Tracheoesophageal fistula	Bronchiectasis
α_1-Antitrypsin deficiency	Mediastinal bronchial compression (including tumor or lymph node)
Vascular ring	Recurrent aspiration
Infections	*Cardiac*
Bronchiolitis	Congestive heart failure
Pneumonia (viral, bacterial, myco-bacterial, fungal)	Pulmonary edema

Table 92.3. Differential Diagnosis for Wheezing

Physical Examination

As noted previously, the physical examination begins immediately with an overall assessment of the child's degree of respiratory distress. Severe retractions, accessory muscle use, nasal flaring, cyanosis, decreased muscle tone, and altered mental status all are indicative of impending or existing respiratory failure and require immediate intervention. The respiratory rate (RR) and heart rate (HR) should be noted and compared to age-appropriate normals (Table 92.2).

The remainder of the respiratory examination includes auscultation for decreased breath sounds, wheezing, rhonchi, and crackles. Crackles can occur and are most often caused by focal areas of atelectasis. Any asymmetry in the pulmonary findings should be noted.

Peak Expiratory Flow Rate

PEFR can serve as a simple, quantitative, reproducible, and inexpensive measure of airway obstruction in the child with mild to moderate distress. Its utility is limited, however, by the inability of children less than 5 to 7 years old and inexperienced patients at any age, to perform the maneuver reliably. In addition, PEFR is effort dependent and measures predominantly large airway disease. Normal PEFR varies based on sex and height as well as on characteristics unique to each peak flow meter model. With increasing use of PEFR to monitor chronic asthma at home, knowledge of the child's personal best PEFR may be available in the ED. A flow rate of less than 80% of predicted or personal best is considered abnormal, and less than 50% indicates moderate to severe obstruction. The degree of improvement after bronchodilator therapy is more useful than the initial value before therapy. Patients with PEFRs below 60% of predicted after ED therapy are more likely to relapse after outpatient therapy.

Oxygen Saturation and Arterial Blood Gases

Although ABGs have an unquestioned role in the evaluation of a severe exacerbation, they have potential disadvantages, particularly in children. They can be technically difficult to obtain, can be painful, and have less reliable results in the crying child. Pulse oximetry, however, provides a noninvasive, continuous, and generally valid measure of arterial hemoglobin oxygen saturation (Sa_{O_2}). Pulse oximetry provides additional data regarding the need and adequacy of supplemental oxygen, response to therapy, and appropriate disposition. If available, it should be measured initially in all children with acute asthma. It is one of the few objective measures in young children who are unable to perform PEFRs reliably. Supplemental oxygen should be provided to maintain an Sa_{O_2} level greater than 90% (95% in young infants), and if hypoxia persists after ED treatment, hospital admission should be considered. For children with lesser degrees of hypoxia, studies have shown that Sa_{O_2} alone does not predict the need for hospitalization accurately for the individual patient. As a rule, however, children with lower oxygen saturations are more likely to relapse. In any case, confirmation of adequate oxygenation is reassuring and obviates the need for ABGs in most mild to moderate exacerbations.

The ABG provides an objective measure of ventilation as well as oxygenation. It is essential in the evaluation of any child in whom impending or existing respiratory failure is suspected clinically, although it should never delay the initiation of therapy. The ABG must be interpreted in conjunction with the clinical picture. The trend of the Pa_{O_2} and Pa_{CO_2} is more

important than the initial value. Mild hypoxia and hypocarbia are expected early in the course of acute asthma. As obstruction progresses and the child becomes fatigued, the hypoxia becomes more severe and the Pa CO_2 rises to “normal” or above “normal” range, resulting in a mixed metabolic and respiratory acidosis. It should be emphasized that a “normal” PaCO_2 of 40 mm Hg in a child with tachypnea or significant respiratory distress may be a sign of impending respiratory failure and requires aggressive management and close monitoring.

Other Studies

The role of chest radiographs in the emergency management of acute asthma is not well defined. Typical findings on routine films such as hyperinflation, atelectasis, and peribronchial thickening do not correlate with severity and rarely alter management. Patients for whom a chest radiograph may be of a higher yield include those with failure to respond to therapy, persistence of focal findings after bronchodilator therapy, reduced oxygen saturation after therapy, or clinical suspicion of a complication or a cause for wheezing other than asthma. These factors also apply to children who present with wheezing for the first time. Radiographic evaluation of the sinuses may be helpful for the child with chronic, persistent wheezing in whom sinusitis is suspected.

The uncommon child taking theophylline may benefit from a theophylline level to help determine further management. The level should be obtained early in the course of therapy. Serum potassium measurement should be considered in children at risk for hypokalemia secondary to receiving frequent b-agonist therapy. A complete blood count (CBC) generally is not useful and, if drawn after adrenergic therapy, often reveals a leukocytosis with neutrophil predominance that should not be misinterpreted as secondary to bacterial infection.

Differential Diagnosis

Wheezing (see Chapter 80) is a continuous, high-pitched, musical, auscultatory finding generally most prominent on expiration; it is caused by obstruction of intrathoracic airways. It must be distinguished from stridor, a harsh, high-pitched, audible sound most prominent on inspiration. Stridor (see Chapter 72) is associated with diseases that cause upper airway obstruction such as croup and epiglottitis, as discussed in Chapter 84. Croup may present with evidence of both upper and lower airway obstruction.

Some children present with chronic cough (see Chapter 15) as the only symptom of hyperreactive airways or “cough variant asthma.” Typically, the cough is worse at night, and the child is asymptomatic during the day. Many of these children have a family history of atopic disease or will have reduced peak flows. There are also children whose acute exacerbations are characterized by severe coughing without obvious wheezing. In the ED, the most practical approach may be a trial of bronchodilators that can be therapeutic as well as diagnostic.

Although wheezing is most commonly associated with asthma, other problems also should be considered (Table 92.3). Several other entities may cause wheezing and usually can be differentiated from asthma through a careful history, physical examination, and attention to the patient's response to therapy. The two most common problems other than asthma that bring children to the ED with wheezing are bronchiolitis and foreign body aspiration.

Bronchiolitis (see Chapter 84) is an acute infection of the small airways most commonly caused by the RSV but also by parainfluenza, adenovirus, and influenza. Outbreaks usually occur during the winter and peak from January through March. It generally affects children less than 1 year of age most severely and manifests with a history of an upper airway infection followed by fever, feeding difficulty, progressive wheezing, respiratory distress, and occasionally, apnea. Some infants, particularly those with chronic lung disease, respond to bronchodilators.

Foreign body aspiration is seen most commonly in children 6 months to 5 years old (see Chapter 29). Although the presentation is usually more subtle, classically, these children have a history of sudden onset of choking, coughing, or wheezing when eating or playing with a small object. The examination may reveal asymmetric breath sounds or wheezing associated with varying levels of respiratory distress. These children may have some, although generally incomplete, response to bronchodilators. The chest radiograph may be normal or show differential hyperinflation on inspiratory/expiratory or bilateral decubitus views, focal atelectasis, or occasionally, a radiopaque foreign body.

Complications

Throughout the ED stay, the potential for complications of acute asthma should be kept in mind. These may be a consequence of the disease itself, the therapy, or both.

The most common pulmonary complication is atelectasis secondary to mucous plugging. Air leaks that lead to a pneumomediastinum and/or a pneumothorax are potentially life-threatening. Children who require mechanical ventilation are at particular risk for air leak complications. A pneumothorax should be suspected in any child with a sudden deterioration associated with chest pain, asymmetry of breath sounds, or a shift of the trachea.

Cardiac arrhythmias are associated with adrenergic agents and with theophylline alike. When these drugs are used together, particularly in association with hypoxemia and acidosis, the risk of arrhythmias is increased.

Frequent b-agonist therapy can cause hypokalemia. The syndrome of inappropriate antidiuretic hormone secretion (SIADH), which may result in dangerous hyponatremia, also is a potential, although rare, complication of acute asthma.

Management

Initial Approach

The primary goals in the acute management phase of an asthma exacerbation are to correct hypoxemia and to rapidly reverse airflow obstruction. Supplemental oxygen, repetitive b $_2$-agonists, and the early addition of systemic corticosteroids achieve this. Patients should be monitored closely and evaluated serially to determine their response to therapy, to identify those who require more aggressive therapy, and to make a final disposition. For children who are discharged, the emergency physician should prescribe an intensified regimen for a minimum of 3 to 5 days and should recommend appropriate follow-up so that chronic management issues can be addressed.

This section of the chapter presents a stepwise approach to the ED management of acute asthma in children. This approach is generally consistent with the Expert Panel 2 (NIH) 1997 recommendations and is summarized in algorithm form in Figure 92.1, with specific dosage recommendations in Table 92.4.

FIGURE 92.1. Approach to acute asthma in children. *PEF,* peak expiratory flow; *FEV_1,* forced expiratory volume in 1 second. (Modified with permission from Expert Panel 2 Report, NIH, 1997.)

Table 92.4. Emergency Department Acute Asthma Therapy

All children with acute asthma can be assumed to be hypoxemic unless oxygen saturation is measured immediately and indicates otherwise. In addition, b-adrenergic therapy may exacerbate hypoxemia transiently by increasing blood flow to poorly ventilated areas of the lung, thereby increasing ventilation-perfusion mismatch. Hence, unless Sa O_2 is greater than 90%, humidified oxygen should be administered immediately. Oxygen is most effectively delivered by mask or nasal cannula, although some small children tolerate oxygen tubing held by their face best. It should be delivered at a flow rate sufficient to eliminate cyanosis and, ideally, to maintain Sa O_2 levels greater than 90% (95% in infants). In contrast to adults, oxygen-induced suppression of respiratory drive is virtually never encountered in asthmatic children.

Repetitive, inhaled b $_2$-agonists are the mainstay of initial bronchodilator therapy in children. They work by relaxing bronchial smooth muscle directly and may also modulate mediator release from mast cells and basophils. In the ED, these always should be delivered in oxygen. Inhalation therapy has been shown to be as effective as subcutaneous injection for mild to moderate obstruction and is associated with fewer systemic side effects. The highly b $_2$-selective agent albuterol offers the additional benefits of reduced cardiotoxicity, longer duration of action, and potent bronchodilation. Frequent (every 15 to 30 minutes) doses of nebulized albuterol appear to be effective in reversing airway obstruction. Although the ideal dose of albuterol (0.5%) has not been determined, the Expert Panel 2 (NIH) recommends 0.15 mg/kg per dose. From a practical standpoint, patients older than 1 year who weigh less than 30 kg should be given 2.5 mg (0.5 mL) and those who weigh more than 30 kg should be given 5 mg (1 mL). A minimum of 1.25 mg (0.25 mL) is used for infants less than 1 year old. Recent evidence suggests that an albuterol metered-dose inhaler (MDI) and chamber may be just as effective as nebulized treatments. Recommendations for this approach are outlined on Table 92.4.

Subcutaneous injection of epinephrine or terbutaline remains an acceptable alternative in settings in which nebulized therapy is unavailable or delayed, or for the toddler resisting an inhalation treatment. It also may be indicated as initial therapy for the child with severe obstruction, hypoventilation, or apnea in whom the delivery of nebulized medication to the airways is believed to be inadequate. Under these circumstances, the injection can be given simultaneously with the initial aerosol and, if indicated, by mask ventilation during preparation for intubation.

The recognition that inflammation is central to the pathogenesis of acute asthma has meant that corticosteroids have assumed an increasingly important role in the acute and chronic management of asthma. Early treatment of asthma

exacerbations with steroids has been shown to prevent progression of airway obstruction, to decrease the need for emergency treatment and hospitalization, and to reduce morbidity. Steroids are believed to potentiate the effect of b-adrenergic agents within hours, in part through alteration of cell membrane receptors and downregulation of inflammatory mediator generation. They also appear to decrease small airway inflammation and edema within 24 hours. Steroid therapy may be particularly beneficial for infants in whom the primary pathophysiology is small airway edema and whose response to bronchodilators may be limited. Because there is a time lag between the administration of steroids and the onset of clinical effect, the first dose is administered as soon as possible. As a rule, almost all children who have had a significant exacerbation ultimately receive steroids. An exception is made for children with mild symptoms who require either no nebulizer treatments or, at worst, one treatment that immediately produces adequate resolution. Exposure to chickenpox in the unprotected host is one of the rare instances in which steroids may need to be avoided acutely. Depending on the level of distress and the child's ability to tolerate oral medications, the dose of corticosteroid is given either intravenously (methylprednisolone 2 mg/kg or equivalent; maximum 125 mg) or by mouth (prednisone or prednisolone 2 mg/kg; maximum 80 mg). Both forms are equally efficacious. Recent studies suggest that nebulized steroids may have a role in the management of acute asthma exacerbations. In addition, children taking inhaled steroids with minor exacerbations may sometimes be adequately managed by doubling their inhaled steroid dose. In general, this should be done in consultation with the physician who manages the patient's asthma.

Ipratropium bromide (Atrovent) is a quaternary ammonium derivative of atropine that limits systemic absorption and decreases its side effects. Ipratropium appears to act synergistically with albuterol, adding additional bronchodilation particularly for patients with moderate to severe air flow obstruction. Ipratropium may be mixed with albuterol and delivered simultaneously. Recommendations vary, but the NIH guidelines suggest 0.25 mg for children (0.5 mg in adolescents and adults) every 20 to 30 minutes mixed with the first three albuterol treatments, then every 2 to 4 hours as needed.

Theophylline has no role in the management of acute asthma and the Expert Panel 2 (NIH) no longer recommends theophylline for admitted patients.

Some children with acute asthma will be dehydrated. These children should receive an initial fluid bolus calculated to return them to a normovolemic state, followed by a maintenance infusion. There is no evidence that overhydration is advantageous. In addition, SIADH is a potential complication.

Antibiotics are indicated only for specific bacterial infections such as sinusitis or otitis media.

After 2 to 4 hours of frequent bronchodilator treatments and the initiation of corticosteroid therapy, the limit of ED management has been reached and a disposition decision should be made. If appropriate resources are available, continued management of the patient in an “observation unit” or “clinical decision unit” for up to 24 hours may avoid the need for hospital admission.

Approach to the Child with Respiratory Failure

There is no universally accepted approach to the child with severe asthma who presents in respiratory failure or deteriorates in the ED despite the therapy already outlined. The options include continuous nebulized albuterol, intravenous (IV) b_2-agonist therapy, and/or mechanical ventilation. The choice of therapy should be guided by the child's mental status, response to therapy, ability to sustain the increased work of breathing, degree of hypoxia, trend in Pa CO_2, and the physician's familiarity and comfort with the various treatment options. In all cases, these patients require continuous monitoring and constant involvement of ED personnel. Arrangements should be made for admission to an ICU setting with skills to handle the child.

The use of continuous nebulized therapy is well established in the ICU setting and currently is under study in EDs. Continuous terbutaline and albuterol have been demonstrated to reverse respiratory failure and to eliminate the need for mechanical ventilation. Albuterol is administered as 0.5 mg/kg per hour (maximum, 15 mg/hour).

IV b_2-agonist therapy is an option for children who fail continuous nebulized therapy. In the United States, terbutaline is administered as a 10 µg/kg loading dose over 10 minutes followed by an initial infusion of 0.4 µg/kg per minute. The infusion is titrated up to effect in increments of 0.2 µg/kg per minute while the child is monitored for unacceptable tachycardia. The usual effective range is 3 to 6 µg/kg per minute. Although not yet available in the United States, albuterol is the favored IV agent in Canada and Europe.

If the child continues to deteriorate, intubation and mechanical ventilation should be considered. There is no single ideal approach to the intubation of children with acute asthma, although some general recommendations can be made. Intubation of these children can be hazardous and should be performed in the presence of the most skilled personnel available. The airway should be managed assuming a full stomach, as discussed in Chapter 5. Many authorities consider ketamine (1 to 2 mg/kg by IV) to be the induction agent of choice because of its bronchodilating effects. Agents that may increase bronchospasm through histamine release such as meperidine, morphine, D-tubocurare, and atracurium are best avoided. After intubation, all b_2-agonist, anticholinergic, and antiinflammatory drug therapy should continue.

Volume-controlled ventilation is preferred using larger-than-average tidal volumes (10 to 20 mL/kg), normal respiratory rates for age, and high flow rates to ensure long expiratory times. To do this, inspiratory pressures often exceed 50 to 60 cm H_2O. In an effort to minimize barotrauma, incomplete correction of the respiratory acidosis or “controlled hypoventilation” (PaCO_2 greater than 50 mm Hg) should be the goal with much higher PaCO_2 necessary in selected cases. In addition, sedatives and neuromuscular relaxants generally are required. Surveillance for barotrauma is critical.

Investigational Approaches to Acute Asthma Exacerbations

Heliox. Heliox is a mixture of helium and oxygen. The gas mixture has a lower density than oxygen and therefore theoretically reduces turbulent flow and airway resistance. This effect reduces work of breathing, which may in turn limit or delay respiratory muscle fatigue and allow more time for standard therapeutic agents to take effect. The lower gas density may also improve ventilation to alveoli with longer time constants resulting in better matching of ventilation and perfusion and more effective delivery of aerosolized medications. Heliox must contain a high concentration of helium (60 to 80%) that requires a tight-fitting mask, limiting its acceptance in young children. Data are limited and conflicting, particularly in children, but there is some suggestion that Heliox may be an effective adjunct for severe exacerbations.

Intravenous Magnesium Sulfate. Although IV magnesium sulfate has been studied extensively in adults and appears to improve pulmonary function, there is no consensus regarding its role in the management of asthma exacerbations. A recent study of children with moderate to severe exacerbations showed that the group treated with magnesium (25 mg/kg by IV; maximum, 2 g) had greater improvement in FEV_1, were less likely to require admission, and had no significant adverse effects compared with the group treated with placebo. This study suggests that IV magnesium may have a role as an adjunct in treatment of children with moderate to severe acute asthma exacerbations.

Disposition. Criteria for the disposition of acutely ill asthmatic children after ED management are difficult to specifically define. Scoring systems that use various assessment tools have not withstood prospective evaluation. As a guideline, however, admission should be considered for children who meet any of the following criteria:

1. Persistent respiratory distress
2. Sao_2 of 91% or less in room air
3. PEFR less than 50% of predicted levels
4. Inability to tolerate oral medications (i.e., vomiting)
5. Previous emergency treatment in last 24 hours
6. Underlying high-risk factors: congenital heart disease, bronchopulmonary dysplasia, cystic fibrosis, and neuromuscular disease
7. Evidence of air leak

Other factors that should be considered in conjunction with these criteria include access to emergency care and medical advice, family reliability, sophistication of available home therapy, and severity of past exacerbations.

Children who also meet the criteria listed in Table 92.5 should be admitted to an ICU setting.

Severe Respiratory Distress	Significant Complications
Estimate in severe range after therapy[a]	Pneumothorax
Pao_2 <60 mm Hg or Sao_2 <90% in 40% O_2	Arrhythmia
$Paco_2$ <42 mm Hg	Theophylline toxicity

[a]See Table 92.2.

Table 92.5. Criteria for Admission to the Intensive Care Unit

Discharge Management. Children who have an adequate clinical response to ED therapy may be discharged to home. Ideally, they should be observed for 30 to 60 minutes after their last treatment to ensure that they do not relapse immediately. Many of these children will experience persistent mild to moderate symptoms and considerable acute disability. It is important to understand that the basic pathophysiology that consists of small airway obstruction, inflammation, and altered lung mechanics is not immediately reversed in the ED and additional therapy will be required. An effort also should be made to remove the trigger, if possible.

In general, if a child already on a regimen of medication has had an exacerbation that required emergency management, this regimen must be intensified, at least for the next 3 to 5 days. Short-course, high-dose oral steroids (i.e., prednisone, 2 mg/kg per day up to 80 mg/day for 3 to 5 days) should be prescribed and administered for essentially all children who present to the ED with a significant exacerbation. In addition, all patients currently taking or who have recently been taking oral or inhaled corticosteroids must be given steroids as part of the acute management of their exacerbation. Children who experience frequent acute exacerbations, nocturnal symptoms, or multiple absences from school also may benefit from the addition of a systematic or inhaled corticosteroid to their regular regimen.

For children who experience their first episode of wheezing or who are not receiving long-term therapy, an inhaled albuterol is generally well tolerated in the subacute phase following the acute episodes. Children less than 5 years old should use an MDI with a spacer and mask or a nebulizer. The use of a spacer device in all children will improve delivery of medications in MDIs. If the child is receiving other long-term therapy, such as cromolyn sodium or inhaled steroids, it is important to continue it during acute exacerbations. Table 92.6 lists outpatient treatment options.

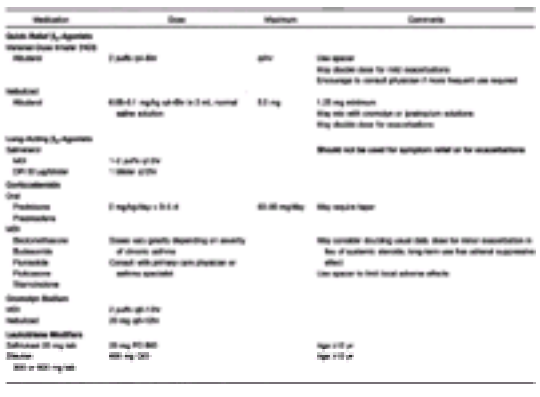

Table 92.6. Outpatient Asthma Therapy

It must be emphasized again that the ED plays a role beyond the management of the acute episode. If possible, ED personnel should take advantage of the educational opportunity and instruct the patient and family on the proper use of the inhaler and peak flow meter, environmental issues, and appropriate use of medications. Patients should leave with specific written instructions and be referred for follow-up appointment in the next 2 to 5 days to ensure resolution of the acute episode and to review long-term management.

ANAPHYLAXIS

Background

Anaphylaxis is a potentially life-threatening manifestation of immediate hypersensitivity. The severity of these reactions varies from mild urticaria to shock and death. Anaphylaxis most commonly involves the pulmonary, circulatory, cutaneous, gastrointestinal (GI), and central neurologic systems.

The classic anaphylactic response is an IgE-mediated reaction that occurs after reexposure to an antigen to which the patient has previously been sensitized. The term *anaphylactoid reaction* sometimes is used to refer to a clinically similar syndrome that is not IgE mediated and does not necessarily require previous exposure to the inciting agent. It has become common practice to use *anaphylaxis* to describe the clinical syndrome regardless of the responsible mechanism.

Any route of exposure, including parenteral, oral, and inhalation, has been associated with anaphylaxis. The most common inciting agents are Hymenoptera stings, drugs, foods, immunotherapy, radiocontrast media, and blood products (Table 92.7). IgE-mediated anaphylaxis to the latex present in gloves, Foley catheters, and endotracheal tubes was first recognized in the late 1970s. Patients who undergo multiple procedures, such as those with myelomeningocele and genitourinary dysplasias, as well as health care workers appear to be at greatest risk.

Insect Venom	*Foods*
Hymenoptera	Peanuts
Fire ants	Milk
Drugs	Seafood—shellfish
Antibiotics—penicillin,	Grains
cephalosporins,	*Blood Products*
sulfonamides	*Immunotherapy*
Local anesthetics—	Allergen extracts
lidocaine	*Other*
Aspirin	Latex
Radiocontrast media	Idiopathic

Table 92.7. Common Causes of Anaphylaxis

Pathophysiology

Currently, there are three well-established mechanisms that lead to anaphylaxis after exposure to a foreign substance. The first is the classic IgE-mediated reaction. The IgE antibodies form when a person is exposed to the foreign antigen (either in its native state or as a hapten attached to a carrier protein) for the first time. IgE binds to high-affinity receptors on mast cells and basophils. On reexposure, the antigen induces bridging of IgE molecules, leading to degranulation of these cells and to the release of various preformed and rapidly generated mediators. Immune complexes or other agents capable of activating the complement cascade induce the second mechanism. This results in the formation of anaphylatoxins such as C3a and C5a, which directly trigger release of mediators from mast cells and basophils. The third mechanism involves the ability of certain agents to stimulate the release of mediators directly by an unknown mechanism that does not involve IgE or complement. Agents capable of direct stimulation include hyperosmolar solutions such as mannitol and radiocontrast media.

The sudden release of numerous mediators from mast cells and, perhaps, from basophils is presumed to be responsible for the pathophysiologic features of anaphylaxis (bronchospasm, increased vascular permeability, and altered systemic and pulmonary vascular smooth-muscle tone). The most notable of these mediators is histamine, but others that have

been implicated include prostaglandin D_2, leukotriene C_4, platelet-activating factor, tryptase, chymase, heparin, and chondroitin sulfate.

Other causes of apparent anaphylaxis for which no clear mechanism has been identified exist. These include reactions after the ingestion of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) and exercise-induced anaphylaxis in which vigorous exercise is the trigger.

Clinical Findings

The time between exposure to the inciting agent and onset of symptoms can vary from minutes to hours, although most reactions occur within 1 hour. This interval depends on the sensitivity of the patient and the route, quantity, and rate of administration of the antigen. Although uncommon, some patients experience a biphasic reaction in which symptoms may recur up to 12 hours after the initial reaction.

The signs and symptoms of anaphylaxis vary in both the spectrum and severity of involvement. Reactions may be limited to the skin, as in a mild urticarial reaction, or catastrophically involve multiple systems, leading to shock and death.

In general, systemic reactions include cutaneous involvement such as pruritus, flushing, erythema, urticaria, and in more severe cases, angioedema. A more detailed discussion of urticaria is found at the end of this section (see also Chapter 66). Mucous membrane involvement may be limited to pruritus and congestion of the eyes, nose, and mouth. Swelling of the lips or tongue can potentially impair swallowing and ventilation.

An immediate life-threatening feature of anaphylaxis is upper airway obstruction that results from edema of the larynx, epiglottis, and other surrounding structures. This may be experienced as subtle discomfort of the throat or as obvious stridor and respiratory distress. Anaphylaxis also can cause lower airway disease secondary to bronchospasm. This leads to findings similar to acute asthma, such as a sense of chest tightness, cough, dyspnea, wheezing, and retractions.

