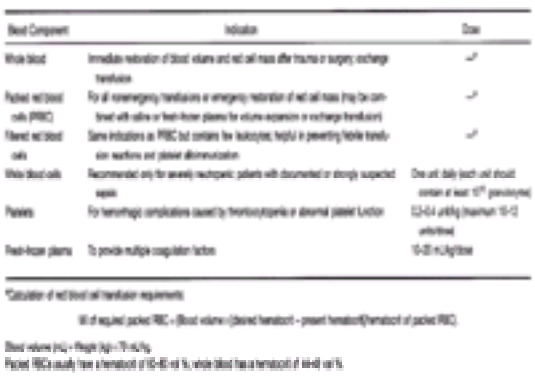

Table 87.1. Guidelines to Transfusion Therapy

1. If bleeding has been controlled, vital signs are stable, the hematocrit remains above 20%, and further bleeding is considered unlikely, the initially crossmatched blood should be held for at least 24 hours and then released for other use if no longer required for this patient.
2. If bleeding has led to hypovolemic shock but tissue oxygenation is not critically affected, intravascular volume should be supported with crystalloid or colloid solutions until a crossmatch has been performed and compatible donor blood is available. If necessary, group and Rh type-specific but non–cross-matched blood can be used. A similar approach should be used if the hematocrit slowly falls to a level less than 15 to 20% or if the hematocrit remains stable at a low level but further bleeding is considered likely (e.g., esophageal varices).
3. Only when bleeding is accompanied by life-threatening hypoxia should non–cross-matched group O, Rh-negative blood be administered. Transfusion of blood with minor blood group incompatibilities may result in immediate hemolysis and renal failure or, more commonly, may result in sensitization of the recipient to red cell antigens, making future blood compatibility testing difficult. The determination of the patient's ABO or Rh blood group can be performed within a few minutes, so selection of ABO- and Rh-compatible donor units is almost always feasible.

A common pitfall in the assessment and treatment of the bleeding patient is the underestimation of the amount of blood loss. Neither the history of bleeding nor the initial hemoglobin level may accurately reflect the severity of hemorrhage. For example, a child with upper GI bleeding may have a modest amount of hematemesis or melena and a hemoglobin of 8 g/dL when initially evaluated in the ED. However, within an hour, the child may pass a large amount of tarry stool and the hemoglobin level may fall to 3 g/dL. Tachycardia or hypotension in a patient with only a moderate degree of anemia should serve as a warning that intravascular blood loss is out of proportion to the hemoglobin level and that early replenishment of intravascular volume is essential.

Increased Red Cell Destruction

Membrane Disorders

The anemia in disorders of the red cell membrane (hereditary spherocytosis, hereditary elliptocytosis, stomatocytosis, liver disease) is rarely severe enough to constitute a hematologic emergency. However, the hemoglobin level may fall even further when red cell destruction increases (hemolytic crisis) or red cell production slows (aplastic crisis). Hemolytic crises are usually associated with acute infections and are self-limiting. Most aplastic crises accompany parvovirus infection; anemia may be the only manifestation of the infectious process.

The hemoglobin level and reticulocyte count should be routinely checked when children with known disorders of the red cell membrane develop increasing jaundice or pallor associated with an infectious illness. The hemolytic crisis is characterized by worsening jaundice, falling hemoglobin level, and increasing reticulocyte count. In contrast, the aplastic crisis is associated with slowly increasing pallor, worsening anemia, and low or absent reticulocytes. In children whose underlying red cell membrane disorder is associated with brisk hemolysis (hemoglobin level less than 8 to 9 g/dL and reticulocytes greater than 5 to 7%), these crises may produce acute symptoms of anemia. If the hemoglobin level falls below 3 to 4 g/dL or if cardiovascular stability is threatened, red cell transfusions may be necessary. One unit or less of red cells is usually sufficient to support the patient until the hemolytic or aplastic crisis is over.

For some children, an aplastic crisis may be the first clinical manifestation of an undiagnosed membrane disorder or

other chronic hemolytic anemia. The low hemoglobin level and reticulocyte count may suggest a pure problem of red cell production such as transient erythroblastopenia of childhood or Diamond-Blackfan anemia. However, a careful history for features such as neonatal jaundice or splenectomy in other family members, a thorough physical examination to assess spleen size, and a review of the peripheral smear to look for spherocytes or other abnormalities may identify the underlying hemolytic anemia.

The need for transfusions in an aplastic crisis should be considered carefully because the relatively slow development of the anemia usually allows adequate time for compensatory physiologic responses to the anemia. An increase in cardiac output keeps the patient hemodynamically stable even at very low hemoglobin levels. Moreover, many patients with aplastic crises are already beginning to resume red cell production when the crises are recognized, and the reemergence of reticulocytes in the peripheral blood or the presence of mature erythrocyte precursors in the bone marrow often precludes the need for red cell transfusions.

Older children and adolescents with red cell membrane disorders may develop gallstones because of increased red cell destruction and bilirubin release. Cholelithiasis or cholecystitis in affected patients should be managed the same way as in patients without underlying hematologic disease (see Chapter 93).

Metabolic Abnormalities

Like the red cell membrane disorders, erythrocyte metabolic abnormalities usually do not cause severe anemia. However, episodes of acute and sometimes life-threatening hemolysis can occur in many variants of glucose-6-phosphate dehydrogenase (G6PD) deficiency, including the A $^{-}$ variant found in 10% of African-American boys, after exposure to drugs or chemicals (Table 87.2) or during an infectious illness. Ingestion of naphthalene-containing mothballs is the most common cause of severe hemolysis in American children with G6PD deficiency, and parents should be asked about the presence of mothballs as part of the evaluation of any child with an acute hemolytic anemia. The acute intravascular hemolysis of G6PD deficiency usually occurs within 1 to 3 days of oxidant exposure and is characterized by pallor, malaise, fever, scleral icterus, abdominal and back pain, and dark urine. The anemia is accompanied by an increased reticulocyte count, and diagnostic blister cells are present on the peripheral smear. Hematologic changes may be minimal or absent in the first 24 hours after ingestion. Careful monitoring of the patient should continue for at least another day. Treatment should include removal of the offending agent and fluid administration to prevent renal tubular damage. When hemolysis is severe, red cell transfusions may be required. However, if the diagnosis is uncertain, a pretransfusion blood sample should be saved for measurement of specific enzyme levels. Because enzyme levels are higher in younger red cells, the diagnosis of G6PD or other enzyme deficiencies may be obscured at the time of acute hemolysis and a high reticulocyte count.

Antimalarials (primaquine)
Sulfonamides (including sulfasalazine and trimethoprim-sulfamethoxazole)
Nalidixic acid and nitrofurantoin
Naphthalene (moth balls)
Fava beans
Aspirin (does not cause acute hemolysis with G6PD deficiency in African-Americans when used in therapeutic doses)

Table 87.2. Drugs and Substances Associated with Acute Hemolysis in Children with Glucose-6-Phosphate Dehydrogenase (G6PD) Deficiency

Aplastic crises may occur in more severe variants of G6PD deficiency and other red cell metabolic disorders such as pyruvate kinase deficiency that are associated with chronic hemolysis. Diagnosis and treatment of this complication are the same as described in the previous section regarding membrane disorders.

Autoimmune Hemolytic Anemia

Background

One of the most serious causes of severe anemia in children is autoimmune hemolytic anemia (AIHA). This antibody-mediated disorder occurs most commonly in young children. Affected erythrocytes are lysed intravascularly or removed prematurely from the circulation by macrophages of the reticuloendothelial system. AIHA may be associated with infections, drugs, inflammatory diseases, or malignancies, but a specific cause is rarely identified in pediatric patients.

Clinical Manifestations

Although this disorder may occasionally be indolent and may go undetected for days or weeks, AIHA is usually associated with the sudden onset of pallor, jaundice, and dark urine. The hemoglobin level may be as low as 1 to 2 g/dL at the time of diagnosis. When the anemia is this severe, the child may appear moribund and desperately ill. Signs of congestive heart failure may be prominent.

The anemia is usually accompanied by reticulocytosis, although the reticulocyte count may be below 5% during the first

few days of the illness. Occasionally, patients remain reticulocytopenic for prolonged periods. Spherocytes are often found on the peripheral smear, and red cell fragments may sometimes be present. Free hemoglobin in the urine produces a positive dipstick reaction for blood in the absence of red cells on microscopic urinalysis. When hemolysis is severe enough to exceed the renal clearance of hemoglobin, the plasma will be pink, and careful inspection of the plasma layer of a spun hematocrit may provide an early diagnostic clue. The direct Coombs test using broad-spectrum Coombs serum (IgG, IgM, and complement) is usually positive in childhood AIHA. Acute hemolysis is most commonly associated with IgG antibody and/or complement but may also occur with IgM-mediated disease. Although the antibody may appear to have specificity in vitro (usually in the Rh system), the shortened survival of “compatible” blood suggests the presence of wider activity of the identified antibody or the presence of additional undetected antibodies in many cases. However, certain specific antibodies are associated with infectious causes of AIHA, such as *Mycoplasma* (anti-I) or infectious mononucleosis (anti-i).

Management

The management of the child with AIHA should be aggressive because the hemoglobin level may fall precipitously (Table 87.3). Hospitalization for careful observation and treatment is usually necessary. The immediate institution of corticosteroid therapy (prednisone 2 to 4 mg/kg per day or equivalent doses of parenteral preparations) may prevent or reduce the need for red cell transfusions. Alternatively, the patient may be treated with g-globulin 1 g/kg by IV infusion. For life-threatening AIHA, the use of steroids and g-globulin should be considered. Patients with cold-reacting antibodies (most IgM and some IgG antibodies) do not respond as favorably to steroids and g-globulin as those with warm-reacting antibodies (most IgG antibodies), but a trial of either therapy is still warranted in the severely anemic patient. The response to steroids or g-globulin in AIHA usually occurs within a few hours or days.

Maintain normal or increased urine output with intravenous (IV) fluids.
Immediately begin corticosteroid therapy with prednisone 2 mg/kg/day or a parenteral preparation in an equivalent dose. Alternatively, administer γ-globulin 1 g/kg by IV, alone or in combination with corticosteroid.
Administer red cell transfusions when severe anemia is accompanied by signs of hypoxia or cardiac failure.
Give first 5 mL in 10–15 min and observe for symptoms of acute hemolysis.
Check plasma layer of a spun hematocrit for pink color indicative of hemolysis of the transfused red cells.
If symptoms or signs of worsening hemolysis are present, try a different unit of red cells.
If hemoglobin level does not increase after transfusion:
Increase steroid dosage to 4 mg/kg/day; or
Administer IV γ-globulin 1 g/kg; or
Begin plasmapheresis or exchange transfusion; or
Perform splenectomy.

Table 87.3. Treatment of Severe Autoimmune Hemolytic Anemia

Red cell transfusions are hazardous in patients with AIHA and should be reserved for children with severe anemia and signs of hypoxia or cardiac failure. The presence of a nonspecific antibody in the patient's serum makes it difficult to find a unit of donor blood compatible in the major cross-match (donor cells and patient serum). The finding of an apparently compatible unit may pose even greater danger because the physician is lured into a false sense of confidence when, in fact, an undetected antibody may still cause a severe hemolytic transfusion reaction. The use of the “least incompatible” unit is a common practice, although data to support this approach are lacking. The best policy is to avoid transfusion when possible. If red cells are required and a compatible donor unit can be found, this unit should be used. Otherwise, ABO- and, if possible, Rh-compatible units should be administered despite the incompatibility in vitro. The recognition of the risks of transfusion in children with AIHA should not lead to the withholding of “incompatible” blood when transfusion therapy is required to prevent severe morbidity or death.

Whether the unit of red cells appears compatible or incompatible on the basis of serologic studies, special precautions should be taken during the actual transfusion. The first 5 mL should be administered in 10 to 15 minutes, and the patient should be observed closely for malaise, back pain, fever, and other signs of acute hemolysis. The plasma layer of the spun hematocrit should be carefully inspected for the pink color of free hemoglobin. If any of these findings is present, the transfusion should be stopped and normal saline should be administered until a new unit can be prepared. If the patient is asymptomatic and the plasma is clear, the remainder of the unit should be given with continuing close observation. Blood administered to patients with cold antibodies should be infused through a warmer.

In rare instances, the hemoglobin level continues to fall despite steroids, g-globulin, and red cell transfusion, necessitating alternative therapeutic attempts to sustain life. Plasmapheresis may remove sufficient antibody to reduce the destruction of the patient's erythrocytes and to allow improved survival of transfused red cells. If this measure fails, emergency splenectomy may be required.

Nonimmune Acquired Hemolytic Anemia

Acute hemolytic anemia in children may be caused by infections, chemicals, or drugs that damage the red cell directly. These disorders resemble AIHA in their clinical presentation and should be considered in the child with acquired hemolytic anemia and a negative Coombs test. Infectious agents that may induce hemolytic anemia include malaria (which is of particular importance in Southeast Asian and African immigrants), other protozoa, and a wide variety of Gram-positive and Gram-negative organisms. Chemicals and drugs that cause oxidative hemolysis include naphthalene, nitrofurantoin, and sulfasalazine. Treatment is directed at elimination of the offending agent. Red cell transfusions are usually unnecessary unless anemia is severe (hematocrit less than 15%) or accompanied by signs of cardiovascular compromise.

Erythrocyte Fragmentation Syndromes

Red cells undergo fragmentation and lysis when subjected to excessive physical trauma within the cardiovascular system. Hemolytic anemias as a result of red cell fragmentation have been associated with abnormalities of the heart (valve homografts and synthetic prostheses, uncorrected valvular disease), great vessels (coarctation of the aorta), and small vessels (hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, collagen vascular disease, hemangiomas). Physical findings are related to the underlying disorder. The presence of red cell fragments on the peripheral smear strongly suggests mechanical damage to the erythrocyte. When small vessels are involved, thrombocytopenia may also be present. Hemolytic anemia associated with valvular or great vessel disease rarely causes severe anemia. However, iron deficiency as a result of intravascular lysis and urinary excretion of hemosiderin in renal tubular epithelial cells may aggravate the hemolytic anemia. Oral iron supplementation may obviate the need for transfusions. When hemolysis is a result of small vessel disease, treatment of the underlying disorder (e.g., collagen vascular disease) or primarily affected organs (e.g., renal failure in hemolytic uremic syndrome) is the first priority. Red cell transfusions should be reserved for the treatment of symptomatic anemia. Because the hemolysis is caused by extracorpuscular factors, survival of transfused cells may be markedly shortened. The management of intravascular coagulation associated with several of these disorders is discussed later in this chapter.

Decreased Red Cell Production

Disorders of red cell production, unless accompanied by shortened red cell survival, are characterized by a slowly progressive anemia. Consequently, the physician does not often encounter many of the difficulties associated with acute, life-threatening hemolysis or severe bleeding. However, the insidious onset of anemia when erythropoiesis is impaired may delay recognition of the disorder, and severe anemia and cardiac failure may be present at the time of diagnosis. Tissue oxygenation may be inadequate because of the low hemoglobin level, and conditions that increase the cardiac rate or output (fever, exercise) may precipitate congestive heart failure in the previously compensated patient. In addition, anemia secondary to diminished red cell production may be associated with an underlying, severe illness such as leukemia, neuroblastoma, or aplastic anemia in which other life-threatening hematologic abnormalities (severe neutropenia or thrombocytopenia) may be present. Thus, the patient with impaired production of erythrocytes may be as ill as the patient with acute hemolysis.

The important role of the history, physical examination, and laboratory studies in the initial evaluation of the child with decreased red cell production is described in Chapter 59. Initial management should include basic support of cardiorespiratory function and identification and treatment of conditions such as fever, which may be compounding the problems of severe anemia. The patient with hypoxia or cardiac failure requires red cell transfusions. As described earlier, the urgency of the clinical situation rarely dictates the need to abbreviate the standard cross-matching procedures. A pretransfusion anticoagulated blood sample and a serum sample should always be saved for further diagnostic studies as well as for the determination of the patient's red cell antigen profile should chronic transfusion therapy be necessary. The initial transfusion should be given as a small aliquot of packed red cells. In many instances, the symptoms of severe anemia will be relieved after the hemoglobin level has risen only 1 or 2 g/dL. The administration of additional blood is rarely necessary in the early stages of therapy. Furthermore, the added volume may precipitate cardiac failure in the face of a preexisting high output state. A helpful rule is to administer a number of milliliters per kilogram of packed red cells equivalent to the hemoglobin level. For example, in a child with aplastic anemia, a hemoglobin level of 3 g/dL and early signs of cardiovascular compromise would indicate that 3 mL/kg of packed red cells be given. Some physicians routinely administer diuretics (e.g., furosemide 1 mg/kg per dose) during the transfusion of a severely anemic patient. An alternative approach is to reserve diuretic therapy for those patient who develop signs of increasing cardiac compromise during the transfusion.

Aplastic and Hypoplastic Anemias

The differential diagnosis of aplastic and hypoplastic anemias is discussed in Chapter 59. Most of these disorders have a protracted course and, after initial stabilization of the patient, require intensive diagnostic evaluation and careful assessment of chronic therapy rather than emergency management. Transfusion should be used with particular caution in the initial management of patients with hypoplastic and aplastic anemias because exposure to human leukocyte antigen (HLA) and other antigens may adversely affect engraftment of transplanted bone marrow in patients who might otherwise have benefited from this procedure. If transfusions are required for severe anemia (hemoglobin less than 3 to 4 g/dL) and signs of cardiac failure or poor oxygenation, the goal of treatment should be relief of symptoms, not restoration of a normal hemoglobin level. When possible, filtered red cells should be used to decrease exposure to donor white cells, which contribute significantly to refractoriness to platelet transfusions. Related family members should not be used as blood donors. If the patient is cytomegalovirus (CMV) seronegative, the use of filtered blood or blood from CMV-seronegative donors may decrease the likelihood of CMV-related complications if a bone marrow transplant is later performed.

For patients with a hypoplastic anemia suggestive of transient erythroblastopenia of childhood, a bone marrow aspirate may be helpful in predicting the course of the disease during the next few days and, in particular, the likelihood that red cell transfusions will be required later. For example, a patient with transient erythroblastopenia of childhood has a hemoglobin level of 4 g/dL and absent reticulocytes at the time of diagnosis. If examination of the bone marrow reveals only an occasional pronormoblast, a further decrease of the hemoglobin concentration should be anticipated and red cell transfusions will almost certainly be required. However, if the bone marrow aspirate shows numerous erythrocyte precursors progressing through all levels of red cell maturation, a peripheral reticulocytosis can be expected within 24 hours and red cell transfusions will be unnecessary (Fig. 87.1).

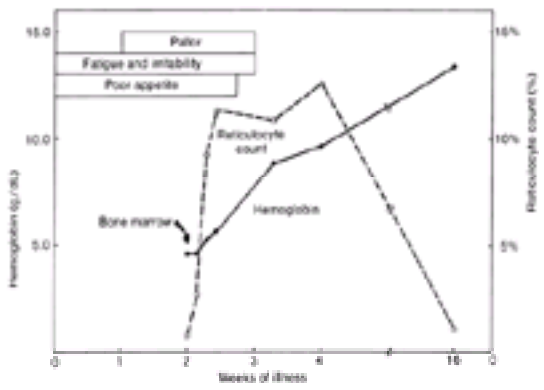

FIGURE 87.1. Clinical course of transient erythroblastopenia of childhood (TEC) in a 2-year-old girl. There was a 1- to 2-week history of pallor, fatigue, and decreased appetite. A bone marrow aspirate showed an active erythroid series that was reflected in the subsequent reticulocytosis and full hematologic recovery.

Nutritional Anemias

Nutritional anemias in children constitute more of a public health problem than a hematologic emergency. However, on occasion, the hemoglobin level may be very low at the time of diagnosis. Severe iron deficiency occurs mainly in 1- to 2-year-old children who drink 1 quart or more of cow's milk daily and have little room for other foods richer in iron. Adolescent girls make up another group at high risk for iron deficiency because a diet normally marginal in iron content becomes totally inadequate in the face of menstrual blood losses. The presenting complaint in severe iron deficiency anemia is usually pallor, lethargy, irritability, or poor exercise tolerance. In megaloblastic anemias such as vitamin B_{12} deficiency in an infant exclusively breast-fed by a vegetarian mother or in folic acid deficiency caused by impaired folate absorption, nonhematologic symptoms such as diarrhea, slowed development, or coma may be more prominent than the symptoms of anemia.

Stabilization and improvement can usually be achieved with replacement of the deficient nutrient. Nucleated red cells or reticulocytes usually appear within 48 hours of replacement therapy in folic acid or vitamin B_{12} deficiency and within 72 hours of therapy in severe iron deficiency anemia. Because of this rapid response, red cell transfusions are rarely required unless symptoms associated with the anemia pose a serious threat. A response to replacement therapy should not preclude further investigation of the origin of the anemia, especially when the dietary history is inconclusive. For example, iron deficiency anemia may result from repeated small pulmonary hemorrhages or chronic bleeding from an intestinal lesion rather than from inadequate iron intake. Similarly, megaloblastic anemias may be caused by deficient intrinsic factor or abnormalities of folic acid transport rather than from a seriously altered diet.

Iron replacement therapy consists of 3 to 6 mg/kg per day of elemental iron given orally as ferrous sulfate in two or three divided doses. Parenteral iron is painful and dangerous. Moreover, the hematologic response to intramuscular or IV iron dextran is no faster than the response to oral iron. Replacement doses of 1 mg of folic acid and 100 µg of vitamin B_{12} daily are undoubtedly excessive, but their common use reflects the safety and the concentrations of the available compounds.

The administration of supplemental iron, vitamin B_{12}, or folic acid should not be considered a substitute for adequate dietary intake when nutritional deficiency is recognized. Unlike most hematologic emergencies, the rapid improvement after treatment of these disorders may reduce the likelihood of further visits despite attempts to ensure adequate follow-up care. Therefore, a strong effort to restructure the diet should begin at the time of the initial contact.

DISORDERS OF HEMOGLOBIN STRUCTURE AND PRODUCTION

The disorders of hemoglobin structure and production that are most often encountered in a pediatric ED are the sickle hemoglobin syndromes (e.g., sickle cell anemia, hemoglobin sickle cell disease, hemoglobin S-b-thalassemia). Although many physicians are familiar with these diseases, the frequency with which affected patients are seen may lead to a false sense of complacency, leaving subtle findings undetected. Thalassemia major and methemoglobinemia occur much less commonly than the sickling disorders. Lack of familiarity with these diseases may delay recognition of serious illness, resulting in severe morbidity and even death. In the section that follows, particular attention is paid to the recognition of unusual but serious diseases and the management of the many and diverse complications associated with the hemoglobinopathies.

Sickle Hemoglobin Disorders

Background

The sickling disorders are responsible for a large percentage of hematologic emergencies and a major proportion of total visits for any reason in many urban pediatric EDs. Although the basic molecular lesion in these disorders is well defined, the mechanisms responsible for the numerous complications remain poorly understood and treatment is often unsatisfactory. Nonetheless, early recognition and aggressive management of specific problems may alleviate unnecessary suffering and prevent much of the morbidity and mortality associated with the sickling disorders. Optimal long-term care should be provided at a center with specialists who are familiar with sickle cell disease and its complications.

Clinical Manifestations/Management

Presentation

Newborn screening for sickling disorders is now common in the United States. However, newborns may occasionally elude testing or may rarely be misidentified as having sickle trait. In some instances, the information regarding the newborn screening is not available at the time of the ED visit.

It is important to identify the ill child with an undiagnosed or unrevealed sickling disorder so that appropriate therapy is instituted. The diagnosis of sickle cell disease should be considered in African-American children with unexplained pain or swelling (especially of the hands or feet), pneumonia, meningitis, sepsis, neurologic abnormalities, splenomegaly, or anemia. The hemoglobin level and reticulocyte count are inadequate screening tests for the sickle hemoglobinopathies because values in affected patients (especially those with hemoglobin sickle cell disease and S-b-thalassemia) may overlap with normal values. Similarly, the peripheral smear may be devoid of sickled cells. Definitive testing for sickling disorders can be accomplished quickly by hemoglobin electrophoresis, isoelectric focusing, or high-pressure liquid chromatography (HPLC). If these tests are not available, standard solubility tests can be used to identify the presence of sickle hemoglobin. However, solubility tests do not distinguish patients with sickle cell trait, hemoglobin sickle cell disease, or other sickle variants from patients with sickle cell anemia (hemoglobin SS). Therefore, the results of solubility screening tests must be considered in the context of the clinical presentation and other laboratory studies. In addition, whether the screening test is positive or negative, confirmatory testing by hemoglobin electrophoresis or another method is mandatory in all patients with hematologic or nonhematologic emergencies that may be related to sickle cell anemia.

Sepsis

A combination of impaired immunologic functions, including early loss of normal splenic activity, contributes to the significantly increased frequency of sepsis in patients with sickle cell disease and the fulminant nature of this complication. The risk of bacterial sepsis in the patient with sickle cell disease is increased several hundredfold in comparison with the normal population. *Streptococcus pneumoniae* and *Haemophilus influenzae* are the most common pathogens in young children, although *Escherichia coli* and *Salmonella* are more frequent causes of bacteremia in older children. The period of greatest risk is between the ages of 6 months and 3 years, when development of protective antibodies is limited and splenic function is diminished or absent.

The incidence of bacteremia in children with hemoglobin SS during the first 3 years of life is 7.98 per 100 patient-years. Approximately one-fifth of these children die. The comparable incidence rate for children with hemoglobin sickle cell disease in the first 3 years of life is 3.54 per 100 patient-years, although mortality is not as high as in patients with hemoglobin SS. Immunization with pneumococcal and *H. influenzae* vaccines and administration of prophylactic penicillin help prevent serious infections but certainly do not eliminate this complication of sickling disorders.

The common occurrence of fever with no obvious source in young children with sickle cell disease makes the distinction between serious bacterial infections and benign, self-limiting viral disorders a particularly frustrating problem. Unfortunately, no single physical finding or laboratory test (other than blood culture) can accurately identify the septic patient. The physician consequently must choose among several options including routine admission, prolonged observation, or outpatient management. No matter which option is selected, the goal is to be certain that all children with sickle cell disease and sepsis receive appropriate antimicrobial therapy. Thus, the cornerstone of management in the ED is rapid initiation of antibiotics after obtaining appropriate cultures. Differences in subsequent management should not detract from the importance of this early step.

The treatment of the very ill-appearing child with sickle cell disease and probable sepsis should include the rapid institution of antibiotic therapy and aggressive management of septic shock. As in other patients with reduced or absent splenic function, clinical deterioration may be extremely rapid. The patient who is alert on arrival to the ED may be moribund and hypotensive 30 minutes later. Because of the emergence of penicillin-resistant strains of *S. pneumoniae,* vancomycin may be added. Septic shock should be treated in the same way as in patients without hematologic disorders (see Chapter 3). Simple red cell transfusions or exchange transfusions may be needed to correct severe anemia or to reduce the likelihood of secondary organ damage caused by massive sickling in the presence of hypoxia, stasis, and acidosis.

In many centers, children with sickle cell disease and fever who do not appear to be seriously ill, but who nonetheless are at increased risk for sepsis, continue to be admitted to the hospital for at least 48 hours. Ampicillin or a third-generation cephalosporin is usually administered intravenously until the cultures are confirmed to be negative.

As an alternative to conventional inpatient management, other centers now treat selected children with sickle cell disease and fever as outpatients. This approach is usually restricted to children who do not appear acutely ill and who, on physical examination, do not have findings such as pallor, rales, or increased spleen size that indicate additional problems. Some centers employ additional criteria such as age, previous history, temperature, and white blood cell count. Young children are at higher risk of bacterial sepsis and may be more difficult to assess for early signs of sepsis than older children. A history of bacterial infection may be a risk factor for a subsequent episode. Temperatures greater than 39 to 40 degrees Centigrade have been associated with an increased likelihood of sepsis in some studies of children with sickle cell disease, although lesser degrees of elevation do not guarantee negative blood cultures.

Those children who do not appear to be seriously ill and who, on the basis of physical findings and results of laboratory tests, are judged to be at low risk for bacteremia, are treated in the ED with a long-acting cephalosporin such as ceftriaxone (75 mg/kg) and then discharged. A compromise between outpatient therapy and inpatient care is the use of a short-stay unit. With this approach, the patient receives a long-acting cephalosporin and is observed for 4 to 24 hours.

Newer culture systems detect most cases of bacteremia with *S. pneumoniae* within this time frame. Further therapy after discharge from the ED or short-stay unit varies among centers but may include 1 to 3 days of an oral antibiotic such as amoxicillin. A key component of the outpatient management of children with sickle cell disease and fever is a return visit or telephone report within 24 hours after discharge from the ED or short-stay unit. Inpatient care should be strongly considered for children whose families are unlikely to comply with this followup.

Because unexplained fever is uncommon in older children in general, the diagnosis of bacterial sepsis should be strongly considered in the older child with sickle cell anemia and fever. A careful assessment of the child's clinical condition should take into account the factors noted earlier. If the child appears toxic, admission for antibiotic treatment is advisable even in the absence of high fever or leukocytosis. Once again, good follow-up care must be ensured if the patient is managed as an outpatient.

Other Infections

Children with sickle cell disease are affected more often with infections other than sepsis in comparison with their hematologically normal counterparts. Meningitis, pneumonia, septic arthritis, and osteomyelitis may be responsible for substantial morbidity and mortality unless promptly recognized and appropriately treated. The level of suspicion for meningitis should be particularly high in the young, irritable child with sickle cell disease and unexplained fever. Antibiotic therapy of meningitis is similar to that recommended for hematologically normal children with this disorder (see Chapter 84). In particular, the possibility of resistant *S. pneumoniae* should guide treatment. Exchange transfusion to lower the percentage of sickle hemoglobin may reduce the risk of intracerebral sickling and infarction in areas of local swelling and possible red cell sludging. This procedure may also help resolve the conflict between the need for maintenance or greater fluid therapy to prevent vaso-occlusion and the need to restrict fluids in the face of cerebral swelling and possible inappropriate antidiuretic hormone secretion. When hemoglobin S is less than 30% of the total hemoglobin, sickling is unlikely and fluid management can be dictated by the central nervous system findings.

Acute chest syndrome, which includes pneumonia as well as pulmonary infarction, is one of the most common reasons for hospital admission for children with sickle cell anemia. The affected patient is usually tachypneic, even after antipyretic therapy. Rales, rhonchi, and physical findings of lobar consolidation may be present. However, in some children, particularly those who are somewhat dehydrated, physical findings may be far less striking. Rales may be heard only after several hours of rehydration. Because acute chest syndrome may escape detection on physical examination, a chest radiograph should be obtained in children with sickle cell disease and unexplained fever or chest pain. A decrease in oxygen saturation, readily measured in the ED and compared with baseline values, may identify patients with early acute chest syndrome.

The problem of identifying a responsible pathogen in patients with sickling disorders and acute chest syndrome is similar to that encountered in hematologically normal children with pneumonia (see Chapter 84). Although pneumonia caused by *Mycoplasma pneumoniae, S. pneumoniae, Chlamydia trachomatis,* and Gram-negative organisms is more common in sickle cell disease, a causative organism is rarely identified in cultures of the blood and sputum or in counterimmunoelectrophoresis or latex agglutination studies of the blood and urine. The initial white count and differential are usually not helpful in distinguishing patients with bacterial pneumonia from those with viral pneumonia or pulmonary infarction. The hemoglobin level is more likely to fall and the fever is more likely to persist during the course of bacterial pneumonia, but this information is not yet known, of course, when the patient is first seen in the ED.

Because a responsible organism for acute chest syndrome is nearly never known at the outset, treatment is begun with IV-administered ampicillin or a third generation of cephalosporin and modified according to the clinical response. In the very ill child, the identification of the causative organism should be pursued more vigorously with tracheal aspirate, aspiration of pleural fluid when present, or aspiration of lung tissue. Initial therapy of the child with severe acute chest syndrome should also include erythromycin. Oxygen should be administered to children with acute chest syndrome who have evidence of respiratory distress or hypoxia. Red cell transfusions or exchange transfusion should be used very early in the course when the patient is severely anemic (e.g., hemoglobin less than 5 g/dL), is hypoxic, or has radiologic or other evidence of severe or rapidly progressive disease.

Septic arthritis and osteomyelitis present particularly difficult diagnostic problems in children with sickle cell disease because the clinical findings so closely resemble those found in infarctions of the bone. A careful physical examination and judicious use of laboratory tests help the physician weigh the relative likelihood of infection and infarction. If symptoms are of recent onset (less than 3 days), a ^{99m}Tc-diphosphonate bone scan in conjunction with a ^{99m}Tc-sulfur colloid bone marrow scan may be helpful in distinguishing the two processes. In osteomyelitis, the bone scan shows increased uptake and the bone marrow scan is normal. In bone infarction, the bone scan is normal but the bone marrow scan shows decreased uptake. Magnetic resonance imaging (MRI), gallium scans, and radiolabeled white cell scans may also be of diagnostic help, but the value of these techniques in distinguishing bone infection from infarction remains to be proven. Closed or open bone aspiration should precede the institution of antibiotic therapy in the patient with suspected osteomyelitis. Similarly, aspiration of an affected joint should be performed if septic arthritis is strongly suspected. In most instances, swollen, warm, and tender joints are caused by local infarction. The presence of other sites of concurrent infarction and the patient's description of the pain as typical “crisis pain” may be helpful in identifying the cause as vaso-occlusion. The total white cell count and differential count of the joint fluid may be similar in both septic arthritis and sterile effusion secondary to infarction. Therefore, the Gram stain and culture are especially important. Septic arthritis of the hip deserves special mention because delayed intervention may result in necrosis of the femoral head. Children with this complication usually appear quite ill and hold the limb in a “frog-leg” position. Confirmation of septic arthritis by joint aspirate should be followed as soon as possible by surgical decompression.

Vaso-Occlusion

Infarction of bone, soft tissue, and viscera may occur as a result of intravascular sickling and vessel occlusion. Physiologic or environmental factors that initiate the process of vaso-occlusion and pain are rarely identified, although

swimming in cold water may be one important cause of painful crisis. Children may have only pain or may have symptoms related to the affected organ (e.g., hematuria in papillary necrosis, jaundice in hepatic infarct, seizures or weakness in central nervous system ischemia, respiratory distress in pulmonary infarction). Initial management usually centers around control of pain, general supportive measures, and differentiation of vaso-occlusion and disorders unrelated to the hematologic abnormality.

The treatment of the child with a painful crisis requires an objective assessment of the severity of the discomfort and an appropriate use of analgesic therapy (Table 87.4). Once nonsickling disorders have been ruled out, hydration should be undertaken with D5¼ normal saline solution (NSS) or D5½ NSS at a rate of 1.5 maintenance fluid requirements (see Chapter 18 and Chapter 84). The choice of analgesic is aided by familiarity with the patient's previous crises. Hesitancy to use parenteral narcotics may result in inadequate pain relief, mounting anxiety, and a loss of trust between physician and patient. This is a particularly common occurrence when the patient has had repeated visits to the ED and physicians are suspicious of the stated degree of discomfort. The use of the placebo saline injection is to be decried as an insensitive and potentially cruel test of the patient's pain level. For moderate or severe vaso-occlusive pain, morphine sulfate (0.10 to 0.15 mg/kg) should be administered by IV, and further therapy should be based on the degree of pain and the duration of pain control. Admission to the hospital is necessary if continuing parenteral analgesic therapy is required, fluid intake is inadequate, or the child has had several visits for the same problem. Repeated prolonged stays in the ED often leave the child and family exhausted and rarely prevent hospital admission.

Mild or Moderate Pain
Hydration—1½ × maintenance with oral fluids or IV D5¼ normal saline solution (NSS) or D5½ NSS
Analgesia—Acetaminophen with or without codeine
Disposition—Admit if pain worsens, oral fluid intake is inadequate, or repeat visits to the emergency department have occurred
Severe pain
Hydration—1½ × maintenance with IV D5¼ NSS or D5½ NSS
Analgesia—Morphine sulfate, 0.10–0.15 mg/kg IV
Disposition—Admit unless pain is markedly reduced and patient can take oral fluids

Table 87.4. Management of Vaso-Occlusive Crisis in Sickle Cell Crisis

Several specific areas of vaso-occlusion deserve special attention. Between 6 and 24 months of age, dactylitis is a common manifestation of sickle cell disease. Infarction of the metarcarpals and metatarsals results in swelling of the hands and feet. These episodes recur frequently. Pain usually resolves after several days, but swelling may persist for 1 or 2 weeks. Treatment is similar to that described for a painful crisis.

Because it is difficult to distinguish pulmonary infarction from pneumonia on the basis of physical findings and noninvasive laboratory studies, these two disorders are classified together under the heading of acute chest syndrome. Pulmonary infarction may be associated with severe respiratory distress and substantial morbidity in children with sickle cell disease. The patient's clinical condition should be monitored closely. Pulse oximetry may help determine the need for arterial blood gas measurement and additional therapy. Treatment of acute chest syndrome is described on page 867.

Infarction of abdominal and retroperitoneal organs may produce clinical findings that closely resemble the findings in a variety of nonhematologic diseases. The distinction between occlusion of the mesenteric vessels and appendicitis or other causes of an acute abdomen is, at times, particularly difficult. Physical findings and laboratory studies are remarkably similar. The onset and quality of the pain may be familiar to the patient and readily recognized as typical “crisis pain.” The patient may describe the symptoms as distinctly different from episodes of infarction, however, giving support to the diagnosis of an acute abdomen. Because painful crises occur far more often than appendicitis and other causes of acute abdomen, a period of careful observation is warranted unless the patient is severely ill (e.g., perforated appendix). Repeated assessment of the abdominal examination and the clinical response to fluid therapy help identify the child with an acute abdomen and reduces unnecessary and risky emergency surgical procedures in children with sickle cell disease. The hours required for transfusion before surgery provide an additional period of observation, during which time symptoms may abate.

Hepatic infarction may also create a diagnostic dilemma because the acute onset of jaundice and abdominal pain that characterize this disorder are similar to the symptoms of hepatitis, cholecystitis, and biliary obstruction. In addition, vaso-occlusion elsewhere in the abdomen that causes right upper quadrant pain may mimic biliary tract disease. The distinction between infarction and cholecystitis or biliary obstruction is particularly important because recurrent gallbladder disease is an indication for cholecystectomy. In both hepatic infarction and biliary obstruction, the alanine aminotransferase (ALT) and direct bilirubin levels may be increased. Ultrasonography of the abdomen often shows a dilated common bile duct or the presence of stones in the duct in children with biliary tract disease when the study is performed shortly after the onset of symptoms. In many instances, however, biliary tract disease and vaso-occlusion cannot be definitively distinguished, and the clinician must depend on a pattern of recurrence for additional information. The initial management of these disorders is similar to that described for vaso-occlusive crises (i.e., fluids, analgesics). A nasogastric tube may relieve abdominal discomfort caused by distension.

The major emergencies related to vaso-occlusion within the genitourinary tract are hematuria that results from renal papillary necrosis and priapism. The hematuria of papillary necrosis is usually painless and often persistent. A history of recent trauma, streptococcal infection, or recurrent urinary tract infection should alert the physician to other causes of hematuria. Similarly, hypertension suggests the presence of nephritis rather than simple vaso-occlusion. In papillary

necrosis, microscopic examination of the urine shows numerous red cells, but red cell casts are rarely seen. Pyuria and proteinuria in excess of what might be attributed to the blood in the urine are not found in papillary necrosis but may indicate nephritis. The hematocrit or hemoglobin level should be measured because the hematuria, if persistent or severe, may markedly worsen the chronic anemia. For the patient who is otherwise well, diagnostic studies can be accomplished on an outpatient basis, and a trial of increased oral fluids (twice maintenance) should be undertaken. In many instances, however, admission to the hospital is required for IV hydration. Alkalinization of the urine may reduce bleeding but is difficult to accomplish and usually unnecessary. Administration of antifibrinolytic drugs such as epsilon aminocaproic acid (Amicar) (100 mg/ kg every 6 hours) or tranexamic acid (25 mg/kg every 6 to 8 hours) may stop bleeding but carries a risk of ureteral clot formation. When hematuria is severe, red cell transfusions are sometimes required for treatment of anemia. Transfusions or exchange transfusions may also be useful in shortening the course of hematuria.

Priapism is an unusually painful and frightening form of vaso-occlusion. The penis becomes swollen, edematous, and very tender. Urination may be difficult. The initial treatment consists of fluid therapy and analgesics (Table 87.5). Once again, red cell transfusions or exchange transfusion may promote resolution, but these forms of therapy should be reserved for patients without a rapid response to other measures. An increased risk of complications of the central nervous system, including stroke, has been associated with exchange transfusion for priapism. Early aspiration of the corpora has been recommended to abort the course of priapism and preserve later potency. The relationship between duration of priapism and later potency in boys with sickle cell disease is still unclear, adding to the uncertainty of when to use particular therapies. However, the trend is toward more aggressive treatment to promote earlier resolution.

Hospitalize if erection persists or if pain is severe.
Intravenous hydration with D5¼ normal saline solution (NSS) or D5½ NSS at 1½–2 x maintenance for 24–48 hr.
Consider aspiration of the corpora.
If swelling does not decrease, transfuse with red cells to raise hemoglobin level to 9–10 g/dL.
If no improvement after simple transfusion, institute exchange transfusion to reduce HbS to less than 30% of total hemoglobin.
Reserve shunting procedures for patients who have failed other forms of therapy in the first 72 hr.

Table 87.5. Management of Priapism in Sickle Cell Anemia

Infarction of the central nervous system is a catastrophic form of vaso-occlusion. The initial presentation varies from the mild and fleeting symptoms of a transient ischemic attack to seizures, hemiparesis, coma, and death. Physical findings usually define, and MRI usually confirms, the area of cortical infarction. Supportive therapy should be instituted immediately (Table 87.6). A 1.5 or 2 volume exchange transfusion should begin as soon as the blood is ready. This procedure reduces the likelihood of further intravascular sickling and may prevent extension of cortical damage.

1. Obtain computed tomography scan or magnetic resonance imaging to identify an area of infarction or to rule out a ruptured cerebral aneurysm or other intracranial bleed.
2. Immediately begin 1½–2 volume exchange transfusion to reduce HbS below 30% of total hemoglobin.
a. Use whole blood less than 3–5 days old or use packed red cells less than 3–5 days old reconstituted with fresh-frozen plasma.
3. Reserve pretransfusion blood sample for characterization of red cell antigens in preparation for chronic transfusion program.

Table 87.6. Management of Stroke in Sickle Cell Anemia

Cerebral aneurysms occur with increased frequency in patients with sickle cell disease. The origin of this complication, which is usually detected in teenagers or adults, remains obscure but may be related to local vessel occlusion or ischemia. Unfortunately, the aneurysm often escapes detection until after major, and often fatal, subarachnoid or intracerebral bleeding. The severe morbidity and high mortality associated with ruptured cerebral aneurysms require careful evaluation of the patient with sickle cell disease and headaches or neurologic findings. If the aneurysm is accessible and bleeding persists, surgical intervention should follow radiologic confirmation.

Less common areas of infarction that may be particularly confusing to the physician include the orbits and cervical spine. Vaso-occlusion that involves the bones of the orbit may produce findings similar to those of orbital cellulitis. Tenderness and fever may be present in bony infarction but are sometimes less remarkable than when found in cellulitis. A bone marrow scan using ^{99m}Tc-sulfur colloid may demonstrate decreased uptake in the affected area, confirming vaso-occlusion and avoiding the need for prolonged antibiotic therapy. Vaso-occlusion that presumably occurs in the cervical spine may cause meningismus. A lumbar puncture is sometimes necessary to rule out meningitis. As in other situations, the patient's evaluation of the pain may be helpful in distinguishing vaso-occlusion processes from more

serious disorders.

Splenic Sequestration Crisis

The sudden enlargement of the spleen with resulting sequestration of a substantial portion of the blood volume is a life-threatening complication of sickle cell disease. Because this crisis requires the presence of vascularized splenic tissue, it usually occurs before 5 years of age in patients with homozygous sickle cell disease but may occur much later in children with milder sickling disorders such as sickle cell disease or S-b $^{+}$-thalassemia. The patient undergoing a severe sequestration crisis may first complain of left upper quadrant pain (Table 87.7 and Table 87.8). Within hours, the patient becomes very pale, lethargic, and disoriented, and appears ill. The physical examination shows evidence of cardiovascular collapse; hypotension and tachycardia are often present. The level of consciousness falls. The hallmark of a severe sequestration crisis is a spleen that is significantly enlarged in comparison with previous examinations and is unusually hard. The hematocrit or hemoglobin level is much lower than during routine visits, and the reticulocyte count is usually increased (Fig. 87.2). Mild neutropenia or thrombocytopenia may be present.

Symptoms	Laboratory Findings
Left upper quadrant pain	Severe anemia
Pallor	Increased reticulocytes
Lethargy	Mild to moderate thrombocytopenia and neutropenia
Signs	
Hypotension	Management
Tachycardia	Immediate volume replacement
Markedly enlarged and firm spleen	Transfusion with packed red cells or whole blood

Table 87.7. Splenic Sequestration Crisis

	Sequestration Crisis	Aplastic Crisis	Hemolytic Crisis
Onset	Sudden	Gradual	Sudden
Pallor	Present	Present	Present
Jaundice	Normal	Normal	Increased
Abdominal pain	Present	Absent	Absent
Hemoglobin level	Very low	Low or very low	Low
Reticulocytes	Unchanged or increased	Decreased	Increased
Marrow erythroid activity	Unchanged or increased	Decreased	Increased

Table 87.8. Comparison of Findings in Sequestration, Aplastic, and Hemolytic Crises in Sickle Cell Disease

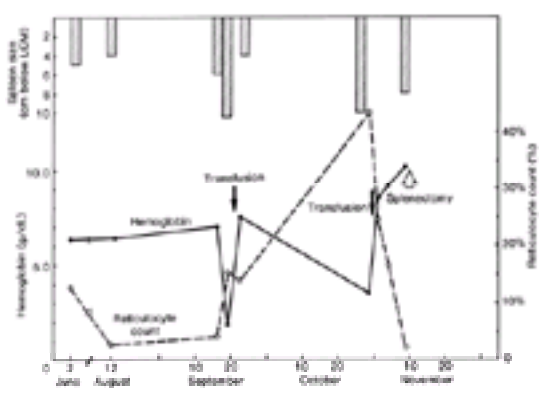

FIGURE 87.2. Clinical course of a 6-year-old girl with hemoglobin S-b°-thalassemia and two splenic sequestration crises that were characterized by abdominal pain, increased splenic size, and a rapid fall in hemoglobin concentration.

Recognition of this complication should be immediate so that lifesaving therapy begins without delay. The rapid infusion of large amounts of normal saline or albumin is necessary to restore intravascular volume. Although a sufficient number of red cells to relieve tissue hypoxia may be released by the spleen after initial fluid resuscitation, transfusion with packed red cells (2 to 10 mL/kg) is often required in more severe cases. Whole blood transfusion may help relieve the dual problems of intravascular volume depletion and impaired tissue oxygenation. Reversal of shock and a rising hematocrit signal improvement of a sequestration crisis. The spleen gradually becomes less firm and smaller.

Aplastic Crisis

Increased bone marrow erythroid activity (as reflected by the elevated reticulocyte count and presence of nucleated red

cells in the peripheral blood) partially compensates for the shortened red cell survival in sickle cell anemia and other hemolytic disorders. If erythropoiesis slows or ceases, this precarious balance is disturbed, and the hemoglobin level may gradually fall (Table 87.8). The event that most commonly causes erythroid aplasia is a parvovirus infection. Progressive pallor is unaccompanied by jaundice or other signs of hemolysis. Severe anemia may result in dyspnea and changes in level of consciousness. The hemoglobin level is unusually low, and reticulocytes are decreased or absent (Fig. 87.3). In the early phase of an aplastic crisis, the bone marrow has a paucity of erythroid activity. During the recovery stages, erythroid activity increases and the cells steadily mature. The level of red cell maturity can be used to predict the appearance of reticulocytosis in the peripheral blood, and this information may be helpful in determining whether the patient needs a red cell transfusion or can await the recovery of the bone marrow without further compromising oxygen delivery. If a red cell transfusion is required, a small aliquot is usually sufficient to raise the hemoglobin concentration to a level that ensures adequate oxygenation until red cell production recovers.

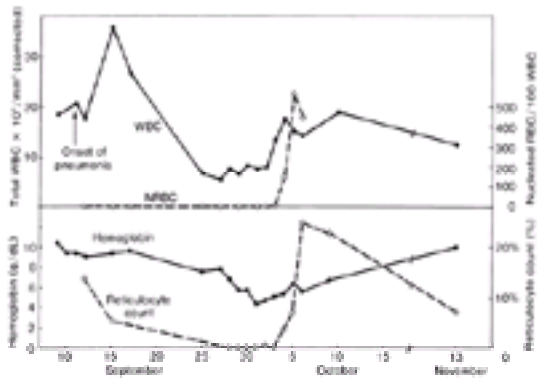

FIGURE 87.3. Aplastic crisis in a 5-year-old girl with sickle cell anemia and *Mycoplasma pneumoniae* pneumonia. Her aplastic crisis was characterized by a low hemoglobin level and reticulocytopenia. The white blood cell count was also transiently decreased. Recovery was characterized by reticulocytosis, marked increased in the number of nucleated red blood cells, and a rise in hemoglobin level.

Hemolytic Crisis

Worsening anemia and increasing reticulocytosis may accompany viral and bacterial infections in children with sickle cell disease (Table 87.8). Scleral icterus is more prominent than usual. The findings are consistent with an increasing degree of active hemolysis. The hemoglobin level rarely falls low enough to require specific therapy. Hematologic values return to the usual level as the infection process resolves.

Comment

The long-term management of many of the complications of sickle cell disease is beyond the scope of this chapter but has been discussed in detail in review articles and textbooks. In most instances, a thorough understanding of the extended care is necessary for correct management of the initial stages of hematologic emergencies. The clinical course and previous laboratory data of the patient should be familiar to someone involved in the care of the acute problem. Therefore, the treatment of hematologic emergencies in children with sickle cell disease is accomplished best in a center that also provides comprehensive care to affected patients.

Thalassemia Major (Cooley's Anemia)

Background

The thalassemias are disorders characterized by an inability to synthesize sufficient amounts of the globin component of hemoglobin. In b-thalassemia major, the most common of the homozygous thalassemia syndromes, the affected child produces little or no hemoglobin A and is usually transfusion-dependent from early childhood. The b-thalassemia gene occurs commonly in countries that border the Mediterranean Sea as well as in Southeast Asia. Other thalassemic disorders that may be associated with severe anemia include hemoglobin E-b°-thalassemia and hemoglobin H disease (absence of three of the four normal a-globin genes). Although most of the problems associated with these disorders are the result of long-term transfusion therapy, the severe anemia at the time of diagnosis may constitute a hematologic emergency.

Clinical Manifestations

Children with thalassemia major usually develop a sallow complexion and increasing fatigue between the ages of 6 and 24 months. Weight gain and linear growth may be retarded. Physical examination shows pallor and enlargement of the liver and spleen. The hemoglobin level may be as low as 3 or 4 g/dL, and the mean corpuscular volume (MCV) is usually low. The red cells are hypochromic and microcytic with striking variation in size and shape; nucleated red cells are present in the peripheral smear. Thalassemia major is readily distinguishable from severe nutritional iron deficiency. In the latter disorder, the dietary history is grossly abnormal, organomegaly is uncommon, changes in red cell morphology are less impressive, and nucleated red cells are rarely seen in the peripheral smear. The diagnosis of thalassemia major should be considered in a child with severe microcytic anemia and an appropriate ethnic background. Although severe anemia is extremely rare in heterozygous thalassemia disorders, thalassemia trait and concomitant iron deficiency may be particularly difficult to distinguish from a homozygous thalassemia disorder.

Management

The moderate anemia usually apparent at presentation allows sufficient time for a careful diagnostic evaluation and outpatient transfusion therapy. However, when anemia is severe and congestive heart failure is present or imminent, the need for red cell transfusion may be urgent. In such instances, pretransfusion blood should be saved for appropriate diagnostic studies (hemoglobin electrophoresis) and initial red cell antigen typing. If transfusion is necessary, small aliquots of red cells (2 to 3 mL/kg) should be given. The administration of a rapid-acting diuretic (furosemide 1 mg/kg per dose) may diminish the risk of fluid overload. Partial exchange transfusion has also been recommended for patients with severe anemia to prevent further increases in intravascular volume and myocardial stress. Because patients with thalassemia major and severe anemia invariably have a lifelong dependence on red cell transfusions, the use of non–cross-matched blood should be scrupulously avoided at the time of presentation to prevent sensitization to foreign red cell antigens.

Methemoglobinemia

Background

Methemoglobinemia is an uncommon cause of cyanosis in infants and children but is capable of causing severe problems and even death. Cyanosis results from a disproportionate amount of heme iron being present in the ferric rather than ferrous state. Under these conditions, oxygen binding of hemoglobin is severely impaired. The diagnosis of methemoglobinemia should be considered when cyanosis occurs in the absence of demonstrable cardiac or pulmonary disease.

The disturbance in the usual balance between ferrous and ferric iron may be a result of alterations of hemoglobin structure (hemoglobin M), abnormalities of red cell enzymes (methemoglobin reductase), or exposure to oxidant drugs or chemicals (Table 87.9). Infants are particularly susceptible to acute methemoglobinemia because of the relative immaturity of the enzyme system required to maintain hemoglobin iron in a reduced state. Acute infectious illnesses such as gastroenteritis may cause symptomatic methemoglobinemia in infants. The inherited forms of methemoglobinemia may be characterized by chronic cyanosis. However, in the absence of a specific oxidant stress, further symptoms are uncommon and treatment is given primarily for cosmetic reasons. When acute methemoglobinemia results from an oxidant stress, oxygen delivery may be severely compromised and the patient becomes acutely ill. If the agent acts as a direct oxidant, the onset of symptoms is rapid. However, if methemoglobin formation is caused by a metabolite of the original compound or secondary alterations in red cell metabolism, symptoms may be delayed. For example, methemoglobinemia is seen 12 to 15 hours after exposure to nitrobenzene.

Drugs
Sulfonamide antibiotics
Quinones
Phenacetin
Benzocaine
Domestic and Environmental Substances
Foods containing nitrates or nitrites
Well water containing nitrates
Aniline dyes (certain marking inks, dyes for some clothing and shoes, some crayons)
Naphthalene (mothballs)
Soap enemas
Certain industrial compounds (nitrobenzenes, nitrous gases, organic amines)

Table 87.9. Substances and Drugs Implicated in the Formation of Methemoglobin in Children

Clinical Manifestations

Symptoms depend on the concentration of methemoglobin (Table 87.10). When methemoglobin constitutes approximately 10 to 30% of total hemoglobin, only cyanosis occurs. As the level rises to 30 to 50%, dyspnea, tachycardia, dizziness, fatigue, and headache may be noted. Severe lethargy and stupor are often present when the methemoglobin concentration exceeds 50%, and death may occur at concentrations greater than 70%. If anemia is present, oxygen delivery is further compromised and toxicity may be more severe at lower concentrations of methemoglobin.

Methemoglobin Level	Symptoms
10–30%	Cyanosis
30–50%	Dyspnea, tachycardia, dizziness, fatigue, headache
50–70%	Lethargy, stupor
>70%	Death

Table 87.10. Symptoms and Signs According to Severity of Methemoglobinemia

Accurate diagnosis and rapid therapy prevent serious damage. The diagnosis should be strongly suspected when oxygen administration fails to affect the cyanosis. To eliminate an anatomic abnormality as a cause of oxygen-unresponsive cyanosis, an attempt should be made to oxygenate the patient's blood in vitro. As a rapid screening test, a drop of blood is placed on filter paper. After the filter paper is waved in the air for 30 to 60 seconds, normal blood appears bright red, whereas blood from a patient with methemoglobinemia remains reddish-brown. Arterial blood oxygen saturation is low when measured directly by blood oximetry rather than calculated, even though P_{O_2} is normal. Although blood oximetry measures oxyhemoglobin as a percent of total hemoglobin, including methemoglobin that is nonfunctional, pulse oximetry devices measure oxygen saturation of only that hemoglobin that is available for saturation. Thus, a patient with methemoglobinemia and obvious cyanosis may have normal oxygen saturation as measured by pulse oximetry. Spectrophotometric assays can be used for confirmation of methemoglobinemia as well as for determination of the level of methemoglobin.

Management

The treatment of methemoglobinemia depends on the clinical severity (Table 87.11). In all cases, an attempt should be made to identify an oxidant stress and, once identified, to remove the causative substance. If symptoms are mild after oxidant exposure, therapy is unnecessary. Red cells with normal metabolism will reduce the methemoglobin in several hours. If the symptoms are severe, 1 to 2 mg/kg of methylene blue as a 1% solution in saline should be infused over 5 minutes. A second dose can be given if symptoms are still present 1 hour later. Because methylene blue can act as an oxidant at high dosages, the total dosage should not exceed 7 mg/kg. Failure of methylene blue to improve the course of methemoglobinemia may be a result of concomitant G6PD deficiency because the therapeutic effect requires an intact hexose monophosphate shunt. For patients with G6PD deficiency, ascorbic acid (500 mg orally) may be of some value, but if symptoms are severe, exchange transfusion or hyperbaric oxygen may be required. Even if treatment with methylene blue or ascorbic acid in the ED is successful, any child with symptomatic methemoglobinemia should be admitted to the hospital for close observation and further evaluation of the underlying abnormality or causative agent.

Methemoglobin Level	Treatment
<30%	Not needed
30–70%	Methylene blue, 2 mg/kg of a 1% solution, infused intravenously over 5 min[a]
Severely ill and no response to methylene blue	Hyperbaric oxygen or exchange transfusion

[a]If no response to two doses of methylene blue in a noncritically ill patient or a patient with known G6PD deficiency, use ascorbic acid 500 mg orally.

Table 87.11. Treatment of Methemoglobinemia

DISORDERS OF WHITE BLOOD CELLS

Infection is the most significant complication associated with quantitative or qualitative white cell disorders. In some children, death may follow a single episode of acute, overwhelming sepsis. In others, repeated local infections may cause severe organ damage or may culminate in a fatal, disseminated fungal infection. The appropriate emergency management of the child with white cell abnormalities and fever or other signs of infection may have a profound impact on the length and quality of the patient's life.

Neutropenia

The most common forms of neutropenia and abnormal neutrophil function are listed in Table 87.12. Neutropenia is usually defined as an absolute neutrophil count below 1000 to 1500/mm^3. When the neutrophil count falls below 500/mm^3, the patient exhibits an increased susceptibility to infections caused by normal skin, respiratory, or GI flora. Between 500 and 1000/mm^3, susceptibility to infection is less significant but the host's ability to combat more typical infections is impaired. However, management of the patient cannot be based on the absolute neutrophil count alone because other, often unknown factors contribute to the severity of the clinical course. For example, serious, recurrent bacterial infections are common in Kostmann's neutropenia, and in the absence of treatment with growth factors, death often occurs in early childhood. In contrast, the clinical course of chronic benign neutropenia is much milder. Yet, the absolute neutrophil counts in the two disorders sometimes overlap. Similarly, serious infection is unusual in immune-mediated neutropenia, although the absolute neutrophil count may be less than 500/mm^3, a level at which severe morbidity and substantial mortality may be found in children with leukemia undergoing chemotherapy.

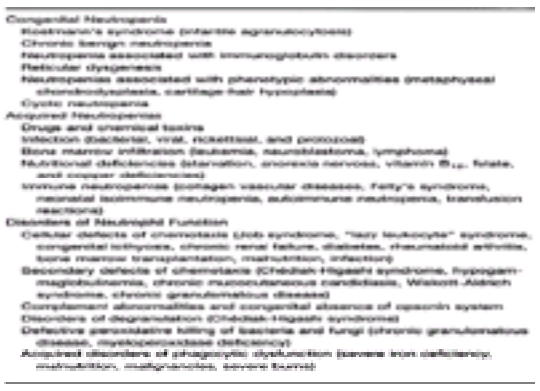

Table 87.12. Causes of Neutropenia and Disorders of Neutrophil Function in Children

The management of localized infection or unexplained fever in the child with neutropenia depends in large part on the underlying disorder and on the patient's history of infection. In neutropenic states associated with repeated, severe infections, an aggressive attempt to identify a causative organism should be undertaken. Blood and urine cultures, along with appropriate cultures from identified areas of infection (e.g., skin abscess, cellulitis), should be obtained. The cerebrospinal fluid should be examined and cultured when central nervous system infection is suspected. If the child appears ill or toxic, broad-spectrum IV antibiotic therapy should be instituted with modification of therapy when culture results are available. Initial treatment should include antibiotics effective against *Staphylococcus aureus* and other Gram-positive organisms as well as gram-negative bacteria, including *Pseudomonas aeruginosa.* If no source of fever is identified and the child appears well, observation in the hospital without antibiotic therapy may be considered.

Decisions regarding admission to the hospital and treatment are often more difficult in children with more benign neutropenic states. Although infections are usually mild and localized in these patients, severe infections rarely may occur. A white cell count and differential may be valuable because, in some children, the white count will rise to normal or near-normal levels during acute infection. Further laboratory investigation and treatment once again depend on the physical examination of the child as and the history of infection. In most instances, antibiotic therapy can be reserved for children with a specific source of bacterial infection. However, careful follow-up is required for untreated children in whom fever is unexplained or attributed to probable viral infection.

A particularly perplexing problem arises when a child is found to be neutropenic during an evaluation of fever. In most instances, both the fever and neutropenia are results of a viral illness. Under these circumstances, serious secondary bacterial infections are unlikely to occur, and admission to the hospital and antibiotic therapy are probably unnecessary. However, because the neutropenia usually cannot be attributed with certainty to a viral illness, other causes of neutropenia should be carefully sought. The patient or parents should be questioned about the use of drugs associated with neutropenia (e.g., penicillins, phenothiazines, phenytoin). The family history should be explored for recurrent infections or deaths in early childhood that might suggest a congenital neutropenia. Underlying disorders such as malignancies or nutritional disturbances should be considered. If the child appears even moderately ill, admission to the hospital for further evaluation is appropriate.

Disorders of Neutrophil Function

Numerous disorders of neutrophil function have been described. These disorders are associated with serious infections to a variable extent. Therefore, the evaluation and treatment of the patient with abnormal neutrophil function should be based on the specific cause and the history of serious infection. Particular attention should be paid to disorders such as chronic granulomatous disease in which the site of infection (liver, bones, GI tract) and causative organisms (*Aspergillus* species, *Pseudomonas cepacia, Serratia marcescens*) are distinctly unusual.

DISORDERS OF PLATELETS

The clinical course and management of patients with platelet abnormalities are determined primarily by the cause of the underlying disorder. For example, at the same level of thrombocytopenia, bleeding is more common in disorders of platelet production than in immune-mediated disorders of platelet survival. Consequently, the treatment of suspected bleeding after trauma should be more aggressive in the former disorder. The numerous causes of thrombocytopenia and abnormal platelet function are discussed in Chapter 65 and form an important background to the section that follows in which emphasis is placed on the management of bleeding emergencies in accordance with the underlying causes. The approach to a child with purpura or bleeding and no history of a bleeding disorder can also be found in Chapter 65. Finally, a discussion of the management of the many problems of lesser urgency that are associated with chronic platelet disorders is provided by textbooks of pediatric hematology.

Idiopathic Thrombocytopenic Purpura

Background

Idiopathic thrombocytopenic purpura (ITP) is the most commonly encountered platelet disorder in children. Serious bleeding is rare, occurring in only 2 to 4% of cases. This low incidence is particularly remarkable because the disease is most common between the ages of 1 and 4 years, when children are particularly prone to trauma as they learn to walk, run, and climb. The risk of serious bleeding decreases sharply after the first week of illness, reflecting the presence of newly formed platelets with greater hemostatic capability.

Clinical Manifestations

The diagnosis of ITP is made readily in the child with newly acquired petechiae and ecchymoses, thrombocytopenia, normal or increased megakaryocytes in the bone marrow, and the absence of any underlying disease. Epistaxis, gum bleeding, and hematuria occur less commonly than simple bruising and petechiae, but when persistent, these hemorrhagic manifestations can lead to moderate or even severe anemia. In teenage girls with ITP, heavy and prolonged menstrual bleeding can also cause a severe fall in the hemoglobin level. Fortunately, the development of anemia in children with ITP is gradual; acute, massive blood loss is extremely rare.

The major life-threatening complication of ITP is intracranial hemorrhage. This catastrophic problem may occur within a few days of diagnosis of the platelet disorder or months later. Although a history of head trauma in a child with ITP should alert the physician to the possibility of intracranial bleeding, the absence of any recognized injury is surprisingly common in patients with this complication. The symptoms of intracranial hemorrhage may be subtle, such as persistent mild headache, or they may be dramatic, such as severe headache, vomiting, and generalized or localized weakness. Intracranial bleeding in ITP is unusual once the platelet count has risen above 50,000/mm ^{3} unless a significant injury has occurred or platelet function is also impaired (e.g., as in the patient who has received aspirin).

Management

Controversy continues to surround the management of the patient with newly diagnosed ITP who has no serious bleeding. In many centers, such patients are treated with g-globulin at a dosage of 0.8 to 1.0 g/kg by IV infusion, with a second dose 24 hours later if the platelet count remains below 40,000 to 50,000/mm ^{3}. This therapy is effective in raising the platelet count in approximately 85% of patients with acute ITP. However, the low incidence of serious hemorrhagic complications of ITP, such as intracranial bleeding, has made it impossible to ascertain the overall benefits of this therapy. IV g-globulin exerts its major therapeutic effect by blocking the uptake of antibody-coated platelets by macrophages in the spleen. Unfortunately, one of the more common side effects of IV g-globulin is headache, and when this symptom persists despite slowing the rate of infusion, imaging studies of the brain may be necessary to investigate possible intracranial bleeding.