Another potential life-threatening feature of anaphylaxis is cardiovascular collapse and hypotensive shock. Although the mechanisms are not fully understood, these cardiopulmonary manifestations are thought to result from profound vasodilation, increased vascular permeability, capillary leak, and intravascular volume depletion, as well as a possible direct toxic effect of circulating mediators. Arrhythmias and electrocardiographic evidence of myocardial ischemia also may be seen.

Central nervous system (CNS) involvement can include dizziness, syncope, seizures, and an altered level of consciousness. These may occur as a result of hypoperfusion or, possibly, as a direct toxic effect of mediator release.

GI symptoms are relatively common and include nausea, vomiting, diarrhea, and crampy abdominal pain.

Urticaria is a common manifestation of immediate hypersensitivity reactions as well as a number of other disease processes (Table 92.8). In the patient with acute urticaria from an IgE-mediated process, the urticaria may be localized to the area of exposure, such as the area around a sting. In addition to the localized urticaria, there may be a systemic reaction. Urticaria may be associated with angioedema—swelling of the lower dermis and subcutaneous tissues. The angioedema associated with urticaria is pruritic. Angioedema without pruritus usually is secondary to processes other than immediate hypersensitivity.

Dermographism	Familial urticaria
Physical urticaria	Hereditary angioedema
Cold	Familial cold urticaria
Cholinergic	Urticaria secondary to common agents
Pressure	Urticaria secondary to serum sickness
Solar	

Table 92.8. Urticaria: Classification

Urticaria can be separated into those that are acute and those that are chronic. Most immediate hypersensitivity reactions are associated with an acute reaction, but chronic, recurrent urticaria can be mediated by recurrent exposure to an unknown antigen. In determining the cause of an urticarial reaction, the classification shown in Table 92.8 is important because management may vary.

The physical urticarial reactions may be life-threatening, and they should be included in the differential diagnosis of anaphylaxis. Cold urticaria is an acute reaction to cold temperatures with hives at the site of cold exposure. Generalized cold exposure, such as immersion in a cold pool, can precipitate an anaphylactic reaction with hypotension and shock. The cold urticarias often are acquired and may follow viral infections. There is a familial cold urticaria that is rare and associated with a delayed onset, leukocytosis, and pain that distinguishes it from acquired cold urticaria. Cholinergic urticaria is characterized by punctate hives surrounded by an erythematous flare. Exercise, anxiety, shivers, and environmental temperature change can precipitate the reaction. It has been associated with exercise-induced

anaphylaxis and often causes systemic manifestations (e.g., abdominal pain, headaches). Solar urticaria is a reaction to light, often sunlight, with the development of pruritus, erythema, and edema. Solar urticaria can be a manifestation of porphyria. Pressure urticaria is associated with hives that develop at the site of significant prolonged pressure in areas of the body. It often is associated with tight clothing.

Management

Initial Assessment

Immediate resuscitative efforts must be initiated for the child who manifests the full-blown syndrome or any of the independent life-threatening manifestations, such as upper airway obstruction or shock. All patients who complain of an "allergic reaction" should be evaluated expeditiously to determine the extent of involvement, signs of progression, and the need for urgent intervention.

History

The history should be directed toward determining the nature and severity of the reaction, the rapidity with which symptoms evolved, and evidence of ongoing progression. Change in voice, difficulty in swallowing, dyspnea, and a sense of impending doom all are characteristic of potentially serious reactions.

Attempts also should be made to determine the offending agent. This may be obvious as in a reaction to a bee sting. The history should focus on the 1- to 2-hour period before the onset of symptoms. The association of anaphylactic reactions to food often is confusing. Although patients often focus on a particular food as the cause, a more detailed history may implicate something else in the meal. For example, it is common to associate reactions with chocolate, whereas the nuts in many chocolate preparations generally are the offending agents.

Physical Examination

A rapid cardiopulmonary assessment should precede any detailed physical examination. It should be quickly determined whether any evidence of upper airway obstruction, bronchospasm, or shock exists. Once these issues have been addressed, a more detailed physical examination should be performed to evaluate the patient for less serious cutaneous and GI manifestations of the reaction.

Management of a life-threatening anaphylactic reaction requires simultaneous evaluation and management of the airway, breathing, and circulation (ABCs), and the immediate administration of epinephrine as illustrated in Figure 92.2 and discussed in sequence in the following.

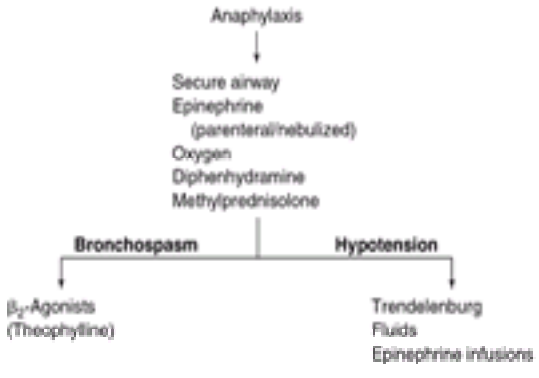

FIGURE 92.2. Management of anaphylaxis.

Maintenance of the Airway and Oxygenation

The physician should administer 100% oxygen with bag-valve-mask ventilation, as indicated, to assist ventilation. If there is complete airway obstruction, immediate endotracheal intubation should be attempted. If intubation is unsuccessful, cricothyrotomy is indicated. Rapid administration of epinephrine may lessen the difficulty of airway management.

Epinephrine, the first-line drug for anaphylaxis, should be administered *simultaneously.* It has several beneficial actions. As an a-adrenergic agonist, epinephrine promotes vasoconstriction, which increases blood pressure and decreases capillary leakage. As a b-adrenergic agonist, it relaxes bronchial smooth muscle, increases cardiac rate and contractility, and inhibits further mediator release. Epinephrine can be administered subcutaneously in the patient with reasonable perfusion (epinephrine 1:1000, 0.01 mL/kg to a maximum of 0.5 mL). If the patient is hypotensive or hypoperfused or if the initial subcutaneous dose is ineffective, the epinephrine should be administered by IV or through an intraosseous needle as a 1:10,000 solution, 10 µg/kg (0.1 mL/kg) over 1 to 2 minutes. In severe cases, this may need to be followed by a continuous epinephrine infusion of 0.1 µg/kg per minute, which can be titrated to effect up to a maximum of 1.0 µg/kg per minute (6 mg epinephrine should be added to 100 mL D5W normal saline solution; 1 µg/kg per minute = 1 mL/kg per hour).

Bronchospasm should be treated aggressively with supplemental oxygen, b_2-agonists such as albuterol or epinephrine, and corticosteroids, as outlined in the previous section on asthma. Some authorities believe that theophylline has a role

in the treatment of bronchospasm secondary to anaphylaxis.

Although not studied specifically in this setting, some authors recommend nebulized epinephrine (2.5 mL undiluted 1:1000) or racemic epinephrine 2.5% (0.5 mL in 2.5 mL normal saline) for relief of both the upper and lower airway obstruction associated with anaphylaxis.

Maintenance of the Circulation

Hypotensive patients should be placed in the Trendelenburg position, and a rapid bolus of 20 mL/kg of a crystalloid solution should be administered immediately and repeated as necessary. Because plasma volume may fall precipitously by 20 to 40%, large amounts of fluid may be necessary. If hypotension persists after epinephrine, normal saline bolus, and positioning, a continuous infusion of epinephrine should be started as previously described.

Other Therapy

The H_1-receptor antihistamines such as diphenhydramine (1 to 2 mg/kg intramuscularly or intravenously; maximum, 50 mg) are indicated in histamine-mediated allergic reactions. They work synergistically with the epinephrine therapy.

Corticosteroids do not take effect during the initial resuscitative phase of anaphylaxis. In significant reactions, however, their early administration may block or reduce the late-phase reactions over the next several hours or days. They can be administered as methylprednisolone 1 to 2 mg/kg by IV (maximum, 125 mg) or prednisone 1 to 2 mg/kg by mouth (maximum, 80 mg).

Many authorities recommend H_2-blocking antihistamines such as cimetidine (5 mg/kg; maximum, 300 mg) or ranitidine (1 to 2 mg/kg; maximum, 50 mg) in addition to H_1-blocking antihistamines, particularly for more severe reactions. These agents may work synergistically with the H_1-blocking antihistamines.

On occasion, in severe reactions from injection, a venous tourniquet above the injection site of the offending agent and local infiltration of epinephrine 1:1000 (0.005 mL/kg) and/or the application of ice may decrease further absorption.

Management of Limited Reactions

Most children with allergic reactions present with involvement limited to a diffuse, pruritic rash; localized swelling; or benign involvement of the mucous membranes. Appropriate management of these children varies according to the specific presentation. Options include subcutaneous epinephrine (e.g., for evolving urticaria), antihistamines, and corticosteroids.

Diphenhydramine (5 mg/kg per day divided every 4 to 6 hours, with a maximum of 300 mg/24 hours) and hydroxyzine (2 mg/kg per day divided every 4 to 6 hours, with a maximum of 200 mg/day) are the antihistamines most commonly prescribed for urticaria. In the case of cold urticaria, cyproheptadine (0.25 to 0.5 mg/kg per day divided every 12 hours, with a maximum of 32 mg/day) is the drug of choice, whereas hydroxyzine is preferred for cholinergic urticaria or most other chronic urticarias.

Disposition

Patients with severe reactions that involve upper airway obstruction or shock generally should be monitored for a minimum of 8 to 24 hours. Children with a history of asthma appear to be at increased risk for delayed and severe reactions and may also require prolonged monitoring.

Patients with less severe manifestations can be discharged home on a course of antihistamines and, in selected cases, corticosteroids. As a rule, therapy initiated in the ED should be continued for a minimum of 48 hours. Follow-up with the child's primary care physician also is advised.

Strategies to avoid exposure to the offending agent should be discussed. All children with a history of significant anaphylaxis with an antigen that cannot be avoided totally (e.g., Hymenoptera venom or food) should be instructed to carry a preloaded syringe of epinephrine to be used in emergencies (EpiPen).

SERUM SICKNESS

Background

Serum sickness is an immune complex–mediated disease. It was first described in 1905 in patients who had received heterologous antisera, which, at that time, was used routinely to treat various infectious diseases. Today, the most common cause of serum sickness is exposure to medication.

The clinical syndromes secondary to an immediate hypersensitivity reaction may appear similar to serum sickness. In the former, IgE is primarily responsible, whereas IgG or IgM immune complexes classically mediate the latter. In many cases, however, elements of both processes are involved. More recently, a clinical syndrome similar to serum sickness but apparently not mediated by immune complexes has been reported. These reactions are referred to as serum sickness-like reactions and appear to be responsible for the relatively common reactions seen in association with cefaclor.

Currently, the most common medications implicated in serum sickness or serum sickness-like reactions include the

penicillins, sulfonamides, cephalosporins, streptomycin, the hydantoins, and thiouracil. Because these drugs are all low-molecular-weight substances, they cannot act as antigens directly but must bind to proteins, usually through their metabolites. Therefore, it is often difficult to substantiate sensitization.

The use of agents made from heterologous serum has decreased dramatically. These preparations currently are found in antithymocyte globulins used to prevent organ transplant rejection and in antitoxins for the management of clostridial infections, diphtheria, tetanus, and specific arachnid and snake envenomations.

Less commonly, exposures to various chemical, infectious agents, or autologous antigens result in a serum sickness-like illness.

Pathophysiology

In the classical serum sickness model, an animal is injected with foreign serum protein. The animal develops the symptoms characteristic of serum sickness 7 to 10 days later. During the initial period after the injection of the foreign protein, there is a period of antigen excess (Fig. 92.3). This is a period during which no antibody has been formed. Antibodies develop approximately 6 to 10 days after the initial antigen is injected, and antibody–antigen complexes then form. These immune complexes deposit in the tissues and also may activate complement. After this period of immune complex formation, there is a period of antibody excess during which antigen clears from the system. Symptoms develop when soluble immune complexes are being cleared by the body.

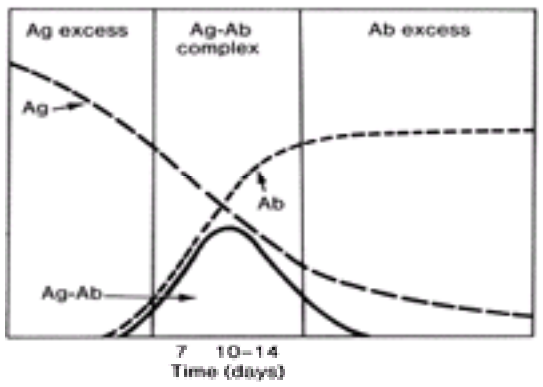

FIGURE 92.3. Time course of immune complex formation.

These immune complexes can activate the classical complement pathway. The classical pathway of activation begins with the formation of the C1q antibody complex, which activates a C1 esterase that cleaves the fourth and second complement components (C4 and C2). The C4 and C2 that have been activated can then cleave C3. It is cleavage of C3 and generation of all of its active components that allow for the activation of the late-acting complement components (C5–C9). Because the immune complex activation involves the classical components, C4, C2, and C3, their serum concentration decreases. The complement activation generates the anaphylatoxins C3a and C5a, which then increase vascular permeability, release histamine, and can produce bronchospasm. They activate many other cells in the inflammatory process and lead to inflammation around deposits of complexes in various tissues.

Clearance of immune complexes depends on their size and the effectiveness of the reticuloendothelial system. The most vulnerable organs to injury include the kidneys and the vascular system.

It also had been shown in experimental animals that immune complex deposition can be enhanced by concomitant activation of an immediate hypersensitivity reaction. The IgE-mediated mast cell degranulation increases vascular permeability, which, in turn, enhances immune complex deposition.

Clinical Findings

The severity of serum sickness and the specific clinical manifestations vary widely. The reaction is characterized by fever, malaise, and a rash that is most commonly urticarial but also may appear as maculopapular or vasculitic. Other manifestations include arthralgias or arthritis, lymphadenopathy, angioedema, and nephritis. Other less common problems include abdominal pain, carditis, anemia, and neuritis. Serum sickness is usually self-limited and typically resolves within 1 to 2 weeks with or without therapy.

Characteristically, the onset of symptoms occurs 7 to 14 days after the primary exposure. If there has been prior sensitization, however, reexposure can result in onset of a few days.

History

The history should be directed toward identifying the offending agent and determining the extent and severity of the symptoms.

The physician should review possible exposures up to 14 days before symptoms to ascertain a possible cause for the process. Because a secondary exposure can produce a more rapid onset of symptoms (1 to 4 days), inquiries about this interval and about previous exposures may also be revealing.

The history should elicit information about the extent of systemic illness and the involvement of specific organ systems. It is important to determine the time course and nature of the rash, the degree of joint pain, swelling or warmth, and evidence of renal involvement such as hematuria, edema, and reduced urine output. In light of the potential for involvement of other organ systems, a complete review of systems is indicated.

Physical Examination

Perform a thorough physical examination to determine the severity and extent of involvement of the reaction. A general inspection will help determine how ill and uncomfortable the child is. Examination of the skin may reveal a maculopapular eruption, urticaria, or the palpable purpura of a cutaneous vasculitis. Painful angioedema is commonly present. Generalized lymphadenopathy often occurs. In more severe reactions, the joints show erythema, warmth, and effusion. Wheezes may be appreciated on auscultation of the lungs, and a pericardial friction rub may be audible if pericarditis is present. The liver and spleen often enlarge. Rarely, neurologic deficits occur secondary to a vasculitis of the central nervous system.

Laboratory

The selection of laboratory studies should be determined by the severity of the reaction, evidence of specific organ system involvement, and the degree of diagnostic uncertainty. For most patients, a urinalysis to look for evidence of renal involvement is all that is required. A list of other studies that may be indicated for individual patients with immune complex–mediated disease is outlined in Table 92.9.

Blood Tests	Hepatitis B screen
Erythrocyte sedimentation rate	Heterophil antibody
Complete blood count with differential	Immune complex assay
CH_{50}, C3, C4	*Other Laboratory Tests*
Blood urea nitrogen, creatinine	Urinalysis
Antinuclear antibody	Electrocardiogram
Rheumatoid factor	Stool Hematest
Hepatic enzymes	Computed tomography scan

[a]Laboratory evaluation should be tailored for each individual patient as noted in text.

Table 92.9. Possible Laboratory Evaluation of Serum Sickness[a]

The erythrocyte sedimentation rate (ESR) may be elevated. A CBC and differential may reveal leukopenia or leukocytosis. The C3, C4, and CH_{50} may decrease because of complement activation. Any of the tests for circulating immune complexes (e.g., cryoglobulins) may be elevated. Stool Hematest should be performed, and an echocardiogram should be considered for patients with abdominal pain or other symptoms involving the GI tract. If carditis is suspected, a screening electrocardiogram should be performed. Severe headache or focal neurologic deficits are indications for a computed tomography (CT) scan.

Management

The treatment of serum sickness is based on the extent and severity of the patient's disease. Keeping in mind that the reaction is usually self-limited, the goal is to provide symptomatic relief and monitor for complications. If possible, the offending antigen should be eliminated. It has been demonstrated in animal models that elimination of the antigen allows more rapid resolution of immunopathologic damage.

Pharmacologic management usually involves one or more of the following: antihistamines, NSAIDs, and corticosteroids. Pruritus, rash, and angioedema can be managed with an antihistamine such as hydroxyzine (2 mg/kg per 24 hours divided every 6 to 8 hours, with a maximum of 200 mg/24 hours). Although experience in the treatment of serum sickness is limited, use of the second-generation nonsedating antihistamines may also be considered (Table 92.10). Urticarial lesions and angioedema that evolves rapidly may respond acutely to subcutaneous epinephrine (1:1000, 0.01 mL/kg subcutaneously, with a maximum 0.30 mL) and/or longer-acting Sus-Phrine (0.005 mL/kg subcutaneously, with a maximum of 0.15 mL). Mild joint involvement and/or fever often improve with use of an NSAID such as ibuprofen (30 to 50 mg/kg per 24 hours divided every 6 to 8 hours up to a maximum 2.4 g/24 hours). In more severe disease or after failure to respond to these measures, a burst of corticosteroids may be indicated. This involves the use of 1 to 2 mg/kg per day of prednisone in divided doses for 7 to 10 days, followed by a taper for 3 to 4 weeks (maximum, 80 mg/day). In life-threatening serum sickness with significant circulating immune complexes, plasmapheresis may play a role, but this procedure has not been used extensively for treatment of this disease.

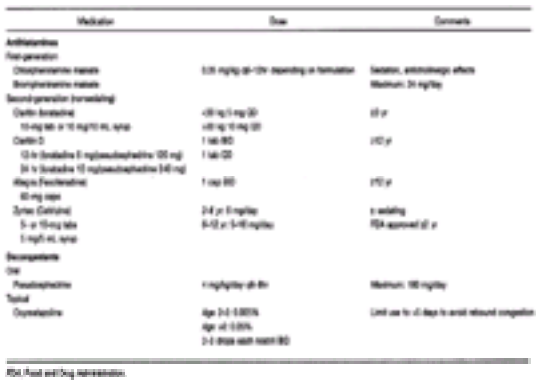

Table 92.10. Emergency Department Management of Allergic Rhinitis

Most children with serum sickness can be managed as outpatients with close follow-up by their primary care physicians. Children with more severe involvement may benefit from hospitalization.

ALLERGIC RHINITIS

Background

Allergic rhinitis is the most common manifestation of atopic disease. Peak incidence occurs in the pediatric age group, affecting up to 30% of children and adolescents. Although not a life-threatening problem, allergic rhinitis can have a significant, often underestimated, negative impact on the quality of life of affected children. The morbidity of allergic rhinitis results from the direct manifestations of the disease as well as from associated complications such as serous OM, sinusitis, acute asthma, sleep disturbances, dysosmia, and the consequences of chronic mouth breathing.

Pathophysiology

Allergic rhinitis is caused by an IgE-mediated hypersensitivity response of the nasal mucosa to foreign allergens. Following sensitization to a foreign antigen, reexposure triggers an immediate hypersensitivity reaction. This early response is characterized by activation of mast cells and release of preformed mediators of inflammation such as histamine and chemotactic factors and newly formed mediators such as prostaglandins and leukotrienes. These mediators cause vasodilation, mucosal edema, mucus secretion, stimulation of itch receptors, and reduction in the threshold for sneezing.

Many children experience a late-phase allergic response that consists of spontaneous release of inflammatory mediators 3 to 12 hours after exposure. There also is a “priming effect” that leads to increased responsiveness to small antigen loads and hyperresponsiveness to environmental irritants.

Seasonal allergic rhinitis is most commonly caused by exposure to tree pollens (early spring), grass pollens (late spring and early summer), and ragweed or other weed pollens (late summer and fall). Allergens responsible for *perennial* allergic rhinitis include animal dander, house dust mites, and mold spores.

Clinical Findings

The classic symptoms of allergic rhinitis include nasal congestion, paroxysmal sneezing, pruritus of the nose and eyes, and watery, profuse rhinorrhea. Other complaints may include noisy breathing, snoring, repeated throat clearing or cough, itching of the palate and throat, “popping” of the ears, and ocular complaints such as redness, itching, and tearing.

The physical examination is variable but may reveal the “gaping” look of a mouth breather, dark discoloration of the infraorbital ridge caused by venous congestion (allergic shiners), and a transverse external nasal wrinkle secondary to chronic rubbing of the nose (allergic salute). Intranasal findings are variable. The mucosa often is edematous and may appear pale or violaceous. The nasal secretions may be clear, mucoid, or opaque.

Management

There are several approaches to the management of allergic rhinitis. These include identification and avoidance of environmental allergens and irritants, an antihistamine generally prescribed together with an oral or topical decongestant, topical corticosteroids, and immunotherapy.

Recognizing that long-term therapy must be highly individualized, the emergency physician will generally limit interventions to those that safely provide rapid, symptomatic relief and then refer the child to the primary care physician for long-term therapy. In addition, topical corticosteroids, first-line therapy for chronic allergic rhinitis, may require as long as 2 weeks to achieve maximal relief. Rapid relief can generally be achieved by prescribing an antihistamine in combination with a decongestant (Table 92.10).

Antihistamines acutely reduce the rhinorrhea, pruritus, and sneezing associated with allergic rhinitis. Because they do not reduce congestion caused by mucosal edema, they are most effective in combination with a decongestant. The newer second-generation H_1-receptor antagonists are preferred over older antihistamines because they are generally

nonsedating, longer acting, and devoid of anticholinergic effects.

Oral decongestants, such as pseudoephedrine, relieve nasal congestion through their a-adrenergic activity. Potential adverse effects include headache, restlessness, insomnia, and decreased appetite. Topical decongestants such as oxymetazoline hydrochloride present another alternative but should be prescribed for only brief periods (less than 5 days) to avoid tachyphylaxis.

Environmental approaches and an antihistamine–decongestant combination may be all that is required for the child with only mild, self-limited episodes of allergic rhinitis. As already noted, children with more severe or chronic allergic rhinitis should be referred to their primary care physicians who can determine the best alternative for long-term management.

The first-line approach for patients who require long-term therapy is topical corticosteroids (Table 92.11) with or without a second-generation oral antihistamine. For completeness, other categories of topical treatment are also listed in Table 92.11. Children with significant ocular symptoms may also benefit from topical ophthalmic treatment (Table 92.12).

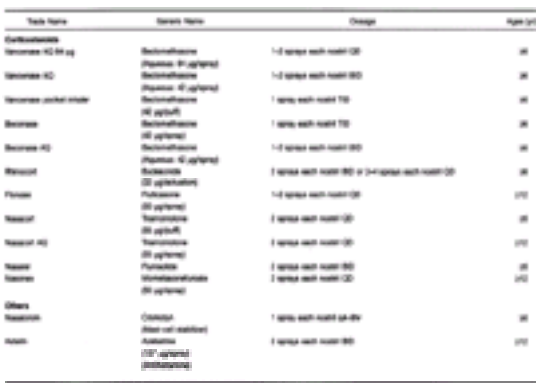

Table 92.11. Topical Treatment for Allergic Rhinitis

Trade Name	Generic Name	Category	Dosage	Ages (yr)
Naphcon-A	Naphazoline and Pheniramine	Antihistamine–decongestant	1–2 gtt QID	≥6
Livostin	Levocabastine	Antihistamine	1–2 gtt QID	≥12
Alomide	Lodoxamide Tromethamine	Mast-cell stabilizer	1–2 gtt QID	≥2
Patanol	Olopatadine	Mast-cell stabilizer and antihistamine	1–2 gtt BID	≥3
Acular	Ketotifen	NSAID	1–2 gtt QID	≥12

NSAID, nonsteroidal anti-inflammatory drug.

CHAPTER 93

Gastrointestinal Emergencies

[*]DENNIS R. DURBIN, MD, MSCE and [†]CHRIS A. LIACOURAS, MD

*Departments of Pediatrics and Epidemiology, *Division of Emergency Medicine, †Division of Gastroenterology and Nutrition, The University of Pennsylvania School of Medicine, and †Department of Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

GASTROINTESTINAL BLEEDING

Gastrointestinal (GI) bleeding is a common and occasionally life-threatening condition in infants and children. An orderly approach to this problem is essential and is outlined in Chapter 30. One of the most important initial steps in establishing the cause of GI bleeding in children is determining whether the source of bleeding is the upper or lower intestinal tract. The following discussion of general principles of management, as well as specific diagnoses is, therefore, organized accordingly. Only those conditions most appropriately classified as medical diagnoses are described in this chapter. Additional causes of GI bleeding that are more appropriately classified as surgical diagnoses, including intestinal malrotation with volvulus, intestinal duplications, intussusception, and Meckel's diverticulum, are discussed in detail in Chapter 118.

General Principles of Management

In contrast to the adult experience, most children presenting to the emergency department (ED) with either upper or lower GI bleeding have not experienced significant blood loss. Most children can be managed successfully with judicious laboratory investigation, conservative supportive care, and follow-up with the patient's primary care provider or an appropriate subspecialist. A detailed discussion of pertinent laboratory evaluation and initial management for each of the most common causes of GI bleeding in children is provided in the following sections.

Severe GI bleeding should be considered a potentially life-threatening emergency that may require the cooperation of a team, including the emergency physician, surgeon, and gastroenterologist. Similar to the management of all potentially life-threatening conditions in children, the initial approach to the child with significant GI hemorrhage begins with an assessment of the child's airway, breathing, and circulation. A child with overt hemodynamic instability or suspected significant volume loss should be positioned with legs elevated and given nasal oxygen. Patients who have hematemesis should have the head elevated 30 to 45 degrees to lessen the chance of pulmonary aspiration of blood. In massive upper intestinal bleeding, protecting the airway with an endotracheal tube may be lifesaving. The next priority is the insertion of two large-bore intravenous catheters (14- to 20-gauge in the child and at least 22-gauge in small infants). A percutaneous central venous line or cutdown should be placed if the person administering the intravenous line has difficulty obtaining adequate peripheral venous access; the intraosseous route provides a temporary alternative.

Immediate blood studies in any patient with severe GI bleeding should include 1) type and crossmatch, 2) complete blood count (CBC), 3) platelet count, 4) prothrombin time (PT), and 5) partial thromboplastin time (PTT). Additional laboratory studies may be indicated based on the differential diagnosis of the most likely cause of the patient's bleeding, and are discussed later in this section. These studies should be done at the time of insertion of the intravenous lines. Arterial blood gases are also important parameters to follow in severe blood loss associated with shock. The hematocrit is an unreliable initial index of acute blood loss because it may be normal or only slightly decreased. Its subsequent fall will depend on 1) the rate and type of fluid replacement and 2) the body's own hemostatic mechanisms, resulting in both renal conservation of fluid and electrolytes and gradual shifts of fluid from extravascular to intravascular compartments.

Intravenous therapy has two major objectives: 1) restoration of intravascular volume (reflected in blood pressure or pulse)

and 2) restoration of oxygen-carrying capacity (reflected in hemoglobin and hematocrit values). The former objective can be accomplished both by nonsanguineous crystalloid or colloid solution or blood products, whereas the latter objective can be accomplished solely by the infusion of blood. The practical limitations of time required to properly type and crossmatch blood make nonsanguineous solution the mainstay of early resuscitation. In the rare circumstance of massive, ongoing hemorrhage in which low oxygen-carrying capacity is believed to be an important factor at onset of resuscitation, Rh and type-specific blood can usually be provided in 10 to 15 minutes. If type-specific blood is not immediately available, O-negative blood may be used. In most cases, proper type and crossmatch can be performed while intravascular volume is restored by nonsanguineous solutions. The exact type of solution to be used is controversial. Studies in both animals and humans have shown a reduction in intravascular as well as extravascular volume in acute blood loss; therefore, the preferred method is manual infusion of crystalloid solutions, such as normal saline or Ringer's lactate, in 20 mL/kg boluses until intravascular volume is minimally restored as indicated by a rise in blood pressure and disappearance of clinical signs of peripheral vasoconstriction. Colloid solutions such as albumin, plasma, or Hetastarch should be used only when blood loss is massive and continuous because in this situation respiratory insufficiency or shock lung may develop with a fall in plasma oncotic pressure. Dextran is to be avoided because it may affect platelet function. Patients who are in shock at the time of admission should have the urinary bladder catheterized in the ED to accurately measure urine output and to allow for early detection of acute tubular necrosis.

Overexpansion of intravascular volume is potentially dangerous, particularly in bleeding varices but also in bleeding gastric or duodenal ulcers. Therefore, after correction of shock and restoration of urine flow, further intravenous volume replacement should be titrated to match continuing blood loss. The decision to begin transfusion depends on the level of hematocrit taken at the time of restoration of blood volume and on evidence of ongoing bleeding. For a patient who has stopped bleeding, blood transfusion is given to allow some reserve in case of rebleeding. Under most circumstances, slow transfusion to return hematocrit to approximately 30% is recommended to achieve this objective. In this case, packed cells (10 mL/kg) are used to reduce the volume load to the patient. In addition, packed blood cells contain considerably less ammonia than whole blood, an important factor for patients who have severe liver disease. For a patient who has continuous bleeding, ongoing blood transfusion is the only means of maintaining adequate oxygen-carrying capacity. In this case, the rate of bleeding determines the rate of transfusion. A sustained rate of transfusion is recommended and is best achieved with an electrical infusion pump, not by gravity. Potential complications of massive transfusions include hypercitrinemia, hyperlacticacidemia, hypocalcemia, decreased levels of clotting factors, and thrombocytopenia. The risks inherent in massive transfusions are definitely lowered by using packed red blood cells, fresh-frozen plasma, proper filters, and blood warmers. Any patient with or without a previous history of liver disease who presents with GI bleeding associated with an abnormal PT should receive vitamin K (5 to 10 mg intramuscularly or intravenously) as soon as possible.

UPPER GASTROINTESTINAL BLEEDING

Background

Upper GI bleeding is generally regarded as originating proximal to the ligament of Treitz. Hematemesis or bloody gastric aspirates from a nasogastric tube may originate from the mouth, nasopharynx, esophagus, stomach, biliary tree, or duodenum. The most common causes of upper GI bleeding in children are mucosal lesions, including esophagitis, gastritis, Mallory-Weiss tear, peptic ulcer disease, and duodenitis. Less common but important causes include bleeding esophageal varices and vascular lesions. The profile of common diagnoses has changed recently because increasing use of endoscopy enables specific, often microscopic, diagnoses to be substituted for previously documented “bleeding of unknown origin.” Endoscopy, when performed by a well-trained physician, is the most sensitive and specific diagnostic procedure for determining the cause and site of upper GI bleeding. Specific diagnosis should be pursued in patients who have 1) active bleeding documented by nasogastric lavage; 2) evidence of severe hemorrhage (hemodynamic instability or equilibrated hemoglobin level less than 10 g/dL); 3) conditions that affect healing or clotting, such as catabolic state or serious chronic disease; 4) a history of previous unexplained gross or occult bleeding or unexplained iron deficiency anemia; or 5) a history of chronic dyspepsia (vomiting, abdominal pain, nausea, oral regurgitation, heartburn, dysphagia).

The pathophysiology, clinical manifestations, and specific management issues related to each of the most common causes of upper GI bleeding in children are discussed. As noted in Chapter 30, an upper tract source for GI bleeding is often indicated by a history of hematemesis or by obtaining fresh (red) or old (coffee ground) blood via gastric lavage after placement of a nasogastric tube.

General Principles of Nasogastric Lavage

Not every child with a history of possible upper GI bleeding requires nasogastric lavage. Patients who have a history of acute self-limited hematemesis of streaks of blood or a small amount of coffee-ground material in the context of forceful emesis, recurrent gastroesophageal reflux, symptoms of infectious gastroenteritis, or epistaxis can often be managed presumptively without gastric lavage. However, nasogastric lavage should be performed in all patients suspected of having significant GI bleeding that is indicated by either history or physical examination (e.g., pallor, unexplained tachycardia, poor perfusion). The purpose of gastric lavage is to confirm the level of bleeding and to estimate the rate of bleeding. There is no evidence that gastric lavage has any therapeutic role in controlling hemorrhage. It is important to realize that a clear nasogastric aspirate does not exclude major bleeding from the upper GI tract.

Most patients can be effectively lavaged with a nasogastric sump tube (12 Fr in small children; 14 to 16 Fr in older children). Verification of the location of the tube in the stomach by injection of air and auscultation over the stomach is essential. The recommended volume for each saline infusion depends on age: 50 mL for infants, 100 to 200 mL for older children. With the patient's head elevated 30 degrees, the solution, at room temperature, is rapidly infused into the stomach, allowed to stand for 2 to 3 minutes, and then aspirated by gentle suction. Return volumes should approximate input volumes, and discrepancies should be recorded. If aspiration meets with significant resistance, the physician should either reposition the tube, reposition the patient, or increase the amount of solution introduced. Saline lavage of

the stomach should be performed by two people. One person fills and empties the stomach while the other person empties and fills the syringes.

Blood-flecked gastric aspirate or coffee-ground material indicates a low rate of bleeding. In contrast, bright red blood, especially if it does not clear with repeated lavage for 5 to 10 minutes, suggests a significant or ongoing hemorrhage. No benefit is derived from continuous lavage longer than 10 minutes if return is not clearing. The tube can be left to gravity or low suction and irrigated every 15 to 30 minutes to assess the activity of the bleeding. The presumed lesion causing the bleeding determines the subsequent management of the patient.

Nonspecific Mucosal Lesions

Background

GI bleeding may be a complication of all acute and chronic nonspecific upper GI mucosal lesions (esophagitis, gastritis, Mallory-Weiss tears, and duodenitis). Regardless of the cause, upper GI bleeding usually stops spontaneously, often by the time the patient arrives in the ED. Esophagitis as a result of gastroesophageal reflux (GER) is being diagnosed more often with improved pediatric fiberoptic endoscopes. Increasing use of endoscopic biopsy has documented esophagitis in 60% of patients with clinically significant GER. Exposure to aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., ibuprofen, naproxen) has also been associated with gastritis and mucosal ulceration. A recent large, randomized clinical trial designed to assess the risk of serious GI bleeding (requiring hospitalization) in febrile children after the use of ibuprofen demonstrated no greater risk than with acetaminophen. The study was not able to assess less serious (and clinically inapparent) occurrences of GI bleeding. Mallory-Weiss tears are mucosal lacerations of the gastric cardia or gastroesophageal junction induced by retching or vomiting. These lesions are relatively rare in children, accounting for approximately 5% of cases of upper GI bleeding.

Pathophysiology

The upper GI mucosa bleeds when an ulcerating process erodes into a blood vessel, usually an artery in the base of the ulcer. In most cases, normal mechanisms of thrombosis and healing stop the bleeding and prevent recurrent bleeding. Erosion of larger arteries, however, in which blood flow exceeds the capacity of normal hemostasis, results in continuous hemorrhage. A more common scenario is that thrombosis temporarily stops the bleeding, but aneurysmal dilation of the artery in the recanalization process or continuing arteritis from the chemical irritation of acid digestion facilitate recurrent hemorrhage. Acid and pepsin also produce profound adverse effects on platelet aggregation and plasma coagulation. The pathogenesis of Mallory-Weiss tears involves the production of transient large gradients between the intragastric and intrathoracic pressures at the gastroesophageal junction as a result of forceful retching. The gradient results in dilation of the gastroesophageal junction, and thus, tears.

Clinical Manifestations

Diagnosis is usually suspected by an antecedent history of vomiting and/or abdominal pain and absence of physical findings suggestive of chronic liver disease or portal hypertension. Reflux esophagitis is suspected in infants, usually less than 1 year of age, who have a history of recurrent nonprojectile emesis, “wet burps,” after feeding, or a documented diagnosis of GER and who present with emesis that is blood streaked or contains a small amount of coffee-ground material. Infants may be fussy but consolable and may have been previously diagnosed with colic. Reflux esophagitis should also be suspected in infants with guaiac-positive stools or iron deficiency anemia. A history of repeated aspirin or NSAID use for control of fever and/or pain should also prompt suspicion for gastric mucosal lesions as the cause of upper GI bleeding. Mallory-Weiss tears should be suspected in older children with a history of protracted forceful vomiting and streaks of hematemesis appearing after several episodes of nonbloody emesis.

Management

For patients who have significant bleeding and for whom nasogastric lavage was initiated, if gastric contents clear following initial saline lavage and immediate endoscopy is not planned, gastric irrigation is performed every 15 minutes for 1 hour, then every hour for 2 to 3 hours. Antacid (e.g., Maalox®, 15 mL, infants; 30 mL, preschool-age children; 60 mL, school-age children) is infused into the tube after every lavage. The dosage of antacid is titrated during the hourly monitoring so that gastric pH 1 hour after antacid infusion is greater than 3.5. If the patient is hemodynamically stable and gastric return remains clear for the aforementioned period, the tube is electively removed. Persistent nausea or vomiting or the presence of ileus points to the need for continued drainage.

Patients with nonspecific mucosal lesions theoretically should benefit from neutralization of intragastric acidity by antacids and reduction of gastric acid and pepsin secretion by H_2-receptor antagonists. For patients with significant symptoms or blood loss, H_2-antagonists may be given initially by the intravenous route, switching to the oral route when the nasogastric tube is removed. Either ranitidine (1.0 to 1.5 mg/kg per dose intravenously every 6 hours or 2 mg/kg per dose orally two times a day) or cimetidine (6.0 to 7.5 mg/kg per dose intravenously every 6 hours or 10 mg/kg per dose orally four times a day) is appropriate. For patients who have acute self-limited bleeding and who are not considered candidates for endoscopy, oral H_2-antagonists are continued for 2 to 4 weeks, at which time they are empirically discontinued if the patient is asymptomatic.

In general, all patients with a history suggestive of significant upper GI bleeding should be admitted to the hospital for observation. A clear nasogastric aspirate should never be used as an indication to discharge a patient from the ED if the history suggests significant bleeding. The main reason for admission is the unknown incidence of rebleeding from these lesions in children. Unremitting or recurrent mucosal bleeding requires either therapeutic endoscopy, therapeutic angiography, or surgery. In the hands of a qualified endoscopist, therapeutic endoscopy using either a heater probe or

multipolar electrocoagulation is the treatment of choice.

Esophageal Varices

Background

Portal hypertension may result from either extrahepatic presinusoidal obstruction (50 to 65% of cases in children) or from hepatic parenchymal disorders. Extrahepatic obstruction (e.g., portal or splenic vein obstruction) is associated with omphalitis, dehydration, sepsis, and umbilical vein catheterization. Hepatic parenchymal disease may result from biliary cirrhosis associated with biliary atresia, cystic fibrosis, hepatitis, a $_1$-antitrypsin deficiency, or congenital hepatic fibrosis. Patients with both types of portal hypertension are susceptible to GI hemorrhage from bleeding esophageal varices and from congestive or hemorrhagic gastritis. After development of portal hypertension, the onset of esophageal varices can be variable, from a few months to many years.

Pathophysiology

Portal hypertension results from relative obstruction of portal venous blood flow, leading to the development of portal systemic collateral veins, or varices. Portal-systemic collaterals will develop in any area where veins draining the portal venous system are in close approximation to veins draining into the caval system (i.e., submucosa of the esophagus, submucosa of the rectum, and anterior abdominal wall). Esophageal and gastric fundal varices, connecting branches of the coronary veins with branches of the azygous vein, are the most likely to be the site of spontaneous hemorrhage (Fig. 93.1).

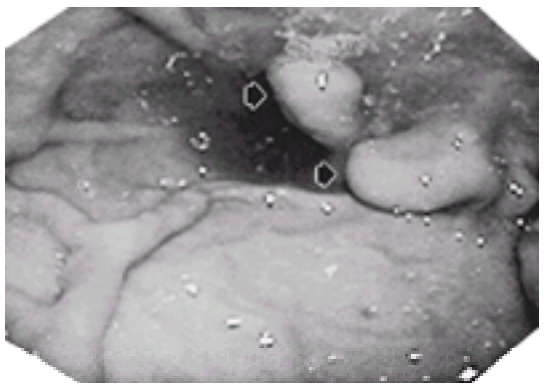

FIGURE 93.1. Gastric varices. The arrows represent 2 large blood-filled varices in the gastric cardia.

Clinical Manifestations

Patients with portal hypertension may have occult bleeding, but more commonly, the bleeding is brisk, and patients will have melena and/or hematemesis. The possibility of bleeding esophageal varices should be considered in any patient with a history of jaundice (beyond the newborn period), hepatitis, blood transfusion, chronic right-sided heart failure, pulmonary hypertension, omphalitis, umbilical vein catheterization, or one of the hepatic parenchymal diseases previously noted. Accordingly, the physical examination may reveal stigmata of the underlying disease leading to portal hypertension, including jaundice, ascites, rectal hemorrhoids, and hepatosplenomegaly.

Management

The initial management of suspected variceal hemorrhage is identical to that of massive upper GI bleeding from any source. Overexpansion of the intravascular volume should be avoided because it contributes to rebleeding. Coagulation abnormalities should be managed aggressively with intravenous vitamin K, fresh-frozen plasma, and platelets. Bleeding varices may be the initial sign of sepsis in patients who have cirrhosis; therefore, any patient who has fever should be started on broad-spectrum antibiotics such as ampicillin 200 mg/kg per day and gentamicin 5 to 7.5 mg/kg per day pending results of blood cultures.

Suspicion of variceal bleeding is not a contraindication to pass a nasogastric tube. If bleeding ceases during the initial gastric lavage, the tube should be managed as previously described. Antacids and H $_2$-antagonists are given in the doses used for mucosal lesions. Pharmacologic therapy of acute variceal hemorrhage uses the splanchnic arterial constrictor vasopressin and the prokinetic agent metoclopramide. Vasopressin administration has been well documented to decrease blood flow and pressure through the portal circulation. Infusion may be initiated before diagnostic endoscopy if variceal bleeding is suspected. The physician should begin infusing 0.1 unit/minute and increase the dosage by 0.05 unit/minute hourly up to a maximum of 0.2 unit/minute in children less than 5 years old, 0.3 unit/minute in children 5 to 12 years old, and 0.4 unit/minute in adolescents more than 12 years old. Side effects can be significant; thus, the child must be monitored carefully. Major complications include myocardial ischemia, life-threatening arrhythmias, and limb vasoconstriction or ischemia. Minor complications include water retention with sodium depletion, benign arrhythmias, and acrocyanosis. The vasopressin is usually given in 5% dextrose in water; the exact dilution is based on overall volumes of fluids being infused. Infusing vasopressin through a large-bore, preferably central venous, line is the safest method. The reported success rate of vasopressin infusion in adults is 50 to 70%. Because of the high rate of rebleeding, once begun, the drug should be continued at the dosage that controls bleeding for a minimum of 12 to 24 hours after all bleeding has stopped. This management plan stems from studies showing sustained vasoconstrictive effects of vasopressin on splanchnic vessels in dogs for more than 24 hours. However, this point is controversial because tachyphylaxis reportedly

also develops with prolonged use of vasopressin.

If bleeding continues after the use of vasopressin, emergency flexible endoscopy should be performed as soon as the patient's vital signs have been stabilized. Actively bleeding esophageal varices or an overlying clot on a varix confirms variceal bleeding. The endoscopist may choose to perform emergency sclerotherapy at that point. Alternatively, sclerotherapy may be delayed until hemorrhaging has been controlled by pharmacologic agents or balloon tamponade, especially if the endoscopist has difficulty obtaining a clear field of vision. Sclerotherapy should not be considered a therapeutic option to control bleeding gastric varices.

Gastroesophageal balloon tamponade is a highrisk procedure. It should be considered only for endoscopically proven gastric or esophageal varices. Indications of these varices include massive, life-threatening hemorrhage or continued bleeding despite 2 to 6 hours of intravenous vasopressin. Either a Sengstaken-Blakemore (S-B) (Fig. 93.2) or a Linton tube may be used. The S-B tube has both gastric and esophageal balloon tubes, whereas the Linton tube has a single lavage gastric balloon. Gastroesophageal tamponade is reported to arrest bleeding initially in 50 to 80% of cases. However, the reported incidence of major complications from use of the S-B tube ranges from 9 to 35%. Death directly attributed to the use of the tube has been reported in 5 to 20% of patients on whom the tube was used. Other major complications include rupture or erosion of the esophageal or gastric fundal mucosa, occlusion of the airway by the balloon, and aspiration of secretions resulting from inadequate drainage of the occluded esophagus.

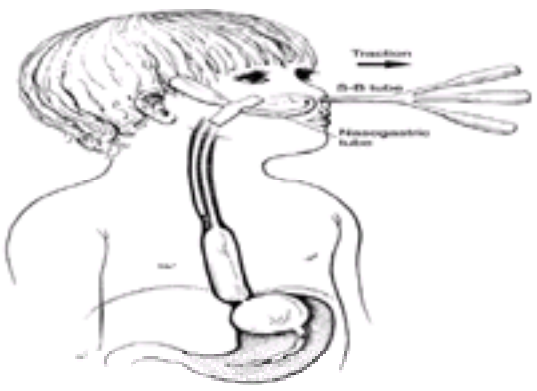

FIGURE 93.2. Gastroesophageal tamponade using a Sengstaken-Blakemore tube.

When a hemostatic tube is used, it should be inserted only by a physician who is skilled in its use. The S-B tube is preferred (Fig. 90.2). A pediatric tube is used for children less than 11 to 13 years old; the adult tube is used in adolescents. Passage through the nose is the procedure of choice, but in small children, passage through the mouth may be necessary. Intranasal oxymetazoline hydrochloride (0.05%) is used for local vasoconstriction. Each balloon is pretested for air leaks before insertion. The tube is heavily lubricated and passed through the nose to its full length; 50 to 100 mL of air is instilled into the gastric balloon and the balloon pulled up until the resistance of the gastroesophageal junction is encountered. An emergency radiograph is then performed to ensure correct balloon position immediately below the diaphragm. Additional air is then instilled into the gastric balloon, up to 150 mL in the pediatric balloon and 250 mL in the adult balloon; the tube is pulled taut and is taped at the nose. In many cases, the gastric balloon alone will stop bleeding by preventing flow of blood from the stomach into the esophagus or by directly occluding a gastric varix. It is absolutely essential to pass a second nasoesophageal tube to aspirate saliva and blood from ongoing esophageal hemorrhage. If esophageal bleeding continues, the esophageal balloon is inflated with air. The volume in the esophageal balloon is determined by the pressure within the balloon, which is measured by connecting its inflow tube to a sphygmomanometer. The pressure is maintained at the minimum required to control bleeding, with the maximum being no more than 40 mm Hg.

If bleeding is controlled, the balloons are kept inflated for 24 hours. The esophageal balloon is deflated first, then the gastric balloon approximately 1 hour later. The gastric tube is irrigated every 30 minutes for 1 to 2 hours more, and then the tube is removed.

A patient with an indwelling S-B tube must be transferred to an intensive care unit. A pair of scissors should be kept at the bedside; if any respiratory embarrassment occurs, the tube should be cut immediately, thereby deflating the balloons.

Endoscopic sclerotherapy should be performed on an elective basis within 6 to 24 hours after active bleeding has been controlled by pharmacologic therapy or balloon tamponade. Recent reports have noted success with endoscopic variceal ligation (EVL) using an elastic band ligature device in children. Randomized studies of endoscopic variceal sclerotherapy (EVS) versus EVL in adults have demonstrated that EVL has a lower complication rate, less recurrent bleeding, and better variceal eradication than EVS. In a recent case series of EVL in children, 55% of children achieved variceal eradication with EVL after an average of four treatment sessions. Urgent shunt surgery is indicated only if two attempts at sclerotherapy fail to control active or recurrent bleeding. An alternative to shunt surgery in patients with cirrhotic portal hypertension is esophageal transection with or without devascularization.

Miscellaneous Causes of Upper Gastrointestinal Bleeding

In the first few days of life, or in breast-fed infants, *swallowed maternal blood* may be the cause of hematemesis or melena in an infant who otherwise appears healthy. Performing a guaiac test on expressed breast milk may suggest the diagnosis. An Apt-Downey test should be performed on a sample of emesis or nasogastric aspirate to definitively diagnose the condition. Blood from the aspirate is placed on filter paper and mixed with 1% NaOH. Adult hemoglobin will be reduced to form a rusty brown or yellow color. Fetal hemoglobin is resistant to denaturation and will retain a bright

pink or red color.

Dieulafoy lesion is an unusual cause of GI bleeding in which massive hemorrhage occurs from a pinpoint nonulcerated arterial lesion, usually high in the fundus of the stomach. The bleeding results from an unusually large submucosal artery that travels a tortuous course through the submucosa and may erode through a mucosal defect. Its characteristic presentation is one of recurrent, massive hematemesis, usually without any prodromal symptoms. This diagnosis is primarily made in adults, but patients as young as 20 months have been diagnosed with a Dieulafoy lesion, and most series contain a number of teenagers. Management is similar to that for any patient with a significant GI hemorrhage. Diagnosis can be made by endoscopy, during which the Dieulafoy lesion can usually be located.

Finally, swallowed foreign bodies can cause significant trauma and GI bleeding. Most swallowed foreign bodies, even those with sharp edges, will pass spontaneously and require no specific therapy. However, on occasion, a sharp foreign body may be the cause of GI bleeding (Fig. 93.3). Removal by endoscopy is indicated if significant bleeding occurs.

FIGURE 93.3. Gastric foreign body. This 6-year-old developmentally delayed patient ingested a large straight pin that caused bleeding of the gastric antrum. The arrow represents the foreign body. An opaque gastrostomy tube is also radiographically present.

LOWER GASTROINTESTINAL BLEEDING

Background

Rectal bleeding is a relatively uncommon but worrisome complaint in the ambulatory or ED setting. A recent case series of children presenting with rectal bleeding to the ED at Boston Children's Hospital indicated that rectal bleeding was involved in the chief complaint of 0.3% of all ED visits during a 1-year period. The average age of patients was approximately 5 years, with nearly half of the patients less than 1 year old. No patient in the series was judged hemodynamically unstable in the ED, nor did any patient require a blood transfusion. The most common presentation was for hematochezia (98% of patients), with 10% of patients presenting with melena (some patients presented with both complaints). Diarrhea (37% of patients), abdominal pain (43%), and constipation (22%) were the most common associated symptoms, with only 2% of patients presenting with fever. Presumptive diagnoses were made in two-thirds of patients, most of which (81%) did not change with follow-up. Potentially life-threatening disorders (intussusception and Meckel's diverticulum) were found in 4% of cases.