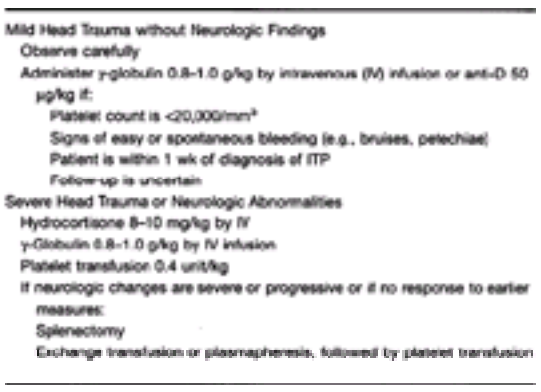
An alternative approach to the treatment of the stable patient with ITP is a 4- to 8-week course of prednisone, beginning with 2 mg/kg per day. Like g-globulin, steroids block the Fc receptors of splenic macrophages. Neither drug shortens the time until spontaneous recovery occurs. Some physicians have argued that a bone marrow aspirate to confirm the diagnosis of ITP is unnecessary in the patient with typical findings of the disorder and an absence of neutropenia or anemia. However, if steroids are used, a bone marrow aspirate should always be obtained before beginning therapy to be certain the diagnosis is absolutely correct. If a patient with acute leukemia is mistakenly diagnosed as having ITP and treated with steroids, the correct diagnosis may be delayed and long-term outcome may be affected adversely.

A more recent option for the treatment of acute ITP is the administration of antibody directed against the D-antigen of red cells. The antibody-coated erythrocytes are sacrificed to the reticuloendothelial system so that the antibody-coated platelets can continue to circulate. The effect of anti- D, usually given at a dosage of 50 µg/kg by IV infusion, is slightly delayed compared with g-globulin, and the peak platelet count may be somewhat lower. However, anti- D has the advantage of being administered over minutes rather than hours, and it rarely causes severe headache. Mild to moderate hemolysis may follow the administration of anti- D with a fall in hemoglobin level of 0.5 to 2.0 g/dL. This therapy is effective only in Rh-positive patients.

Not every physician considers it necessary to treat all patients newly diagnosed with ITP. The usually benign course of this disease must be weighed against the side effects of corticosteroids, g-globulin, and anti- D, and especially the high cost of the latter two drugs. Therefore, specific therapy with steroids, g-globulin, or anti- D may be reserved for patients with sufficient bleeding to cause moderate or severe anemia, for patients who remain severely thrombocytopenic (platelet count less than 10,000/mm^3) several weeks after diagnosis, or for patients whose physical activities cannot be effectively restricted.

For the patient with ITP and active bleeding, local therapeutic measures may be helpful until corticosteroids or infusions of g-globulin or anti- D raise the platelet count to a hemostatic level or when these drugs become ineffective. Nasal packing and topical phenylephrine are useful for persistent epistaxis. Excessive menstrual bleeding may require hormonal therapy. If bleeding does not stop despite these measures, plasmapheresis should be undertaken and, if necessary, followed by a transfusion of 0.2 unit/kg (maximum 10 to 12 units) of platelets (Table 87.2). The removal of antiplatelet antibody by plasmapheresis may increase the survival of transfused platelets sufficiently to stop or retard active bleeding.

Intracranial hemorrhage, the major cause of death in ITP, requires immediate recognition and therapy. The child with ITP who has sustained head trauma or developed signs of increased intracranial pressure (e.g., headache, vomiting, lethargy) or focal neurologic deficits should be evaluated immediately. The platelet count should be measured because intracranial hemorrhage is unusual in the child with ITP whose platelet count is above 50,000/mm ^{3}, unless trauma is exceptionally severe. The child with mild head trauma and no symptoms or signs of intracranial bleeding should be observed carefully. Whether to treat the asymptomatic child is a common and perplexing problem. Although no firm rules exist, management should be based on the duration of ITP, tendency to bleed as demonstrated by petechiae or ecchymoses, platelet count, and likelihood of careful follow-up (Table 87.13). If the head trauma has occurred within 1 week of diagnosis, the patient is still having spontaneous bleeding, the platelet count is less than 20,000/mm ^{3}, or follow-up is uncertain, one or two IV infusions of g-globulin (0.8 to 1.0 g/kg) or anti- D (50 µg/kg) may be given.



Mild Head Trauma without Neurologic Findings
- Observe carefully
- Administer γ-globulin 0.8–1.0 g/kg by intravenous (IV) infusion or anti-D 50 μg/kg if:
  - Platelet count is <20,000/mm³
  - Signs of easy or spontaneous bleeding (e.g., bruises, petechiae)
  - Patient is within 1 wk of diagnosis of ITP
  - Follow-up is uncertain

Severe Head Trauma or Neurologic Abnormalities
- Hydrocortisone 8–10 mg/kg by IV
- γ-Globulin 0.8–1.0 g/kg by IV infusion
- Platelet transfusion 0.4 unit/kg
- If neurologic changes are severe or progressive or if no response to earlier measures:
  - Splenectomy
  - Exchange transfusion or plasmapheresis, followed by platelet transfusion

Table 87.13. Management of Head Trauma in Idiopathic Thrombocytopenic Purpura (ITP)

If severe head trauma has occurred or if neurologic abnormalities are present, hydrocortisone (8 to 10 mg/kg) and g-globulin (0.8 to 1.0 g/kg) should be administered by IV and random donor platelets (0.4 unit/kg, maximum 20 units) should be infused immediately thereafter. If necessary, the volume of plasma in the platelet preparation can be reduced by centrifuging the platelets, removing a portion of the plasma, and resuspending the platelets.

If the platelet count of a patient with ITP and intracranial bleeding does not increase after steroids, g-globulin, and platelet transfusions, or if the initial neurologic changes are severe, the patient should undergo splenectomy and, if appropriate, neurosurgical exploration. If the spleen has been removed previously and if steroids, g-globulin, and platelet transfusions have failed to raise the platelet count, an exchange transfusion or plasmapheresis with subsequent platelet transfusion should be performed. However, this is a desperate situation and full recovery is unlikely.

Immune-Mediated Neonatal Purpura

Serious bleeding may occur in the newborn or young infant with isoimmune thrombocytopenia or in the infant born to a mother with ITP. A discussion of the pathophysiology and diagnosis of these disorders is beyond the scope of this section. However, because mortality may be high in these disorders, particularly in isoimmune thrombocytopenia, the management of actual or potential bleeding deserves special emphasis. The brain is the major site of serious bleeding, perhaps because of trauma sustained during vaginal delivery. IV administration of g-globulin raises the platelet count in infants with isoimmune thrombocytopenia or alloimmune thrombocytopenia caused by maternal ITP. Steroid therapy may also be effective. In isoimmune thrombocytopenia, transfusion of random donor platelets is usually ineffective; the platelets are destroyed rapidly because of the presence of the same offending antigen as that found on the infant's platelets. However, the blood center may be able to provide platelets free of the offending antigen. Maternal platelets will survive normally and may be used for the affected infant after removal of the maternal plasma, which may contain the offending antibody. Transfusion of the thrombocytopenic infant born to a mother with ITP is more difficult because survival of all donor platelets is significantly shortened. If signs of generalized bleeding are present or if vital organs are impaired by local hemorrhage, and if IV g-globulin fails to raise the platelet count, a 2-volume exchange transfusion should be performed to remove a portion of the circulating antiplatelet antibody. A platelet transfusion should be administered immediately after completion of the exchange transfusion.

The recognition of immune-mediated neonatal thrombocytopenia is important for counseling of the parents and for preparation for future deliveries, as well as for the treatment of the affected child. In some instances, maternal ITP has been recognized only after delivery of a thrombocytopenic newborn. In isoimmune thrombocytopenia, accurate diagnosis allows appropriate counseling regarding the risk to infants born of subsequent pregnancies and the management of the mother and the affected fetus. If necessary, maternal platelets can be prepared just before future deliveries so that they are available for immediate transfusion if required. These factors make it imperative for the physician to obtain appropriate diagnostic studies in the thrombocytopenic infant.

Nonimmune Thrombocytopenia and Abnormalities of Platelet Function

Serious bleeding as a result of decreased platelet production or impaired platelet function usually responds rapidly to an infusion of random donor platelets (0.4 unit/kg, maximum 10 to 20 units). However, unless they are part of a program of prophylactic therapy, transfusions should be reserved for severe or persistent bleeding. Many affected patients have chronic disorders and require repeated transfusion. The excessive use of platelet transfusions, whether prepared from multiple, single, or HLA-matched donors, may contribute to the early formation of antiplatelet antibodies, making future transfusions more difficult and, in many instances, less effective. The use of leukocyte-depleted blood products, including platelets, reduces the risk of alloimmunization and is strongly preferred in this setting.

DISORDERS OF COAGULATION

Coagulation abnormalities are responsible for a large proportion of hematologic emergencies. Indeed, parents of children with hemophilia often use the ED as their primary source of acute care because bleeding episodes often occur at odd hours and require immediate treatment. This section places particular emphasis on the management of bleeding that poses a direct threat to life or to normal, long-term organ function in children with common inherited and acquired coagulopathies. The more rare inherited disorders of coagulation are not discussed in detail. Bleeding episodes are usually similar to those found in the more common disorders. Appropriate replacement products are listed in Table 87.14.

Factor Deficiency	Replacement Therapy
Fibrinogen (I) (also dysfibrinogenemias)	Cryoprecipitate Fresh-frozen plasma
Prothrombin (II)	Fresh-frozen plasma Prothrombin complex concentrate
Factor V	Fresh-frozen plasma
Factor VII	Fresh-frozen plasma Prothrombin complex concentrates Factor VIIa (recombinant) concentrate
Factor VIII	Factor VIII concentrates DDAVP
Factor IX	Prothrombin complex concentrates Factor IX concentrates
Factor X	Fresh-frozen plasma Prothrombin complex concentrates
Factor XI	Fresh-frozen plasma
Factor XIII	Cryoprecipitate Fresh-frozen plasma
von Willebrand's disease	DDAVP[a] Certain factor VIII concentrates

Table 87.14. Specific Factor Deficiencies and Replacement Therapy

Inherited Bleeding Disorders

Background

The most common inherited bleeding disorders are factor VIII deficiency (hemophilia A), factor IX deficiency (hemophilia B), and von Willebrand's disease. The severity of bleeding in the hemophilias can usually be predicted from the level of factor coagulant activity. If less than 1% of the deficient factor is present (severe hemophilia), bleeding episodes occur frequently and are often unrelated to trauma. If the factor level is between 1 and 5% (moderate hemophilia), spontaneous hemorrhage is less common but bleeding often occurs in response to minor trauma. If the factor level is greater than 5% (mild hemophilia), significant trauma is usually required to induce bleeding. Although very low levels of factor VIII coagulant activity, von Willebrand–related antigen, and ristocetin cofactor activity are associated with severe bleeding in the rare type III (autosomal-recessive) von Willebrand's disease, the relationship between laboratory findings and clinical course is less predictable in common type I von Willebrand's disease than in hemophilia. The severity of type I von Willebrand's disease in a particular child is best judged on the basis of the patient's bleeding history.

The classification of inherited bleeding disorders according to severity is important in assessing patients who have sustained trauma or who have signs of active bleeding. For example, after mild head trauma, the patient with severe hemophilia is at greater risk of developing intracranial bleeding than the patient with mild hemophilia and therefore must be managed more aggressively. When extensive hemorrhage is seen in a child with mild hemophilia, however, significant trauma has probably occurred and injury to deeper organs should be suspected.

Human immunodeficiency virus (HIV) infection has added a new dimension to the acute and long-term management of children with hemophilia. Approximately 80% of patients with factor VIII deficiency who were treated with factor VIII concentrate between 1978 and 1985 are infected with the virus. Approximately 50% of comparably treated patients with severe factor IX deficiency are also seropositive. In general, the emergency management of HIV-related problems such as pneumonia and diarrhea is similar to the management of nonhemophiliacs with HIV infection, as described in Chapter 85. However, situations in which the presence of HIV infection alters the usual management of hemophilia emergencies are noted in the sections that follow.

Clinical Manifestations and Management

Joint Bleeding

Hemarthroses are a common complication in hemophilia that often occur in the absence of known trauma in severe disease. The large joints such as the knees and elbows are most commonly affected. Initial replacement therapy should be designed to raise the factor level to 30 to 50%. Some centers treat all joint bleeds with one or two additional doses of factor replacement, whereas others reserve further treatment for patients with persistent pain or increasing swelling. When the involved joint has been the site of recurrent hemorrhages, several doses of replacement therapy are usually required. Initial immobilization of the joint is often helpful and can be easily accomplished with a splint that extends to the next joint distally. The pain associated with joint bleeding usually resolves within a few hours of treatment; therefore, analgesics are often unnecessary. If pain is severe, however, analgesic therapy should be given orally. Aspirin must not be used because its inhibitory effect on platelet function may further aggravate the clotting disorder. Acetaminophen, either alone or in combination with codeine, is usually sufficient. Repeated, prolonged outpatient therapy with narcotics should be avoided.

Bleeding in the hip is a particularly serious problem. As the joint becomes distended, blood flow to the femoral head may be impeded, resulting in aseptic necrosis. The hip is also a difficult joint to immobilize. Consequently, rebleeding is more likely in the hip than in other joints. Local tenderness is usually present, and the child prefers to lie in the frog-leg position. A radiograph of the hip shows widening of the joint space, and ultrasonography may demonstrate fluid. Because of the importance of achieving and maintaining hemostasis in this joint, initial correction to 70 to 100% is usually followed by several days of continuing replacement therapy (30 to 50% correction every 12 hours for factor VIII deficiency or every 24 hours for factor IX deficiency). Hospitalization may be required for immobilization, using either strict bed rest or traction.

The role of arthrocentesis in the management of a hemarthrosis varies from center to center. Removal of the blood from the joint has been helpful in allowing early mobilization and maintaining normal range of motion. Other indications for arthrocentesis include relief of pain if the joint is severely distended and prevention of further synovial damage in the chronically affected joint. Although the physical examination and laboratory findings may be similar in septic arthritis and hemarthrosis, the history and the patient's description of the pain (“just like my other bleeds”) are usually sufficient to

distinguish these two disorders, making arthrocentesis for diagnostic purposes unnecessary. Furthermore, even though joint bleeding is common in hemophilia, septic arthritis is extremely rare. A possible exception is the HIV-positive hemophiliac who may have an increased risk of septic arthritis. If a decision is made to tap a joint, correction to 70 to 100% should be achieved beforehand. How prominent a role arthrocentesis plays in the emergency management of joint bleeds may ultimately depend on the availability of consistent experienced orthopedic care. As in most procedures, the risk:benefit ratio of a joint tap is greatly reduced if the physician has extensive experience with the procedure and its role in the care of the particular disease.

Muscle Bleeding

Most muscle bleeding is superficial and easily controlled with a single dose of replacement therapy to achieve 30 to 50% correction. However, emergencies may arise when substantial blood loss occurs or when nerve function is impaired. Extensive hemorrhage is most commonly found in retroperitoneal bleeds (e.g., ilealpsoas) or thigh bleeds. Retroperitoneal bleeds are often accompanied by lower abdominal pain. A mass is sometimes palpable deep in the abdomen, and sensation in the distribution of the femoral nerve may be diminished. Loss of the psoas shadow may be seen on an abdominal radiograph, and a hematoma may be demonstrated by ultrasonography. The hemoglobin level should be measured initially and, if bleeding persists, at regular intervals thereafter. Treatment consists of hospitalization, bed rest, initial correction to 70 to 100%, and maintenance of a 30 to 50% factor level until pain has resolved and ambulation has been successfully achieved.

Nerve paralysis and contracture are associated with bleeding into the volar compartment of the forearm or the lower leg. Consequently, hemorrhage in these areas should be treated with an initial correction of 70 to 100% and, if abnormal muscle or nerve function is present or if swelling increases, maintenance of factor levels above 30 to 50% until resolution of symptoms. Orthopedic consultation should be obtained to help assess the pressure in the soft-tissue compartment and to determine the possible role of surgical decompression. Patchy sensory loss is often associated with compression of superficial nerves and may persist for several months before normal sensation reappears.

Subcutaneous Bleeding

Hemorrhage under the skin may cause extensive discoloration but is rarely dangerous and usually requires no therapy unless compression of critical organs occurs. However, pressure on the airway from a subcutaneous bleed of the neck may be life-threatening, requiring steps to ensure airway patency, such as placement of an endotracheal tube, in addition to correction of the factor level to 100%. Careful observation of children with bleeding in the muscles of the neck is mandatory because airway obstruction may be sudden.

Infants with undiagnosed hemophilia may present to the ED with prolonged bleeding from the site of circumcision. A partial thromboplastin time (PTT) should be measured and interpreted carefully because of the wide normal range in healthy newborns. Additional blood should be saved for assays of specific factors. If bleeding is not severe, correction can await determination of the type of hemophilia so that a treatment product specific for the identified deficiency can be used. If immediate replacement therapy is necessary, fresh-frozen plasma should be used because it will correct both factor VIII and factor IX deficiency as well as less common inherited clotting factor deficiencies.

Oral Bleeding

Mouth bleeds are particularly common in young children with hemophilia. The presence of fibrinolysins in saliva may lead to persistent oozing in the absence of aggressive management. The site of bleeding should be identified. If a weak clot is present, it should be removed and dry topical thrombin placed on the site. Initial correction should be 70 to 100%. Often, one or more additional treatments are necessary to achieve adequate clot formation and to prevent rebleeding when the clot falls off. The antifibrinolytic agents, e-aminocaproic acid (EACA) and tranexamic acid, are useful adjuncts in the treatment of oral bleeding. EACA should be administered orally for 5 days at a dosage of 100 mg/kg every 6 hours, with a maximum of 24 g/day. Tranexamic acid is administered orally at a dosage of 25 mg/kg three or four times daily. Because children may swallow a substantial amount of blood, acute, actual blood loss may be underestimated by the patient or family, and measurement of the hemoglobin level is helpful, particularly if bleeding has persisted for more than 24 hours. As in bleeds of the neck muscles, careful evaluation of airway patency is essential. Complete airway obstruction may result from extensive bleeding in the tongue.

Gastrointestinal Bleeding

Hemorrhage from the GI tract is rarely severe in hemophilia unless an anatomic lesion such as a duodenal ulcer or diverticulum is present. Maintenance of the factor level above 30 to 50% for 2 or 3 days after initial correction to 70 to 100% is usually sufficient. If bleeding persists, appropriate diagnostic studies are necessary. A careful search for infectious causes of GI bleeding is important in HIV-positive hemophiliacs.

Urinary Tract Bleeding

Atraumatic, painless hematuria is the most common manifestation of renal bleeding in children with hemophilia. Specific lesions are rarely identified, and IV pyelography can often be reserved for patients who fail to respond to initial replacement therapy. Ultrasonography carries no risk, however, and may be helpful in identifying the occasional patient with a subcapsular or intrarenal hemorrhage. If bleeding is persistent, moderate to severe anemia may develop and the hemoglobin level should be carefully monitored. In the absence of trauma or a demonstrable lesion, several approaches to ensuring hemostasis seem equally effective. Bed rest without replacement therapy is often successful. In some centers, one or more doses of factor replacement (70 to 100%) are used in combination with bed rest for at least 24 hours after gross hematuria has ceased. A brief course of orally administered prednisone has also been effective.

Although disagreement regarding the optimal method of treating painless hematuria still persists, there is no difference of

opinion regarding the potential hazard of EACA in affected patients. The strong, antifibrinolytic activity of this drug may cause formation of ureteral clots and outflow obstruction. Although EACA is an effective and seemingly safe agent in the treatment of hematuria associated with sickle cell anemia or sickle cell trait, its use in children with hemophilia has been accompanied by obstructive uropathy and should therefore be avoided.

When the child with hemophilia develops hematuria or flank tenderness after trauma, a more aggressive approach to diagnosis and treatment is required. Ultrasonography or IV pyelography should be performed as soon as possible to look for subcapsular or intrarenal bleeding or an obstructive clot at the pelvic–ureteral junction. To prevent parenchymal damage and deterioration of renal function, replacement therapy to achieve a level of 70 to 100% should be administered immediately. If a lesion is demonstrated using the techniques noted already, replacement therapy should be continued for 5 to 10 days. If no lesion has been identified, a shorter course of therapy is usually sufficient, using resolution of pain and hematuria as an end-point. The hemoglobin level and renal function tests should be followed carefully.

Intracranial Hemorrhage

Bleeding within the cranial vault is a complication of hemophilia that fully justifies the concern, anxiety, and urgency attached to it. In practical terms, however, head trauma in children with hemophilia is common, whereas intracranial hemorrhage is comparatively rare. Thus, the physician must be able to recognize as well as treat the child at risk without exposing other patients to unnecessary hospitalization, diagnostic studies, or therapy.

The management of the hemophiliac child with head trauma but no neurologic signs requires careful attention to the severity of the bleeding disorder, type of trauma, history of intracranial bleeding, and likelihood of close follow-up. Even with consideration of these factors, good fortune remains an important ingredient. Children with seemingly insignificant trauma may develop the first obvious signs of intracranial bleeding several days later when concern has diminished. To prevent such occurrences, every child with severe hemophilia and reported head trauma is treated with at least one dose of replacement therapy in some centers. However, this approach carries the risk and expense of frequent therapy. Moreover, in an effort to prevent yet another visit to the ED, the child or parent may fail to report a serious episode of trauma. Consequently, other centers use an approach that is still conservative although slightly less rigid. If the trauma is mild (e.g., a light bump on the forehead), the child is observed at home for the usual signs of intracranial hemorrhage or increased intracranial pressure. When the trauma is somewhat more substantial (e.g., falling down two or three carpeted stairs), the child with severe hemophilia is evaluated by the physician, given replacement therapy to achieve a level of 70 to 100%, observed for several hours in the office or ED, and, if well, is discharged. The child with mild hemophilia usually does not need replacement therapy under these circumstances, whereas the child with moderate hemophilia needs particularly careful attention to the type of trauma and bleeding history for the physician to decide whether to use replacement therapy. A computed tomography (CT) scan may be useful in identifying intracranial bleeding that requires more intensive and prolonged treatment. However, the imaging study should not be used to decide on administration of an initial dose of replacement factor that should, in fact, always be given before the study is performed to avoid unnecessary delays.

If more severe trauma (e.g., hitting the head on the dashboard, falling off a changing table onto a hard floor) has occurred in any hemophiliac child, hospital admission and repeated doses of replacement therapy are essential. The initial dose of replacement should be administered as soon as it is available. A CT scan should be performed after initial correction to search for intracranial bleeding and help determine the duration of treatment.

Unfortunately, the severity of trauma usually defies quantitative analysis, and the physician is left with substantial uncertainty. When the child with head trauma is not hospitalized, parents should be well informed about signs of intracranial bleeding. In particular, parents (and physicians) must remember that bleeding may be slow, initial imaging studies may be normal, and neurologic symptoms and signs may be delayed. Repeated visits may be necessary to monitor the child's neurologic examination accurately to detect intracranial hemorrhage as early as possible. At the first suggestion of the complication (e.g., headache, vomiting), hospitalization and treatment are mandatory.

The management of the patient with hemophilia who has neurologic findings in the presence or absence of head trauma begins with replacement therapy and those measures required for life support and treatment of increased intracranial pressure. Levels of the appropriate factor should be raised to 100%. The indications for surgery are similar to those for children without coagulation disorders, provided an appropriate correction of clotting abnormalities has been achieved.

Acute neurologic changes, such as decreasing level of consciousness or seizures, may result from direct HIV infection of the brain or from associated infections that affect the immunocompromised host (see Chapter 85). In the HIV-positive hemophiliac patient, these changes may mimic the signs and symptoms of intracranial hemorrhage. Similarly, changes in vision that result from retinitis caused by CMV may be similar to visual changes caused by intraocular bleeding. The physician evaluating an HIV-positive hemophiliac patient with new neurologic findings should consider both infectious and hemorrhagic causes, and the absence of demonstrable hemorrhage on imaging studies should prompt careful attention to HIV-related disorders.

Preparation of the Hemophiliac for Emergency Surgery

The child with hemophilia is subject to the surgical emergencies that affect children with normal hemostasis (e.g., appendicitis, compound fractures) as well as those hemorrhagic complications that require immediate operative intervention. In some instances, a bleeding episode may be confused with an acute abdomen. For example, retroperitoneal hemorrhage may mimic acute appendicitis. If time allows, a trial of replacement therapy may be helpful in distinguishing the two disorders. If, however, the child's clinical condition worsens or the need for surgery has been definitely established, correction up to 100% should be given, and the PTT should be measured to ensure its normalization. Because the PTT may be normal when the factor VIII or IX level is as low as 20 to 30%, measurement of factor coagulant level is needed to assess the adequacy of response to treatment when levels above 30% are desired. This test cannot always be performed before surgery but is essential in the postoperative management of the patient with

hemophilia. Therefore, surgery in a child with hemophilia should rarely, if ever, be undertaken in a hospital without appropriate laboratory facilities.

Bleeding in von Willebrand's Disease

The sites of bleeding in mild von Willebrand's disease resemble those found in patients with platelet disorders. Epistaxis, oral bleeding, and menorrhagia are common while joint bleeding is very unusual. Children affected with more severe forms, in which the factor VIII level is very low, may have bleeding problems that resemble those found in both hemophilia and von Willebrand's disease.

Replacement Products

The four products commonly used for the treatment of children with hemophilia and other bleeding disorders are lyophilized factor concentrates, 1-deamino-8- D-arginine vasopressin (DDAVP), fresh-frozen plasma, and cryoprecipitate. The correct use of these products is important not only to ensure adequate hemostasis but also to minimize risks associated with treatment and to reduce costs when possible.

Factor Concentrates

In recent years, the development of new factor concentrates has dramatically improved the care of children with hemophilia. Recombinant factor VIII and factor IX products are presently used for almost all newly diagnosed children and for most older children as well. The recombinant factor VIII products currently available in the United States continue to have a small amount of human albumin while the recombinant factor IX product is free of all human blood components. The higher cost of these products is balanced by their extremely low likelihood of transmitting infectious diseases. Plasma-derived factor VIII and factor IX concentrates also remain available. These products are made by immunoaffinity column or related techniques that remove many contaminating plasma proteins. A variety of additional steps are used to reduce or eliminate viral contamination, a critical process since most of the plasma-derived concentrates are made from plasma collected from thousands of donors. The amount of factor in each vial of recombinant or plasma-derived factor is printed on the label so the physician can determine the exact amount administered.

Some of the factor VIII concentrates also have a relatively high concentration of von Willebrand protein, making them particularly useful for the treatment of bleeding in patient's with severe, Type 3 von Willebrand's disease or in patients with Type 2 von Willebrand's disease in which other therapies are unsafe or unavailable (see below).

Prothrombin complex concentrates are used primarily for the treatment of patients with factor VIII deficiency and inhibitors (see below) and for the treatment of the relatively rare disorders of factor II, VII, or X deficiency. The use of this product for factor IX deficiency has diminished since the pure factor IX concentrates became available. Activated prothrombin complex concentrates are used exclusively in the management of patients with inhibitors.

Fresh-Frozen Plasma

Fresh-frozen plasma contains all plasma clotting factors and is therefore particularly useful when a child with a previously undiagnosed bleeding disorder presents to the ED with a hemorrhage that requires therapy before the specific factor deficiency can be ascertained. The recent availability of fresh frozen plasma that has been treated with a solvent-detergent solution to inactivate viruses with lipid envelopes (e.g., HIV, hepatitis C) has increased the safety of this product. Nonetheless, its use is generally restricted to the treatment of an unknown inherited factor deficiency or a deficiency of a factor such as factor XI for which there is no available factor concentrate. Although the average concentration of factor in fresh-frozen plasma is 1 unit/ml, the actual concentration in a particular unit may vary widely (0.5–1.5 unit/ml) and is rarely measured. If only one or two units are being transfused, the total amount of the desired factor that is being administered is unpredictable because the units may contain unusually high or low activity. Therefore, if one chooses to use fresh-frozen plasma to treat an infant with bleeding and a suspected but uncharacterized inherited coagulopathy, one must be aware that the actual amount of transfused factor may be as little as 50% of the calculated replacement. Extra plasma may address this problem if volume is not a limiting factor.

Cryoprecipitaet

When plasma is frozen and then slowly thawed, the precipitate contains enriched factor VIII coagulant activity, von Willebrand protein, fibrinogen, and factor XIII. However, like fresh-frozen plasma, the actual amount of these clotting factors in a single unit depends on the level in the donor and may be considerably less than average. If multiple units are administered, the total factor content is more likely to reflect the average activity for units of cryoprecipitate prepared in that particular blood center.

The availability of recombinant factor VIII and, to a lesser degree, plasma-derived concentrates with an excellent safety record, makes cryoprecipitate, which does not undergo virucidal treatment, an unsuitable choice for the treatment of factor VIII deficiency and a very unlikely choice for the treatment of von Willebrand's disease. In the latter instance, cryoprecipitate may be considered in a small child for whom the limited donor exposures might appear attractive in comparison with a plasma-derived concentrate. However, the limited number of donors also carries with it the concern about underestimating the total amount of replacement factor.

Comment

Most patients seen in the ED are accustomed to receiving a particular product in their regular hemophilia care. The treating physician should pay careful attention to the patient's treatment plan as developed by the hemophilia center. The ED is rarely the place to alter the long-term treatment program for a patient with hemophilia. A particularly important situation is the treatment of a child with a previously undiagnosed bleeding disorder. Whenever possible, the diagnosis

should be established before treatment is begun. For example, the diagnosis of factor VIII or IX deficiency might save a child a one-time exposure to a plasma product. In addition, trials of treatment products are frequently available to a newly diagnosed, previously untreated child with hemophilia. A single exposure to plasma or another product may make him or her ineligible for a study that could save his or her family hundreds of thousands of dollars in drug costs. However, an unavoidable delay in making a diagnosis of a specific factor deficiency or concern about eligibility for a study should not take precedence over the timely management of a serious bleeding episode.

Calculation of Dosage

Two formulas are commonly used for determining the number of units of factor VIII or factor IX necessary to achieve a specific level:

Factor VIII:

1. Weight of patient (kg) × desired level of correction (%) × 0.5 (for recombinant) or 0.5–1.0 (for plasma-derived concentrate) = number of units
2. One unit of factor VIII per kg raises the measured factor level by 2% for recombinant product ([desired level/2] × weight of patient [kg] = number of units) or by 1–2% for plasma-derived concentrate ([desired level/1–2] × weight of patient [kg] = number of units)

Factor IX:

1. Weight of patient (kg) × desired level of correction (%) × 1.2 (recombinant factor IX) or 1.0 (plasma-derived factor IX) = number of units
2. One unit of factor IX per kg raises the measured factor IX level by 0.83% for recombinant factor IX or by 1% for plasma-derived factor IX ([desired level/1.0 × weight of patient [kg] = number of units):([desired level/0.83] × weight of patient [kg] = number of units)

In the treatment of major hemorrhages, the achieved level of factor activity should be measured directly because the recovery *in vivo* varies widely among patients and because inadequate hemostasis may lead to severe morbidity or death. In addition, the dose of plasma-derived factor VIII required in children to achieve a particular factor VIII level may be 50 to 100% greater than in adults. If a minor bleed fails to respond to conventional dosing, the post-treatment factor level should be measured to be certain that the desired level is being achieved.

When children with von Willebrand's disease are treated with concentrate or rarely with cryoprecipitate, doses of 15 to 25 units of factor VIII activity/kg and 30 to 50 units of factor VIII activity/kg are commonly used for the treatment of minor and major hemorrhages, respectively. However, the response to treatment is not as predictable in this disorder as it is in factor VIII deficiency. The clinical course is the most useful measurement of the response to therapy and the need for further treatment in von Willebrand's disease. The choice of laboratory tests with which to monitor the treatment of von Willebrand's disease is controversial. Some physicians use the bleeding time, others use the factor VIII activity, and still others use the ristocetin cofactor level.

1-Deamino-8-D-Arginine Vasopressin

After the administration of DDAVP, levels of factor VIII coagulant activity, von Willebrand antigen, and ristocetin cofactor activity increase by about threefold in most people. This activity makes DDAVP an excellent alternative to blood products for the treatment of minor bleeding episodes in patients with mild hemophilia and for the treatment of most bleeding episodes in patients with the common form (type I) of von Willebrand's disease. Because some patients with these disorders do not respond to DDAVP, it is strongly recommended that children with mild hemophilia or type I von Willebrand's disease receive a trial dose of DDAVP when well to assess individual responses to this therapy before needing treatment for a bleeding episode. The dose of DDAVP is 0.3 µg/kg, administered by IV over 30 minutes. Side effects include facial flushing, headache, and rarely, hypertension, hypotension, and water retention. Hyponatremic seizures have occurred, and the patient should avoid excessive water intake. Subsequent doses may be less effective because the drug acts by releasing factor VIII and von Willebrand protein rather than by increasing their synthesis. In patients with severe factor VIII deficiency, DDAVP is ineffective. This is also true for many patients with severe (type III) von Willebrand's disease because the baseline factor VIII level is so low. In the rare Type IIB von Willebrand's disease, DDAVP may cause or aggravate thrombocytopenia and therefore should be used with caution.

DDAVP is also available as a concentrated nasal spray that should be distinguished from the more diluted formed used for enuresis or diabetes insipidus. For patients who have been previously shown to respond adequately to this form of therapy, the nasal spray is an alternative to an IV infusion. However, the nasal spray is designed primarily for use at home. DDAVP-responsive patients who come to the ED may have already tried the intranasal spray unsuccessfully or may have bleeding that requires other therapy.

Management of Patients with Inhibitors

The treatment of bleeding episodes in the child with hemophilia and antibodies against the missing or diminished factor is difficult, controversial, and often unsatisfying. Extensive resources, experience, and ingenuity are necessary to achieve hemostasis. For serious bleeding in patients with factor VIII deficiency and relatively low inhibitor titers (less than 10 Bethesda units), large doses of factor VIII may be sufficient to overwhelm the antibody and raise the factor VIII level to hemostatic levels. Doses as high as 100 to 200 units/kg may be necessary. However, those patients who are “high responders” to the factor VIII antigen will develop rising titers of antibody within 3 to 5 days, reducing or eliminating the usefulness of further therapy with factor VIII. Despite the subsequent rise in inhibitor titer, this brief period of initial factor VIII therapy may be sufficient to stop bleeding in critical organs such as the brain. On the other hand, factor VIII replacement should not be used as initial therapy for a minor bleed in a patient with a high responding inhibitor since the

anamnestic antibody response may impair the management of a later, more serious bleed.

If the initial inhibitor titer in a patient with critical bleeding is too high to warrant a trial of factor VIII therapy, or if no response to factor VIII is obtained, alternative approaches should be initiated. Porcine factor VIII can achieve hemostatic levels in patients whose inhibitor does not cross-react with this animal protein. As with human factor VIII, treatment with porcine factor VIII can be monitored by improvement in the PTT and an increase in the factor VIII level. Another advantage of porcine factor VIII is its excellent record of viral safety. Ideally, patients with factor VIII antibodies should be tested electively to determine whether the antibody cross-reacts with porcine factor VIII. In this way, emergency treatment can be reserved for those patients who are likely to respond favorably. Unfortunately, even if there are not cross-reactive antibodies at the outset, antibodies to porcine factor VIII may develop early in the course of therapy.

Another approach to the treatment of serious bleeding in the patient with factor VIII deficiency and inhibitors is the administration of prothrombin complex concentrate or activated prothrombin complex concentrate. These products presumably are effective because of their ability to bypass factor VIII through the presence of factors II, VII, and X. The activated prothrombin complex concentrate is somewhat more effective than the nonactivated product and is generally preferred for serious bleeding. However, neither product is uniformly effective, and treatment cannot be monitored by the PTT or factor levels but only by clinical response. A new option for the treatment of bleeding in children with high-titer inhibitors is recombinant factor VIIa. This product is not derived from plasma and therefore should have little or no risk of viral transmission. However, factor VIIa has a very short half-life and must be administered every two hours. As with the prothrombin complex concentrates, success of treatment must be judged clinically rather than by changes in laboratory values.

Occasionally the condition of the patient with inhibitors will worsen despite factor therapy. For example, the child with an intracranial hemorrhage may have continued bleeding and neurologic deterioration despite high-dose factor VIII or activated prothrombin complex concentrate. In such instances, plasmapheresis may remove sufficient antibody to allow a response to factor VIII administration. However, because 50% of the IgG inhibitor is tissue-bound and will rapidly return to the plasma, further infusions of factor VIII will be unsuccessful unless preceded by additional plasmaphereses.

Minor bleeds in the patient with factor VIII deficiency and inhibitors can be treated with any of the products described above for use with major bleeds. Factor VIII is the product of choice for patients with low titer inhibitors who can achieve hemostatic factor VIII levels without anamnesis. Patients with low titer inhibitors who are unresponsive to factor VIII and patients with high titer inhibitors, joint bleeds, and other minor hemorrhages should be treated with prothrombin complex concentrate, activated prothrombin complex concentrate, porcine factor VIII, or recombinant factor VIIa. Since the clinical response to these products may be unsatisfactory or, at best, unpredictable, good local care, including splinting for joint bleeds and topical thrombin for accessible oral bleeding, remains a cornerstone of therapy.

The treatment of the rare patients with antibodies to factor IX has not been clearly defined. Nonactivated and activated prothrombin complex concentrates have been beneficial in some cases. Exchange transfusion followed by infusion of factor IX concentrate may also be useful if the hemorrhage is severe or life-threatening. However, some patients with factor IX inhibitors have developed anaphylaxis when treated with these products, even if they received them without difficulty before the inhibitor appeared. Fortunately, the incidence of factor IX deficiency is only 15% of the incidence of factor VIII deficiency, and the proportion of patients who develop inhibitors is smaller in factor IX deficiency.

The recognition of a newly developed inhibitor may be equally important as the treatment of a patient with a known inhibitor. With the development of an inhibitor, patients with severe hemophilia often experience no change in their already difficult clinical course. However, the response to therapy is usually noted to be less satisfactory. Patients with moderate hemophilia who develop inhibitors have more bleeding and an inadequate response to treatment. If an inhibitor is suspected at the time of emergency therapy, a PTT should be measured after therapy because, in the presence of a strong inhibitor, a level of factor activity adequate to normalize the PTT (20 to 30% factor VIII) is rarely achieved. An inhibitor screen can also be performed by mixing the patient's plasma with normal plasma and by demonstrating a prolonged PTT compared with normal plasma mixed with saline. The level of inhibitor can be measured using more sophisticated techniques. Although the PTT need not be measured after routine treatment of minor hemorrhages, it should always be used to demonstrate an appropriate response in vitro to the treatment of major hemorrhage because a failure to respond to initial therapy may compromise organ function or life itself.

Inherited Hypercoagulable Conditions

Background

Hemostasis is a balance between the activities of proteins that promote and inhibit clotting. Deficiencies of the factor that promote clotting, such as factor VIII and factor IX, lead to abnormal bleeding, and the recognition and emergency treatment of the hemophilias and related disorders are familiar to many physicians. Deficiencies of the factors that inhibit coagulation lead to local and sometimes disseminated thrombosis. In contrast to bleeding disorders, the identification and emergency management of these unusual hypercoagulable disorders is likely to be unfamiliar to many clinicians. In fact, the role of some of these inhibitory proteins is only now being characterized.

Clinical Manifestations

The three major proteins that serve as brakes on the coagulation pathway are antithrombin III, protein C, and protein S. Antithrombin III inactivates the serine proteases that normally promote hemostasis. Patients heterozygous for antithrombin III deficiency have an increased risk of deep vein thrombosis and pulmonary embolus. Protein C, with its cofactor protein S, inactivates factors V and VIII. Persons heterozygous for protein C or protein S deficiency have an increased risk of venous thrombosis and, to a lesser degree, arterial thrombosis. Clinical findings in heterozygotes usually appear in adolescence or adulthood. In contrast, homozygous protein C deficiency causes widespread thrombosis in the neonatal period; homozygous protein S deficiency is rarer but may have similarly severe and early

clinical manifestations. This syndrome of purpura fulminans, sometimes accompanied by cerebral thrombosis, is a dire emergency that requires immediate intervention to preserve any chance of a good outcome.

The most common inherited cause of thrombosis, factor V Leiden, is a single gene mutation that alters the amino acid composition of factor V and makes this coagulation protein resistant to the anti-thrombotic activity of protein C. Factor V Leiden is found in nearly one-half of young men and women with a venous thrombosis. It may also be a risk factor for both venous and arterial thrombosis in ill neonates. Other inherited conditions that may increase the risk of thrombosis include dysfibrinogenemias, a prothrombin variant, abnormalities in the fibrinolytic pathway, and homocystinuria.

Management

Patients who are heterozygous for antithrombin III, protein C, protein S deficiency, or factor V Leiden and who develop a venous thrombosis should be treated with heparin by IV infusion. Treatment is usually initiated with a bolus injection of 50 to 100 units/kg body weight followed by a constant infusion of 25 units/kg per hour. The heparin dose should be adjusted to maintain the PTT between 1.5 and 2.0 times normal. Once adequate anticoagulation with heparin has been achieved, warfarin should be given orally. Long-term therapy with warfarin is effective because the drug inhibits synthesis of the vitamin K–dependent clotting factors. However, in the first few days of therapy, warfarin may inhibit disproportionately the synthesis of protein C, which is also vitamin K dependent and short-lived, leading to the paradoxical effect of increased hypercoagulability. Thus, the use of warfarin as initial therapy (i.e., without heparin) should be avoided because it may cause increased clotting, which manifests as skin necrosis.

Newborns with homozygous protein C deficiency and purpura fulminans should receive fresh-frozen plasma 8 to 12 mL/kg body weight every 12 hours. Long-term therapy includes regular infusions of fresh-frozen plasma or oral anticoagulation. Cryoprecipitate plays an analogous role in the acute and chronic therapy of homozygous protein S deficiency.

In many instances, a venous thrombosis is diagnosed in a patient without a previous diagnosis of an inherited hypercoagulable condition. The family history should be carefully reviewed for the occurrence of venous thrombosis or pulmonary embolus in otherwise healthy adults. Pretreatment plasma should be obtained for measurement of antithrombin III, protein C, and protein S. Molecular analysis for the factor V Leiden mutation can be performed before or after treatment. Because levels of these proteins may be transiently decreased after a large thrombosis, the diagnosis of a specific deficiency may be difficult. Measurement of antithrombin III, protein C, and protein S levels in both parents may help clarify the diagnosis in the child with a thrombosis and a possible inherited hypercoagulable condition.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is an acquired disorder of hemostasis that may be a result of numerous causes, but in children, it most commonly accompanies septic shock. The clinical and laboratory findings of DIC are described in Chapter 65. The treatment of this disorder should be directed primarily toward correction of the underlying disorder. Although correction of the hemostatic abnormality may temporarily decrease bleeding or prevent formation or extension of thrombosis, mortality remains extremely high when shock is not reversed in the first several hours.

Abnormal coagulation studies are often found in the absence of actual bleeding in DIC. Attempts to correct these abnormalities are of little or no value in preventing later bleeding or in altering the outcome of the underlying illness. If persistent or severe bleeding occurs, replacement of the consumed blood products may be helpful. Platelet transfusions (0.2 to 0.4 unit/kg) and fresh-frozen plasma (15 mL/kg) should be used to correct severe thrombocytopenia or substantially prolonged tests of clotting function. Although the administration of platelets and clotting factors may theoretically provide the necessary ingredients for further pathologic clotting, there is little evidence to suggest that such therapy is, in practice, responsible for worsening organ damage. However, replacement therapy should be stopped if bleeding does not improve after one or two infusions of the appropriate product. Preliminary studies suggest a possible role for AT-III concentrates in reducing intravascular clotting or in facilitating heparin therapy (see below).

The role of therapy with heparin in DIC remains controversial. Although anticoagulation may slow the progression of disseminated thrombosis and resulting ischemia and hemorrhage, such therapy itself may lead to fatal bleeding complications. Furthermore, as noted earlier, anticoagulation does not appear to affect patient survival and therefore should not interfere with the primary goal of reversing shock. Nevertheless, administration of heparin is commonly recommended for patients with DIC and purpura fulminans (see Chapter 65) or severely compromised renal function caused by thrombosis and ischemia. Heparin may be given by intermittent IV injection (50 to 100 units/kg every 4 hours) or continuous IV infusion (12.5 to 25 units/kg per hour after an initial bolus injection of 50 to 100 units/kg). The dosage should be adjusted to maintain the PTT at 1.5 to 2 times the normal value. Once further consumption of coagulation factors has been slowed or halted, administration of plasma and platelets may restore normal components of clotting. However, the actual benefit of the seemingly paradoxical use of anticoagulants and coagulation factors is unproved.

OTHER HEMATOLOGIC EMERGENCIES

Postsplenectomy Sepsis

Splenectomy may cure or ameliorate several hematologic disorders. However, loss of the spleen is associated with a greatly increased risk of sepsis caused by *S. pneumoniae, Neisseria meningitidis, E. coli, H. influenzae,* and other bacteria, especially in young children. The frequency of pneumococcal sepsis is particularly high; this organism accounts for 50% of the episodes of postsplenectomy sepsis. If the hematologic disorder is immunologic in origin (autoimmune hemolytic anemia) or accompanied by other gaps in host defense (Wiskott-Aldrich syndrome), the incidence of sepsis is especially high. More important, the mortality from sepsis in asplenic patients is significantly increased, averaging higher than 50% and rising to more than 80% in the presence of some immunologic abnormalities.

Although pneumococcal, *H. influenzae,* and meningococcal immunization and prophylactic antibiotics may reduce the occurrence of postsplenectomy sepsis, the most important facet of management is early detection and treatment. The presence of fever in an asplenic patient demands an immediate and careful evaluation to identify a source of infection. If the fever cannot be definitely attributed to a benign process such as an upper respiratory infection or if the patient appears unusually ill, the institution of parenteral antibiotic therapy pending results of cultures is usually indicated. The rapidity with which patients develop irreversible shock makes even a brief period of observation very risky and underscores the need for aggressive management of the symptomatic child. Antibiotic therapy is similar to that described above for children with sickle cell disease and fever.

Transfusion Reaction

Background

Acute hemolytic transfusion reactions that result from blood group incompatibility constitute a major hematologic emergency and may result in massive hemorrhage, renal failure, and death. The uncommon occurrence of this problem is, in large part, a tribute to careful blood banking practices and close attention to the administration of the red cell product. Unfortunately, the rarity of acute hemolytic reactions may lead to a sense of complacency regarding transfusion and a loss of familiarity with the signs and symptoms of massive red cell destruction.

Clinical Manifestations and Management

The characteristic findings of an acute hemolytic transfusion reaction include apprehension, fever, chills, abdominal or flank pain, chest tightness, and hypotension. If one or more of these findings develops, the transfusion should be stopped immediately because the severity of symptoms is related directly to the amount of hemolysis. Saline should be administered at 1.5 to 2 times the maintenance rate (see Chapter 18). A spun hematocrit should be examined for the presence of hemoglobin, which imparts a pink color to the plasma. The urine should also be examined for hemoglobin, which causes a positive dipstick reaction for blood in the absence of red cells on microscopic analysis. The name, identification number, and blood type of the patient should be compared with those on the unit of blood to ensure that the blood was given to the patient for whom it was intended. Finally, an aliquot of the unit should be returned to the blood bank for confirmation of the original compatibility testing and labeling. A newly positive direct Coombs test confirms the diagnosis.

Further management of an acute hemolytic transfusion reaction is directed toward maintenance of normal blood pressure and urine output and treatment of intravascular coagulation. Rapid IV hydration is mandatory to prevent renal shutdown. Diuretics, including mannitol (1 g/kg), may also be helpful. Intravascular coagulation should be treated with heparin, using doses similar to those described earlier for DIC from other causes.

Delayed hemolytic transfusion reactions can occur 3 to 14 days after administration of red cells. These reactions may be due to late formation of an antibody in response to a newly encountered red cell antigen or, alternatively, to an anamnestic response of an antibody that originally developed in response to a previous transfusion but was undetectable at the time of the most recent cross-match. The rate of red cell destruction is usually slower with a delayed hemolytic transfusion reaction than with an acute hemolytic reaction. Therefore, the most prominent signs and symptoms are those of anemia and hyperbilirubinemia rather than shock and renal shutdown. Laboratory testing demonstrates a positive direct Coombs test. Antibody in the serum or in the red cell eluate is specific for the offending red cell antigen. Transfusion with compatible red cells will relieve severe or symptomatic anemia.

Nonhemolytic transfusion reactions are more common and, in most instances, less severe than hemolytic reactions. Sensitization to plasma proteins may cause urticaria. Fever, chills, and headache commonly occur in repeatedly transfused patients who have become sensitized to white cell and platelet antigens. Although these reactions pose little danger to the patient, they may be difficult to distinguish from the more urgent hemolytic reaction. Before continuing the transfusion, urine and plasma should be checked for the presence of hemoglobin. If these studies are unrewarding, the physician must decide whether the clinical condition of the child warrants discarding the remainder of the unit or finishing the transfusion with supportive therapy such as antipyretics or antihistamines. The use of filters to remove white cells has drastically reduced the incidence of nonhemolytic reactions in chronically transfused patients. As a corollary, a hemolytic reaction should be given particularly strong consideration when fever and chills occur in a child receiving filtered red cells.

CHAPTER 88

Toxicologic Emergencies

***KEVIN C. OSTERHOUDT, MD, †MICHAEL SHANNON, MD, MPH, and ‡FRED M. HENRETIG, MD**

**Department of Pediatrics, The University of Pennsylvania School of Medicine; Division of Emergency Medicine, The Children's Hospital of Philadelphia; †Department of Pediatrics, Harvard Medical School, Division of Emergency Medicine, Boston, Massachusetts; ‡Departments of Pediatrics and Emergency Medicine, The University of Pennsylvania School of Medicine, Section of Clinical Toxicology, The Children's Hospital of Philadelphia, and The Poison Control Center, Philadelphia, Pennsylvania*

POISONED CHILD

Poisoning represents one of the most common medical emergencies encountered by young children and accounts for a significant fraction of emergency department (ED) visits in the adolescent population.

Estimates of poisoning episodes annually in the United States range in the millions. Poisonings may be unintentional or intentional. Unintentional poisonings make up some 80 to 85% or more of all poisoning exposures, whereas intentional poisonings comprise the other 10 to 15%. Persons in this latter group have much higher rates of treatment in the ED, hospitalization, and intensive care. Among children aged 5 years and younger, most poisonings are unintentional events related to exploratory behavior, or they result from willful child abuse. Although less common, the physician must also consider the possibility of environmental exposures, suicide attempts in children, and neonates exposed to toxins in utero.

The unintentional ingestion of a toxin by a toddler represents a complex interplay of host, agent, and environmental factors and may be considered a subset of the modern traumatic injury model. In this model, each factor contributes, more or less, in a given context to the probability of the injury occurring. Some children are more at risk because of peak age of 1 to 4 years, male gender, temperament that leans toward hyperactivity, and increased finger–mouth activity and/or pica. Some agents are more culpable because of ease of access, attractiveness/palatability, and toxic potential. Two classic examples are iron tablets—they look like candy, are widely available over the counter (OTC), and are toxic in significant overdose—and mouthwash—it has a bright color, pleasant taste, and smell and is packaged in large volumes without safety caps and has a surprisingly high ethanol content (15 to 25%). Typical environmental factors include an acute stressor, such as a recent move or new baby in the household, and chronic issues, such as parental illness/disability. The concordance of child, agent, and environmental factors may lead predictably to the statistical

likelihood of a toddler ingestion. Pediatricians have led the way in poison prevention strategies by modifying these risk factors with traditional anticipatory guidance and by spearheading the lobby for child-safety caps on particularly dangerous medications and household products. These efforts have resulted in a dramatic decrease in childhood poisoning morbidity and mortality over the past three decades, but such poisonings continue to occur and demand the emergency physician's attention.

The scope of toxic substances involved in poisonings is broad, requiring a wide range of knowledge. Table 88.1 presents the categories of substances most commonly reported in human exposures in the United States for the year 1997. Table 88.2 presents the 10 most common toxic exposures involved in human deaths for the year 1997. The former listing much more closely approximates the profile of pediatric poisonings, whereas the latter is more typical of intentional adult exposures. The most important difference between the pediatric and the adult profile by type of agent is in the higher percentage of cases in which psychopharmacologic drugs (sedatives, tranquilizers, and antidepressants) cause poisoning in adults and the much higher frequency of exposures to household and personal care products and plants in children.

Substance	Percentage of Total Exposures
Cleaning products	10.4
Analgesics	10.3
Cosmetics	9.0
Plants	5.6
Cough and cold preparations	5.1
Bites/envenomations	4.4
Foreign bodies	4.3
Insecticides/pesticides	4.0
Topicals	3.7
Food products/food poisoning	3.6

Table 88.2. Toxic Exposures Associated with the Most Deaths

There are six basic modes of exposure to poisoning: ingestion, ocular exposure, topical exposure, envenomation, inhalation, and transplacental exposure. Poisonings may be the result of acute or chronic exposures. Most poisonings are acute, and the victims are typified by the child who surreptitiously invades the medicine cabinet or the storage area for household cleaners or the adolescent or adult who takes a massive number of pills in a fit of despair. *Chronic poisoning* refers to toxicity produced over time in which a substance accumulates in the body, producing toxic results; it is best exemplified by environmental exposure to lead or other heavy metals. In the drug category, chronic toxicity can also exist. Acetaminophen hepatotoxicity that occurs in infants and small children or aspirin poisoning in older adults as a result of salicylate accumulation after administration of too much drug for too long is typical of chronic toxicity. Chronic toxicity is a special problem for the clinician because the source is not always apparent, the toxicity is not always clear, and the toxic process is not often obvious until serious clinical derangements occur.

GENERAL APPROACH TO THE POISONED CHILD

Following the analogy between unintentional accidental poisoning and traumatic injury, a similar model may be used in formulating a management approach. The poisoned patient often represents an acute-onset emergency with a broad spectrum of multiorgan system pathophysiology that shares many features with the multiple trauma victim. In essence, poisoning might be viewed as a multiple chemical trauma. The concept of a brief window of opportunity to make critical diagnostic and management decisions is likewise analogous. Thus, with a nod toward the widely acclaimed Advanced Trauma Life Support model of the American College of Surgeons, one may conceptualize a management approach that attempts to prioritize critical assessment and, at times, simultaneous management interventions (Table 88.3). The initial phase (or “primary survey”) addresses traditional ABCs of airway securement and cardiorespiratory support, with a slight additional emphasis on emergent toxicologic considerations. The more specific evaluation and detoxification phase (or “secondary survey”) is aimed at simultaneously initiating generic treatment while assessing the actual extent of intoxication (in cases of known or presumed exposures) and/or identifying the actual toxins involved (in unknown, but highly suspected intoxications).

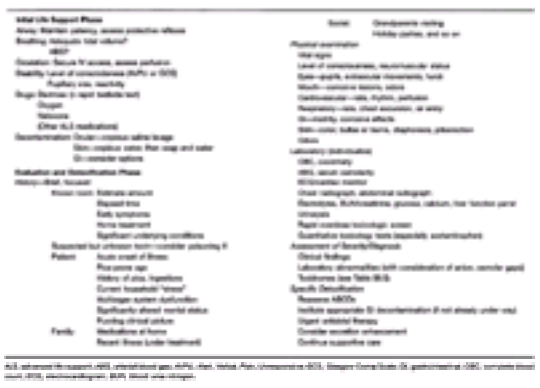

Table 88.3. General Approach to the Known or Suspected Intoxication

Initial Life Support Phase

The general approach to recognition and support of vital airway and cardiorespiratory functions (or “ABCDs”) is well known to most readers and is covered in detail in Chapter 1. In the context of the poisoned child, a few points deserve special emphasis. In addition to the usual signs of airway obstruction, the physician must pay special attention to evidence of disturbed airway protective reflexes. Many poisoned patients will vomit or undergo procedures such as gastric lavage or administration of charcoal, which pose an aspiration risk. Elective endotracheal intubation (see Chapter 5) may thus be indicated at a slightly lower threshold in this context than in another child with comparable central nervous system (CNS) depression.

It is also particularly important to anticipate imminent respiratory failure in the deeply comatose poisoned child. Cyanosis and overt apnea are late findings with progressive drug-induced medullary depression. Thus, clinical assessment of early ventilatory insufficiency and/or measurement of P_{CO_2} on arterial blood gas analysis is critical in such patients, to avoid the chaos of a precipitous respiratory arrest. Likewise, it is far easier to establish intravenous (IV) access in a child with normal circulatory status than in a child in shock; early efforts to obtain a secure IV line in symptomatic overdose patients are thus well worth the time and effort.

Having reached the “D” in our mnemonic, the patient is evaluated for “ *d*isability” (e.g., neurologic status), empiric “ *d*rug” treatment, and emergent “*d*econtamination.” Level of consciousness may be assessed rapidly with a semiquantitative scale such as the Glasgow Coma Scale or the AVPU scale (spontaneously *a*lert, response to *v*erbal stimulation or *p*ain, or *u*nresponsive). Pupillary size and reactivity may be quickly noted. Rapid changes in mental status are common in serious intoxications and may herald precipitous cardiorespiratory failure.

Empiric drug treatment is warranted for most symptomatic poisoned children with altered mental status. All such patients may initially be given humidified *oxygen* and their oxyhemoglobin saturation monitored, if possible, by pulse oximetry. If available, rapid bedside blood glucose testing may be used; if low, or not readily available, a trial dosage of 0.25 to 1.0 g/kg glucose as 10 to 25% solution should be infused. It should be noted that drug- or toxin-induced hypoglycemia does not present uniformly with coma or seizures. Almost any neuropsychiatric picture may predominate, including aphasia; slurred, dysarthric speech; and focal neurologic signs. Adrenergic signs, such as diaphoresis and tachycardia, are not uniformly present. Hypoglycemia is a complication seen in ingestions of ethanol, oral hypoglycemics, b-blockers, salicylates, and of course, insulin injection. As basic as this intervention seems, in our experience, it is still one of the most often missed (or more accurately, *delayed*) critical treatments in the management of the poisoned patient.

Thiamine (100 mg IV), although routinely administered to adult overdose patients who receive hypertonic glucose to obviate precipitating Wernicke's encephalopathy, is not generally warranted in the pediatric population. Perhaps it should be considered in adolescent patients who may be thiamine deficient secondary to eating disorders, chronic disease (e.g., inflammatory bowel disease), or alcoholism. Last, empiric naloxone therapy is just as important in potentially poisoned toddlers with altered mental status as it is in adults. Although substance abuse is admittedly uncommon in the average 2-year-old child, it is amazing how many narcotics find their way into the curious child's mouth. Many households contain a variety of oral opioid analgesic agents, as well as cough medicines (codeine, dextromethorphan), antidiarrheal agents (paregoric, diphenoxylate), and partially naloxone-responsive antihypertensive agents such as clonidine. In addition, the possibility of unintentional ingestion of a “stash” of illicit opioids does exist. Thus, naloxone should be used as a therapeutic/diagnostic trial when there is a reasonable possibility that altered mental status is drug induced. Previous recommendations have based dosing on weight (e.g., 0.01 to 0.1 mg/kg); however, many authorities now prefer a unified dose of 1 to 2 mg for acute overdose patients of all ages (outside the neonatal period). Such an approach conceptualizes naloxone dosing as based on total narcotic load and number of opioid receptors that require competition for binding sites. In general, this latter approach is easier to remember and has not been associated with complication in the ED. Adolescent patients with a strong clinical picture for opioid intoxication (without habituation) may receive 2-mg bolus doses every 2 minutes, up to a total dose of 8 to 10 mg before abandoning hope of benefit because several congeners of morphine (e.g., propoxyphene, illicit fentanyl derivatives, pentazocine) may require such large doses. If chronic abuse is suspected, lower initial doses (0.2–0.11 mg) are warranted. Administration of flumazenil to adolescents exhibiting depressed consciousness after an unknown drug overdose is contraindicated (see also discussion in Sedative-Hypnotic section).

The rationale for decontamination of the poisoned child is discussed in the following section, Evaluation and Detoxification. This treatment phase may begin urgently, after, or in concert with attention to the ABCDs. At times, a decision to perform gastric decontamination through the preferred technique can be made almost immediately upon presentation and, if so, should be instituted as soon as possible in light of the patient's clinical status and the number of hands available to assist in management. For example, a toddler with coma, shock, and massive hematochezia who is

rushed into the ED by the rescue squad—and for whom there is witnessed or strong circumstantial evidence of massive iron overdose—requires a concerted team effort directed toward resuscitation, stabilization, and urgent gastric decontamination—in this case, probably initiated with gastric lavage after endotracheal intubation. However, an apparently asymptomatic adolescent who admits to ingesting 10 g of acetaminophen 2 hours before arrival at the ED may be more fully evaluated in a timely but orderly manner (as outlined in the next section) and within short order can be considered for less emergent gastric decontamination—in this case, likely an oral dose of activated charcoal. Significant dermal or ocular exposures require immediate copious lavage, and precautions from exposure should be taken to protect the health care providers tending to the patient.

At the completion of this initial life support phase, the poisoned patient should have been assessed for compromise of vital airway and cardiorespiratory function and for global neurologic status and should have had resuscitative measures instituted. Patients with significant altered mental status have been critically evaluated for respiratory status, have had IV access secured, and have had their therapeutic trials of oxygen, glucose, and naloxone. Other advanced life support interventions such as anticonvulsants or antiarrhythmics have been instituted as necessary. Consideration of decontamination options has begun.

Evaluation and Detoxification Phase

History

A brief and focused *historical evaluation* should be addressed as soon as the life support phase has been accomplished. The primary goal is to determine the potential severity of the exposure. This assessment requires toxin and patient-related data alike.

For a known or highly suspected toxin, an attempt is made to estimate the total amount ingested (number of pills missing, ounces left in the bottle, dosage of pills, concentration of alcohol, and so forth). The best estimate of time elapsed since ingestion is also sought. Parents should be questioned regarding early symptoms noted at home or on route to the ED, and any treatments administered before arrival. Certain underlying medical conditions may be relevant (e.g., glucose-6-phosphate dehydrogenase [G6PD] deficiency for mothball ingestions); thus, any significant past medical history ought to be noted.

Often, children who are poisoned do not come to the ED with a clear history of exposure followed by onset of symptoms. Often, they develop signs and symptoms that mimic other diseases and give no history of toxic exposure. Thus, the ED staff must always consider the possibility of an ingestion when treating young children.

General historical features that suggest the possibility of poisoning include 1) acute onset; 2) age range of 1 to 5 years; 3) history of pica or known, unintentional ingestion; 4) substantial environmental stress, either acute (e.g., arrival of a new baby, serious illness in a parent) or chronic (marital conflict, parental disability); 5) multiple organ system involvement; 6) significant alteration in level of consciousness; and 7) a clinical picture that seems especially puzzling.

Certain family and social history variables are also important. Medications used by other household members, and particularly new medications introduced into the home environment by virtue of recent illnesses or visits from grandparents and other relatives, are a common source of ingested drugs. Changes in routine and large family gatherings (e.g., holiday parties, moving to a new home) are particularly risky occasions for decreased parental supervision and new (or less carefully guarded) potentially toxic medications or household products.

Physical Examination

The focused physical examination should begin with a reassessment of vital functions and complete recording of vital signs, including core temperature. With secure airway and cardiorespiratory function confirmed, the examination should then focus on the central and autonomic nervous systems, eye findings, changes in the skin and/or oral and gastrointestinal (GI) mucous membranes, and odors (see Chapter 47) on the breath or clothing of the patient. These features represent those areas most likely affected in toxic syndromes and, when taken together, often form a constellation of signs and symptoms referred to as toxidromes (Table 88.4 and Table 88.5). Such toxidromes may be so characteristic as to provide guidance for early therapeutic trials before precise historical or laboratory confirmation of a specific exposure is available.

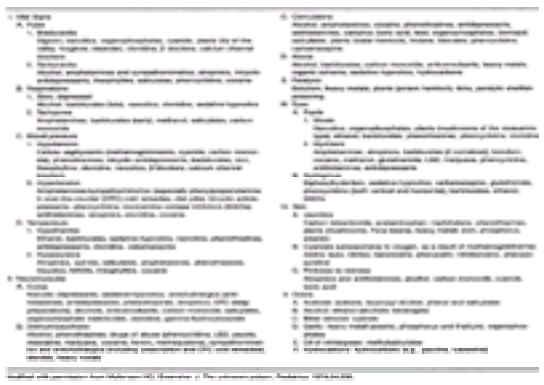

Table 88.4. Clinical Manifestations of Poisoning

	Sympathomimetics (Antipsychotics, Cocaine)	Anticholinergics (Antihistamines, Many Others)	Organophosphates (Insecticides, Nerve Gases)	Opiates/ Clonidine	Barbiturates/ Sedative-Hypnotics	Salicylates	Theophylline
Mental status/ CNS	Agitation, delirium, psychosis, convulsions	Delirium, psychosis, coma, convulsions	Confusion, fasciculations, coma	Euphoria, somnolence, coma	Somnolence, coma	Lethargy, convulsions	Agitation, tremor, convulsions
Heart rate	Increased	Increased	Decreased or increased	Decreased	–	–	Increased

CNS, Central nervous system.
*"SLUDGE" is a mnemonic representing salivation, lacrimation, urination, defecation, gastric cramping, and emesis.

Table 88.5. Toxidromes

Laboratory Evaluation

The laboratory may be helpful in confirming diagnostic impressions or in demonstrating toxin-induced metabolic aberrations. However, there is no “tox panel” that is uniformly helpful or necessary. Most poisonings can be managed appropriately without extensive laboratory studies, and in particular, the reflex ordering of rapid overdose toxicology “screens” has been found to be rarely helpful in acute patient management. They have important, nonemergent roles (e.g., in resolving medicolegal issues or considering drug-induced causes of behavioral changes in a psychiatric patient). In toddlers with a known or strongly suspected specific ingestion, rapid drug screens are rarely indicated. In the adolescent intentional overdose patient who is not critically ill or who does not have a particularly puzzling clinical picture, the drug screen again is rarely helpful, although the finding of an unexpected toxic level of acetaminophen (which may have been omitted in the history) may impact on management, and some authors recommend that quantitative acetaminophen levels (in lieu of “tox screens”) be sought in such patients.

The comprehensive drug screen that requires blood and urine samples may be useful for patients who are seriously ill with an occult ingestion or for the occasional intentional overdose adolescent patient whose clinical picture does not fit with the stated history. Often of greater help is the critical interpretation of routine measurements of serum chemistries and osmolarity in patients with altered mental status. The presence of hypoglycemia or aberrations of serum electrolytes may be crucial information about the poisoned patient. In certain circumstances, tests of liver or renal function, urinalysis, creatine phosphokinase levels, and other select tests may be useful. Metabolic acidosis with a high anion gap is found in many clinical syndromes and toxidromes, reflected by the often-cited mnemonic *MUDPILES*, for *m*ethanol and *m*etformin; *u*remia; *d*iabetic and other ketoacidoses; *p*araldehyde; *i*soniazid, *i*ron, and *i*nborn errors of metabolism; *l*actic acidosis (seen with hypoxia, shock, carbon monoxide, cyanide, and many drugs that cause compromised cardiorespiratory status or prolonged seizures); *e*thanol and *e*thylene glycol; and *s*alicylates. Differences between calculated and measured serum osmolarity (Calculated = 2 × [Serum Na] + BUN/2.8 + glucose/18 with normal osmolarity = 290 mOsm/kg) may suggest intoxication with ethanol, isopropanol, or more rarely in pediatric patients, methanol or ethylene glycol.

An immediate determination of quantitative levels is helpful in making management decisions for some drugs, and these are outlined in Table 88.6. Furthermore, many important causes of coma and altered vital signs are not detected on even the most sophisticated “comprehensive” toxicology panels (which are usually biased toward psychoactive medications and illicit drugs). An overview of such agents is presented in Table 88.7. An electrocardiogram (ECG) should be performed in all seriously ill patients in whom poisoning is being considered. Detectable conduction delays may precede life-threatening cardiac rhythm disturbances.

Drug/Toxin	Optimal Time After Ingestion
Acetaminophen	4 hr
Carbamazepine	2–4 hr
Carboxyhemoglobin	Immediate
Digoxin	4–6 hr
Ethanol	½–1 hr
Ethylene glycol	½–1 hr
Iron	4 hr
Lithium	2–4 hr*
Methanol	½–1 hr
Methemoglobin	Immediate
Phenobarbital	1–2 hr
Phenytoin	1–2 hr
Salicylates	2–4 hr*
Theophylline	1–2 hr*

Table 88.7. Important Drugs and Toxins Not Detected by Most Drug Screens

Assessment of Severity and Diagnosis

At this juncture, most intoxicated patients may be readily stratified by specific toxin or category of drug(s) ingested and some judgment made as to the potential or current severity of the exposure. For some children, clinical features of a complex illness of acute onset may suggest an intoxication without a specific history of such ingestion. In a few cases, some laboratory confirmation of clinical suspicion will be available on an immediate basis. Using all the clinical clues available and with some familiarity of the “toxidrome” approach to differential diagnosis as detailed previously (Table 88.4 and Table 88.5) and, at times, with help from the laboratory, the emergency physician must now establish a working diagnosis and proceed with consideration of options for specific detoxification.

Specific Detoxification

Again, the proviso that the patient be continually reassessed and managed for impaired vital function is addressed. All decisions about further decontamination and/or specific antidotal therapy involve a complex interplay of toxin-related and patient's condition-related factors.

Gastrointestinal Decontamination

The effort to “get the poison out” has long been a mainstay of the traditional discussion of toxicologic management. Recently, considerable controversy has arisen over the optimal method of gastric emptying and its overall value in the management of poisoned patients. Many authorities now eschew gastric emptying in all but a few select cases, preferring an enlarged role for the early use of activated charcoal. Many studies that support this trend have been published over the past 10 years. It is emphasized here that many of the relevant human studies used relatively nontoxic “overdoses” in adult volunteers or excluded (at the attending physician's discretion) most critically ill patients. Few young children were included in any of these studies. It is likely that as further research is conducted, particularly as directed toward the pediatric population, current dogma regarding optimal GI decontamination will evolve. For the sections that follow, several appropriate techniques for gastric decontamination are reviewed, all of which may be useful under certain circumstances. An approach to the overall decision process in a given patient is then offered.

Simple Dilution. Dilution may be indicated only when the toxin produces local irritation or corrosion. Water or milk is an acceptable diluent. For drug ingestion, however, dilution alone should not be used because it may increase absorption by increasing dissolution rates of the tablets or capsules, or it may promote more rapid transit into the lower GI tract. However, administration of fluids during the induction of emesis is appropriate.

Gastric Emptying. The goal of gastric emptying is to rid the stomach of remaining poison to prevent further local effect or systemic absorption. The utility of gastric emptying diminishes with time and is most effective if done within the first hour. In certain circumstances, such as the delayed gastric emptying accompanying intoxication with anticholinergic drugs, benefit may be noted longer after ingestion. *Emesis* was once a favored means of gastric emptying, but currently induction of emesis is typically limited to first aid in the home setting. The drug of choice for inducing emesis is syrup of ipecac. A dose of 30 mL for adolescents, 15 mL for children, and 10 mL for infants 6 to 12 months of age, given with 8 oz of water or other liquid, reliably produces vomiting. If vomiting does not occur in 20 minutes, the dose should be repeated.

The efficacy of ipecac-induced emesis in reducing bioavailability of ingested drug has recently been called into question. Study results have varied widely with ranges from 0 to 70% decrease in absorption. Despite a long history of use, it has been difficult to prove improved clinical outcome in poisoned patients given ipecac compared with patients treated with activated charcoal alone. Ipecac has a long record of safe pediatric experience, and despite rare case reports of complications secondary to particularly prolonged or forceful emesis, its administration is generally well tolerated by patients and parents. It may be the most useful decontamination procedure for young children who ingest plant parts, seeds, mushrooms, and the like, in whom lavage is less apt to be successful because of particle size and for whom charcoal alone may not be as effective. Ipecac has been found to delay the time to administration of activated charcoal and some specific antidotes. It is contraindicated when patients have ingested caustics or hydrocarbons, when patients have uncontrolled hypertension or increased intracranial pressure, and when the presence or possibility of compromised airway protective reflexes exists.

An alternative to ipecac-induced emesis for emptying the stomach is *gastric lavage.* This procedure is usually reserved for patients who have ingested a potentially life-threatening amount of a poison, in cases where the procedure can be performed safely within 60 minutes of ingestion and charcoal alone is not believed to be adequate. To carry out a satisfactory lavage, the patient should be on his or her left side, head slightly lower than feet, and the largest orogastric

lavage tube that can reasonably be passed should be used (e.g., 24-Fr orogastric tube for a toddler, 36-Fr orogastric tube for an adolescent). A smaller caliber nasogastric (NG) tube is sufficient for only some liquid toxins. Gastric contents should be aspirated initially before any lavage fluid is introduced. Normal saline aliquots of 50 to 100 mL in young children and 150 to 200 mL in adolescents can be lavaged repeatedly until the return is clear. Like induced emesis, gastric lavage's efficacy in reducing drug absorption has been reviewed critically in recent studies. Again, the efficacy has been highly variable and lavage has not been demonstrated to improve outcome in poisoned patients. Several important risks are associated with gastric lavage, including oxygen desaturation, aspiration, and mechanical trauma to the oropharynx and esophagus.

Activated Charcoal. Activated charcoal minimizes absorption of drugs by adsorbing them onto its surface. Charcoal administration has become the decontamination strategy of choice for most pediatric poisonings and is most effective when used in the first few hours after ingestion. A number of notable compounds, such as iron and lithium, do not adsorb well to activated charcoal (Table 88.8). The usual dose of activated charcoal is 1 g/kg; adolescents and adults should receive 50 to 100 g. Most activated charcoal is now available premixed with water to make a slurry that can be taken orally or administered by NG tube. Considerable pharmaceutical research is being done toward the goal of making charcoal easier to administer and more palatable. “Superactivated” charcoals are available with increased adsorptive surface area. It should be noted that the once advocated “universal antidote” that consisted of activated charcoal, magnesium oxide, and tannic acid is not recommended. Similarly, burnt toast is not effective.

Substances poorly (or not) adsorbed
Common electrolytes
Iron
Mineral acids or bases
Alcohols
Cyanide
Most solvents
Most water-insoluble compounds (e.g., hydrocarbons)

Table 88.8. Activated Charcoal

Activated charcoal was “rediscovered” by the toxicology community during the 1980s, with several studies finding its use to be superior to gastric emptying alone, and at least equivalent to the combination of gastric emptying plus charcoal administration. The use of charcoal alone is less invasive and intuitively is probably less likely to be associated with complications in the clinical setting than gastric emptying. Aspiration of charcoal can be a serious concern in patients with poor airway protective reflexes, and vomiting remains the most common difficulty associated with its use. Some preparations of activated charcoal are premixed with a sorbitol cathartic in an effort to speed fecal toxin elimination and reduce constipation. Charcoal might be contraindicated in patients with an unprotected airway or a disrupted GI tract (e.g., after severe caustic ingestion) or in patients in whom charcoal therapy may increase the risk and severity of aspiration (e.g., hydrocarbons). The use of multiple doses of activated charcoal is addressed later in this chapter.

Catharsis. Two types of osmotic cathartics have been used to treat poisoned patients: the saccharide cathartics (e.g., sorbitol) and the saline cathartics (e.g., magnesium citrate, magnesium sulfate). A special type of catharsis, *whole bowel irrigation (WBI),* is discussed in the next section. Unfortunately, little evidence exists to suggest that standard cathartics accomplish their goal of reducing drug absorption by decreasing GI transit time. It is still unclear whether cathartics administered with activated charcoal reduce subsequent constipation, and some believe cathartics increase the incidence of vomiting. Repetitive doses of osmotic cathartics are associated with considerable diarrhea and cramping, and hypernatremic dehydration has been reported in young infants. A single dose of premixed charcoal/sorbitol is safe for most pediatric ingestions, but this preparation should be used with caution in young infants. Mineral oil or stimulant cathartics such as castor oil are discouraged because they may increase absorption of some poisons or unnecessarily extend the cathartic effect.

Whole Bowel Irrigation. An additional technique of GI decontamination that has been developed over the past several years is that of intestinal irrigation with large volumes and flow rates of a polyethylene glycol-balanced electrolyte solution such as Colyte or GoLYTELY. These solutions are not significantly absorbed nor do they exert an osmotic effect, so the patient's net fluid/electrolyte status is unchanged. They have a long track record of safe use, including in infants, in the surgical application of preoperative bowel preparation. WBI has been found to be particularly useful in pediatric iron overdoses, in which gastric lavage may be limited by tube size and the substance is not bound to charcoal. It has been used for other metal ingestions (e.g., lead), for overdoses of sustained-release medications (e.g., lithium, theophylline) with increasing levels after initial decontamination, and for ingestions of crack vials or cocaine packets. It might also be useful in particularly massive and/or late-presenting overdoses for which the efficacy of gastric emptying and/or charcoal is expected to be suboptimal. The technique may be used by mouth in cooperative patients or by NG tube; the usual recommended dosing is 500 mL/hour in toddlers and 2 L/hour in adolescents and adults.

Gastrointestinal Decontamination Strategies

It should be apparent that no unique approach to GI decontamination of all poisoned patients is optimal in every case. Factors to be considered include the expected degree of toxicity from the drug, the physical nature of the drug, the current location of the drug within the body, and the presence of contraindications or alternatives. A risk-benefit decision

must be made before the institution of any decontamination strategy.

Syrup of ipecac is used primarily as first-aid treatment of recent potentially toxic ingestions in the home. Today, induced emesis is rarely favored in the ED. Its use may be considered after ingestions of particulate poisons, like plant leaves, in toddlers. The use of gastric lavage as a decontamination strategy has become more limited in recent years. It is still considered to have a potentially important role in patients with recent ingestions of extremely toxic substances that put them at risk for a lethal course, especially when those substances do not bind well to charcoal. Likewise, patients with truly massive overdoses may benefit from gastric lavage because standard charcoal preparations have diminished effectiveness when the charcoal to drug ratio is less than 10:1. The correct technique for gastric lavage requires that careful attention be given to prevent aspiration and anatomic trauma.

Some of the patients in question will have undergone endotracheal intubation during the initial life support phase of management, as detailed previously, or they may be strong candidates for such airway protection because of borderline mental status and in anticipation of their ensuing critical course. Others may be awake, alert, and cooperative and may have normal airway protective reflexes, and thus be managed by elective, voluntary lavage without prior endotracheal intubation. The combative, agitated patient poses a dilemma and must be carefully managed on an individualized basis—the benefit of a rapid sequence endotracheal intubation performed primarily to allow gastric lavage, per se, would only occasionally outweigh the risks involved. A severely depressed, uncooperative adolescent or a frightened, combative toddler who had ingested a full bottle of colchicine or lithium within 1 hour of presentation might be such an example. A similar overdose of only benzodiazepine, or only acetaminophen, would probably not.

Overall, the mortality from acute poisoning is less than 1%. Suicidal overdoses in adolescents typically have more inherent lethality than unintentional overdoses in toddlers. When gastric decontamination is warranted, the administration of activated charcoal, without gastric emptying, is most often the appropriate choice. WBI is of theoretic benefit to body packers and stuffers, and patients who have ingested toxic amounts of sustained-release preparations or agents not adsorbed well by activated charcoal. An attempt to summarize these considerations is diagrammed in Figure 88.1, although it should be reiterated that all decisions regarding gastric decontamination involve multiple patient and toxin-related factors and should not be made with a “cookbook” approach.

FIGURE 88.1. Approach to gastrointestinal decontamination. [a]For patients in whom the toxin is no longer believed to be in the stomach, activated charcoal administration and/or whole bowel irrigation might still be valid considerations.

Antidotal Therapy

The overall number of ingestions for which a specific antidote is necessary or available is small. When a specific antidote can be used, it is vital that it be administered as early as possible and in an appropriately monitored dose. Those antidotes that should be available for immediate administration include sodium bicarbonate (cyclic antidepressants), sodium nitrite/sodium thiosulfate (cyanide), atropine and pralidoxime (cholinesterase inhibitors), ethanol or 4-methylpyrazole (ethylene glycol and methanol), deferoxamine (iron), dextrose (ethanol, salicylates, oral hypoglycemics), methylene blue (methemoglobinemic agents), oxygen (carbon monoxide), flumazenil (benzodiazepines), and naloxone (opioids). Other antidotes usually do not require such urgent administration and may be given subsequent to initiation of other management modalities. Even when available, antidotes do not diminish the need for meticulous supportive care or other therapy. Indiscriminant use of antidotes without other forms of management should be discouraged. Table 88.9 summarizes a list of commonly used antidotes, suggested doses, and their indications for use. Because of its frequent use, naloxone is discussed further here.

Table 88.9. Summary of Antidotes

Naloxone. Naloxone, a pure narcotic antagonist, is one of the broadest acting, safest, and most effective of any true antidotes now available. It is effective against all opioids. Naloxone is a synthetic congener of oxymorphone but is devoid of morphine agonist or depressant effects. It has no significant side effects in the treatment of acute overdose except narcotic withdrawal symptoms in the addicted patient. These symptoms include GI upset, tachycardia, hyperpnea, mydriasis, rhinorrhea, diaphoresis, sialorrhea, increased blood pressure, anxiety, restlessness, discomfort, and hyperalgesia. These symptoms are not life-threatening to teenagers and adults but can be fatal to an infant born to an addicted mother. Withdrawal symptoms, if observed during acute overdose treatment, would be expected to last no more than 30 minutes and should generally be treated with supportive care. The serum half-life of naloxone is 1 hour; its duration of action 1 to 4 hours. Initial reversal of narcosis may then revert to coma, requiring ongoing reassessment and readministration of naloxone. There are a few case reports of other adverse effects, including hypertension, pulmonary edema, ventricular irritability, and seizures after naloxone-induced reversal of narcosis in the perioperative setting, typically in patients with underlying cardiopulmonary disease and in the presence of additional medications or anesthetic agent use.

The mechanism of action of naloxone is by competitive displacement of narcotic analgesics at central narcotic receptor sites. It can be used as a diagnostic test when faced with a questionable history. Current dosage recommendations reflect the proven safety of naloxone in large doses and the necessity of such doses to reverse effects of synthetic opioids such as propoxyphene and pentazocine. If respiratory depression is present, the initial dose should be 2 mg IV in any patient. Repeat doses may be given every 2 minutes until 10 mg have been administered for adolescent patients with suspected opioid overdose who fail to respond to the lower dosages. Of course, concomitant airway management is vital. In patients without respiratory depression, an initial dose of 1.0 mg can be used. In adolescents suspected of chronic opiate abuse, smaller initial doses (e.g., 0.2–0.4 mg) are warranted. Again, if there is no response but a strong clinical suspicion, 2-mg doses can be repeated up to a total of 10 mg before concluding that further dosing will be of no benefit. Naloxone can also be given intramuscularly, sublingually, or by endotracheal tube if no IV access is available.

If a lightening response occurs, naloxone will have to be repeated at the effective total dose every 20 to 60 minutes. An alternative approach is to provide a continuous IV infusion; generally about two-thirds of the total reversal dose will need to be infused per hour initially, with subsequent adjustments as necessary.

Nalmefene and naltrexone are longer-acting opioid antagonists that may have use in some clinical situations in which a longer duration of action (4 to 6 hours for nalmefene, 24 hours for naltrexone) is deemed beneficial, such as in reversal of postoperative opioid depression or as aids in opioid detoxification programs. However, as antidotes for acute opioid overdose in the adolescent or pediatric population, their longer duration may be problematic in assessing the actual time course for resolution of clinical toxicity and/or in precipitating prolonged withdrawal symptoms in habituated patients. Nalmefene may be a useful substitute for prolonged naloxone infusions in cases for which such opioid antagonism is necessary, but little pediatric experience and few dosing guidelines for its use are currently available.

Enhancing Excretion

The procedures available for enhancing the elimination of an absorbed poison that have the greatest value are multiple-dose activated charcoal, ionized diuresis, dialysis, and hemoperfusion. Because some risk is involved, these measures are indicated only in those cases in which the patient's recovery would be otherwise unlikely or in which a specific significant benefit is expected.

Diuresis

Diuresis has historically been advocated in cases of poisoning with agents that are excreted primarily by the renal route. Although it is important to maintain high glomerular filtration rates in the presence of rhabdomyolysis or when chelating with agents such as ethylenediaminetetraacetic acid (EDTA), forced diuresis has limited value in the treatment of acute poisoning. Similarly, diuretic use has fallen out of favor with the possible exception of mannitol therapy for ciguatera poisoning.

Ionized diuresis takes advantage of the principle that excretion is favored when a drug is in its ionized state. Urinary alkalinization promotes excretion of salicylate (a weak acid) and may also enhance clearance of phenobarbital, chlorpropamide, and chlorophenoxy herbicides. Urine alkalinization can be initiated with sodium bicarbonate at a dose of 1 to 2 mEq/kg by IV over a 1- to 2-hour period. Careful attention should be given to total fluid and sodium load administered, especially in patients at risk for congestive heart failure or pulmonary edema. Hypokalemia can interfere with the ability to alkalinize the urine and should be corrected. The rate of bicarbonate infusion can be adjusted to maintain a urinary pH of 7.5 to 8.5. Urinary acidification is almost never indicated because it may lead to serious side effects such as systemic acidosis and exacerbation of renal impairment in the context of myoglobinuria.

Dialysis

Dialysis is indicated for selected cases of severe poisoning or when renal failure is present. Indications for dialysis depend on patient-related and drug-related criteria. Patient-related criteria include 1) anticipated prolonged coma with the high likelihood of attendant complications, 2) development of renal failure or impairment of normal excretory pathways, and 3) progressive clinical deterioration despite careful medical supervision. Drug-related criteria are 1) satisfactory membrane permeability, 2) a correlation between plasma drug concentration and drug toxicity of the agent, 3) plasma levels in the potentially fatal range or the presence of a significant quantity of an agent that is normally metabolized to a toxic substance, and 4) significant enhancement of clearance. Hemodialysis is the most effective means of dialysis. Because it requires highly technical skills, as well as a physician and a technician, it is not always available,

but is an essential consultative service for units that manage severe poisoning cases.

Hemoperfusion

Hemoperfusion, the process of passing blood through an extracorporeal circuit and a cartridge containing an adsorbent after which the detoxified blood is returned to the patient, is also effective in drug removal. Although there are some reservations regarding the extent to which hemoperfusion can be used, it appears to be at least as effective as and possibly more effective than hemodialysis for a number of agents. Indications for use are similar to those for hemodialysis. Table 88.10 summarizes the generally accepted common drugs and drug concentrations for which hemodialysis and hemoperfusion should be considered, in light of the previous discussion regarding clinical criteria.

Hemodialysis	Hemperfusion
Lithium, 4.0 mEq/L	Phenobarbital, 100 mg/L
Ethylene glycol, 50 mg/dL	Theophylline, 6–10 mg/dL (60–100 mg/L)
Methanol, 50 mg/dL	Paraquat, 0.1 mg/dL
Salicylates, 100 mg/dL	Glutethimide, 4 mg/dL
	Methaqualone, 4 mg/dL
	Ethchlorvynol, 15 mg/dL
	Meprobamate, 10 mg/dL

Table 88.10. Drugs and Their Plasma Concentrations for Which Hemodialysis or Hemoperfusion Should Be Considered

Multiple-Dose Activated Charcoal (Gastrointestinal Dialysis)

Several studies have shown significant increase in clearance for a number of drugs when repeated doses of 0.5 to 1.0 g/kg of activated charcoal are given every 4 to 6 hours. By using a nearly continuous stream of fresh charcoal that descends through the intestinal tract, a constant concentration gradient is maintained that favors the back diffusion of free drug from periluminal capillary blood into the intestinal lumen, where it may be bound immediately to the newer charcoal, so that the free drug concentration in the intestinal lumen remains low. In addition, enterohepatic recirculation of some drugs may be interrupted as reabsorption from bile is prevented. To be safe and effective, this technique requires active peristalsis and an intact gag reflex or a protected airway. Common pediatric poisonings for which repetitive charcoal dosing may be indicated include phenobarbital, carbamazepine, phenytoin, digoxin, salicylates, and theophylline. Cathartics, such as sorbitol, should be administered no more frequently than every third dose.

Supportive Care

The final step in optimizing treatment for the poisoned child is the direction of scrupulous attention to supportive care, including continued close monitoring of ABCDs, fluid and electrolyte status, urine output, and level of consciousness. The value of these efforts usually far outweighs that which may be ascribed to any specific toxicologic interventions in most cases. Severely symptomatic patients are most properly cared for in specialized facilities that have skilled pediatric critical care staff and access to toxicology consultation.

NONTOXIC INGESTION

Often, the emergency physician will be asked about a childhood ingestion of some common household products, many of which are nontoxic, unless taken in huge amounts. The availability of a list of such nontoxic products often leads to immediate relief of parental anxiety and avoids the institution of unnecessary noxious interventions. Before using such a list, however, several precautions need to be borne in mind. The fact that an ingestion is nontoxic does not necessarily mean that it has no medical significance. Ingestions often occur in the context of a suboptimal environment. There may be poor supervision or unusual family stresses surrounding the accident, or the ingestion may not have been accidental. Several criteria have been suggested by Mofenson and Greensher to qualify an ingestion as “nontoxic.” These include the assurance that only one identifiable product is ingested in a well-approximated amount, that the product label includes no cautionary signal word, that the child is symptom-free and less than 5 years old, and that an appropriate mechanism is available for telephone follow-up. When used with these criteria, Table 88.11 provides an updated list of nontoxic ingestions. In certain cases, consultation with a regional poison control center is often helpful.

Table 88.11. Products That Are Nontoxic When Ingested In Small Amounts

PEDIATRIC OVERDOSES

The following section highlights selected agents that are ingested by children. They have been chosen because of their common occurrence, because they represent the potential for serious or life-threatening toxicity, and because timely recognition and appropriate treatment may be lifesaving.

Acetaminophen

Background

Acetaminophen, *N*-acetyl-*p*-aminophenol (APAP), is the most popular pediatric analgesic-antipyretic and has now become one of the most common pharmaceutical preparations ingested by young children. It is also one of the 10 most common drugs used by adolescents and adults in intentional self-poisoning. Acetaminophen also occasionally turns up as an unreported coingestant in intentional overdoses. Fortunately, accidental ingestion in young children has been associated with little morbidity, although occasional cases of hepatotoxicity occur, particularly in the context of inadvertent repetitive overdosing.

Pathophysiology

The major toxicity of APAP is severe hepatic damage. Acetaminophen is metabolized in three ways by the liver: 1) glucuronidation, 2) sulfation, and 3) metabolism through the cytochrome P-450 pathway to form a potentially toxic intermediate, which conjugates with glutathione. In a massive overdose, glutathione becomes depleted, thus allowing the undetoxified intermediate to bind to hepatocytes, leading to cellular necrosis. This damage is reflected by rising liver enzymes, hepatic dysfunction, and in severe poisonings, hepatic failure and death. The use of *N*-acetylcysteine as an antidote relates in part to this molecule's ability to act as a glutathione precursor.

Clinical Findings

Initially, the signs and symptoms of APAP ingestion are vague and nonspecific but include nausea and vomiting, anorexia, pallor, and diaphoresis. These manifestations usually resolve within 12 to 24 hours, and the patient appears well for 1 to 4 days. During this latent period, liver enzymes may rise, and jaundice with liver tenderness may ensue. Most patients have a gradual resolution of their hepatic dysfunction, although without antidotal treatment, about 2 to 4% of intoxications that develop toxic plasma levels will go on to hepatic failure and death. Such patients with severe toxicity develop further clinical evidence of hepatic disease at 3 to 5 days after ingestion and some develop renal damage. Anorexia, malaise, and abdominal pain may progress to signs of liver failure with hepatic coma.

The potential severity of an acute intoxication may be predicted by the amount ingested, if accurately known, and the plasma level of APAP. APAP in single doses of less than 150 mg/kg in children is likely to be harmless. Severe toxicity in adolescents or adults usually occurs with overdoses of 10 to 15 g. Initial GI symptoms, although vague, are generally more pronounced when the overdose is large. However, the only reliable indication of the potential severity of the hepatic damage is the plasma APAP level, taken at least 4 hours after ingestion. A nomogram (Fig. 88.2) is available for using this value in the prediction of likely toxicity. We recommend use of the lower line of the nomogram, plotted 25% below the possible toxicity line, to err on the safe side in making therapeutic decisions.

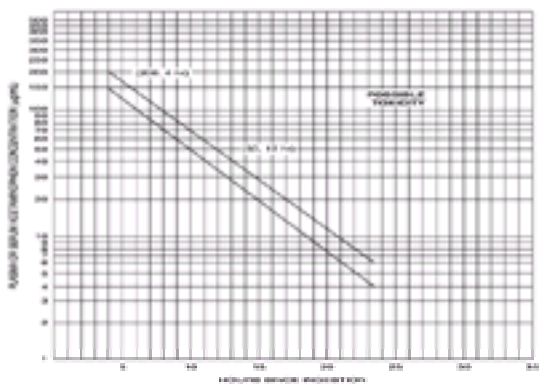

FIGURE 88.2. Nomogram for estimating severity of acute acetaminophen poisoning. (Modified with permission from Rumack BH, Matthew H. Pediatrics 1975;55:871–876. Copyright, American Academy of Pediatrics, 1975.)

Management

The basic toxicologic principles of preventing absorption apply to APAP overdoses, with a few points deserving special emphasis. Immediate-release acetaminophen is rapidly absorbed, and it would generally be unlikely to expect significant return from a gastric emptying procedure done much after 1 hour after ingestion. An extended-release preparation of acetaminophen has recently been marketed, and this preparation may be more amenable to gastric emptying.

Furthermore, many patients will require the use of the oral antidote, *N*-acetylcysteine (NAC), and patients given ipecac often have prolonged vomiting when attempting to drink the unpleasant tasting NAC. Although some have speculated that activated charcoal would decrease the bioavailability of the NAC and thus should be avoided, recent studies have demonstrated clinically insignificant decreases in NAC absorption, even when using large doses of charcoal. In general, acetaminophen ingestions presenting within less than 1 hour may rarely benefit from gastric emptying, particularly for massive overdoses or in the context of mixed ingestions when the coingestant is particularly toxic. However, for most cases of acetaminophen overdose per se, and particularly for those typically seen 2 to 4 hours after ingestion, charcoal alone is probably effective and should not significantly alter the ability to use NAC several hours later. In cases that present after 4 hours have elapsed, gastric decontamination is usually not warranted.

NAC, given orally, essentially prevents the occurrence of hepatotoxicity when instituted within 8 hours of ingestion. It also lessens the severity of hepatic damage if used within 16 hours. This antidote can be mixed with fruit juice or soda to disguise its foul smell, or it can be administered by lavage tube. Only mild GI side effects result from its use. Persistent vomiting is an occasional obstacle to completing the 72-hour course of therapy. This may be obviated by giving the dose slowly or by NG or duodenal tube infusion. Antiemetic therapy with metoclopramide or ondansetron may also be helpful. An IV preparation is currently undergoing clinical trials in the United States and has been used in Canada and Europe for some time with good effects, with the advantage of utility in the face of protracted vomiting or other GI complications from coingestants or coincident medical problems; however, its use has been associated with occasional anaphylactoid reactions.

The protocol for NAC therapy may be summarized as follows:

1. Consider GI decontamination options as already noted.
2. If patient presents less than 4 hours after ingestion, wait to draw 4-hour level and base therapeutic decision on nomogram (assumes rapid turnaround time so that level will be available by 8 hours after ingestion); if necessary, initiate treatment as described next. For extended-release preparations, McNeil Consumer Products Co., a manufacturer of acetaminophen, suggests a second APAP level drawn 4 hours after the first; antidotal therapy is to be instituted if either level suggests possible toxicity.
3. If patient presents more than 6 to 8 hours after ingestion, give a loading dose of NAC, 140 mg/kg orally (regardless of time since ingestion, consider increasing dose by 40%, or repeating the loading dose, if charcoal had been given within the preceding 1 to 2 hours). Obtain level and base subsequent course of therapy on nomogram.
4. If level plots out above the lower line on the nomogram, admit the patient to hospital and continue NAC at 70 mg/kg orally every 4 hours for a total of 17 doses. Monitor complete blood count (CBC), renal, and liver function tests.
5. Treatment for patients who present more than 24 hours after ingestion is controversial, as is treatment for patients with subacute, repetitive overdosing over several days. We generally advise treatment for children who receive more than 150 mg/kg per day for 1 to 2 days or more and/or patients with levels above 10 µg/mL who present more than 24 hours after ingestion.
6. In rare cases, oral administration of NAC may be impossible. Protocols exist for the IV administration of the oral NAC preparation. A regional poison control center may be able to assist in this situation.

Alcohols and Glycols

The alcohols and glycols are some of the most commonly found organic compounds in the environment. Ethanol is a commonly encountered solvent and is used as a topical antiseptic, chemical intermediate, beverage, and in some instances, a rubbing alcohol. It is also an ingredient in most perfumes, colognes, and toilet waters. Methanol, or methyl alcohol, functions as an antifreeze (in windshield washers/de-icers and gasoline antifreeze) and as a solvent in many industrial and home products. Isopropyl alcohol serves as a rubefacient. Ethylene glycol is used primarily as a de-icer or antifreeze. A related class of compounds, the glycol ethers, are widely used in rug shampoos and other cleaning compounds. The toxicity of these agents is thought to be comparable to (if not more severe than) ethylene glycol.

Ethanol

The most commonly ingested alcohol is ethanol. After ingesting ethanol, children may develop nausea, vomiting, stupor, and ataxia. Coma and death from apnea may occur if significant quantities are consumed. In adolescents, blood concentrations of less than 50 mg/dL rarely result in sensory or motor impairment. Values of 100 to 150 mg/dL are consistent with intoxication and cause mild neurologic findings. Lethal blood alcohol concentrations are generally greater than 500 mg/dL. Infants and toddlers who ingest ethanol have a clinical course that is significantly different from that in adolescents and adults; a triad of coma, hypothermia, and hypoglycemia appears once ethanol levels exceed 50 to 100 mg/dL. This triad may be accompanied by metabolic acidosis.

The blood ethanol level may be estimated by calculating the osmolol gap (measured serum osmolality - [2 × Serum Na + BUN/2.8 + Serum glucose/18]). An osmolal gap of 22 to 25 mOsm/kg H_2O exists for every 100 mg/dL of ethanol in the serum.

The amount of an ethanol-containing liquid that is of concern when ingested by a child depends on the alcohol concentration. However, a rough rule is that ingestion of 1 g/kg of ethanol is sufficient to raise blood alcohol to 100 mg/dL. Therefore, for a beverage such as beer (5% alcohol), approximately 10 to 15 mL/kg must be ingested before serious toxicity results. Similar estimates are 4 to 6 mL/kg for wine (14% alcohol) and 1 to 2 mL/kg for an 80-proof liquor (40% alcohol).

The management of ethanol ingestion in children begins with prompt recognition and evaluation of blood glucose. Airway or ventilatory compromise should be treated with endotracheal intubation. If seizures result from hypoglycemia, they should be promptly treated with 10 to 50% (0.25 to 1.0 g/kg) IV glucose and anticonvulsants if necessary. Warming techniques should be instituted to increase core temperature. Because ethanol is rapidly absorbed from the gut and is not adsorbed by activated charcoal, there is rarely a role for GI decontamination if the patient presents more than 1 to 2

hours after ingestion. However, if presentation is earlier, gastric lavage should be performed. Because of the high risk of drug coingestion, activated charcoal should be administered to adolescents.

Alcohol is metabolized by the hepatic enzyme alcohol dehydrogenase; its elimination rate is dose dependent. This means that the higher the blood alcohol concentrations, the longer the elimination process because the capacity of the body to produce alcohol dehydrogenase is limited. The rate of reduction in blood alcohol concentration varies from 10 to 25 mg/dL per hour. Although hemodialysis effectively enhances elimination (threefold to fourfold), it is rarely necessary. The institution of hemodialysis may be useful in those patients who have impaired liver function or a blood alcohol concentration greater than 450 to 500 mg/dL.

Isopropyl Alcohol

Poisoning with isopropyl alcohol may be particularly insidious because oral ingestion is not the only route of exposure. Children may develop severe intoxication, including coma, after topical application of isopropyl alcohol for the relief of fever (although such exposure may represent inhalational exposure rather than direct, dermal absorption). Because isopropyl alcohol is usually available in a 70% concentration by volume, ingestion of 2 to 2.5 mL/kg of this solution may lead to symptoms. Ingestion of this compound causes many of the same features as ethanol ingestion, with the additional complication of severe gastritis. Unlike the other toxic alcohols, isopropyl does not lead to metabolic acidosis. This is because its metabolite, acetone, is not an acid. However, it is approximately twice as intoxicating as ethanol, leading to greater mental status impairment at comparable serum levels. The life-threatening toxicity of isopropyl alcohol is cardiac; at high serum concentrations, direct myocardial depression occurs, leading to hypotension and shock.

In any patient with coma and an unexplained osmolar gap (the difference between calculated and observed osmolarity), isopropyl alcohol should be strongly considered. The presence of ketonuria in conjunction with the absence of metabolic acidosis effectively makes the diagnosis of isopropyl intoxication.

Isopropyl alcohol is easily removed by hemodialysis. However, hemodialysis is rarely necessary because life-threatening toxicity does not occur until serum levels exceed 400 to 500 mg/dL. Therefore, the sole indication for hemodialysis is considered hemodynamic instability, regardless of serum concentration. Treatment is otherwise supportive.

Methanol

Although methanol is used primarily as a solvent for industrial purposes, it is found in other household products, including fuels for stoves, jelled fuels for heating small dishes (e.g., Sterno), paint removers, and antifreezes.

Methanol is a model for the few drugs that, rather than being detoxified, become more toxic as they are metabolized. Thus, although methanol has little or no inherent toxicity, its metabolism by alcohol dehydrogenase to form formaldehyde and formic acid creates highly toxic compounds. Formic acid is a potent organic acid that results in severe metabolic acidosis and ocular symptoms. Fortunately, because methanol is metabolized slowly, toxicity appears after some delay, permitting time for intervention. Ingestions approaching 100 mg/kg should be considered dangerous.

The clinical effects of a methanol ingestion usually occur after a latent period of 8 to 24 hours. This delay occurs as the result of the metabolic conversion of methanol to its toxic byproducts. In large ingestions, acute methanol poisoning may cause severe CNS depression, metabolic acidosis, and a number of reversible or irreversible optic changes. In the early stages of intoxication, funduscopic examination may be remarkable for hyperemia. However, left untreated, methanol intoxication results in blindness with the appearance of a pale, avascular retina. In subacute ingestions, the nonspecific neurologic symptoms of methanol intoxication resemble those of ethanol with a “hangover,” malaise, headache, and dizziness. During recovery from a mild ingestion, occasional paresthesias of the extremities may develop.

The most significant clinical concern from a methanol ingestion is severe metabolic acidosis. This acidosis is primarily the result of formic acid production. The metabolic acidosis may be intractable and results in multiorgan dysfunction, which includes cardiac arrhythmias, seizures, and pancreatitis. The ophthalmologic abnormalities that develop during methanol intoxication may be temporary or permanent. These include blurred or double vision, changes in color perception, and sharply reduced visual acuity. Permanent abnormalities may include diminished pupillary light reaction or frank blindness. The occurrence of permanent visual defects correlates directly with the degree of metabolic acidosis, the duration of the acidosis, and the quantity of methanol ingested.

Management

The treatment of methanol ingestion consists of supportive care, administration of specific therapies, and enhancement of elimination. As with other alcohol ingestions, emesis or gastric lavage should be performed only if the ingestion occurs within 2 hours of ED presentation. Activated charcoal does not adsorb methanol effectively and is unnecessary.

Laboratory assessment includes serial arterial blood gases, electrolytes, BUN, creatinine, glucose, toxin screen, serum osmolality, and methanol level. Serum methanol concentration in milligrams per deciliter can be estimated by the formula (osmolal gap × 3).

There are three specific treatments for methanol intoxication: sodium bicarbonate, folic acid, and ethanol (or 4-methylpyrazole—see the following). Sodium bicarbonate should be administered aggressively to correct metabolic acidosis. Folate is provided because of its role in formic acid disposition within the tetrahydrofolate cycle. Customary doses are 1 mg/kg IV every 6 hours.

Because serum methanol levels of 20 mg/dL or greater are associated with toxicity if untreated, higher levels require treatment to prevent its metabolism and/or interventions to enhance its elimination. Ethanol, which has a higher affinity for alcohol dehydrogenase than methanol, is provided to “block” further production of toxic metabolites. 4-Methylpyrazole,

another alcohol dehydrogenase antagonist, shows promise as an antidote for methanol intoxication. Currently in the United States, it has received indication for use only in adult ethylene glycol poisoning (see next section). Its use in childhood methanol poisoning is still experimental at this time.

Ethanol should be instituted if the calculated or measured methanol concentration is 20 mg/dL or greater. It is administered with the goal of maintaining serum ethanol concentrations at 100 mg/dL or greater. Ethanol may be given by continuous IV infusion (600 mg/kg bolus followed by a 110 mg/kg per hour) or by oral administration. IV ethanol is preferred but has the problems of being often unavailable, hyperosmolar (preventing its administration in small veins), and requiring large fluid volumes. Therefore, the oral route must often be used in children. Given orally, any beverage that contains ethanol may be used. It must be remembered that proof designation of a beverage is twice the alcohol concentration expressed as a percentage (e.g., 80 proof equals 40% alcohol). Children must be closely monitored for the complications of ethanol administration, including mental status depression, hypoglycemia, and hypothermia.

Patients who have a blood methanol concentration of 50 mg/dL or greater require hemodialysis in addition to ethanol administration. During hemodialysis, the infusion rate of the ethanol must be doubled because hemodialysis will also remove ethanol.

Ethylene Glycol

The ingestion of ethylene glycol, although uncommon, causes significant morbidity and occasional mortality in adolescents and young adults. The toxicity of ethylene glycol, like that of methanol, is the result of drug toxification; ethylene glycol has virtually no toxicity in its parent state. However, metabolism by alcohol dehydrogenase produces several toxic intermediates, including glycolaldehyde, glycolic acid, and oxalate. These metabolites result in severe metabolic acidosis and deposition of calcium oxalate crystals in all vital organs. Therefore, ethylene glycol intoxication is associated with more systemic toxicity than methanol poisoning. Also, because ethylene glycol is metabolized more rapidly than methanol (elimination half-life approximately 3 hours), toxicity appears rapidly after ingestion.

The clinical syndrome of ethylene glycol intoxication appears in three different stages. The first stage consists predominantly of CNS manifestations and is accompanied by a profound metabolic acidosis. In this early stage, mild hypertension, tachycardia, and a leukocytosis are often present. Nausea and vomiting commonly occur, and with larger doses, coma and convulsions may appear within a few hours. Another common finding is the presence of hypocalcemia. This is believed to result from the widespread formation of calcium oxalate. Hypocalcemia may be severe enough to cause tetany and cardiac conduction disturbances. Urinalysis usually reveals a low specific gravity, proteinuria, microscopic hematuria, and crystalluria. The second distinct state is ushered in by coma and cardiopulmonary failure; it is usually the result of acidosis and hypocalcemia. The third stage usually occurs after 24 to 72 hours. Here, renal failure emerges as the dominant problem. Usually, a picture of acute tubular necrosis develops with either polyuria or anuria. Urine sediment contains blood, protein, and casts. Victims often require dialysis for extended periods and may be left with permanent renal insufficiency.

Consideration of ethylene glycol poisoning should be based either on the history or, in the absence of diabetic ketoacidosis, the presence of any of the following criteria: 1) alcohol-like intoxication without the odor of alcohol, 2) large anion-gap metabolic acidosis, 3) an elevated osmolar gap in the absence of ethanol or methanol ingestion, or 4) a urinalysis that demonstrates oxalate crystals. Another diagnostic tool is to perform a Woods' lamp examination of urine. If the ingested substance is radiator antifreeze, the fluorescein dye that it contains will be excreted in urine and fluoresce under Woods' lamp. Arterial blood gases should be obtained frequently because of the rapid evolution of metabolic acidosis. The availability of ethylene glycol levels varies by institution.

Gastric emptying is the only decontamination measure that is effective after ethylene glycol ingestion and should be performed if the patient arrives within 1 hour of ingestion. Activated charcoal negligibly adsorbs ethylene glycol and is unnecessary.

As with methanol intoxication, treatment of ethylene glycol poisoning falls into three areas: supportive care, administration of pharmacologic agents, and enhancement of elimination. Supportive care includes close monitoring of vital signs and anticipation of life-threatening events, particularly cardiac arrhythmias secondary to hypocalcemia. An ECG should be obtained, and the patient should be placed on a cardiac monitor. Intubation and mechanical ventilation should be provided as needed for control of acid-base balance.

Pharmacologic therapy is subdivided into four areas: administration of sodium bicarbonate, calcium, pyridoxine with thiamine, and ethanol or 4-methylpyrazole. Correction of acidosis should begin immediately with the administration of sodium bicarbonate and appropriate ventilation. Hypocalcemia may present as skeletal muscle disturbances (tetany) or cardiac dysfunction (prolonged Q-T interval). These may be alleviated by the prompt institution of calcium (e.g., 10% calcium gluconate, 0.3–0.6 ml/kg). Thiamine and pyridoxine are vitamins that act as cofactors in the nontoxic metabolic pathways of ethylene glycol and, theoretically, divert its metabolism toward formation of nontoxic metabolites. Therefore, thiamine (0.25 to 0.5 mg/kg) and pyridoxine (1 to 2 mg/kg) are recommended for the first 24 hours of treatment.

Ethanol administration is one option to inhibit ethylene glycol metabolism by alcohol dehydrogenase (previously discussed under Methanol). It should be initiated as soon as possible to interrupt further formation of organic acids. As with methanol, ethanol is indicated for ethylene glycol concentrations of 20 mg/dL or greater. If a serum ethylene glycol cannot be obtained in a timely fashion, it can be estimated by the formula (osmolar gap × 6), assuming that no other alcohols are contributing to the osmolar gap. For serum ethylene glycol concentrations of 50 mg/dL or greater, both ethanol and hemodialysis are recommended. Hemodialysis is also indicated if there is renal failure or severe electrolyte disturbances, regardless of the serum ethylene glycol concentration.

4-Methylpyrazole is a competitive inhibitor of alcohol dehydrogenase recently approved for the treatment of ethylene glycol poisoning in adults. Currently, use of ethanol is recommended in children; but if available, 4-methylpyrazole could

be considered therapeutically for adolescent patients. 4-Methylpyrazole is an oral or IV agent with quick onset of action, and unlike ethanol, its use is not associated with CNS depression. The loading dose is 15 mg/kg IV. The maintenance dose is 10 mg/kg every 12 hours for four doses, then 15 mg/kg every 12 hours thereafter. During hemodialysis, additional doses may be required.

Antihistamines

Antihistamines are used to treat children with allergic diseases, as sedatives and antinauseants, and to prevent motion sickness. They are present in many cough syrups, available both OTC and by prescription. Antihistamines may also be found in combination with analgesics, sympathomimetic amines, and caffeine for the symptomatic relief of the common cold. They are combined with analgesics, such as salicylamide, and an anticholinergic drug, such as scopolamine, for use as a nonprescription sleep medication. Finally, they are included in some liquid cough and cold preparations that also may contain ethanol as the solvent.

Antihistamines may depress or stimulate the CNS. Used therapeutically, CNS depression is most commonly seen as drowsiness or dizziness. With increasing doses, stimulation results in insomnia, nervousness, and restlessness. In antihistamine overdose, the CNS stimulatory effects of the drug predominate. In children, CNS stimulation causes excitement, tremors, hyperactivity, hallucinations, and with higher dosages, tonic-clonic convulsions. Children are also more likely to have signs and symptoms of anticholinergic poisoning: flushed skin, fever, tachycardia, and fixed dilated pupils. The nonsedating antihistamines terfenadine (no longer available in the United States) and astemizole have caused cardiac arrhythmia after overdose and as a result of drug–drug interactions. Cetirizine, loratadine, and fexophenadine have not produced this complication. Death from antihistamine ingestion in children usually is the result of uncontrolled seizures that progress to coma and cardiorespiratory arrest.

The treatment of antihistamine poisoning requires an accurate history of the time of ingestion and the type and quantity of drug consumed. Of particular importance is the type of drug ingested because numerous sustained-release antihistamine products are on the market. Options for GI decontamination include gastric emptying and the use of activated charcoal, as described in general previously. Overdoses with the sustained-release preparations may benefit from WBI.

Patients with seizures (see Chapter 70 and Chapter 83) require anticonvulsant therapy immediately. Preferably, short-term control may be gained using diazepam, in a dose of 0.1 to 0.2 mg/kg IV. Severely agitated patients with a clear anticholinergic toxidrome may have improved sensorium after administration of physostigmine. This is usually administered in an initial dose of 0.5 mg IV slowly over 3 minutes. The 0.5-mg dose may be repeated every 10 to 15 minutes (maximum 2 mg) to establish the effective total dose. This minimal effective dose may be repeated in several hours if necessary. It should be noted that when administered too rapidly or in too large a dose, physostigmine may precipitate seizures or asystole. Physostigmine would be particularly dangerous to use in the context of any coingestants that might affect intracardiac conduction, such as tricyclic antidepressants. A 12-lead ECG should be examined for conduction delays before physostigmine is given. Cardiac rhythm should be monitored closely during antidote infusion, and atropine should be available to reverse severe cholinergic effects that may also occur with physostigmine use. The potential risks encountered with physostigmine may favor use of a benzodiazepine for treatment of anticholinergic delirium.

Meticulous attention to supportive care is critical. Some patients may develop extreme hyperthermia and thus require aggressive measures to reduce core body temperature, including ice water baths and fans. There is little evidence for therapeutic efficacy of dialysis or hemoperfusion because of the high-plasma protein binding and large volumes of distribution for most of these agents.

Aspirin

Background

Aspirin continues to be a common cause of poisoning in children and adolescents. Salicylism is the result of acute ingestion in about 60% of cases and chronic ingestion in the remaining 40%. Clinical features of acute versus chronic salicylate intoxication often require a different management approach, depending on the manner of intoxication.

Several factors work in concert to make chronic salicylate intoxication so common. The primary factor is aspirin's elimination pattern. As serum salicylate concentrations increase, the ability of the liver to metabolize the drug diminishes until predictable, first-order elimination kinetics are replaced by unpredictable, dose-dependent, zero-order elimination. Thereafter, increments in dose are associated with disproportionate increases in serum salicylate concentration. Also, much of aspirin elimination is through urinary excretion of unchanged drug. Therefore, in the face of dehydration and decreased glomerular filtration, drug clearance is impaired even more. Finally, because aspirin is often prescribed for illnesses that may be associated with hepatic dysfunction, reduced biotransformation initiates the spiraling increase in serum concentration. Unfortunately, because chronic salicylism is associated with nonspecific symptoms (e.g., fever, vomiting, tachypnea), diagnosis may be delayed until more striking signs of intoxication appear.

Pathophysiology

The direct effects of aspirin on metabolism are multiple. Aspirin stimulates the medullary respiratory center, which leads to tachypnea and respiratory alkalosis—its hallmark. Metabolic disturbances are widespread and include hyperglycemia (or, with chronic salicylism, hypoglycemia), as well as abnormalities in lipid and amino acid metabolism. Inhibition of Krebs cycle enzymes and uncoupling of oxidative phosphorylation in conjunction with lipid disturbances create the combined lactic and ketoacidosis responsible for metabolic acidosis (which leads to the mixed respiratory alkalosis and metabolic acidosis found on the arterial blood gas). In addition to inhibiting platelet function, aspirin intoxication is associated with disturbances in vitamin K–dependent and vitamin K–independent clotting factors, resulting in a

significant coagulopathy. Mild elevations in liver enzymes are also common. Other features of aspirin intoxication include leukocytosis and electrolyte disturbances, particularly hypokalemia. Physical manifestations include fever, tachypnea, nausea, vomiting, lethargy, slurred speech, and seizures. Children with chronic salicylism are more likely to present with severe metabolic acidosis and seizures than those with acute intoxication.

The combination of respiratory alkalosis with metabolic acidosis produces an arterial blood gas that is almost pathognomonic for salicylism. Serum pH typically ranges from 7.41 to 7.55, except in severe cases in which metabolic acidosis combined with respiratory acidosis from severe CNS depression leads to pH less than 7.35, and P_{CO_2} is generally less than 30 mm Hg. Serum bicarbonate is mildly depressed, often ranging from 15 to 20 mEq/L. However, although adults may continue to hyperventilate for extended periods when poisoned with salicylates, children with mild to moderate poisoning quickly lose this respiratory drive and are more likely to present with metabolic and respiratory acidosis.

As mentioned, glucose homeostasis is seriously altered in acute aspirin poisoning. Early in the course, hyperglycemia usually occurs because of glycogenolysis and decreased peripheral use. Later, hypoglycemia may supervene as glucose stores are depleted.

Fluid and electrolyte disturbances are multifactorial, resulting in dehydration, hyponatremia or hypernatremia, and hypokalemia. Among contributing factors are increased insensible water losses through both skin and lungs, emesis, and increased renal water and potassium loss. The patient with severe salicylate poisoning may lose 4 to 6 L of water/m^2.

Clinical Findings

The initial clinical signs and symptoms, the estimate of dose ingested, and the measurement of salicylate levels all serve to gauge the severity of a given acute aspirin poisoning. However, in cases of chronic therapeutic salicylism, the clinical picture is the most useful guideline. Because of the nonspecific nature of symptoms with salicylism, the initial differential diagnosis is broad and may include diabetic ketoacidosis, iron intoxication, and ethylene glycol ingestion.

Signs and symptoms of salicylism depend on the method and severity of intoxication. Acute ingestion amounts of 150 to 300 mg/kg are associated with mild symptoms, 300 to 500 mg/kg are associated with moderate toxicity, and more than 500 mg/kg are associated with death. With mild toxicity (serum concentrations 30 to 50 mg/dL), manifestations may be confined to GI upset, tinnitus, and mild tachypnea. With moderate salicylate poisoning (serum level 50 to 100 mg/dL), more visible signs of toxicity—fever, diaphoresis, and agitation—appear. After severe salicylate poisoning (serum concentrations greater than 100 mg/dL), signs and symptoms are primarily neurologic and consist of dysarthria, coma, and seizures. Pulmonary manifestations, particularly pulmonary edema, may appear in severe cases. In victims of chronic salicylism, these same conditions appear at significantly lower serum salicylate concentrations. Death from salicylism results from severe CNS toxicity with complete loss of function in cardiorespiratory centers, leading to respiratory and/or cardiac arrest. A nomogram that strives to correlate clinical toxicity with serum salicylate levels and the time of ingestion exists. This nomogram has many shortcomings that diminish its clinical utility. Severity of salicylate intoxication is best assessed by physical examination, electrolytes, and blood gas analysis.

Management

Assessment of the victim of salicylate intoxication begins with an accurate history that identifies the patient as having acute or chronic poisoning. Laboratory assessment is extensive and includes serum salicylate concentration, electrolytes, arterial blood gas, liver function tests, CBCs, prothrombin and partial thromboplastin times, urinalysis, and an ECG. In the case of intentional ingestions by adolescents, a complete toxin screen should be obtained with particular attention to a serum acetaminophen measurement (because many OTC analgesics contain aspirin and acetaminophen in combination).

Supportive care includes assessment of ventilatory function, cardiac monitoring, and vascular access. Because aspirin overdose is associated with delayed gastric emptying and drug coalescence to form bezoars, GI decontamination should receive careful consideration in those patients who present within 4 to 6 hours of ingestion. In patients who present more than 6 hours after ingestion or in those with chronic salicylism, activated charcoal should still be administered because it may enhance postabsorptive elimination of salicylates (through GI dialysis).

Specific therapeutic goals in salicylate intoxication include correction of fluid and electrolyte disturbances and the enhancement of salicylate excretion.

Fluid therapy should be aimed at restoring hydration and electrolyte balance and at promoting renal salicylate excretion. If dehydration is significant, the fluid infusion rate should be 10 to 15 mL/kg per hour to initiate fluid resuscitation. However, fluids should be given prudently to prevent precipitation of pulmonary edema, particularly in patients with severe intoxication. For patients with symptomatic salicylate intoxication, urine alkalinization should be combined with fluid resuscitation. The administration of sodium bicarbonate, by increasing urinary pH, ionizes filtered aspirin, increasing tubular secretion and inhibiting its tubular reabsorption (ion trapping). The initial fluid is therefore designed to replace both sodium and bicarbonate losses as well as promote urine alkalinization. It should contain 5% dextrose with 50 to 100 mEq/L of sodium bicarbonate. In cases of severe acidosis, additional bicarbonate may be necessary. Because hypokalemia impairs the ability of the urine to create an alkaline urine and is exacerbated by administration of sodium bicarbonate, potassium must be added to IV fluids. Forced diuresis does not appear to enhance salicylate excretion more than the clearance accomplished by alkalinization alone. Therefore, fluids are only given as needed to restore normal hydration and to produce 1 to 2 mL/kg per hour of urine. Calcium homeostasis should also be monitored during therapy with exogenous bicarbonate. Both urine alkalinization and repetitive oral charcoal should be continued until salicylate concentration falls below 30 to 40 mg/dL and symptoms resolve.

Salicylate elimination can be also be enhanced by hemodialysis or hemoperfusion. Although hemoperfusion results in

superior clearance technique, hemodialysis is usually preferred because it permits correction of fluid and electrolyte imbalances. Hemodialysis should be reserved for seriously ill patients. Specific indications include 1) serum salicylate levels greater than 100 mg/dL after acute ingestion, 2) a serum salicylate level of 60 to 70 mg/dL or greater after chronic salicylism, 3) severe acidosis or other electrolyte disturbance, 4) renal failure, 5) persistent neurologic dysfunction, and/or 6) progressive clinical deterioration despite standard treatment.

Cardiac Drugs

b-***Adrenergic Blockers and Calcium Channel Blockers***

The approach to overdoses of these two categories of cardiovascular agents are discussed together because of similarities of clinical presentation and management approach. They are both commonly prescribed to adult patients with a variety of cardiovascular disorders, including angina and status postmyocardial infarction, hypertension, and arrhythmias. As such, experience with pediatric overdoses has been increasing in recent years.

b-Blockers (BBs) vary considerably in terms of receptor specificity and pharmacokinetics, but most overdose experience is with propranolol. Similarly, the three calcium channel blockers (CCBs) most commonly used in the United States (verapamil, nifedipine, and diltiazem) are chemically dissimilar and have varied degrees of effect on vasodilation, myocardial contractility, and sinoatrial (SA)–atrioventricular (AV) node function. Most of the clinical overdose experience is with verapamil.

Both BBs and CCBs may present with fulminant cardiovascular and neurologic findings after a large overdose. Typical presentations of both agents include marked bradycardia and hypotension; particularly with the CCBs, common additional findings are those of abnormal AV node conduction, with AV block or accelerated junctional rhythm. The CNS may also be affected, with coma and/or convulsions that occur in either category of overdoses. Metabolic disturbances include hypoglycemia with BBs and hyperglycemia and metabolic acidosis with CCBs. Bronchospasm may complicate BB toxicity further in patients with underlying reactive airway disease.

Management begins with aggressive gastric decontamination for both types of agents. Gastric lavage may be considered for the child who presents early after overdose. Activated charcoal/cathartic should be administered. Sustained-release preparations may cause prolonged effects, and WBI may be considered in this context. Bradycardia and hypotension may improve with standard treatment such as atropine, fluid boluses, and pressors; however, many cases prove resistant to these measures.

Additional therapy includes calcium infusion for the CCBs, with the recommended adult initial dose being 10 mL of 10% calcium chloride, or 30 mL of 10% calcium gluconate, which may be repeated two or three times as necessary (e.g., an initial pediatric dose of approximately 0.2 mL/kg calcium chloride or 0.6 mL/kg of calcium gluconate). Serum calcium should be monitored if several doses are used to avoid severe hypercalcemia. Glucagon increases intracellular cyclic adenosine monophosphate (cAMP) by a mechanism independent of b receptors or sites of calcium antagonist action and has been used with success to improve heart rate and blood pressure in overdoses of both types of agents. The usual adult dosing regimen is 3 to 5 mg by IV bolus, which may be repeated to a total dose of 10 mg, followed by infusion at 2 to 5 mg/hour. Such dosing translates to 50 to 150 µg/kg boluses and similar amounts per hour for pediatric patients.

Currently the role of euglycemic insulin/glucose administration is being investigated. Another experimental antidote, 4-aminopyridine, has shown promise in Eastern European studies for CCB overdose. Severe cases may also benefit from pacemaker insertion and consideration of aortic balloon pump and/or cardiopulmonary bypass. It is unlikely that hemodialysis or hemoperfusion would benefit most of these cases.

Clonidine

Clonidine is an antihypertensive that appears to have growing popularity, part of which comes from its efficacy in illnesses other than hypertension, including nicotine withdrawal and attention deficit disorder. Also, the advent of clonidine in transdermal patches has become a convenient and somewhat unique vehicle for drug administration.

Clonidine exerts its antihypertensive effect through stimulation of CNS a $_2$-adrenergic receptors. These receptors are located on presynaptic neurons in cardiorespiratory centers of the midbrain. Their stimulation results in decreased secretion of catecholamines into the synaptic cleft, resulting in decreased pulse and blood pressure. In addition, clonidine appears to interact with or modulate CNS opiate receptors; this interaction has been used to explain clonidine's efficacy in opiate withdrawal and the picture of coma and miosis that accompanies clonidine intoxication. An imidazoline compound, clonidine is related to other medications, including tetrahydrozoline and oxymetazoline—common vasoconstrictors found in nasal decongestants and ophthalmic agents.

Clonidine is an extremely potent drug with typical doses of 100 to 200 µg in adults. Therefore, ingestions of small amounts can potentially lead to significant toxicity in children. Initial toxic manifestations include altered mental status that may range from lethargy to coma. Victims also may develop significant hypothermia. In severe intoxications, coma, miosis, and respiratory depression may appear. The cardiovascular changes that accompany clonidine intoxications may range from profound hypotension and bradycardia to hypertension. Clonidine-induced hypertension occurs uncommonly and is thought to result from a-adrenergic effects at peripheral vascular receptors that override the central, antihypertensive effect. The clinical picture of clonidine intoxication typically lasts 8 to 24 hours.

Management

The treatment of clonidine intoxication requires immediate assessment of the ABCs. Because patients with severe intoxication often have coma and respiratory depression, emergency endotracheal intubation may be necessary. Also, because of blood pressure instability, vascular access should be achieved immediately for better hemodynamic control.

Hypotension should be treated with fluids and vasopressors as needed. Hypertension is generally uncommon, very transient, and would rarely require specific treatment.

GI decontamination may be ineffective more than 2 hours after ingestion because clonidine is rapidly absorbed from the GI tract. However, the potential benefits of activated charcoal administration far outweigh any of its risks.

In addition to supportive care measures, other pharmacologic interventions may be effective. Naloxone has been suggested as a specific antidotal agent after clonidine intoxication, based on case reports of improved mental status and cardiorespiratory function after its administration. However, in reported case series, there have not been consistent improvements after naloxone administration.

Because naloxone is a benign agent and may potentially improve mental status to the extent that intubation becomes unnecessary, a trial dose of 1 to 2 mg should be administered. Large amounts of naloxone (up to 8 mg) must be provided before it can be concluded that the intoxication is not responsive to this therapy. If effective, repeat doses or a continuous infusion of naloxone may become necessary. Other pharmacologic agents that have been used include yohimbine, tolazoline, and phentolamine. Specific efficacy from these agents has not been demonstrated, and they are not considered important in the treatment of clonidine intoxication.

Digoxin

Digoxin, although less commonly used, remains an important cardiac inotrope. It is still widely used in young infants with congenital heart disease as well as elderly patients with congestive heart failure. This continued popularity, its narrow therapeutic index, and the appealing color of digoxin elixir make it a source of many childhood poisoning episodes annually. Also, related agents, particularly the foxglove and oleander plants, are occasionally ingested by children, leading to a clinical picture identical to that of digoxin.

Digoxin's primary pharmacologic action is to inhibit activity of sodium-potassium adenosine triphosphatase (ATPase), which is responsible for maintaining the electrical potential of excitable tissues through transmembrane concentration of electrolytes. Therefore, the effects of digoxin are largely related to disturbances in this action.

In all victims of digoxin poisoning, two distinct pictures of toxicity exist: acute and chronic. These pictures have several differences: The victim of acute digoxin ingestion is typically a toddler who ingests a relative's medication. The toddler is generally healthy with no underlying cardiac disease. The child with chronic digoxin poisoning, however, by definition has preexisting heart disease and is likely to be taking other medications known to modulate the effects of digoxin poisoning (e.g., diuretics). Therefore, it is the latter victim who is more likely to have severe toxic manifestations after digoxin intoxication.

Digoxin pharmacokinetics are complex. After ingestion, absorption is complete within 2 to 4 hours. However, after peak serum levels are achieved, the drug is rapidly redistributed, resulting in dramatic falls in serum concentration. This has particular importance with the victim of acute digoxin intoxication who may have an initial serum digoxin concentration in the highly toxic range that falls to the therapeutic range within a matter of hours. After redistribution, digoxin elimination occurs primarily through renal excretion of unchanged drug. Therefore, any condition associated with decreased renal function may be associated with the insidious development of intoxication.

The therapeutic serum digoxin concentration (SDC) is less than 2 ng/mL. A concentration in the slightly higher range often does not correlate with clinical manifestations and may be of limited value. However, when SDC exceeds 4 ng/mL, some evidence of intoxication usually appears. This toxicity is influenced by many host factors, including patient age, underlying illness, and disturbances in serum potassium, magnesium, and calcium.

With significant intoxication, the symptoms of digoxin poisoning include nausea, vomiting, and visual disturbances. With more severe intoxication, additional symptoms, including lethargy, disorientation, electrolyte disturbances, and cardiac disturbances, appear. The hallmark of severe acute digoxin toxicity is hyperkalemia, the result of profound inhibition of sodium-potassium ATPase activity. The typical pattern of cardiac toxicity with digoxin overdose initially is prolonged atrioventricular dissociation that appears as heart block that ranges from first to third degree. These conduction disturbances can lead to the development of ventricular or supraventricular escape rhythms. In patients with chronic digoxin intoxication, these symptoms may be more striking than in those with acute, single digoxin overdoses. In fact, children with acute digoxin intoxication rarely develop life-threatening illness if their peak SDC remains below 10 ng/mL.

Management

The management of the patient with digoxin intoxication begins with evaluation of the vital signs, particularly hemodynamic status. Patients should have an ECG followed by continuous cardiac monitoring. If significant cardiac arrhythmias are already present, they are treated initially according to advanced cardiac life support protocols.

GI decontamination should include administration of activated charcoal with a cathartic. Clinical assessment requires an ECG, electrolytes (including magnesium and calcium), urinalysis, and SDC. If coingestants are suspected, a complete toxin screen should also be performed. Electrolyte disturbances should be treated aggressively because they will aggravate any digoxin-induced arrhythmias.

Some digoxin-specific antibody fragments have become specific antidotal therapy for reversing the toxic manifestations. These fragments are the result of sheep-derived immunoglobulin that is cleaved to extract only the Fab fragment. This small-molecular-weight antibody fragment is capable of avidly binding free digoxin so that a gradient results that favors digoxin removal from receptor sites into interstitial water. The effect of this gradient is that sodium-potassium ATPase function is immediately restored. The digoxin-antibody complex is then rapidly excreted in the urine. Of note, after digoxin antibody fragments are administered, SDC increases astronomically, reflecting bound, inactive digoxin that has diffused

into the vascular compartment.