The cause of lower GI bleeding varies with age. Among infants less than 6 months of age, the most common diagnoses are milk-protein sensitivity (allergic colitis), anorectal fissures, and infectious gastroenteritis. Children 1 to 5 years of age are most likely to have infectious gastroenteritis, intussusception, Meckel's diverticulum, colonic polyps, and anorectal fissures. Older children typically have infectious gastroenteritis, inflammatory bowel disease (IBD), and hemorrhoids/rectal varices. The pathophysiology, clinical manifestations, and specific management indicated for the most common conditions causing lower GI bleeding in children are discussed in the following sections.

Anorectal Fissures and Hemorrhoids

Anal fissures are the most common proctologic disorder during infancy and childhood. Most occur in infants less than 1 year of age. Anal fissure may result from diarrhea, which causes perineal irritation, but it is more commonly associated with constipation. The fissure usually starts when passage of a hard stool tears the sensitive squamous lining of the anal canal. Subsequent bowel movements are associated with pain and/or bleeding. Bright red blood is seen coating the stool. The infant begins to withhold stool, leading to increasing constipation and a vicious cycle of hard stools, bleeding, and pain. Anal fissure can be seen by spreading the perineal skin to evert the anal canal. Simply spreading the buttocks to view the anal opening is not sufficient. Treatment consists of local skin care combined with stool softeners. Malt extract (Maltsupex 1 to 3 tablespoons/day) or mineral oil (1 to 3 tablespoons/day) can be given to soften the stool. Local care involves sitz baths four times a day, a perianal cleansing lotion (Balneol) after bowel movements, and an emollient protective ointment (Balmex) after each bowel movement.

Small varicosities of the external hemorrhoidal plexus (i.e., hemorrhoids) may occur in the healing process associated with anal fissure. They rarely cause pain or bleeding. Therapy is directed at treatment of the anal fissure. The presence of external hemorrhoids does not imply associated internal hemorrhoids. The latter may develop in response to portal hypertension and may be a cause of painless rectal bleeding.

All patients with perianal excoriation, multiple anal fissures, recurrent anal fissure, or fissure resistant to conservative management should have perianal cultures for b-hemolytic streptococcus. If this organism is recovered, the patient

should receive a 7-day course of oral penicillin.

Polyps

There are two major types of polyps that may be diagnosed in infancy or childhood: hamartomatous and adenomatous. Hamartomatous polyps are generally benign and are the usual type of polyp found in juvenile polyps, juvenile polyposis coli, and Peutz-Jeghers syndrome. Adenomatous polyps are potentially premalignant and are found in a number of syndromes, including familial adenomatous polyposis and Gardner's syndrome.

Juvenile polyps are the most common of the polyp syndromes in children, found in 15% of patients in one series who had colonoscopy for rectal bleeding (Fig. 93.4). More than one polyp may be found in more than 50% of cases of juvenile polyps. Most (75%) of the polyps are rectosigmoid or in the descending colon, 15% are found in the transverse colon, and 10% in the ascending colon. Autoamputation of juvenile polyps, especially in the rectum, occurs spontaneously in most cases. In juvenile polyposis coli, multiple juvenile polyps are found throughout the colon. Peutz-Jeghers syndrome is the association of mucocutaneous pigmented lesions and hamartomatous polyps. It has autosomal-dominant inheritance with a high degree of penetrance. The macular, melanin-containing pigmented lesions characteristically occur on the buccal mucosa, lips, face, arms, palms and soles, and perianal region. The polyps are typically located in the small intestine but can be found throughout the GI tract.

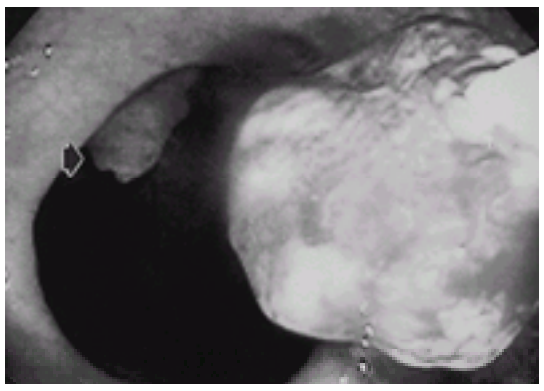

FIGURE 93.4. Juvenile polyp. The arrow demonstrates the cauterized polyp stalk.

Familial adenomatous polyposis is an autosomal-dominant inherited syndrome consisting of multiple adenomatous polyps that are generally confined to the colon but that can be found throughout the GI tract. A 6% incidence of malignant transformation of these lesions is present by age 15 years, prompting recommendations for total proctocolectomy by age 18. Gardner's syndrome is an autosomal-dominant inherited syndrome consisting of hereditary adenomatous polyps of the small and large intestine and soft tissue and bony tumors. The tumors are often epidermoid cysts, fibromas, or osteomas of the skull and mandible and are often the initial manifestation of the disease.

Pathophysiology

Juvenile polyps are proliferations of mature colonic epithelium with aggregates of lymphoid tissue and cystic dilation of normal glandular elements. This histopathology has prompted the use of other terms such as *retention, inflammatory,* or *hyperplastic polyps.* The surface epithelium is often ulcerated, with a loss of mucosal surface. Adenomatous polyps may appear grossly similar to juvenile polyps, although on microscopic examination, adenomatous polyps are distinguished by the amount of cellular atypia seen within colonic epithelial cells.

Clinical Manifestations

The most common presentation for juvenile polyps is painless rectal bleeding, often with blood streaking the outside of the stools. The peak incidence for presentation is between 4 and 5 years of age. Prolapse of the polyp through the rectum may occur. The polyp may also form the “lead point” of an intussusception. All patients with rectal bleeding should have a careful rectal examination because 30 to 40% of polyps are palpable by rectal examination.

Polyps may be part of various inherited syndromes; therefore, a complete physical examination should be performed on any patient with rectal bleeding. A careful search for pigmented lesions or soft tissue and bony tumors may aid in the diagnosis of inherited polyposis syndromes as previously described.

Management

The initial ED management of patients who have suspected polyps is aimed at assessing the amount of blood loss and arranging the appropriate diagnostic study. Blood loss is rarely life-threatening, but significant losses may be noted from chronic intermittent bleeding. All patients should have a CBC performed, and if the history of blood loss is significant, a type and crossmatch may also be indicated. Patients with palpable polyps on rectal examination should have elective flexible colonoscopy. Endoscopic removal of a polyp is safe and effective therapy even in a young child. For patients with painless hematochezia and for whom rectal examination is negative, a Meckel's diverticulum must also be considered. This possibility may prompt a decision to perform a ^{99m}Tc radionucleotide scan before colonoscopy in an effort to identify the possible location of bleeding.

Dietary Protein Sensitivity Syndromes (“Allergic Colitis”)

Dietary proteins are capable of inducing significant bowel injury and may be the cause of several different types of enterocolitis presenting throughout childhood. Each condition, by definition, is induced by a dietary protein and resolves completely after the protein is eliminated from the diet. Immunologic responses may vary from classic allergic mast cell activation to immune complex formation. The development of proctocolitis in response to cow's milk protein exposure was among the first to be described. Subsequently, a similar condition has been described in response to soybean-based formula and among exclusively breast-fed infants, presumably in response to maternal dietary protein intake.

Pathophysiology

The appearance of the rectum and colon on colonoscopic examination characteristically consists of diffuse inflammation, friability, edema, and frequent focal ulcerations. Rectal biopsies demonstrate both acute and chronic inflammatory changes and eosinophilic infiltration is often present.

Clinical Manifestations

The typical presentation of milk-protein sensitivity colitis is that of acute onset of blood-streaked, mucoid diarrheal stools in an otherwise well-appearing infant less than 6 months of age. Mean age of onset among 35 infants in one series was 4.3 + 4.1 weeks. It is unusual to present within the first week of life. Blood loss is typically limited, infants do not appear acutely dehydrated and are afebrile, and weight gain has typically been within normal limits since birth. The differential diagnosis includes anal fissures and infectious enterocolitis. External anal fissures can be ruled out by careful physical examination. Appropriate viral and bacterial cultures of stool may be indicated to rule out infectious causes.

Management

These patients are rarely hemodynamically unstable or seriously ill; therefore, initial ED management is focused on making a presumptive diagnosis based on initial laboratory testing, initiation of appropriate dietary therapy, and arranging adequate follow-up with the patient's primary care physician or a pediatric gastroenterologist. Initial laboratory testing should consist of a CBC with white blood cell (WBC) differential, assessing the hemoglobin as well as assessing for leukocytosis and eosinophilia. Patients with histologically proven milk-protein sensitivity colitis have higher mean peripheral eosinophil counts compared with age-appropriate normal values. However, in the individual patient, a higher-than-normal eosinophil count is actually an insensitive marker (sensitivity = 10%) for histologically proven colitis. In addition, a serum albumin level should be obtained because hypoalbuminemia has been demonstrated to have a sensitivity of approximately 80% for histologic colitis. Examination of stool for blood, fecal leukocytes, and routine bacterial culture should be performed on all infants. Infants who have milk-protein sensitivity colitis will characteristically have leukocytes seen on fecal smear, although eosinophils may not be present in the stool.

Treatment consists of elimination of the offending protein from the infant's diet. The diagnosis is typically confirmed by the rapid resolution of symptoms within 72 hours of the dietary change. Infants receiving cow's milk–based or soy protein formulas should be changed to a formula containing casein hydrolysate as the protein source. (Nutramigen, Pregestimil, and Alimentum are currently available in the United States.) Gross symptoms of allergic colitis respond within a few days to elimination diet therapy, although guaiac-positive stools may persist for several weeks. In exclusively breast-fed infants, elimination of the offending protein from the mother's diet also leads to clinical improvement, and breast-feeding can usually be continued. Persistent evidence of gross bleeding for 5 to 7 days following formula change is indication for flexible proctosigmoidoscopy. Most infants who come to endoscopy are found to have nodular lymphoid hyperplasia. Infants who do respond to dietary elimination should be rechallenged with the original formula in 4 to 6 weeks. Parents should be counseled that symptoms of allergy may change with increasing age such that a positive challenge may evoke vomiting, diarrhea, or GI signs of allergy rather than recurrent rectal bleeding.

Infectious Enterocolitis

Infectious causes of GI bleeding are predominantly a result of bacterial pathogens, including *Campylobacter,* pathogenic *Escherichia coli, Salmonella,* and *Shigella.* Less commonly, infection with *Giardia* or rotavirus is associated with heme-positive stools. A detailed discussion of the pathophysiology, clinical manifestations, and management of bacterial gastroenteritis can be found in Chapter 84.

Pseudomembranous colitis is a form of inflammatory colitis characterized by the pathologic presence of pseudomembranes consisting of mucin, fibrin, necrotic cells, and polymorphonuclear leukocytes. The entity develops as a result of colonic colonization and toxin production by the Gram-positive obligate anaerobe *Clostridium difficile,* in most cases after normal bowel microflora have been altered by antibiotic therapy. All classes of antibiotics have been associated with pseudomembranous colitis. Patients usually present with profuse diarrhea, tenesmus, and crampy abdominal pain, usually beginning during the first week of antibiotic therapy. Frank hematochezia is rare. The diagnosis and management of pseudomembranous colitis is further discussed in Chapter 84.

Miscellaneous Causes of Lower Gastrointestinal Bleeding

Henoch-Schönlein purpura (HSP) (see Chapter 86) is a systemic vasculitis that may cause edema and hemorrhage in the intestinal wall. Peak age of onset is between 3 and 7 years and the male:female ratio is 2:1. The presentation consists of the onset of a purpuric rash, typically confined to the buttocks and lower extremities, followed by arthralgias, angioedema, and diffuse abdominal pain. GI symptoms may precede the usual cutaneous symptoms and include abdominal pain (60 to 70%), occult bleeding (50%), gross bleeding (30%), massive hemorrhage (5 to 10%), and intussusception (3%). In a recent series, thickening of the duodenal wall was noted by ultrasonography in 82% of children who had HSP, with multiple hemorrhagic duodenal erosions noted by endoscopy in two patients. All children with

suspected HSP and GI symptoms should have a stool guaiac test performed, as well as a urinalysis to monitor for the onset of renal involvement (nephritis). Children with HSP limited to involvement of the skin and joints can often be managed as outpatients. However, severe abdominal pain or GI hemorrhage are indications for admission.

Hemolytic uremic syndrome (HUS) (see Chapter 86) is a disorder characterized by the triad of acute microangiopathic hemolytic anemia, thrombocytopenia, and oliguric renal failure. The disease is heralded by a prodrome of intestinal symptoms ranging from diarrhea (in 100% of patients) to hemorrhagic colitis (80%). Fever (20 to 30%), vomiting (75 to 80%), and abdominal pain (60%) are also commonly seen. Acute infectious gastroenteritis or colitis secondary to infection with *E. coli* O157:H7 is now considered the most important initial causative event in both sporadic and epidemic cases of HUS.

All children with HUS require admission to the hospital. Laboratory studies should be obtained, including a CBC, platelet count, PT, PTT, electrolytes, blood urea nitrogen (BUN), and creatinine. Intravenous access needs to be secured immediately for the correction of dehydration and the administration of blood products. As with HSP, the GI manifestations of HUS resolve, usually without sequelae or the need for antibiotic treatment of the initial intestinal infection.

GI *vascular malformations,* including hemangiomas, angiodysplasia, and arteriovenous malformations (AVMs), are rare causes of GI bleeding in children and are often seen as part of congenital syndromes. GI hemangiomas may be part of the Klippel-Trenaunay-Weber syndrome, which consists of a capillary or large vessel hemangioma on an extremity with hypertrophy of that limb. Diffuse visceral hemangiomatosis is rare, often fatal, and is always associated with cutaneous vascular lesions. GI hemangiomatosis should be suspected in any child with unexplained anemia and a syndrome of cutaneous hemangiomata.

Intestinal AVMs are rare in the pediatric age group, may occur both as solitary as well as multiple AVMs, and are typically part of a congenital syndrome (e.g., Osler-Weber-Rendu disease). Many GI vascular malformations, particularly cavernous hemangiomas and AVMs, can be detected using computed tomographic scans with intravenous contrast. Intestinal angiography or tagged red blood cell scans are often used to identify the source of bleeding during an acute hemorrhage. ED management of patients with GI bleeding from vascular malformations is the same as for any patient with potentially significant blood loss. After initial stabilization, referral to an appropriate subspecialist for diagnosis and definitive treatment is warranted.

INFLAMMATORY BOWEL DISEASE

Background

The term *inflammatory bowel disease* (IBD) is used to designate two chronic intestinal disorders of unknown origin: 1) ulcerative colitis, characterized by inflammation and ulceration confined to the colonic mucosa; and 2) Crohn's disease, manifested by transmural inflammation and frequent granulomas that may affect any segment of the GI tract. Approximately 25 to 30% of patients who have Crohn's disease and 20% of those who have ulcerative colitis present before age 20 years, most between the ages of 10 and 16 years, making these diagnoses relatively common in the pediatric age group. Many clinical features are common to both disorders, including diarrhea, GI blood and protein loss, abdominal pain, fever, anemia, weight loss, and growth failure. Extraintestinal manifestations involving the joints (arthritis), skin (erythema nodosum), eyes (uveitis), and liver (chronic hepatitis and sclerosing cholangitis) are seen with both disorders, although they are generally more common with Crohn's disease.

Ulcerative colitis invariably involves the rectum and extends proximally without skip areas (Fig. 93.5). In contrast, Crohn's disease has discontinuous, patchy involvement of the GI tract. The anatomic distribution of Crohn's disease in children is similar to that in adults; 40% of children have small bowel involvement, more than 50% have involvement of the ileum and colon, and about 10% have involvement of the colon alone (Fig. 93.6). Oral, esophageal, and gastric involvement is uncommon in children. The onset of both ulcerative colitis and Crohn's disease is usually insidious, consisting of growth failure, weight loss, diarrhea, and occult rectal bleeding, but may be more dramatic and extensive.

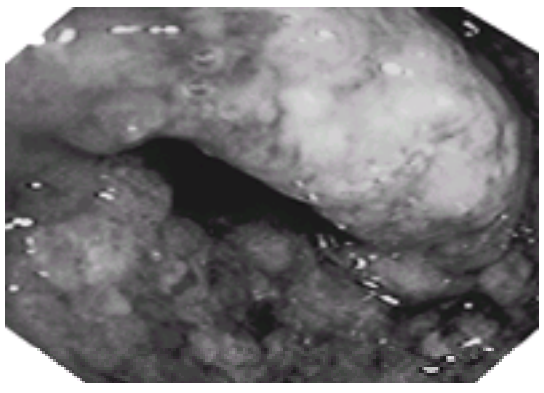

FIGURE 93.5. Severe ulcerative colitis. The mucosa appears granular, nodular, edematous and is actively bleeding.

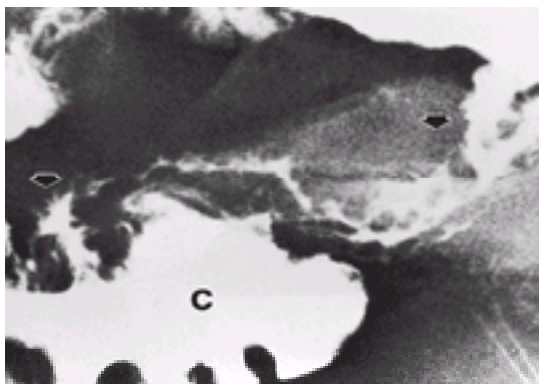

FIGURE 93.6. Crohn's disease of the terminal ileum demonstrated by severe narrowing of the terminal ileum (as shown between the two arrows). The cecum is represented by the “C.”

Pathophysiology

The cause of growth failure in patients with IBD is multifactorial, but inadequate nutrient intake is most likely the final common pathway. Growth failure is twice as likely in children who have Crohn's disease as it is in those who have ulcerative colitis. Malabsorption, especially with small bowel involvement of the disease, may lead to reduced assimilation of fats, vitamins, and minerals. Hematochezia, protein-losing enteropathy, and increased fecal losses of cellular constituents result from chronic inflammation and damage to the intestinal mucosa. The cause of diarrhea is also multifactorial, resulting from extensive mucosal dysfunction, bile acid malabsorption in terminal ileal disease, bacterial overgrowth secondary to strictures and disordered motility, and protein exudation from inflamed surfaces. Extraintestinal manifestations of the disease are often partially the result of a breakdown in the normal barrier and immunoregulatory functions of the GI tract as a result of chronic inflammation. This reaction enables bacterial products and inflammatory mediators (e.g., cytokines) to enter the circulation and subsequently to be deposited in various sites such as the eyes, skin, and joints, leading to localized inflammatory responses.

Clinical Manifestations

Clinical manifestations of IBD can be varied and related to either GI inflammation or the development of either GI tract or extraintestinal complications. Severe abdominal pain is among the most common complaints prompting an ED visit by the patient with IBD. Abdominal pain and diarrhea with or without occult blood are the most common symptoms at presentation. The pain is often colicky and, in Crohn's disease, may localize to the right lower quadrant or periumbilical area, prompting a consideration of acute appendicitis in the differential diagnosis. The abdominal examination may elicit guarding and rebound tenderness. Frank rectal bleeding occurs in fewer than 25% of all cases but is more common in ulcerative colitis. Perianal disease, including fissures, skin tags, fistulae, and abscesses, occurs in 15% of children with Crohn's disease. Perianal disease may precede the appearance of the intestinal manifestations of Crohn's disease by several years.

A low-grade fever and mild leukocytosis commonly occur. Approximately 10% of children with ulcerative colitis and a lesser percentage of those with Crohn's disease present with a fulminant onset of fever, abdominal cramps, and severe diarrhea with blood, mucus, and pus in the stools. A fulminant episode may also occur in the patient who has a known disease. There may be associated anemia and dehydration. IBD occasionally causes massive lower GI bleeding. Rarely, Crohn's disease causes complete intestinal obstruction. The patient always gives a history of antecedent abdominal pain, diarrhea, and weight loss. The presence of abdominal distention, accompanied by diminished or absent bowel sounds, should raise the suspicion of actual or impending perforation, even in the absence of severe pain. Perforation may occur after even minor abdominal trauma and must be ruled out when patients with known IBD complain of abdominal pain after trauma.

The development of massive colonic distension is a rare complication of both ulcerative colitis and Crohn's disease. Toxic megacolon represents a life-threatening emergency that has a reported mortality rate as high as 25%. Approximately 40% of the cases occur with the first attack of IBD; another 40% are seen in patients receiving high-dose steroid therapy for fulminant colitis. Toxic megacolon almost always involves the transverse colon. The pathophysiology is believed to be an extension of the inflammatory process through all layers of the bowel wall with resulting microperforation, localized ileus, and loss of colonic tone. The result is imminent major perforation, peritonitis, and overwhelming sepsis. Antecedent barium enema, opiates, or anticholinergics may all precipitate toxic megacolon. Clinical features include 1) a rapidly worsening clinical course usually associated with fever, malaise, and even lethargy; 2) abdominal distension and tenderness usually developing over a few hours or days; 3) a temperature of 38.5°C (101.3°>F) or higher and a neutrophilic leukocytosis; and 4) an abdominal radiograph showing distension of the transverse colon of more than 5 to 7 cm. The differential diagnosis of acute fulminant colitis includes acute bacterial enteritis, amebic dysentery, ischemic bowel disease, and radiation colitis.

Other potential clinical manifestations of IBD related to extraintestinal complications include thrombosis of cerebral, retinal, or peripheral vessels that may lead to coma, seizures, or focal visual or motor deficits; renal calculi leading to hematuria; and pancreatitis.

Management

The initial ED management of IBD is determined primarily by whether the patient is known to have been previously diagnosed with ulcerative colitis or Crohn's disease and by an assessment of the severity of GI symptoms and systemic toxicity. Several clinical classification systems are used, but in general, mild disease is associated with less than six

stools per day and an absence of systemic signs such as fever and severe anemia. Moderate disease is characterized by more than six stools per day, fever (higher than 38°C [100.4°F]), hypoalbuminemia (serum protein less than 3.2 g/dL), and anemia (hemoglobin concentration less than 10 g/dL). Severe disease is indicated by more than eight stools per day, marked abdominal cramping and tenderness, high fever, significant anemia (hemoglobin concentration less than 8 g/dL), leukocytosis (WBC count greater than 15,000), and occasionally, toxic megacolon.

Initial blood studies most commonly needed to evaluate patients who have known or suspected IBD include a CBC, serum electrolytes, BUN, serum albumin and total protein, transaminases (alanine aminotransferase [ALT] and aspartate aminotransferase [AST]), and depending on the amount of suspected blood loss, a blood type and crossmatch. The erythrocyte sedimentation rate can be a useful marker of inflammation; it is elevated in up to 90% of patients with Crohn's disease and in more than 50% of those with ulcerative colitis. The diagnostic yield of plain supine and upright or decubitus abdominal radiographs is relatively low (10% or less) in terms of positive findings of clinical relevance. Nevertheless, plain films can be useful in establishing the diagnosis of toxic megacolon, bowel obstruction, or perforation and should be strongly considered in the initial management of any patient with known or suspected IBD and who presents to the ED with abdominal pain or tenderness.

Stool examination for occult blood and fecal leukocytes may indicate the presence of active inflammation. For patients who have not been previously diagnosed with IBD, as well as during flare-ups in patients with a known diagnosis, stool should be obtained for culture to rule out infectious colitis, which may often either mimic IBD or complicate a known case. Noninfectious causes of rectal bleeding, including polyps, Meckel's diverticulum, HSP, and HUS, as discussed further in this and other chapters (see Chapter 86 and Chapter 118), may also be considered in some instances, with appropriate diagnostic evaluation tailored accordingly.

Patients with known or previously undiagnosed IBD, who have mild manifestations of disease, and whose initial laboratory and radiographic studies do not reveal significant abnormality can be discharged from the ED after arranging follow-up with an appropriate specialist (pediatric or general gastroenterologist). Further diagnostic studies such as sigmoidoscopy, colonoscopy, or air-contrast barium enema, as well as the institution of medical management with corticosteroids and/or sulfasalazine, can be arranged on an outpatient basis.

The goal of initial management of patients with moderately severe disease is supportive, and intravenous hydration with crystalloid solutions is often necessary to correct acute dehydration. Normal saline may be given as a 20 mL/kg bolus infusion and repeated as necessary to achieve hemodynamic stability. An infusion of a dextrose-containing electrolyte solution may then be initiated based on the initial serum electrolytes. When severe abdominal pain occurs in a patient who is not known to have IBD, surgical consultation is indicated if diagnoses such as acute appendicitis or bowel obstruction are possibilities. Hospitalization of patients with moderately severe disease is often indicated to initiate or modify specific therapy such as systemic corticosteroids or immunosuppressive agents such as azathioprine or 6-mercaptopurine. In addition, improved nutritional intake, either via enteral or parenteral means, is often necessary.

All patients with acute fulminant colitis should be admitted to the hospital. Oral intake should be discontinued and an intravenous infusion begun with normal saline until electrolyte and BUN levels are known. Opiate or anticholinergic drugs should be avoided because they may precipitate toxic megacolon. If toxic megacolon is suspected, arrangements should be made for admission to an intensive care unit. The patient should discontinue all antidiarrheal and anticholinergic medicines. The first priority in the management of children with toxic megacolon is the treatment of intravascular dehydration and shock. Intensive intravenous therapy with normal saline, albumin, or blood must be sufficient to correct hypotension and to ensure adequate urine flow. A nasogastric tube, or preferably a Miller-Abbott tube for small bowel decompression, should be placed. Patients should be started on broad-spectrum antibiotics such as ampicillin (200 mg/kg per day), gentamicin (5 to 7.5 mg/kg per day), and clindamycin (40 mg/kg per day) in combination. Suitable alternative therapies include either ampicillin/sulbactam or cefoxitin in combination with gentamicin.

Management of significant GI bleeding should be performed as described earlier in this chapter. Emergency management of suspected intestinal obstruction includes gastric decompression with nasogastric drainage and intravenous rehydration, initially with normal saline. Patients with fulminant colitis, suspected toxic megacolon, significant GI bleeding, or suspected intestinal obstruction should all receive prompt surgical consultation as part of their initial ED evaluation.

PEPTIC ULCER DISEASE

Background

The term *peptic ulcer disease* describes a group of disorders, consisting of primary and secondary gastric and duodenal ulcers, as well as nodular gastritis, rather than a single disease. With increasing use of endoscopy in children, peptic ulcer disease is a more commonly recognized disorder, although it is still far less common than in adults. Good incidence data in children are generally lacking, although several studies have suggested that large pediatric referral centers diagnose approximately 5 new cases per year or 1 case per 2500 hospital admissions. Primary ulcers have traditionally been defined as those that have no known underlying cause. In contrast, secondary ulcers are those that result from a known ulcerogenic event, such as stress, burns, or the use of NSAIDs.

Primary duodenal ulcers are far more common than primary gastric ulcers in children and typically occur in older children and adolescents (Fig. 93.7). A family history of peptic ulcer disease is typically present in 50% or more of children with duodenal ulcers. Secondary peptic ulceration can be either gastric or duodenal and is most commonly a result of stress from critical illness or injury. Stress ulcers account for 80% of peptic disease in infancy and early childhood. These ulcers often present as medical emergencies as a result of perforation or hemorrhage.

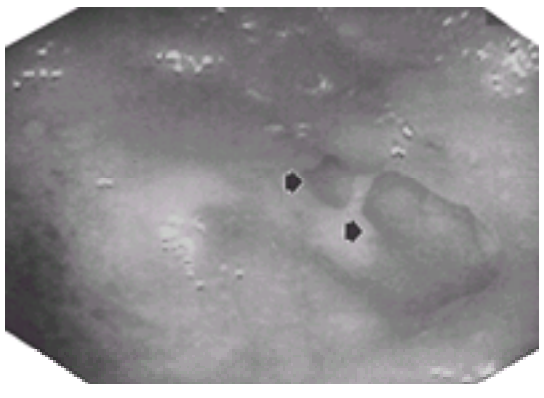

FIGURE 93.7. Duodenal bulb ulcers. The arrows show two individual duodenal nonbleeding ulcers.

Recently, the role of the bacterium *Helicobacter pylori* in the etiology of peptic ulcer disease in children has been vigorously investigated. A recent European study found the prevalence of *H. pylori* infection diagnosed by urea breath test to be 13.7% among healthy preschool-age children. Most children with *H. pylori* infections are asymptomatic. Available evidence to date shows a strong association between *H. pylori* infection and antral gastritis and duodenal ulcer disease in children. However, little to no evidence has been presented for an association with gastric ulcer or recurrent abdominal pain in children. The specific role of *H. pylori* in the pathogenesis and treatment of peptic ulcer disease is discussed in the following section.

Pathophysiology

Traditional teaching regarding the pathogenesis of peptic ulcer disease can be summarized by the adage, “no acid, no ulcer.” Gastric acid is produced by parietal cells in the stomach and is controlled primarily by histamine, acetylcholine, and gastrin. The ability of H_2-receptor antagonists to suppress all modes of gastric acid secretion underscores the central regulatory role of histamine. All agents that stimulate gastric acid secretion also stimulate pepsin secretion. Pepsins are enzymes that hydrolyze proteins, as well as gastric mucus glycoproteins, in an acid pH environment. They are secreted by gastric chief cells as pepsinogens and are converted to active pepsin by gastric acidity.

H. pylori possesses a number of virulence factors that render it particularly pathogenic in the acidic gastric environment. *H. pylori* normally adheres only to gastric mucosa in vivo. It is a flagellated organism with the capacity for active motility, giving it the ability to penetrate the mucous layer overlying the gastric mucosa. It also possesses potent urease activity, converting urea, which is abundant in gastric epithelium, to ammonia and bicarbonate. This capacity has been proposed as both a survival mechanism for the organism (the bicarbonate may moderate the pH of the local environment of the organism), as well as a pathogenic mechanism (the ammonia functions as a gastric irritant). *H. pylori* invariably produces a localized inflammatory reaction that may contribute to epithelial damage either by direct toxic effect or via immunopathologic means (Fig. 93.8).

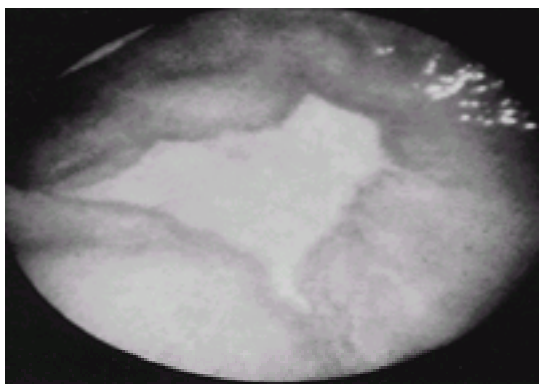

FIGURE 93.8. A large duodenal bulb ulcer secondary to *Helicobacter pylori* infection.

A simplified summary of how duodenal ulcers are formed is that they result when offensive factors, including acid secretion, decreased local blood flow, and *H. pylori* infection, overwhelm protective factors, including the thick layer of mucous gel and the secretion of bicarbonate from surface epithelial cells. The underlying mechanism of gastric ulcer formation is less well understood. Local blood flow, delayed gastric emptying, duodenal reflux, and other factors have all been suggested as important predictors of gastric ulceration. The exact interplay of gastric acid, *H. pylori,* local blood flow, and other factors in the pathogenesis of peptic ulcer disease is the subject of intensive investigation but currently remains unclear.

Clinical Manifestations

Symptoms of peptic ulcer disease vary with the patient's age. Nonspecific signs and symptoms predominate among infants and preschool-age children, with boys and girls affected equally. The older the child, the more specific (and similar to adult patterns of presentation) the signs and symptoms become. Among teenagers with peptic ulcer disease, a male predominance is seen, with boys outnumbering girls nearly 4:1. Infants with peptic ulcer disease (usually secondary to some other condition) may present either with nonspecific feeding difficulties and vomiting, or more fulminantly with upper GI bleeding or perforation. Preschool-age children often complain of poorly localized abdominal pain, vomiting, or

GI hemorrhage and either manifest as hematemesis or melena. Older children and adolescents present almost invariably with abdominal pain, which is described as waxing and waning, sharp or gnawing, and localized to the epigastrium. It may awaken the child at night or in the early hours of the morning. The presence of nocturnal pain may assist in distinguishing recurrent abdominal pain as a result of peptic ulcer disease from functional abdominal pain, which rarely occurs at night. A careful history of the pain as well as a family history of peptic ulcer disease will often suggest the diagnosis of peptic ulcer disease in the older child. History should also be obtained regarding the presence of predisposing factors such as smoking or regular use of NSAIDs.

Physical examination may reveal abdominal tenderness, poorly localized in young children and more commonly localized to the epigastrium or to the right of the midline in older children and adolescents. Stool should be tested for occult blood, and the remainder of the physical examination should be directed toward an assessment of the hemodynamic stability of the patient and, in younger children, to an identification of the underlying condition (e.g., sepsis) that may have predisposed them to the development of peptic ulcer disease. Weight loss may be noted.

Differential Diagnosis

A number of conditions may mimic the presentation of peptic ulcer disease. Abdominal pain is a common symptom during childhood, occurring in 10 to 15% of school-age children. Most children with recurrent abdominal pain have a “functional” cause. These patients typically do not have any weight loss or vomiting and report that their pain is localized to the umbilical area. Further discussion regarding the differential diagnosis of abdominal pain can be found in Chapter 50. It should be noted that the prevalence of *H. pylori* infection in children who have recurrent abdominal pain varies widely in the literature, with most patients studied selected from among those presenting to tertiary hospital gastroenterology clinics. Children with *H. pylori* infection are characteristically asymptomatic. In fact, a recent population-based study found less GI symptoms among children infected with *H. pylori* than in those without infection.

Gastritis, distal esophagitis, *Giardiasis,* and pancreatitis may all cause epigastric pain and tenderness. Biliary tract disease and a ureteropelvic junction obstruction may cause right upper quadrant tenderness. Children who have IBD, HSP, or diabetes mellitus may also present with abdominal pain, tenderness, or GI bleeding.

Diagnosis

Radiologic examination, with either single- or double-contrast (with air) barium upper GI series, is not an effective diagnostic tool to either confirm or rule out the presence of peptic ulcer disease in children. These studies often do not detect superficial ulcers, and conversely, barium trapped in a gastric or duodenal fold may falsely give the impression of an ulcer. However, radiologic examination may be used to rule out other conditions such as malrotation with volvulus or other structural anomalies of the GI tract.

Flexible fiberoptic esophagogastroduodenoscopy with mucosal biopsy is the most accurate method of diagnosing peptic ulcer disease in children. In most tertiary care referral centers, this procedure can be performed safely even on infants. It is typically not performed in the presence of active hemorrhage, although some centers are gathering experience with the use of therapeutic endoscopy to control significant bleeding. When performed, biopsy specimens should routinely be obtained from any area of endoscopic abnormality, as well as from the distal esophagus, antrum, and second part of the duodenum. No clear guidelines exist to indicate which pediatric patients should undergo endoscopy for evaluation of peptic ulcer disease. Suggested guidelines include any child with chronic abdominal pain (longer than 3 months) associated with any of the following signs and symptoms: 1) hematemesis, 2) a history of peptic ulcer disease in a first-degree relative, 3) nocturnal pain, 4) pain occurring within 1 hour of eating or relieved by eating, 5) recurrent vomiting, 6) weight loss, or 7) abdominal tenderness localized to the epigastrium (particularly in older children). In addition, endoscopy should be strongly considered in any patient presenting acutely with significant upper GI bleeding.

All patients for whom an obvious cause of secondary gastric or duodenal ulceration (e.g., stress, sepsis, burns) does not exist should undergo diagnostic evaluation for the presence of *H. pylori* infection. *H. pylori* infection can be confirmed in a variety of ways in patients with primary peptic ulcer disease. Histologic examination of biopsy specimens obtained during endoscopy should routinely be performed because *H. pylori* is readily seen using a variety of staining techniques. In centers with appropriate facilities for culturing the organism, biopsy specimens may also yield growth of the organism, which can assist in the choice of appropriate antibiotic therapy, particularly in recalcitrant infections. A variety of commercially available assays take advantage of the urease activity of the organism for diagnostic purposes. A biopsy specimen is mixed with the assay, which typically contains urea and an indicator dye that changes color when the urea is converted to ammonia by the organism. The urease activity can also be detected through the use of breath tests in which radiolabeled (^{13}C or ^{14}C) urea is ingested by the patient. Degradation of the urea by *H. pylori* results in the release of the radiolabeled carbon, which can be detected in the expired air. Finally, enzyme-linked immunosorbent assays are available for the detection of immunoglobulin G (IgG) antibodies to *H. pylori* in serum. Noninvasive tests such as serology and breath tests, are useful but should not be promoted as the sole method of diagnosing *H. pylori*–associated peptic ulcer disease in children because they cannot distinguish between incidental infection and the presence of peptic ulceration. At this time, therefore, the presence of suspected peptic ulcer disease should be confirmed by endoscopy using the guidelines for performance of endoscopy previously suggested.

Management

The focus of ED management of patients with suspected peptic ulcer disease is on the detection and stabilization of life-threatening complications such as perforation and major GI hemorrhage and on ruling out other potential serious or life-threatening conditions that may require urgent intervention. Depending on the suspected amount of blood loss, all patients with GI bleeding should have a CBC and blood type and screen obtained. If vomiting has been prominent, electrolytes, BUN, creatinine, serum amylase, and lipase should also be obtained. If physical examination findings suggest significant abdominal tenderness with guarding or rebound tenderness, plain radiographs of the abdomen should be obtained to rule out a perforation or bowel obstruction. Intravenous access should be obtained in all patients who

have significant emesis, dehydration, weight loss, or concerning abdominal examination findings. An initial bolus of normal saline (20 mL/kg) should be given and vital signs monitored frequently, with additional boluses given as needed to achieve hemodynamic stability.

A number of approaches are available for treatment of peptic ulcer disease in children. Therapies can be categorized as those that either neutralize acid, block acid secretion, are cytoprotective, or are anti-infective. Antacids are a low-cost, safe, and effective means of treating peptic ulcer disease in children and can be used in patients of any age. Side effects of antacids are related to the cation present in the preparation: magnesium-containing products cause diarrhea, whereas aluminum-containing products cause constipation. Some products are available combining the two to minimize these effects. The usual dosage for children is 0.5 mL/kg, given 1 hour after eating and before bed. Patients with food-related or nocturnal abdominal pain without associated signs of serious illness can be started on empirical therapy with antacids, assuming good follow-up with a primary care physician. Referral to a pediatric gastroenterologist can then be made if the patient fails to respond to 2 weeks of therapy.

H_2-receptor antagonists are the most common agents used to treat peptic ulcer disease. Patients with significant GI bleeding, vomiting, or abdominal tenderness should be admitted to the hospital and begun on intravenous therapy with an H_2-receptor antagonist. Currently, more physicians have pediatric experience with the use of cimetidine and ranitidine than with famotidine. All three agents are competitive H_2-receptor antagonists that reduce gastric acid output, thereby raising gastric pH. Structural differences among the three agents render famotidine the most potent and longest acting, followed by ranitidine and then cimetidine. In addition, ranitidine and famotidine generally have fewer side effects than cimetidine. The recommended oral dosage for cimetidine is 7 mg/kg given every 6 to 8 hours. The dosage of ranitidine commonly used to treat peptic ulcer disease is 1 to 2 mg/kg given every 8 hours in infants and younger children, every 12 hours in older children. Less published experience exists with the use of famotidine in pediatrics. Available data suggest a starting dosage for children older than 1 year of age of 0.5 mg/kg given intravenously every 8 to 12 hours. Patients for whom initial outpatient therapy is appropriate can be started on an H_2-receptor antagonist following an ED visit, but this therapy is best done in consultation with either the patient's primary care physician or pediatric gastroenterologist, who will establish appropriate follow-up for the patient.

Sucralfate is an aluminum salt that “coats” damaged gastric mucosa, effectively insulating it from further damage by acid, pepsin, or bile. It is typically given as a slurry and can be used with H_2-receptor antagonists, provided the drugs are given at least 1 hour apart. The usual adult dosage is 1 g four times a day; this can be titrated down for pediatric patients, although firm dosage guidelines for pediatric use are currently unavailable.

Results of a national consensus conference on *H. pylori* in peptic ulcer disease recommend that ulcer patients with *H. pylori* infection receive antimicrobial treatment as well as antisecretory drugs, both at first presentation as well as for recurrent disease. Eradication of *H. pylori* infection has been shown to reduce the recurrence of primary duodenal ulcers in children. Most children with *H. pylori* infection are asymptomatic, and no convincing evidence that *H. pylori* causes symptoms in the absence of ulceration has been presented; therefore, antimicrobial therapy is currently not recommended for children without ulcers or gastritis who harbor the organism. Several antimicrobial agents, either alone or in combination, have been studied. Although optimal treatment guidelines have not been established for children, several studies have demonstrated that omeprazole in combination with clarithromycin and amoxicillin or metronidazole is an effective regimen for clearance of the organism in those infected. Optimal length of therapy has also not been clearly established. Most authorities currently recommend a 2- to 3-week course of therapy.

REYE SYNDROME

Background

Reye syndrome is a distinct, reversible, clinicopathologic syndrome of unknown origin characterized by severe noninflammatory encephalopathy and fatty degeneration of the viscera. The incidence has dramatically decreased since the early 1980s, when a series of case-control studies established a link between antecedent aspirin exposure and the onset of Reye syndrome. The causality of the relationship between the subsequent decline in aspirin use and the incidence of Reye syndrome in the United States, however, remains controversial.

Pathophysiology

The pathogenesis of Reye syndrome centers around a primary mitochondrial injury in all tissues of the body. Abnormally low mitochondrial enzyme activities parallel histopathologic observations of mitochondrial degeneration in virtually every tissue studied by electron microscopy, including liver, brain, kidney, skeletal muscle, pancreas, and heart. The mitochondrial injury results in decreased activities of enzymes involved in the Krebs' cycle, gluconeogenesis, and urea biosynthesis. Most of the clinical features of Reye syndrome, including lactic acidosis, elevated fatty acids, nitrogen wasting, hyperammonemia, cellular fat accumulation, and cytotoxic cerebral edema, may be explained in the context of primary mitochondrial damage.

Clinical Manifestations

Reye syndrome affects children of all ages. No sex difference is apparent. A biphasic clinical history is remarkably constant (Fig. 93.9). First, the child has a history of a recent, usually febrile, illness that is waning or has resolved. Approximately 90% of the children have an antecedent upper respiratory infection, and 57% of cases are associated with antecedent varicella. The abrupt onset of protracted vomiting usually starts within 1 week following the prodromal illness. The vomiting is unresponsive to restriction of oral intake or to antiemetic therapy.

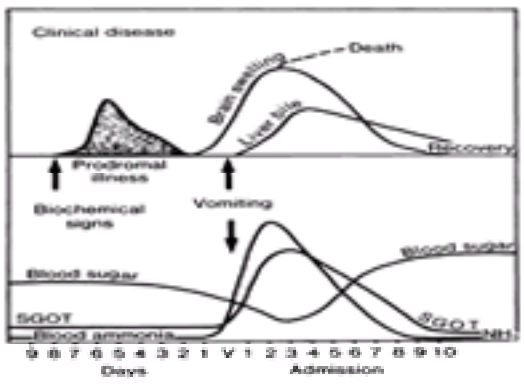

FIGURE 93.9. Clinical history in Reye syndrome.

Coincident with the onset of vomiting (or shortly thereafter), signs of encephalopathy appear. At first, encephalopathy may be manifested by unusual quietness or disinterest. However, a rapid sequential progression to irritability, combativeness, confusion, disorientation, delirium, stupor, and coma may occur. Seizures are a late sign in older children but may occur during early stages of encephalopathy in infancy (usually secondary to hypoglycemia).

In the ED, patients are usually afebrile. Tachycardia and hyperventilation commonly occur. At the initial presentation, only 50% of patients have hepatomegaly. The liver usually increases in size during the first 24 to 48 hours after the diagnosis is made. Absence of jaundice and scleral icterus is characteristic and is the major mitigating clinical sign against hepatic encephalopathy secondary to acute fulminant hepatitis. Despite evidence of encephalopathy, no focal neurological signs or signs of meningeal irritation are apparent.

The diagnosis of Reye syndrome is suggested by the clinical presentation, supported by characteristic biochemical findings, and confirmed by characteristic histologic findings on liver biopsy. The hallmark of the acute encephalopathy of Reye syndrome is the associated evidence of liver abnormality. Transaminases (ALT and AST) and blood ammonia are almost always elevated at the time of the onset of protracted vomiting. The range of transaminase elevation is highly variable and has not been shown to correlate well with severity of the disease. Ammonia levels greater than 300 µg/L have been shown to be an indicator of a poor prognosis. The PT is less than 50% of control in at least one-half the patients, although clinical bleeding is rare and evidence of disseminated intravascular coagulation is absent. The serum bilirubin may be greater than 2 mg/100 mL in 10 to 15% of patients; however, the highest reported value in an accepted case of Reye syndrome is only 3.5 mg/100 mL. The direct reacting fraction of the total bilirubin usually is greater than 15% of the total. Hypoglycemia is rare, except in children who present in stage IV coma and in infants less than 1 year old, in whom the incidence is reported to be as high as 70 to 80%. Azotemia is seen 30 to 40% of the time and ketonuria, 80%. Both reactions are believed to be secondary to starvation and dehydration from vomiting and poor oral intake. Patients most often have a mixed respiratory alkalosis and mild metabolic acidosis. The metabolic acidosis correlates with the level of ammonia elevation and reflects the degree of mitochondrial dysfunction.

Management

Once the diagnosis is suspected, immediate plans should be made to admit the child to a center with a staff and facilities to monitor intracranial pressure. A hospital without such facilities should not observe a patient in the early stages of Reye syndrome because too often the progression of the encephalopathy may proceed rapidly, resulting in increased morbidity and mortality. During the first 72 hours, Reye syndrome should always be managed in an intensive care unit.

Despite the generalized nature of the mitochondrial insult in Reye syndrome, the brain is the principal organ affected by the syndrome. Increased intracranial pressure (ICP) secondary to cerebral edema is the major factor contributing to morbidity and mortality in Reye syndrome. The effectiveness of accurate ICP monitoring via a subarachnoid bolt or intraventricular catheter is now well established. With the ability to monitor ICP, a number of different invasive therapies have been introduced in an attempt to rapidly reduce and control cerebral edema. None of these therapies, including hyperventilation and muscle paralysis using neuromuscular blocking drugs, hyperosmolar agents, high-dose barbiturates, exchange transfusions, or hypothermia, has been clearly proven to protect the brain from progressive ischemic insult.

The proper initial staging of coma is essential (Table 93.1). The survival of the patient is definitely related to the stage of the disease upon admission. The management of Reye syndrome is supportive because no specific curative therapy is currently available. Patients presenting in stage I coma should have initial blood and cerebrospinal fluid studies sent (Table 93.2), and be admitted to an intensive care unit where they should be closely monitored and receive intravenous hydration at a rate of two-thirds maintenance with a 10% dextrose solution to protect against hypoglycemia.

Stage I	Vomiting, lethargy, and sleepiness
Stage II	Disorientation, delirium, combativeness; hyperventilation, hyperreflexia, appropriate responses to noxious stimuli
Stage III	Obtunded, coma, hyperventilation; inappropriate response to noxious stimuli; decorticate posturing; preservation of pupillary, light reflexes and oculovestibular reflexes (doll's eyes)
Stage IV	Deeper coma, decerebrate rigidity, loss of oculovestibular reflexes, dilated fixed pupils, dysconjugate eye movements in response to caloric stimulation
Stage V	Seizures, absent deep tendon reflexes, respiratory reflexes, flaccid paralysis

Table 93.1. Clinical Staging of Reye Syndrome (Lovejoy)

I. Abnormal Studies	F. Ketonuria
A. Evaluation of SGOT, SGPT (at least 2 times normal)	G. Hypoglycemia
B. Elevation of blood ammonia (at least 1.5 times control)	H. Decreased serum bicarbonate
C. Prolongation of prothrombin time	I. Decreased arterial Pco_2
D. Hyperaminoacidemia (particularly glutamine, alanine, lysine)	J. Bilirubin <3.0 mg/100 mL
E. Elevated blood urea nitrogen	II. Normal Studies
	A. Spinal fluid cell count, protein, Gram stain
	B. Platelet count and blood smear
	C. Drug toxic screen
	D. Amylase

Table 93.2. Biochemical Evaluation of Reye Syndrome

In addition to these supportive interventions, stage II patients with blood ammonia less than 300 µg/L should receive lactulose syrup (0.67 g/mL) 0.20.4 g/kg per dose by nasogastric tube every 6 hours to reduce blood ammonia. In addition, mannitol (20% solution) 1 g/kg intravenously over 30 minutes should be given every 6 hours. Mannitol is a hyperosmolar agent that dehydrates the brain by withdrawing fluid from the tissues. Dexamethasone may be used at a loading dose of 0.2 mg/kg intravenously, followed by 0.1 mg/kg every 6 hours. The site of action of steroids on brain edema is still unknown.

For stage II coma with blood ammonia greater than 300 µg/L, and stage III, stage IV, and stage V coma, treatment includes elective intubation and hyperventilation.

ACUTE BILIARY TRACT DISEASE

Background

Acute biliary disease occurs occasionally in children (more often in adolescents) and is associated with a wide spectrum of clinical manifestations. Acute cholecystitis is typically a complication of cholelithiasis, which is primarily associated with hemolytic anemias (pigment stones), such as sickle cell disease and hereditary spherocytosis. Adolescent girls develop cholecystitis more often than boys (cholesterol stones). Gallstones may be asymptomatic and their prevalence increases with age. Acalculous cholecystitis, or acute inflammation of the gallbladder in the absence of gallstones, is actually more common than cholelithiasis in children and has been associated with bacterial enteric infections (typhoid, shigellosis, *E. coli,* scarlet fever, pneumonia, Kawasaki disease, leptospirosis, hepatitis, polyarteritis nodosa, and parasitic infections [ascaris and *Giardia*]). Acute cholangitis resulting from an ascending biliary infection or obstruction is seen primarily in the pediatric patient who has had surgical correction of congenital biliary tract obstruction (biliary atresia, choledochal cyst). Finally, hydrops of the gallbladder, causing jaundice and a right upper quadrant mass effect with pain, is a complication of Kawasaki disease.

Pathophysiology

Biliary colic results from acute transient obstruction of the cystic duct or common bile duct by gallstone(s). Cholecystitis is an aseptic inflammatory process that develops as a reaction to chemical injury triggered by obstruction to the cystic duct by a gallstone. This inflammation is mediated by 1) lysolecithin, which is formed from biliary lecithin by refluxed pancreatic enzyme phospholipase A; 2) refluxed proteolytic pancreatic enzymes; and 3) unconjugated bile salts. The cause of acalculous cholecystitis is unknown. The condition is commonly associated with gallbladder distension, called acute hydrops of the gallbladder. In infectious syndromes, inflammation of the cystic duct and/or enlargement of mesenteric lymph nodes may result in obstruction to bile flow. In vasculitis syndromes, such as mucocutaneous lymph node syndrome (Kawasaki disease) or polyarteritis nodosa, there may be a reactive serositis or vasculitis with increased mucus secretion by the gallbladder that, when coupled with factors that contribute to bile stasis such as fever, prolonged fasting, ileus, or dehydration, may result in gallbladder distension that in turn may kink the cystic duct. Cholangitis results from secondary bacterial infection by enteric organisms in the face of biliary tract obstruction or after surgical manipulation of the biliary tract. Acute cholangitis may be mild and superficial, producing only short-lived symptoms, or it may be severe, causing suppurative cholangitis with septic shock and formation of hepatic abscesses.