These antibody fragments are indicated in the following circumstances after digoxin poisoning: 1) progressive signs and symptoms of intoxication, 2) life-threatening cardiac arrhythmias, or 3) severe hyperkalemia (defined as a serum potassium of 5.5 mEq/L or greater). The dose of antibody fragments is calculated on the basis of ingested digoxin dose (in the case of acute intoxication) or on the basis of SDC (in the case of chronic intoxication). Each 40-mg vial of digoxin-Fab will bind 0.6 mg of digoxin. The total dose of Fab needed (in vials) may be estimated by dividing a known ingested dose by 0.6, or calculated for the steady state context as body load of digoxin:

$$\text{No. of vials} = \frac{\text{SDC (ng/mL)} \times \text{wt (in kg)}}{100}$$

Complications from the administration of antibody fragments are low and consist of an allergic reaction (in approximately 0.6% of patients), precipitation of congestive heart failure (secondary to the abrupt loss of digoxin's inotropic action), and rebound hypokalemia. These complications should be anticipated and treated accordingly.

Disc Batteries

The development and widespread use of disc batteries in home toys and appliances has led to a burgeoning increase in the rate of disc battery ingestions in young children. A somewhat unusual feature of these ingestions is the frequency among children 4 to 8 years of age who often ingest them accidentally or out of curiosity. Children with hearing aids form another group at particular risk.

Disc batteries contain a number of potentially toxic substances, including mercury, lithium, and potassium hydroxide. However, their toxic potential is primarily confined to their corrosive action when they are in contact with a mucosal surface for an extended time. Thus, disc batteries that are placed in nasal or aural cavities should be removed immediately.

With the history of a disc battery ingestion, all patients should receive an immediate chest radiograph. This is because disc batteries that are retained in the esophagus act as local corrosives, leading to esophageal injury or perforation. If the disc battery is found in the esophagus, it must be removed immediately. If the battery is beyond the esophagus, the patient may be discharged.

The natural history of disc battery ingestion is that the object is usually expelled within 72 hours of ingestion without inducing symptoms. Therefore, the treatment of these ingestions involves no intervention. Rather, parents are asked to monitor stools for 3 days to document passage of the battery. In the event the battery is not passed within that time, an abdominal radiograph should be obtained to confirm that the battery has not been incarcerated in a bowel loop. If the battery is still in the gut, there is continued observation. Surgical removal of these objects is almost never necessary.

Foods/Fish

In addition to drugs and medications and household products and plants, toxic ingestions may occur through normal diet when the ingested product contains a toxin that is preformed by microorganisms. The largest class of such toxins are the enterotoxins produced by organisms that include *Shigella, Salmonella, Yersinia, Escherichia coli, Staphylococcus, Bacillus cereus, Clostridium, Vibrio, and Clostridium botulinum*. After this large group of toxins, the next most common cause of foodborne intoxications results from the ingestion of contaminated marine life.

The general approach to the patient with diarrhea and infectious causes of the gastroenteritis syndrome is discussed in Chapter 19 and Chapter 84, respectively. The association of hemolytic uremic syndrome with GI infection by *E. coli* O157:H7 is discussed in Chapter 84 and Chapter 86. Plant toxicity is discussed later in this chapter under its own heading. Here, the common causes of acute bacterial toxin-induced food poisoning are outlined, followed by a discussion of marine-related illness.

When similar GI symptoms occur in a group of persons who share the same meal or the same food on separate occasions, the emergency physician may consider the possibility of foodborne disease. Detailed epidemiologic investigations are usually beyond the capacity of the ED setting, but the hospital infection control officer and/or local health department can often be helpful.

Staphylococcal food poisoning is probably the most common cause of such cases in the United States. The heat-stable toxins typically produce acute abdominal pain, nausea, vomiting, and diarrhea within 1 to 6 hours of eating the contaminated meal. The illness is usually self-limiting, although occasional patients develop severe symptoms and dehydration.

Other bacterial toxin-induced diarrheal food poisonings include those secondary to *Bacillus cereus, Clostridium perfringens*, and *Vibrio* species. The onset of clinical illness and usual food sources of these and staphylococcal disease are outlined in Table 88.12. All these illnesses are generally self-limiting, and treatment is supportive, with careful attention given to fluid and electrolyte status in unusually severe cases (e.g., the rare occurrence of cholera in the United States).

Table 88.12. Common Causes of Diarrheal Food Poisoning in the United States

Infant botulism shares many pathophysiologic and clinical features with foodborne botulism (it is discussed in detail in Chapter 83). The etiology of the foodborne disease differs, of course, in that preformed toxin is ingested at the time of consuming contaminated food, typically improperly home-canned, low-acidity vegetables (e.g., potatoes, onions, beans) or poorly refrigerated pot pies or meats. The incubation period is usually 12 to 36 hours, with initial GI symptoms soon followed by weakness, malaise, and then cranial nerve symptoms, particularly diplopia, dysphagia, and dysarthria. The neurologic examination is notable for normal mental status and symmetric ocular findings, such as ptosis, lateral rectus weakness, and pupillary abnormalities.

Diagnosis should be suspected clinically and may be buttressed with positive serum or stool analyses for botulinum toxin and suggestive electromyelograph (EMG) findings. The management of foodborne botulism shares with infant botulism the requirement for meticulous, intensive supportive care, with special attention to airway and ventilatory status. In addition, unlike the case in infant botulism, administration of trivalent antitoxin is recommended for all symptomatic patients. This antitoxin and details regarding its optimal use are available from the Centers for Disease Control and Prevention (404-639-2206 during workdays; 404-639-2888 after hours).

Scombroid Poisoning

Scombroid poisoning is an intoxication that occurs shortly after ingestion of spoiled fish from the Scombroidea family (e.g., tuna, bonita, skipjack), as well as ingestion of non-Scombroidea fish (e.g., bluefish, mahi-mahi). The ingested toxin(s) has not been completely characterized, but large quantities of histamine are invariably found in fish that produce scombroid.

The clinical picture of scombroid poisoning consists of sudden-onset headache, facial flushing, a peppery taste in the mouth, dizziness, nausea, and vomiting. An urticarial eruption with pruritus may develop. In its extreme, victims may develop tachycardia, bronchospasm, respiratory distress, and hypotension.

In patients with severe symptoms, treatment is directed toward ensuring adequate ventilation and hemodynamic stability. Fluids and vasopressor support may be needed to treat hypotension. Pharmacologic treatment of scombroid poisoning includes administration of antihistamines, corticosteroids, and if necessary, adrenergic agents. Both diphenhydramine and cimetidine have been used successfully to treat the symptoms of scombroid poisoning. In the event of severe bronchospasm, other bronchodilators, including inhaled b_2 agonists may be necessary adjuncts.

Ciguatera

Ciguatera is an illness endemic to the South Pacific but is considerably less common in the continental United States, where it is largely confined to the lower Atlantic states. However, because it does occasionally appear in the United States or may occur in recent visitors from endemic areas, its clinical manifestations should be recognized.

Ciguatera results from ingestion of a toxin elaborated by the dinoflagellate, *Gambierdiscus toxicus.* This parasite is ingested by small fish that begin to concentrate the toxin. As predators ingest those small fish, the toxin ascends the food chain until ingested by humans. The fish that most commonly harbor ciguatoxin include barracuda, grouper, red snapper, and parrot fish. The physiologic actions of ciguatoxin are primarily neurologic. The toxin decreases CNS concentrations of gamma-aminobutyric acid (GABA) and dopamine. This action occurs in conjunction with sodium channels being "locked-open," permitting unrestricted sodium ingress.

The clinical picture of ciguatera poisoning begins 4 to 36 hours after ingestion of contaminated fish. After a brief period of nausea and vomiting, victims develop paresthesias, particularly perioral, or weakness. A hallmark of ciguatera toxin is the reversal of hot–cold sensation. In severe cases, CNS dysfunction, including coma, may appear. Toxic manifestations may persist for days to months after significant exposure.

The diagnosis of ciguatera intoxication is clinical, based on the history of ingestion of a fish known to carry this toxin. Because symptoms appear many hours after ingestion of contaminated fish, there is no clear role for GI decontamination.

Management of ciguatera is supportive. Primary attention should be paid to CNS status and its effects on airway and ventilation. IV mannitol has shown great promise in reversing many of the neurologic manifestations, particularly coma. It is administered in a dose of 0.5 to 1.0 g/kg.

Paralytic Shellfish Poisoning

The dinoflagellate *Gonyaulax* is responsible for elaborating the toxin (saxitoxin) that causes paralytic shellfish poisoning (PSP). The name red tide is based on the characteristic red pigment of the *Gonyaulax.* Paralytic shellfish poisoning appears in large bloom between the months of May and October and is found primarily along the eastern seaboard (although blooms have increased across the world in recent years and may be found on either U.S. coast). The animals that ingest and concentrate this toxin are primarily bivalve shellfish, including mussels, clams, oysters, and uncommonly, scallops. The toxin, saxitoxin, is capable of reversibly binding neuronal sodium channels, resulting in depolarization disturbances. The toxin is heat stable.

After ingestion of contaminated shellfish, victims quickly develop GI distress with nausea and vomiting. This is followed

by generalized paresthesias, cranial nerve disturbances, and weakness. In severe intoxications, cardiorespiratory failure may ensue.

Treatment of PSP is supportive. Victims may require ventilatory support until the intoxication resolves over hours to days.

Household Cleaning Products and Caustics

Household Cleaning Products

Background

Until the early 1950s, cleaning products used for home laundering, household maintenance, and personal hygiene were usually some form of soap. However, soap has the disadvantage of forming an insoluble precipitate that clings to surfaces such as skin, bathtubs, clothes, and dishes. Most products today use synthetic detergents that do not form such precipitates. Soap is one type of surface active agent ("surfactant"). A "detergent" is any cleansing product. However, in common use, the word *detergent* has come to mean a household cleaning product that is based on nonsoap surfactants, used mainly for laundering and dishwashing. Other cleaning products include disinfectant cleaners; cleaners for drains, ovens, and toilet bowls; bleaches; and ammonia. These agents are of concern because their accessibility to children makes them commonly involved in human ingestions. Furthermore, animal studies and clinical observations have shown some of these products to be injurious after topical applications.

Each year, about 6% of reported unintentional ingestions involve soap, detergents, or cleaners; 2 to 3% involve household bleaches; and 1 to 2% involve corrosive acids and alkalis (e.g., ammonia, drain cleaners). Most of these cases involve children less than 5 years of age, of whom only 1 to 2% of those ingesting noncorrosive products require hospitalization. Most such exposures occur inside the home, while the product is in use. In almost half of these cases, the product had been transferred out of its original container, often unfortunately, to an empty glass or soda bottle.

Caustics

Background and Pathophysiology

Many agents possess corrosive potential when they are placed in direct contact with biologic tissues. These agents, collectively referred to as corrosives, may be acidic, alkaline, or rarely, have neutral pH (e.g., silver nitrate, concentrated hydrogen peroxide). Essentially all corrosives found in the home are acids or alkalis. Strong alkalis and acids cause direct destruction of tissue but with differing histopathologic patterns. Acids produce coagulation necrosis that usually causes superficial damage, rather than deep, penetrating burns. Alkalis, in contrast, cause a deep and penetrating liquefaction necrosis, that often has severe consequences, such as esophageal perforation. Such deep burns are often associated with severe scarring and, ultimately, with stricture formation. Acid corrosives include the mineral acids, such as hydrochloric, sulfuric, nitric, and hydrofluoric acids. Common household products that contain acid corrosives include toilet bowl and drain cleaners. However, many home accidents involve acids brought home (often in unmarked food containers) by parents from the workplace.

Alkali caustics are found in several household products. Sodium hydroxide (lye), which is available in crystalline and liquid forms, is used primarily as an oven cleaner or drain pipe cleaner (e.g., Drano, Liquid Plumr, Easy-Off). Sodium hydroxide is also an ingredient in the tablets used to test for glycosuria (Clinitest). Other products may contain alkaline corrosives, including powdered laundry and dishwasher detergents.

Clinical Findings

Ingestions of acid and alkali corrosives cause immediate severe burning of exposed surfaces, usually with intense dysphagia. Associated glottic edema may cause airway obstruction and asphyxia. Severe acid ingestions most often cause gastric necrosis and may be complicated by gastric perforation and peritonitis. With alkalis, severe damage is more commonly found in the esophagus; deep-tissue injury may quickly lead to esophageal perforation, mediastinitis, and death. As already noted, alkalis also produce severe esophageal strictures in survivors.

Management

The initial step in the management of a caustic ingestion is to determine whether the agent is, in fact, corrosive and, if so, whether it is an alkaline or acid corrosive. Many products that are thought to have corrosive potential (e.g., household bleach) are simple irritants and do not require intervention. Identification of ingredients and their corrosive potential can be found in texts on household products or through consultation with a regional poison control center.

The approach to management of cleaning products and caustic ingestions, as outlined in Figure 88.3 and Figure 88.4, begins with rapid clinical assessment of cardiorespiratory function, neurologic status, and evidence of GI hemorrhage. Life support measures may be needed emergently to secure the airway and to treat shock or metabolic acidosis. As noted previously, most patients with significant exposures develop symptoms early and may appear critically ill. However, even patients with minimal symptoms and the absence of oral lesions may have significant esophageal injury; thus, all patients with a convincing history of exposure to a caustic substance need esophagoscopy to be evaluated fully for the presence of esophageal burns.

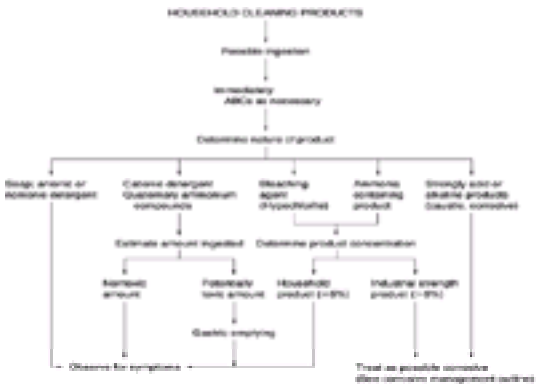

FIGURE 88.3. Algorithm for management of household cleaning product ingestion. (Modified with permission from Temple AR, Lovejoy FH Jr. Cleaning Products and Their Accidental Ingestion. New York: Soap and Detergent Association, 1980.)

FIGURE 88.4. Algorithm for management of corrosive ingestion. (Modified with permission from Temple AR, Lovejoy FH Jr. Cleaning Products and Their Accidental Ingestion. New York: Soap and Detergent Association, 1980.)

Simple dilution has been suggested as being safe and potentially diagnostic. However, there are several reasons why this should not be attempted. First, in the event esophageal injury or perforation has occurred, fluids may extravasate, inducing severe mediastinitis. Also, because esophagoscopy is the diagnostic procedure of choice in establishing the extent of injuries, an empty stomach is necessary for minimizing the risks of anesthesia. Finally, if administered fluids are alkaline or acidic, an exothermic reaction may occur that also can worsen esophageal injury. No GI decontamination is conducted after the ingestion of corrosive agents.

If the eyes are involved (something that should always be considered if a caustic has splashed on the face), copious irrigation should be provided and carried out for at least 15 minutes, with longer periods for crystalline caustics. The physician should perform pH testing of fluids in the ocular cul-de-sac after irrigation to confirm that corrosives have been neutralized; the normal pH of tears is 7. Alkali eye injuries require urgent ophthalmologic consultation. Skin contamination also deserves prolonged rinsing with water and removal of contaminated clothing. Irrigation should continue until the skin is free of alkali, as determined by disappearance of the soapy sensation.

The next phase of management calls for further evaluation. All exposed surfaces, especially the oropharynx, should be examined scrupulously. A CBC and chest radiograph should be obtained, the latter particularly if any respiratory signs or symptoms are noted. Referral to an endoscopist must be done on an immediate basis.

Analgesic therapy may be necessary for severe pain. An IV line should be established if not previously done for basic life support. Conflicting data regarding the role of corticosteroids in the treatment of corrosive esophageal injury exist. First-degree burns typically heal without long-term sequelae. Circumferential second-degree burns may be less likely to stricture after steroid administration; therefore, corticosteroids with empiric antibiotics may be considered in this scenario. Third-degree burns are likely to scar despite treatment, and administration of steroids in this situation may provide more risk than benefit. The consulting otolaryngologist may elect to administer steroids in select patients based on endoscopic findings. All patients are admitted for supportive care and monitoring for acute complications such as mediastinitis, pneumonitis, and peritonitis.

The long-term management of survivors with severe caustic esophageal burns and stricture formation is complex, involving many surgical, medical, and psychologic stresses to the patient. Years of repeated bougienage may be necessary, and some patients will require esophagectomy with colonic interposition in an effort to replace the destroyed esophagus. The patient may be incapable of tolerating solid foods for prolonged periods.

Hydrocarbons

Hydrocarbons are carbon compounds that become liquid at room temperature. The term *hydrocarbons* is somewhat confusing and is often used interchangeably with the term *petroleum distillates.* However, whereas all petroleum distillates are hydrocarbons, not all hydrocarbons are petroleum distillates (e.g., pine oil). Hydrocarbons can be found in solvents, fuels, household cleaners, and polishes.

Hydrocarbons are typically divided into three categories: the aliphatic hydrocarbons, the aromatics, and the “toxic”

hydrocarbons. The aliphatic hydrocarbons are petroleum distillates and are found in such household products as furniture polish, lamp oils, and lighter fluids. The aromatics are cyclic structures and include toluene, xylene, and benzene. These agents are found in solvents, glues, nail polish, paints, and paint removers. The “toxic” hydrocarbons consist of a broad class of substances that possess no specific profile of toxicity. These agents include halogenated hydrocarbons and hydrocarbons that serve as vehicles for toxic substances such as pesticides.

The major toxicity of hydrocarbons varies from class to class. However, the feature that these agents have in common is a low viscosity that permits them to spread freely over large surface areas, such as the lungs, when aspirated. This property (plus their solvent actions) leads to a necrotizing, often fatal chemical pneumonitis when these compounds are aspirated. The high volatility of these substances is responsible for alterations in mental status, including narcosis, inebriation, and frank coma. In addition to these toxicities, the solvents possess additional toxicities (see Inhalants), including the risk of bone marrow injury (in the case of benzene). Finally, with the toxic hydrocarbons, additional toxicities may occur as a result of actions such as cardiotoxicity or as a result of the pharmacologic properties of the other agents contained within these compounds. The major toxicity of hydrocarbons is classified in Table 88.13.

Nontoxic (unless complicated by gross aspiration)
Asphalt, tars
Mineral oil
Liquid petrolatum
Motor oil, axle grease
Baby oils, suntan oils
Systemic Toxicity
Halogenated (carbon tetrachloride, trichloroethane)
Aromatic (benzene, toluene, xylene)
Additives (camphor, organophosphates, heavy metals)
Aspiration Hazard (without significant systemic toxicity unless ingested in massive quantity)
Turpentine
Gasoline
Kerosene
Mineral seal oil (furniture polish)
Charcoal lighter fluid
Cigarette lighter fluid
Mineral spirits

Table 88.13. Classification of Hydrocarbons

The amount of a hydrocarbon that has been ingested by a pediatric patient is often difficult to quantify. However, any degree of aspiration results in signs, including coughing, gagging, or tachypnea. Less than 1 mL of some compounds, when aspirated directly into the trachea, may produce severe pneumonitis and eventual death. When ingested, these compounds are poorly absorbed from the GI tract. In a retrospective study of hydrocarbon ingestions in children, most children (880 of 950) developed no symptoms.

The major aspiration hazard associated with hydrocarbons can be quantified by their viscosity. Products with a viscosity of 150 to 250 Saybolt Seconds Units (SSU), such as oils, pose a small risk of chemical pneumonitis; those with a viscosity under 60 SSU, such as furniture oils or polishes, have a high aspiration hazard.

Clinical manifestations of hydrocarbon ingestion depend largely on the specific profile of toxicity of the ingested substances. All these agents cause significant GI irritation that may be associated with nausea and bloody emesis. CNS effects may range from inebriation to coma. Hemolysis with hemoglobinuria has been reported after significant ingestions. Finally, hydrocarbon ingestion may be associated with the development of fever and leukocytosis in up to 15% of patients in the absence of clinically evident pneumonitis.

Because most hydrocarbons cause clinical toxicity only when aspirated, the mainstay of treatment is to leave ingested compounds in the gut (when possible) and to prevent emesis or reflux. Gastric emptying is generally reserved only for those compounds with the potential for systemic toxic effects (Table 88.13). These compounds include the halogenated hydrocarbons (e.g., trichloroethane, carbon tetrachloride) and aromatic hydrocarbons (e.g., toluene, xylene, benzene). In addition, all petroleum distillates, regardless of their viscosity, should be evacuated from the GI tract if they contain dangerous additives, such as heavy metals or insecticides. Finally, gastric emptying should be considered when a huge amount of hydrocarbon has been ingested, as in a suicide attempt.

Patients who have aspirated may exhibit immediate choking, coughing, and gagging as the product is swallowed and then vomited after ingestion. Aspiration of the product may also occur at the time of the initial swallowing. ED management of these patients is outlined in Figure 88.5. If the patient has any cough or respiratory symptoms upon arrival to the ED, a chest radiograph should be obtained immediately. Because there is a gradual evolution of abnormal radiographs, an initially negative chest radiograph should be repeated at 4 to 6 hours after ingestion. All patients with abnormal chest radiographs or persistent respiratory symptoms after 4 to 6 hours of ED observation should be admitted for observation. Patients who are asymptomatic after this period of observation may be discharged. Because pneumonitis occasionally appears 12 to 24 hours after exposure, detailed instructions should be provided for warning signs of respiratory dysfunction.

FIGURE 88.5. Management of petroleum distillate ingestion. (Modified with permission from Shannon M. Petroleum Distillate Poisoning. Harwood-Nuss A, ed. Philadelphia: JB Lippincott, 1991.)

Treatment of hydrocarbon pneumonitis consists of airway control if there is mental status depression and intubation if ventilation is impaired. Adult respiratory distress syndrome may ensue, and heroic measures such as extracorporeal membrane oxygenation has been successfully employed. Antibiotics should not be used prophylactically but should be reserved for specific infections, should they develop. The use of corticosteroids in the treatment of aspiration from hydrocarbons has been associated with increased morbidity and is not recommended. In the event of hypotension or bronchospasm, epinephrine is contraindicated because hydrocarbons are known to cause ventricular irritability and predispose to fibrillation, an effect that is exacerbated by catecholamines.

Iron

Background

Iron poisoning is one of the most common, potentially fatal intoxications in children. Most serious childhood poisonings result from ingestion of prenatal vitamins or ferrous sulfate tablets (which unfortunately look much like candy) that were intended for adults. A common scenario is that the victim is a toddler whose mother has just had a new baby; the increased demands on the mother's attention and almost universal prescription of iron to postpartum women combine to set the stage for this ingestion. In addition, numerous exposures result from ingestion of iron-fortified children's vitamins, but these tend to be far less toxic.

Sufficient data to define a safe lower limit for toxic iron ingestions are not available. As little as 20 mg/kg of elemental iron has caused toxicity, whereas ingestions of more than 50 mg/kg often produce toxic effects. Of course, it is often impossible to know the exact number of tablets ingested. As few as ten 300-mg $FeSO_4$ tablets have been fatal to a young child. Furthermore, the elemental iron content of whole bottles of chewable vitamins is usually about 1200 mg. Legislation now demands child-proof caps for vitamin bottles that contain more than 250 mg of elemental iron.

Pathophysiology

Iron toxicity results from the direct caustic effect on the GI mucosa and the presence of free iron in the circulation. Pathologic changes include hemorrhagic necrosis of stomach and intestinal mucosa and lesions in the liver that range from cloudy swelling to areas of complete necrosis. Occasionally, pulmonary congestion and hemorrhage are noted. Excess free iron is believed to act as a mitochondrial poison, particularly in the liver, with resulting changes in cellular energy metabolism and the production of metabolic acidosis.

Clinical Manifestations

The clinical effects of iron poisoning are classically divided into four phases. Phase I represents the effects of direct mucosal injury and usually lasts 6 hours. Vomiting, diarrhea, and GI blood loss are the prominent early signs; when severe, the patient may lapse into early coma and shock caused by volume loss and metabolic acidosis.

Phase II, which lasts from 6 to 24 hours after ingestion, is marked by diminution of the GI symptoms. With appropriate therapy to replace fluid and/or blood losses, the child may seem relatively well and often goes on to full recovery without any subsequent symptoms. However, this remission may be transient and may be followed by phase III, characterized by cyanosis and profound metabolic acidosis. The child may develop coma, seizures, and intractable shock. This phase is believed to represent hepatocellular injury with consequent disturbed energy metabolism; elevated levels of lactic and citric acids are noted in experimental iron poisoning before cardiac or respiratory failure occurs. Jaundice and elevated transaminases are noted in this phase. A phase IV has been described in survivors of severe iron poisoning, marked by pyloric stenosis that results from scarring and consequent obstruction.

Laboratory abnormalities often associated with severe iron intoxication include metabolic acidosis, leukocytosis, hyperglycemia, hyperbilirubinemia and increased liver enzymes, and a prolonged prothrombin time. If fluid loss is significant, there will be hemoconcentration and elevated BUN. Abdominal films may show radiopaque material in the stomach, but the absence of this finding does not indicate a trivial ingestion.

Management

All children alleged to have ingested iron are potentially at significant risk for life-threatening illness. However, severe iron poisoning is uncommon compared with the number of children who develop only mild symptoms or remain entirely

asymptomatic. Thus, the emergency physician needs an approach that encompasses the response to the severely poisoned child and to most who will remain well.

As noted earlier, the amount of iron ingested is often hard to quantify, and minimal “safe” amounts are not well established. Serum iron levels have been shown to correlate with the likelihood of developing symptoms (usually a reflection of the serum iron that exceeds the iron-binding capacity and results in free-circulating iron). Usually, iron levels below 350 µg/dL, when drawn 3 to 5 hours after ingestion, predict an asymptomatic course. Patients with levels in the 350 to 500 µg/dL range often show mild phase I symptoms but rarely develop serious complications. Levels higher than 500 µg/dL suggest significant risk for phase III manifestations. However, the serum iron determination is not always available on a stat basis.

Although serum iron levels are useful, toxicity from iron overdose remains a clinical diagnosis. Ill patients require vigorous hydration and support. Children who are completely asymptomatic 6 hours after ingestion are unlikely to develop systemic illness. Among laboratory studies, the presence of metabolic acidosis or acidemia probably best correlates with toxicity. A white blood cell (WBC) count higher than 15,000/mm ^{3} paired with a serum glucose higher than 150 mg/dL is fairly predictive of elevated serum iron levels (but are not sensitive). Radiopaque material on abdominal radiograph also suggests significant absorption of iron. Measurement of the total iron-binding capacity is no longer believed to be useful in acute management. With these observations in mind, it is possible to construct a protocol for the triage and initial management of the patient who has ingested a possibly toxic amount of iron (Fig. 88.6).

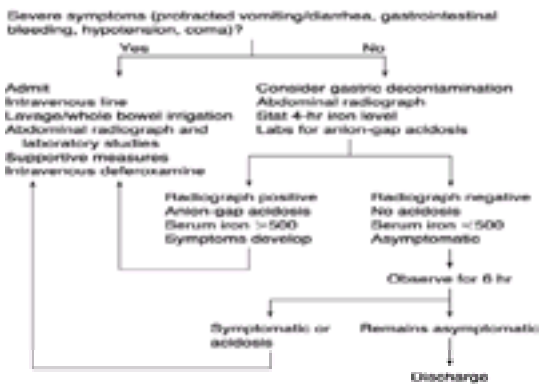

FIGURE 88.6. The initial approach to the patient ingesting a possibly toxic dose of iron.

Categorization

Patients who arrive with severe early symptoms, including vomiting, diarrhea, GI bleeding, depressed sensorium, or circulatory compromise require urgent, intensive treatment in the ED. The first priority is to obtain venous access. Simultaneously, blood is drawn for CBC, blood glucose, electrolytes, BUN, liver function tests, serum iron, and type and crossmatch. GI decontamination is begun as detailed in the following. Blood pressure should be supported with normal saline or Ringer's lactate (see Chapter 3). Specific chelation therapy with IV deferoxamine is begun immediately in all severely poisoned patients. An abdominal radiograph should be obtained as soon as possible after GI decontamination to determine its efficacy and to investigate for the presence of iron-pill concretions.

Patients with only mild vomiting and diarrhea in the early postingestion period still need urgent treatment but usually do well. Again, GI decontamination strategies should be promptly addressed. Blood studies, as previously noted, are drawn, and parenteral deferoxamine therapy is begun.

The asymptomatic patient who has presumably ingested iron in toxic amounts and who presents within 30 minutes of ingestion may benefit from ipecac-induced emesis if spontaneous vomiting has not occurred. If serum iron levels are available, blood should be sent for this study, an abdominal radiograph should be obtained, and the patient should be observed for 6 hours. An iron level of less than 350 µg/dL taken 3 to 5 hours after ingestion in an asymptomatic patient with a normal radiograph suggests that the patient is at minimal risk and may be discharged. Iron levels greater than 500 µg/dL, the development of any symptoms, or a positive radiograph should lead to admission and management as previously described for the mild to moderately ill patient.

When serum iron levels are not available on an emergency basis, the WBC count and serum glucose may be used as screening laboratory tests, in addition to the electrolytes and abdominal radiograph. Patients are observed for 6 hours in the ED. Those who have normal screening tests and remain asymptomatic may be discharged. Patients with abnormal screening laboratory tests should have an iron level sent for later reference. Acidotic or symptomatic patients should be admitted and treated with deferoxamine. Although rarely used today, the deferoxamine challenge test (50 mg/kg IM up to a maximum of 1 g) may be useful when iron levels are unavailable and the patient's screening laboratory studies and clinical status are borderline. The appearance of a pinkish-orange (vin rose) color to the urine indicates the presence of iron-deferoxamine complex and correlates well with a significantly elevated serum iron level. A positive deferoxamine challenge also mandates admission and further treatment. Patients asymptomatic after 6 hours with a negative challenge may be discharged.

Treatment

The treatment for acute iron poisoning includes efforts to decrease absorption and hasten excretion, as well as appropriate supportive care.

Ipecac-induced emesis may be helpful in preventing absorption, if the patient presents within 30 minutes, has a normal level of consciousness, and has an intact gag reflex. However, most children with toxic iron exposures will exhibit spontaneous vomiting. Furthermore, the empiric early use of ipecac may interfere with the clinical interpretation of early signs of iron toxicity, as detailed previously. Activated charcoal is not effective in binding iron salts. For serious poisonings, gastric lavage with normal saline can be considered in patients who present early in the hope of minimizing any direct mucosal injury caused by residual particulate matter and possibly contributing to the dissolution of pill concretions.

The mainstay of GI decontamination currently for iron-poisoned patients is the early and aggressive use of WBI (p. 894). This approach is believed effective in decreasing iron absorption and additionally in breaking up pill concretions that might be a risk for direct mucosal injury. As noted previously, an abdominal radiograph should be obtained early in the evaluation of symptomatic patients, but after gastric emptying procedures if these have been used. If this study demonstrates significant radiopaque material and the patient's condition allows it, WBI should be instituted for at least 4 to 6 hours. A few hours of WBI (until rectal effluent is clear) may be indicated in symptomatic cases even without definite radiographic findings to hasten elimination of residual iron pill particles or “sludge,” as long as there is no evidence of peritonitis or perforation. In patients with considerable initial radiographic findings, particularly pill concretions, a follow-up radiograph should be obtained to assess the adequacy of bowel cleansing. Further options of gastroscopy or even gastrotomy are reserved as last resorts to effect iron pill removal. Large clumps of coalesced iron tablets in the stomach or duodenum have led to severe hemorrhagic infarction of these viscera with subsequent perforation, peritonitis, and death. As previously noted, even in such patients who survive the acute phase, there is considerable risk of subsequent pyloric or bowel stenosis with obstruction, usually 4 to 6 weeks after ingestion. In this regard, we also urge early pediatric surgical consultation for patients in the first few days after ingestion who show any evidence of peritoneal irritation.

Chelation therapy with parenteral deferoxamine enhances the excretion of iron. The most efficacious route is a continuous IV infusion, and the maximum recommended dose is 15 mg/kg per hour (maximum daily dose 360 mg/kg, up to 6 g total). A higher infusion rate has been associated with hypotension but may be necessary (in conjunction with blood pressure support) for severe ingestions. Chelation is continued until the serum iron level returns to normal, metabolic acidosis has resolved, the patient is clinically improved, and the urine color returns to normal. The dose of deferoxamine may be titrated down in concert with the patient's clinical response and fall in iron levels.

Once the patient has been stabilized initially, further problems may include hypotension, profound metabolic acidosis, hypoglycemia or hyperglycemia, anemia and colloid loss caused by GI hemorrhage (after equilibration), renal shutdown resulting from shock, and hepatic failure with an associated bleeding diathesis. The maintenance of an adequate urine output is critical to prevent renal failure and to foster excretion of the iron-deferoxamine complex. If renal failure supervenes, chelation may be continued with concurrent dialysis because the complex is dialyzable.

Isoniazid

The recent increase in the incidence of tuberculosis has escalated the use of isoniazid (INH), the primary treatment for this infection. Thus, cases of INH poisoning in children continue to increase. Because this poisoning can be recognized promptly and specific antidotal therapy is available, a review of its toxicity is warranted.

The greatest increases in tuberculosis have been found in select groups, including new immigrants, the homeless, and people with acquired immunodeficiency syndrome (AIDS). Therefore, these people and their children form the primary at-risk group for such toxic ingestions.

Even when taken appropriately INH has many actions that can lead to clinical toxicity. These include hepatic dysfunction and interactions with foods such as those containing tyramine. However, its greatest toxicity appears after acute single ingestions of more than 20 mg/kg in children or more than 1.5 g in an adult.

INH's mechanism of toxicity is incompletely understood but seems to involve its potent effect at reversing the biologic activity of vitamin B_6 (pyridoxine). This action, as well as other effects on the synthesis of catecholamines and the neurotransmitter GABA, provides an explanation for the epileptogenic toxicity of the drug. INH also prevents hepatic conversion of lactate to pyruvate.

In overdose, the hallmark of INH poisoning is the triad of seizures, metabolic acidosis, and coma. Seizures induced by INH are typically generalized and appear to have a rhythmic recurrence. They are generally difficult to treat; patients usually remain comatose between seizures. The metabolic acidosis of INH can be severe; pH values of as low as 6.4 have been reported. This places INH on the list of substances associated with the development of high-anion gap metabolic acidosis (see MUDPILES mnemonic on p. 892). Of all these drugs, only INH possesses seizures as a prominent characteristic. Interestingly, in animal models of INH poisoning, metabolic acidosis does not occur if seizures are prevented through paralysis. Finally, the coma of INH intoxication can be severe and prolonged.

Because of the striking clinical picture of INH poisoning, diagnosis is often easily made on the basis of demographic characteristics and clinical manifestations. INH is not usually detected on routine toxin screens, and serum concentrations are of little value in acute management. Laboratory tests that are important in initial assessment include arterial blood gas, electrolytes, liver function tests, creatine kinase, and urinalysis.

Management

Management of INH intoxication begins with advanced life support. Because of seizures and coma, airway protection and ventilation are typically necessary. Cardiac monitoring should be initiated to monitor for the development of cardiac

arrhythmias (resulting from severe metabolic acidosis).

Aggressive GI decontamination is warranted if ingestion occurs within 2 to 3 hours of ED arrival. Syrup of ipecac is contraindicated after INH overdose because of the risk of rapid-onset seizures. Therefore, gastric emptying, if performed, is best accomplished by orogastric lavage. Activated charcoal with a cathartic should be administered. Theoretically, giving multiple doses of activated charcoal to enhance postabsorptive elimination of INH is advantageous.

Pharmacologic treatment for INH intoxication includes sodium bicarbonate, anticonvulsants, and pyridoxine. Sodium bicarbonate is provided as needed to restore serum pH to normal. In treating seizures, effective anticonvulsants include the benzodiazepines or phenobarbital (both of which are GABA agonists). Either diazepam (0.1 to 0.3 mg/kg) or lorazepam (0.1 mg/kg) should be administered IV to terminate seizures.

Administration of pyridoxine has been shown to provide specific antidotal therapy for INH poisoning. After administration of vitamin B_6, seizures and metabolic acidosis promptly resolve. Pyridoxine is given by IV in a dose that equals the estimated dose of INH in milligrams. In cases in which the ingested amount is unknown, a single dose of 5 g (70 mg/kg in children) of pyridoxine is administered. Rarely, repeat administration is necessary.

Although INH clearance can be enhanced by hemodialysis or hemoperfusion, these techniques are rarely necessary if pyridoxine, activated charcoal, and aggressive supportive care are provided.

Lead

Background

Although lead poisoning is usually the result of chronic ingestion by pica-prone children or of occupational exposure in adults, patients with lead poisoning may come to the ED with varied complaints of recent onset that often mimic diverse acute illnesses. Fortunately, severe lead encephalopathy is now rare, attributable in large part to widespread screening programs and early treatment of asymptomatic or mildly ill children. However, the risk of lead intoxication still exists, and the emergency physician and pediatrician in every community must maintain an index of suspicion.

Sources of Lead

The major source of excess lead absorption in children is lead-based paint, widely used in home interiors through the 1950s. In addition to the ingestion of macroscopic-sized chips of paint, inner-city children are often exposed to house dust, with a high lead content that results from finely crumbled paint particles, which gets on their hands and toys. Repetitive mouthing can lead to increased lead exposure even in the absence of observable pica. Although classically a disease of poor inner city residents, the recent phenomenon of young, middle socioeconomic level families moving into older sections of large cities and renovating townhouses has led to an expanded population at risk. This is because the sanding, stripping, and burning of lead-based paint from woodwork in such houses has also been associated with lead intoxication in the occupants. Other unusual sources of lead exposure include the burning of battery casings for heat, soft well water carried by outdated lead pipes, improperly home-glazed ceramics, drinking glass glazed decals, and dust or dirt alongside heavily traveled roads (resulting from auto emissions in communities still using leaded gasoline). Infants have also been demonstrated to develop elevated lead levels when parents prepare formula with first-draw tap water or when they boil the water before mixing.

Pathophysiology

Absorption of lead occurs through GI and pulmonary routes, although the former predominates in pediatric intoxications. Lead is then compartmentalized into three main areas: bone, soft tissues, and blood. Excretion occurs slowly through urine, feces, and sweat. Children are probably at double jeopardy compared with adults in that there is experimental evidence that younger animals have increased absorption and also a heavier distribution into soft tissues (including the brain). Concomitant nutritional deficiency, especially low dietary iron and calcium, may enhance intestinal lead absorption. Unfortunately, the same children at greatest risk for lead poisoning by virtue of age and residence are also likely to be at risk for dietary deficiency, especially iron.

Lead exerts its toxic effect principally by two mechanisms: by interference with calcium function at the cellular level and by enzyme inhibition, particularly on enzymes rich in sulfhydryl groups. In humans, the most obvious effects are on neurologic function and on the heme synthesis pathway, which is interrupted at several points, resulting in abnormally high levels of porphyrins and their precursors.

Clinical Findings

Early signs and symptoms of plumbism are notably vague and nonspecific. Abdominal complaints, including colicky pain, constipation, anorexia, and intermittent vomiting, are common; of course, these same symptoms are often ascribed to relatively normal 2 year olds by their parents. The child with early plumbism may also show listlessness and irritability. When encephalopathy begins, the child develops persistent vomiting and becomes drowsy, clumsy, or frankly ataxic. As encephalopathy worsens, the level of consciousness deteriorates further, and seizures commonly occur. Pathologic examination of brains of children who have died of lead encephalopathy shows severe cerebral edema with vascular damage; intracranial pressure is often, although not invariably, increased during the encephalopathy. When spinal fluid is examined, it often reveals a picture similar to that of aseptic meningitis with a mononuclear pleocytosis and elevated protein; however, lumbar puncture should be avoided if possible because of the risk of subsequent herniation. Peripheral neuropathy often occurs in adults with lead poisoning but is rare in children, although it is seen occasionally in those with an underlying hemoglobinopathy. Other organs may be damaged by lead. The kidneys may develop disturbances that range from slight aminoaciduria to a full Fanconi's syndrome with glycosuria and phosphaturia (in addition to aminoaciduria). High levels are also associated with a microcytic anemia that results from a defect in hemoglobin

synthesis. However, most anemia seen in children with excess lead levels is actually caused by concurrent iron deficiency. A moderately sensitive laboratory measure of lead effect on heme synthesis is the evaluation of erythrocyte protoporphyrin (EP), a heme precursor. Moderately elevated EP levels are seen in iron deficiency, but levels above 250 to 300 µg/dL are almost always the result of chronic lead poisoning.

Management

The asymptomatic child discovered to have a lead level in the 20 to 44 µg/dL range, particularly if the EP is greater than 250 µg/dL, deserves immediate referral to a pediatrician or toxicologist. Such children require environmental investigation, further evaluation, and possibly, chelation therapy. All symptomatic children and those with lead levels higher than 44 µg/dL need urgent treatment as outlined next, as well as pediatric consultation to ensure adequate postchelation follow-up.

The remainder of this discussion is addressed primarily to the early recognition and treatment of plumbism, including acute lead encephalopathy. This single aspect of chronic childhood lead poisoning is focused on because it represents a true medical emergency.

Recognition

As stated previously, to recognize mildly symptomatic patients with lead poisoning (or asymptomatic children with high lead levels at great risk to soon become symptomatic) requires a high index of suspicion. All children between 1 and 5 years of age are suspect if they have 1) persistent vomiting, listlessness or irritability, clumsiness, or loss of recently acquired developmental skills; 2) afebrile convulsions; 3) a strong tendency to pica, including a history of acute accidental ingestions or aural or nasal foreign body; 4) a deteriorating pre–World War II house or a parent with industrial exposures; 5) a family history of lead poisoning; 6) iron deficiency anemia; or 7) evidence of child abuse or neglect.

The child aged 1 to 5 years who comes to the ED with an acute encephalopathy presents the physician with a dilemma: lead intoxication requires urgent diagnosis, but confirmation with a blood level is usually not available on an immediate basis. A constellation of historical features of lead poisoning increases the likelihood of the diagnosis. These features include 1) a prodromal illness of several days' to weeks' duration (suggestive of mild symptomatic plumbism); 2) a history of pica; and 3) a source of exposure to lead. Several nonspecific laboratory findings make lead poisoning likely enough to warrant presumptive chelation therapy until confirmation by lead levels is available. These findings include 1) microcytic anemia; 2) elevated EP level, especially if greater than 250 µg/dL (conversely, a normal or minimally elevated EP level, less than 50 µg/dL, would make lead encephalopathy caused by chronic lead paint exposure unlikely); 3)basophilic stippling of peripheral erythrocytes or, if feasible, of red cell precursors on bone marrow examination; 4) elevated urinary coproporphyrins; 5) glycosuria; 6) aminoaciduria; 7) radiopaque flecks on abdominal radiographs; and 8) dense metaphyseal bands on radiographs of knees and wrists (lead lines).

Abnormalities on examination of cerebrospinal fluid (CSF) are also indicative of lead encephalopathy, including a lymphocytic pleocytosis, elevated protein, and increased pressure. However, a lumbar puncture should not be performed if lead encephalopathy is strongly suspected because the risk of herniation is considerable. If CSF must be examined to rule out bacterial meningitis, the minimal amount (less than 1 mL) necessary should be obtained. Alternatively, one might institute treatment for presumed meningitis, perform a determination of the lead level, and consider a delayed lumbar puncture after several days if the lead level is normal.

Treatment

The treatment of lead poisoning involves relocation of the child to a lead-free environment, chelation therapy, and appropriate supportive care. Symptomatic patients are at risk of developing encephalopathy with subsequent death or neurologic sequelae. In addition, asymptomatic patients with high lead levels (especially greater than 100 µg/dL) are also at significant risk for developing CNS involvement and might require urgent treatment.

The specific chelating drugs commonly used for symptomatic lead intoxication are edathamil calcium disodium (CaEDTA) and 2,4-dimercaptopropanol (British Anti-Lewisite or BAL) (Table 88.14). Side effects of CaEDTA include local reactions at injection sites, fever, hypercalcemia, and renal dysfunction manifested by rising BUN and abnormal urine sediment with proteinuria, hematuria, and/or epithelial cells. The major side effects of BAL include nausea and vomiting, so for the first day or two of BAL therapy, it is prudent to maintain the patient on IV fluids and clear liquids or nothing by mouth. BAL also induces hemolysis in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Its use is hazardous if the patient has severe hepatic dysfunction, and it forms a toxic complex if given concurrently with iron. Succimer (dimercaptosuccinic acid, or DMSA) has been approved for pediatric use in cases in which lead levels exceed 45 µg/dL (see Table 88.14). This water-soluble analog of BAL may be taken orally, and several studies have found such use to be as effective as CaEDTA given parenterally. However, experience with its use in symptomatic patients is limited.

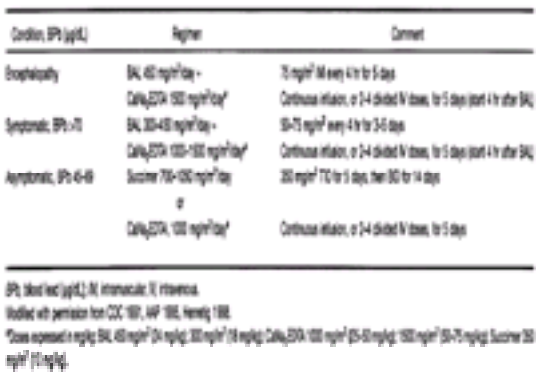

Table 88.14. Guidelines for Chelation Therapy of Lead Poisoning

Asymptomatic children found to have lead levels of 45 to 69 µg/dL should have urgent referral and treatment for 5 days with CaEDTA or DMSA alone. If the lead level is above 69 µg/dL, BAL and EDTA are used for at least the first 2 days (Table 88.14). Supportive care includes adequate hydration to promote good urine output. Symptomatic children without frank encephalopathy should receive chelation therapy with a combination of CaEDTA and BAL for 5 days. Supportive care includes close monitoring for signs of encephalopathy and, again, maintenance of urine flow.

Patients with encephalopathy require combination chelation therapy with CaEDTA and BAL, as well as intensive supportive care. Fluid therapy is critical and must be individualized. Adequate urine flow is needed to excrete the lead-chelate complexes; however, fluid overload must be avoided so that cerebral edema is not exacerbated. A reasonable goal is to supply basal water requirements, maintaining urine production at 0.35 to 0.5 mL/kcal per 24 hours. Basal water needs in children average 1 mL/kcal and may be calculated as 100 kcal/kg for 0 to 10 kg, plus 50 kcal/kg for 10 to 20 kg, plus 20 kcal/kg for each kilogram above 20 kg.

Seizures commonly occur in acute encephalopathy and should be controlled with anticonvulsant drugs (see Chapter 83). Hypothetical precautions have been made about the use of phenobarbital in lead encephalopathy (i.e., synergistic disturbances in porphyrin metabolism), but its clinical use has not been associated with any noticeable deleterious effect.

Recent advances in the management of cerebral edema and increased intracranial pressure (see Chapter 125) have not been evaluated in a controlled fashion in the context of lead encephalopathy. However, it seems reasonable to expect that such measures as forced hyperventilation, mannitol or glycerol osmotic therapy, and high-dose steroids would have a salutary effect. Whether more aggressive measures such as continuous intracranial pressure monitoring, induced hypothermia, and barbiturate coma would decrease mortality or morbidity any further is unknown.

Oral Hypoglycemics

Although almost all juvenile diabetics require insulin therapy for control, the frequent prescription of oral hypoglycemic agents for patients with non–insulin-dependent, adult-onset diabetes has made the availability and, consequently, the ingestion of these medications commonplace among toddlers. The scenario typically involves visits to a grandparent's home (or conversely, a visit by the grandparent to the child's home). The sulfonylureas (chlorpropamide, glipizide, glyburide) are capable of inducing significant hypoglycemia in a toddler after the ingestion of a single tablet. In addition, the onset of hypoglycemia may be delayed up to 16 to 24 hours after ingestion. Thus, prudent management of such exposures generally implies 24-hour hospitalization with close observation and frequent blood glucose testing. All such patients should receive charcoal/cathartic. There may be theoretic benefit to the use of repeat charcoal dosing for ingestions of glipizide, which has an enterohepatic circulation. Excretion of chlorpropamide may be enhanced by urinary alkalinization. The biguanides (e.g., metformin) are unlikely to create hypoglycemia but may promote metabolic acidosis.

Maintenance of euglycemia is usually accomplished in symptomatic patients with the infusion of hypertonic glucose (e.g., 10 to 20%) solutions, supplemented as necessary by bolus doses. Occasionally, patients may still exhibit hypoglycemia, requiring additional treatment. Diazoxide has been a useful adjunct to glucose infusion, in similar doses to its more familiar role as an antihypertensive (e.g., 3 to 5 mg/kg), although given slowly over 30 minutes, to limit any hypotensive effect. This dose may be repeated every 4 to 6 hours. An oral form is also available. Recently, octreotide (1–10 mcg/kg), a somatostatin analog, has been used effectively in cases of refractory hypoglycemia. Occasionally, patients require glucose infusion for several days; as their condition improves, the glucose load may be tapered gradually with frequent monitoring.

Organophosphates

Background

Organophosphates are lipid-soluble insecticides that are commonly applied in sprayed dust or emulsion formulations. These compounds are found in agricultural and home use, and they form the basis of “nerve gases” in chemical warfare agents (see Chapter 132). Organophosphates are readily degraded in the environment and metabolized in mammals by hydrolic cleavage. Some of these chemicals are “systemic” insecticides, meaning that they are taken up by the roots of the plants and translocated into foliage, flowers, and/or fruit.

Pathophysiology

Compounds of this class can be absorbed by inhalation, ingestion, and skin penetration. They irreversibly phosphorylate the enzyme acetylcholinesterase in tissues, allowing acetylcholine accumulation at cholinergic junctions in autonomic effector sites (causing muscarinic effects), in skeletal muscle or autonomic ganglia (causing nicotinic effects), and in the CNS.

Clinical Findings

The symptoms of acute poisoning usually develop during the first 12 hours of contact. These include findings related to the CNS (dizziness, headache, ataxia, convulsions, and coma); nicotinic signs, including sweating, muscle twitching, tremors, weakness, and paralysis; and muscarinic signs characterized by the SLUDGE mnemonic, including *s*alivation, *l*acrimation, *u*rination, *d*efecation, *g*astrointestinal cramping, and *e*mesis. In addition there may be miosis, bradycardia,

bronchorrhea, and wheezing; in severe cases, pulmonary edema develops. Severe intoxications may also cause a toxic psychosis that resembles alcoholism.

A history of exposure to organophosphates and the clinical manifestations already discussed are the best clues to an organophosphate poisoning. A depression of plasma or red blood cell cholinesterase activity provides the best laboratory marker of excessive absorption of organophosphates, although it is rarely available on a stat basis. A decrease in the cholinesterase activity of the red blood cells is more specific for organophosphate inhibition than is the plasma assay. Although plasma cholinesterase is depressed by liver injury from various causes, and a small percentage of the population has a genetically determined deficiency of plasma cholinesterase activity, a depression of 25% or more is strong evidence of excessive organophosphate absorption. However, it is important that treatment not be delayed until confirmation of plasma cholinesterase is obtained.

Management

The management of a patient who has ingested organophosphates must always include safeguards against exposure for the persons who treat the patient. If the compound is ingested orally, gastric lavage should be considered; care should be taken that the gastric aspirate or vomitus not be splashed on the ED staff because the organophosphates are readily absorbed through the skin and mucous membranes. Patients who have been poisoned by the topical application of organophosphates should receive a thorough scrubbing with a soap solution on admission to prevent further absorption of organophosphates. In addition, all contaminated clothing must be removed and stored in a plastic bag to protect the institutional personnel. Activated charcoal should be instilled for those who have been poisoned by the oral route.

After decontamination, antidotal therapy begins with the administration of atropine sulfate given in a dose of 0.05 to 0.1 mg/kg to children and 2 to 5 mg for adolescents and adults. This dose should be repeated every 10 to 30 minutes or as needed to obtain and maintain full atropinization, as indicated by clearing of bronchial secretions and pulmonary rales. Therapy is continued until all absorbed organophosphate has been metabolized and may require 2 mg to more than 2000 mg of atropine over the course of a few hours to several days. After atropinization has been instituted, severe poisonings should be treated with the addition of pralidoxime. This drug is particularly useful in poisonings characterized by profound weakness and muscle twitching. A dose of 25 to 50 mg/kg should be administered in 250 mL of saline by infusion over approximately 30 minutes; adults may receive 1 to 2 g by IV. This may be repeated at 1 hour intervals if muscle weakness is not relieved and then at intervals of 6 to 8 hours for 24 to 48 hours. In patients with severe poisoning, a 2.5% concentration may be infused continuously at the rate of 500 mg/hour in adolescents and adults, or approximately 20 mg/kg per hour in children. Occasionally, patients may require more than 48 hours of therapy; the end-point should be persistent relief of neurologic and cholinergic signs.

Organophosphates are usually dissolved in hydrocarbon bases; thus, the clinician should be prepared to treat hydrocarbon pneumonitis if it develops. Also, bronchopneumonia that complicates the pulmonary edema has been observed in acute poisonings.

Because the organophosphates cause elevated levels of acetylcholine in the plasma, compounds that effect the uptake of acetylcholine and/or its release should be avoided in the management of these patients. Specifically, aminophylline and phenothiazines are contraindicated. In situations in which identification of the ingested insecticides is difficult, consultation may be obtained from the National Insecticide/Pesticide Hotline (800-858-7378). This hotline provides an around-the-clock consultation service for advice on pesticides.

Phenothiazines

Background and Pathophysiologys

The phenothiazines are commonly prescribed major tranquilizers. Phenothiazines are also often used to treat nausea and vomiting in young children. The toxic effects of phenothiazines primarily involve the three components of the nervous system: central, autonomic, and extrapyramidal.

The three subgroups of phenothiazines—aliphatic, piperazine, and piperidine—vary in their effects on the different components of the CNS. In general, the aliphatic group (e.g., chlorpromazine) may cause sedation and hypotension in overdose. The piperazine group (e.g., prochlorperazine) are more likely to create extrapyramidal side effects.

Clinical Findings

The manifestations of phenothiazine toxicity may be dose dependent or dose independent (idiosyncratic). These have significantly different features.

With dose-dependent effects, the manifestations of intoxication after acute ingestion vary from mild to severe. In mild intoxication, CNS signs such as sedation, ataxia, and slurred speech occur. The anticholinergic effects of these drugs may cause constipation, urinary retention, and blurred vision. Because phenothiazines have potent actions on the temperature-regulating center of the hypothalamus, temperature disturbances occur in up to 30% of patients and may consist of hypothermia or hyperthermia. Orthostatic hypotension, the probable result of peripheral vasodilation, may also be noted with mild intoxication.

In moderate intoxications, the patients may have significant depression in level of consciousness. Extrapyramidal effects become notable at this level of intoxication with muscle stiffness or “cogwheel” rigidity seen on passive movement of the neck, biceps, or quadriceps. Anticholinergic manifestations are severe and include acute urinary retention and paralytic ileus; hypotension may be profound. Cardiac conduction disturbances may make their appearance and are often heralded by a prolonged Q-T interval.

In severe overdoses, patients are unarousable. Deep tendon reflexes may be hyperactive. Dystonic reactions may occur, involving the head and neck and the cranial nerves (torticollis and opisthotonos). Arrhythmias and shock may result in death.

The dose-independent effect of the phenothiazines is the dystonic reaction. This striking clinical occurrence consists of episodic spasm of voluntary muscles, particularly those of the head and neck. Patients may develop torticollis, bruxism, tongue protrusion, or oculogyric crisis. Dystonic reactions are unrelated to the amount of ingested phenothiazine. They may or may not occur after the first dose. Their onset is 8 to 40 hours after ingestion of a single dose of phenothiazine. This marked delay between ingestion and manifestations often interferes with obtaining an accurate history of ingestion. Fortunately, although painful and distressing, dystonic reactions are rarely life-threatening and usually resolve quickly after administration of anticholinergics.

Management

Treatment of acute phenothiazine intoxication hinges on the severity of ingestion. In patients with mild overdose, hospitalization is usually unnecessary. The autonomic signs and symptoms are most often transient and require no treatment. In patients with moderate or severe overdoses, the potential for life-threatening manifestation requires prompt evaluation of vital signs, GI decontamination (if ingestion was within 4 to 6 hours of ED arrival), vascular access, and cardiac monitoring. Pressors such as norepinephrine (see Chapter 3) may be used to correct the hypotension. In those rare instances of hypertension, the use of nitroprusside (see Chapter 35) may be indicated. Severe arrhythmias should be treated aggressively as detailed later under Tricyclic Antidepressants (p. 926) and in Chapter 82. Attention should be directed to the treatment of temperature instability and other autonomic disturbances.

Dystonic reactions are effectively controlled by the IM or IV administration of diphenhydramine in a dose 1 to 2 mg/kg. This dose may be repeated within 15 to 20 minutes if no effect is noted. An alternative agent is benztropine mesylate (1 to 2 mg for an older child, adolescent). This agent reportedly causes less sedation than diphenhydramine. After resolution of the dystonic reaction, oral treatment should be continued for an additional 24 to 48 hours to prevent recurrences.

Plants/Mushrooms

Plant Toxicity

Plants are among the more commonly reported accidental ingestions in children. Most such ingestions involve common house and garden plants. Fortunately, of the many varieties of such plants, only a small fraction pose a serious toxic hazard (Table 88.15 and Table 88.16).

Table 88.15. Common Nontoxic Plants

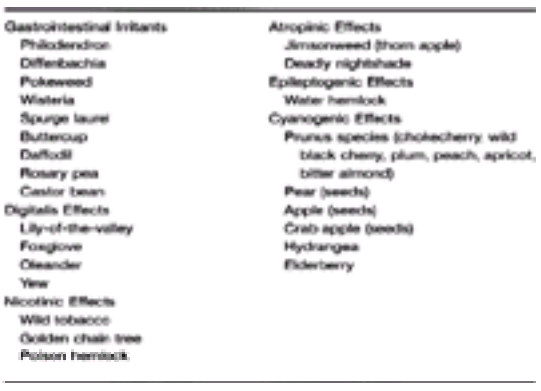

Table 88.16. Common Plant Toxidromes

When a child visits the ED after a plant ingestion, a general evaluation should be performed. Unless the plant can be identified absolutely and is known to be nontoxic, ipecac may be considered. Activated charcoal may also be extremely useful in adsorbing plant toxins. If the plant is subsequently identified and not believed to have serious toxic potential, or if the plant is not available (or recognizable) for identification, the child should be observed for a short period in the ED.

The child who remains asymptomatic may then be discharged and observed at home. Children who develop symptoms or for whom there is strong suspicion or confirmation that the ingested plant poses a potentially serious intoxication should be admitted for further observation and specific or supportive treatment.

Specific Categories of Plant Toxidromes

Plants with Gastrointestinal Irritation

Plants that cause GI irritation account for most plant poisonings in the United States. The range of symptoms extends from mild oral burning to a severe gastroenteritis syndrome. Representative species include *Philodendron* and *Dieffenbachia* species (leaves), which cause minor mouth and throat burning; pokeweed (roots, stem), Wisteria (seeds), spurge laurel (berries), buttercup (leaves) and daffodil (bulbs, accidentally substituted for onions), which cause severe vomiting, colicky abdominal pain, and diarrhea; and the toxalbumin-containing plants such as rosary pea and castor bean (seeds), which can cause a violent hemorrhagic gastroenteritis that leads to profound dehydration and circulatory collapse when the seeds are chewed up. The management of this group of ingestions consists essentially of fluid and electrolyte therapy.

Plants with Digitalis Effects

Several common garden or wildflowers contain digitalis, and they have been responsible for fatal ingestions. Instances of chewing on leaves or flowers or swallowing the berries of lily-of-the-valley, foxglove, squill, and oleander all have led to such poisonings. Intoxication has even occurred when water from a vase that contained these flowers was ingested. Early after ingestion, the child may complain of intestinal symptoms such as mouth irritation, vomiting, and diarrhea. As the digitalis is absorbed, typical digitalis effects may ensue, with conduction defects and, at times, serious arrhythmias. Treatment may include administration of digoxin-specific antibody fragments as was previously discussed (p. 908).

Plants with Nicotinic Effects

Several species of plants contain nicotine or closely related alkaloids. Ingestion of wild tobacco (leaves), golden chain tree (seeds), and poison hemlock (leaves, seeds) usually leads to spontaneous vomiting within 1 hour. Salivation, headache, fever, mental confusion, and muscular weakness may follow, and the child may deteriorate to convulsions, coma, and death from respiratory failure. Charcoal is especially useful in adsorbing these nicotinic alkaloids. Further treatment consists of intensive supportive care, with anticonvulsants and ventilatory assistance.

Plants with Atropinic Effects

The most common atropine-containing plant in the United States is jimsonweed, which is widely distributed. Cases most commonly occur in rural areas but have been seen in inner-city children who managed to find this weed growing in their neighborhoods, where flora in general is scarce.

Symptoms and signs are those of atropinization (Table 88.7) and include visual blurring, dilated pupils, dryness of the mouth, hot, dry skin, fever, delirium, and psychosis. Convulsions and coma may follow. Treatment consists of supportive care and, in severe cases, physiologic antagonism with physostigmine (Table 88.4).

Plants That Cause Convulsions

Convulsions represent the principal toxic effect of some plants. Water hemlock, with its potent cicutoxin, is the main species to cause convulsions in the United States. Within 1 hour after ingestion, nausea, vomiting, and profuse salivation occur. These initial symptoms are followed by tremors, muscle rigidity, and multiple major motor seizures. Treatment is with anticonvulsants, as for status epilepticus (see Chapter 70 and Chapter 83).

Plants That Contain Cyanogenic Glycosides

Many plants and particularly fruit seeds (pits) contain the cyanogenic glycoside amygdalin (Table 88.16). Symptoms and signs after ingestion are those of cyanide poisoning, with resultant cellular hypoxia. Initially, there is CNS stimulation and headache, with tachypnea, hypertension, and reflex bradycardia. Anxiety and excitation may progress to opisthotonus and seizures. Respiratory depression, with cyanosis, tachycardia, and hypotension, follows. An odor of bitter almonds may be detected. Treatment is initiated with 100% oxygen and cardiopulmonary resuscitation (CPR) as necessary. Antidotal therapy with amyl nitrite, sodium nitrite, and sodium thiosulfate is administered as detailed in Table 88.9 and in Chapter 132.

Mushrooms

Mushrooms cause an estimated 50% of all deaths from plant poisoning in the United States. The difficulty in accurate identification of mushrooms makes reliance on such identification for appropriate management of ingestions extremely hazardous in the ED. Rather, the approach advocated by Lampe is reviewed here.

Two main groups of mushrooms can be characterized on the basis of the time interval between ingestion and symptom onset: those with the immediate onset of symptoms and those with delayed onset. Regardless of the mushroom, the initial management for all suspected poisonings includes activated charcoal and catharsis.

Onset of symptoms within 6 hours of ingestion usually confers a benign prognosis, although careful attention to fluid and electrolyte management is critical. Most mushrooms have GI effects. There are five general classes of mushrooms in this group, each possessing a unique toxicologic feature. Some “early-onset” mushrooms cause muscarinic effects, usually

within 15 minutes, such as sweating, salivation, colic, and pulmonary edema. This syndrome responds to atropine therapy. Other early-onset mushrooms cause anticholinergic effects, including drowsiness, followed by mania and hallucinations. Another subgroup of early onset mushrooms produces a severe gastroenteritis syndrome. Hallucinogenic mushrooms such as psilocybin make up another class of mushrooms with early-onset symptoms. Finally, some mushrooms precipitate an Antabuse reaction if they are coingested with alcohol. Management for all these agents consists of supportive care and careful monitoring of fluid status.

The second, more important, category of mushrooms that are responsible for 90% of mushroom-related deaths are those associated with onset of symptoms that occur more than 6 hours after ingestion. The most important members of this group are those mushrooms that belong to the *Amanita phalloides* species. With these mushrooms, after a latent period of many hours, GI upset appears. Approximately 24 hours after ingestion, hepatic dysfunction appears, which results in fulminant hepatic failure. Without liver transplantation, such victims generally die.

Two compounds are known to produce the toxic effects of *A. phalloides.* Phallotoxin acts first, causing GI symptoms, including nausea, vomiting, abdominal pain, and diarrhea. Fever, tachycardia, and hyperglycemia may also occur during this stage. The other toxin, amatoxin, causes renal tubular and hepatic necrosis.

Treatment of the gastroenteric phase includes fluid and electrolyte replacement. If renal failure develops, dialysis may be necessary. Hepatic damage after *A. phalloides* ingestion may be attenuated by early use of repetitive activated charcoal, which appears to interrupt enterohepatic recirculation of amatoxin.

Additional therapies have shown mixed results in the treatment of *A. phalloides* poisoning. High-dose penicillin, cimetidine, thioctic acid, prophylactic charcoal hemoperfusion, and other modalities await further investigation. A regional poison control center may offer guidance with experimental therapies, but multiple-dose activated charcoal and vigorous attention to supportive care remain the standard.

In management of mushroom ingestions in which the specific mushroom cannot be identified, GI decontamination, including activated charcoal, should always be provided. Identification of the agent may be possible through consultation with a local mycologist, although mushroom cohabitation makes identification uncertain even if a fragment of mushroom is brought for direct inspection.

Theophylline

Theophylline was once the primary agent in the treatment of reactive airway diseases, including asthma. Since the advent of specific b-adrenergic agonists, however, it has become less widely used. Nonetheless, theophylline continues to be commonly prescribed for asthma, as well as for neonatal apnea. Because of its narrow therapeutic index, theophylline also continues to be a common cause of intoxication. In overdose, it may lead to clinical toxicity, including nausea, vomiting, muscle tremor, electrolyte disturbances, hypotension, cardiac arrhythmias, seizures, and death.

Theophylline has many physiologic actions, including bronchodilation, respiratory stimulation, diuresis, and augmented cardiac output. However, its exact mechanism of action remains uncertain. Formerly thought to act through inhibition of the enzyme phosphodiesterase, thereby potentiating intracellular activity of cAMP, current evidence indicates that this is not the case. More recent theories suggest that theophylline acts as an antagonist at adenosine receptors. These receptors are found on bronchial smooth muscle, in the CNS and on the myocardium.

The pharmacokinetics of theophylline are complex and responsible for many of the drug-disease or disease-disease interactions that so often result in accidental intoxication. Metabolism of theophylline is by the hepatic mixed function oxidases (cytochrome P-450), with the production of inactive metabolites. The metabolic rate is subject to considerable variability based on factors such as age (with neonates having significantly longer elimination half-lives compared with children and adolescents), viral illness (which may decrease P-450 activity), concomitant medications (including erythromycin and cimetidine, both potent inhibitors of P-450 activity), and drug dose. Because theophylline has a Michaelis-Menten elimination pattern, increases in dose are associated with a reduction in elimination rate and greater risk of intoxication.

To a limited extent, clinical manifestations of theophylline toxicity correlate with serum theophylline concentration. The therapeutic theophylline level is 10 to 20 µg/mL, although, even in this range, signs of toxicity such as nausea and vomiting may be present. With serum levels of 20 to 50 µg/mL, toxicity generally consists of nausea, vomiting, and muscle tremor. When theophylline exceeds 60 to 70 µg/mL, severe toxicity appears with the development of seizures and arrhythmias. However, this correlation only exists for those patients with acute, single overdoses of theophylline rather than those with chronic intoxication. Because differences in toxic manifestations appear between acute and chronic theophylline intoxication, it is necessary to determine the method of intoxication as soon as this poisoning is recognized.

In addition to the clinical manifestations, theophylline may cause a number of metabolic disturbances, including hyperglycemia, hypokalemia (with serum potassium as low as 2.2 mEq/L), metabolic acidosis, hypercalcemia, and hypophosphatemia.

Management

Emergency management of theophylline intoxication begins with rapid assessment of vital signs. If seizures are present, airway protection may be necessary, followed by the administration of anticonvulsants (see Chapter 83). Preferred anticonvulsants with theophylline poisoning are benzodiazepines and barbiturates. Blood pressure is typically low with theophylline poisoning. If there is significant hemodynamic compromise, fluid administration followed by vasopressor support may be necessary (see Chapter 3). Cardiac monitoring should be provided immediately; arrhythmias are treated according to standard protocols (see Chapter 1 and Chapter 82).

GI decontamination is important after acute theophylline overdose because sustained-release preparations often lead to delayed peak absorption. Activated charcoal has an important role in the treatment of theophylline poisoning, and antiemetics should be administered aggressively to permit charcoal retention. Antiemetics may include metoclopramide or ondansetron. In addition, ranitidine, which reduces gastric secretions, may reduce vomiting. Phenothiazines are relatively contraindicated because they may lower seizure threshold. For the patient with significant overdose of sustained-release preparations or increasing serum theophylline levels despite adequate initial GI decontamination, use of WBI may be valuable (p. 894).

Laboratory assessment should include electrolytes, blood glucose, urinalysis, and theophylline level. A complete toxin screen should be obtained if coingestants are suspected. Because of the unpredictable absorption pattern that follows overdoses of sustained-release preparations, serial theophylline concentrations (every 2 to 4 hours) should be obtained until a plateau has been identified.

There are several methods of enhancing theophylline elimination. Activated charcoal, through GI dialysis, is capable of enhancing fecal elimination of theophylline; it is highly effective even if theophylline intoxication is the result of IV administration. Therefore, the foundation of treatment is repeated doses of oral charcoal (0.5 to 1.0 g/kg), every 2 to 4 hours. This regimen generally requires coadministration of antiemetics. In addition to multiple-dose activated charcoal, both hemodialysis and hemoperfusion are highly effective at removing theophylline. Hemoperfusion is the preferred procedure because it increases theophylline elimination fourfold to sixfold. However, because it is not widely available, hemodialysis is an acceptable alternative, capable of doubling theophylline clearance. These procedures appear to be effective only as prophylactic measures; if they are performed before the appearance of seizures or arrhythmias, they can prevent their occurrence. However, if they are initiated after seizures or arrhythmias develop, they do not clearly alter clinical course. The indications for hemoperfusion or hemodialysis in otherwise healthy children are generally considered to be 1) serum theophylline level greater than 80 to 100 µg/mL in the patient with acute theophylline poisoning; 2) serum theophylline level greater than 40 µg/mL in the patient with chronic theophylline poisoning; or 3) severe toxicity unresponsive to supportive measures, regardless of serum concentration. All patients who meet these criteria should be admitted to the intensive care unit or referred to a tertiary care medical center for intervention and close observation.

Tricyclic Antidepressants

Background

The ingestion of tricyclic antidepressant compounds is a significant problem in pediatric patients. The availability of these compounds in the household may be the result of therapy for depression for a parent or a grandparent or of treatment for enuresis in the patient or a sibling.

Clinical Findings

The ingestion of 10 to 20 mg/kg of most tricyclic antidepressants represents a moderate to serious exposure, with coma and cardiovascular symptoms expected. The ingestion of 35 to 50 mg/kg may result in death. Children have been reported to be more sensitive than adults to tricyclic antidepressants and often have symptoms at lower dosages.

Cyclic antidepressants have many pharmacologic effects. Anticholinergic activity causes altered sensorium and sinus tachycardia. a-Adrenergic blockade may lead to hypotension. However, the more severe cardiovascular effects are primarily caused by the membrane-depressant or quinidinelike effects that depress myocardial conduction and may lead to multiple focal premature ventricular contractions and ventricular tachycardia. It has been shown that a QRS interval over 0.1 second is associated with a significant morbidity and mortality in these patients; this delay in conduction may progress to complete heart block and cardiac standstill and/or the previously mentioned ventricular arrhythmias. Another typical electrocardiographic finding suggestive of cyclic antidepressant poisoning is the finding of an R wave of greater than 3-mm amplitude in the QRS complex in lead aVR.

Neurologic findings include lethargy, disorientation, ataxia, hallucinations, and with severe overdoses, coma, and seizures. Fever is commonly present initially, but hypothermia may occur later. Additional anticholinergic symptomatology includes decreased GI motility, which delays gastric emptying time, and urinary retention. Muscle twitching has been observed and may be associated with increased deep tendon reflexes. Although the pupils may be dilated, they usually respond to light.

Management

Severe tricyclic antidepressant overdoses require gastric decontamination. Lavage can be considered even for those patients who present as late as 4 to 12 hours after ingestion. Because tricyclic antidepressants decrease GI motility, unabsorbed drug may be left in the stomach for prolonged periods. Certainly, the administration of activated charcoal should be performed. Significant conduction delays or arrhythmias resulting from tricyclic antidepressants may benefit from alkalinization of the blood. A sodium bicarbonate bolus of 1 to 2 mEq/kg can be given during continuous ECG monitoring. Bicarbonate infusion can then be used to keep the serum pH at 7.45 to 7.55. These therapeutic maneuvers likely serve to decrease drug binding to the myocardium. Additional bolus doses of sodium bicarbonate may be required if the QRS interval is noted to widen. An additional benefit of the sodium cation may be to partially overcome the sodium channel blockade that is believed to represent the biomolecular substrate of the membrane depressant effect of these agents. If arrhythmias persist, appropriate antiarrhythmic therapy should be instituted, perhaps using lidocaine (see Chapter 1 and Chapter 82). Quinidine or procainamide should be avoided because each may increase heart block in this situation. Physostigmine, although previously recommended for its antidotal effects on the anticholinergic aspects of these poisonings, has the potential to worsen ventricular conduction defects and to lower the seizure threshold. Its use is currently considered to be contraindicated in cyclic antidepressant overdoses. In the presence of hypotension, many clinicians have advocated the use of norepinephrine infusions (0.1 to 0.3 µg/kg per minute). This is based on the

observation that the hypotension is the result of norepinephrine depletion secondary to the block of catecholamine uptake caused by tricyclic antidepressants. Other clinicians have reported that dopamine is as effective; however, the occurrence of ventricular arrhythmias has been reported with dopamine. During the recovery period, serum electrolytes should also be monitored because the infusion of bicarbonate may cause hypokalemia, which may aggravate tricyclic antidepressant-induced cardiac arrhythmias. It must be remembered in the treatment of such antidepressants that these compounds have long half-lives and slow elimination rates; therefore, the therapy for these ingestions is often protracted and intensive.

Other Antidepressants

Besides the trycyclic antidepressants, numerous agents designed to elevate mood are prescribed. The chemical structure of these agents and their profile of toxicity are diverse. Major groupings of nontricyclic antidepressants include 1) the selective serotonin reuptake inhibitors (SSRIs) (e.g., fluoxetine, sertraline), 2) the monoamine oxidase inhibitors (e.g., phenelzine, tranylcypromine), and 3) other atypical antidepressants (e.g., amoxapine, venlafaxine, bupropion).

SSRIs most commonly produce CNS depression in overdose. Seizures may occur after large ingestions. Life-threatening events from acute overdose of these compounds rarely occurs. The serotonin syndrome, manifested by muscular rigidity, myoclonus, flushing, and autonomic instability, more typically occurs as the result of drug interaction and is potentially lethal. Amoxapine has anticholinergic activity but is best known for its convulsant properties and the tendency for victims to present with status epilepticus. Bupropion, prescribed perhaps most commonly in smoking cessation programs, prevents reuptake of biogenic amines and is also seizurogenic. The a-adrenergic antagonism of trazodone may lead to hypotension.

The monoamine oxidase inhibitors (MAOIs), although pharmacologically effective and therapeutically important, are some of the most toxic medications known. Acute single overdoses of as little as 6 mg/kg have been associated with a fatal outcome. In addition, because of their irreversible inhibition of the enzyme monoamine oxidase, which is responsible for the degradation of most biogenic amines, MAOIs possess several important interactions with foods and other medications that can lead to severe toxicity, even in the patient who takes them in appropriate doses. There are three important clinical pictures of MAOI toxicity. First, because GI tract activity of monoamine oxidase is also inhibited by these drugs, patients who take them appropriately and then ingest foods or drugs that contain biogenic amines (e.g., tyramine in wines, cheese, or soy sauce and decongestants) may develop severe hypertension with headache, seizures, or stroke. The second picture of MAOI toxicity appears when those who take the drug therapeutically are given certain sympathomimetic or serotonergic agents causing the serotonin syndrome. Important examples of such drugs include common agents in OTC cough and cold preparations such as dextromethorphan, analgesics such as meperidine, and psychotropic medications such as clomipramine and fluoxetine or other SSRIs. In these patients, this drug combination may quickly lead to hyperpyrexia, skeletal muscle rigidity, cardiac arrhythmias, and death. This is one of the few fatal drug interactions known. Finally, those with acute MAOI overdoses develop a clinical syndrome that includes blood pressure instability, hyperpyrexia, skeletal muscle rigidity, seizures, and death.

Because of the toxicity of these agents and the frequent delay in their onset of activity (up to 24 hours), all patients with a history of MAOI ingestion, regardless of symptoms, should be admitted to the hospital for 24 hours. Management of the patient with MAOI toxicity is largely dictated by the specific toxic manifestations. In those with hypertensive reactions, treatment consists of the immediate administration of an antihypertensive. The ideal agent may be nitroprusside because its brief duration of action permits titration of effect. In the treatment of hyperpyrexia, cooling measures are promptly instituted. Because hyperpyrexia is often accompanied by skeletal muscle rigidity and rhabdomyolysis, serum creatine kinase should be measured and close attention should be paid to the urine for any signs of myoglobinuria. Benzodiazepines are often helpful in this situation and neuromuscular blockade may be beneficial in patients who have severe muscle rigidity with hyperthermia. In the patient with acute overdose, treatment is directed to hemodynamic stability. Because blood pressure changes occur quickly and consist of hypotension and hypertension, hypertension should be treated with short-acting agents (see Chapter 35) and hypotension with fluid and vasopressor support (see Chapter 3). Intensive care unit admission is mandatory for these patients because of their clinical instability.

Drugs Dangerous in Small Doses

Toddlers often are brought to EDs for evaluation after possibly having ingested one or two doses of a medication. This can be a particularly vexing problem. Most often these children will be fine with little treatment beyond reassurance. There are circumstances, however, when this situation can be life-threatening and proper intervention can be lifesaving. A large list of chemicals and poisons can be extremely toxic in small amounts, and that is beyond the scope of this discussion. However, it is wise to be familiar with a modest list of pharmaceuticals that may cause dangerous toxicity to young children with just one or two doses (Table 88.17). Many of these agents have been discussed earlier in this chapter. The actual incidence of life-threatening toxicity of each of these drugs, when just one or two doses has been ingested, is as yet undefined.

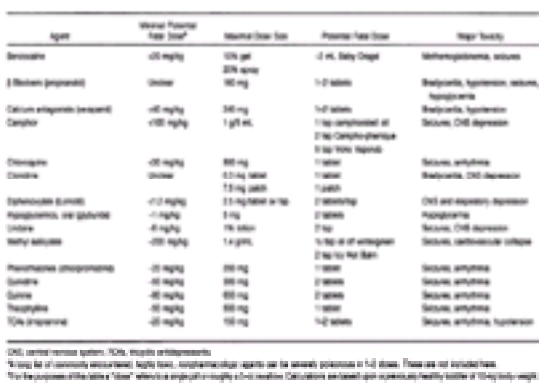

Table 88.17. Medications Dangerous to Toddlers in 1–2 Doses [a]

A systematic approach to these patients includes a careful history, an examination with attention to the presence of toxidromes (Table 88.5), and a guided laboratory assessment. This approach may allow narrowing of the differential diagnosis and may allow a determination of the possible severity of the ingestion. If the differential diagnosis includes any of the drugs listed in Table 88.17, it may be prudent to provide decontamination and prolonged observation. An algorithmic approach to this situation is provided in Figure 88.7.

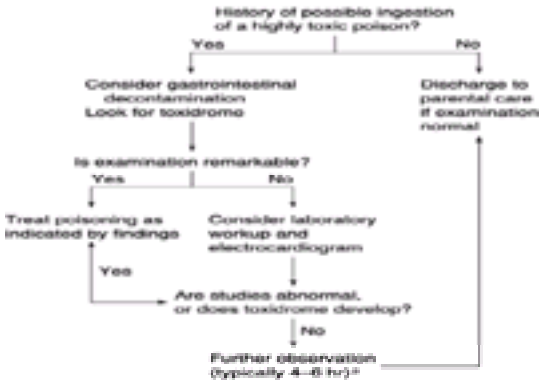

FIGURE 88.7. Algorithmic approach to toddler having ingested 1 to 2 doses (1–2 pills or 5–10 cc swallow) of a drug. [a]Medications notorious for their ability to have delayed onset in toxicity, beyond 4–6 hours, include oral hypoglycemic agents, sustained-release preparations, monoamine oxidase inhibitors, drugs taken concomitantly with anticholinergic agents, and acetaminophen.

SUBSTANCE ABUSE

As a special category of pediatric toxicology, exposures to psychoactive drugs is outlined in this section. In a discussion of substance abuse, three distinct age populations in the pediatric group may be placed at risk from such exposures: 1) the adolescent or preadolescent who abuses drugs for their mind-altering effects (and, in the case of females, may do so when pregnant); 2) the neonate who is exposed to substances of abuse during gestation and manifests signs of intoxication or abstinence after birth; and 3) the infant or toddler who becomes exposed to drugs of abuse either through active administration by a caretaker (“chemical child abuse”), the ingestion of a drug left in an accessible place (e.g., the coffee table), or passive exposure created by being in an environment where drugs of abuse are used (e.g., marijuana, cocaine, PCP, methamphetamine). In any of these circumstances, the exposure can be sufficient to produce severe intoxication. Thus, knowledge of the epidemiology and manifestations of substance abuse become important in the management of children of all ages.

Further discussion regarding the general phenomenon of chronic adolescent drug abuse and addiction, including alcoholism, is found in Chapter 130.

Clinical Manifestations

The drug-abusing child or adolescent may present to the ED after an accidental overdose, a suicidal gesture, suicide attempt, sudden bizarre behavior, or after multiple trauma (e.g., assault, motor vehicle accident). Often, the history of drug exposure is undeclared and may not be diagnosed unless there is a high index of suspicion and appropriate diagnostic tests are performed. In such cases, the patient's mental status can range from fully awake and responsive to comatose; physical examination can be without any signs of drug exposure or with overt signs of toxicity (e.g., seizures). Table 88.18 provides a summary of the common drugs of abuse, their typical routes of administration, associated symptoms, toxic levels, and duration of action.

Table 88.18. Drug Abuse: Summary of Toxicity

Initial history from patient, family, or friends must specify drugs taken and estimate quantities when a history of exposure is given. In the absence of a history of exposure, it is important to inquire whether the patient has a history of any psychoactive drug abuse. In many cases, the patient may admit to using a drug but may identify it by a street name. Although drug terminology tables are often available in pharmacology or toxicology texts or on the Internet, temporal and regional changes in street drug terminology generally make such tables of limited value.

Management

Primary attention is paid toward assessment of vital signs and life support as needed to provide a patent, secure airway; to ensure adequate respiratory function; and to treat seizures, shock, or cardiorespiratory arrest. A key but often overlooked feature in the assessment of such patients is an accurate temperature because many drug intoxications are associated with hyperpyrexia. If there is any suspicion of hyperthermia, a rectal temperature must be obtained. In the agitated patient, physical and/or chemical restraint may be necessary to obtain vital signs. Chemical restraint should be used liberally to prevent the patient from harming himself or others. The preferred agents in such cases are diazepam (0.1 to 0.3 mg/kg IV) or midazolam (0.05 to 0.1 mg/kg IV). Haloperidol (0.05 mg/kg) given intramuscularly is also effective but reduces heat-dissipating capability and lowers the seizure threshold.

Management must also include consideration of the need for GI decontamination. It is common with psychoactive drug use that several distinct routes of exposure are possible (e.g., ingestion, inhalation, injection, nasal insufflation). Therefore, GI decontamination is not always necessary or appropriate. However, because those who abuse drugs almost invariably use more than one drug, decontamination must be performed if there is any possibility of an ingestion. In the event that decontamination seems appropriate, assessment of the patient's mental status and gag reflex must be performed; in the presence of obtundation or a diminished gag reflex, airway protection by endotracheal intubation should be accomplished before decontamination measures.

Disposition

In the case of the adolescent who presents with intentional drug abuse, after initial assessment and medical stabilization, an evaluation must be made of the severity of the drug use problem. This is accomplished through discussion with the parents or caretakers. Although issues of patient confidentiality may require the physician to provide limited information to parents, obtaining a thorough psychosocial evaluation is necessary for complete management of the acute event. Such discussions may require or may be facilitated by an interview with a social services or psychiatry consultant. Once the severity of the drug problem has been established, referral to a treatment program should be discussed. Primary care physicians may be comfortable managing those patients who have no long-standing histories of drug abuse. Compulsive users or anyone who presents with a drug abstinence syndrome must be referred for intensive rehabilitation. Family therapy often is a component of this rehabilitation.

SPECIFIC DRUGS

The major categories of drugs of abuse that require the physician's familiarity with the whole spectrum of their physiologic effects are 1) hallucinogens (phencyclidine, lysergic acid diethylamide [LSD], marijuana), 2) stimulants (amphetamines, cocaine), 3) central anticholinergics, 4) sedatives (benzodiazepines, barbiturates), 5) opioids (morphine, codeine, heroin, methadone), 6) inhalants, and 7) alcohol. (Acute alcohol overdose is discussed in the previous section; chronic alcoholism in teenagers is discussed in Chapter 130.)

Hallucinogens (Psychedelics)

No single characteristic distinguishes psychedelics from other classes of centrally active drugs such as anticholinergics, cocaine, and amphetamines. All of these drugs can produce a number of mental status changes, including illusions, hallucinations, delusions, and paranoid ideation. However, the psychedelic state is described as consisting of vivid and unusual visual experiences with diminished control over what is experienced. Images and sensations take on profound meaning, and the ability to differentiate oneself from the environment is decreased. Most drugs in this category are related to the indolealkylamines (e.g., LSD, psilocybin, dimethyltryptamine, and diethyltryptamine), to the phenylethylamines (mescaline), or to phenylethylamines (methylenedioxymethamphetamine MDMA, Ecstasy]).

Phencyclidine (Angel Dust)

Identification

PCP was developed in the 1950s as a general anesthetic. It rapidly fell into disuse because of disturbing emergence syndromes that developed in postoperative patients. Sporadic abuse occurred in the 1960s, but its popularity peaked in the 1970s. The drug remains common in several metropolitan areas and a similar agent, ketamine, is finding increased popularity. PCP is easily synthesized and is often sold on the streets misrepresented as LSD, mescaline, or marijuana. It is well absorbed across all mucous membranes and is most popularly used by inhalation (often mixed into cigarettes or marijuana “joints”), but it can be ingested, injected, or insufflated.

Chemically, PCP is an arylcyclohexylamine. This group of drugs has a range of CNS actions that range from hallucinations with smaller doses, to stimulation with moderate doses (occasionally associated with seizures), to profound CNS depression with respiratory arrest with large doses.

Pharmacodynamics

There is great variability in the metabolism of PCP. In general, 0.1 µg/mL is considered a toxic serum level. One cigarette

may contain 1 to 100 mg. A dose of 5 to 10 mg may produce stupor and coma; with doses exceeding 10 mg, respiratory depression and convulsions occur. A fatal dose is in the range of 1 mg/kg. Because PCP has a long elimination half-life (18 hours), clinical symptoms may last for more than 12 hours; also, patients may have cyclic symptoms because the drug is enterogastrically recirculated.

Pharmacologically, PCP acts as a dissociative anesthetic, meaning that it interferes potently with association pathways that link the cerebral cortex with deeper structures in the brain, thus diminishing the ability to integrate sensory input into meaningful behavior. Its anesthetic actions also lead to a marked diminution of pain sensation. In conjunction with bizarre behavior, this often leads victims to have feelings of invulnerability and to attempt life-threatening actions (e.g., stepping into automobile traffic).

Clinical Symptoms

Small doses of PCP produce signs and symptoms of inebriation with staggering gait, slurred speech, and nystagmus (vertical or rotatory). Users may also be diaphoretic and have catatonic muscular rigidity with a blank stare. Having sympathomimetic actions, it is often associated with hypertension and tachycardia. Moderate doses cause other signs of intoxication, including hypersalivation, pyrexia, repetitive movements, and muscle rigidity. Larger doses can cause seizures, coma, or respiratory arrest. The typical “high” from a single dose lasts 4 to 6 hours and is followed by an extended “coming-down”; PCP-induced psychotic states may be long lasting and may recur (“flashbacks”). Tolerance develops to the behavioral and toxic effects of the drug. Chronic users report persistent difficulties with recent memory, speech, and thinking that last from 6 months to 1 year after the last dose; they also may be left with personality changes such as withdrawal, isolation, anxiety, nervousness, and depression.

Management

PCP is easily detected through a qualitative analysis of urine. Serum levels are rarely available and do not correlate with clinical manifestations. Therefore, management must often be based solely on a history of exposure or index of suspicion. Initial treatment is directed at stabilizing vital signs and treating life-threatening events such as seizures. If exposure is the result of ingestion, GI decontamination should be performed by administration of activated charcoal. A quiet room may be helpful, although the ability to monitor the patient cannot be compromised. Physical restraints should be avoided if possible because they may lead to significant rhabdomyolysis with resulting myoglobinuria and renal injury. For chemical restraint diazepam (0.1 to 0.3 mg/kg IV) or lorazepam (0.1 mg/kg IV) may be effective, although a major tranquilizer (e.g., haloperidol) is often necessary.

Although urine acidification (pH below 5.0) enhances the urinary excretion of PCP, it should never be performed in these patients because it exacerbates metabolic acidosis and may promote deposition of myoglobin in renal tubules. In a review of 27 confirmed cases of PCP poisoning, 3 patients developed rhabdomyolysis and 2 progressed to acute renal failure. Both patients had received acidification measures before diagnosis. If tests for muscle enzymes and/or renal function are abnormal and the urine has a positive test for hemoglobin without red blood cells, the patient should be assumed to have rhabdomyolysis and should be treated accordingly (see Chapter 86).

LSD (Blotter, Acid)

Pathophysiology

LSD and related psychedelic drugs such as psilocybin, mescaline, and dimethyltryptamine (DMT) have actions at multiple sites in the CNS (from the cortex to the spinal cord). In addition, dozens of congeners of these agents exist in mushrooms or have been synthesized, and they also cause signs and symptoms similar to LSD. The pharmacologic action that these drugs seem to have in common is as agonists of presynaptic serotonin-2 receptors (which modulate serotonin release into the synaptic cleft). These agents all have structural similarities to serotonin (5-hydroxytryptamine).

Pharmacodynamics

In humans, the somatic symptoms of dizziness, weakness, drowsiness, nausea, and paresthesias may be observed after one oral dose of 0.5 to 2 µg/kg. Between the dose range of 1 to 16 µg/kg, the intensity of LSD's psychoactive effects is proportional to the dose. A typical LSD “hit” is 200 to 400 µg. A high degree of tolerance to the behavioral effects develops after three to four daily doses, with sensitivity returning after a drug-free interval. Deaths directly attributable to LSD are virtually unknown, although fatal accidents and suicides have occurred during states of intoxication.

Clinical Symptoms

In general, the somatic effects of hallucinogens are sympathomimetic and include pupillary dilation, hypertension, tachycardia, hyperreflexia, and hyperpyrexia. Doses as low as 20 to 25 µg can produce CNS effects such as euphoria, visual perceptual distortions, alteration of subjective time so that time passes slowly, lability of mood, or even an acute panic episode. Hallucinations and psychosis with hyperalertness are commonly seen. The clinical duration of action of LSD is somewhat dose dependent but averages 6 to 12 hours. The psychedelic state includes a heightened awareness of sensory input, often accompanied by an enhanced sense of clarity but a diminished control over what is experienced. There is often a feeling that one part of the self is a passive observer while another part receives vivid sensory input. The ability to separate one object from another or to separate self from the environment is diminished. There is an enhanced sense of oneness with mankind or the cosmos.

Management

LSD intoxication is rarely associated with life-threatening events. However, vital signs should be assessed to ensure that

the patient is stable and in the event there has been drug coingestion.

Because LSD is ingested in minuscule doses and onset of symptoms occurs hours after ingestion, GI decontamination is unnecessary, unless coingestion is suspected.

Clinical management involves placing the patient in a quiet room. Someone who knows the patient may be able to quietly “talk down” and reassure the patient. The patient's loss of boundaries and fear of fragmentation or self-disintegration create a need for a structuring or a supportive environment. Both benzodiazepines (e.g., diazepam 0.1 to 0.3 mg/kg IV or midazolam 0.05 to 0.1 mg/kg IV) and haloperidol 0.05 mg/kg IM are effective tranquilizers in the event that anxiety or agitation persists.

Marijuana (Pot, Reefer, Smoke, Grass, Hemp)

Pathophysiology

With the exception of ethanol, marijuana remains the most popular psychoactive drug of abuse. It is typically sold in “nickel” bags that produce two to three joints. Marijuana is occasionally laced with other psychoactive substances, including PCP and cocaine. Hashish is the concentrated resin of marijuana.

The flowering tops of the female marijuana plant contain the highest concentration of the active constituent, tetrahydrocannabinol (THC). In the 1970s, most marijuana contained approximately 1 to 2% THC by weight. Recently, cultivated seedless varieties of marijuana (“sensimilla”) have become popular, and they contain 5 to 8% THC by weight. Therefore, a joint is now likely to lead to a greater degree of altered mental status than previously.

Within minutes of smoking this material, perceptual, behavioral, and emotional states become altered for several hours. Patients often have the appearance of inebriation with dysarthria and ataxia. However, violence, hallucinations, and agitation are uncommon after marijuana use.

Pharmacodynamics

It is estimated that no more than 50% of THC in a marijuana cigarette is actually absorbed. Pharmacologic effects begin immediately. In contrast, the onset of effects after ingestion occurs in 30 minutes to 1 hour, and peak effects may not occur until the second and third hours after ingestion; THC is three times more potent when smoked than when taken by mouth.

Clinical Symptoms

The most prominent effects in humans are on the CNS and cardiovascular system. In doses of up to 20 mg, THC produces effects on mood, memory, motor coordination, cognitive ability, sensorium, time sense, and self-perception. There is an increased sense of well-being or euphoria accompanied by feelings of relaxation or sleepiness when subjects are alone. With greater intake of THC, short-term memory is impaired, and the capacity to carry out tasks that require multiple mental steps to reach a specific goal deteriorates. This effect on memory-dependent, goal-directed behavior has been called temporal disintegration and is correlated with a tendency to confuse past, present, and future and with depersonalization, a sense of strangeness and unreality about one's self. Marijuana smokers often report a voracious appetite (“the munchies”), dry mouth and throat, more vivid visual imagery, and a keener sense of hearing. Altered time perception is a consistent effect of cannabinoids, so minutes seem like hours. Larger doses of THC can produce frank hallucinations, delusions, and paranoid feelings. Thinking becomes confused and disorganized. Anxiety that reaches panic proportions may replace euphoria, often as a feeling that the drug-induced state will never end. Because of the rapid onset of effects when marijuana is smoked, most users can regulate their intake to avoid the excessive doses that produce these unpleasant effects. Marijuana may cause an acute exacerbation of symptoms in stabilized schizophrenics. Cardiovascular effects include tachycardia, hypertension, and marked conjunctival injection. Chronic smoking of marijuana and hashish is associated with bronchitis and asthma, even though THC is a mild bronchodilator.

Infants and toddlers passively exposed to marijuana may develop profound lethargy or coma, occasionally with tachycardia.

Management

In general, the only treatment required is discontinuation of the drug. In the adolescent patient with a psychotic reaction or acute toxic delirium, a sedative such as diazepam, 5 to 10 mg by mouth or 0.1 mg/kg by IV, may be necessary. These acute symptoms should improve with drug abstinence over 4 to 6 hours.

Stimulants

Amphetamines (Crank, Speed)

Pathophysiology

Amphetamines have powerful CNS stimulant actions, in addition to peripheral adrenergic actions. Unlike epinephrine, amphetamines are effective after oral administration. However, they are often taken by injection and nasal insufflation. Amphetamines have been used medically to treat narcolepsy, obesity, fatigue, and nasal congestion. Several decongestant nasal inhalers continue to add amphetamine agents that may be extracted and ingested by drug-seeking adolescents. The pharmacologic effects of amphetamines include increased blood pressure, occasionally with a reflex slowing of heart rate, contraction of bladder sphincter, and dramatic CNS stimulation. Like other indirect

sympathomimetics, amphetamines act by releasing endogenous biogenic amines from the presynaptic neurons.

Methamphetamine is the most commonly abused of these drugs, reportedly because its greater lipid solubility is associated with more potent CNS effects.

Abuse patterns of amphetamines have changed in recent years because these drugs have begun to approach cocaine as widely abused stimulants. This increase has paralleled government interdiction efforts that have reduced the illegal entry of cocaine. Many drug users prefer amphetamines over cocaine because the clinical duration of action is considerably longer than that of cocaine. Also, a smokable form of methamphetamine (“ice”) has appeared, associated with more striking and prolonged alterations in CNS function. Finally, amphetamines have become a popular substance of abuse in pregnant women, leading to increases in neonatal intoxication or abstinence syndromes.

Pharmacodynamics

The therapeutic dose of dextroamphetamine in adolescents is typically 5 mg three times daily. The toxic dose is variable but is rarely less than 15 mg. Severe reactions have been reported at 30 mg, yet doses up to 400 to 500 mg may cause only mild symptoms. Tolerance is striking, with chronic users taking 10 to 15 g daily without ill effects. The elimination half-life of the amphetamines is about 3 hours, with much of the drug being excreted in the urine unchanged.

Clinical Symptoms

The psychic effect of amphetamines depends on the dose, mental state, and personality of the drug user. In general, 10 to 30 mg cause wakefulness, alertness, decreased sense of fatigue, and elevation of mood, with increased initiative, self-confidence, ability to concentrate, elation, euphoria, and increase in motor and speech activity. Physical performance in athletes may be improved. Prolonged use of large doses is followed by depression and fatigue. Amphetamines have an appetite-suppressant effect through an action on the lateral hypothalamic feeding center. However, tolerance to this effect also develops; thereafter, the effect is insufficient to reduce weight for a sustained period.

The acute toxic effects of amphetamine are usually extensions of its therapeutic actions. The central effects induce euphoria, restlessness, dizziness, tremor, hyperactive reflexes, talkativeness, irritability, weakness, insomnia, and fever. In addition, confusion, assaultiveness, anxiety, delirium, paranoid hallucinations, panic states, and suicidal or homicidal tendencies can occur, especially in patients who have underlying mental illnesses. However, these psychotic effects may occur in anyone who chronically abuses amphetamines. Cardiotoxic effects include palpitations, anginal pain, and rarely, hypertensive crisis or circulatory collapse. GI effects include anorexia, nausea, vomiting, diarrhea, and abdominal cramps. Severe overdoses may cause convulsions, coma, and cerebrovascular accidents. Both psychological and physical dependence occurs with chronic use. Chronic amphetamine abuse causes symptoms similar to many of those seen after acute overdose. The most common serious effect is a psychotic reaction with vivid hallucinations and paranoid delusions, often mistaken for schizophrenia. Recovery may or may not occur after withdrawal of the drug. In patients with persistent psychotic symptoms, it has been theorized that the amphetamine has hastened the onset of incipient schizophrenia. Chronic amphetamine abuse is also associated with the development of cerebral vasculitis.

An amphetamine derivative, methylenedioxymethamphetamine (MDMA or Ecstasy), has become popular among drug-abusing college students and may find its way into the high school scene. It is a drug with mildly hallucinogenic effects. In larger doses, it causes perceptual distortions, hallucinations, and agitation.

Management

Treatment of intoxication after ingestion of these agents should include GI decontamination. For severe agitation, specific treatment consists of administration of a benzodiazepine (e.g., diazepam 0.1 to 0.2 mg/kg IV) or haloperidol (0.01 to 0.05 mg/kg IM). Severe hypertension unresponsive to benzodiazepines may be treated with such agents as phentolamine, hydralazine, or IV sodium nitroprusside. Because up to 45% of amphetamines are excreted in the urine unchanged, ample fluids are beneficial.

Cocaine

Pathophysiology

Cocaine occurs in the leaves of *Erythroxylon coca* and other species of *Erythroxylon* trees indigenous to Peru and Bolivia, where the leaves have been used for centuries by the natives to increase endurance and to promote a sense of well-being. Chemically, cocaine is benzoylmethylecgonine. Ecgonine is an amino alcohol base closely related to tropine, the amino alcohol in atropine. Cocaine may be used by injection, inhalation (in the form of cocaine alkaloid or “crack”), nasal insufflation, and rarely, ingestion. Although ingestion is uncommon, there are two circumstances under which cocaine may be ingested in toxic quantities: the “body packer” and the “body stuffer.” In the body packer, large quantities of cocaine are enclosed in plastic and ingested in an attempt to smuggle the drug, usually across international boundaries. In the case of the body stuffer, the person in fear of being found with the substance suddenly ingests cocaine. Body stuffers are typically at greater risk of cocaine intoxication because they do not take sufficient care to guarantee that the cocaine does not leech from the bag.

Cocaine is reportedly used in up to 15% of women during pregnancy. This has led to epidemic increases in the number of “cocaine babies” who are often preterm, small for age, irritable, and show neurodevelopmental delay. Beyond the postnatal age, passive cocaine exposure in infants and toddlers has been associated with severe intoxication, including the development of convulsions.

Pharmacodynamics

The relief from fatigue that occurs with cocaine use results from central stimulation that masks the sensation of fatigue. Cocaine potentiates the excitatory and inhibitory responses of sympathetically innervated organs to norepinephrine and epinephrine by blocking the reuptake of catecholamines at adrenergic nerve endings. This explains why cocaine, unlike other local anesthetics, produces vasoconstriction and mydriasis. The most important pharmacologic action is its ability to block the initiation or conduction of the nerve impulse after local application. Cocaine is still widely used as a local anesthetic for ophthalmologic or otorhinolaryngologic procedures. It is also used as a topical anesthetic for laceration repair in the form of TAC (tetracaine, adrenaline, cocaine).

Although fatalities have been associated with cocaine doses as low as 30 mg, 1 to 2 g is generally the lethal dose in adults. Ingested cocaine is less toxic than that taken by other routes because of its prolonged absorption by this route. The elimination half-life of cocaine is approximately 1 hour. Cocaine metabolism is complex and consists of nonenzymatic degradation to form benzoylecgonine and metabolism by plasma cholinesterases to form ecgonine methyl ester. A small fraction of cocaine is also metabolized through the cytochrome P-450 enzymes to form norcocaine. People with congenital deficiencies in plasma cholinesterase are thought to have exaggerated responses to cocaine; cocaine abusers have been known to ingest inhibitors of cholinesterases or P-450 enzymes (e.g., organophosphate insecticides, cimetidine) to enhance the effect of the cocaine. Cocaine metabolites are readily detected in urine for approximately 3 days after exposure.

Cocaine is absorbed from all sites of application, including GI mucosa. Body-packing may lead to severe toxicity (seizures and cardiorespiratory collapse) if the container ruptures. If smuggling is suspected, a flat plate may show opaque densities within the bowel highlighted by a gas halo.

In addition to nasal application, cocaine can be used by injection or inhalation. The latter is called freebase (crack) and is a dangerous practice. In making crack, street cocaine (which is in the form of cocaine hydrochloride) is converted to cocaine alkaloid by removal of the salt moiety. This is accomplished by mixing the cocaine with water and sodium bicarbonate. The crack is then separated from the water by filtration and drying. The paste hardens and is cut into chips that resemble soap. It is then smoked in a pipe or sprinkled onto a cigarette or joint. A small piece, called a quarter rock, produces a 20- to 30-minute high when smoked in a water pipe. Probably because of its enhanced lipid solubility, crack crosses the blood–brain barrier rapidly, causing an intense rush of pleasure. This habit is highly addictive. Presently crack is primarily used by older teenagers and persons in their early twenties, in part because it is relatively inexpensive (approximately $5 to $10 per rock).

Clinical Symptoms

Cocaine's most dramatic clinical effect is CNS stimulation. In humans, this manifests in a feeling of well-being and euphoria, often accompanied by garrulousness, restlessness, excitement, and a sense of clarity. However, as the dose is increased, tremors, forced speech, agitation, and even tonic-clonic convulsions may result from excessive stimulation.

Initially, small doses (1 to 1.5 mg/kg) may slow the heart rate through central vagal stimulation. After moderate doses, pulse increases, the result of both central and peripheral adrenergic effects. Hypertension may appear abruptly and lead to cerebrovascular accidents. Fortunately, hypertension is generally short lived. Larger doses of cocaine may cause hypertension that may be followed quickly by cardiovascular collapse, often the result of myocardial ischemia and infarction. Myocardial injury that ranges from angina pectoris to massive infarction can be seen in young adults after acute cocaine exposure. With chronic cocaine use, a cardiomyopathy may develop that results in depressed cardiac function and death.

Rhythm disturbances are also characteristic of acute cocaine intoxication. These may consist of ventricular or supraventricular tachyarrhythmias and may be intractable. Arrhythmias are the most common cause of death after severe cocaine exposure.

Use of crack has been associated with a number of pulmonary disturbances, including bronchospasm, hemoptysis, pneumothorax, and pneumomediastinum. These are thought to result from the barotrauma associated with inhalation of hot, particulate matter, followed by a Valsalva maneuver.

Cocaine has been associated with other syndromes of organ dysfunction, including hyperpyrexia and renal failure. “Coke fever” (or pyrexia) is a common occurrence after acute cocaine use. It is often associated with muscle rigidity (resembling neuroleptic malignant syndrome) or rhabdomyolysis (the result of agitation and/or physical restraint). Rhabdomyolysis may go on to induce myoglobinuric renal failure if not promptly recognized and treated.

Infants exposed to cocaine may also exhibit CNS excitation that includes hyperactivity, dystonic posturing, altered mental status, or frank seizures.

Management

Among substances of abuse, cocaine is most likely to create the unstable patient with life-threatening manifestations. Therefore, this intoxication requires rapid, thorough assessment and management. Immediate attention should be paid to the vital signs, including temperature (which should be obtained rectally). The patient who develops seizures requires immediate airway control as well as anticonvulsant therapy. Benzodiazepines (e.g., diazepam 0.1 to 0.3 mg/kg) are considered the anticonvulsants of choice because of their rapid onset of action and because animal data have associated their use with decreased mortality from cocaine intoxication. Benzodiazepines should also be administered liberally to the patient with mild to moderate toxicity (agitation, hypertension, tachycardia) because of their efficacy in

reversing many of these clinical manifestations.

Because circulatory function can range from hypertensive crisis to cardiovascular collapse, early vascular access is important. Blood pressure instability should be anticipated and treated accordingly. For treatment of hypertensive crises, liberal benzodiazepine use may be combined with a short-acting antihypertensive (e.g., nitroprusside). Immediate treatment of hypertension is recommended because it may lead to cerebrovascular or myocardial injury. Cardiac arrhythmias are treated according to advanced cardiac life support protocols (see Chapter 1 and Chapter 82).

Hyperthermia must be recognized and treated promptly to prevent its complications. Management is discussed in Chapter 89. Diuresis should be induced if urinalysis is suggestive of myoglobinuria. Patients with CNS depression or a lateralizing neurologic examination should receive cranial tomography to rule out an intracranial vascular event.

Because cocaine is rarely ingested, the need for GI decontamination is confined to body packers/stuffers or when drug coingestion is suspected. With body stuffers, because bag leakage can lead to abrupt onset of severe intoxication and possibly death, activated charcoal should be administered immediately. Gastric emptying maneuvers and endoscopic removal of cocaine bags are relatively contraindicated because of the risk of bag rupture. Instead, decontamination is confined to administration of activated charcoal and WBI. Multiple-dose activated charcoal is recommended to maximize the opportunity for cocaine to be adsorbed by the charcoal. Because cocaine bags and crack vials are radiopaque in up to 50% of cases, an abdominal radiograph is recommended to determine the location and extent of retained packets after decontamination has been initiated. A contrast study may be considered to improve detection.

In the event of severe intoxication or ingestion of more than 1 to 2 g of cocaine, transfer to the intensive care unit is essential for appropriate monitoring.

Central Anticholinergics

Pathophysiology

Increasingly, drugs, plants, and mushrooms with anticholinergic properties are ingested for their psychoactive effects. Because compounds such as antidepressants, antihistamines, antispasmodics, and belladonna alkaloids are in widespread use, these are more readily available than illicit psychoactive substances. Also, many OTC drugs having anticholinergic activity are available without prescription and are ingested to get “high.” All of these agents are competitive antagonists with acetylcholine at the neuroreceptor site (Table 88.19). The major effects of these drugs are on the myocardium, CNS, smooth muscle, and exocrine glands. These effects include tachycardia, mydriasis, facial flushing, hyperpyrexia, cardiac arrhythmias, urinary retention, dry mucous membranes, decreased sweating, and decreased or absent bowel sounds. CNS effects include delirium, anxiety, hyperactivity, visual hallucinations, illusions, and disorientation. These signs and symptoms lead to the common mnemonic, “Mad as a hatter, red as a beet, dry as a bone, blind as a bat, and hot as Hades.” In excess, anticholinergics may lead to severe toxicity that includes cardiac arrhythmias, seizures, and death.

Antidepressants: amitriptyline (Elavil), imipramine (Tofranil), doxepin (Sinequan, Adapin)
Antihistamines: chlorpheniramine (Ornade, Teldrin), diphenhydramine (Benadryl), orphenadrine (Norflex)
Ophthalmologic Preparations: cyclopentolate (Cyclogel), tropicamide (Mydriacyl)
Antispasmodic Agents: propantheline (Probanthine), clidinium bromide (Librax)
Antiparkinson Agents: trihexyphenidyl (Artane), benztropine (Cogentin), procyclidine (Kemadrin)
Proprietary Drugs: Sleep-Ezs (scopolamine, methapyrilene), Dominex (scopolamine, methapyrilene), Asthma-Cor (belladonna alkaloids), Excedrin-PM (methapyrilene)
Belladonna Alkaloids: Atropine, homatropine, hyoscine, hyoscyamus, scopolamine
Toxic Plants: Mushroom (*Amanita muscaria*), bitter-sweet (*Solanum dulcamara*), Jimson weed (*Datura stramonium*), potato leaves and sprouts (*Solanum tuberosum*), deadly nightshade (*Atropa belladonna*)

Table 88.19. Drugs and Chemicals That May Produce the Central Anticholinergic Syndrome

Pharmacodynamics

The effects of anticholinergics vary according to the specific drug ingested, particularly because the many classes of drugs lead to secondary actions that are independent of anticholinergic actions. An important, universal anticholinergic effect, however, is decreased GI motility. This is associated with delayed absorption of drug and, if GI decontamination is not performed, the appearance of severe toxicity may be delayed 12 to 24 hours after ingestion.

Management

The management of a patient with a known central anticholinergic syndrome is a challenge, particularly because one must also be prepared for the other distinct toxicities of the ingested drug or plant. Also, most plants and many drugs are not detected on toxin screen, so the diagnosis must rely on history and clinical suspicion. Along similar lines, serum drug levels do not predict the degree of anticholinergic symptoms.

GI decontamination is essential after anticholinergic ingestion. Unlike most toxic ingestions, there is clear efficacy to decontamination 12 to 24 hours after ingestion because of the likelihood of drug persistence in the gut lumen for an extended time. Even gastric emptying may be effective for many hours after ingestion and should be considered for

patients who present within 4 to 8 hours of ingestion. Activated charcoal with a cathartic is added to enhance fecal expulsion of the drug-charcoal complex in the face of diminished gut motility.

Based on presenting signs and symptoms, the patient may require sedation, and monitoring in an intensive care unit setting to provide ventilatory support for coma, anticonvulsants for seizures, and antiarrhythmic drugs for cardiac arrhythmias. Adequate sedation may be achieved with titrated doses of benzodiazepines. Physostigmine, a potent anticholinesterase, is a recognized antidote for anticholinergic-induced mental status alterations; however, its use is controversial. Physostigmine can produce bronchospasm, bradycardia, hypotension, and seizures. It is therefore reserved for those who have normal ECGs and mental status dysfunction confined to hallucinations or severe agitation. The adult dose is 1 to 2 mg via slow IV infusion over 5 minutes. The trial dose can be repeated in 10 to 15 minutes up to a maximum of 4 mg. The pediatric dose is 0.5 mg administered slowly intravenously, with repeat every 10 minutes up to a maximum of 2 mg. The smallest effective dose may be repeated every 30 to 60 minutes if symptoms recur over 6 to 8 hours. The muscarinic toxicity of physostigmine may be treated with IV atropine at one-half the physostigmine dose given; physostigmine-related seizures may be treated with benzodiazepines.

Central Nervous System Sedative-Hypnotics

Pathophysiology

The sedative-hypnotics reversibly depress the activity of all excitable tissues. For most of these agents, CNS effects occur with little action on skeletal, cardiac, or smooth muscle. Uncommonly, serious depression in cardiovascular and other functions may occur. The prevalence of abuse of these agents was formerly exceeded by opioid abuse. However, with the increasing popularity of cocaine, these agents have become the preferred choice in treating cocaine-induced tension and anxiety. Many of these agents, including glutethimide, meprobamate, methaqualone, and barbiturates, are uncommonly available and have been replaced by the benzodiazepines. Because they have retained some popularity and still make periodic appearances on the streets, however, they should be included in discussions of such drugs.

Pharmacodynamics

The sedative-hypnotics have tranquilizing, euphoriant effects that may be similar to morphine. With all these agents—prescribed for this tranquilizing action—it is difficult to draw the line between appropriate use, abuse, habituation, and addiction. However, for all, tolerance is common and physical dependence quickly develops. Therefore, their abuse potential is considered high.

The pharmacologic characteristics of each drug are largely determined by their specific chemical nature. For example, all barbiturates are bound by plasma proteins. These characteristics have important implications in affecting their renal elimination and the effectiveness of extracorporeal drug removal techniques (hemodialysis, hemoperfusion).

For all sedative-hypnotics, patterns of abuse vary, ranging from infrequent sprees of intoxication to compulsive daily use. Introduction to these drugs may be through street use or drug trade (which is most common in adolescents), but, commonly, exposure is initiated through a physician's prescription to a parent for insomnia or anxiety. Because tolerance develops to most of the actions of these drugs, no signs of chronic use may be apparent.

Clinical Symptoms

After sedative-hypnotic use the adolescent may exhibit sluggishness, difficulty in thinking, dysarthria, poor memory, faulty judgment, emotional lability, and short attention span. Irritability and lability are common. With chronic use, these drugs also lead to dependence so that a picture of abstinence may appear after their disuse, with clinical manifestations of apathy, weakness, tremulousness, agitation, or frank convulsions. In its mildest form, the abstinence syndrome may consist only of rebound increases of rapid eye movement sleep, insomnia, or anxiety.

Management

With victims of acute sedative-hypnotic ingestion, attention should be directed to ensuring a patent airway and an intact gag reflex. Cardiovascular disturbances are rare after sedative use, but because of the possibility of drug coingestion, thorough hemodynamic assessment is necessary. Most sedative-hypnotics are detectable on comprehensive toxin screens so that specimens of serum and urine should be sent for analysis. GI decontamination should be considered and can typically be confined to administration of activated charcoal with a cathartic. Repeated doses of charcoal with cathartic have been shown to enhance clearance of certain barbiturates and benzodiazepines. Urinary alkalinization (p. 898) aids in the excretion of phenobarbital. In extreme cases, charcoal hemoperfusion should be considered.

Optional treatment of sedative overdose includes continuous monitoring in an intensive care unit with intubation and ventilator support as indicated. Flumazenil, a recently released benzodiazepine antagonist, can be administered in cases of suspected benzodiazepine ingestion. Its pediatric dose is 0.01 to 0.02 mg/kg IV. Indications for flumazenil administration may be 1) to reverse a witnessed, unintentional benzodiazepine overdose in a young child, or 2) to prevent airway intubation after an iatrogenic overdose. Flumazenil must not be given empirically in unknown or intentional overdoses for which induction of seizures may be life-threatening.

Opioids (Morphine, Codeine, Heroin, Methadone, Propoxyphene)

Pathophysiology

In the United States, three distinct groups who abuse opioids have been described: 1) those who are prescribed an opioid as medical treatment and then go on to become dependent and develop drug-seeking behaviors (this group

constitutes a minority of opioid abusers); 2) those who begin with recreational drug use and quickly progress to regular use; and 3) women who abuse opioids when pregnant. Such women and their offspring are at risk for a number of adverse pregnancy outcomes. For the patient who abuses opiates through injection (the most common route of abuse), other consequences include the risk of hepatitis, endocarditis, AIDS, and vasculitis.

The opioids produce their major effects by combining with receptors in the brain and other tissues. Effects include analgesia, drowsiness, change in mood, respiratory depression, decreased GI motility, nausea, and vomiting. The opiate receptors appear to be the normal sites of action of several endogenous opioidlike substances (e.g., the endorphins).

Pharmacodynamics

Generally, the toxic opioid dose for a person who is not addicted depends on the particular drug. For example, with morphine, clinical toxicity (excessive sedation) may appear with doses that exceed 5 mg in the adolescent. Tolerance rapidly develops to many CNS effects. However, death may occur as a result of marked respiratory depression and consequent anoxia. Other toxicities of opiates include (neurogenic) pulmonary edema, mast cell degranulation (which leads to histamine release and an “anaphylactoid” reaction), cardiac disturbances (with propoxyphene intoxication), and neurotoxicity with seizures (with meperidine intoxication).

Clinical Symptoms

Opioids invariably cause miosis, even after development of tolerance. Respiration may be depressed because of decreased responsiveness of brain stem respiratory centers to increases in carbon dioxide tension. Therapeutic doses of morphine have no effect on blood pressure or cardiac rate or rhythm. When blood pressure changes occur, they result from histamine release. Because histamine dilates capacitance blood vessels and decreases the ability of the cardiovascular system to respond to gravitational shifts, sitting or standing may produce orthostatic hypotension.

Many opioids have extensive effects on the GI tract. They decrease secretion of hydrochloric acid, GI motility, and pancreatic secretions while increasing colonic tone to the point of spasm. In addition, the tone of the anal sphincter is augmented. Therapeutic doses of morphine and codeine can also increase biliary tract pressure, producing epigastric distress and biliary colic.

Management

The presence of coma, pinpoint pupils, and depressed respiration should suggest opioid poisoning in the absence of history. The finding of needle marks on the body further suggests this diagnosis. To confirm the diagnosis, toxicologic analysis of urine and serum should be conducted.

The first management step with opioid intoxication is to ensure adequate ventilation of the patient. Endotracheal intubation may be necessary if there is severe respiratory depression or pulmonary edema. If appropriate, GI decontamination should be performed. The narcotic antagonist naloxone (1 to 2 mg) should be given by IV. If there is no response despite the suspicion of opiate intoxication, the naloxone dose should be repeated (up to 8 to 10 mg), depending on effect and level of suspicion. Naloxone can precipitate an abstinence syndrome in those who have developed physical dependence; in such patients, smaller initial doses of 0.2 to 0.4 µg, with upward titration as needed, are preferable.

When patients who are addicted to opiates are hospitalized, small doses of an opiate may be necessary to prevent severe withdrawal. Methadone substitution is the preferred agent, because in small doses, it is less euphorigenic and its long elimination half-life permits once- or twice-daily dosing. With the patient under observation, 10 to 20 mg of methadone are given, ideally before the appearance of withdrawal symptoms (insomnia, irritability, agitation, piloerection).

Gamma Hydroxybutyrate and Gamma Hydroxybutyrolactone

The related agents, gamma hydroxybutyrate (GHB) and gamma hydroxybutyrolactone (GBL), have become popular substances of abuse among teenagers and young adults. GHB is an endogenous compound with neurotransmitter and/or neuromodulator function, and interacts with dopamine, serotonin, GABA, and endogenous opioid-based neural systems. GHB sales and transportation across state lines is currently restricted by federal law, and possession is illegal in some states. However, it is widely available through the purchase of kits (e.g., by mail order, via the Internet) that allow its home synthesis. GBL is actually a precursor to GHB and is the primary ingredient of such kits, and continues to be legally sold in health food stores. However, GBL is rapidly metabolized in vivo to GHB, and the clinical effects of ingesting either agent are nearly indistinguishable. These agents are used for a variety of reasons, but primarily as euphoriants and aphrodisiacs at parties or all-night dance clubs (“raves”). GHB has gained a particular notoriety as a date-rape agent. They also have a reputation in the body-builder community as growth hormone stimulants and thus enhancers of muscle development and fat loss.

GHB and GBL are CNS depressants that cause rapid onset of deep sleep that can progress to coma and respiratory depression. Patients who have overdosed may have transient seizure activity, and are often hypothermic and bradycardic. The coma is usually relatively short in duration, on the order of 1 to 2 hours. During emergence, transient delirium and vomiting are often observed. Depressed respiratory effort and airway-protective reflexes are common in the more severe cases, although aspiration pneumonia as a complication has been rare. Many patients are surprisingly responsive to stimulus, and attempts at laryngoscopy to effect endotracheal intubation in a seemingly deeply comatose patient may result in an angry, combative patient who sits up and swears at the endoscopist.

Most patients with acute overdose can be managed with the provision of ambient oxygen, suctioning, and airway and antiaspiration positioning. A nasal trumpet is helpful in some cases, and endotracheal intubation may be required

occasionally, although it may necessitate rapid sequence induction for the reasons previously noted. Atropine has been used for severe bradycardia with success. Blood pressure support is rarely necessary.

Inhalants

The High School Senior Survey, conducted by the National Institute on Drug Abuse, has suggested that the abuse of inhalants is relatively common in adolescents with a lifetime prevalence rate of up to 20%. Additional data suggest that these psychoactive agents are even more common in school-aged children and preadolescents. The prevalence of inhalant abuse among young children has been related to the ready availability of these products. Patterns of abuse are also strikingly region specific, with the highest rates of abuse in the southwestern and southeastern United States.

The psychoactive inhalants can be placed into three broad categories: 1) hydrocarbons, 2) nitrous oxide, and 3) nitrites. The hydrocarbons can be subdivided further into the aliphatic hydrocarbons, the halogenated hydrocarbons, and solvents. Regardless of class, all inhalants possess the pharmacologic property of narcosis, leading to euphoria and light-headedness after inhalation. Typically, the agents are abused by “huffing” or “bagging.” In huffing, the agent is placed into a rag or handkerchief, held under the nose, and then deeply inhaled. With bagging, a common method of abuse at parties, the compound is placed into a large bag (e.g., garbage bag) with the drug user placing his or her head into the bag.

Several distinct profiles of toxicity have been described after inhalant abuse. The inebriation that these agents produce may be associated with mental status changes that include coma with respiratory arrest or aspiration. The halogenated hydrocarbons all possess potent cardiotoxicity, leading to myocardial irritability and cardiac arrhythmias. This action has been associated with many reports of spontaneous ventricular fibrillation in adolescents during a binge. Finally, the act of bagging is associated with the risk of simple asphyxia. A syndrome known as sudden sniffing death has been described in adolescents who abuse inhalants. This syndrome may be the result of any of these previously described toxicities. Finally, acute exposure to inhalants may lead to methemoglobinemia, often severe.

Other toxicities are associated with chronic inhalant abuse. The solvents, particularly toluene, may lead to a syndrome that includes abdominal pain, muscle wasting, electrolyte disturbances, and renal tubular acidosis. Victims of chronic solvent abuse also may develop a leukoencephalomalacia with cerebral atrophy.

Management

Because inhalant abuse may lead to the development of life-threatening symptoms, close attention should be directed to the vital signs and their stability. Patients with depressed levels of consciousness may require airway support and ventilation. Because of the risk of cardiac arrhythmias, vascular access should be established early. Arrhythmias should be treated according to standard protocol (see Chapter 1 and Chapter 82); however, the use of epinephrine is relatively contraindicated because it has been associated with worsening of rhythm disturbances. As a part of the evaluation, a complete metabolic panel that includes electrolytes with calcium, phosphate and magnesium, amylase, liver function tests, creatine phosphokinase, and urinalysis should be obtained.

Treatment of methemoglobinemia is discussed in Chapter 87.

CHAPTER 89

Environmental Emergencies

CARL R. BAUM, MD

Department of Pediatrics, Northwestern University Medical School, Division of Emergency Medicine/Toxicology Service, Children's Memorial Hospital, and Division of Occupational and Environmental Medicine, Toxikon Consortium, Cook County Hospital, Chicago, Illinois

DROWNING AND NEAR DROWNING

Background

Drowning is defined as water submersion with resultant asphyxiation and death within 24 hours; *near drowning* implies that resuscitation has extended survival beyond 24 hours. Each term is further classified according to whether aspiration has occurred.

Drowning is responsible for approximately 4000 deaths per year in the United States, affecting all age groups and affecting males two to three times more often than females. Drowning ranked fourth among unintentional injury deaths in recent years.

Older infants and toddlers are disproportionately represented in these accidents, and their survival rates are lower. They are vulnerable to immersion in household buckets, bath and hot tubs, swimming pools, and other bodies of water near their homes. Young teenagers are also at greater risk because adult supervision decreases and bravado increases. However, coexisting trauma, drug or alcohol use, and suicidal intent must be considered in each case. The importance of careful surveillance and public safety measures, such as fences around pools, cannot be overemphasized.

Pathophysiology

When a child is submerged, either breath-holding or laryngospasm occurs. If hypoxemia follows, loss of consciousness and cardiovascular collapse may occur without aspiration of fluid. Alternatively, submersion and frantic struggling may result in gasping, with subsequent aspiration. If antecedent head trauma, drug ingestion, seizure activity, or cardiac arrhythmia impair consciousness and protective airway reflexes, aspiration is more likely to occur. Although most organs may become involved, the major morbidity occurs in the pulmonary and central nervous systems.

Fresh water aspirated into the lungs is rapidly taken up into the circulation, resulting in a transient rise in circulating blood volume that is quickly redistributed through the body. In a canine study of cold water drowning, aspiration of fresh water caused body weight to increase an average of 16.5% with concomitant hemodilution. Aspiration of salt water caused body weight to increase only 6% with hemoconcentration and diminished intravascular volume. In humans, changes in the hematocrit are not predictable, and those that occur are more closely related to coexisting trauma than to effects of hypertonic or hypotonic fluids. Occasionally, however, massive hemolysis may occur. Electrolyte abnormalities that occur after massive aspiration in laboratory animals rarely achieve clinical significance in either adult or child victims.

However, even small (1 to 3 mL/kg) quantities of fresh water cause disruption of surfactant, a rise in surface tension in the lungs, and alveolar instability. Capillary and alveolar membrane damage allow fluid to leak into the alveoli with subsequent pulmonary edema.

Aspiration of salt water (osmolality greater than normal saline) does not denature surfactant but creates an osmotic gradient for fluid to accumulate in the lungs. This accumulated fluid greatly exceeds the volume that was aspirated and effectively removes surfactant from the alveolar–gas interface.

Both fresh and salt water aspiration decrease pulmonary compliance, increase airway resistance and pulmonary artery pressure, and diminish pulmonary flow. As nonventilated alveoli are perfused, an intrapulmonary shunt develops, leading to a drastic fall in partial pressure of arterial oxygen (Pa O_2).

In other animal studies, aspiration of as little as 2.2 mL/kg of fresh water led to a fall in Pa O_2 to about 60 mm Hg in 3 minutes, whereas a similar amount of sea water precipitated an even greater drop (to about 40 mm Hg). In humans, even lower levels of PaO_2 are seen; tissue hypoxia then leads to severe metabolic acidosis. The victim is usually able to correct a rise in partial pressure of arterial carbon dioxide (Pa CO_2). Aspiration of bacteria, gastric contents, and foreign materials may cause additional trauma to the lungs.

Hypoxemia, whether secondary to upper airway obstruction (here, laryngospasm) or to impaired gas exchange after aspiration, results in loss of consciousness. If anoxia ensues, irreversible central nervous system (CNS) damage begins after 4 to 6 minutes. Fear or cold may trigger the diving reflex (commonly encountered in infancy), which shunts blood to the brain and heart primarily and affords several minutes of additional perfusion. Experience with drowning victims and in cardiovascular surgery indicates that cold water is relatively protective of the CNS, but probably only if immersion hypothermia develops very rapidly or before compromise of oxygenation. Onset of hypothermia is more rapid in the victim who is younger (greater surface:volume ratio) or is struggling in or swallowing icy water. If, however, laryngospasm or aspiration occurs before a fall in core body temperature and cerebral metabolic rate, protection is probably minimal.

Cardiovascular effects are primarily those expected with myocardial ischemia, severe systemic acidosis, hypothermia, and intravascular volume changes. After aspiration of fresh water, the transient rise in intravascular volume later contributes to problems of cerebral edema and pulmonary function.

Clinical Manifestations

In the first moments after rescue, the appearance of the child who has nearly drowned may range from apparently normal to apparently dead. Body temperature is often low, even in temperate, warm-water environments. Respiratory efforts may be absent, irregular, or labored, with pallor or cyanosis, retractions, grunting, and cough productive of pink, frothy material. The lungs may be clear, or there may be rales, rhonchi, and wheezing. Infection may develop as a consequence of aspirated mouth flora or organisms in stagnant water, but this is not usually important in the first 24 hours.

Respiratory function may improve spontaneously or deteriorate rapidly as pulmonary edema and small airway dysfunction worsen. Alternatively, deterioration may ensue slowly over 12 to 24 hours.

Intense peripheral vasoconstriction and myocardial depression may produce apparent or actual pulselessness.

Neurologic assessment may show an alert, normal child or any level of CNS compromise. A child may display agitation and combative behavior, blunted responsiveness to the environment, or profound coma with stereotypic posturing or flaccid extremities. Superficial evidence of head trauma may be noted in a few children whose submersion episode was a secondary event.

Pulmonary and neurologic damage need not occur together. Although extensive pulmonary destruction and resultant hypoxemia may cause neurologic damage, all combinations of mild and severe lung and brain damage are possible.

Management

The ultimate outcome of serious immersion accidents depends on the duration of submersion, the degree of pulmonary damage by aspiration, and in some cases, effectiveness of initial resuscitative measures. When all children who experience immersion accidents are considered as a group, most are salvageable, and all should receive the benefit of excellent cardiopulmonary resuscitation without delay at the scene, according to the principles elaborated in Chapter 1. In particular, children should be given the maximum concentration of supplemental oxygen possible (100%) in transport to an emergency facility. Even those rescued with spontaneous ventilation and minimal or no neurologic dysfunction should receive the benefit of supplemental oxygen to minimize the risk of progressive hypoxemia and acidosis with secondary myocardial and cerebral damage. Physical examination is notoriously insensitive to hypoxemia; a seriously hypoxemic child may be alert and talking. Once the child has arrived at an emergency facility (and cardiovascular stability is achieved), pulmonary and neurologic assessment should guide further treatment.

Several recent pediatric studies have attempted to predict outcome in submersion accidents. One prospective investigation devised a prediction rule for children submerged in nonicy water who presented to the emergency department (ED) in a comatose state: lack of pupillary light reflex, male sex, and initial blood glucose were variables used to predict unfavorable outcome (vegetative state or death). A retrospective study of children presenting to the ED after warm-water submersion suggested that hemodynamic, rather than neurologic, status was more highly predictive of poor neurologic outcome.

Effective therapy of near drowning depends on the reversal of hypoxemia and metabolic acidosis. The pulmonary status is assessed initially with a chest radiograph (Fig. 89.1) and with measurement of arterial oxygen saturation ($Sa{O_2}$) and arterial blood gas (ABG), as in Table 89.1. If oxygenation is normal on breathing room air, the child can be assumed to have suffered near drowning without aspiration. Observation for 12 to 24 hours with repeat ($Sa\ O_2$) or ABG determination should be sufficient to assess the possibility of late deterioration in gas exchange.