Clinical Manifestations

The pain of biliary colic is acute in onset, often follows a meal, and is usually localized to the epigastrium or right upper quadrant. Some children may localize the pain to the periumbilical area. Characteristically, the pain increases to a plateau of intensity over 5 to 20 minutes, typically after meals, and persists for a variable duration, usually less than 4 hours (although less than 1 hour in 50% of patients). In contrast to the colicky pain of intestinal or ureteral origin, biliary colic does not worsen in relatively short cyclic paroxysms or bursts but instead is characterized by its sustained, intense quality. Unlike pancreatitis, the patient tends to move about restlessly and the pain is not improved by changes in position. In addition, referred pain is common, particularly to the dorsal lumbar back near the tip of the right scapula. Nausea and vomiting are commonly associated with biliary colic but are not severe and protracted as seen with pancreatitis. Mild jaundice occurs in 25% of patients, but the serum bilirubin rarely exceeds 4 mg/dL. An attack of acute

cholecystitis begins with biliary colic, which increases progressively in severity or duration. Pain lasting longer than 4 hours suggests cholecystitis. As the inflammation worsens, the pain changes character, becoming more generalized in the upper abdomen and increased by deep respiration and jarring motions. The temperature is usually mildly elevated, ranging from 37.5° to 38.5°C (99.5° to 101.3°F).

In contrast, acute cholangitis should be suspected in the patient who has right upper quadrant abdominal pain, shaking chills, and spiking fever (temperature higher than 39°C [102.2°F]) with jaundice (Charcot's triad). These patients usually have a history of abdominal surgery. The danger of this disorder is that overwhelming sepsis can develop rapidly. Listlessness and shock are characteristic of advanced or severe cholangitis and usually reflect Gram-negative septicemia. Cholangitis can evolve rapidly before development of significant jaundice. Clinically apparent jaundice may be absent even in postsurgical biliary atresia patients. Hydrops of the gallbladder is associated with a palpable right upper quadrant mass and pain. Fever and jaundice generally do not occur.

In addition to scleral icterus, nonspecific physical findings that suggest gallbladder disease include right upper quadrant guarding; Murphy's sign (production of pain by deep inspiration or cough when the physician's fingers are depressing the abdomen below the right costal margin in the midclavicular line and abrupt cessation of inspiration because of pain); and production of pain or tenderness by a light blow applied with the ulnar surface of the hand to the subcostal area. In about one-third of patients with cholecystitis, the gallbladder is palpable as a sausage-shaped mass lateral to the midclavicular line. A rigid abdomen or rebound tenderness suggests local perforation or gangrene of the gallbladder.

Laboratory tests are typically nonspecific. A CBC and blood smear may show evidence of hemolysis. The leukocyte count averages 12,000 to 15,000/mm^3 with a neutrophilic leukocytosis. Leukocyte counts greater than 15,000 ^{3} suggest cholangitis. The serum bilirubin may be elevated but rarely exceeds 4 mg/dL. Higher values are more compatible with either complete common duct obstruction or cholangitis. Serum transaminases, ALT and AST, and alkaline phosphatase may be mildly elevated but are often normal. Marked elevation of transaminases may occur with acute, complete common duct obstruction. Serum amylase may be mildly elevated without other evidence of pancreatitis. Abdominal flat and upright radiographs may show right upper quadrant calcification of gallstones, particularly in patients with hemolytic anemia (pigment stones), or a right upper quadrant mass. Abdominal radiographs are particularly important to rule out perforation. The erythrocyte sedimentation rate is often elevated in children with cholangitis, and organisms may be recovered by blood culture.

Abdominal ultrasound is the most commonly used test to confirm gallbladder disease. This test is noninvasive, easily performed, and provides information on the surrounding organs such as the liver, pancreas, and kidneys. Ultrasound can determine the presence of most gallstones, dilated bile ducts, a thickened gallbladder wall or hydropic gallbladder, sludge, and hepatic abscesses. Other radiographic tests, such as cholecystograph or radionuclide testing, are not typically used in the emergency setting.

Other conditions to be considered in the differential diagnosis of biliary tract disease include perforated peptic ulcer, pneumonia, intercostal neuritis, pancreatitis, hepatitis, and hepatic and abdominal sickle cell crisis. Therefore, evaluation should also include stool guaiac, chest radiograph, amylase:creatinine ratio, and a peripheral blood smear.

Management

All patients with suspected acute biliary tract disease and acute symptoms should be admitted to the hospital. The exception is patients with biliary colic that has resolved spontaneously, in which case an urgent outpatient evaluation by ultrasound can be pursued. Conditions associated with acalculous cholecystitis should be evaluated and treated if identified. General ED management includes discontinuation of oral intake, support with intravenous fluids, and surgical consultation. Cholecystitis and cholangitis associated with gallstones are general indications for surgery. The patient should be made NPO (nothing by mouth) and given intravenous fluids, pain medication, and antibiotics, if cholangitis is considered. Antibiotic coverage should include Gram-negative organisms as well as enterococcus. Ampicillin (200 mg/kg per dose) and gentamicin (5 to 7.5 mg/kg per day) provide good coverage; ampicillin and sulbactam (ampicillin 200 mg/kg per day) can also be used. Narcotics are useful to alleviate the pain and to reduce gallbladder mucosal secretion; however, pain medication should be withheld until a tentative decision regarding early surgery is reached. When given, meperidine 1 to 2 mg/kg per dose is the treatment of choice.

In all patients with suspected cholangitis, blood cultures should be drawn before antibiotics are administered. When possible, antibiotics should be withheld pending a liver biopsy for definitive culture. However, the exception is the clinically septic child in whom antibiotic coverage should be immediately instituted with ampicillin (200 mg/kg per day) or a cephalosporin, such as cefazolin (100 mg/kg per day), and gentamicin (5 to 7.5 mg/kg per day). In these cases, a liver biopsy performed after the institution of antibiotics may still show histologic evidence of cholangitis.

ACUTE PANCREATITIS

Background

Although uncommon, the diagnosis of pancreatitis is often overlooked because no specific pathognomonic symptoms are associated with the condition. Pancreatitis should be considered in any child with acute or chronic epigastric abdominal pain and vomiting, ascites of obscure origin, and following upper abdominal trauma. Table 93.3 lists the causes of pancreatitis. In 30% of cases, the precipitating factor is unknown. Approximately 50% of cases are associated with an infectious agent or blunt trauma. Mumps pancreatitis is seldom severe and rarely occurs in children less than 5 years old; clinical mumps is present in only 50 to 60% of cases. Most blunt injuries to the pancreas are the result of automobile crashes or falls from bicycles; however, because the pancreas is a fixed retroperitoneal structure, mild trauma from small pointed objects, such as sticks, handlebars, or fence posts, may transmit injury directly to the organ.

I	Trauma: blunt, penetrating, surgical
II	Infectious: mumps, coxsackievirus B, hemolytic streptococcus, salmonella, hepatitis A and B
III	Obstructive: cholelithiasis, ascaris, congenital duodenal stenosis, duplications, tumor, choledochal cyst
IV	Drugs: steroids, chlorothiazides, salicylazosulfapyridine, azothiaprine, alcohol, valproic acid, tetracyclines, borates, oral contraceptives
V	Systemic: systemic lupus erythematosus, periarteritis nodosa, malnutrition, peptic ulcer, uremia
VI	Endocrine: hyperparathyroidism
VII	Metabolic: hypercholesterolemia, cystic fibrosis, vitamin A and D deficiency
VIII	Hereditary
IX	Idiopathic

Table 93.3. Causes of Acute Pancreatitis in Children

Pathophysiology

Regardless of the initiating event, the pathophysiology of acute pancreatitis is probably similar. Activation of the numerous pancreatic enzymes, including proteolytic enzymes, lipase, amylase, elastase, and phospholipase A, produces autodigestion of the gland. The process may be focal or diffuse. In mild cases, there is interstitial edema and inflammatory infiltrate without significant cell necrosis. This type of pancreatitis, called acute edematous pancreatitis, is by far the most common form seen in children and is usually self-limiting and associated with complete recovery. When the autodigestive process intensifies with increased inflammation, fat necrosis, and hemorrhagic changes, the process is called necrotic or hemorrhagic pancreatitis. This type of pancreatitis is associated with a 20 to 40% mortality and significant morbidity. It is unclear why the autodigestive process is arrested in some cases and not others, but one factor may be the magnitude of the initial triggering mechanism.

The morbidity and mortality associated with pancreatitis is related to complications from the autodigestive process. Fat necrosis of neighboring tissue and saponification of calcium often result from release of pancreatic lipase. Released proteolytic enzymes may extend the inflammatory process into the retroperitoneum as well as the peritoneal cavity. Proteolytic enzymes may activate kallikrein, a potent vasoactive polypeptide that may mediate systemic vasodilation and increase vascular permeability, producing severe hypotension, shock, and renal and/or pulmonary insufficiency that may prove fatal. Secondary infection may lead to abscess formation, and walling off the autodigestive process may result in pseudocyst formation.

Clinical Manifestations

Epigastric abdominal pain is the most consistent symptom of pancreatitis and may vary from tolerable distress to severe incapacitating pain. Symptoms may be chronic and insidious, but they typically progress rapidly, building to a crescendo over several hours. The pain is usually localized to the epigastrium and may radiate to the back (left or right scapula) or the right or left upper quadrants. The pain is usually described as knifelike and boring in quality and is aggravated when the patient lies supine. Classically, the pain of pancreatitis is constant, as opposed to colicky pain, which waxes and wanes. Nausea and vomiting are the most common associated symptoms. Vomiting may be severe and protracted. Low-grade fever (temperature below 38.5°C [101.3°F]) is present in 50 to 60% of cases. In cases of severe necrotic pancreatitis, patients may complain of dizziness. Mental aberrations are common in necrotic pancreatitis; patients may act overtly psychotic or present in coma.

Early in the course of the disease, there may be a discrepancy between the severity of the patient's subjective pain and the objective physical findings. During the examination, patients are usually quiet and prefer sitting or lying on their side with knees flexed. The abdomen may be distended but is usually not rigid. There may be mild to moderate voluntary guarding in the epigastrium. A palpable epigastric mass suggests pseudocyst. Ascites is rare. Bowel sounds may be decreased or absent. Associated physical findings may include signs of parotitis, mild hepatosplenomegaly, epigastric mass, pleural effusions, and mild icterus. Although rare, rebound tenderness or a rigid abdomen are poor prognostic signs if present. A bluish discoloration around the umbilicus (Cullen's sign) or flanks (Grey Turner's sign) is also a poor prognostic sign and evidence of hemorrhagic pancreatitis. Signs of overt hemodynamic instability are rarely evident at initial presentation. It is particularly important to evaluate patients for clinical signs of hypocalcemia (Trousseau and Chvostek signs).

The clinical diagnosis is often tentative because the same constellation of symptoms (abdominal pain, vomiting, and low-grade fever) and signs (abdominal tenderness and guarding) may be mimicked by several other conditions, including penetrating peptic ulcer, gastritis, esophagitis, biliary colic, acute cholecystitis, intestinal obstruction, and appendicitis.

Currently, two easily attainable laboratory tests are used to make a diagnosis of pancreatitis: serum amylase and serum lipase. The combination of the aforementioned clinical symptoms and an elevation of the level of one or both of these enzymes strongly points to pancreatitis. In acute pancreatitis, the serum amylase increases hours after the onset of the autodigestive process and returns to normal within 3 to 5 days; elevated serum triglycerides may interfere with the assay and result in false-normal values. The degree of serum amylase elevation rarely corresponds to the severity of pancreatic inflammation. Although controversial in the past, lipase assays are now accurate and commonly used to diagnose pancreatitis. Serum lipase may remain elevated for up to 14 days after the onset of acute pancreatitis. Generally, because amylase is rapidly cleared by the kidneys, serum amylase may return to normal after several days even though pain persists. In these cases, following the serum lipase may be more beneficial. Normalization of serum amylase typically indicates resolution of disease, but occasionally hemorrhagic or necrotizing pancreatitis may develop in patients with normal amylase.

Serum amylase and lipase are not pathognomonic for pancreatitis. Many situations, including penetrating or perforated ulcer, intestinal obstruction or infarction, Crohn's disease, pneumonia, hepatitis, liver trauma, acute biliary tract disease, salpingitis, salivary adenitis, renal failure, diabetic ketoacidosis, and benign macroamylasemia, can cause an amylase elevation. Causes for an elevated serum lipase include perforated peptic ulcer and bone fracture with pulmonary fat embolism.

Radiographically, the abdominal ultrasound provides a noninvasive, direct view of the pancreas and is probably the most useful test in diagnosing pancreatitis. Ultrasound can assess pancreatic size, contour, and the presence of calcifications and pseudocyst formation. Ultrasound should be considered in all cases of suspected pancreatitis. Abdominal computed tomography and endoscopic retrograde cholangiopancreatography (ERCP) are being used more often to assess the severity of pancreatitis and pseudocyst formation and to determine possible causes of pancreatitis. However, ERCP should not be performed in the acute phase or in patients with acute pseudocyst formation or pancreatic abscess formation but should be reserved for patients with chronic, recurrent pancreatitis. Rarely, ERCP may be indicated in acute pancreatitis if an obstructing gallstone is present in the common bile duct.

Management

All patients with evidence of pancreatitis or suspected pancreatitis should be admitted to the hospital. Treatment, however, should begin in the ED. The goals of medical treatment include suppression of pancreatic secretion and relief of pain. Morbidity and mortality in pancreatitis are directly related to complications that may already be present at the time of initial presentation. Therefore, aggressive early maintenance of intravascular volume and treatment of hypocalcemia, respiratory distress, and suspected infection are mandatory.

Intravenous fluids should be immediately started, and the patient's oral intake should be discontinued. The patient should be assessed for hypotension. When the patient is judged stable, intravenous fluids should be given at 1.5 times the maintenance rate. Vital signs and urine output should be monitored frequently. Continuous nasogastric suction should be started; aspiration of gastric contents is based on the premise that prevention of delivery of gastric acid into the duodenum will diminish hormonal stimulation of the pancreas. Nasogastric suction also relieves pain and prevents development of ileus. Use of anticholinergics or cimetidine to reduce gastric secretions is controversial and is not recommended in the initial management of patients. A crucial part of management is the treatment of abdominal pain. Pain should be treated with Nubain (0.1 mg/kg per dose intravenously, maximum of 20 mg) or meperidine (1 to 2 mg/kg intravenously, maximum 100 mg). Morphine or codeine should not be used because they increase spasm at the sphincter of Oddi.

Blood studies that should be performed in the ED include amylase, lipase, CBC, electrolytes, BUN, calcium, glucose, SGOT, SGPT, bilirubin, alkaline phosphatase, triglyceride, PT, and PTT. Arterial blood gases should be obtained in patients with tachypnea. A chest radiograph should be obtained and evaluated for pleural effusion, interstitial pneumonic infiltrates, and basilar atelectasis. A flat and upright abdominal radiograph is needed to rule out perforation, ascites, and pancreatic calcifications. In severe cases or in those cases of questionable diagnosis, an abdominal ultrasound should be obtained.

In most cases, maintenance of intravascular volume and relief of pain will result in rapid resolution of symptoms. Prognostic indicators of necrotizing or hemorrhagic pancreatitis include hypocalcemia (less than 8.0 mg/dL), hyperglycemia (greater than 200 mg/dL), clinical shock, elevated hematocrit or BUN, ascites, and oxygen partial pressure less than 60 mm Hg. Such patients should be admitted to an intensive care unit, given sufficient colloid (albumin 0.25 g/kg) to maintain normal intravascular volume, and have more extensive monitoring with an arterial line and urinary catheter. A PaO_2 lower than 60 mm Hg is an indication for elective intubation. Early peritoneal dialysis should be started if rapid clinical deterioration occurs.

Antibiotics are not indicated in the initial management of pancreatitis. Pancreatic abscess should be considered if the patient's temperature is higher than 38.5°C (101.3°F). In those cases, broad-spectrum antibiotic coverage with ampicillin (200 mg/kg per day) and gentamicin (5 to 7.5 mg/kg per day) is indicated pending the results of blood cultures and diagnostic ultrasound. Emergency surgery is rarely necessary in acute pancreatitis; however, indications for surgery include active intraperitoneal bleeding, suspected abscess, biliary duct obstruction, and suspected traumatic transection. Therapeutic surgery for acute, necrotizing pancreatitis has been reported in adults, but this approach has not been accepted in pediatrics.

FULMINANT LIVER FAILURE

Background

Fulminant liver failure occurs when the vital functions of the liver fail, including the development of a coagulopathy, hypoglycemia, hyperbilirubinemia, hypoproteinemia, and encephalopathy. Liver failure can develop acutely or it may be chronically progressive. The cause of liver failure is diverse and includes infectious processes (e.g., viral hepatitis), metabolic diseases (e.g., Wilson's disease), pharmacologic agents, ischemia, and malignancy. Acute liver failure can be a life-threatening problem that causes a severe coagulopathy, hypoglycemia, and encephalopathy. Aggressive supportive medical management is required in most cases.

Pathophysiology

The pathogenesis of fulminant liver failure requires the progression of several key steps that lead to irreversible hepatocyte injury. The initiating step is the exposure of the susceptible person to the inciting agent, which leads to widespread hepatocyte injury. Hepatocyte necrosis may occur secondary to an infectious agent (viral hepatitis), a toxin (various pharmacologic substances), or a metabolic byproduct. Following hepatocyte death, the potentiation of the

responsible agent is necessary to continue the hepatic destructive process. Normally, the liver is capable of regeneration; however, the regenerative process is inhibited in patients who develop liver failure. These steps may lead to terminal hepatic failure in which the liver becomes incapable of supporting those events required for life.

Although infectious agents and toxins are responsible for most proven cases of liver failure, in most cases, no cause is determined. Common drugs and toxins that cause liver failure include acetaminophen, salicylates, solvents, valproic acid, amiodarone, isoniazid, NSAIDs, tetracycline, and chlorinated hydrocarbons. Rarely, metabolic diseases can lead to liver failure. These diseases include galactosemia, tyrosinemia, Wilson's disease, neonatal hemochromatosis, disorders of fatty acid oxidation, bile acid synthetic disorders, and hereditary fructose intolerance.

Clinical Manifestations

Many patients do not exhibit serious clinical features of acute liver failure. Typically, pediatric patients who develop acute liver failure were previously healthy and had no prior medical problems. Patients may initially complain of fatigue, nausea, vomiting, and diffuse abdominal pain. Occasionally, right upper quadrant pain may be severe. Commonly, a history of a prodromal viral illness can be elicited. The presence of jaundice usually initiates the first visit to the physician. As liver failure progresses, patients become more jaundiced and lethargic and begin to develop tremors. In a short time, they become confused or somnolent and may begin to have problems with easy bruising or bleeding.

The onset of encephalopathy occurs in conjunction with the severity and progression of liver failure. Encephalopathy is graded on a scale from I to IV. Grade I is manifested by a coherent individual who shows mild or episodic drowsiness, poor concentration, and impaired intellect. In grade II, the patient continues to be coherent and conversant but also becomes disoriented and fatigued. Agitation and aggressive behavior in conjunction with extreme drowsiness is manifested in grade III encephalopathy. Unresponsive patients who respond only to painful stimuli and who have evidence of cerebral edema are labeled as having grade IV encephalopathy. The clinical features of increased ICP include systemic hypertension, “decerebrate posturing,” hyperventilation, abnormal pupillary responses, and impairment of brainstem reflexes. Cerebral edema is associated with increased mortality and requires aggressive supportive management. Finally, bleeding esophageal and gastric varices as well as ascites may rapidly develop secondary to increased portal hypertension.

Laboratory Findings

Because it may be difficult to diagnose patients clinically, biochemical evidence may be collected that provides evidence of liver failure. The liver plays an important role in hemostasis because the liver synthesizes a number of coagulation factors. An uncorrectable coagulopathy is usually the first laboratory manifestation of liver failure. Other factors may have a shorter half-life, but the PT is the most commonly used marker of the severity of liver disease. A prolonged PT despite intravenous supplementation of vitamin K should alert the physician to impending liver failure. Other laboratory markers suggestive of liver failure include evidence of increasing cholestasis manifested by a rising serum bilirubin, hypoalbuminemia, and hypoglycemia.

It is also important to monitor serum transaminases. Falling transaminases usually indicate resolving liver disease, whereas a decrease in transaminases in association with increasing jaundice and coagulopathy indicates hepatocyte death rather than hepatocyte repair. Monitoring for hypoglycemia is extremely important because the liver is the primary organ for gluconeogenesis. Serum fibrinogen is usually decreased in patients with liver failure. In cases in which the patient has splenomegaly, thrombocytopenia and leukocytopenia may be present.

Hypoglycemia almost always accompanies acute liver failure and may complicate the signs of encephalopathy. Portal hypertension may cause bleeding from esophageal varices or ascites. Hepatorenal syndrome occurs in approximately 75% of patients who reach grade IV encephalopathy. The cause of hepatorenal syndrome is unclear; however, the result is oliguria in the presence of near normal intravascular pressures. Metabolic acidosis occurs in approximately 30% of patients who have liver failure, and the risk of sepsis is increased secondary to the patient's compromised immune function.

Management

All patients suspected of having liver failure should undergo a complete physical examination, including a thorough neurologic evaluation. Laboratory testing should include serum glucose, transaminases, total and direct bilirubin, albumin, PT, GGTP, CBC with differential, electrolytes, blood culture, and fibrinogen. Patients with hypoglycemia should be given intravenous fluids with 10% dextrose and should undergo frequent blood glucose monitoring (every 1 hour) until their blood sugar stabilizes. Metabolic acidosis should be corrected; however, correction of hyponatremia should be gradual in patients with ascites. Patients who have a coagulopathy should be given intravenous vitamin K (2.5 mg in infants; 5 mg in older children and adolescents). A repeat PT should be performed 6 to 8 hours after administration. An uncorrectable PT is suggestive of severe hepatocyte damage. The management of bleeding esophageal varices has been previously discussed in this chapter. Therapeutic management of ascites should occur only in the face of respiratory distress or renal failure; otherwise, the introduction of a diuretic (Aldactone) to achieve a slow, gradual change in ascites is all that is initially required.

Patients with encephalopathy should be frequently monitored for changes in neurologic function. In cases in which the patient has developed cerebral edema, management consists of an intensive care setting, insertion of a subdural transducer, mechanical ventilation (hyperventilation), and administration of mannitol (0.3 to 0.4 mg/kg) to maintain near normal levels of intracranial pressure.

ACUTE VIRAL HEPATITIS

Background

The existing alphabet of viral hepatitis is now up to E, with new variants awaiting discovery. Hepatitis A (HAV), the cause of “infectious” or epidemic hepatitis, is transmitted by the fecal–oral route. On a worldwide scale, fewer than 5% of cases are clinically recognized. HAV is a rare cause of fulminant hepatitis. No chronic carrier state exists. Maintenance of the virus in the human population is through person-to-person spread. Hepatitis B (HBV) is endemic in the human population. Although predominantly transmitted by the parenteral route or sexual contact, the high incidence of infection in family contacts suggests that the virus may also be spread by saliva or breast milk. The ability of HBV to produce a chronic carrier state in 5 to 10% of infected subjects allows maintenance of an infectious pool without serial transmission. Hepatitis C (HCV) accounts for about 95% of hepatitis infections in recipients of blood transfusion and 50% of cases of sporadic non-A, non-B hepatitis. Most of these patients will progress to chronic hepatitis, and about 20% develop cirrhosis. Hepatitis D (HDV) requires hepatitis B helper functions for propagation in hepatocytes, and may occur simultaneously with hepatitis B infection (coinfection), or as superinfection in chronic hepatitis B carriers. Hepatitis E is an enterically transmitted virus responsible for large epidemics of acute hepatitis in Asia, the Middle East, and parts of Africa.

Clinical Manifestations

Most childhood cases of acute hepatitis produce minimal symptoms, are anicteric, and unless suspected by palpation of tender hepatomegaly, are usually confused with a GI flulike illness. Clinical hepatitis classically consists of a 5- to 7-day prodrome of variable constitutional symptoms (low-grade fever, anorexia, nausea, vomiting, malaise, fatigue, and epigastric or right upper quadrant abdominal pain), followed by acute onset of scleral icterus, jaundice, and passage of dark urine. Pruritus and diarrhea are rare. Physical examination after the onset of jaundice may reveal tender hepatomegaly. Mild splenomegaly is present in 25 to 50% of patients. HBV patients may also present with extrahepatic signs and symptoms, such as arthralgia, arthritis, or papular acrodermatitis (on face, buttocks, and extensor surfaces of arms and legs). When the rash is associated with lymphadenopathy and fever, it is called the Gianotti-Crosti syndrome. Onset of the icteric phase of acute hepatitis most commonly is temporarily associated with improvement in the constitutional symptoms. In up to 15% of cases, severe fatigue, anorexia, nausea, and vomiting persist. The icteric period usually lasts 1 to 4 weeks. Occasionally, the jaundice is prolonged for 4 to 6 weeks with increasing pruritus at 2 to 3 weeks.

Differential Diagnosis

A number of infectious agents may mimic a viral hepatitislike illness. The most common are Epstein-Barr virus (EBV, infectious mononucleosis) and cytomegalovirus (CMV). Both agents rarely produce clinical jaundice, and high fever and diffuse adenopathy are more characteristic. Less common agents include herpes, adenovirus, coxsackievirus, rheovirus, echovirus, rubella, arbovirus, leptospirosis, toxoplasmosis, and tuberculosis.

Diagnostic Evaluation

The following laboratory tests are usually performed in all cases of suspected viral hepatitis: serum transaminases (AST and ALT), alkaline phosphatase, total and direct bilirubin, CBC, PT, electrolytes, BUN, glucose, total protein, albumin, globulin, and in patients who are older than 5 years of age, ceruloplasmin. AST and ALT are the best indicators of ongoing hepatocellular injury. Alkaline phosphatase levels are usually less than two times the upper limit of normal for age. Levels greater than three times normal should raise suspicions of EBV or CMV hepatitis or biliary tract disease. Hepatitis classically produces direct fractions of serum bilirubin in excess of 30% of total, indicating definite liver disease. Hyperbilirubinemia may be present in the absence of scleral icterus or jaundice because these signs usually cannot be appreciated until levels of total bilirubin exceed 3 to 4 mg/dL. Serum bilirubin levels peak 5 to 7 days after the onset of jaundice. The initial biochemical screen may reveal several indicators of severe hepatocellular injury, including 1) total bilirubin greater than 20 mg/dL, 2) serum transaminases that exceed 3,000 units/L, 3) WBC count greater than 25,000/mm^3, 4) elevated PT, and 5) hypoglycemia.

Serum albumin and globulin are usually normal. Decreased albumin or increased globulin should suggest an acute flare of chronic liver disease. Serum ceruloplasmin level should be drawn in all patients older than 5 years of age who have suspected hepatitis to rule out Wilson's disease. A chest radiograph may reveal cardiomegaly if any suspicion of low cardiac output states exists. Figure 93.10 and Figure 93.11 contrast the sequence of clinical, biochemical, and serologic events in typical HAV and HBV infection. The serodiagnosis of acute hepatitis is best approached by first testing for anti-HAV IgM, HB surface antigen, HB e antigen, HB serum DNA, anti-HB core Ab, anti-HCV, anti-CMV, and EBV serology. The finding of serum IgM anti-HAV is diagnostic of acute HAV infection because the antibody is present at the time of clinical symptoms. A positive HB Surface antigen suggests the diagnosis of HBV in a symptomatic patient. A positive HB e antigen or anti-HB core Ab are helpful in the rare patient who rapidly clears HB surface antigen from the serum. It is also important to note that in chronic HB surface antigen carriers who have HDV superinfection, the suppression of HBV replication may lead to a transient absence of HBV markers in the serum; unless HDV markers in the serum are sought, the diagnosis may be missed. Anti-HCV does not appear in the patient's circulation until 1 to 3 months after onset of acute illness, and in rare cases, detectable levels may not be demonstrated for up to 1 year. Thus, unless the acute presentation is actually a flare of chronic HCV, serodiagnosis will await long-term follow-up.

Management

No specific treatment is available for acute viral hepatitis. Most patients can be managed at home. No restrictions in diet or ambulation are necessary. The traditional recommendations of a low-fat, high-carbohydrate diet and bed rest are now recognized to have no effect on the symptoms or duration of the disease. Parents should be told that anorexia and fatigue are common symptoms. Small, frequent feedings may be helpful. Drugs should be strictly avoided. The key for both the patient and other household contacts is personal hygiene. Infants and children should avoid contact with the patient even after they have received immunoprophylaxis. In HAV, shedding of the virus may occur for up to 2 weeks after the onset of jaundice. Patients should be kept at home during this time. After this, they may return to school. Indications for hospitalization of a patient who has acute hepatitis include the following:

1. Dehydration secondary to anorexia and vomiting
2. Bilirubin level greater than 20 mg/dL
3. Abnormal PT
4. WBC count greater than 25,000/mm^3
5. Level of transaminases greater than 3,000 units/L

Patients who have acute hepatitis and who are hospitalized should be isolated. Follow-up studies of all patients with acute hepatitis should be performed to document biochemical resolution. Follow-up serology may also establish a specific cause in cases of apparent non-A, non-B hepatitis (fourfold increase in CMV serology, development of anti-HCV). Reevaluation of patients with HBV is especially important to ensure clearance of HB surface antigen, or to recognize the development of the HB surface antigen carrier state.

Postexposure Prophylaxis

Hepatitis A

The mean incubation period for HAV infection is about 4 weeks (range 15 to 45 days). Conventional immune serum globulin (ISG 0.02 mL/kg intramuscularly) confers passive protection against clinical HAV infection if given during the incubation period up until 6 days before the onset of symptoms. Individuals exposed during the late incubation period or early acute phase of illness should also be promptly immunized. Seventy-five percent of this group will develop detectable levels of anti-HAV IgM, suggesting passive–active immunity. Postexposure immunoprophylaxis is suggested for 1) household and close personal contacts, 2) institutionalized contacts, and 3) contacts within a daycare facility. Grade-school classroom contacts of an isolated case and routine play contacts do not require ISG. However, a second case within a class is indication for immunoprophylaxis of the rest of the class. An alternative method for determining who should receive ISG is to test high-risk contacts for anti-HAV IgG.

Hepatitis B

Prophylactic treatment to prevent infection after exposure to HBV should be considered in the following situations seen in the ED: 1) sexual exposure to the HBV surface antigen–positive patient; 2) inadvertent percutaneous or permucosal

exposure to HBV surface antigen–positive blood; and 3) household exposure of an infant less than 12 months of age to a primary caregiver who has acute HBV. Before treatment in the first two situations, testing for susceptibility is recommended if it does not delay treatment beyond 14 days after exposure. Testing for anti-HBV core Ab is the most efficient prescreening procedure. All susceptible persons should receive a single dose of hepatitis B immunoglobulin (0.06 mL/kg) intramuscularly and hepatitis B vaccine in recommended doses.

CHAPTER 94

Pediatric and Adolescent Gynecology

JAN E. PARADISE, MD

Department of Pediatrics, Boston University School of Medicine, and Boston Medical Center, Boston, Massachusetts

INTRODUCTION

Evaluation of Premenarchal Girls

Among premenarchal girls with gynecologic complaints, the most commonly encountered specific entities are vaginal infections, urethral prolapse, trauma, and suspected sexual abuse. Many other patients have nonspecific genital irritation. In assessing any child with a gynecologic complaint, the physician must be alert to the possibility that sexual abuse is the underlying problem.

The premenarchal girl should not receive a standard pelvic examination, including the use of a speculum and vaginoabdominal palpation, because such an examination is uncomfortable and unnecessary for diagnosis. An exception to this rule is the girl with vaginal bleeding caused by an injury. If an external source for the bleeding cannot be identified, speculum examination of the vaginal vault under sedation or anesthesia is warranted to allow visualization of the injury. Some major vaginal lacerations produce only mild pain or minimal bleeding. For most premenarchal girls, the history, a general physical examination including inspection of the vulva (Fig. 94.1) and visualization the vagina, and culture of a vaginal discharge, if one is present, will lead promptly to a diagnosis.

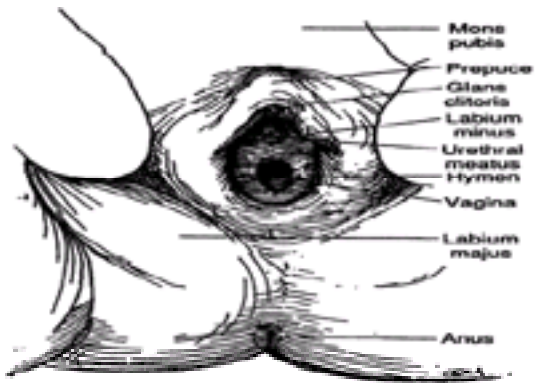

FIGURE 94.1. Anatomy of the normal female external genitalia.

Most young children will cooperate readily for initial inspection of the external genitalia either on the examining table or while held on a parent's lap. The child should be placed in the supine position with flexed hips and knees and with heels touching (Fig. 94.2). In most cases, the examiner can obtain a good view of the child's introitus by grasping the labia majora firmly and exerting gentle laterocaudal traction. For inspection of the vaginal vault, the knee–chest position is helpful. Most children more than 4 years old can cooperate for this maneuver. The child is first asked to “get up on your hands and knees like you are going to crawl.” She is then instructed to rest her head on her folded arms, facing her parent. The examiner or an assistant gently presses the child's buttocks and labia upward and outward. If the child

relaxes her abdominal muscles and back at this point, her vagina will usually fall open, permitting inspection of the vault using an otoscope as a light source (Fig. 94.2). If the child has a vaginal discharge or bleeding, she should then be returned to the supine position so that specimens for culture can be obtained, using either a soft plastic medicine dropper or a cotton-tipped swab moistened with nonbacteriostatic saline solution. A rectal examination should be performed if there is abdominal pain or a lower abdominal mass. Rectoabdominal palpation may be helpful if a hard vaginal foreign body is suspected, but nearly all vaginal foreign bodies are composed of toilet tissue and are therefore not palpable. On rectal examination, a child's cervix is normally felt as a firm, midline button of tissue, but the uterus and ovaries should not be palpable.

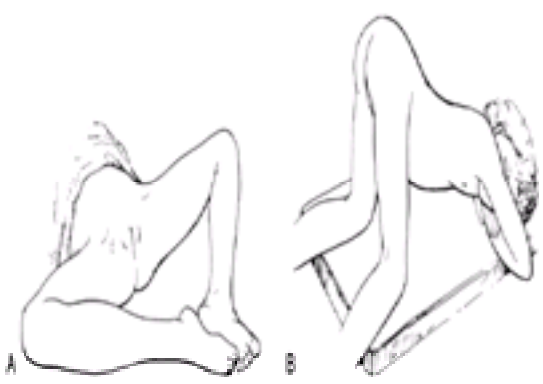

FIGURE 94.2. A. Girl in the frog-leg position for examination of the external genitalia. **B.** Girl in the knee–chest position with exaggerated lordosis and relaxed abdominal muscles. The examiner can inspect the interior of her vagina by gently separating her buttocks and labia, using an otoscope without an attached speculum for illumination.

Evaluation of Adolescent Girls

The differential diagnosis of gynecologic symptoms and signs in an adolescent girl who has experienced sexual intercourse includes a number of major entities (e.g., pregnancy, pelvic inflammatory disease [PID], tubo-ovarian abscess) that do not pertain to the teenager who is not sexually experienced. Therefore, considering the substantial proportion of American teenagers who are sexually experienced (Fig. 94.3), the emergency physician evaluating an adolescent girl must routinely inquire about sexual activity and, if the response is positive, about contraceptive use, prior sexually transmitted infections, pregnancies, and abortions. A detailed menstrual history—age at menarche, characteristics of the menstrual cycle, date of last menstrual period, presence or absence of dysmenorrhea—should be obtained from every adolescent patient.

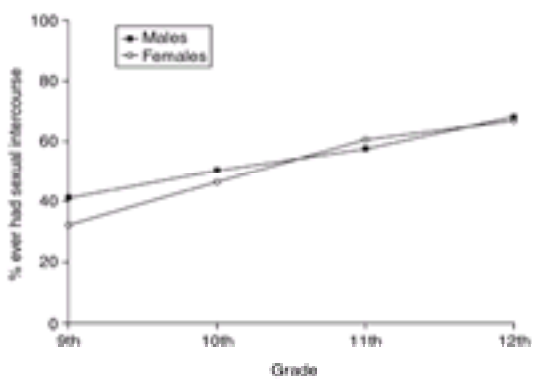

FIGURE 94.3. Percentage of U.S. high school students who have ever had sexual intercourse. (Adapted from Kann L, Warren CW, Harris WA, et al. Youth risk behavior surveillance—United States, 1995. In: CDC Surveillance Summaries, Sept 27, 1996. MMWR 1996;45[SS-4]:66.)

Obtaining a candid history of sexual activity from adolescent girls is not always a simple matter, but the emergency physician can maximize honest reporting by using some basic interviewing principles. First, the teenage girl who asks for a female physician is stating directly what will make her more comfortable. Her request should therefore be honored if it is possible to do so. Second, questions to the teenager about sexual activity (as well as other potentially sensitive subjects like contraception and substance abuse) should not be asked while a parent is present. This is accomplished by asking the parent to leave the room during the daughter's physical examination. Third, before any questions are asked, it is helpful to assure the teenager that if she wishes, her answers will be kept confidential. [1] Finally, the physician who adopts an empathetic, nonauthoritarian interviewing style is most likely to win the teenager's trust.

Most virginal adolescents with menstrual cramps, mittelschmerz, or vaginal discharge do not require full pelvic examinations because the likelihood that occult pelvic pathology will be found is small. Rectoabdominal palpation can be used to evaluate the virginal patient with undiagnosed lower abdominal pain or a mass. However, trauma and vaginal bleeding are indications for pelvic examination, even among patients who have never been sexually active.

Every sexually experienced adolescent girl who comes to the emergency department (ED) for abdominal pain or a gynecologic complaint must receive a pelvic examination because such patients have high rates of pregnancy and sexually transmitted disease (STD). Before the examination, the patient should be given a chance to empty her bladder.

If the physician is male, he should always be accompanied by a female chaperone during the examination. In the emergency setting, a chaperone may also be considered for female physicians. After the patient is situated in the lithotomy position and draped, her vulva is inspected, and a narrow speculum is inserted for visualization of her vagina and cervix. A sterile cotton-tipped swab is used to collect endocervical secretions for culture of *Neisseria gonorrhoeae.* A second endocervical specimen is obtained to test for *Chlamydia trachomatis* antigen. After a sample of vaginal discharge for microscopic examination has been taken with a third swab, the speculum is removed. If the physician suspects gonococcal infection, urethral and rectal swabs may also be taken. The endocervical specimens should be obtained before bimanual palpation is done because lubricating jelly can inhibit growth of *N. gonorrhoeae.* During the bimanual examination, the cervix is assessed for softness, patency of the os, and pain elicited by lateral cervical movement. The size and consistency of the uterus are determined, and the adnexal areas are palpated for masses and tenderness. Last, rectovaginal palpation is performed, checking again for masses and local tenderness.

The emergency physician can add an ounce of prevention to the care of the sexually active teenage girl if he or she not only provides treatment for the patient's current problem but also determines whether she has been receiving routine outpatient gynecologic care. The ED should maintain a list of local programs that provide health care to adolescents so that referral can be made easily. Many communities have specialized services for teenagers sponsored by hospitals, health departments, or private agencies. Similarly, because previously unrecognized pregnancy is a common ED diagnosis, procedures should be established to facilitate prompt referral of teenagers who need counseling, prenatal care, and therapeutic abortion to the appropriate services.

GYNECOLOGIC DISORDERS OF CHILDHOOD

Congenital Vaginal Obstruction

Background

Definition

In normal females, the vagina provides an outlet for genital secretions and menstrual blood. If the vagina is obstructed, accumulating fluid will eventually distend it, causing symptoms to develop either during infancy or after menarche. During infancy, vaginal distension with mucus secreted as a result of stimulation by maternal hormones is called hydrocolpos or mucocolpos. If the volume of secretions is so large that the uterus is also distended, this condition is called hydrometrocolpos. If an obstructing congenital malformation is not recognized before menarche, menstrual blood will gradually fill the vagina, producing hematocolpos or, less commonly, hematometrocolpos.

Etiology

For hydrocolpos or one of its variations to arise, a female must have vaginal obstruction, a uterus, and a patent cervix. The two most common anomalies with these features are transverse vaginal septum (sometimes called vaginal atresia), and imperforate hymen. Although the embryologic origin of these malformations is not fully understood, they are probably produced between the 16th and 20th weeks of gestation if the developing vaginal plate fails to perforate at its junction with either the fused paramesonephric (Müllerian) ducts proximally or the urogenital sinus caudally. Most patients with complete agenesis of the vagina (Rokitansky-Küster-Hauser syndrome) have rudimentary uteri or none at all, so hydrocolpos does not occur.

Epidemiology

Transverse vaginal septum occurs sporadically, with an estimated incidence of 1 in 2,000 to 84,000 girls. However, a few inbred kindreds have been described with transverse vaginal septum, polydactyly, and congenital heart disease (McKusick-Kaufman syndrome). In one survey, imperforate hymen occurred in 0.1% of term female neonates. Epidemiologic studies may be confounded because the two conditions can be confused with each other and because a congenitally imperforate hymen occasionally may open spontaneously during infancy.

Clinical Manifestations

Infancy

Although vaginal obstruction should properly be identified during the initial examination of the newborn female, infants with hydrocolpos often go unrecognized until days or weeks later when they develop the three hallmarks of this condition: 1) a lower abdominal mass, 2) difficulty with urination, and 3) a visible bulging membrane at the introitus. Except in mild cases, the lower abdominal mass consists of the bladder as well as the hydrocolpos itself. The infant strains to micturate or has urinary retention because the urethra is obstructed extrinsically. In more severe cases, infants may also have constipation, hydronephrosis, edema of the lower extremities, and hypoventilation. Inspection of the perineum should immediately indicate the proper diagnosis.

Adolescence

The girl with congenital vaginal obstruction who escapes notice during infancy will not come to attention until late in puberty when she presents with either primary amenorrhea or lower abdominal pain. She will have had satisfactory pubertal development until her menarche apparently fails to occur. Accumulating menstrual blood will then eventually produce vague lower abdominal pain that is not necessarily cyclic. As the hematocolpos grows, it will finally interfere with comfortable micturition, producing symptoms of urgency, frequency, or dysuria. The history of amenorrhea and the finding of a lower abdominal mass may lead the physician to suspect a tumor or even pregnancy, but the characteristic appearance of the introitus covered by a bluish bulging membrane is diagnostic of hematocolpos with imperforate hymen

(Fig. 94.4). Patients with a high transverse vaginal septum will not be so easily diagnosed because the introitus will appear normal. However, palpation of the vagina will promptly show that it is obstructed and that the cervix cannot be felt.

FIGURE 94.4. Hematocolpos in a 15-year-old patient with an imperforate hymen. The membrane bulges at the introitus underneath the labia minora (see also Fig. 94.5).

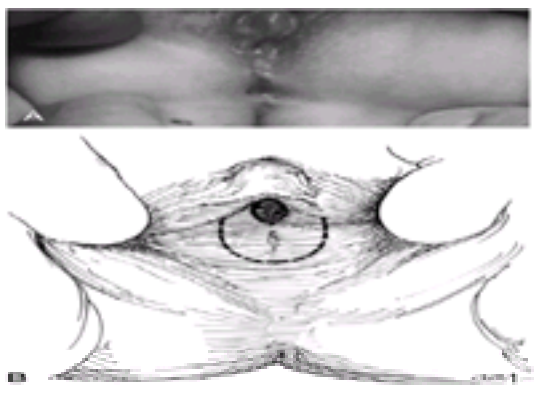

FIGURE 94.5. A. Labial adhesion in an asymptomatic 3-year-old girl. **B.** A flat surface, a dense central line of fusion, and an opening below the clitoris are characteristic features of labial adhesions, which cover the introitus (see also Fig. 94.4).

Complications

The complication of congenital vaginal obstruction most likely to require urgent attention among both infants and adolescents is acute urinary retention. This condition can be managed readily after the primary diagnosis has been recognized. Patients without complete urethral obstruction can instead have variable degrees of hydroureter or hydronephrosis as a result of the chronic extrinsic pressure. Rarely, an infant may have respiratory insufficiency or inferior vena caval obstruction because of the large mass. Imperforate hymen is usually an isolated anomaly, but other types of obstruction, chiefly transverse vaginal septum, are regularly associated with renal malformations, including hypoplastic or single kidneys, and duplicated or ectopic collecting systems. Therefore, the patient's laboratory evaluation should include assessment of both renal function and urinary tract anatomy. Endometriosis can be a late complication of severe hematocolpos.

Differential Diagnosis

The differential diagnosis of hydrocolpos and its variations includes patients with either a lower abdominal or pelvic mass but no vaginal obstruction, and patients with apparent vaginal obstruction. In the former category, the physician simply needs to demonstrate that the patient has a patent genital tract. The usual measures for diagnosis of the mass can then be undertaken. The latter group includes girls with microperforate hymen, labial adhesions, Gartner's (mesonephric) duct cysts, and rarely, complete agenesis of the vagina and testicular feminization. The microperforate hymen has a tiny orifice just below the urethra and requires only careful inspection for its diagnosis. Adhesions of the labia minora are superficial to the plane of the hymen and are characterized by a central vertical line of fusion (Fig. 94.5). A large vaginal Gartner's duct cyst can resemble an imperforate hymen, but it can be seen to protrude through the hymenal ring, which is itself patent. Patients with complete agenesis of the vagina have only a rugated dimple or shallow indentation at the introitus. A short blind vagina also occurs in testicular feminization, a disorder characterized by end-organ insensitivity to androgen. These patients are phenotypic females with an XY karyotype who undergo breast development at puberty but lack pubic hair and female reproductive organs.

Management

Patients with congenital vaginal obstruction need surgical treatment. Hydrocolpos or hematocolpos complicated by respiratory insufficiency, compression of the inferior vena cava, or hydronephrosis must be corrected without delay. The management of simple imperforate hymen can be modified according to the patient's age. Surgery should be scheduled promptly for adolescents but can be performed electively for asymptomatic infants and children.

Labial Adhesions

Background

Labial adhesions are an acquired attachment of the medial surfaces of the labia minora to each other. The terms *labial fusion, synechiae,* and *agglutination* are also often used to describe this condition. Labial adhesions are a common gynecologic condition, occurring in approximately 3 to 7% of girls between the ages of 3 months and 5 years. Most patients are between the ages of 1 and 6 years, but adhesions have been reported in girls as young as 6 weeks of age. The median age at diagnosis is 2 years.

Pathophysiology

A cause for labial adhesions has never been established. However, it is generally agreed that they are a concomitant of the child's normally low levels of endogenous estrogen. Without estrogen, the genital epithelium is relatively thin and susceptible to irritation. Possibly following some episode of inflammation, the two labial surfaces gradually stick together, with the line of fusion usually advancing anteriorly from the posterior frenulum of the labia minora.

Clinical Manifestations

The parent who notices a daughter's labial adhesions at home usually brings her to the ED with a chief complaint that the child's vagina is “closing up.” Alternatively, a physician may notice the adhesions during the child's routine physical examination. The situation is much more difficult when, as occasionally happens, the child is brought to the ED for evaluation because another clinician has mistakenly informed the parents that their daughter has congenital absence of the vagina or ambiguous genitalia. Imperforate hymen is another notable misdiagnosis. In these cases, primary focus must be to provide a careful explanation and reassurance for the distressed parents because the condition is essentially minor.

The diagnosis of labial adhesions can be made promptly and confidently by simple inspection of the child's genitalia. When the labia majora are gently retracted laterally, a flat plane of tissue marked by a central vertical line of adhesion obstructs the view of the introitus within (Fig. 94.5B). This thin vertical raphe is pathognomonic of labial adhesions. It is occasionally difficult to detect if the child's adhesions are old and dense. The length of the adhesions is variable, and they can be perforated. They are usually thickest posteriorly and stop below the clitoris. Even when adhesions appear to have closed the vulva completely, a pinpoint opening generally permits the egress of urine.

Most girls with labial adhesions are asymptomatic. A few have associated dysuria, frequency, or refusal to void that may be a result of either the obvious mechanical obstruction or concurrent urinary tract infection. Whether associated urinary tract infections are a cause or an effect of adhesions is uncertain, but they are a recognized complication of the condition. Girls with urinary tract symptoms should receive urine cultures and appropriate medical follow-up. Because vaginal infection is not associated with adhesions, vaginal cultures are not indicated except in patients who have concurrent vaginal discharge. Asymptomatic girls need no laboratory evaluation.

Management

Treatment is not indicated for asymptomatic girls with labial adhesions because the condition spontaneously remits early in puberty as a result of increasing endogenous estrogen. Some parents, however, prefer that their daughters be treated. Of girls with labial adhesions, 90% can be treated successfully with a small amount of estrogen cream (Premarin or Dienestrol) dabbed onto the adhesions at bedtime for 2 to 4 weeks. After the labia have separated, an inert cream (zinc oxide, Vaseline, Desitin) is applied nightly for an additional 2 weeks to keep the labia apart while healing is completed. Because pharmacies often supply estrogen cream in large tubes, parents should be warned specifically that prolonged use of the hormone can stimulate breast growth in children. Vulvar hyperpigmentation is a common, transient side effect of treatment. Labial adhesions should never be manually separated. The procedure is painful and usually results in relapse when the raw, newly separated labia adhere again. Topical estrogen cream is a painless, inexpensive, and effective therapeutic alternative.

Urethral Prolapse

Background

Urethral prolapse is the protrusion of the distal urethral mucosa outward through its meatus, with a cleavage plane between the longitudinal and circular-oblique smooth muscle layers of the urethra. The prolapsed segment is constricted at the meatus, and venous blood flow is impaired, so the involved tissue becomes swollen, edematous, and dark red or purplish. If the process is not corrected, the tissue can become thrombosed and necrotic.

About half of affected females are prepubertal children, and most of the remainder are postmenopausal women. Most prolapses during childhood occur in girls between the ages of 2 and 10 years. Nearly 95% of affected girls reported in the English-language literature since 1937 have been African-American. This racial disparity among affected children remains unexplained. In contrast, race does not appear to be a risk factor for prolapse among postmenopausal women.

Although the cause of urethral prolapse is not well understood, a sudden or recurrent increase in intra-abdominal pressure (severe coughing, seizure, constipation, lifting heavy objects) has been noted to precede some cases. Other proposed causes of prolapse include local trauma, redundant urethral tissue, neuromuscular dysfunction, and inadequate pelvic support of the bladder neck and urethra, but no convincing evidence has been presented to support any of these hypotheses.

Clinical Manifestations

Vaginal bleeding or spotting is the chief complaint of 90% of children with significant urethral prolapses. The bleeding is painless, occasionally misinterpreted as hematuria or menstruation, and accompanied by urinary frequency or dysuria in about one-fourth of cases. Only a minority of girls or their parents are aware of the presence of a vulvar mass. On the other hand, it is not rare for the physician simply to note a small prolapse during the routine examination of an asymptomatic child.

On examination of the child's vulva, a red or purplish, soft, doughnut-shaped mass is seen (Fig. 94.6). Most prolapses are not tender and measure 1 to 2 cm in diameter. By retracting the labia majora posterolaterally, the examiner can often demonstrate that the mass is separate from and anterior to the vaginal introitus, but this process may be difficult if the prolapse is large. A small central dimple in the mass indicates the urethral lumen. This dimple can be missed if lighting is inadequate, bleeding is active, or mucosal edema is significant. In most cases, the appearance of the prolapse is diagnostic. However, if the diagnosis is in doubt, sterile straight catheterization of the bladder through the mass can be performed to demonstrate the anatomic relationships safely and rapidly. No other test is needed. If urinalysis is performed on a spontaneously voided specimen, red blood cells are likely to be found, but urine cultures are routinely sterile. Urethral polyps, prolapsed ureterocele, sarcoma botryoides, and urethral carcinoma may be included in the differential diagnosis, but these entities are rare in children and lack the characteristically annular appearance of a urethral prolapse.