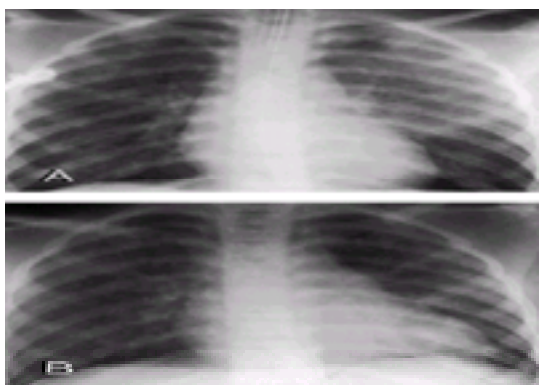

FIGURE 89.1. Near drowning in a 4-month-old girl. **A.** There is bilateral disseminated alveolar pattern, more on the left than on the right, consistent with the pulmonary edema of near drowning. This change may be the result of neurologic pulmonary edema rather than aspirated water. **B.** Two days later, the patient has been extubated and there is marked improvement in appearance of pulmonary edema secondary to near drowning. (Courtesy of Soroosh Mahboubi, MD).

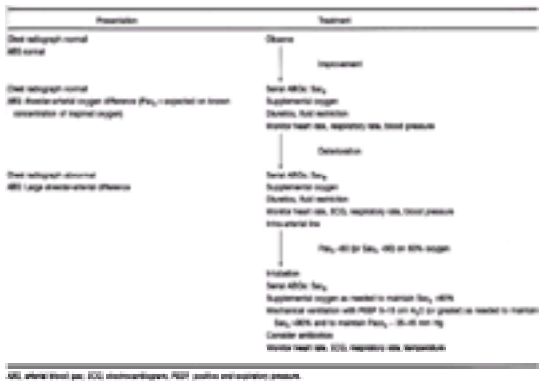

Table 89.1. Pulmonary Assessment after Near Drowning

Other initial laboratory evaluation should include complete blood count (CBC), electrolytes, and urinalysis.

Patients with abnormalities of gas exchange and acid-base status (but with normal chest radiographs) can usually be managed with supplemental oxygen, pulmonary physiotherapy, and bicarbonate therapy. Additional blood gas analysis should be done to document adequate oxygenation and reversal of metabolic acidosis. Any change in mental status or increase in respiratory distress may reflect arterial hypoxemia and should also prompt a repeat ABG determination. Continuous Sa_{O_2} or serial Pa_{O_2} measurements will guide the physician to continue conservative treatment or to intensify ventilatory support.

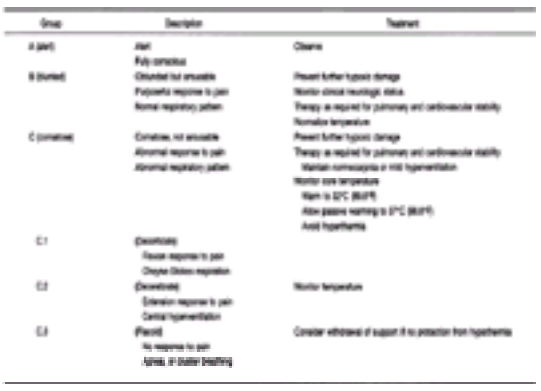
Patients with obvious respiratory distress, hypoxemia (Sa_{O_2} less than 90% or Pa_{O_2} less than 60 on 60% inspired oxygen) and extensive pulmonary edema or infiltration generally require more vigorous treatment and more extensive monitoring. All should be monitored for heart rate, cardiac rhythm, respiratory rate, and blood pressure. Most will require frequent blood gas analysis and may be more easily monitored through arterial cannulation. Intubation, supplemental oxygen, and mechanical ventilation with positive end-expiratory pressure (PEEP, 5 to 15 cm H_2O) should be provided.

Once blood pressure is stabilized, fluid restriction (to approximately one-half the maintenance rate) and diuretic therapy (e.g., furosemide 0.5 to 1 mg/kg intravenously) may improve gas exchange. In the setting of extensive pulmonary damage, pulmonary and cardiovascular components of the disease are intimately entwined. Optimum management requires monitoring of blood gases and systemic arterial pressure.

The risk of pulmonary infection is always present, but retrospective studies have not demonstrated benefit from prophylactic antibiotics, which should be reserved for proven bacterial infection. Exceptions may be made when grossly contaminated water is aspirated and, in the worst cases, when maximal ventilatory support is required to provide any margin for survival. Most studies of bronchoalveolar lavage show no improvement. Steroids have no demonstrated benefit.

Renal function must be maintained. If significant hemoglobinuria exists, forced diuresis is required. Maintenance of an adequate hemoglobin level (more than 10 g/100 mL) and normal electrolytes is obviously necessary. Specific problems vary from patient to patient in an unpredictable way, and an understanding of the principles outlined in Chapter 86 and Chapter 87 is essential.

The patient's clinical condition in the ED dictates further management and may provide prognostic clues. Patients may be assigned to one of three groups (Table 89.2). Those who are awake, alert, and fully responsive have survived the episode, presumably without CNS damage. Conservative observation for only 12 to 24 hours is warranted. The second group includes those who are obtunded but arousable and exhibit a normal respiratory pattern and purposeful responses to pain. These patients have suffered certain but reversible CNS hypoxia; the goal is to prevent further hypoxic damage through intensive management of cardiopulmonary disease. Repeated neurologic evaluation is essential, and fluid restriction and diuretic therapy within the limits of cardiovascular stability may decrease the risk of cerebral edema. There is no demonstrated value in the use of steroids in this setting (see Chapter 125). In both groups, temperature normalization should be prompt. If reversal of coexisting pulmonary damage is effective, neurologic recovery should be complete.



Group	Description	Treatment
A (alert)	Alert Fully conscious	Observe
B (stunned)	Obtunded but arousable Purposeful response to pain Normal respiratory pattern	Prevent further hypoxic damage Monitor clinical neurologic status Therapy as required for pulmonary and cardiovascular stability Normalize temperature
C (unresponsive)	Comatose, not arousable Abnormal response to pain Abnormal respiratory pattern	Prevent further hypoxic damage Therapy as required for pulmonary and cardiovascular stability Maintain normocapnia or mild hyperventilation Monitor core temperature Warm to 32°C (89.6°F) Allow passive warming to 37°C (98.6°F) Avoid hyperthermia
C.1	(Decorticate) Flexion response to pain Cheyne-Stokes respiration	
C.2	(Decerebrate) Extension response to pain Central hyperventilation	Monitor temperature
C.3	(Flaccid) No response to pain Apneustic or fixed breathing	Consider withdrawal of support if no protection from hypothermia

Table 89.2. Neurologic Assessment after Near Drowning

There is controversy over patients in a third group—those who have experienced severe CNS asphyxia. These children are not arousable and can be further divided into three subcategories according to neurologic findings: 1) those with decorticate response to pain and Cheyne-Stokes breathing; 2) those with decerebrate response to pain and central hyperventilation; and 3) those who are flaccid with fixed, dilated pupils and apneustic breathing or apnea. Again, reversal of hypoxemia and acidosis is critical. Fluid resuscitation should be designed to prevent hyperglycemia. Avoiding hypercapnia and resultant cerebral hyperemia is generally accepted, but hyperventilation, barbiturate coma, and other measures initially thought to provide cerebral protection and prevent or treat elevated intracranial pressure have not been helpful in these patients.

Hypothermia does appear to have some protective value. Extreme hypothermia should be corrected to at least 32°C (89.6°F) to achieve hemodynamic stability and to minimize the risk of infection. The child should then be allowed to rewarm passively. Although data in humans are limited, animal studies suggest that maintenance of mild brain hypothermia may minimize reperfusion injury. Hyperthermia, a common result of active rewarming, should be avoided.

The prognosis for this group is certainly more grim, with a much greater risk of death or severe anoxic/ischemic encephalopathy. Risk increases with depth of coma on presentation. Patients in the third subdivision (flaccid with fixed, dilated pupils) rarely survive intact regardless of treatment, although coexistent hypothermia has provided some remarkable exceptions.

Recent studies indicate that patients with asystole on arrival in the ED have uniformly poor neurologic outcomes. In each case, consideration should be given to the possibility that continued resuscitation will salvage only the cardiovascular system; in these cases, the physician may reasonably discontinue resuscitative efforts.

SMOKE INHALATION

Background

Among unintentional injuries, fires rank fifth, killing nearly 4000 people annually in the United States. Although fire has been the cause of much death and misery throughout human history, the importance of smoke inhalation has been recognized only in the last 50 years. Respiratory complications of smoke inhalation rank with carbon monoxide poisoning (see next section) as a major cause of early death from fire. Although serious pulmonary disease may occur in the absence of cutaneous injury, inhalation injury dramatically increases the morbidity and mortality associated with any given percent body surface area burn.

The severity of carbon monoxide inhalation and respiratory problems is related to the duration of exposure, the occurrence in a closed space (more likely in very young or elderly victims), the nature of materials involved, and the presence of products of incomplete combustion. Severe hypovolemic shock, massive tissue destruction, extensive fluid resuscitation, and infection further complicate direct inhalation trauma.

Pathophysiology

The relatively low heat capacity of dry air and the excellent heat exchange properties of the nasopharynx usually limit direct thermal injury to the upper airway. Dry air above 160°C (320°F) has little effect on the lower airway. The greater heat capacity of steam increases the risk of lower airway damage. In addition, continuing combustion of soot particles carried deeply into the lung may exacerbate thermal injury.

Chemical injury may occur at any level of the respiratory tract. Oxides of sulfur and nitrogen combine with lung water to form corrosive acids. Incomplete combustion of any carbon-containing material, such as wood, may produce carbon monoxide. Combustion of cotton or plastic generates aldehydes that cause protein denaturation and cellular damage. One example is acrolein, known to cause upper airway irritation at concentrations of 5.5 parts per million (ppm) and pulmonary edema within seconds at 10 ppm. Polyvinylchloride releases chlorine and hydrochloric acid, whereas polyethylene produces hydrocarbons, ketones, and other acids. One of the hydrocarbons, benzene, may anesthetize the upper airway to facilitate passage of toxins and particles. Burning polyurethane may produce cyanide gas. Fire retardants that contain phosphorus may actually produce phosgene gas. The upper airway filters most soot particles, but those carried into the lung may adsorb various substances and cause reflex bronchospasm to further extend chemical damage.

Upper airway lesions include actual burns of varying severity as well as severe edema of the nose, mouth, pharynx, and laryngeal structures. A murine model of wood smoke inhalation suggests that combustion produces hydroxyl radicals in

the gas phase of smoke that cause a reflex apneic response. In the investigation, a hydroxyl radical scavenger, applied to the larynx, attenuated the response. Upper airway edema increases inspiratory and expiratory resistance and causes a dramatic increase in the work of breathing. If airway narrowing is severe or complete, acute respiratory failure with hypercarbia and hypoxemia occurs and sets the stage for subsequent cardiovascular collapse.

Lower airway lesions depend on the toxin involved. A variety of features may aggravate pulmonary pathology, including circulatory, metabolic, and infectious complications, as well as therapeutic interventions such as endotracheal intubation, oxygen administration, mechanical ventilation, and fluid therapy.

Immediate effects of smoke inhalation on the lower airway include loss of ciliary action, mucosal edema, bronchiolitis, alveolar epithelial damage, and impaired gas exchange, particularly oxygenation. In addition, areas of atelectasis or air trapping worsen ventilation-perfusion mismatch and hypoxemia. Loss of surfactant activity exaggerates this phenomenon. Hours later, sloughing of tracheobronchial mucosa and mucopurulent membrane formation increase the degree of obstruction and poor gas exchange as well as the likelihood of infection. Beyond the first 24 hours, pulmonary pathology that results from smoke inhalation is largely indistinguishable from adult respiratory distress syndrome, which arises from other insults.

The Dellwood nursery fire demonstrated that infants who died sustained serious respiratory damage in the absence of cutaneous injury. Necrosis of bronchial, bronchiolar, and alveolar epithelium; vascular engorgement and edema; and formation of membranes or casts of the airway produce small and large airway obstruction. Severe cutaneous injury increases alveolar capillary permeability, leading to pulmonary hemorrhage, edema, and hyaline membrane formation.

Clinical Manifestations

A history of exposure in a closed space should heighten concern for smoke inhalation. Need for cardiopulmonary resuscitation at the site implies significant carbon monoxide poisoning and/or hypoxia secondary to decreased ambient oxygen concentration or severe respiratory disease. The physician should also consider the types of material involved to determine the risk of poisoning from carbon monoxide or other toxins.

Physical examination that reveals facial burns, singed nasal hairs, pharyngeal soot, or carbonaceous sputum justifies a presumption of smoke inhalation. Any sign of neurologic dysfunction, including irritability or depression, should be presumed related to tissue hypoxia until proven otherwise. Signs of respiratory distress may be delayed for 12 to 24 hours, but tachypnea, cough, hoarseness, stridor, decreased breath sounds, wheezing, rhonchi, or rales may be detected on presentation. Auscultatory findings often precede chest radiograph abnormalities by 12 to 24 hours. Radiographic changes may include diffuse interstitial infiltration or local areas of atelectasis and edema (Fig. 89.2).

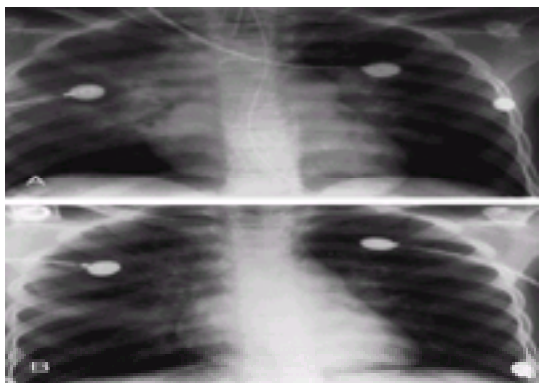


FIGURE 89.2. Smoke inhalation in a 9-year-old girl. **A.** There is bilateral central alveolar process consistent with acute smoke inhalation. **B.** A day later, the patient has been extubated and there is marked improvement in the appearance of pulmonary edema. (Courtesy of Soroosh Mahboubi, MD)

Acute respiratory failure may occur at any point. The cause may be asphyxia or carbon monoxide exposure and subsequent CNS depression initially, or airway obstruction or parenchymal dysfunction later. ABG analysis provides the ultimate assessment of effective respiratory function. Xenon lung scanning may provide evidence for smoke inhalation but does not add significantly to repeated clinical assessment and blood gas determinations in the ED. Bronchoscopy can document the extent of inhalation injury and help remove debris but may worsen airway edema. In general, it is respiratory function, not appearance of lesions, that guides supportive care, and therefore most patients can be treated effectively without bronchoscopy.

Management

Initial assessment and resuscitation at the scene of the fire should proceed according to the principles outlined in Chapter 1. Because of the likelihood of carbon monoxide exposure and the difficulty of assessing hypoxemia clinically, all victims should receive the maximum concentration of inspired oxygen possible in transport and in the ED until further evaluation is complete (Table 89.3).

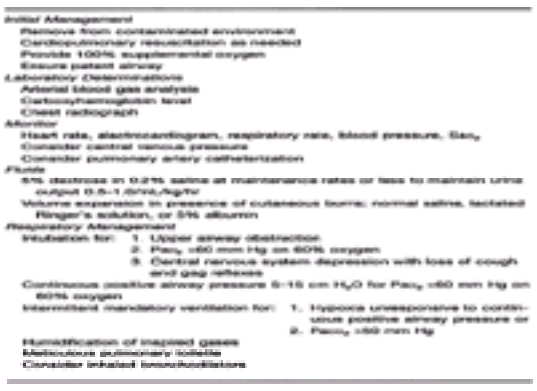

Table 89.3. Management of Smoke Inhalation

Upon the patient's arrival in the ED, assessment of the airway and respiratory functions must proceed simultaneously with cardiovascular stabilization. Thermal injury to the nose, mouth, or face, or compromise of the upper airway (stridor, hoarseness, barking cough, retractions, delayed inspiration, or difficulty handling secretions) indicates the need for direct laryngoscopy. The presence of significant pharyngeal, supraglottic, or glottic edema mandates elective endotracheal intubation. Although some clinicians may elect to observe closely, worsening edema over 24 hours may lead to respiratory arrest and difficult emergency intubation through a distorted airway. Elective tracheostomy may be considered if placing or securing the endotracheal tube will further traumatize an edematous airway or severe facial burns. However, in the presence of extensive cutaneous burns, tracheostomy dramatically increases the risk of systemic and pulmonary infection.

Cardiovascular stabilization depends on fluid replacement, which is complex when major surface burns have occurred. The details of therapy are elaborated in Chapter 114, but in general, the goals are stabilization of cardiovascular function without fluid overload and compromise of gas exchange. Pulse rate and blood pressure should guide administration of fluid volume. Maintenance of urine output of at least 0.5 mL/kg per hour should provide adequate tissue perfusion. Decreased urine output may respond to diuretics or inotropic agents. Although adequate fluid administration is essential, careful monitoring of renal and cardiovascular systems may prevent or minimize acute pulmonary edema and delayed pulmonary dysfunction secondary to late fluid mobilization and infection.

Oxygen saturation and serial blood gas determinations should be obtained to guide oxygen supplementation and to assess adequacy of ventilation. Intubation is indicated if adequate oxygenation (Sa O_2 less than 90 or PaO_2 60 mm Hg or greater) cannot be maintained with an inspired oxygen concentration of 40 to 60%, if Pa CO_2 rises above 50 mm Hg, or if the work of breathing appears unsustainable. In the presence of small airway edema and disrupted surfactant activity, continuous distending airway pressure may improve oxygenation. Spontaneous ventilation with continuous positive airway pressure (CPAP) causes less cardiovascular interference, but in the patient with severe CNS depression or severe pulmonary parenchymal damage, mechanical ventilation with PEEP will likely be necessary. Maximally humidified oxygen should be delivered by mask or artificial airway to prevent inspissation of debris and occlusion of the airway. The patient with a natural airway should also receive humidified gas mixtures and be encouraged to take deep breaths and cough frequently. If an endotracheal tube is necessary, meticulous pulmonary toilette is essential, with frequent suctioning to remove edema fluid, mucus, and sloughed epithelium that may otherwise occlude the endotracheal tube.

A recent study of lung mechanics in children with inhalation injury compared two modes of ventilation. High-frequency percussive ventilation was superior to conventional mechanical ventilation in reducing work of breathing.

After the first few hours, diuretic therapy (furosemide 0.5 to 1 mg/kg intravenously) within the limits of cardiovascular stability may also improve oxygenation and pulmonary compliance, leading to more effective ventilation. Chemical and particulate irritation of upper airway receptors may cause reflex bronchoconstriction and contribute to lower airway obstruction. Bronchodilators such as nebulized albuterol (2.5 mg in 2.5 mL, 0.9% sodium chloride) or intravenous (IV) terbutaline (load 10 µg/kg per dose intravenously or subcutaneously; drip 0.1 to 1.0 µg/kg per minute) may help reverse bronchospasm, but relief depends mostly on removal of secretions and debris from the respiratory tree.

Studies have not demonstrated a role for steroids in reducing airway edema or in decreasing the inflammatory response to smoke inhalation. When steroids are used, there is evidence that sodium and fluid retention increase, healing is delayed and bacterial clearance from the lung is decreased. Little argument remains for their routine use.

Similarly, there is no value in the use of prophylactic antibiotics. Institution of antimicrobial therapy should await specific indications, which rarely occur in the first 24 hours.

CARBON MONOXIDE POISONING

Background

Each year, unintentional carbon monoxide poisoning claims about 500 lives and is largely responsible for early deaths related to fire. However, exposure may occur in a variety of other settings unrelated to accidental fires, including incomplete combustion of any carbon-containing fuel. Poisoning may occur with exposure to improperly vented wood- or coal-burning stoves, and to automobile exhaust in garages (in most cases, garage doors and windows were actually open). Passengers may be poisoned in vehicles with open backs, or with faulty or blocked exhaust systems. During a 1996 blizzard in New York City, snow blocked exhaust pipes of idling automobiles and rendered 21 people (8 less than

16 years of age) unconscious.

Pathophysiology

In the normal person, carboxyhemoglobin levels are less than 1%. In smokers, levels of 5 to 10% are common. Inhaled carbon monoxide has two important effects that conspire to cause tissue hypoxia: 1) carbon monoxide binds to hemoglobin with an affinity 200 to 300 times greater than that of oxygen, and 2) it shifts the oxyhemoglobin dissociation curve to the left and changes the shape from sigmoidal to hyperbolic (Fig. 89.3). The first effect decreases oxygen content of the blood, whereas the second causes oxygen release at lower-than-normal tissue oxygen levels. Other endogenous (anemia) and exogenous (high altitude, consumption, or displacement of ambient oxygen during fires) factors contribute further to hypoxia. Although oxygen content of the blood is low, the Pa O_2 remains normal. Because carotid body receptors respond to Pa O_2, respiration may not be stimulated until late, when metabolic acidosis activates other centers. Tissue hypoxia increases cerebral blood flow, cerebrospinal fluid pressure, and cerebral capillary permeability, which predispose the patient to cerebral edema.

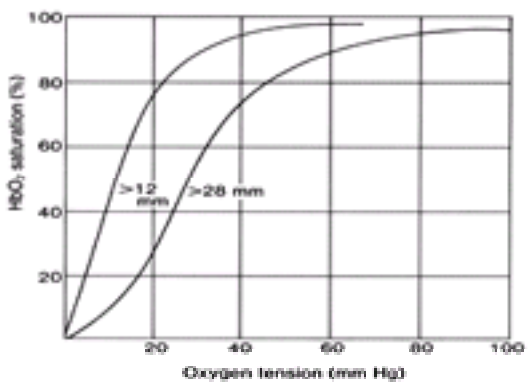

FIGURE 89.3. Carbon monoxide shifts the oxyhemoglobin dissociation curve to the left and changes its shape. This makes unloading of oxygen in the tissues more difficult and provides an inadequate diffusion gradient. (*Left curve,* P_{50} = 12 mm; *right curve,* P_{50} = 28 mm.)

Carbon monoxide interacts with several other cellular proteins, including cytochrome oxidase. It appears to interfere with oxidative energy production and may generate free radicals, which exacerbate CNS dysfunction. Carboxyhemoglobin may even act as a neurotransmitter, altering smooth muscle tone and indirectly contributing to a reperfusion injury.

Clinical Manifestations

History provides the most valuable clue to diagnosis. Carbon monoxide poisoning should be suspected in all fire victims and considered in children exposed to other hazards noted earlier. Presence or absence of the classically described “cherry red” skin color is of no diagnostic value. In fact, patients with thermal injury may appear red, whereas those with vasoconstriction may be quite pale. Both color and respiratory rate may be deceptive and may lead the physician away from recognition of severe tissue hypoxia. Pa O_2 and arterial saturation as determined by pulse oximetry (Sa O_2) are likely to be normal in carbon-monoxide intoxication; low values reflect coexistent pulmonary dysfunction.

Determination of blood levels of carboxyhemoglobin may help document the diagnosis and may aid prognosis. Spectrophotometric methods are most widely used clinically. Venous blood may be used because of the high affinity of carbon monoxide for hemoglobin, but an arterial sample provides more precise information about acid-base balance and adequacy of ventilation. The level of hemoglobin should also be determined.

Levels of carboxyhemoglobin as low as 5% in nonsmokers may impair judgment and fine motor skills. Mild intoxication (20% carboxyhemoglobin) produces headache, mild dyspnea, visual changes, and confusion. Moderate poisoning (20 to 40%) produces drowsiness, faintness, nausea and vomiting, tachycardia, dulled sensation, and decreased awareness of danger. At lower levels, these symptoms are noted only with exertion, but as the fraction approaches 40%, they are present at rest. Between 40 and 60%, weakness, incoordination, and loss of recent memory occur, and cardiovascular and neurologic collapse is imminent. Above 60%, coma, convulsions, and death are almost certain. Although carboxyhemoglobin levels and symptoms tend to follow the pattern just described, individual patients may be more or less symptomatic than predicted. An important caveat is that blood carboxyhemoglobin levels will fall rapidly with time and may not reflect cellular dysfunction, especially in high-demand tissues of the heart and CNS.

Patients with severe poisoning are peculiarly vulnerable to pressure trauma to skin, subcutaneous tissue, and muscle, especially at sites that support body weight or that are pinned under fallen objects. The history may suggest which sites are most vulnerable, and pain is an early symptom. Muscle breakdown and myoglobin deposition in renal tubular cells may precipitate acute renal failure.

A syndrome of delayed neuropsychologic sequelae (DNS) had been described in patients after exposure to carboxyhemoglobin. These patients develop neurologic symptoms acutely, appear to recover with treatment, and then exhibit a broad spectrum of neurologic and psychiatric abnormalities days to weeks after the exposure. Neuropsychiatric testing of children has obvious difficulties. Studies of DNS, many of which are methodologically flawed, have elucidated neither an exact mechanism nor a consensus on prevention and treatment.

Management

Most important and obvious is the immediate need to remove the victim from the contaminated environment (Table 89.4). Resuscitation should proceed according to general principles. As soon as possible, the patient suspected of suffering carbon monoxide poisoning should be provided 100% oxygen. If the patient is breathing spontaneously, this can be accomplished with well-fitting masks supplied with nonrebreathing valves and a reservoir bag. Entrainment of room air precludes simple masks from providing more than 40% oxygen. The half-life of carboxyhemoglobin is approximately 4 hours in a patient breathing room air at sea level and approximately 1 hour if pure oxygen is inspired. The half-life is further reduced to less than 30 minutes if the patient has access to hyperbaric oxygen (HBO) at 2 to 3 atmospheres' pressure. There is no widespread agreement on indications for HBO, and transfer to a hyperbaric chamber should not jeopardize meticulous conventional cardiopulmonary stabilization. However, HBO administration may have effects beyond the mere reduction in carboxyhemoglobin half-life. Some studies in adults suggest a role for HBO in reducing the incidence of mortality and DNS. Well-controlled studies in children would have to be undertaken to answer these questions definitively but would have obvious ethical and methodologic difficulties. In any case, early consultation with an HBO facility should be considered while the patient is receiving 100% oxygen.

Initial Management
Remove from contaminated environment
Cardiopulmonary resuscitation as needed
Provide 100% supplemental oxygen
Laboratory Determinations
Arterial blood gas analysis
Carboxyhemoglobin level
Complete blood count, electrolytes
Urinalysis for myoglobin
Monitor
Heart rate, electrocardiogram, respiratory rate, blood pressure
Treatment
Correct anemia Hgb <10 g/dL
Continue supplemental oxygen until carboxyhemoglobin ≤5%
Decrease oxygen consumption with bedrest, avoid producing anxiety
Maintain urine output >1 mL/kg/hr
Consider hyperbaric oxygen

Table 89.4. Management of Carbon Monoxide Poisoning

Use of inspired gas mixtures that contain carbon dioxide (5%) to increase minute ventilation may precipitate respiratory failure if used at the scene, as ventilation cannot be well monitored or assisted. It may be considered under closely controlled situations in the hospital but probably is of little benefit.

Metabolic acidosis, if present, should be treated with sodium bicarbonate, although adequacy of ventilation must be assessed to prevent paradoxical intracellular acidosis. The possibility of coexistent cyanide poisoning should be considered in patients involved in closed-space fires (especially where nitrogen-containing synthetic materials have burned) who have a persistent metabolic acidosis in the context of normal carboxyhemoglobin and methemoglobin. Cyanide has high mortality but a short half-life (approximately 1 hour), so empiric cyanide levels on patients who have survived the scene are not recommended generally unless confirmation is needed. If cyanide poisoning is strongly suspected in an early-presenting patient, the cyanide antidote kit (formerly known as the Lilly kit) may be considered. This two-step kit must be used with caution because the nitrite-containing first step induces methemoglobinemia. In case of doubt, the thiosulfate-containing second step, which is able to scavenge cyanide without significant additional toxicity, may be given alone. Anemia (hemoglobin less than 10 g/100 mL) must be corrected to maximize oxygen-carrying capacity. If myoglobinemia or myoglobinuria is present, vigorous hydration and forced diuresis with furosemide (1 mg/kg intravenously) and/or mannitol (0.25 to 1 g/kg intravenously) with close attention to urine output may preserve renal function. If hydration and diuresis are ineffective, renal failure should be considered and fluids restricted accordingly (see Chapter 86).

The patient should be observed for at least 24 hours to identify other sequelae of smoke inhalation.

ENVIRONMENTAL AND EXERTIONAL HEAT ILLNESS

Background

Environmental and exertional heat illness occurs with excessive heat generation and storage. These conditions arise when high ambient temperature prevents heat dissipation by radiation or convection, and not on humidity limits cooling by sweat evaporation. The spectrum of illness is broad, including heat cramps, heat exhaustion, and heat stroke; the latter is an acute medical emergency with significant associated morbidity and mortality.

Heat illness is a serious tropical health hazard, but even in the United States, summer heat is implicated in the deaths of more than 4000 people per year. Heat waves bring epidemic illness, but sporadic cases are also common. The elderly are most vulnerable (more than 80% of cases occur in people older than 50), but heat illness is significant among healthy young people as well. Military recruits, laborers, and athletes who work in a hot, humid atmosphere are notoriously vulnerable. Obesity, physical disability, heart disease, and alcohol and drug use increase risk. Pediatricians need to understand the special risk to young athletes, children with cystic fibrosis, infants left in automobiles on hot days, and the rare child with congenital absence of sweat glands. Mortality related to acute heat stroke has been estimated to range from 17 to 70%, depending on the severity of heat stress and age of the patient.

Pathophysiology

Under normal conditions, body core temperature is maintained constant within 0.6°C (1°F) when the environment varies from 9.4° to 60°C (49°–140°F) in dry air. This represents a remarkable balance between heat production and heat loss by the body. Heat is produced as 1) a byproduct of basal metabolism, 2) a consequence of muscle activity (including shivering), and 3) the effects of thyroxine and sympathetic stimulation on cellular processes. Heat is lost by 1) conduction to objects and air, 2) convection through air or liquid that surrounds tissues, 3) evaporation, and 4) radiation of infrared energy.

Conduction to objects represents a small fraction (about 3%) of heat lost. Conduction to air and convection represent another 12% in still air. As air movement increases, the proportion of heat lost by these mechanisms may increase to nearly 60%. Evaporative losses normally account for 25% of heat lost, and radiant heat losses account for about 60%. However, the body gains heat by conduction and radiation when ambient temperature exceeds skin temperature and loses heat only by evaporation. High ambient humidity and absence of convection currents decrease the rate of evaporation.

Heat-sensitive centers of the posterior hypothalamus control sympathetic tone. This tone regulates vasoconstriction of arterioles and subcutaneous arteriovenous anastomoses, which, in turn, controls heat conduction from the body core to the skin. Flow through these areas may represent 0 to 30% of total cardiac output. High flow provides efficient heat transfer from the body core to the skin, which is an effective radiator. Low flow to the skin prevents radiation and allows only inefficient diffusion through the insulating skin and subcutaneous tissues.

When body temperature rises, blood in the preoptic area of the anterior hypothalamus is warmer than optimal. Impulses from this area increase and are conducted through autonomic pathways to the spinal cord and then, through cholinergic fibers to the sweat glands, where sweat is released. Exercise and certain emotional states release circulating epinephrine and norepinephrine to increase sweat production.

The sweat gland is composed of two portions. The deep coiled portion actively elaborates a precursor secretion in response to cholinergic stimulation. At low rates of sweating, much of the sodium chloride (NaCl) contained in the precursor secretion is reabsorbed before the sweat is conducted to the skin surface. At higher rates, flow exceeds the capacity of the duct to reabsorb solute, and substantial total body NaCl depletion may occur.

In the unacclimatized adult, sweating may vary from negligible amounts at rest in a cool, dry environment to 1.5 L/hour during vigorous activity in hot weather. Long-term exposure to tropical weather results in a steady increase in sweating rate over approximately 6 weeks, to a maximum of about 4.0 L/hour. Initially, enormous salt losses may occur (15 to 20 g/day). However, aldosterone secretion rises and stimulates active reabsorption of NaCl in the ducts of sweat glands (as in the kidney), and salt losses decrease to a normal 3 to 5 g/day.

In humans, behavioral control over temperature regulation is probably as important as all other mechanisms. When body temperature changes, sensations of excessive warmth or cold prompt efforts to correct the situation. One moves out of the cold or into the shade, selects warmer or cooler clothing, initiates maneuvers that warm or cool the environment, or alters levels of activity. Choice of clothing that traps a layer of air around the body prevents significant heat loss by convection. A reflective inner surface decreases radiant heat loss by more than half. Light-colored clothing permeable to moisture but impervious to radiant heat from the environment, however, prevents the formation of an insulating layer of air. This allows for heat loss by evaporation and prevents radiant heat gain.

Clinical Findings

Three types of heat illness are recognized and represent different physiologic disturbances (Table 89.5). Heat cramps refer to the sudden onset of brief, intermittent, and excruciating cramps in muscles after they have been subjected to severe work stress. Cramps tend to occur after the work is done, on relaxing or on taking a cool shower. Occasionally, abdominal muscle cramps may simulate an acute abdomen. The usual victim is highly conditioned and acclimatized. Typically, these individuals can produce sweat in large quantities and provide themselves with adequate fluid replacement but inadequate salt replacement. Electrolyte depletion is probably the cause of cramps.

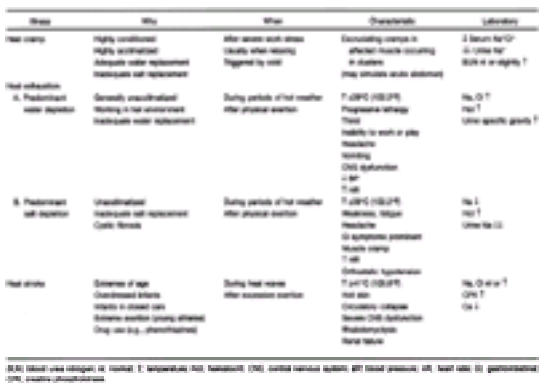

Table 89.5. Characteristics of Heat Illness

Most spasms last less than a minute, but some persist for several minutes, during which a rock-hard mass may be palpated in the affected muscle. Cramps often occur in clusters. Rapid voluntary contraction of a muscle, contact with

cold air or water, or passive extension of a flexed limb may reproduce a cramp. Laboratory investigation reveals hyponatremia and hypochloremia and virtually absent urine sodium. The blood urea nitrogen (BUN) level is usually normal but may be mildly elevated.

Heat exhaustion is less clearly demarcated from heat stroke than are heat cramps. In most cases, water depletion predominates because individuals who live and work in a hot environment do not voluntarily replace their total water deficit. Progressive lethargy, intense thirst, and inability to work or play progress to headache, vomiting, CNS dysfunction (including hyperventilation, paresthesias, agitation, incoordination, or actual psychosis), hypotension, and tachycardia. Hemoconcentration, hypernatremia, hyperchloremia, and urinary concentration are typical. Body temperature may rise but rarely over 39°C (102.2°F). If unattended, heat exhaustion may progress to frank heat stroke.

Heat exhaustion may also occur secondary to predominant salt depletion. As in heat cramp, water losses are replaced but without adequate electrolyte supplementation. Symptoms include profound weakness and fatigue, frontal headache, anorexia, nausea, vomiting, diarrhea, and severe muscle cramps. Tachycardia and orthostatic hypotension may be noted. Unlike heat cramp victims, these patients are typically unacclimatized. Hyponatremia, hemoconcentration and significantly diminished urine sodium are consistent findings. Children with cystic fibrosis, particularly those who are young and unable to meet increased salt requirements, are at risk for electrolyte depletion because salt losses in their sweat apparently do not respond to acclimatization and aldosterone stimulation of the sweat gland.

Heat stroke (Table 89.5) is a life-threatening emergency. Classic signs are hyperpyrexia (41°C [105.8°F] or higher); hot, dry skin that is pink or ashen, depending on the circulatory state; and severe CNS dysfunction. Often, but not invariably, sweating ceases before the onset of heat stroke.

The onset of the CNS disturbance may be abrupt, with sudden loss of consciousness. Often, however, premonitory signs and symptoms exist. These include a sense of impending doom, headache, dizziness, weakness, confusion, euphoria, gait disturbance, and combativeness. Posturing, incontinence, seizures, hemiparesis, and pupillary changes may occur. Any level of coma may be noted. Cerebrospinal fluid findings are usually normal. The extent of damage to the CNS is related to the time and extent of hyperpyrexia and to the adequacy of circulation. Once the body temperature is lowered, consciousness usually is restored quickly, but coma may persist for 24 hours or more.

Patients able to maintain cardiac output adequate to meet the enormously elevated circulatory demand are most likely to survive. Initially, the pulse is rapid and full, with an increased pulse pressure. Total peripheral vascular resistance falls as a result of vasodilation in the skin and muscle beds, and splanchnic flow diminishes. If hyperpyrexia is not corrected, ashen cyanosis and a thin, rapid pulse herald a falling cardiac output. The cause may be either direct thermal damage to the myocardium or significant pulmonary hypertension with secondary right ventricular failure. Even after body temperature is returned to normal, cardiac output remains elevated and peripheral vascular resistance remains low for several hours, resembling the compensatory hyperemia after ischemia noted in posttrauma, postshock, and postseptic states. Persistently circulating vasoactive substances probably account for this phenomenon.

Severe dehydration is not a necessary component of heat stroke but may play a role if prolonged sweating has occurred. Electrolyte abnormalities may occur, especially in the unacclimatized victim, if NaCl has not been replaced. In acclimatized persons, NaCl is conserved but often at the expense of a severe potassium deficit. Polyuria is sometimes noted, often vasopressin resistant and possibly related to hypokalemia. Acute tubular necrosis may be seen in as many as 35% of cases and probably reflects combined thermal, ischemic, and circulating pigment damage. Hypoglycemia may also be noted.

Nontraumatic rhabdomyolysis and acute renal failure have been described as consequences of various insults, including hyperthermia and strenuous exercise in unconditioned persons. Clinically, there may or may not be musculoskeletal pain, tenderness, swelling, or weakness. Laboratory evidence includes elevated serum creatinine phosphokinase (300 to 120,000) and urinalysis that is orthotoludin (Hematest)-positive without red blood cells (RBCs) and shows red–gold granular casts. Typically, serum potassium and creatinine levels rise rapidly relative to BUN. An initial hypocalcemia, possibly a consequence of deposition into damaged muscle, progresses to hypercalcemia during the diuretic phase a few days to two weeks later.

Management

Most cases of heat cramps are mild and do not require specific therapy. Rest and increased salt intake from liberally salted foods are sufficient. In severe cases with prolonged or frequent cramps, IV infusion of normal saline is effective. Approximately 5 to 10 mL/kg over 15 to 20 minutes should be adequate to relieve cramping. Oral intake of fluids and salted foods can then complete restoration of salt and water balance.

Heat exhaustion as a result of predominant water depletion is treated with rehydration and rest in a cooled or well-ventilated place. If the child is able to eat, he or she should be encouraged to drink cool liquids and be allowed unrestricted dietary sodium. If weakness or impaired consciousness preclude oral correction, IV fluids are given as in any hypernatremic dehydration.

Exhaustion caused by predominant salt depletion also requires rest in a cool environment. Alert, reasonably strong children can be given relatively salty drinks such as consommé or tomato juice and should be encouraged to salt solid foods. Hypotonic fluids (e.g., water, Kool-Aid) should be avoided until salt repletion has begun. Patients with CNS symptoms or gastrointestinal dysfunction may be rehydrated with IV isotonic saline or Ringer's lactate. Initial rapid administration of 20 mL/kg over 20 minutes should improve intravascular volume with return of blood pressure and pulse toward normal. Further correction of salt and water stores should be achieved over 12 to 24 hours. In especially severe cases with intractable seizures or muscle cramps, hypertonic saline solutions may be used. The initial dose of 3% saline solution is 5 mL/kg by IV. An additional 5 mL/kg should be infused over the next 4 to 6 hours.

Treatment of heat stroke centers on two priorities: 1) immediate elimination of hyperpyrexia and 2) support of the cardiovascular system (Table 89.6). Clothing should be removed and the patient should be cooled actively. Patients should be transported to an emergency facility in open or air-conditioned vehicles. Ice packs may be placed at the neck, groin, and axilla of the patient. Although immersion in ice water may be a more efficient means of lowering body temperature, it may complicate other support and monitoring. Among the most efficient but invasive methods is iced peritoneal lavage. However, a canine model of heat stroke suggested that an evaporative technique in which fans blew room air over subjects sprayed with 15°C (59°F) tap water was equally efficient. Temperature should be monitored continuously with a rectal probe, and active cooling should be discontinued when rectal temperature falls to approximately 38.5°C (101.3°F).

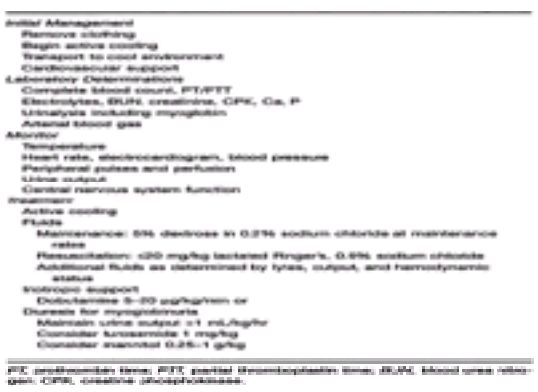

Table 89.6. Management of Heat Stroke

The severity of the patient's presentation determines the degree of cardiovascular support. If the skin is flushed and blood pressure adequate, lowering body temperature with close attention to heart rate and blood pressure may be sufficient. Although severe dehydration and electrolyte disturbances are uncommon, these should be assessed and corrected if necessary. Fluids cooled to 4°C (39.2°F) hasten temperature correction but may precipitate arrhythmias on contact with an already stressed myocardium. Adult patients rarely have required more than 20 mL/kg over the first 4 hours, but determinations of electrolytes, hematocrit, and urine output, and clinical assessment of central vascular volume should guide precise titration of fluids and electrolytes.

Patients with ashen skin, tachycardia, and hypotension demonstrate cardiac output insufficient to meet circulatory demand and are in imminent danger of death. Monitoring of the electrocardiogram (ECG) and arterial blood pressure (with an indwelling arterial line) should determine support.

Inotropic support may be required after a fluid challenge (see Chapter 3). Dobutamine is probably most appropriate: its b-agonist properties increase myocardial contractility and maintain peripheral vasodilation. Isoproterenol has been used successfully in the past but may cause myocardial oxygen consumption to exceed oxygen delivery. Additional fluid resuscitation may be necessary with the initiation of either dobutamine or isoproterenol to fill the effectively increased vascular space. Normal saline or albumin should be given to maintain the arterial blood pressure in the normal range. Dopamine may also be effective, infused at rates compatible with inotropic support without vasoconstriction. In cases of extreme hemodynamic instability, extracorporeal circulation may provide both circulatory support and a means of rapid temperature correction.

Agents with a-agonist characteristics (epinephrine and norepinephrine) are not recommended for initial management; they cause peripheral vasoconstriction, interfere with heat dissipation, and may compromise hepatic and renal flow further. Atropine and other anticholinergic drugs that inhibit sweating should be avoided.

Renal function should be monitored carefully, especially in patients who have been hypotensive or in whom vigorous exercise precipitated heat stroke. In general, BUN, creatinine, electrolytes, calcium, and urinalysis for protein and myoglobin should be obtained. Once the patient's vascular volume has been restored and arterial pressure normalized, hourly urine output should be monitored. If urine output is inadequate (less than 0.5 mL/kg per hour) in the face of normovolemia and adequate cardiac output, furosemide (1 mg/kg by IV) and/or mannitol (0.25 to 1 g/kg by IV) should be given. If the response is poor, acute renal failure should be suspected, and fluids should be restricted accordingly. Rapidly rising BUN or potassium (K^+) should prompt consideration of early dialysis.

ACCIDENTAL HYPOTHERMIA

Background

Elevated body temperature is a routine concern for most physicians, especially pediatricians. However, hypothermia, defined as core temperature at or below 35°C (95°F), is often overlooked. Reduced body temperature may be a consequence or cause of many disorders but is diagnosed only if health care providers maintain a high index of suspicion.

Populations at high risk for hypothermia are similar to those vulnerable to heat illness. Neonates and the elderly are most often affected. Physical disability, especially immobilizing conditions, and drug or alcohol ingestion increase risk at any age. Healthy young people who work or play to exhaustion in a cold environment are also at risk. The rising popularity of cold weather sports is producing more cases of accidental hypothermia. However, environmental conditions need not be

extreme, and the diagnosis should be considered even in temperate climates.

Primary CNS dysfunction, endocrinopathies, sepsis, protein caloric malnutrition, and various metabolic derangements may also depress core temperature.

Mortality rates, reported from 30 to 80%, depend more on the underlying disorder than on the degree of temperature depression.

Pathophysiology

Human core temperature is normally maintained within 0.6 °C (1°F). As described in the section on heat illness, this represents a fine balance between heat production and heat loss. When core temperature begins to fall below 37°C (98.6°F), physiologic mechanisms that produce and conserve heat are activated. Cooled blood stimulates the hypothalamus to increase muscle tone and metabolism (oxidative phosphorylation and high-energy phosphate production) and to augment heat production by 50% during nonshivering thermogenesis. When muscle tone reaches a critical level, shivering begins, and heat production increases two to four times basal levels.

Although surface temperature of the body, especially of the extremities, may drop nearly to environmental temperature, several mechanisms work to conserve heat and to protect blood and core structures from ambient air temperature, humidity, and wind. Sweating is abolished, decreasing heat loss by evaporation (unless there is external moisture), while vasoconstriction of cutaneous and subcutaneous vessels reduce losses further. Piloerection, which in many animal species traps an insulating layer of air next to the skin, occurs but is ineffective in humans.

When any component of the balance between heat production and loss is altered, the risk of hypothermia increases. Neonates, with large surface:volume ratios and small amounts of subcutaneous fat, conserve heat poorly and are unable to produce heat by shivering. The capacity for nonshivering thermogenesis—primarily metabolism of brown fat—is intact, but oxygen consumption is significantly increased. Hypoxemia may result, as well as metabolic acidosis, hypoglycemia, and hypocalcemia. Therefore, minor deviations in the thermal environment may produce hypothermia in neonates. More pronounced environmental stresses are required to overcome the greater compensatory capacity of older children.

Immersion in cold water causes the most rapid fall in body temperature. Struggling or swimming movements increase blood flow to the extremities and hasten hypothermia. Death occurs in 15 minutes in water at 0°C (32°F), but significant hypothermia occurs even in water at 21°C (69.8°F). Exposure to extreme cold is an obvious risk, taxing the body's ability to conserve and produce heat maximally. Voluntary motor activity produces heat, and physically fit, acclimatized persons may be able to increase activity to balance heat loss even in exceptionally cold environments. However, the metabolic cost of physical activity increases in the cold, and less fit persons quickly exhaust muscle glycogen supplies, are unable to maintain adequate heat production, and are likely to become hypothermic quickly. Wet, windy conditions hasten loss of body heat and may precipitate hypothermia even in temperate environments. Adolescents are psychologically less likely to conserve energy and to take preventive or corrective measures, thus increasing their risk of hypothermia.

Once homeostatic mechanisms fail and core temperature falls, predictable physiologic changes take place. If shivering does not occur, basal metabolic rate decreases steadily, reaching 50% of normal at 28°C (82.4°F). As a result, oxygen consumption and carbon dioxide production decline. The oxygen–hemoglobin dissociation curve shifts to the left.

Although respiratory depression occurs late, impaired mental status and cold-induced bronchorrhea predispose the patient to airway obstruction and aspiration. Acid-base balance follows no predictable pattern. Although respiratory acidosis occurs, tissue hypoxia, increased lactic acid production, and decreased lactate clearance by the liver produce metabolic acidosis.

Decreased heart rate contributes primarily to a fall in cardiac output. Peripheral vasoconstriction and an early increase in central vascular volume cause a transient rise in blood pressure, which later falls to become clinically significant below 25°C (77°F). A variety of cardiac conduction abnormalities arise, including decreased sinus rate, T-wave inversion, prolongation of ECG intervals, and the appearance of pathognomonic J waves (Fig. 89.4), which may provide the first clue to the diagnosis. Atrial fibrillation may occur at temperatures below 33°C (91.4°F) but is usually not hemodynamically significant. Below 28°C (82.4°F), myocardial irritability increases dramatically, and ventricular fibrillation becomes likely.

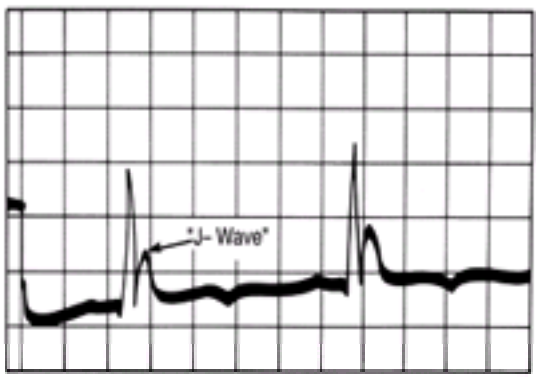

FIGURE 89.4. J wave, pathognomonic of hypothermia. Rounded contour distinguishes it from an RSR' pattern. It may also be confused with a T wave with a short Q-T interval. (Reprinted with permission from Welton D, Mattox K, Miller R, et al. Treatment of profound hypothermia. JAMA 1978;240:2291.)

Cold-induced vasoconstriction and elevated central blood volume and pressure contribute to a diuresis, which subsequently diminishes intravascular volume. At lower temperatures, tubular dysfunction allows salt and water loss. Acidosis causes potassium to shift from cells to the urine, where it is lost. Increased capillary permeability results in loss of fluid into the extracellular space.

Hematologic abnormalities may also occur. Plasma loss causes an increased hematocrit, whereas splenic sequestration may be responsible for a fall in white blood cell and platelet counts. Disseminated intravascular coagulation is sometimes seen.

CNS abnormalities are progressive. Each fall of 1°C produces a 6 to 7% decline in cerebral blood flow. Plasma loss increases blood viscosity, which further contributes to impaired cerebral microcirculation and mentation. Peripheral nerve conduction slows, and deep tendon reflexes decrease. Pupils dilate and react sluggishly, if at all, below 30°C (86°F). The electroencephalogram deteriorates progressively with falling temperature from high-voltage slow waves, to burst suppression patterns, to electrical silence at 20°C (68°F).

Gastrointestinal motility decreases below 34°C (93.2°F). The liver's capacity for detoxification or conjugation of drugs and products of metabolism is poor. Insulin release abates and serum glucose rises. Frank pancreatic necrosis may also occur, producing clinical evidence of pancreatitis.

Clinical Manifestations

The astute clinician must consider the possibility of hypothermia if the diagnosis is to be made in a timely manner. A history of sudden immersion in icy water or prolonged exposure to low environmental temperatures provides the obvious clue, but significantly low core temperatures may occur under much less suggestive circumstances. Examples include trauma victims found unconscious or immobile on a wet, windy, summer day; infants from inadequately heated homes or left exposed during prolonged medical evaluation; adolescents with anorexia nervosa; and patients with sepsis or burns. Severe hypothermia, coma, and cardiac arrest may present as the sudden infant death syndrome. Hypothermia may go undetected if the patient's temperature falls below the lower limit of the thermometer in use or if the thermometer is not shaken down adequately. Low-recording thermometers should be available in EDs and intensive care units. The diagnosis should be borne in mind for any patient with a suggestive history or coma of uncertain cause.

Physical examination reveals a pale or cyanotic patient. At mild levels of hypothermia, mental status may be normal, but CNS function is progressively impaired with falling temperature until frank coma occurs at approximately 27°C (80.6°F). Blood pressure also falls steadily below 33°C (91.4°F) and may be undetectable. Heart rate slows gradually unless atrial or ventricular fibrillation occurs. Intense peripheral vasoconstriction and bradycardia may render the pulse inapparent or absent. Below 32°C (89.6°F), shivering ceases, but muscle rigidity may mimic rigor mortis. Pupils may be dilated and may not react. Deep tendon reflexes are depressed or absent. Evidence of head trauma or other injury, drug ingestion, and frostbite should be sought (Fig. 89.5 and Fig. 89.6).

FIGURE 89.5. Frostbite of toes. Note the line of demarcation and ulcerative lesion.

FIGURE 89.6. Swollen fingers of a child with cold exposure.

Severe hypothermia mimics death. However, the significant decrease in oxygen consumption may allow life to be sustained for long periods, even after cessation of cardiac function. Signs usually associated with certain death (i.e.,

dilated pupils or rigor mortis) have little prognostic value. If the patient's history suggests that hypothermia is the primary event and not a consequence of death, resuscitation should be attempted and death redefined as failure to revive with rewarming.

Initial laboratory tests should include CBC, platelet count, clotting studies, electrolytes, BUN and creatinine, glucose, serum amylase, and ABGs corrected for temperature (Table 89.7). Urine should be sent for drug screening.

	For Each Elevation of 1°C	For Each Depression of 1°C
pH	-0.015	+0.015
$Paco_2$ (mm Hg)	+4.4%	-4.4%
Pao_2 (mm Hg)	+7.2%	-7.2%

Table 89.7. Effect of Body Temperature on Arterial Blood Gases Measured at 37° C (98.6° F)

Management

Therapy for hypothermia can be divided into two parts: general supportive measures and specific rewarming techniques (Table 89.8). Once hypothermia is diagnosed, temperature must be monitored continuously as treatment progresses.

Initial Management
Provide supplemental oxygen
Cardiopulmonary resuscitation for asystole, ventricular fibrillation
Laboratory Determinations
Arterial blood gas analysis corrected for temperature
Complete blood count, platelet count
Prothrombin time, partial thromboplastin time
Electrolytes, blood urea nitrogen, creatinine
Glucose, amylase
Urine drug screen
Monitor
Heart rate, electrocardiogram, respiratory rate, blood pressure
Temperature
Consider central venous pressure
Treatment
Correct hypoxemia, hyperkarbia
Correct hypokalemia
Correct hypoglycemia, 25% dextrose 1 g/kg IV
Tolerate hyperglycemia
Temperature: ≥32°C (89.6°F): passive rewarming or simple external rewarming
<32°C (89.6°F) (acute): external or core rewarming
<32°C (89.6°F) (chronic): core rewarming
Fluid replacement:
(acute) 5% dextrose in 0.2% saline at maintenance rates
(chronic) Normal saline, 5% albumin, fresh-frozen plasma to maintain blood pressure

Table 89.8. Management of Hypothermia

All patients should be given supplemental oxygen. Patients with profuse secretions, respiratory depression, or impaired mental status should be intubated and mechanically ventilated. Intubation should be performed as gently as possible to minimize the risk of arrhythmias.

A decreased metabolic rate produces less carbon dioxide, and usual minute ventilation would produce respiratory alkalosis, increasing the risk of dangerous arrhythmias. Therefore, ventilation should begin at approximately one-half the normal minute ventilation.

Assessment of acid-base status and ventilation in the hypothermic patient is the subject of considerable confusion. Blood gas machines heat the patient's blood sample to 37°C (98.6°F) before measuring pH and gas partial pressures (thus providing theoretical values if the patient were 37°C [98.6°F]). If the patient's actual temperature is provided with the sample, the machine can correct the values according to the nomogram of Kelman and Nunn. (Table 89.7 shows one set of guidelines for appropriate correction.) However, it is most important to understand two concepts. The first is the ectothermic principle, which relies on the following aspect of physiology: dissociation of ions and partial pressures of gases are decreased in cooled blood. In hypothermia, therefore, neutral pH is higher, whereas “normal” P CO_2 is lower than is encountered at 37°C (98.6°F). For example, hypoventilation of the hypothermic patient with a pH of 7.5 would actually induce an undesirable respiratory acidosis. A second, more practical concept is that if the patient's blood volume is restored and oxygenation maintained, acidosis will be corrected spontaneously as the patient is warmed.

Heart rate and rhythm should be monitored continuously and the patient handled gently to avoid precipitation of life-threatening arrhythmias in an exquisitely irritable myocardium. Sinus bradycardia, atrial flutter, and atrial fibrillation are common but rarely of hemodynamic significance. Spontaneous reversion to sinus rhythm is the rule when temperature is corrected. Ventricular fibrillation may occur spontaneously or with trivial stimulation, especially at temperatures below 28° to 29°C (82.4° to 84.2°F). Electrical defibrillation is warranted but frequently often is ineffective until core temperature rises. Closed chest massage should be initiated and maintained until the temperature is above 30°C (86°F), when defibrillation is more likely to be effective. Drug therapy is rarely effective and fraught with hazards associated with decreased hepatic and renal metabolism.

Fluid replacement is essential. Relatively little plasma loss occurs in acute hypothermia (as it does after cold-water immersion), but losses may be great in hypothermia of longer duration. Normal saline or lactated Ringer's solution, warmed to about 43°C (109.4°F) in a blood warming coil, is appropriate initially. Electrolyte determinations should guide further replacement. If clotting abnormalities occur, fresh-frozen plasma (10 mL/kg) is a useful choice for volume expansion (see Chapter 87). As temperature rises and peripheral vasoconstriction diminishes, hypovolemia is expected. Fluid volume should be sufficient to provide an adequate arterial blood pressure.

Hypoglycemia, if present, is treated with glucose (1 g/kg by IV). Hyperglycemia, which may result from impaired insulin release in the hypothermic pancreas, should be tolerated to avoid severe hypoglycemia with rewarming.

A number of rewarming strategies exist (Fig. 89.7). Passive rewarming implies removal of the patient from a cold environment and use of blankets to maximize the effect of basal heat production. For patients with mild hypothermia (temperature over 32°C [89.6°F]), this may be adequate.

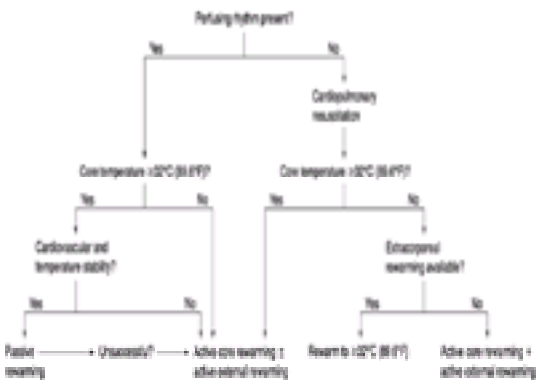

FIGURE 89.7. Algorithm for rewarming. (Adapted from data published in Danzl DF, Pozos RS. Accidental hypothermia. N Engl J Med 1994;331(26):1756–1760.)

Active rewarming is divided into external and core rewarming techniques. Electric blankets, hot water bottles, overhead warmers, and thermal mattresses are simple, easily available sources of external heat. Immersion in warm-water baths is also possible but complicates monitoring or response to arrhythmias. All of these methods, however, cause early warming of the skin and extremities with peripheral vasodilation and shunting of cold, acidemic blood to the core. The well-known “after-drop” of core temperature results. Severe hypotension may also occur in chronic cases as vasodilation increases the effective vascular space. External rewarming techniques limited to the head and trunk may minimize vasodilation and afterdrop. In acute hypothermia, active external rewarming is appropriate, but there is some evidence that in chronic cases (more than 24 hours), mortality is higher if active external rewarming is used instead of simple passive techniques.

Core rewarming techniques are almost certainly more rapid and less likely to be associated with after-drop, dangerous arrhythmias, or significant hypotension. These methods are especially valuable in the setting of severe chronic hypothermia (temperature below 32°C [89.6°F]), where fluid shifts are most likely to occur. A nonshivering human model of severe hypothermia indicated that inhalation rewarming offered no rewarming advantage, whereas forced air warming (approximately 200 W) allowed a sixfold to tenfold increase in rewarming rate over controls. A canine study of experimental hypothermia found that heated aerosol inhalation alone contributed less heat than endogenous metabolism, but that peritoneal lavage and pleural lavage had similar effect on rewarming (6°C/hour per meter squared). In humans, peritoneal dialysis, with dialysate warmed to 43°C (109.4°F), is effective and requires only equipment routinely available in most hospitals. Limited clinical experience suggests that pleural lavage is a relatively simple and useful measure. Hemodialysis, extracorporeal blood rewarming, and mediastinal irrigation are effective but require mobilization of sophisticated equipment and personnel. Gastric or colonic irrigation has also been advocated, but placement of the intragastric balloon may precipitate dysrhythmias.

Each increment in core temperature produces a “new” patient who requires reassessment and appropriate management, but most children with hypothermia have a good prognosis. In patients with mild temperature depression (above 32°C [89.6°F]), external rewarming techniques, and supportive care based on vital signs, ABGs, and metabolic parameters such as glucose and calcium levels, should result in prompt recovery. Patients with temperatures below 32°C (89.6°F), and especially those in whom hypothermia developed over 24 hours or more, require meticulous attention to continuously changing vital signs and metabolic needs. More elaborate core rewarming techniques are appropriate.

ELECTRICAL INJURIES

Background

Since the beginning of time, people have viewed lightning with fear and fascination. This natural phenomenon arises when warm, moist atmospheric air encounters cold air and is forced aloft. As warm air rises, it cools, condenses into a cloud, and loses electrons. A charge differential develops within the cloud, and lower aspects become relatively negatively charged, inducing a positive charge on the ground. Once a critical charge difference develops, electrons are discharged toward the ground, where positive charges meet the current from above. Current then flows to normalize the charge differential and superheats the air, causing the familiar flash of lightning and audible shock waves of thunder.

The last two centuries have witnessed the incorporation of controlled electricity into daily life and a better understanding

of its properties and physiologic effects. Availability of electricity has also meant increased exposure to electrical hazards and accompanying injuries. Electrical injury is responsible for approximately 700 deaths per year, of which 10% are children. No federal safety standards exist for household electrical cords, the major cause of electrocution in children 12 years of age and younger. High-tension electrical injuries dominate in older children who climb on trees, buildings, or utility structures.

Pathophysiology

The spectrum of electrical injury is enormous, ranging from low-voltage household accidents to million-volt lightning strikes (Table 89.9). Appropriate management requires an understanding of the basic physical aspects of electricity, the physiologic responses to injury, and the potential for immediate and delayed damage.

Factor	Lightning	High-Voltage
Duration	Brief	Prolonged
Energy level	100,000,000 V 200,000 amps	Much lower
Type of current	Direct	Usually alternating
Shock wave	Present	Absent
Cardiac	Asystole	Ventricular fibrillation
Burns	Superficial, minor	Deep, frequently obscured
Renal failures	Rare	Common secondary to myoglobinuria
Fasciotomy and amputation	Rare	Common, early, extensive

Table 89.9. Lightning versus High-Voltage Electrical Injury

The severity of electrical injury depends on six factors: 1) the resistance of skin, mucosa, and internal structures; 2) the type of current (alternating or direct); 3) the frequency of the current; 4) the intensity; 5) the duration of contact; and 6) the pathway taken by the current. Precise separation of the effect of these factors, which are interrelated, is impossible. Together, they produce either heat or current, and a variety of injuries result.

Resistance is a major factor determining the amount of current flow through tissue. Tissue injury is inversely related to resistance. Dry skin provides resistance of approximately 40,000 ohms, whereas thick, callused palms may provide up to 1×10^6 ohms. Thin, moist, or soiled skin lowers resistance to the 300- to 1000-ohm range. The highly vascular, moist oral mucosa has even lower resistance.

Once surface resistance is overcome, current flows between points of contact, not necessarily along anatomic structures such as nerves or blood vessels. Although the resistance of various tissues is known, the voltage difference may determine the actual path taken. Low-voltage current usually follows the path of least resistance, whereas high-voltage current follows a more direct course to ground with less regard for tissue type. Assessment of the most likely current pathway does not reliably predict injury. However, current that passes through the head or thorax may cause respiratory center or cardiac injury and increases the risk of cardiopulmonary arrest. Hand-to-hand flow carries risks of 60% mortality related to myocardial injury, spinal cord transection at C4–C8, and tetanic contraction of thoracic muscles with suffocation. Hand-to-foot current passage is associated with cardiac arrhythmias but lower mortality (20%). Foot-to-foot injuries are rarely fatal.

The type of current is another important determinant of injury. Alternating current (AC) at low voltage is able to induce tetanic muscle contraction and is therefore more dangerous than direct current (DC). These contractions prevent the victim from releasing his grip (“ locking-on”), thus extending the duration of contact. Normal household 60-Hz current changes direction 120 times per second, a frequency that induces an indefinite refractory state at neuromuscular junctions. Higher-frequency commercial currents are less likely to induce such a state and may be less harmful.

DC is used in medical settings for cardiac defibrillation, countershock, and pacing. Currents as low as 1 mA may trigger ventricular fibrillation, and high currents may damage the heart and conducting tissues directly. Lightning is another example of DC, discharged in a single, massive bolt that lasts $^1/_{10,000}$ to $^1/_{1,000}$ second. The brevity of exposure makes deep thermal injury unlikely.

In general, high-voltage injury is more dangerous than low-voltage injury. A higher voltage is more likely to cause “locking-on” and associated deep-tissue injury, although its tendency to throw victims from the source of current may mitigate this effect. The possibility of head and cervical spine injuries must be considered in these cases. The value of the current, or amperage, is of even greater importance than the voltage. Flow as low as 1 to 10 mA may be perceived as a tingling sensation. Progressively higher flows may paralyze muscles and ventilation, precipitate ventricular fibrillation, and cause deep-tissue burns.

Clinical Manifestations

Electrical injury may produce a variety of clinical pictures, ranging from local damage to widespread multisystem disturbances. Typically, deceptively small entry and exit wounds mask extensive damage to subcutaneous tissue, muscle, nerves, and blood vessels. Direct effects on the heart and nervous system are particularly common, and injury to all other symptoms can occur. Much of the injury is revealed immediately, but late complications are often encountered.

Victims of the most severe accidents are commonly pulseless, apneic, and unresponsive. Current that passes directly through the heart may induce ventricular fibrillation. Brainstem (medullary) paralysis or tetanic contractions of thoracic muscles may result in cardiopulmonary collapse. Lightning injury is capable of inducing asystole, from which the heart may recover spontaneously, but the accompanying respiratory failure is commonly prolonged. Unless ventilation is initiated promptly, hypoxia leads to secondary ventricular fibrillation and death.

Other cardiac disorders, including arrhythmias and conduction defects, are common among survivors. Supraventricular tachycardia, atrial and ventricular extrasystoles, right bundle branch block, and complete heart block are most common. Complaints of crushing or stabbing precordial pain may accompany nonspecific ST-T wave changes. Some patients sustain myocardial damage or even ventricular wall perforation. Despite evidence of important cardiac injuries, patients without secondary hypoxic-ischemic injury usually regain good myocardial function.

Nervous system injury is also extremely common and may involve the brain, spinal cord, peripheral motor, and sensory nerves, as well as sympathetic fibers. Loss of consciousness, seizures, amnesia, disorientation, deafness, visual disturbances, sensory deficits, hemiplegia, and quadriparesis occur acutely but may be transient. Vascular damage may produce subdural, epidural, or intraventricular hemorrhage.

Additional problems develop within hours to days after injury. The syndrome of inappropriate antidiuretic hormone secretion may precipitate herniation in rare cases. Electroencephalograms reveal diffuse slowing, epileptiform discharges, or burst suppression patterns, but they may not have prognostic significance. Spinal cord dysfunction yields more motor than sensory deficit. Peripheral neuropathies with patchy distribution may reflect direct thermal injury, vascular compromise, or current flow itself. A variety of autonomic disturbances may resolve spontaneously or persist as reflex sympathetic dystrophy.

Ocular damage is common, particularly after lightning strikes. Direct thermal or electrical injury, intensive light, and confusion contribute to the presentation. Findings include corneal lesions, hyphema, uveitis, iridocyclitis, and vitreous hemorrhage. Choroidal rupture, retinal detachment, and chorioretinitis occur less often. Autonomic disturbances in a lightning victim may cause fixed dilated pupils, which should not serve as a criterion for brain death without extensive investigation of other neurologic and ocular functions. Cataracts and optic atrophy are possible late developments.

Electrical injury may induce direct or indirect complications in other organ systems. Tetanic contractions may cause joint dislocations and fractures, especially of the upper extremity long bones and vertebrae. Fractures of the skull and other long bones may occur when high-tension shock throws the victim from the site of contact. Early cardiopulmonary insufficiency, as well as direct renal effects, may cripple renal function. Damaged muscle releases myoglobin and creatinine phosphokinase (CPK). As in crush injuries, myoglobin may induce renal tubular damage and kidney failure. Pleural damage may cause large effusions, whereas primary lung injury or aspiration of gastric contents may lead to pneumonitis. Gastric dilation, ileus, diffuse gastrointestinal hemorrhage, and visceral perforation may occur immediately or later.

In addition to burns at the site of primary contact, burns are common where current has jumped across flexed joints. Such burns are most common on the volar surface of the forearm and across the elbow and axilla. Arcing current may also ignite clothing and produce typical thermal burns. Entry and exit wounds and arc burns are notoriously poor predictors of internal damage. Tissue that appears viable initially may become edematous and then ischemic or frankly gangrenous over several days. Diminished peripheral pulses may provide immediate evidence of vascular damage, but strong pulses do not guarantee vascular integrity. Blood flow falls to a minimum at about 36 hours, but current or thermal damage may lead to vasospasm, delayed thrombosis, ischemic necrosis, or aneurysm formation and hemorrhage weeks after the injury. Viable major arteries near occluded nutrient arteries may account for apparently adequate circulation and uneven destruction of surrounding tissues.

Young children are vulnerable to orofacial burns, especially of the lips (Fig. 89.8). These full-thickness burns of the upper and lower lips and oral commissure usually involve mucosa, submucosa, muscle, nerves, and blood vessels. The lesion usually has a pale, painless, well-demarcated, depressed center with surrounding pale gray tissue and erythematous border. After a few hours, the wound margin extends and marked edema occurs. Drooling is common. The eschar separates in 2 to 3 weeks and bleeding may occur at this time; granulation tissue gradually fills the wound. Scarring may produce lip eversion, microstomia, and loss of function. Damage to facial or even carotid arteries may result in delayed hemorrhage. Devitalization of deciduous and secondary teeth may occur.

FIGURE 89.8. Patient with electrical burns to the corner of the mouth after biting on an electrical cord. (Courtesy of Evaline Alesandria, MD)

Inadequately debrided burned or gangrenous tissue provides a medium for serious infection. Staphylococcal, pseudomonal, and clostridrial species are common pathogens in the extremities. Streptococci and oral anaerobic organisms may infect mouth wounds.

Management

The first step in emergency management (Table 89.10) is to separate the victim from the current source. The rescuer must be well insulated to avoid becoming an additional casualty. If the current cannot be shut off, wires can be cut with a wood-handled ax or appropriately insulated wire cutters. Contrary to popular myth, a lightning stroke victim does not remain “electrified” and presents no risk to another person.

Table 89.10. Management of Electrical Injuries

Any victim in cardiopulmonary arrest should be resuscitated promptly following the guidelines discussed in Chapter 1. Prolonged efforts to restore adequate cardiopulmonary and cerebral function, especially in the lightning victim, may be appropriate in the context of bizarre neurologic phenomena that inhibit ventilatory efforts, consciousness, or pupillary function. The patient who fails to respond to resuscitative efforts over hours to days and meets standard brain death criteria can be pronounced dead with reasonable certainty.

Any patient who sustains electrical injury deserves a comprehensive physical examination. Bleeding or edema from orofacial burns may compromise the upper airway. The head, particularly eyes, and neck should be examined carefully for evidence of trauma. The skin should be examined carefully for burns and bruises. Limbs should be evaluated for pulses, perfusion, and motor and sensory function, as well as for soft-tissue swelling or evidence of fractures. Burns and deep-tissue injury may progress over hours to days, so repeated examination and monitoring are important.

Neurologic evaluation is especially important in all but the most minor, localized peripheral injuries. Level of consciousness and mental status should be assessed according to the child's developmental level. Cranial nerve, cerebellar, motor, and sensory evaluation are essential.

Children who have sustained minor household electrical injuries and are asymptomatic usually do not require laboratory evaluation, cardiac evaluation, or hospitalization. In one series, investigators were unable to assess the clinical significance of loss of consciousness, tetany, wet skin, or current flow across the heart, and recommended cardiac monitoring if any of these factors is present. If the history is one of a high-tension injury or lightning strike, laboratory evaluation should include ECG, CBC, CPK (with fractionation), BUN, creatinine, and urinalysis, including urine myoglobin. Physical examination that reveals evidence of bruises, bony tenderness, or distorted long bones should prompt appropriate radiographic studies.

Most children who sustain burns of the oral commissure (usually after biting an electrical cord) do not require extensive evaluation or admission. In cases of severe orofacial burns, use of an artificial airway should be considered before progressive edema leads to catastrophe. Mechanical ventilation may be necessary to overcome CNS depression or primary lung involvement.

Patients with persistent coma and loss of protective airway reflexes should be intubated to avoid aspiration. Good oxygenation and ventilation adequate to maintain a normal pH and Pa CO_2 of 35 to 40 mm Hg must be ensured. Seizure activity should be treated as indicated (see Chapter 70 and Chapter 83).

Care of the CNS is of utmost importance. The neck and back should be immobilized if the patient was thrown from the site of injury. If the mechanism of injury was severe, the cervical collar should be maintained in place despite normal cervical spine radiographs. If a child fails to regain consciousness within a short time or shows signs of neurologic deterioration, a computed tomography (CT) scan will help exclude intracranial hemorrhage.

Any patient who has sustained cardiopulmonary arrest, loss of consciousness, or deep-tissue injury should be admitted to hospital for evaluation and treatment. Heart rate, respiratory rate, and blood pressure should be monitored regularly. Doppler evaluation may be helpful in cases of vasospasm, which may complicate assessment of blood pressure and subsequent fluid management. True hypotension may require presser support.

Cardiopulmonary support is nonspecific. Most patients resume good circulatory stability unless severe hypoxia and ischemia have weakened the myocardium. Arrhythmias and acidosis should be treated along usual lines (see Chapter 82

and Chapter 86).

Patients struck by lightning require only maintenance fluids. Patients with ordinary thermal burns should be treated according to standard recommendations (see Chapter 114), although body surface area calculations may seriously underestimate fluid requirements. Extensive vascular and deep-tissue destruction may lead to extensive fluid sequestration. Isotonic fluid should be given in amounts to maintain normal pulse and blood pressure. In all cases, fluids should be given judiciously to avoid CNS complications.

Cerebral edema may develop over hours to days after injury, especially after a lightning strike. If the child's neurologic status fails to improve or deteriorates, intracranial pressure monitoring and treatment, including hyperventilation, osmotic or loop diuretics, and sedation and neuromuscular blockade, may be necessary. Serum and urine electrolytes and osmolality should be followed closely to recognize promptly the syndrome of inappropriate antidiuretic hormone secretion.

Myoglobin in the urine is consistent with muscle breakdown and sets the stage for renal failure. Hydration and brisk diuresis with furosemide and/or mannitol may prevent renal damage but must be undertaken with caution if there is coexistent CNS injury. Extensive muscle damage after lightning injury is uncommon, however, and major CNS injury is common. Treatment should proceed with these relative risks in mind until definitive information is available.

Most burns associated with lightning injury are superficial. Although they may become more apparent after several hours, most remain first- or second-degree burns. Minor burns on the extremities can be treated with antibiotic ointment and should be allowed to slough and heal. Oral and plastic surgeons should evaluate children who sustain oral burns. In most cases, similar conservative management is recommended, but a removable stent may be necessary to minimize scarring.

High-voltage injuries commonly require more aggressive treatment, and early surgical evaluation is essential. Fasciotomy may be necessary to restore adequate circulation to an injured extremity. The approach to debridement of wounds is controversial, but most surgeons rely on repeated examinations to detect nonviable tissue. Approximately 30% of survivors of high-tension injuries ultimately require amputation of some part of an extremity.

The risk of infection in patients with deep-tissue injury is high. Any patient not clearly immunized against tetanus should be given tetanus toxoid. Prophylactic antibiotics have been recommended for oral injuries, but in general, antimicrobial therapy should be reserved for proven or strongly suspected infection.

BACKGROUND

The international radiation accident registry maintained at Oak Ridge, Tennessee, lists 394 accidents that have occurred worldwide from 1944 until January 1998. Three thousand people were exposed to significant amounts of radiation, and 113 persons died as a direct result of these radiation accidents. Most of the survivors had no permanent injury as a result of the accident. The major concerns for the survivors are a small increase in the risk of cancer and the psychological stress caused by their concerns and those of their community about the long-term effects of radiation exposure. Of the 394 accidents, 239 occurred in the United States, resulting in 30 fatalities. Worldwide, fewer than 10 fatalities have been reported in children. Although the data collected by accident registries are incomplete, it is clear that radiation accidents that result in medically significant injuries are uncommon.

Despite the rarity of medically significant radiation accidents, the emergency physician needs to be aware of the basic principles and management of radiation accidents for four major reasons. First, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) requires plans for managing environmental accidents, including those involving hazardous materials. Second, although serious radiation accidents are rare, incidents in which radiation is perceived to have an important role are not uncommon. For instance, the discovery of a cardboard box with a radioactive label attached to it in a school play yard is likely to cause considerable concern. Generally, the public perceives radiation to be very hazardous and does not distinguish between amounts of radiation that we are exposed to every day from natural sources and amounts of radiation that have a measurable biologic effect. One definite long-term effect of radiation accidents is psychological stress caused largely by misconceptions and fear of the unknown. If the emergency physician is knowledgeable about the effects of radiation, he or she can correctly counsel the patient and immediately help decrease the psychological trauma. Third, fear of radiation and lack of knowledge about its effects have led to the medical mismanagement of several individuals who were thought to be involved in a radiation accident. Concern about the possible radiation aspects of the accident prevented the medical team from providing the appropriate medical care. Finally, the emergency physician needs to be knowledgeable about the effects of radiation because the rare radiation accident is often not initially recognized. A broad understanding of radiation accidents that have occurred in the past should help physicians recognize situations in which radiation might be considered as a cause. Frequent training and drills are essential to ensure that the emergency department (ED) staff has the procedural skills and supplies to deal with possible radiation accident victims.

PATHOPHYSIOLOGY

Types of Radiation

The source of some of the confusion about the medical consequences of an unintentional exposure to radiation originates in the general lack of understanding of the word *radiation*. *Radiation* is a general term used to describe energy that is emitted from a source (Fig. 90.1). Some forms of radiation are able to deposit a large amount of energy in a small volume of tissue. These energetic forms of radiation are called ionizing radiation because they deposit enough energy to strip electrons from atoms. Other types of radiation are less energetic and are called nonionizing radiation. The

distinction between ionizing and nonionizing radiation is important because their biologic effects are very different.

FIGURE 90.1. Types of radiation.

Ionizing radiation can be further subdivided into types of radiation that have no associated mass (nonparticulate) and those that have mass (particulate). X rays and gamma rays are nonparticulate types of radiation. This type of radiation can penetrate deeply into the body and affect radiation-sensitive tissues (e.g., bone marrow, the lining of the gastrointestinal tract). X rays are emitted by excited electrons, whereas gamma rays are emitted by excited or unstable nuclei. Once an x ray or gamma ray has been emitted, they are indistinguishable.

Particulate radiation can be further divided into particles that are charged and particles that are uncharged. Neutrons, a type of particulate radiation that has no electrical charge, can penetrate the body to depths similar to x rays and gamma rays. Because neutrons deposit their energy in a more concentrated area, neutrons cause more biologic damage than x rays or gamma rays.

Alpha rays and beta rays are charged particles. Alpha rays have a 2+ electrical charge and a large mass (two protons and two neutrons). Beta rays have a single negative charge and a small mass (one electron). Charged particles do not penetrate the body very well. Because of their larger mass and charge, alpha rays cannot penetrate even the dead layers of skin. For example, plutonium-239, an alpha emitter, is a biologic hazard only when it is inhaled, ingested, or otherwise absorbed into the body. Beta rays are more penetrating and can severely damage the skin. Beta rays cannot damage the deep radiation-sensitive organs in the body unless the radioactive source is incorporated into the body. At the Chernobyl nuclear plant accident in Russia, some of the firemen had severe skin damage as a result of intense beta ray exposure. This injury contributed to their deaths.

The words *radiation* and *radioactive* are often confused. An atom that is unstable spontaneously gives off radiation and is radioactive. In contrast, an x-ray machine cannot spontaneously give off radiation. An external power source is needed. Therefore, an x-ray machine is not radioactive. A patient who has been exposed to radiation does not become radioactive. Patients spontaneously give off radiation only if they have radioactive atoms on them (external contamination) or in them (internal contamination).

Amounts of Radiation

Although radiation cannot be perceived by the human senses, Geiger counters can easily measure amounts of radiation that are far below the levels that can be shown to have a measurable biologic effect. Geiger counters are inexpensive and are readily available in the nuclear medicine department at most hospitals. Because a Geiger counter can detect and quantify the radiation hazard, managing a radiation hazard is easier than managing biologic hazards such as human immunodeficiency virus (HIV), meningitis, or methicillin-resistant *Staphylococcus aureus.*

Radiation exposure is commonly measured in three different units: roentgen, rad, and rem. A *roentgen* is a measure of the number of ion pairs that are produced in a volume of air by the radiation from an x-ray machine or from radioactive atoms. The *rad* (roentgen absorbed dose) is a measure of how much energy is deposited per gram of tissue. The absorbed dose depends on the type of radiation and the size, shape, and composition of the object absorbing the radiation. Finally, a *rem* (roentgen equivalent in man) takes into account the biologic effects of various kinds of radiation. Some types of radiation (e.g., neutrons, alpha particles) cause greater biologic harm than x rays or gamma rays. For x rays and gamma rays, a rad and a rem are equivalent. The nomenclature for radiation dose is further complicated by the fact that the international community uses terms that have not yet gained widespread use in the United States. The Standard International Units for radiation dose are listed in Table 90.1.

	Common United States Units		Standard International Units
Exposure	Roentgen, R		None
Dose	Radiation absorbed dose, rad		gray, Gy
	100 rads	=	1 Gy
Dose	Roentgen equivalent in man, rem		sievert, Sv
	100 rems	=	1 Sv
Quantity	Curie, Ci		becquerel, Bq
	(3.7×10^{10} disintegrations/sec)		(1.0 disintegrations/sec)
	1 mCi	=	37 MBq

Table 90.1. Units for Radiation, with Abbreviations

To put these units into perspective, it is helpful to recall that we are exposed to about 300 mrems (1000 mrems = 1 rem) of radiation each year from natural sources. During a 70-year lifetime, the total radiation exposure from natural sources will be more than 20 rems. There is no measurable biologic effect of radiation with acute doses below 10 to 20 rems. Typical radiation exposures that we encounter as part of our daily lives as well as in medicine are listed in Table 90.2.

Sources	Dose
Round-trip intercontinental air flight	2-3 mrems
Chest radiograph	5-10 mrems
Living in brick house	20 mrems/yr
Natural radiation	300 mrems/yr
Angiography	1000 mrems

Table 90.2. Common Radiation Doses

An additional unit, the curie, is used to describe the quantity, or amount, of a radioactive material. The curie is the number of radioactive atoms that are decaying per unit time. One curie of radium equals approximately 1 g of radium. Diagnostic studies in nuclear medicine typically use millicurie amounts of radionuclides. The hazard posed by a radionuclide cannot be inferred easily from knowledge of the amount of the radionuclide. In addition to the amount of the radionuclide (in curies), the hazard posed by a radionuclide depends on its decay scheme, the energies of its emissions, its half-life, and on how long it stays in various organs in the body. If the radionuclide decays only by emitting alpha particles, it is not a hazard if it is kept outside the body. As mentioned previously, alpha rays cannot penetrate even the dead layers of the skin. On the other hand, radionuclides (e.g., iodine-131, hydrogen-3 as water) that are readily absorbed by the body and/or are concentrated by an organ can be a significant hazard even when present in small amounts.

Radiation Safety

The worst radiation accident involving a commercial nuclear power plant in the United States resulted in a radiation dose to off-site medical personnel of 14 mrems. Following the Chernobyl accident, the highest radiation dose to off-site medical personnel was a few rems. These doses should reassure ED personnel that it is extremely unlikely that a radiation accident would ever threaten their own safety.

Patients who have been exposed only to radiation, such as a patient who has just had a chest radiograph taken, are not radioactive and require no special radiation precautions.

Although the radiation doses to ED personnel involved in the care of an accident victim contaminated by radioactive material are likely to be very small, simple protective measures can be used to make the doses even smaller. There are three methods of protection from the radiation exposure: minimizing time of exposure, maximizing distance to the extent practical, and using shielding as appropriate (Fig. 90.2). The amount of exposure received is directly proportional to the time spent near the source of radiation. Distance is the most practical and effective method of reducing radiation exposure because the dose decreases by the square of the distance. Doubling the distance from a source of radiation will reduce the dose by a factor of 4, and tripling the distance will reduce the dose by a factor of 9 (Fig. 90.3). This is known as the inverse square law. Shielding, such as that in the familiar lead apron, although useful in radiology departments where radiation is a hazard because of low-energy scattered radiation, does not play a significant role in radiation accident management. The reason for this is that most sources of radiation that are likely to be encountered have higher energies, and the amount of apron shielding required for useful protection becomes impractical.

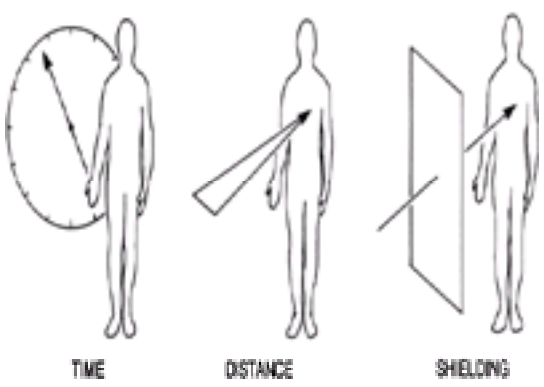

FIGURE 90.2. Three methods of reducing radiation exposure.

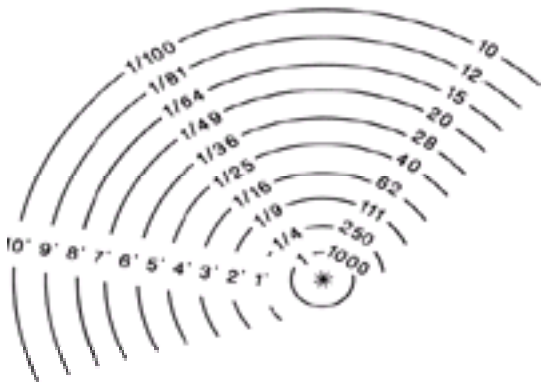

FIGURE 90.3. The effect of distance on radiation exposure from a point source of radiation.

CLINICAL MANIFESTATIONS AND EVALUATION

Recognizing an Accident

Radiation accidents can be recognized by understanding three questions: Who is likely to be affected by a radiation accident? What are the likely sources of radiation? and What are the likely injuries?

Types of Victims

The people who are most likely to be involved in a radiation accident are individuals whose work involves radiation. Although these accidents are usually recognized, several work-related accidents were not initially appreciated. One valuable way to determine whether a radiation accident has occurred is to contact the worker's supervisor and/or the radiation safety officer for the employer. In most instances, they will immediately recognize whether the possibility of a serious radiation exposure exists.

A second group of individuals who may be involved in a radiation accident are members of the general public who inadvertently come into contact with a radiation hazard. An example of this kind of accident occurred in Goiana, Brazil, in September 1987. In this accident, a cesium-137 radiation therapy source was stolen from an abandoned medical clinic. The poachers brought the source to their home, exposing their family and friends to large doses of radiation. Their exposure was worsened when the victims broke open the cesium-137 source, subsequently contaminating their food, their living quarters, and the area surrounding their homes. As a result of this accident, four people, including a 6-year-old girl, died. Hundreds of other people were exposed to nonlethal amounts of radiation. The accident was not recognized until 2 weeks after the source had been opened. When the individuals first became ill, their symptoms were diagnosed as gastroenteritis.

A third group of individuals who may be involved in a radiation accident are people who are unknowingly and intentionally exposed to radiation by another person. An infamous case that happened in the United States involved a 13-year-old boy who was intentionally exposed to radiation by his father. These exposures occurred on multiple occasions during weekend visitations over 6 months. Months later, the son recalled occasionally finding “shiny silver pellets” in the ear pieces of headphones he was told to wear, in a pillow he was told to use, and in a sock he found on his bed. Other injuries suggested that he was exposed at other times while under sedation.

Soon after his first exposure, the boy developed skin lesions, described as bruises, that gradually developed into reddish brown blisters. These lesions were attributed to an infection. Subsequently, he developed lesions on the medial aspects of both thighs, the right ankle, right hand, and left forehead. He also began losing hair from the left side of his head. The lesions became increasingly incapacitating and the boy was admitted to a hospital for 3 weeks. An infectious cause for the lesions could not be established. A psychiatrist suggested a neurodermatitis caused by the conflict between the boy and his father. During a 20-month period, the boy was seen by 16 physicians. Finally, a plastic surgeon recognized the lesions as radiation necrosis. The boy required multiple operations to repair his injuries.

The father, a petroleum engineer, had access to two curie cesium-137 sources. The dose rate at contact for such a source is approximately 500 rads/minute. However, at 1 cm, the dose rate drops to 30 rads/minute and is about 4 rads/minute at 3 cm from the surface. The father was found guilty of child abuse.

Types of Radiation Sources

To cause a significant radiation injury, an intense radiation source is needed. The four major types of possible intense radiation sources are listed in Table 90.3. Because of their different physical properties, different types of sources are likely to cause different types of radiation injuries.

Type of Source	Examples	Likely Injuries
Sealed	Industrial radiography	Contamination unlikely
	Brachytherapy	Local radiation injury with small source
	Some radiation therapy machines	Whole-body exposure with large source
	Industrial sterilizers	
Unsealed	Medical radionuclides (e.g., ^{131}I, ^{99m}Tc)	External and internal contamination likely
	Accidental release by a nuclear power plant	
	Radium dial painters	
Radiation devices	Cyclotron	Local radiation injury likely
	Linear accelerator	
Uncontrolled fission	Nuclear reactor	Large whole-body doses likely
	Uranium enrichment	
	Weapons production	On-site and off-site contamination possible for nuclear reactions

Table 90.3. Intense Radiation Sources

Sealed sources contain a radioactive source in a leak-proof container. Because the containers are leak-proof, these accidents usually cause radiation exposure only. Contamination occurs only if the container is broken open. Examples of sealed sources include industrial radiography sources, some radiation therapy machines, and industrial sterilizers.

By far, industrial radiography sources have caused the most radiation accidents. Thousands of these highly radioactive sources exist in the United States. They are used in industry to radiograph metal parts such as pipe welds. When not in use, the radioactive source is shielded in a thick lead container. To take a radiograph, one must crank the source out of the shield using a cabling system. Until recently, the source was attached to the cable by a simple mechanism that sometimes failed. If the source detached from the cable, it could be lost. The source is about the size of a pen (Fig. 90.4); it is metallic and innocuous appearing. In the past, the source was not labeled; a passerby could find the source and not recognize it to be dangerous. Because this type of source is small, it usually causes a local radiation injury (see the following) involving the hands (from picking up the source) or the buttocks (from putting the source in a pocket).

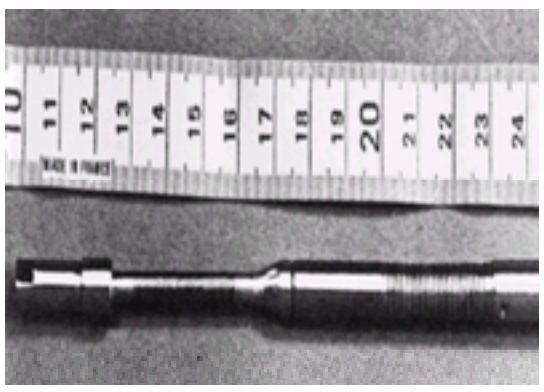

FIGURE 90.4. Source of radiation that affected two Algerian children in 1978.

Sealed sources used in radiation therapy can be small (brachytherapy) or large (cobalt therapy machine). Industrial sterilizers use very large, intense radiation sources to sterilize products (e.g., medical supplies) that would be damaged by other methods of sterilization. Large, sealed sources are more likely to result in whole-body radiation exposure.

Unsealed sources, a second type of radiation source, consist of radioactive material in a form that is dispersed easily (e.g., liquid, powder). The likely injury caused by unsealed sources is external and internal contamination. An unsealed source commonly found in hospitals is a solution of radioactive iodine (iodine-131) that is used to treat some thyroid diseases. If these radioactive atoms are kept on the outside of the body (external contamination), they usually cause only minor harm. The radioactive dirt can be washed from the skin much the way that other kinds of dirt are washed from the skin. If properly managed, external contamination is generally a nuisance rather than a serious health threat to the patient or medical staff. If the radioactive dirt gets into the patient's body (internal contamination) by ingestion, inhalation, or absorption through the skin or a wound, minimizing the radiation dose is more difficult. Other examples of unsealed sources include radium ingested by radium dial painters and radionuclides released during the accident at the Chernobyl nuclear power plant.

Radiation devices, the third potential radiation source listed in Table 90.3, are likely to cause a local radiation injury. Because these devices emit radiation when switched on but are not radioactive, it is unlikely that patients exposed to radiation from radiation devices will be radioactive when they present for treatment.

A fourth possible radiation source is an uncontrolled nuclear reaction (criticality accident). Usually, there is an intense radiation exposure for a very brief period. Criticality accidents have resulted in the largest whole-body radiation exposures that have occurred as the result of radiation accidents. Most of the radiation dose results from neutrons. These accidents can occur at only uranium enrichment facilities and nuclear reactors where there is a critical mass of nuclear material. Fortunately, criticality accidents are rare. Only two criticality accidents have occurred since the late 1960s; one of these was the 1986 accident at Chernobyl. The Chernobyl accident caused the deaths of 31 people who were at the nuclear power plant at the time of the accident. In addition, millions of people were exposed to low levels of radiation when hundreds of square miles of land were contaminated with radioactive debris from the Chernobyl accident.

Types of Radiation Injury

Perceived

There are three major types of radiation injury (Table 90.4). The first and by far the most common injury is the perceived radiation injury. Because of misconceptions about the possible health effects of radiation, members of the general public, fearful of having been exposed, may attribute almost any illness to radiation exposure. Unfortunately, these perceptions are often reinforced by physicians who are not knowledgeable about radiation biology. The psychological stress caused by misdiagnosis can be significant.

Perceived	Contamination
Exposure	External
Whole-body	Internal
Local	Metal fragment
	Hot particle

Table 90.4. Types of Radiation Injuries

Exposure

The second major type of radiation injury is exposure to radiation. Because these patients do not have radioactive dirt on them or in them, they are not radioactive and can be treated without any additional precautions. Two types of radiation exposure are possible. Large doses of penetrating radiation over a short period to a large portion of the body (i.e., whole-body radiation) cause the acute radiation syndrome. Exposure to alpha or beta particles of any source would never cause the syndrome because this type of radiation is nonpenetrating. Large doses of radiation over a short period to a small portion of the body cause a local radiation injury. When only a small portion of the body is exposed, much larger doses of radiation can be tolerated. Analogous medical situations would be whole-body radiation as conditioning for bone marrow transplantation and localized radiation therapy for breast cancer.

Whole-Body Exposure

The signs and symptoms of the acute radiation syndrome (Table 90.5) begin to appear with whole-body radiation doses of 100 rems. Organs with rapidly dividing cells (the bone marrow and the lining of the gastrointestinal tract) are the most susceptible to radiation damage. The amount of damage that occurs depends on the dose as well as on the dose rate. For example, a dose of 100 rads received in 1 minute would probably cause symptoms; however, a dose of 100 rads received at a dose rate of 1 rad/day for 100 days would not cause symptoms. Doses of about 400 rems are lethal in approximately 50% of untreated people. With maximum medical treatment, the dose of radiation that will kill 50% of people may be as high as 650 rems.

Whole-Body Absorbed Dose (rem)	Comments
5	Asymptomatic
10	Asymptomatic (minimal detectable dose using cytogenetics)
50	Asymptomatic (minor depression of white cells and platelets possible)
100	Nausea and vomiting in approximately 15% of patients within 2 days of exposure
200	Nausea and vomiting in most patients Moderate hemopoietic syndrome
400	Nausea, vomiting, and diarrhea within 48 hr; severe hematologic depression; 50% mortality without medical treatment
600	100% mortality within 30 days without medical treatment; 50% mortality with medical treatment
700	Gastrointestinal syndrome; survival unlikely; death within 2–3 wk
5000	Neurovascular syndrome; death in 24–72 hr

Table 90.5. Dose-Effect Relationship after Acute Whole-Body Radiation Exposure

The acute radiation syndrome consists of three distinct phases (Table 90.6). The prodromal phase begins minutes to hours after the radiation exposure and lasts for 2 to 3 days. During the prodromal phase, the patient may have nausea, vomiting, diarrhea, fatigue, and/or headache. The prodromal phase is followed by the latent phase, during which the patient is relatively asymptomatic. The latent phase generally lasts until 3 weeks after the exposure. The third and final phase is the manifest illness phase. During the manifest illness phase, the patient is at greatest risk for infection and bleeding as a result of the bone marrow suppression and gastrointestinal epithelial damage caused by the radiation exposure. As the radiation dose increases, the duration of the prodromal phase increases and the length of the latent

phase decreases.

Prodromal (0–2[a])	Latent (2–20[a])	Manifest Illness (21–60[a])
Fatigue	Asymptomatic	Bone marrow depression
Nausea and vomiting		Sepsis
Diarrhea		Bleeding
Headache		Diarrhea
Dizziness		
Decreased lymphocyte count		

[a]Days after exposure.

Table 90.6. Acute Radiation Syndrome—Signs and Symptoms

With doses of 200 to 400 rems, the primary effect of the whole-body radiation is to depress the bone marrow. Although the lymphocyte count (Fig. 90.5) decreases rapidly within the first 24 hours, there is no need for acute medical treatment. The patient will be at greatest risk 34 weeks after the radiation exposure, when the white cell and platelet counts reach a nadir (Fig. 90.6). At this time, the patient is vulnerable to death from infection and bleeding. If the patient can be supported during this period of vulnerability and if the bone marrow is not irreversibly damaged, a recovery phase ensues (Fig. 90.7).

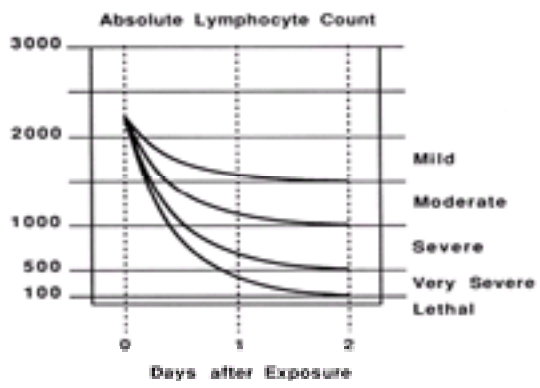

FIGURE 90.5. Effect of whole-body radiation on lymphocytes in the first 2 days after exposure.

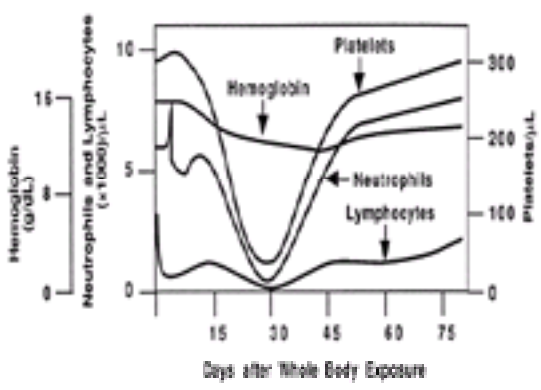

FIGURE 90.6. Effect of whole-body radiation on blood counts in the days after exposure.

FIGURE 90.7. Chernobyl victim suffering from acute radiation syndrome a few weeks after the accident. Note the hair loss, indicating a radiation dose of several hundred rems. Also note injury to the skin of the lower extremities as a result of high (a few thousand rems) doses of beta (nonpenetrating) radiation. (Courtesy of A.M. Davis.)

The gastrointestinal syndrome occurs from absorbed doses of more than approximately 700 rads. During the prodromal phase of this syndrome, there is prompt onset of severe nausea, vomiting, and diarrhea. There is a latent period of approximately 1 week and then recurrence of gastrointestinal symptoms, sepsis, electrolyte imbalance, and likely death. The patient is very susceptible to infection because of the depressed bone marrow and because pathogens can readily enter the body across the damaged gastrointestinal lining.

At dose levels of more than 5000 rads, the cardiovascular/central nervous system (CNS) syndrome predominates. There is almost immediate nausea, vomiting, prostration, hypotension, ataxia, and convulsions. The permeability of blood vessels increases. The patient experiences CNS symptoms as a result of brain edema and also experiences hypotension caused by the difficulty of maintaining a normal intravascular space. Death usually occurs within 1 to 4 days.

Estimating the whole-body radiation dose may be difficult. The signs and symptoms during the prodromal period are nonspecific except for a rapidly decreasing lymphocyte count. Nausea and vomiting is a sensitive but nonspecific finding. Patients who do not have nausea and vomiting are unlikely to have been exposed to a radiation dose that is large enough to cause the acute radiation syndrome. On the other hand, individuals may have nausea and vomiting for reasons other than exposure to radiation. The whole-body radiation dose from radiation accidents is rarely uniform. The nonuniform nature of the radiation dose makes it more difficult to predict the biologic effects of the exposure. Chromosome analysis (cytogenetic dosimetry) may be helpful in estimating the radiation dose, but the results of this study take about 1 week.

A radiation accident involving whole-body exposure to four young (14 to 20 year old) women occurred in Algeria in 1978. In this accident, a 25 Ci iridium-192 industrial radiography source fell from a truck and was found by two young (3 and 7 year old) boys. They played with the source for several hours before taking it home (Fig. 90.8 and Fig. 90.9). The source was taken away by their grandmother who hid it in the kitchen. The source remained in the room for 5 to 6 weeks, irradiating several people, including the four young women. This accident was not discovered until the four women had severe bleeding from the mucous membranes in the mouth, anorexia, nausea, purpura, and bone marrow depression. The lymphocyte count in all four patients was less than 10% of the normal. The whole-body dose over the 5 to 6 weeks was estimated to have been between 600 and 1000 rads. All four patients injured by this accidental exposure survived.

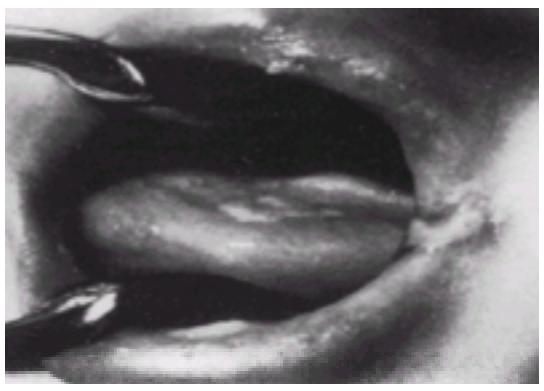

FIGURE 90.8. Mouth lesions caused by radiation of approximately 2500 rads. The lesions healed eventually.

FIGURE 90.9. Radiation burns on the hand of the older Algerian child, from exposure to 1,500 to 10,000 rads. Reconstructive surgery was required.

Local Radiation Exposure

The second type of radiation exposure that can occur involves a large radiation dose to a small part of the body. If only a small part of the body is exposed, much larger doses can be tolerated. Local radiation injuries do not cause bone marrow depression unless they are accompanied by a significant whole-body radiation dose. These injuries are rarely life-threatening, but they are difficult to manage because they often cause a slowly progressive injury that takes months to years to fully evolve. The injury develops slowly because the radiation causes progressive fibrosis of the blood vessels, which, in turn, causes tissue necrosis. The ultimate extent of the injury may not be appreciated initially. Healing after amputation or reconstructive surgery is poor because of deficient blood supply.

The hand is the most common site for localized irradiation injuries because workers carelessly or unknowingly pick up an intense radioactive source or put their hands into an intense radiation field. The next most common sites are the thighs and buttocks because individuals are likely to put things that they find into their pockets. Most of the industrial radiography sources deliver an extremely high dose on direct contact with the skin. For example, the 25 Ci iridium-192 described earlier has a surface dose rate of about 20,000 rads/minute and will cause an absorbed dose of about 12,500 rads/minute at 1 cm depth in tissue. In contrast, analytical x-ray machines, which emit x rays of much lower energy than the photons of iridium-192, are not likely to cause deep blood vessel injury.

Local radiation injuries can be readily differentiated from thermal burns. The effects of a thermal burn are present immediately, and the patient invariably knows when the injury occurred. If a patient presenting with a burnlike injury does not know the cause of the injury, a local radiation injury should be suspected. Table 90.7 lists the dose-related findings expected after a local radiation exposure.

Absorbed Dose (rems)	Findings
300	Threshold for erythema (100 keV diagnostic x-ray)
600	Threshold for erythema (10 MeV therapeutic x-ray)
1500	Moist desquamation
2000	Skin ulceration with slow healing
>3000	Gangrenous changes

Table 90.7. Absorbed Dose to Produce Skin Changes

If erythema is seen within the first 48 hours, ulceration will probably occur. The erythema may come in waves, that is, be present, disappear, and return later. With transepidermal injury, blister formation may occur at 1 to 2 weeks with doses in the range of 10,000 rads and at 3 weeks at dose levels of 3,000 to 5,000 rads. Treatment is required to prevent infection and to relieve pain. Skin grafting, especially musculocutaneous flaps, may be appropriate if the radiation exposure was very localized and superficial. Progressive gangrene, caused by the obliterative changes in the small vessels, will occur if the radiation exposure is large and involves deep structures. Under these circumstances, amputation may be necessary.

The two Algerian boys who found the 25 Ci iridium-192 industrial radiography source described earlier had local radiation injuries. The younger boy was 3 years old and presented with lesions of the mouth and hands (Fig. 90.8). The boy apparently had sucked on the source, receiving an approximate dose of 2,500 rads to the lip surface. The older boy had a necrotic deep ulceration in the hypothenar region of the right hand, apparently from using the source as a drumstick (Fig. 90.9). The estimated dose to the center of the lesion was estimated at 10,000 rads, and at the periphery of the necrosis, 1,500 rads. Ultimately, the oral lesions in the young boy healed. The palmar lesion of the older boy required reconstructive surgery.

Contamination

Contamination represents the third major type of radiation injury. Contamination occurs when radioactive dirt or liquid remains on a patient (external contamination) or, when inhaled or ingested, in the patient (internal contamination). Contamination is the only type of radiation injury that requires the medical staff to take any radiation-related precautions. It should be reemphasized that there is little danger to the medical staff when caring for a contaminated person once he or she has been transported to the hospital. On the other hand, medical personnel who respond to the accident site may be exposed to large, potentially life-threatening doses of radiation. For these rescue workers, 75 to 100 rems is the voluntary limit for lifesaving activities.

External Contamination

External contamination rarely is a significant medical problem. To prevent additional radiation exposure to the patient and unnecessary radiation exposure to the medical staff and the public, external contamination should be removed and dispersal of radioactive materials prevented. Based on the assumption that all radiation exposure is potentially harmful, the goal of the treatment of any contaminated patient is to keep radiation exposures “as low as reasonably achievable.” This is called the ALARA principle and requires advance planning, specific supplies, and appropriate protective clothing. Preventing the dispersal of radioactive materials is accomplished by treating the patient in a single location and controlling access to that location.

Internal Contamination

Internal contamination potentially is a more serious problem. It is much more difficult to eliminate radioactive materials from within the body than it is to remove radioactive dirt on the outside of the body. When external contamination is present, care must be taken to prevent internal contamination. Death resulting from radiation from internal contamination is rare. A few deaths have been caused by medical misadministrations. In the Goiania accident, a 6-year-old girl died from severe internal contamination with cesium-137. Internal contamination, especially with iodine-131, was a concern after the reactor accident at Chernobyl in 1986. A familiar model of internal contamination, for example, is the bone scan

performed in your nuclear medicine department.

Metal Fragment

Another source of contamination that should be separately addressed is a metallic fragment. Metallic fragments can be intensely radioactive. If a radioactive metal fragment is present, it should not be touched with fingers. Tongs or forceps will increase the distance between the radioactive metal fragment and the fingers and thus greatly reduce any radiation dose.

“Hot” Particles

“Hot” particles are microscopic particles that can be intensely radioactive. Typically, they contain cobalt60 or fission products. These particles can be difficult to localize and remove. They may give a large radiation dose to a small volume of tissues. If the particle is trapped under a nail or is in the fold of the skin, routine washings may not dislodge it. The particle can sometimes be localized by using a thick piece of lead. If the lead is placed between the particle and the radiation detector, the exposure rate should decrease substantially. Once the particle is localized, it can usually be removed by using simple mechanical means. Rarely, a punch biopsy of the skin may be necessary.

MANAGEMENT

General Measures

The principles governing the treatment of radiation injuries are similar to the principles governing the treatment of any medical condition, especially those arising from hazardous materials. Treatment objectives must be prioritized (Fig. 90.10). Because no survivable radiation injury requires immediate lifesaving treatment, the medical staff should focus its attention on treating non–radiation-related life-threatening conditions. In the past, some medical personnel were so distracted by the radiation aspects of an accident that routine medical care was delayed.

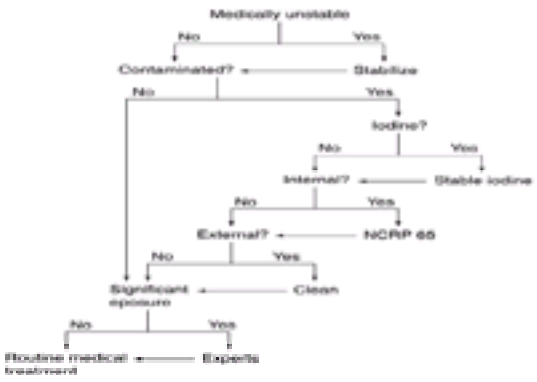

FIGURE 90.10. Treatment of radiation injuries.

Once the patient is stabilized, the radiation-related injuries can be addressed. Because there is no immediate treatment for radiation exposure, the problem of radioactive contamination should be addressed first. In most circumstances, a Geiger counter can be used to determine whether contamination is present. In addition, the probability of contamination can be assessed by obtaining an accurate description of the accident and the likely radiation source.

It must be appreciated that a great deal of the trauma from a radiation accident is related to the psychological stress and concern about cancer risk from the radiation exposure. The emergency physician should make certain that any concerns that the patient has about the long-term effects of radiation will be addressed subsequent to the acute care episode.

Internal Contamination

Treatment of internal contamination is most effective if initiated promptly. The requirement for prompt treatment is a dilemma for the physician. First, it is difficult to determine whether internal contamination is present until the external contamination has been removed. Moistened cotton-tipped applicator can be used to perform nasal swabs. If these have radioactivity on them, inhalation of radioactive materials is possible. The nature of the accident may provide clues to the possibility of internal contamination (e.g., a fire with smoke leading to inhalation of radioactive particles). Second, the most effective treatment requires knowledge of the radionuclide involved and its chemical form. This information is usually not immediately available. Fortunately, there are simple general treatment measures that can be effectively instituted before the magnitude of the internal contamination is fully known.

If given soon after exposure, stable iodine is effective at preventing the uptake of radioactive iodine by the thyroid gland. Prompt administration of stable iodine should be considered if there is the possibility of external contamination with radioactive iodine (Fig. 90.11). Because radioactive iodine is volatile, it is likely to be inhaled. If a contaminated child were brought to the ED after an accident with a radiopharmaceutical truck carrying radioactive iodine, administration of stable iodine would be appropriate. If further investigation revealed no radioactive iodine, little harm would have been done by administering the stable iodine. A single dose of oral iodine is unlikely to cause any adverse reactions even in patients who have serious reactions to iodinated contrast agents or seafood.

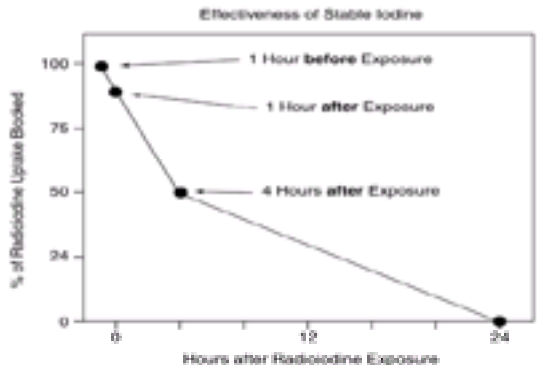

FIGURE 90.11. Stable iodine is most effective if given as soon as possible after the ingestion of radioactive iodine. The dose for children less than 1 year old is 65 mg of potassium iodide per day for 10 days. Children older than 1 year of age should receive 130 mg of potassium iodide a day for 10 days.

After a nuclear reactor accident that results in the release of a large amount of radioactive iodine, three steps can be taken to minimize the adverse effects on the public: 1) stable iodine can be given, 2) the public can be evacuated to prevent further exposure, and 3) the food supply can be monitored carefully to prevent the further ingestion of radioactive iodine. If a reactor accident occurs that involves contamination of members of the public, great panic will ensue. If this happens, emergency medical facilities should try to preserve their valuable resources for patients who need medical treatment. Emergency facilities have no special expertise in the treatment of contamination. If patients are otherwise healthy, they should be referred to other, usually state-designated facilities for the treatment of contamination.

Several simple steps can be taken to treat internal contamination nonspecifically. The goals of treatment are to prevent the absorption of the radionuclide and to enhance its excretion. Safe techniques that prevent the absorption of radionuclides include the administration of activated charcoal and alginate-containing antacids. Enhanced excretion can be achieved by hydration and administration of a purgative. Specific treatment for internal contamination depends on the radionuclide, its chemical and physical form, and the route of internal contamination. Recommendations for many specific treatments can be found in NCRP Report 65. This report should be available to every hospital ED. Initiation of treatments that entail some risk (e.g., pulmonary lavage, intravenous chelating agents) should be undertaken only after consultation with experts. The benefits of the treatment should be significantly greater than the risks of the treatment.

External Contamination

External contamination is treated in the same way as contamination by other hazardous chemical or biologic agents. To make certain that the hazard is treated appropriately, it is easiest to imagine that the patient has been covered with an easily detectable noxious agent (e.g., sewage, bacteria, viruses). Under this circumstance, the caretakers would wear gloves, a gown, shoe covers, and a mask. The purpose of wearing these garments is primarily to keep caretakers clean and to make cleanup easier. The garments do not decrease the exposure to penetrating radiation. The mask is recommended to prevent individuals from inadvertently touching their contaminated fingers to their nose or mouth. If available, film badges or other devices should be worn by the hospital staff who are in close contact with the patient.

If the external contamination is widespread, it may be helpful to cover the floor. If only a small area of contamination is present, spread of the contamination can be prevented by simply wrapping the contaminated area until it can be cleaned. Because it is much easier to detect radioactive contamination than chemical or biologic hazards, cleanup after a radiation accident will be much more effective and documentable. Precautions that are taken to prevent the inadvertent spread of contamination will make cleanup much easier.

External contamination rarely is a significant medical problem; however, logistical problems that must be addressed require preplanning. To minimize the chances of contaminating an unnecessarily large area of the ED, the patient should be admitted through a separate entrance. If this is not possible, the patient can be placed on a clean stretcher outside the ED and wrapped in a cloth (not plastic) sheet and then transported to the desired area of the hospital. Access to the treatment area should be controlled.

Removal of the patient's clothing will usually eliminate 70 to 90% of the external contamination (Table 90.8). Contaminated articles should be placed in labeled plastic bags. Residual contamination is likely to be on the hands, face, and hair. These should be washed with washcloths, using lukewarm water and soap. Particular attention should be paid to folds in the skin, the ears, and the area under the fingernails. Cleaning the skin with damp washcloths is much better than cleaning with running water. The radioactive dirt on the damp washcloth can be contained by placing the cloth in a plastic bag. Radioactive dirt that is in wash water is much more difficult to control. Shaving should not be performed because this may make small cuts and increase absorption through the skin. Excessive rubbing of the skin also may increase transdermal uptake.

Remove clothes.	Cover clean wounds to prevent contamination.
Wash with a damp cloth and tepid water.	Prevent external contamination from becoming internal.
Pay special attention to skin folds and fingernails.	Do not abrade the skin.

Table 90.8. Decontamination

Open, uncontaminated wounds should be covered to prevent them from becoming contaminated. Contaminated wounds should be cleaned like any other dirty wound. All samples from the patient should be saved and labeled.

A Geiger counter should be used to monitor and document the progress of the decontamination efforts. If contamination persists, the source may be fixed to the skin or it may be internal. Radiation experts should be consulted before more aggressive decontamination attempts are made. Some residual contamination may be acceptable.

Exposure

There is no emergency treatment for whole-body or local radiation exposure. Medically significant whole-body radiation exposure is unlikely if the patient does not have nausea and vomiting. Serial complete blood counts are also helpful in excluding the diagnosis of a recent large whole-body exposure to radiation (Table 90.9). In the absence of other major trauma, the absolute lymphocyte count will rapidly fall in patients who have been exposed to a large radiation dose. If a patient has been exposed to a large dose of radiation, very little needs to be done in the ED. The threat to the patient's life will occur a few weeks after the exposure.

In the Emergency Department	Later
Complete blood count, and	Cytogenetics
every 6 hours for 24 hours	Sperm count
Nasal swabs	Eye examination (baseline for cataracts)
Collect all excreta	Human leukocyte antigen typing

Table 90.9. Appropriate Laboratory Tests for Patients Involved in a Significant Radiation Accident

The diagnosis of a local radiation injury requires vigilance. The physician should consider the possibility of a local radiation injury when there is an unexplained painless “burn.” A complete blood count to exclude an accompanying whole-body exposure is indicated. The prognosis of a local radiation injury depends on the dose. The dose can be estimated only by having a qualified physicist reconstruct the accident that led to the exposure.

CHAPTER 91

Bites and Stings

[*]DEE HODGE III, MD and [†]FREDERICK W. TECKLENBURG, MD

[*]*Department of Pediatrics, Washington University School of Medicine, and Clinical Affairs, Emergency Services, St. Louis Children's Hospital, St. Louis, Missouri;* [†]*Department of Pediatrics, The Medical University of South Carolina, and Division of Emergency/Critical Care, MUSC Children's Hospital, Charleston, South Carolina*

This chapter is oriented to the clinical diagnosis and management of injuries that result from bites and stings, especially as they relate to children. Although the largest proportion of the morbidity and mortality from these injuries occurs in the pediatric age group, little attention has been focused in the pediatric literature on the specifics of treatment.

An overall assessment should include vital signs, location and size of fang or sting marks, pain, swelling, color of surrounding skin, and any systemic symptoms. General care should include relief of pain and itching, tetanus prophylaxis, antibiotics if needed, and emotional support. Animals must be identified as venomous or not. Venomous animals are those that inject their toxin into other animals to produce a harmful effect. Poisonous creatures are those whose tissues are toxic, either in whole or in part. This chapter deals with venomous bites and stings and with wounds inflicted by nonvenomous animals. In evaluating any potential venomous bite or sting, the physician must distinguish between the asymptomatic and the symptomatic bite or sting. Clinical observation may be the only means of distinguishing between the two.

Only those venomous animals found within the continental United States and Canada are discussed here. Of marine life, only that within the tidal zone or commonly washed ashore is considered. This chapter covers marine invertebrates and vertebrates, terrestrial invertebrates, venomous reptiles, and common mammalian bites.

MARINE INVERTEBRATES

Phylum Coelenterata (Cnidaria)

The phylum is divided into three large classes: the *Hydrozoa* (hydras, Portuguese man-of-war), *Scyphozoa* (true jellyfish), and *Anthozoa* (soft corals, stone corals, anemones).

The phylum includes some of the most beautiful and deadly marine creatures. All members of the phylum have specialized organelles called nematocysts, which are used for entangling, penetrating, anchoring, and poisoning prey (Fig. 91.1). When the tentacles touch an object, the nematocysts fire, releasing toxin-coated, barbed threads. Firing of the nematocysts is not fully understood; the process may be protein- or cation-mediated. The nematocysts of most species cannot penetrate human skin. However, those that do may cause severe pain, serious illness, or even death. The severity of envenomation is related to the degree of toxicity of venom, number of nematocysts discharged, and general condition of the victim. Stings from sessile forms are generally not as severe as stings from free-floating forms. The various toxins have been named and described but not completely biochemically characterized. Venom varies from species to species. Paralysis and central nervous system (CNS) effects appear to be related primarily to toxic proteins and peptides. Burning pain and urticaria are secondary to the presence of serotonin, histamine, or histamine-releasing agents in the venom.

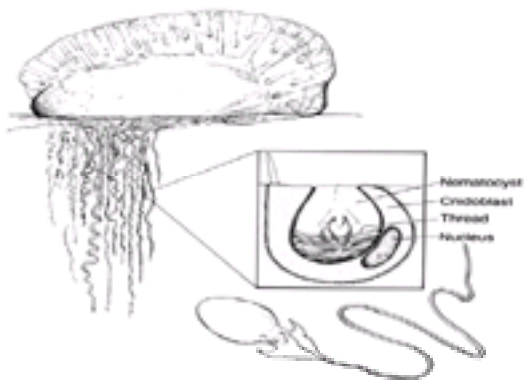

FIGURE 91.1. Marine invertebrate causing human sting.

Class Hydrozoa

Feathered hydroid *(Pennaria tiarelia)* is found from Maine to Florida and along the Texas coast just below the low-tide line. It is attached to solid objects, including pilings and floats. The mild sting that occurs with handling may be treated with local care.

Portuguese man-of-war *(Physalia physalis)*—commonly considered a jellyfish—is in reality a hydrozoan colony. The float can be up to 30 cm in length. The tentacles hang from the float, may reach a length of more than 75 feet, and contain about 750,000 nematocysts each. This pelagic animal is often driven ashore by storms all along the Atlantic coast. Releasing one of the most powerful marine toxins, the nematocysts may discharge even when the animal is dead and on the beach. Because of the length and transparency of the tentacles in the water, swimmers are often stung without seeing the animal. The toxin contains polypeptides and degradative enzymes. Local effects include pain and irritation. Systemic reactions include headache, myalgias, fever, abdominal rigidity, arthralgias, nausea and vomiting, pallor, respiratory distress, hemolysis, renal failure, and coma. Death may occur if the area stung is extensive in relation to the size of the victim. Treatment is discussed in the next section, Scyphozoa.

Class Scyphozoa

The common purple jellyfish *(Pelagia noctiluca)* is only mildly toxic. Local skin irritation is the major clinical manifestation.

Sea nettle *(Chrysaora guinguecinda)* is a common jellyfish found along the Atlantic coast. Clinical manifestations are the same as those for purple jellyfish.

Lion's mane *(Cyanea capillata)* is a highly toxic creature that received considerable publicity as the instrument of death in the Sherlock Holmes classic *Adventure of the Lion's Mane.* The animal reaches a width of 244 cm, with tentacles as long as 61 cm. The shaggy clusters of the golden yellow tentacles that hang from the medusa resemble the mane of a lion. The animal is found along both coasts. Contact with the tentacles produces severe burning. Prolonged exposure causes muscle cramps and respiratory failure.

Treatment of hydrozoan and scyphozoan stings is based on the same general principles. It is directed at three objectives: relieving pain, alleviating effects of venom, and controlling shock. The most important step is to remove the tentacles; as long as the tentacle adheres to the skin, the nematocysts continue to discharge. Inactivate the unexploded nematocysts by topical application for 30 minutes with vinegar (3% acetic acid), a slurry of baking soda, or meat tenderizer (papain). The area should be washed with sea water or normal saline. Any adherent tentacles should be carefully removed with instruments or a gloved hand, and the wound area should be immobilized. There is no antivenin available for *Physalia* or the scyphozoans except for the sea wasp, *Chironex fleckeri,* of Australia. General supportive measures for systemic reactions include oral antihistamines, oral corticosteroids, and codeine or meperidine for pain. Cardiac and respiratory support may be required. Muscle spasms have been treated with 10% solution of calcium gluconate 0.1 mL/kg given intravenously. Local dermatitis should be treated with a topical corticosteroid cream.

Class Anthozoa

The anemones found within United States tidal zones are only mildly toxic at worst. Coral cuts and stings can be a problem for swimmers off the Florida coast. The stinging ability of stony corals is not well defined but is considered to be of minor significance. Coral cuts, however, are important. The severity of coral cuts stems from a combination of factors, including laceration of tissue, nematocyst venom, foreign debris in the wound, and secondary bacterial infection. The clinical picture is one of stinging sensation followed by wheal formation and itching. If the wound is untreated, an ulcer with an erythematous base may form within a few days. Cellulitis, lymphangitis, fever, and malaise commonly occur.

Treatment consists of cleaning the wound and irrigation with copious amounts of saline. Removal of foreign particles must be accomplished, and debridement may be necessary. The sea provides an excellent inoculum for wound infections. Marine bacteria are generally heterotrophic, motile, and facultatively anaerobic, Gram-negative rods. Organisms include *Vibrio* species, *Erysipelothrix rhusiopathiae,* and *Mycobacterium marinum.* Wounds should be left open. Broad-spectrum antibiotic therapy, particularly tetracycline, at a dosage of 40 mg/kg per day in four divided doses, has been advocated but cannot be used in children younger than 8 years old. For children younger than 8 years, cephalexin (50 mg/kg per day in four divided doses) or trimethoprim–sulfamethoxazole should be used.

Phylum Echinodermata

Phylum Echinodermata includes starfish, sea urchins, and sea cucumbers. Of the three classes, only the *Echinoedae*—sea urchins—have clinical relevance for American children. The long-spined urchins (e.g., *Diadema*) are dangerous to handle. They do not appear to possess venom as do some of the tropical urchins, but the spines, composed of calcium carbonate, easily pierce the skin and lodge deep in the flesh. The spines may break off readily into the wound and can penetrate wet suits and sneakers. Most injuries occur during wading in shallow water. Clinically, penetration is accompanied by intense pain followed by redness, swelling, and aching. Complications include tattooing of the skin, secondary infection, and granuloma formation.

In treatment, all spines should be removed as completely as possible. If spines break off in the wound, debridement should be performed with local anesthetic under aseptic conditions, but any spines not reachable will be absorbed in time. Soaking the wound in warm water may be helpful. Systemic antistaphylococcal antibiotics should be used if infection develops.

MARINE VERTEBRATES

Stingrays

Background

Stingrays are the single most important group of venomous fishes, accounting for an estimated 750 attacks per year in North America. Stingrays are bottom feeders that have a habit of burying themselves in sand or mud of bays, shoal lagoons, and river mouths. The animals are found along the Atlantic, Pacific, and Gulf coasts and range from several inches in diameter to more than 14 feet in length. Six different species are represented in North American waters. Envenomations usually occur when an unsuspecting swimmer steps on the back of the animal and causes it to hurl its barbed tail upward into the victim as a reflex defense response. Most injuries are confined to the lower extremities, although wounds to the chest and abdomen have been reported.

The venom apparatus consists of a serrated, retropointed, dentinal caudal spine located on the dorsum of the tail. Spines vary in length, depending on the size of the ray, but may reach a length of 122 cm in some species. The spine is encased in an integumentary sheath that contains specialized secretory cells that hold the venom. When the stingray's barb strikes the victim, it easily penetrates the skin, rupturing the integumentary sheath over the spine and causing the venom to pass along the ventrolateral grooves of the barb into the wound. Laceration of the victim's tissues when the spine is withdrawn facilitates the absorption and distribution of the toxin. The venom is a heat-labile toxin that has been shown to contain at least 15 fractions, including serotonin, 5-nucleotidase, and phosphodiesterase. The toxin depresses medullary respiratory centers, interferes with the cardiac conduction system, and produces severe local pain.

Clinical Manifestations

Because the barb is retropointed, the wound it produces is a combination of puncture and laceration. Wounds may vary in length from 3.5 to 15 cm. The sting is followed immediately by pain, which spreads from the site of injury over the next 30 minutes and usually reaches its greatest intensity within 90 minutes. Pain and edema are most often localized to the area of injury; however, syncope, weakness, nausea, and anxiety are common complaints attributed to both the effects of the venom and the vagal response to the pain. Among other generalized symptoms are vomiting, diarrhea, sweating, and muscle fasciculations of the affected extremity. Generalized cramps, paresthesias, hypotension, arrhythmias, and death may occur. The wound often has a jagged edge that bleeds profusely, and the wound edges may be discolored. Discoloration may extend several centimeters from the wound within hours after injury and may subsequently necrose if untreated. Often, parts of the stingray's integumentary sheath contaminate the wound.

Management

Treatment is aimed at 1) preventing complications evoked by the venom, 2) alleviating the pain, and 3) preventing secondary infection. At the scene, the wound should be irrigated with cold salt water. Flushing can help remove much of the venom. Bleeding should be controlled with direct pressure. On the patient's arrival in the emergency department (ED), shock, if present, should be treated with intravenous (IV) fluids. An attempt should be made to remove any remnants of the integumentary sheath if it can be seen in the wound. The extremity should be placed in hot water (40° to 45°C [104° to 113°F]) for 30 to 90 minutes. After soaking, the wound should be reexplored. Further debridement can then be accomplished and the wound can be closed. Pain relief may be achieved with meperidine (1 to 2 mg/kg). Tetanus prophylaxis should always be considered, but antibiotics are reserved for wounds that become secondarily infected.

Sharks

Background

Fear of sharks is as old as human history. Sensational media reports of shark attacks—and several popular movies—have asked whether it is safe to go into the water. The answer may be no, but not because of sharks. The chance of being assaulted by a shark along the North American coast is roughly 1 in 5 million. Because of the large number of sporting activities that take place in the ocean environment, however, clinicians who practice in coastal areas may be called on to manage a victim of these primitive creatures.

In U.S. waters, most attacks are by the gray reef, great white, blue, and mako sharks. Factors that increase a risk of attack include swimming near sewer outlets, time of day (late afternoon and early evening), murky warm water, increased

commotion, deep channels, and bright objects. Attacks of surfers along the northern California coast were believed to be caused by sharks mistaking surfboard shapes in the water for elephant seals, part of the shark's usual diet.

Clinical Manifestations

Attack victims usually do not see the shark before it strikes. Occasionally, the attack is preceded by one or more "bumps," during which the victim may sustain extensive abrasions from the rough denticles of the shark's skin. Two types of bite wounds are described: tangential injury and a definitive bite. Tangential injury is caused by the slashing movement of the open mouth as the shark makes a close pass. Severe lacerations, incised wounds, and loss of tissue are seen. Definitive bite wounds vary according to the part of the body seized by the shark. Lacerations, loss of soft tissue, amputations, and comminuted fractures are recorded. Most injuries involve only one or two bites and are confined to the extremities.

Management

Hypovolemic shock is the immediate threat to life in shark attacks. Bleeding should be controlled at the scene with direct compression, and intravascular volume should be replaced with crystalloid until blood products are available. The victim should be kept warm and given oxygen when being transported to an ED. Wounds should not be explored in the field. Tetanus toxoid and tetanus immune globulin should be considered, and prophylactic antibiotics with a third-generation cephalosporin or trimethoprim– sulfamethoxazole is suggested.

Scorpaenidae

Background

The 80 species found in the *Scorpaenidae* family include the zebrafish, scorpionfish proper, and the stonefish. In California, the sculpin is commonly involved. *Scorpaenidae* are generally found in shallow water, around reefs, kelp beds, or coral. All members of the family are nonmigratory, slow swimming, and often buried in sand. The venom apparatus consists of a number of dorsal, anal, and pelvic spines covered by integumentary sheaths containing venom glands that lie within anterolateral grooves. The venoms are unstable, heat-labile compounds. Most often envenomation occurs when the fish are handled during fishing excursions.

Clinical Manifestations

The clinical signs and symptoms are essentially the same, varying among the species in degree only. Severe pain at the site of the wound is the first and primary clinical sign for all species. The wound and surrounding area becomes ischemic and then cyanotic. Paresthesia and paralysis of the extremity may occur. Other clinical signs include nausea, vomiting, hypotension, tachypnea proceeding to apnea, and myocardial ischemia with electrocardiographic (ECG) changes.

Management

Treatment involves irrigating the wound with sterile saline. The injured extremity is then immersed in very hot water (40° to 45°C [104° to 113°F]) for 30 to 60 minutes or until the agonizing pain is completely relieved. Meperidine hydrochloride (1 to 2 mg/kg) may be required for pain. The patient should be monitored carefully for cardiotoxic effects and respiratory depression. Antivenin is available only for the stings of the stonefish of Australia.

Catfish

Background

The catfish is a popular food and sport fish found in many lakes and rivers throughout the United States. The venom apparatus consists of a number of spines located in the dorsal and pectoral fins. The integumentary sheaths covering the spines contain venom glands. The venoms are unstable, heat-labile compounds. Most often envenomation occurs when the fish are handled during fishing excursions. A combination of injuries are seen; wounds secondary to puncture and laceration, foreign body reaction, and the effects of venom.

Clinical Manifestations

The spines inflict a puncture wound or laceration. The spines may become imbedded in the flesh of the victim causing soft-tissue swelling, which may become infected or lead to a foreign body reaction. The venom produces a local inflammatory response—local intense pain, edema, hemorrhage, and tissue necrosis.

Management

Treatment involves irrigating the wound with sterile saline. The injured extremity is then immersed in hot water (40° to 45°C [104° to 113°F]) for 30 to 60 minutes or until pain is relieved. Meperidine hydrochloride (1 to 2 mg/kg) may be required for analgesia. The wound should be explored to locate any retained spines. Adequate debridement is essential. Systemic antibiotics to cover Gram-negative organisms are recommended. Wounds may be closed using a delayed primary closure.

TERRESTRIAL INVERTEBRATES

Phylum Arthropoda

The arthropods make up the largest phylum in the animal kingdom. All *Arthropoda* have an exoskeleton with jointed appendages. The phylum is divided into two subphyla: the Chelicerata, which includes scorpions, spiders, ticks, and mites, and the Mandibulata, which includes insects.

Scorpions

Background

Of 650 known scorpion species (class Arachnida), only a limited number are dangerous to humans. In the southwest United States, *Centruroides sculpturatus* is the potentially lethal inhabitant. Although *C*. *sculpturatus* and *C. exilicauda* (Fig. 91.2) have been considered separate species in the past, recent taxonomic classification treats the two as one species. The animal has two pinching claws anteriorly and a tail or pseudoabdomen that ends in a telson (Fig. 91.2). The telson houses a pair of poison glands and a stinger. Normally, scorpions grasp their prey with pincers and then sting the victims by arching their tails over their heads. The animals are nocturnal, and during the day, they seek shelter under stones and debris. They often crawl into sleeping bags and unoccupied clothing. In one report, 80% of stings occurred in children less than 10 years old.

FIGURE 91.2. *Centruroides exilcauda (sculpturatus).* (Courtesy of F. E. Russell.)

Clinical Manifestations

The scorpion's poison gland produces a neurotoxin. The general neurotoxicity is excitatory, affecting the autonomic and skeletal neuromuscular system. Common symptoms include local pain, restlessness, hyperactivity, roving eye movements, and respiratory distress. Other associated signs may include convulsions, drooling, wheezing, hyperthermia, cyanosis, and respiratory failure. The diagnosis may be difficult because a history of a sting may not be forthcoming. There is no laboratory test for confirmation of envenomation.

Management

Numerous treatment modalities have been used in addition to general supportive care. Cryotherapy of the site of sting has been advocated to reduce swelling and local induration. An antivenin has been developed that may be advantageous in decreasing the severity and duration of symptoms. Antivenin should be considered after general supportive care has been instituted only if the following symptoms persist: tachycardia, hyperthermia, severe hypertension, and agitation. Antivenin that is not approved by the Federal Drug Administration (FDA) is available through the Antivenom Production Laboratory in Arizona State University in Tempe, Arizona. Sedative-anticonvulsants, in particular phenobarbital (5 to 10 mg/kg), have been used to treat persistent hyperactivity, convulsions, and/or agitation. Calcium gluconate (0.1 mL/kg of the 10% solution) has been given intravenously to reduce muscular contractions and associated pain, but benefit has not been proved. Corticosteroids and antihistamines have little if any proven benefit.

Spiders

More than 100,000 species of spiders (class Arachnida) are known to exist. All are carnivorous and have fangs and venom by which they immobilize and kill their prey. The risk of serious bites is small, except in a few species. In most species, the fangs are too short and fragile to penetrate human skin, and the venom is mild. Although most spiders are shy and retiring creatures that will not bite people unless provoked, two species in the United States are capable of producing more severe reactions.

Loxoscelism (Bite of the Brown Recluse Spider)

Three species of *Loxosceles* have caused envenomation, primarily in the southern and midwestern states. These small spiders (1 to 1.5 cm in length) are characterized by a brown violin-shaped mark on the dorsum of the cephalothorax. They are found outdoors but will establish nests indoors, especially in closets. The most common species, *Loxosceles reclusa,* is, as its name implies, shy and will only attack when provoked. The venom is cytotoxic and also contains a factor similar to hyaluronidase.

Clinical Manifestations. Clinically, the bite is usually innocuous. Because the bite is initially unnoticed, there is sometimes a delay in seeking medical attention. The spectrum of reaction ranges from minor local reaction to severe necrotic arachnidism (Fig. 91.3). The local reaction is characterized by mild to moderate pain 2 to 8 hours after the bite.

At the site of the bite, erythema develops with a central blister or pustule. Within 24 hours, subcutaneous discoloration appears and spreads over the next 3 to 4 days, reaching a size of 10 to 15 cm. At this time, the pustule drains, producing an ulcerated “crater.” The local reaction varies with the amount of venom injected. Scar formation is rare if there is no evidence clinically of necrosis within 72 hours of the bite. Systemic reaction is most commonly noted in small children. Symptoms are noted 24 to 48 hours after the bite and include fever, chills, malaise, weakness, nausea, vomiting, joint pain, morbilliform eruption with petechiae, intravascular hemolysis, hematuria, and renal failure.

FIGURE 91.3. Spider bite necrotizing.

Management. Because of the delay in initial diagnosis, treatment varies with the clinical stage of the bite. There is no specific serologic, biochemical, or histologic test to diagnose envenomation accurately. Unless all or part of the spider is brought for identification, definitive diagnosis cannot be made. Table 91.1 lists the spiders found in the United States known to cause necrotic lesions. An algorithm for management of suspected bites is shown in Figure 91.4. One recent series of adult patients suggests that serious complications are rare. Most victims will heal with supportive care. Large-dose steroids have been advocated in the past; however, recent studies have found no significant alteration of necrosis from the venom by steroids or heparin. Once large areas of necrosis have become demarcated, surgical excision and skin grafting are required, although the need for grafting is rare. The use of dapsone continues to be controversial. Animal studies do not support the use of dapsone, hyperbaric oxygen, or the two in combination in the treatment of these envenomations. However, current recommendations are to limit the use of dapsone to adults with proven brown recluse bites. Dapsone should not be used in children because of methemoglobinemia. Antivenom is not yet commercially available. For systemic manifestations, vigorous supportive care is needed. Platelet count for evidence of hemolysis is needed as well as monitoring of hemoglobin, urine sediment, blood urea nitrogen (BUN), and creatinine for evidence of hemolysis and renal failure.

Genus Names	Common Name	Geographic Distribution
Argiope	Golden orb weaver	Throughout North America (individual species more restrictive)
Chiracanthium	Running spider	Throughout United States
Loxosole	Brown recluse	Kansas and Missouri to Texas West to California
Lycosa	Wolf spider	Throughout United States
Phidippus	Black jumping spider	Atlantic Coast to Rocky Mountains

Table 91.1. Spider Known to Cause Necrotic Lesions

FIGURE 91.4. Management of suspected brown recluse spider bite.

Latrodectism (Bite of the Black Widow Spider)

The bite of *Latrodectus mactans* is the leading cause of death from spider bites in the United States. The animal is shiny

black with a brilliant red hourglass marking on the abdomen. The marking is found on the mature female and may be present on the male. The male is not a threat because it is only one-quarter the size of the female, meaning its fangs are unable to penetrate human skin. The webs are usually found in corners or out-of-the-way places. The female is not aggressive unless guarding her egg sac or provoked. The venom, a complex protein that includes a neurotoxin, stimulates myoneural junctions, nerves, and nerve endings.

Clinical Manifestations. Reaction is generalized pain and rigidity of muscles 1 to 8 hours after the bite. No local symptoms are associated with the bite itself. The pain is felt in the abdomen, flanks, thighs, and chest and is described as cramping. Nausea and vomiting are often reported in children. Respiratory distress can occur. Chills, urinary retention, and priapism have been reported. There is a 4 to 5% mortality rate, with death resulting from cardiovascular collapse. The mortality rate in young children may be as high as 50%.

Management. Because of the size, color, and distinctive markings of this spider, bites are seldom mistaken if the child is old enough to describe the spider. A child who has severe pain and muscle rigidity after a spider bite should be considered a *Latrodectus* bite victim. A clinical grading scale has been developed by Clark (Table 91.2). Treatment with *Latrodectus* antivenin (Lyovac; Merck, Sharp & Dohme) should be instituted as soon as a bite is confirmed in children who weigh less than 40 kg; the usual dose is 2.5 mL (one vial). Antivenin should be administered following the package insert and after skin testing to determine the risk of hypersensitivity to horse serum. For children who weigh more than 40 kg, it is not as urgent to institute antivenin treatment, but indications for its use include patients who are less than 16 years old, who have respiratory difficulty, or who have significant hypertension (grades II and III). Serum sickness is a possible side effect. Because the dosage is low, however, serum sickness is uncommon, with a rate lower than those reported for other types of antivenom. Calcium gluconate 10% solution is often given for control of leg and abdominal cramps. The dosage is 0.1 mL/kg per dose as IV push over 5 minutes. A recent series found calcium gluconate effective in only 4% of cases. Methocarbamol (Robaxin) does not appear to be as efficacious as calcium gluconate. Muscle relaxants such as diazepam also have been advocated, but they are variably effective and the effects are short lived. Analgesia may be achieved with morphine or meperidine.

Grade	Symptoms
1	Asymptomatic
	Local pain at bite site
	Normal vital signs
2	Muscular pain—localized
	Diaphoresis—localized
	Normal vital signs
3	Muscular pain—generalized
	Abnormal vital signs
	Nausea, vomiting
	Headaches
	Diaphoresis

Table 91.2. Grading Scale for *Latrodectus* Envenomation

Tarantulas and Others

Tarantulas, although fearsome in size and appearance, do not bite unless provoked. The venom is mild, and envenomation is not a problem. The wolf spider (*Lycosa* species) and the jumping spider (*Phidippus* species) also have been implicated in bites. Like the tarantula, they have a mild venom that causes only local reactions. Bites from all three of these spiders should be treated with local wound care.

Ticks

Ticks are responsible for transmitting a variety of infectious agents, including spirochetes, viruses, rickettsiae, bacteria, and protozoa. Examples of tickborne illness include Rocky Mountain spotted fever (RMSF), Lyme disease, tularemia, ehrlichiosis, babesiosis, relapsing fever, and Colorado tick fever (see Chapter 84). In addition, tick paralysis is associated with the bite of the wood tick, *Dermacentor andersonii;* the dog tick, *Dermacentor variabilii;* and the deer tick, *Ixodes scapularii.* The gravid engorged tick releases a neurotoxin that can produce cerebellar dysfunction or an ascending weakness. The mechanism of action of the toxin is not well understood.

Clinical Manifestations. Following tick attachment there is a latent period of 4 to 7 days followed by symptoms of restlessness, irritability, and ascending flaccid paralysis. Respiratory paralysis and death may follow if the tick is not detected. Laboratory data, including cerebrospinal fluid (CSF) are usually normal, but lymphocytic pleocytosis has been reported.

Management. Management is based on general supportive care and a diligent search for the tick. Ticks should be removed using blunt forceps or tweezers. The tick should be grasped as close to the skin surface as possible and pulled upward with a steady even pressure. A twisting or jerking motion may cause the mouth parts to break off. Do not squeeze or crush the body of the tick because this may introduce infective agents. After the tick is removed, the bite site should be cleaned. Once the tick is removed, the paralysis is reversible without apparent sequelae.

Centipedes and Millipedes

Centipedes (class *Myriapode* order *Chilopoda*) are venomous, biting with jaws that act like stinging pincers. Bites can be extremely painful; however, the toxin is relatively innocuous, causing only local reaction. Treatment consists of injection

of local anesthetic at the wound site and local wound care.

American millipedes (order *Diplopoda*) are generally harmless.

Insects

The insects (class Insecta) constitute the largest number of animal species. Hymenoptera is the most important order of the class and includes bees, wasps, hornets, yellow jackets, and ants (Fig. 91.5). Because of differences in venom composition and rate of systemic reactions, ants are covered separately in this chapter. Hymenoptera are responsible for 50% of human deaths from venomous bites and stings. A variety of toxic reactions are seen, but the most common is allergic.

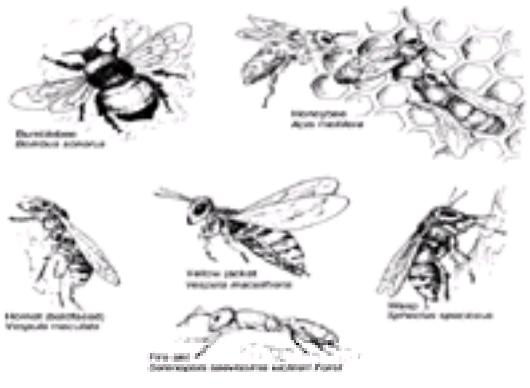

FIGURE 91.5. Hymenoptera capable of causing allergic reactions.

Bee, Hornet, Yellow Jacket, Wasp (Fig. 91.5)

Clinical Manifestations. Clinically, the stings of bees and wasps differ because the barbed stinger of the bee remains in the victim's skin, whereas the wasp may sting multiple times. Reactions may vary. The venoms of the bee, hornet, yellow jacket, and wasp contain protein antigens that can elicit an immunoglobulin E (IgE) antibody response in those who are stung. In addition, venoms contain various biogenic amines, phospholipase, phosphatase, and hyaluronidase. Because of the similarity of the venoms, crossreactivity can occur. The allergic reactions may be grouped by severity. Group I consist of a local response at the site of bite or sting. Group II includes the mild systemic reactions typified by generalized pruritus and urticaria. Group III consists of severe systemic reactions, including wheezing, angioneurotic edema, nausea, and vomiting. Group IV consists of life-threatening systemic reactions, including laryngoedema, hypotension, and shock. Anaphylactic reactions secondary to insect stings occur in 0.5 to 5% of the population.

Management. Because the barbed honeybee stinger with venom sac is avulsed and often remains in the victim's skin, it must be removed if seen. In the past, texts suggested that removal was best accomplished by scraping the stinger and that squeezing or pulling must be avoided. A recent study compared the effects of delays in removing stings with the effects of different methods of removal. The findings showed that the method of removal is irrelevant (scraping versus pulling) but that delays in removal are likely to increase the dose of venom received. Stings do not need to be dried with baking soda.

Treatment of stings is based on the severity of the allergic reaction. Group I reactions can be treated with cold compresses at the site of sting. Group II reactions are treated with diphenhydramine hydrochloride 4 to 5 mg/kg per day (maximum 200 mg) orally in four divided doses for several days. Group III reactions are treated with epinephrine 1:1000 solution 0.01 mL/kg (maximum 0.3 mL) injected subcutaneously followed by diphenhydramine orally. In addition H_2-blockers may provide additional benefit. Ranitidine or cimetidine can be used. These children should be observed in the hospital for 24 hours. Group IV reactions may require intubation if upper airway obstruction is present. Wheezing refractory to epinephrine should be treated with an aminophylline bolus of 6 mg/kg over 20 minutes, followed by a 1.1 mg/kg per hour infusion if needed. Hypotension should be treated with a fluid bolus of saline or lactated Ringer's solution 10 to 20 mL/kg given over 20 to 30 minutes. IV epinephrine (1:10,000) should be considered if hypotension fails to respond to subcutaneous epinephrine and fluid bolus. Hydrocortisone (2 mg/kg) may be given intravenously every 6 hours for 2 to 4 days. All children in this group should be admitted to an intensive care unit (ICU). Children who have had a group III or IV reaction should be followed by an allergist for hyposensitization. Parents of these children should keep an insect sting emergency kit. The EpiPen or EpiPen Jr are spring-loaded autoinjectors triggered by placing pressure on the thigh with the instrument. The pens inject 0.3 or 0.15 mg (EpiPen and EpiPen Jr, respectively) of epinephrine. The pens are used as first aid in the field by the parent or guardian and are not meant to substitute for prompt definitive treatment at a medical facility. Parents should receive information regarding the avoidance of situations and behaviors that would attract stinging insects.

Fire Ants

Clinical Manifestations. An increasing number of bites and envenomations in the South has been accounted for by fire ants (*Solenopsis richteri* and *Solenopsis invicta*). The venom differs from the other Hymenoptera in that it is an alkaloid with a direct toxic effect on mast cell membranes. There is no crossreactivity with other members of the order.

The fire ant bites with well-developed jaws and then uses its head as a pivot to inflict multiple stings. The clinical picture of fire ant sting is one of immediate wheal and flare at the site. The local reaction varies from 1 to 2 mm up to 10 cm,

depending on the amount of venom injected. Within 4 hours, a superficial vesicle appears. After 8 to 10 hours, the fluid in the vesicle changes from clear to cloudy (pustule) and becomes umbilicated. After 24 hours, it is surrounded by a painful erythematous area that persists for 3 to 10 days. Edema, induration, and pruritus at the site occur in up to 50% of patients. Occasionally, systemic reactions occur as with other Hymenoptera.

Management. Treatment of fire ant stings is symptomatic. Local care, such as ice applied to the reactive area, and frequent cleansing of the lesions to prevent secondary infection are all that is usually required. Topical steroids, antibacterial medications, and antihistamines do not appear to be efficacious in prevention of pustule formation. Antihistamines are useful for pruritus. Systemic reactions are rare and should be treated similarly to other Hymenoptera reactions.

TERRESTRIAL VERTEBRATES

Venomous Reptiles

Background

God said to the serpent,

> Be accursed beyond all cattle, all wild beasts. You shall crawl on your belly and eat dust every day of your life. I will make you enemies of each other: you and the woman, your offspring and her offspring.
>
> —Genesis 3:14

Throughout recorded history, serpents and their encounters with humans have evoked strong emotions, folklore, and medicinal practices. Research during the past several decades has lessened the mystique surrounding the venomous substances secreted by 15% of this country's 120 snake species. The recent emphasis on antivenin therapy and expedient supportive medical care has dramatically reduced mortality and morbidity from poisonous snakebites.

In the United States, an estimated 8000 people are bitten annually by poisonous snakes. Predictably, the pediatric population, especially males, aged 5 to 19 years, accounts for a disproportionately large number of these victims. The highest incidence occurs in the Southeast and Southwest between April and October, although venomous snakebite occur at least sporadically in most states. Only 10 to 15 deaths are reported per year, but the morbidity in limb dysfunction and other complications, although unknown, is undoubtedly much higher. With appropriate therapy, most long-term morbidity can be prevented.

The poisonous snakes indigenous to the United States are members of the Crotalidae (pit viper) or *Elapidae* families (Table 91.3). The rattlesnake, water moccasin, and copperhead are pit vipers and are responsible for 99% of venomous snakebites. The coral snake is the only member of the *Elapidae* family in this country and, along with imported exotic snakes, accounts for the remaining 1% of serious snakebites.

Family	Genus	Species	Common Name
Crotalidae			Pit vipers
	Crotalus		Rattlesnakes
		C. adamanteus	Eastern diamondback
		C. atrox	Western diamondback
		C. horridus	Timber rattlesnake
		C. viridis	Western rattlesnake
		C.v. viridis	Prairie rattlesnake
		C.v. helleri	Southern Pacific rattlesnake
		C.v. oreganus	Northern Pacific rattlesnake
		C.v. abyssus	Grand Canyon rattlesnake
		C.v. lutosus	Great Basin rattlesnake
		C. cerastes	Sidewinder
		C. ruber	Red diamond rattlesnake
		C. mitchelli	Speckled rattlesnake
		C. lepidus	Rock rattlesnake
		C. tigris	Tiger rattlesnake
		C. willardi	Ridge-nosed rattlesnake
		C. scutulatus	Mojave rattlesnake
		C. molossus	Black-tailed rattlesnake
		C. pricei	Twin-spotted rattlesnake
	Sistrurus		
		S. catenatus	Massasuga rattlesnake
		S. miliarius	Pygmy rattlesnake
	Agkistrodon		
		A. piscivorus	Water moccasin
		A. contortrix	Copperhead
Elapidae		Micruroides euryxanthus	Sonoran (Arizona) coral snake
		Micrurus fulvius	Eastern coral snake

Table 91.3. Poisonous Snakes Indigenous to the United States

The pit vipers have several characteristic features that distinguish them from the nonvenomous snakes (Fig. 91.6): 1) a pit that contains heat-sensitive organs that assist these poor-visioned reptiles to localize their prey is located on each side of the head between the eye and nostril; 2) the pupils are elliptical and vertically oriented in contrast to the usually round pupil of a harmless snake; 3) two curved fangs or hollow maxillary teeth that are 5 to 20 mm long and, in larger snakes, may be spaced as wide as 3 cm are folded posteriorly against the palate and advance forward when the pit viper strikes; 4) the head is relatively more triangular than that of most nonvenomous snakes; and 5) the scutes, or scales, on the ventral portion caudad to the anal plate continue in a single row, whereas nonpoisonous snakes have a cleft, or double row.

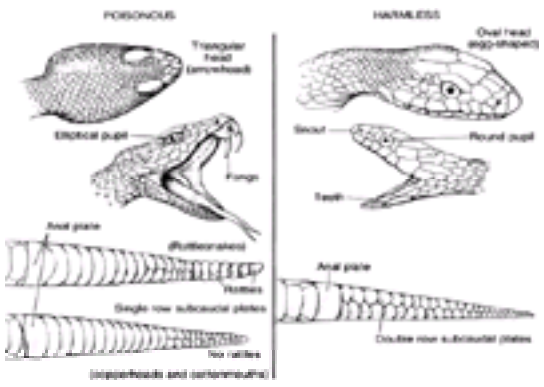

FIGURE 91.6. Comparison of poisonous and nonpoisonous snakes.

The rattlesnake *(Crotalus)* is distributed widely throughout most of the United States and is the culprit in approximately 60% of all pit viper attacks. Several species are notably more menacing and toxic to humans. The large and cold diamondbacks (*Crotalus adamanteus* and *Crotalua atrox*) often stand their ground when approached by humans and inflict most lethal snakebites in North America. Other rattlesnakes that commonly cause the more severe bites include the timber *(Crotalus horridus),* prairie, and pacific *(Crotalus viridus)* rattlesnakes. Several other *Crotalus* species are implicated in less severe human envenomation.

Rattlesnakes vary considerably in size and color, even among species. The eastern diamondback, which inhabits the coastal Southeast, may be as large as 2 m long and 7 kg in weight; it usually has a brightly outlined symmetrical diamond pattern. The timber rattler found in the Northeast and Southeast westward to Texas may be only 1 m long and have nearly black scales (especially in colder climates). Emergency physicians must become familiar with the particular species in their areas.

The pygmy rattler and massasanga are considered rattlesnakes because, in common with *Crotalus* species, they possess a “rattler” on their tail. These two relatively small snakes are members of the genus *Sistrorus,* however, and their bites are not as toxic as those of true rattlesnakes.

The copperhead *(Agkistrodon contortrix)* is a very common poisonous snake that lives in the Southeast and much of the Northeast, extending westward as far as Texas and Nebraska. This snake accounts for approximately 30% of venomous snake bites but, luckily, is seldom a serious threat to life or limb. *A*. *contortrix* is usually 0.6 to 1 m in length and has a light pink to red–brown body with darker brown crossbands shaped like hourglasses. The head has a coppery tinge.

The water moccasin, also known as the cottonmouth *(Agkistrodon piscivorus),* is a semiaquatic pit viper indigenous to the Southeast, including the Gulf states and the Mississippi valley as far north as southern Illinois. These are larger and more belligerent snakes, often traveling with their heads in an aggressive 45-degree angle from the horizontal. Their body is olive brown to black, with darker markings on the sides that often fade over the dorsum. The ventral surface is lighter in color. The oral mucosa is distinctively white, hence the name cottonmouth. Like the copperhead, bites from this species are, in general, less serious than *Crotalus* species.

The relatively passive coral snake is responsible for only 10 to 15 snakebite cases per year in this country. As a member of the *Elapidae* family, it does not share the pit viper's distinctive physical characteristics (i.e., it has round pupils, a blunt head, and ventral caudal scutes, and lack pits). Unlike the nonpoisonous snakes, the coral snake has two small maxillary fangs. The snout of the coral snake is always black and is followed by a yellow ring and subsequent black band. Red and black bands then alternate down the approximately 2-ft length of the coral snake, with narrow yellow rings bordering the red band (Fig. 91.7). The nonvenomous king snake is often confused with the coral; it has red bands directly bordered by black bands. The yellow rings in this snake are within the black bands. The adage about coral snakes holds true:

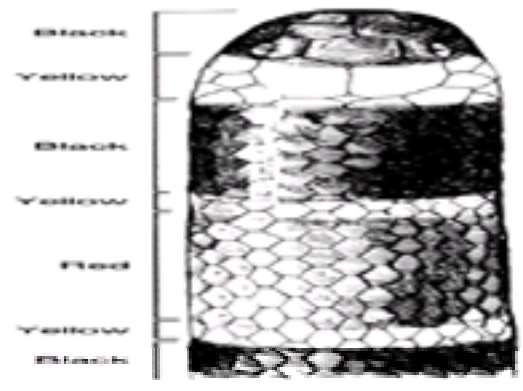

FIGURE 91.7. Coral snake.

Red on yellow, kill a fellow.
Red on black, venom lack.

There are two species of coral snake, the eastern *(Micrurus fulvius)* and the Arizona *(Micruroides euryxanthus). M*. *fulvius* is responsible for most human envenomations and is found in most states east of the Mississippi, with the exception of

the Northeast. *M*. *euryxanthus* is indigenous only to Arizona and New Mexico.

Pathophysiology

Snakebite envenomation is a complex poisoning because of the assorted deleterious effects of venoms and the multiple human and snake variables that influence venom toxicity. Venoms are mixtures of potent enzymes, primarily proteinases, and low-molecular peptides that possess extensive pathophysiologic properties. A crotalid venom often has a combination of necrotizing, hemotoxic, neurotoxic, nephrotoxic, and/or cardiotoxic substances. The neurotoxins make up a large fraction of the venom of the Mojave rattlesnake. These toxins are related to phospholipase A and bind the nicotinic acetylcholine receptors and thus prevent the depolarizing action of acetylcholine. Proteolytic enzymes aided by hyaluronidase cause much of the local tissue destruction. Many venoms induce increased endothelial permeability and venous pooling, creating intravascular depletion. A transient hemoconcentration may be present during this plasma "leak." Hemotoxic effects induce hemolysis, fibrinogen proteolysis, and thrombocytopenia, which, along with activation of plasminogen, can lead to a bleeding diathesis in severe envenomation. Respiratory failure may occur secondary to pulmonary edema or a shock state.

The ultimate toxicity of the snakebite also depends on human and snake variables. Human factors include the victim's size and general health and wound characteristics that affect venom absorption. A small child is more susceptible to a given volume of venom than a larger person. (Unfortunately, young children are commonly bitten more than once.) Fang penetration of a vessel or subfascial compartment ensures a more rapid absorption and serious systemic effects. Likewise, a bite on the head, neck, or trunk (3% of snakebites) hastens systemic absorption. Approximately one-third of snakebites involve the upper extremity and cause a higher long-term functional morbidity than do lower extremity wounds.

Snake variables include the snake's size, the amount of venom injected, and the potency of the particular species' venom. Venom secretion is under voluntary muscular control; any condition that facilitates it (e.g., long, healthy fangs, or full stores of venom) adds to the toxicity of the bite. An angered and hungry rattlesnake unloads more venom than a recently satiated and surprised rattlesnake.

Clinical Manifestations

Pit Viper

Local pain after a *Crotalus* envenomation is typically intense, and a sensation of burning occurs within a couple of minutes. The pain is greater with ensuing edema and presumably increases with larger inocula of venom. Victims of a significant rattlesnake bite often complain within minutes of a perioral numbness, extending to the scalp and periphery. This paresthesia may be accompanied by a metallic taste in the mouth. These patients also may have nausea, vomiting, weakness, chills, sweating, syncope, and other more ominous symptoms of systemic venom absorption. A copperhead or pygmy rattlesnake envenomation produces less local symptoms, and systemic consequences are often minimal or nonexistent unless a small child, multiple bites, or larger than average snake is involved. The water moccasin's effects are more variable.

There is a relative lack of serious pain or swelling with the Mojave rattler bite, although, as in other *Crotalus* bites, the patient may complain of paresthesia in the affected extremity. Within several hours, these patients may develop neuromuscular symptoms such as diplopia, difficulty in swallowing, lethargy, nausea, and progressive weakness from the large portion of neurotoxin in this species.

The wound should be inspected for fang punctures, and if two are present, the distance between them should be noted. An interfang distance of less than 8 mm suggests a small snake; 8 to 12 mm, a medium snake; and more than 12 mm, a larger snake. Fang wounds by small snakes such as the pygmy rattler may be extremely subtle; in larger crotalid snakebites, the fang marks may be hidden within hemorrhagic blebs and edema. Occasionally, only one puncture or two scratches will be present, but both wounds may be potentially venomous. However, not all crotalid bites are envenomated; 10 to 20% of known rattlesnake strikes do *not* inject venom. Other causes of puncture wounds also must be kept in mind—notably rodent bites and thorn wounds. Nonpoisonous snakes sometimes leave an imprint of their two rows of teeth, but the wounds should lack fang puncture marks.

Pit viper envenomations are characterized by intense pain, erythema, and edema at the wound site within 5 to 10 minutes. There may be bloody serosanguinous fluid dripping from the fang punctures. Progressive swelling proportional to the inoculum of venom develops over the next 8 hours and may continue to some degree for an additional 24 hours. Rarely, the venom is deposited predominantly in a muscle compartment, resulting in a deceptively minimal amount of edema. The Mojave rattlesnake bite provides another example of a seemingly innocuous local wound in the setting of a potentially serious envenomation. In a severe diamondback rattlesnake bite, an entire extremity may be swollen within 1 hour.

Local ecchymoses and vesicles usually appear within the first few hours, and hemorrhagic blebs are often present by 24 hours. Lymphadenitis and lymph node enlargement also may become apparent.

Without appropriate therapy, these local manifestations progress to necrosis and may extend throughout the bitten extremity, effectively maiming the victim. Also, as in any animal wound, secondary infection is a risk; the snake's oral flora includes Gram-negative bacteria. Table 91.4 summarizes local characteristics of pit viper bites.

Pain	Ecchymosis
Edema	Vesicles
Erythema	Hemorrhagic blebs

Table 91.4. Local Signs of Pit Viper Envenomation

The dramatic signs of crotalid envenomation are derived primarily from the victim's hypovolemic state, hemorrhagic tendencies, and neuromuscular dysfunction. Table 91.5 outlines the more notable physical signs.

General
Anxiety, diaphoresis, pallor, unresponsiveness
Cardiovascular
Tachycardia, decreased capillary perfusion, hypotension, shock
Pulmonary
Pulmonary edema, respiratory failure
Renal
Oliguria, hemoglobinuria, hematuria
Neuromuscular
Fasciculations, weakness, paralysis, convulsions
Hematologic
Bleeding diathesis

Table 91.5. Systemic Signs of Crotalid (Pit Viper) Envenomation

Coral Snake

Coral snakes leave unimpressive local signs but can neurologically cripple their prey. The bite may have one or two punctures, at most 7 to 8 mm apart, as well as other small teeth marks. There is usually only mild pain and little, if any, swelling. Local wound and, eventually, extremity paresthesia and weakness may be reported. Over several hours, generalized malaise and nausea, fasciculations, and weakness develop insidiously. The patient may complain of diplopia and have difficulty talking or swallowing. Physical examination reveals bulbar dysfunction and generalized weakness. Respiratory failure may ensue.

Management

Pit Viper

As in all medical emergencies, the airway, breathing, and circulation (ABCs) of the patient must be addressed before attending to the snakebite (Fig. 91.8). The first priority of prehospital care of the snakebite victim is rapid transport to a medical facility. Time is of the essence, and all activities in the field must be tempered by this fact.

FIGURE 91.8. Management of pit viper bite. [a]Perform within 5 to 10 minutes of bite; continue suction for 30 to 60 minutes. [b]Complete blood count, platelet count, prothrombin time, partial thromboplastin time, urinalysis, type and hold; in moderate or severe cases, add fibrinogen, arterial blood gases, electrolytes, blood urea nitrogen, and creatinine. [c]Seldom need antivenin; exceptions with large snakes and small children. [d]1:100 dilution if allergy history; saline control; resuscitation medications at hand; antivenin seldom indicated if greater than 12 to 24 hours since bite.

It is important to approach the patient with reassurance and to place him or her at rest. The affected extremity should be stripped of any jewelry or clothing and immobilized in a position of function below the level of the heart. The patient should be kept warm and not allowed anything by mouth.

Tourniquets, inadvertently tightened for prolonged full vascular occlusion, have created more problems than they have solved and therefore cannot be recommended for prehospital care. In experienced hands, however, a *constriction band* that obstructs lymph and venous flow can be valuable when *incision and suction* are indicated or when a long transport is anticipated (longer than 30 to 60 minutes). The band should be at least 2 cm wide and placed 5 to 10 cm proximal to the wound (proximal to the nearest joint if the wound is nearby). The constriction should be loose enough to admit a finger and preserve good distal arterial pulses. Vigilant observation for adequate perfusion is necessary because of progressive edema; the constriction band should be shifted to remain proximal to the swelling. To be effective, the band must be applied initially within 1 hour of the pit viper bite. It may be removed when antivenin therapy is started.

Incision and suction of the pit viper wound are indicated only if they are started within 5 to 10 minutes of the snake's strike. A constriction band should be placed, then liner incisions, approximately 1 × 0.5 cm deep, should be made through the fang marks along the long axis of the extremity, thus avoiding tendons or neurovascular structures. Suction is then applied with a snakebite kit suction cup for the next 30 to 60 minutes. A large syringe with the end cut off also can serve as a suction device. Incision and suction are relatively useless unless initiated within 5 to 10 minutes after the bite occurred. (Note that constriction bands and incision and suction are not recommended in coral snake envenomation.)

In the rare situation in which skilled personnel and supplies are at the scene and a long transport is expected, it would be reasonable to allow one or two attempts at IV access. Many authorities also suggest capturing or killing the snake for later verification, but again, prudence dictates that time not be wasted in this adventure and that an inexperienced person not risk the bite of an agitated snake. If the snake arrives in the ED, treat it with respect—more than one person has been bitten by a “dead” snake, and decapitated snakes can bite reflexly for up to 1 hour.

A complete blood count (CBC), coagulation studies, platelet count, urinalysis, and blood crossmatching should be obtained on all patients with suspected venomous snakebite. (Blood may be difficult to crossmatch after massive hemolysis.) In moderate or severe poisoning, serum electrolytes, BUN, creatinine, fibrinogen, and arterial blood gases also are indicated. Hemolysis, anemia, thrombocytopenia, hypofibrinogenemia, prolonged bleeding times, and metabolic acidosis all may be seen in severe poisoning. Repeat the laboratory studies every 6 hours to ensure no significant changes occur.

Therapy will be based on the clinician's overall grading of venom toxicity. Local and systemic manifestations, as well as laboratory findings, weigh heavily in this judgment. The clinical pattern may change dramatically as the venom's effects unfold; thus, frequent reassessment is crucial. The physician should measure and record the circumference of the injured extremity at the leading point of edema and 10 cm (4 in) proximal to this level every 30 minutes for 6 hours then at least every 4 hours for a total of 24 hours. Table 91.6 is derived from a grading system suggested by the Scientific Review Subcommittee of The American Association of Poison Control Centers.

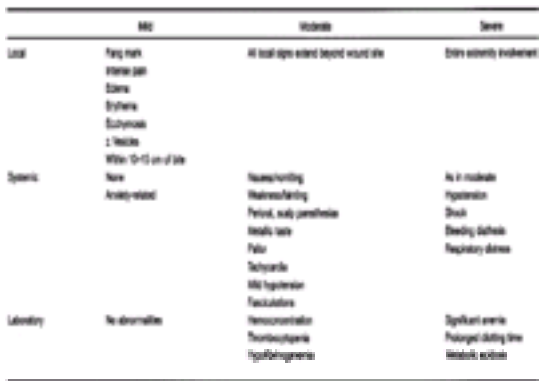

Table 91.6. Grading of Crotalid (Pit Viper) Snakebites

If the history and physical examination on arrival in the ED are consistent with a venomous snakebite, immediate laboratory evaluation and IV access are indicated. Aggressive supportive medical care must be available if signs of major system dysfunction are present. Any prehospital care (e.g., extremity immobilization) should be rechecked. If an occluding tourniquet is inappropriately present, the physician should place a more proximal constriction band and then cautiously remove the tourniquet, being prepared to respond therapeutically to a systemic release of venom.

One antivenin (antivenin crotalidae polyvalent: Wyeth Laboratories) is effective for the rattlesnake, water moccasin, and copperhead. For maximal venom binding, the antivenin should be given within 4 hours of the snake strike. Benefits of antivenin administration after 12 hours are questionable, and use is not indicated after 24 hours (an exception may be continued coagulopathy). The initial recommended dosage varies with the severity of the envenomation. The amount of antivenin is not calculated on a weight basis; children require more than adults as a rule. Dosages in the higher range are used when snake or human variables associated with higher morbidity/mortality are present. For example, a child with two eastern diamondback bites should receive a large dose on the basis of potential severity. On the other hand, a copperhead bite is usually mild and often may be observed for progression without any antivenin given.

Antivenin is highly antigenic horse serum; therefore, skin testing is mandatory (read package insert). Resuscitation equipment, including airways and oxygen, IV epinephrine (1:10,000), antihistamines, and steroids must be kept in close

proximity. The standard skin test involves an intradermal injection of 0.02 mL of 1:10 dilution of reconstituted antivenin. If the history suggests a likely reaction, use a more diluted (1:100 or greater) preparation. A saline control in the opposite extremity is useful for judging a positive-reaction wheal, which is usually apparent within 15 minutes.

If the skin test is negative, the reconstituted antivenin (one vial with 10 mL of saline) is diluted with normal saline in a 1:4 dilution. The antivenin should be infused by IV slowly (1 to 2 mL/hr). During the first 10 to 20 minutes, signs or symptoms of an allergic reaction should be observed for. If no reaction occurs, the rate of infusion should be increased so that the total volume is completed over 2 hours; extremity edema and vital signs should be measured every 15 minutes for evidence of progressive venom toxicity. The initial dose of antivenin should be repeated every 2 hours until the progression of the swelling has stopped. The number of antivenin vials initially anticipated is a rough estimate; more or less antivenin may be required as the clinical reassessment dictates (as many as 75 vials have been used in a child).

Positive skin tests or allergic signs during antivenin infusion warrant consultation with a medical herpetologist. The absolute threat to life must be reassessed, and if present, plans must be made to continue the antivenin. If mild allergic manifestations develop, the infusion should be stopped and diphenhydramine (1 to 2 mg/kg IV) given. Once the allergic symptoms have resolved, a minimum of 5 minutes should pass, then the infusion should be restarted at a slower rate. If symptoms recur, the antivenin should be stopped again; further therapy at this point is controversial. Some authorities recommend an epinephrine drip that is titrated to minimize any allergic phenomena when the antivenin is restarted. If this option is suggested by your consultant, an epinephrine infusion (starting at 0.1 µg/kg per minute) would be a reasonable dosage. Steroids (prednisone 1 to 2 mg/kg per day) are also recommended.

An alternative desensitization method for allergic reactions is described in the product insert but requires at least 3 hours to achieve and thus is not practical in severe envenomations. If life-threatening anaphylaxis occurs, epinephrine 1:10,000 (0.01 mL/kg), diphenhydramine (1 to 2 mg), and steroids (methylprednisolone 2 mg/kg every 6 hours) are given by IV immediately, and other supportive measures are instituted as needed.

Wound care includes irrigation, cleansing, a loose dressing, and consideration of tetanus prophylaxis. The affected extremity should be maintained just below the level of the heart and in a position of function. Cotton padding between swollen digits is useful. Broad-spectrum prophylactic antibiotics are recommended by most authorities. Analgesics for pain may be offered if the cardiorespiratory status is not in question. Surgical excision of the wound, routine fasciotomy, and application of ice are contraindicated. Excision of the wound does not remove significant venom after 30 minutes, and cryotherapy has been associated with increased extremity necrosis and amputations. Fasciotomy should be reserved for the very rare case of a true compartmental syndrome. Necrosis is usually the result of the proteolytic enzymes or inappropriate therapy and is not caused by compartmental pressure. Superficial debridement will be required at 3 to 6 days; a wound care regimen suggested at this stage includes local oxygen, aluminum acetate (1:20 solution) soaks, and triple dye. Physical therapy is beneficial during the healing phase.

The major thrust of supportive care is correction of the intravascular depletion that results from increased venous capacitance, interstitial third spacing, and hemorrhagic losses. Moderate or severe envenomation mandates two IV lines for separate but simultaneous antivenin therapy and volume replacement. Shock usually develops between 6 and 24 hours after the snakebite but may present within the first hour in severe envenomation. Signs of hypovolemia (e.g., decreased capillary perfusion, oliguria, tachycardia, anemia, hypotension) deserve aggressive therapy. Central vascular monitoring and accurate urine output measurements are desirable for optimal therapy. Normal saline or lactated Ringer's solution (20 mL/kg over 1 hour), followed by fresh whole blood or other blood components, often corrects the hypovolemia (see Chapter 3). Vasopressors are usually needed only transiently in the more severe cases. A bleeding diathesis is best managed with fresh whole blood, or blood component therapy, primarily packed cells (10 mL/kg), and fresh-frozen plasma (10 mL/kg). With life-threatening bleeding, platelets (0.2 units/kg) and a more concentrated fibrinogen source (cryoprecipitate—dose 1 bag/5 kg body weight) also should be considered. Abnormal clotting parameters, including fibrinogen and platelet and blood counts, should be reevaluated every 4 to 6 hours. Respiratory support also is commonly required when shock has developed. Renal failure is another potential problem in this setting.

As many as 75% of antivenin recipients may develop a serum sickness syndrome approximately 4 days to 3 weeks after treatment. Serum sickness is almost ensured with doses greater than seven vials of antivenin. Rashes, arthralgias, edema, malaise, lymphadenopathy, fever, and/or gastrointestinal symptoms evolve over several days. High-dose prednisone (2 mg/kg per day, maximum 80 mg) until symptoms abate (and then a tapering schedule) has been used with success in most cases. Diphenhydramine (5 mg/kg per day) is often given as an adjunct.

Coral Snake

When coral snake wounds are present or the history or specimen is consistent with an eastern coral snakebite, antivenin for *Micrurus fulvius* (Wyeth) is administered before development of further symptoms. This is also an equine serum and requires preliminary skin testing (see package insert). The initial recommended dosage is three to five vials by IV; an additional three to five vials may be given as needed for signs of venom toxicity. There is no antivenin available for the Arizona coral snake *(Micruroides euryxanthus).* Supportive care should provide a satisfactory outcome in these cases. Constriction bands, suction and drainage, and other local measures do not retard coral snake venom absorption and, hence, are not indicated.

Exotic Snakes

The clinician confronted with an exotic snakebite or a clinician inexperienced in snakebites should consult a local medical herpetologist, poison control center, or the Oklahoma Poison Control Center (405-271-5454), which indexes the availability of unusual antivenins. Report all illegally possessed reptiles to the police or to the appropriate Fish and Game Agency.

Mammalian Bites

Background

Children suffer the majority of casualties in this country's growing epidemic of mammalian bites. The overall morbidity of mammalian bites is staggering in terms of infectious complications, cosmesis, disability, psychological trauma, and medical expenses. At least 1 million people are bitten each year, and about 1% of ED visits are prompted by bite wounds.

Dog bites account for the overwhelming majority (80 to 90%) of these injuries and thus have been the subject of numerous investigations. The most common dog attack involves a 5- to 14-year-old boy close to home and a large-breed or mixed-breed canine. The dog's owner can be identified 85 to 90% of the time; in fact, in 15 to 30% of cases, the dog belongs to the victim's family. Usually, the dog has never previously bitten anyone and often has been provoked, although unintentionally. However, animal jealousy has been implicated in unprovoked biting of infants. A seldom realized mortality of approximately 10 cases, primarily young children and infants, occurs each year in the United States.

The remainder of the mammalian bites are perpetrated by cats (5 to 10%), rodents (2 to 3%), and other wild or domesticated animals. Another mammalian species, *Homo sapiens,* inflicts approximately 2 to 3% of the bite wounds that present to medical attention. Human bites share with cat wounds a notoriously high infectious complication rate.

Pathophysiology

Anatomic wound characteristics and the microbiologic inoculum of the offending species determines the pathologic consequences of the bite. For example, many dog bites are localized crush injuries with a substantial amount of infection-prone devitalized tissue—a result of the enormous pressures dogs generate in their bites. Forces of 200 to 400 pounds per square inch, sufficient to perforate sheet metal, have been documented in dogs. Overall, however, only 5 to 10% of dog bites becomes infected, probably because the resulting lacerations and abrasions are so accessible to good wound hygiene. The typical feline bite, however, is a deep puncture wound and is difficult to irrigate or cleanse, thus subjecting it to a high infection rate (up to 50% in some series). The penetration of tendons, vessels, facial compartments, and bones also has a high infectious risk with increased morbidity. The hand offers all these anatomic components in a relatively small cross-sectional area and therefore is potentially prone to serious infections regardless of the biting species. Injuries to deeper structures, including major vasculature, the brain, peritoneum, abdominal organs, and airways also have been sporadically reported.

Scores of aerobic and anaerobic bacteria indigenous to mammalian oral flora are inoculated into the wound during biting. Cultures of fresh wounds before clinical infection reflect the variety of these contaminants but are not predictive of the causative organism in later infections. The most commonly isolated bacteria in infected cat and dog bite wounds are *Staphylococcus aureus* and *Pasteurella multocida,* a Gram-negative rod. In one series, *P. multocida* was found in 50 and 80% of infected dog and cat wounds, respectively. Other series have isolated *P. multocida* in only 10 to 20% of infected dog wounds and incriminated other more common bacteria: streptococci, coagulase-negative staphylococci, *S. aureus,* and enteric bacteria. Some unusual isolates in clinical infection have included unnamed bacteria—Center for Disease Control and Prevention types II-J and EF-4. At least 25% of all infected mammalian bites yield mixed cultures of aerobes and often anaerobes, if carefully sought. Anaerobic bacteria usually are recovered (not alone but only in mixed cultures with aerobes).

Human bite infections are mixed bacterial infections, with *Streptococcus viridans* or *S. aureus* being the predominant organism. Anaerobic bacteria, especially *Bacteroides* and *Peptostreptococcus* species, are commonly cultured. The more serious morbidity in infected human bites of the hand has been correlated with *S. aureus* isolation and, more recently, with *Eikenella corrodens*, a facultative anaerobe.

Finally, the multiple systemic diseases that may be transmitted by mammalian bites need to be considered.

Clinical Manifestations

Mammalian bite wounds cause a spectrum of tissue injuries from trivial to life-threatening. Scratches, abrasions, contusions, punctures, lacerations, and their complications are seen commonly in the ED. The complications usually involve secondary infections or damage to structures that underlie the bite.

Although dog bites are insignificant lesions in at least half of the cases that come to medical attention, 5 to 10% warrant suturing and 2%, hospital admission. Approximately 33% of dog bites involve the upper extremity, presumably while the victim is fending off the attack. Another 33% of wounds are located on the lower extremities and 20% on the head and neck area. The remainder of bites involves multiple areas. Other than bites on the hand, the rate of secondary infection in dog bites given good local care approximates that of nonbite wounds.

Predictably, young children suffer more serious canine injuries. The dog strikes the head and neck in 60 to 70% of victims less than 5 years old and in 50% those less than 10 years old. These wounds most often involve the lips, nose, and cheek areas, and on rare occasions, they penetrate the skull, with resulting depressed skull fractures and intracranial lesions. It has been estimated that each year 44,000 children suffer facial dog bite wounds, one-third of them requiring complex repair. The uncommon life-threatening injuries occur almost exclusively in young children and include major vascular injury, visceral penetration, and chest trauma. The deaths are usually secondary to acute hemorrhagic shock.

Cat bites are located in the infection-prone upper extremities in two-thirds of cases and usually are puncture wounds rather than lacerations or contusions. Infections that complicate these wounds result from the same organisms isolated in dog bites, but a higher incidence of *P. multocida* is found. *P. multocida* infections characteristically present within 12 to

24 hours of the injury and rapidly display erythema, significant swelling, and intense pain. These infections often respond slowly to adequate drainage and antibiotic therapy. Local infections from other organisms usually present 24 to 72 hours after the bite in a less fulminant manner. Viridans streptococcal infections are occasional exceptions to this generalization and may resemble a *P. multocida* clinical course.

Cat scratches are most commonly located on the victim's upper extremities or periorbital region and are more likely to develop secondary bacterial infection than scratches from the other common domesticated species. Corneal abrasions also are occasionally associated with the periorbital wounds. Cat-scratch disease, an uncommon complication of these injuries, is characterized by a papule at the scratch site and a subsequent regional lymphadenitis. The primary lesion is typically a crusted, erythematous papule, 2 to 6 mm in diameter, that develops 3 to 10 days after the scratch. A tender regional lymphadenopathy occurs 2 weeks after the primary lesion. Malaise and fever are associated symptoms in approximately 25% of patients. Unusual manifestations of this disease include encephalopathy, exanthem, atypical pneumonia, and parotid swelling. The disease is self-limiting, with resolution of the symptoms within 2 to 3 months. *Bartonella henselae* is considered to be the causative organism in most cases. An indirect fluorescent antibody test to *Bartonella* is useful in the diagnosis and is available through the Centers for Disease Control and Prevention.

Human bites in older children and adolescents are most commonly incurred when a clenched fist strikes the teeth of an adversary. The wound typically overlies the metacarpal-phalangeal joint, and on relaxation of the fist, the bacterial inoculum penetrates more deeply into the relatively avascular fascial layers. Hand infections, regardless of infection site, usually present with mild swelling over the dorsum of the hand 1 to 2 days after injury. Infected hand bites may be superficial and localized to the wound, but if there is pain with active or passive finger motion, a more serious deep compartmental infection or tendonitis should be suspected. Osteomyelitis occasionally occurs in hand infections. In younger children, human bites are more often on the face or trunk than on the hands. Often, a playmate inflicts the wound, but child abuse must always be considered. Systemic diseases that may be spread by human bites include hepatitis B and syphilis.

Rodent bites usually occur in disadvantaged socioeconomic groups or among laboratory workers and have a relatively low incidence of secondary infection (10%). Ratbite fever is a rare disease that may present after a 1- to 3-week incubation period with chills, fever, malaise, headache, and a maculopapular or petechial rash. There are two forms: Haverhill fever *(Streptobacillus moniliformis)* and Sodoku *(Spirullum minus),* both of which are responsive to IV penicillin.

Another uncommon bacterium for which lagomorphs, particularly rabbits, are hosts is *Francisella tularensis.* Tularemia is usually spread to humans by rabbit bites, although contact with or ingestion of contaminated animals or insect vectors is sufficient for transmission. Ulceroglandular tularemia is the most common form of the disease, and streptomycin is the agent of first choice in its treatment.

Serious infections from multiple bacteria, including osteomyelitis, sepsis, endocarditis, and meningitis, have been reported as complications of mammalian bite wounds as well as the more esoteric diseases already mentioned. The risk of rabies or tetanus always must be considered in animal bites.

Management

Meticulous and prompt local care of the bite wound is the most important factor in satisfactory healing and prevention of infection. In more extensive wounds, local anesthesia is achieved before wound hygiene. Then, the skin surrounding the wound should be cleaned with a soft sponge and 1% providone iodine solution can remove obvious contaminants. The wound itself should be forcefully irrigated with a minimum of 200 mL normal saline. A 19-gauge needle or catheter attached to a 30-mL syringe will supply sufficient pressure for wound decontamination and will decrease the infection rate by twentyfold. Stronger irrigant antiseptics—povidone–iodine scrub preparation, 20% hexachlorophene, alcohols, or hydrogen peroxide—may damage wound surfaces and delay healing. Soaking in various preparations has not proved helpful in reducing infections.

Most open lacerations from mammalian bites can be sutured if local care is effected within several hours of the injury and good surgical technique is used. Facial wounds often mandate primary closure for cosmetic reasons and, overall, are low infection risks because of the good vascular supply. In fact, Callaham has demonstrated a lower infection rate in sutured dog bite wounds than in those left open. The exceptions to suturing are minor hand wounds and other high-risk bites. In large hand wounds, hemorrhage should be carefully controlled. We suggest closing the subcutaneous dead space in these wounds with a minimal amount of absorbable suture material. Cutaneous sutures can be placed after 3 to 5 days if there is no evidence of infection.

Extremities with extensive wounds should be immobilized in a position of function and kept elevated as much as possible. This is especially true of hand wounds, which should have bulky mitten dressings and be supported by an arm sling. All significant wounds should be rechecked in follow-up in 24 to 48 hours.

The following wounds may be considered at high risk for infection: puncture wounds, minor hand or foot wounds, wounds given initial care after 12 hours, cat or human bites, and wounds in immunosuppressed patients. As a rule, these wounds should not be sutured, and prophylactic antibiotics are indicated. No single antibiotic is ideal for all of the most common organisms involved in infected mammalian bite wounds. Amoxicillin–clavulanic acid (Augmentin) comes close. It is effective in *P. multocida, Streptococcus, Staphylococcus,* and anaerobe control, as well as in providing staphylococcus coverage. Combination therapy with phenoxymethyl penicillin (penicillin V) and cephalexin or dicloxacillin has been suggested by some authorities. For high-risk wounds, we recommend amoxicillin–clavulanic acid (30 to 50 mg/kg per day) alone for initial therapy. Erythromycin (40 mg/kg per day) is an alternative for the penicillin-allergic patient. The initial dosage of antibiotic should be given in the ED and continued for the next 3 to 5 days. It must be emphasized that local care ultimately prevents infection more effectively than any prophylactic antibiotics. Studies indicate that prophylactic oral antibiotics for low-risk dog bite wounds are not indicated because the differences in the rate of infection

are not significant and the cost benefit ratio not worth the risks of allergic reactions.

Any bite wound with signs of infection deserves aggressive drainage and debridement and antibiotic therapy after aerobic and anaerobic cultures are obtained. Moderate to severe hand infections or other wounds that involve deep structures usually require debridement and exploration under general anesthesia. Culture swabs should sample the depth of the wound; or, in cases of cellulitis, the specimen can be collected by needle aspiration of the leading edge of erythema. While awaiting cultures, a Gram stain is often helpful in differentiating the probability of staphylococci or streptococci from *P. multocida.*

Parenteral antibiotics and admission to the hospital are indicated if the child has systemic symptoms or has wounds with potential functional or cosmetic morbidity. The choice of parenteral antibiotics should be governed by the same factors considered in selection of prophylactic antibiotics and then modified by culture results.

Tetanus immunization status should be checked in every injury that violates the epidermis, regardless of the cause. Recommendations for tetanus immunoglobulin and immunization are noted elsewhere.

Concern for rabies is the factor that prompts many patients to seek medical care. Although the incidence of rabies (1 to 5 cases per year) is extremely low, the physician must always assess the possibility of rabies exposure and promptly initiate prophylaxis when indicated. The history should include the apparent health of the animal and any provocation for attack. Wild carnivores and bats generally should be regarded as rabid; rodents (rats, squirrels) and lagomorphs (rabbits) can usually be considered no risk. Exposure to bats even without bite or scratch should warrant serious consideration of prophylaxis. Rabies prophylaxis is not indicated in bites by a healthy dog or cat with a known owner, assuming the animal's health does not deteriorate over the following 10 to 14 days. Bites by strays and other domesticated mammals should be considered individually and with consultation of the local health department. Scratches, abrasions, and animal saliva contact with the victim's mucous membranes all are capable of rabies spread.

If postexposure antirabies immunization is indicated both passive antibody (RIG) and vaccine (HDCV) should be given. Immunization with RIG (rabies immune globulin, human) is administered only once, in a dose of 20 IU/kg. Half the dose is given intramuscularly, and the remainder is infiltrated locally around the wound. The HDCV immunization (human diploid cell rabies vaccine) should be administered on days 0, 3, 7, 14, and 28 for a total of five doses, each 1.0 mL given intramuscularly.

ASTHMA

Background

Asthma is the most common chronic disease of childhood, affecting approximately 5 to 10% of children. Many of these children, particularly those who are economically disadvantaged, are treated in the emergency department (ED) only during acute exacerbations and receive no other ongoing, consistent care. This places the additional burden on the emergency physician for facilitating appropriate follow-up care as well as for managing acute exacerbations.

There has been a dramatic increase in hospitalizations for asthma since the 1960s, despite only modest increases in prevalence. More alarming is the increase in asthma-related deaths in children over the past decade despite several "advances" in therapy. The reasons for this apparent increase in the severity of childhood asthma is a subject of active investigation and has not been fully elucidated. However, socioeconomic factors appear to play a major role. Risk factors for life-threatening asthma have been identified and are listed in Table 92.1. Unfortunately, despite these alarming statistics, patients, parents, and physicians often grossly underestimate the life-threatening potential of asthma.

Previous life-threatening exacerbation	Lack of access to emergency medical care
>2 hospital admissions within past year	History of noncompliance and/or medication abuse
>3 visits to the emergency department within past year	Psychological and/or psychosocial problems
Inadequate general medical management	

[a]Note: Although these factors are associated with life-threatening disease in studies of large numbers of patients, individual children with some of these findings may be appropriately discharged after treatment.

Table 92.1. Risk Factors for Life-Threatening Asthma[a]

The approach to the assessment and management of acute asthma has undergone many changes in recent years and remains controversial. This chapter presents an approach based on current knowledge and is intended to provide a set of guidelines that can be adapted, as needed, to meet the needs of the individual patient or ED setting. The approach is in general agreement with the Practical Guide for the Diagnosis and Management of Asthma developed by the Expert Panel 2 Report of the National Asthma Education Program and the National Heart, Lung, and Blood Institutes, published in 1991 and updated in 1997. Areas of controversy and new therapies under investigation also are discussed.

Pathophysiology

Over the past decade, research has further refined the definition of asthma to accentuate the chronic inflammatory nature of the illness. Therapy must ideally reverse the airway narrowing as well as block or modify the impact of the cellular role of mast cells, eosinophils, macrophages, neutrophils, T lymphocytes, and epithelial cells.

The two most important components that impact on bronchospasm in asthma occur through immunoglobulin E (IgE)-mediated mast cell degranulation and the recruitment of other cellular components that contribute to the "late-phase" reaction and the more inflammatory aspect of the disease. Clinically, this separates the immediate redirection in pulmonary function due to antigen stimulation in the first hours from a later redirection beginning at 4 to 12 hours associated with cellular recruitment. Key to this late-phase response is the attraction and impact of inflammatory cells with T-helper lymphocytes contributing greatly. Release of leukotrienes, granular proteins, and other mediators cascade this process.

In patients with hyperreactive airways, it is clear that viral infection, including respiratory syncytial virus (RSV) and rhinovirus, increase the responsiveness of the airways and bronchial inflammation probably by cytokine-triggered upregulation.

The physiologic consequences of asthma are progressive air trapping with dead space ventilation, increased airway resistance, and mismatching of alveolar ventilation-perfusion. As the acute episode progresses, there is further decrease in forced vital capacity (FVC), forced expiratory volume at one second (FEV_1), and peak expiratory flow rate (PEFR). Each breath is initiated at higher lung volumes that lie on the steep, stiff portion of the compliance curve. At this point, high-pressure changes are required to achieve acceptable tidal volumes. Arterial oxygen saturation decreases with ventilation-perfusion abnormalities. Hypoxemia may cause pulmonary artery hypertension and hyperventilation. Hyperventilation occurs early in the course of acute asthma, out of proportion to any respiratory or metabolic demands. It may be caused by stimulation of pulmonary receptors innervated by the vagus nerve through inflammatory irritation or by stretch receptor activity. If the acute asthmatic process continues unchecked, minute ventilation cannot be maintained and $PaCO_2$ ultimately rises as the child becomes fatigued.

Metabolic changes also occur with acute asthma. The increased work of breathing increases oxygen and energy consumption, leading to a metabolic acidosis. Compensation for this acidosis may not be possible because of already maximal respiratory effort. As respiratory muscles fatigue, respiratory acidosis develops. Combined respiratory and metabolic acidosis sets the stage for respiratory failure.

Although the pathophysiology of acute asthma in children and adults is similar, young children are particularly susceptible to status asthmaticus. In the child less than 5 years of age, peripheral airway resistance is substantially higher than in an adult. A small degree of narrowing of peripheral airways results in disproportionate increases in resistance to air flow. Respiratory reserve in children is limited and increases with age as the size of the conducting airways grow larger. Part of this is related to the respiratory surface area being much smaller in the child less than 5 years old than in the adult. Another age-related mechanical factor, decreased elastic recoil, contributes to earlier small airway closure during normal tidal breathing in young children. This leads to airway collapse and atelectasis during asthma exacerbations or respiratory infection. The horizontal insertion of the diaphragm in infancy makes diaphragmatic recruitment during airway obstruction less efficient. In infants and young children, the contribution of bronchial smooth-muscle constriction to airway obstruction may be less important than edema, mucous plugging, hypersecretion, and atelectasis.

Triggers

Triggers for acute asthma attacks may be nonspecific and include acute viral infection, allergy, weather change, cigarette smoke or other inhaled irritants, exercise, and cold air. Low-level infections in the upper airways, such as sinusitis and otitis media (OM), have been implicated in exacerbations of previously stable asthma in children. Allergic reactions not only trigger acute episodes of asthma but also can induce a state of bronchial lability. Allergy may promote acute attacks through immediate mediator release and by chronic airway obstruction through the late-phase inflammatory response. Drug sensitivity, particularly to aspirin products, may induce hyperreactive airways.

Clinical Findings

In the child with known asthma and an obvious exacerbation, clinical evaluation and initial treatment should begin almost simultaneously. However, for the purposes of clarity, these phases of management are considered in sequence.

The evaluation of the child with wheezing begins with a rapid cardiopulmonary assessment to determine the severity of the episode. This includes the child's general appearance, paying particular attention to the degree of respiratory distress, color, and mental status. Simultaneously, oxygen is administered, and if indicated, immediate resuscitative and therapeutic efforts are initiated, as described in the next section. After a baseline evaluation, the child should be reassessed frequently and, ideally, after each therapeutic intervention.

In addition to the history and physical examination, other selected studies may be useful in the assessment of acute asthma. These studies include PEFR, pulse oximetry, arterial blood gases (ABGs), chest radiograph, and other laboratory evaluations. Each aspect of the assessment is discussed in more detail later in this chapter. A general guide to several parameters useful for estimating the severity of the episode can be found in Table 92.2.

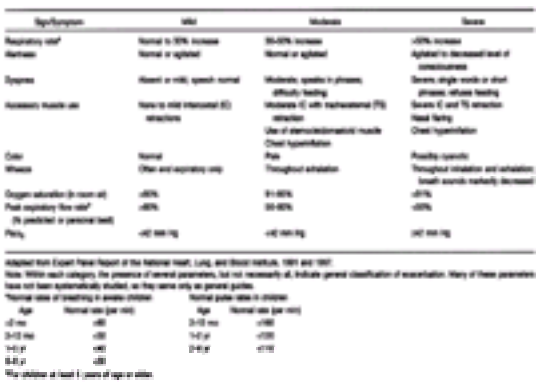

Table 92.2. Estimation of Severity of Acute Asthma Exacerbation

History

The history should include the duration of the current episode and rapidity of onset, the parent's or patient's subjective assessment of severity, other associated symptoms, and the suspected trigger. The child's current medications should be determined, including details of when the medications were started, the dosage, the route, the timing of the last dose, and a history of missed doses from noncompliance or emesis. A history of previous medications, particularly oral or inhaled steroids in the past 6 months, should be elicited. An attempt should be made to estimate the child's severity of disease and risk for a life-threatening episode. Details about past episodes, such as frequency of ED visits, hospital admissions, intensive care unit (ICU) admissions, and episodes of respiratory failure that required mechanical ventilation, should be addressed. For children with their first episode of wheezing, the possibility of a foreign body aspiration or another cause of wheezing should be explored (Table 92.3). A personal or family history of atopic disease is suggestive of asthma. Current hydration status should be evaluated with questions regarding recent fluid intake, emesis, and urine output. The family's ability to cope with the child's disease at home should be assessed in preparation for making a disposition decision.

Congenital	*Allergic*
Cystic fibrosis	Asthma
Lobar emphysema	Anaphylaxis
Tracheobronchomalacia	Allergic pulmonary aspergillosis
Tracheal stenosis	*Acquired*
Bronchial stenosis	Foreign body aspiration
Diaphragmatic hernia	Bronchopulmonary dysplasia