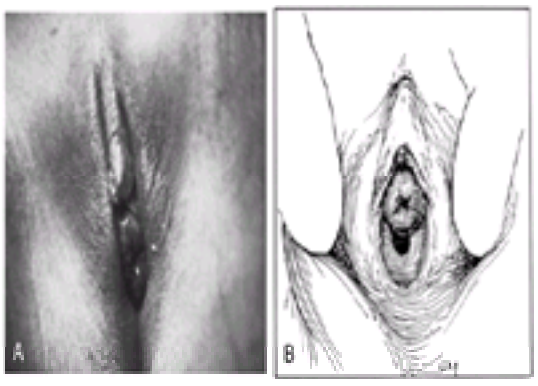

FIGURE 94.6. A. Urethral prolapse in a 6-year-old girl with “vaginal” bleeding. The vaginal orifice cannot be seen. **B.** The smooth doughnut shape and central lumen are characteristic features of a urethral prolapse, which, if large or swollen, often conceals the vagina below it.

Management

For the symptomatic patient with a small segment of prolapsed mucosa that is not necrotic, warm moist compresses or sitz baths, combined with a 2-week course of topical estrogen cream, may be prescribed. Most patients treated in this way have improved within 10 to 14 days and remained normal thereafter, thus avoiding surgery. Patients with dark red or necrotic mucosa should be treated surgically within several days by reduction of the prolapse and/or excision of necrotic tissue. After the diagnosis is confirmed by cystoscopy, the prolapse is excised and the cut edges are sutured together. The procedure is simple and can be carried out in a day surgery unit.

GYNECOLOGIC DISORDERS OF ADOLESCENCE

Dysmenorrhea

Background

Definition

Dysmenorrhea means painful menstruation. It is primary if the pain cannot be attributed to a specific pelvic abnormality such as endometriosis, PID, or a uterine malformation. Menstrual pain resulting from an underlying disorder is termed secondary dysmenorrhea.

Epidemiology

Among all women, and among adolescents in particular, primary dysmenorrhea is far more common than secondary dysmenorrhea. Estimates of the incidence of primary dysmenorrhea have varied, depending on both the age of the women surveyed and the criterion used for a positive response (any pain, pain that interferes with normal activity, or pain that prompts a visit to a physician). In the U.S. National Health Examination Survey (1966 to 1970), 60% of postmenarchal girls between the ages of 12 and 17 years reported having menstrual pain or discomfort. The prevalence of dysmenorrhea increases with increasing chronologic and gynecologic (postmenarchal) age, reflecting the strong association of dysmenorrhea with ovulatory menstrual cycles. At gynecologic age 1, approximately 30% of girls have dysmenorrhea. By gynecologic age 5, the proportion increases to nearly 80%.

Pathophysiology

A pathophysiologic basis for dysmenorrheic pain could not be demonstrated until the 1970s, when numerous investigations indicated that at the end of ovulatory menstrual cycles, prostaglandins $F_{2}a$ and E_2 are synthesized by and released from endometrial tissue. The prostaglandins cause increases in both the uterine resting tone and the amplitude and frequency of myometrial contractions. Uterine contractions that exceed systolic blood pressure produce tissue ischemia and perceptible pain. Intravenous administration of prostaglandins can reproduce the systemic discomforts—vomiting, diarrhea, headache—that often accompany dysmenorrhea. A dose–response relationship has been demonstrated in studies comparing the prostaglandin content of menstrual fluid from women with and without dysmenorrhea and from individual women during painful and pain-free cycles.

The role of ovarian hormones in endometrial prostaglandin production is not completely understood. Progesterone or its withdrawal appears to enhance prostaglandin synthesis during ovulatory cycles. Conversely, progesterone-impregnated intrauterine devices and the inhibition of ovulation by birth control pills are both associated with decreased prostaglandin production and with relief from dysmenorrhea.

Clinical Manifestations

Typical primary dysmenorrhea consists of cramping, dull, midline, or generalized lower abdominal pain at the onset of a menstrual period. The pain may coincide with the start of bleeding or may precede the bleeding by several hours. Many women have associated symptoms including backache, thigh pain, diarrhea, nausea or vomiting, and headache. The discomfort usually abates within 48 hours. Because dysmenorrhea is a hallmark of ovulation, adolescents characteristically do not experience dysmenorrhea until after several months of painless, anovulatory cycles. Menstrual pain that begins either at menarche or more than 4 years after regular cycles have been established is less common. The patient with such early or late dysmenorrhea should be assessed carefully for a possible underlying disorder, but she is still more likely to be having simply a particularly early or late onset of fertile cycles. Because they inhibit ovulation, both combined oral contraceptive pills and contraceptive progestins almost uniformly abolish dysmenorrhea.

Patients with straightforward dysmenorrhea have normal physical examinations and no associated abnormalities on routine laboratory evaluation. PID and congenital abnormalities (rudimentary uterine horn, partially obstructed genital duplications) must be included in the differential diagnosis for sexually active adolescents and those with atypical pain or a pelvic mass. Endometriosis and postoperative adhesions are also potential explanations for chronic, cyclic, undiagnosed pelvic pain in teenagers.

Management

The virginal adolescent with a typical history of dysmenorrhea should undergo a routine physical examination, but a pelvic examination is unnecessary. However, virginal patients with atypical or severe pain should undergo recto-abdominal or one-finger vaginoabdominal palpation. Sexually experienced adolescents with pelvic pain cannot be adequately evaluated without a complete pelvic examination to screen for pelvic infection and unsuspected pregnancy. No specific laboratory or radiologic evaluation is needed for otherwise healthy virginal adolescents. Pelvic ultrasound or laparoscopy may be helpful in the assessment of patients with uncertain diagnoses or with pain unresponsive to adequate treatment (see the following section).

Nonsteroidal anti-inflammatory drugs (NSAIDs) are the treatment of choice for patients with moderate or severe dysmenorrhea, providing pain relief for 60 to 80% of symptomatic women. Aspirin (650 mg four times a day) can be recommended for patients with mild discomfort but is several hundred times less potent an inhibitor of prostaglandin synthesis. Like aspirin, but to a lesser extent, NSAIDs cause gastrointestinal (GI) irritation, inhibit platelet aggregation, and prolong the bleeding time. NSAIDs may also reduce the volume of menstrual blood loss, a little recognized but potentially beneficial side effect. Both NSAIDs and aspirin are contraindicated in patients with aspirin hypersensitivity, GI ulcers, and bleeding disorders. Examples of commonly used NSAID treatment regimens are as follows:

- Mefenamic acid: 500 mg once orally, followed by 250 mg four times a day
- Ibuprofen: 400 to 600 mg orally four times a day
- Naproxen: 500 mg once orally, followed by 250 mg four times a day
- Naproxen sodium: 550 mg once orally, followed by 275 mg four times a day

For sexually active adolescents with dysmenorrhea, birth control pills are an attractive and effective alternative to NSAIDs because they provide both contraception and pain relief. Other agents commonly recommended in the past for the treatment of dysmenorrhea—acetaminophen, caffeine, propoxyphene—lack specific antiprostaglandin action and have only limited effectiveness.

Dysfunctional Uterine Bleeding

Background

Dysfunctional uterine bleeding (DUB) is best characterized as irregular, prolonged, or excessive menstrual bleeding associated with anovulation and unrelated to pregnancy. Ovulatory cycles occur in about 20% of adults with DUB, but this phenomenon is uncommon during the teenage years. Terms often used to categorize patterns of DUB are *metrorrhagia* (irregular or acyclic bleeding) and *menorrhagia* (excessive duration or quantity of bleeding). Menstrual bleeding that persists beyond 9 days, that recurs at intervals of fewer than 21 days, or that produces anemia is abnormal and warrants attention.

DUB is prevalent at the beginning and end of the reproductive years, paralleling the times when anovulatory cycles are most common. In girls during the first year after menarche, about half of menstrual cycles are anovulatory. This proportion decreases gradually, so only 5% of cycles are anovulatory 10 years or more after menarche. Of course, most

adolescents with anovulatory cycles nevertheless experience self-limited, reasonably cyclic bleeding episodes. Why more girls do not develop DUB is not well understood.

Pathophysiology

From the standpoint of ovarian function, the normal ovulatory menstrual cycle is divided into an initial follicular and a subsequent luteal phase. The parallel phases of endometrial development are termed, respectively, *proliferative* and *secretory.* At the start of an ovulatory cycle, pituitary follicle-stimulating hormone (FSH) promotes the growth of ovarian follicles. In turn, the rising concentration of estradiol from these follicles stimulates the proliferation of endometrial stroma and glands, has a negative feedback effect on the secretion of FSH, and finally induces a midcycle surge of luteinizing hormone (LH) that triggers ovulation. The duration of the preovulatory phase of the menstrual cycle is variable but generally lasts about 14 days. After ovulation has occurred, the ruptured ovarian follicle forms a corpus luteum that secretes progesterone as well as estradiol, and levels of both FSH and LH gradually decline. Although progesterone limits the ultimate thickness of the endometrium, it also promotes further growth of the endometrial secretory glands and spiral blood vessels, so they become coiled and tortuous. At the end of the corpus luteum's life span (a highly consistent 14 days unless conception occurs), it degenerates, and circulating levels of both estrogen and progesterone fall, eventually stimulating a resurgence of LH and FSH. As hormonal support wanes, blood flow to the secretory endometrium diminishes, and the spiral arterioles constrict and relax rhythmically under the influence of local prostaglandins. The resulting progressive ischemia leads to endometrial necrosis. Menstrual sloughing begins, and the cycle starts over again.

In contrast, during intervals of anovulation, luteal progesterone is not present to limit the endometrium's thickness or to promote its structural integrity. Parts of the endometrial surface undergo growth and sloughing sporadically, without cyclic coordination. The amount of estrogen secreted by ovarian follicles fluctuates unpredictably, and bleeding can occur either because of a fall in estrogen level (withdrawal bleeding) or despite a sustained level of production (breakthrough bleeding). Relatively constant low levels of estrogen tend to produce intermittent spotty bleeding (metrorrhagia). Larger amounts of estrogen cause greater endometrial proliferation and a cyclic pattern of amenorrhea followed by profuse bleeding (menorrhagia) whenever either the endometrial vessels and glands outstrip their stromal support, or hormone levels spontaneously fall. Compared with the 35 to 75 mL of blood lost during a normal menstrual period, dysfunctional bleeding often results in the loss of 100 to 200 mL each month. It is no surprise, therefore, that iron deficiency with depleted marrow stores or outright anemia is often seen in patients with DUB.

Clinical Manifestations

DUB has a substantial capacity to disrupt the everyday activities of adolescent patients discomfited by an unpredictable, urgent need for bathroom facilities and the risk of visible bloodstains. Large amounts of bleeding often provoke considerable fear in both patients and their parents. These concerns can overshadow the history of the bleeding itself, but the details of the problem's chronology and an estimate of blood loss (in pads per day) will help the physician assess the severity of the bleeding, follow the patient's clinical course, and gauge her prognosis. The symptoms that characteristically accompany only ovulatory menstrual cycles—mittelschmerz, premenstrual breast tenderness, bloating, mood changes, and dysmenorrhea—should be absent. DUB is classically painless, but occasionally, a patient with active bleeding may experience crampy pain if a large quantity of blood is passed rapidly. Weakness or fainting should alert the examiner to the possibility of significant blood loss. Pertinent questions should include whether the patient is pregnant, whether she uses contraception if she has been sexually active, and whether she has an underlying platelet disorder (e.g., thrombocytopenia, von Willebrand's disease).

The physical examination starts with measurement of the patient's vital signs, including a check for orthostatic changes in the pulse and blood pressure. Pertinent signs, including pallor, petechiae or bruises that might indicate a bleeding disorder, and hirsutism or obesity consistent with the polycystic ovary syndrome, should be sought and noted. The pelvic examination is likely to be normal except for the presence of bleeding but should be performed to evaluate the patient for pelvic infections, previously unrecognized pregnancy, and functional ovarian cysts. If necessary, rectoabdominal palpation can be substituted for the standard bimanual examination. Ovarian enlargement is an uncommon finding even among adolescent patients with clear-cut polycystic ovary syndrome. The differential diagnosis of DUB is discussed at greater length in Chapter 76.

Management

A determination of the hemoglobin or hematocrit is essential for the emergency evaluation of patients with DUB because historical estimates of blood loss are imprecise. A platelet count should also be obtained because thrombocytopenia is the most common hematologic disorder that produces menorrhagia. The history and physical examination should be used to guide the choice of additional laboratory tests. Sexually active adolescents should receive a pregnancy test, a cervical culture for gonorrhea, and an antigen-detection test for chlamydial infection because STD-associated endometritis is a common cause of otherwise unexplained uterine bleeding. Patients with menorrhagia beginning at menarche, severe hemorrhage, or a history of bleeding problems should undergo further evaluation for possible disorders of platelet number or function.

In order of decreasing urgency, management of DUB includes the identification and treatment of the following problems: shock or acute hemorrhage, moderate bleeding usually accompanied by anemia, and minor bleeding that produces distress but no imminent danger for the patient (Table 94.1). For patients with brisk hemorrhage or hypotension, prompt hospitalization and volume resuscitation as necessary (see Chapter 3) are the first order of business.

Clinical Situation	Treatment	Comments
Shock, acute hemorrhage	Volume resuscitation Conjugated estrogens 20–25 mg IV every 4 hr with maximum of 6 doses Curettage if estrogen unsuccessful	Add progestin promptly Prescribe iron
Moderate bleeding	Oral estrogen plus progestin, QID regimen Intravenous estrogen if oral treatment unsuccessful	Anemia common Prescribe iron
Minor bleeding	Oral estrogen plus progestin, BID regimen Observation without treatment acceptable	

Table 94.1. Management of Dysfunctional Uterine Bleeding

Control of the bleeding itself is accomplished with hormonal treatment. Regimens vary according to the severity of bleeding and individual preference, but each is designed first to stop the bleeding, second to convert the unstable proliferative uterine endometrium to the secretory state, and finally to allow a self-limited endometrial slough under controlled conditions. (Pregnancy must be excluded in every case before hormonal treatment is begun.) Estrogen is used to support the endometrium acutely and to stop the bleeding. A progestational agent must be administered simultaneously to produce a secretory endometrium; otherwise, the problem will recur predictably whenever the estrogen is stopped. Any of the oral contraceptive pills with 35 or 50 µg of either ethinyl estradiol or mestranol and a progestin provides a convenient means of administering the two hormones together. The dosage for patients with active bleeding and anemia is 1 estrogen–progestin tablet orally four times a day for 5 days. In almost every case, bleeding will decrease substantially within 24 hours and stop within 2 to 3 days. A rarely needed alternative treatment for hospitalized patients consists of conjugated estrogens 20 to 25 mg intravenously every 4 hours until the bleeding stops, with a maximum of six doses. This treatment must be accompanied by a progestational agent (medroxyprogesterone 10 to 20 mg orally per day for 5 to 12 days). If hormonal treatment fails to arrest the bleeding, dilation and curettage should be performed, but the procedure is almost never necessary.

For patients with light but prolonged bleeding and a normal hemoglobin, the oral regimen can be reduced to 1 estrogen–progestin tablet twice a day for 5 days. Nausea is a common side effect of estrogen in each of these regimens and can be treated symptomatically. Vomiting rarely precludes oral therapy. A progestin alone in higher dosages (norethindrone acetate 10 to 20 mg/day for 5 to 12 days) can be used if estrogen is contraindicated or not tolerated, but the resulting hemostasis is less prompt and less predictable.

Treatment with combined estrogen–progestin pills is stopped at the end of 5 days; progestin-only treatment is stopped after 5 to 12 days. After the cessation of treatment, a self-limited, heavy menstrual period will follow within 2 to 3 days. The family must be forewarned so that they anticipate this episode and do not misinterpret it as a recurrence of the DUB. This withdrawal bleeding will stop spontaneously within several days. Subsequent therapy must be tailored to the individual patient. A course of medroxyprogesterone (10 mg orally, daily for 10 to 12 days) can be used every 6 to 8 weeks to produce a secretory endometrium and a controlled withdrawal flow, if spontaneous menstruation has not intervened. For sexually active adolescents and those with chronic or recurrent DUB, long-term combined oral contraceptive pills are an excellent therapeutic choice.

Adolescents with severe, chronic, or recurrent DUB should receive diagnostic investigation to address the question of an underlying endocrinologic disorder (see Chapter 48). Iron supplementation is prudent for all patients with DUB; those without frank anemia are likely to have depleted marrow stores of iron. Finally, outpatient follow-up is an essential component of management because treatment may be needed for months or years and because chronic anovulation is a risk factor for both infertility and the late development of endometrial carcinoma.

Sexual Abuse and Assault

The four major gynecologic aspects of treating a girl who has been sexually abused or assaulted are 1) collection of evidence from the genital area, 2) screening and treatment for STDs, 3) management of injury, and 4) prevention of pregnancy. The overall management of sexually abused children is discussed in Chapter 128.

Police and prosecutors ask physicians to document observations and to collect evidence that may corroborate a patient's history of sexual assault or abuse. This evidence may consist of a child's exact statement concerning the abuse; the finding of prostatic acid phosphatase in vaginal secretions, indicating the presence of seminal fluid; a small bruise on the labia majora; or the discovery of leaf or grass fragments in the underwear of a child who states that she was assaulted in a park. As a rule, any material that might be helpful should be collected if the child has had sexual contact within 72 hours of her evaluation in the ED. A number of commercially available “rape kits” contain swabs, tubes, and evidence tape to simplify this process. However, the clinician should not feel compelled to follow rape kit instructions slavishly because many of the specimens called for (e.g., pubic hair sample, fingernail scrapings) are rarely relevant to the circumstances of victimized children. If material is collected that may be used in court, its movement from physician's possession to locked storage or police officer's custody should be documented with signatures, times, and dates to preserve the chain of evidence that will allow the material's origin to be verified in court. When, as is often the case, a sexually abused child is not examined until several weeks after the most recent episode of sexual contact, the likelihood of the physician's finding physical evidence is low.

STDs are seen in about 5% of abused children, generally mirroring their relative prevalence in the adult population. Although trichomoniasis is among the most common STDs in adults, it is not seen in prepubertal abused girls because trichomonads do not proliferate in the absence of an estrogenic milieu. Syphilis certainly can be transmitted by sexual

assault and abuse, but occurs only rarely. Sexual abuse has been reported as the suspected mode of transmission for some children infected with human immunodeficiency virus (HIV).

In the past, most authorities recommended universal screening of sexually abused children for syphilis and for gonorrhea and *C. trachomatis* from three sites (pharynx, vagina or urethra, and rectum). However, the yield of infections from such surveillance is low, and the cost is substantial. An alternative strategy accepted as appropriate by most experts is to restrict STD screening to high-risk children (children victimized by more than one assailant or by an assailant with a known or suspected STD) and to adolescents. All adolescents are screened because they are at higher risk than younger children of acquiring STDs and, especially, of subsequently developing PID if cervicitis is present. Serologic screening for syphilis and HIV infection should be offered to all children. Before a child is screened for HIV, the parent must be advised that a positive test may indicate vertical transmission and parental infection, rather than acquisition via the assault. Screening for hepatitis B infection can be limited to adolescents who have not received hepatitis B vaccine.

As is true for STD screening, antibiotic prophylaxis after sexual abuse is best limited to children victimized in high-risk situations and to adolescents. The antibiotic regimen should include coverage for both chlamydia and gonorrhea. For adolescents, coverage for trichomonas and bacterial vaginosis (and for hepatitis B if the patient is unvaccinated) should be added. Giving the first vaccine dose (followed in 1 and 6 months by the subsequent doses) is adequate prophylaxis for hepatitis B. As of this writing, the Centers for Disease Control and Prevention (CDC) make no specific recommendation for HIV prophylaxis after sexual assault. However, consideration should be given to offering antiretroviral prophylaxis to children and adolescents when the circumstances of an assault seem to pose a high risk of HIV infection.

For sexually abused children with symptoms or signs of an STD, the question of screening is irrelevant; diagnostic tests should be directed at identifying all suspected infections. The diagnosis and treatment of STDs are reviewed elsewhere in this chapter and in Chapter 84 and Chapter 85. When sexual abuse is involved, for the diagnosis of gonorrhea, chlamydial infection, and herpes simplex virus infection, cultures should be used either in place of or as confirmation of indirect diagnostic methods (e.g., Gram stain, DNA probe, other immunologic tests) because the risk of false-positive presumptive tests is substantial and because test results that may be presented in legal proceedings should be definitive.

Few girls sustain serious physical injuries as a result of sexual abuse or assault. Any sexually abused girl who has vaginal bleeding that cannot be attributed to a clearly visible injury or infection must be examined carefully to determine the source of the bleeding. This will usually require the use of sedation or general anesthesia in premenarchal girls. The management of girls with vaginal bleeding is discussed at greater length in Chapter 76.

The emergency physician must consider the possibility of pregnancy in every postmenarchal girl who has been sexually abused or assaulted. A pregnancy test should be conducted in the ED to ascertain whether the patient is pregnant when she is first evaluated. If an adolescent is not pregnant and is not using hormonal contraception, her risk of becoming pregnant as a result of rape must be assessed. The risk of pregnancy from a single unprotected coitus at midcycle is estimated to be 15%. The risk from coitus occurring more than 6 days before or after ovulation is negligible. Postcoital contraception—100 µg ethinyl estradiol and 1 mg D1-norgestrel (2 Ovral tablets) given once immediately and a second time 12 hours later—reduces the likelihood of pregnancy by about 50% and should be offered to patients seen within 72 hours of a rape. An antiemetic should also be prescribed because the estrogen often produces nausea. The effectiveness of this regimen for preventing pregnancy decreases as the time from coitus to treatment increases. The patient can expect to have her next menstrual period within 21 days after treatment and should be given an appointment for follow-up about 3 weeks after the ED visit.

GENITAL TRACT INFECTIONS

Vaginitis

Background

Definition

Vaginitis, or inflammation of the vagina, can be produced by chemical and mechanical irritants, foreign bodies, and a variety of infectious agents, including viruses, chlamydia, bacteria, fungi, protozoa, and helminths. During childhood, vaginitis is characterized by the presence of vaginal discharge, bleeding, or both. After puberty has begun, girls normally have an asymptomatic vaginal discharge; vaginitis is then indicated by the discomfort it produces or by a change in the character of the discharge. The etiology, clinical manifestations, diagnosis, and treatment of common vaginal infections are presented in this chapter. For a review of the differential diagnosis of vaginal bleeding and discharge, see Chapter 76 and Chapter 77. Table 94.2 and Table 94.3 summarize the treatment of common vaginal infections.

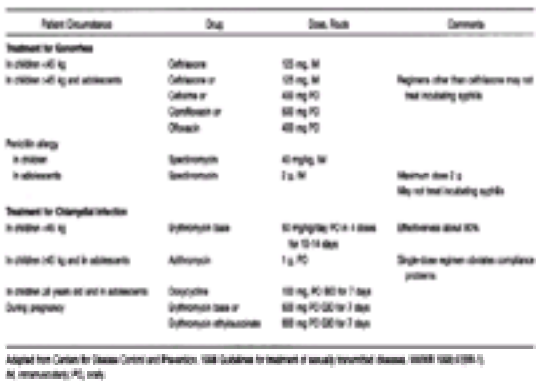

Table 94.3. Summary of Treatment Regimens for Lower Genital Tract Gonorrhea and Chlamydial Infection

Epidemiology

At least half of all symptomatic premenarchal girls with vaginal discharge visible on physical examination will prove to have specific vaginal infections that warrant antimicrobial treatment. Among prepubertal girls in the United States, *N. gonorrhoeae* causes the greatest number of these specific infections. Less common offenders include *Shigella* species, *Streptococcus pyogenes,* and in infants and after puberty has begun, *Trichomonas vaginalis.* Although staphylococci and *Haemophilus influenzae* usually colonize the lower genital tract without producing symptoms, they are associated with vaginal discharge in only a small proportion of patients. *Candida albicans* is the most common vaginal pathogen among both pubertal (but premenarchal) and postmenarchal girls.

The relative prevalence of vaginal infections in a population of postmenarchal adolescents depends primarily on how many of them are sexually active. The proportion of never-married teenagers who have experienced coitus increases steadily with age (Fig. 94.3) and is accompanied by a parallel increase in the prevalence of sexually transmitted infections. Among adult women, bacterial vaginosis is the most common vaginal infection, followed by vulvovaginal candidiasis and trichomoniasis. Bacterial vaginosis is found commonly and nearly exclusively among sexually active adolescents. Diabetes mellitus, pregnancy, immunodeficiency, and use of broad-spectrum antibiotics and corticosteroids predispose patients to developing *Candida* vulvovaginitis, but the infection is most often seen in patients who lack any of these risk factors. Trichomoniasis is transmitted only by sexual contact. Up to one-third of patients with trichomoniasis have concurrent gonorrhea, but there is no increased rate of infection with *C. trachomatis*.

Trichomonal Vaginitis

Clinical Manifestations A small proportion of vaginally delivered female neonates acquire trichomonal vaginitis from their infected mothers. Infants harboring only a few trichomonads may never develop clinical disease, but the remainder will have a thin whitish or yellowish vaginal discharge that appears within 10 days after birth and may persist for several months if untreated. Infected babies may be irritable but are otherwise well.

The classic vaginal discharge of trichomonal vaginitis after puberty is pruritic, frothy, and yellowish. However, many infected women do not complain of excessive discharge, and the discharge may be scant or nondescript. The so-called strawberry cervix with multiple punctate areas of hemorrhage is pathognomonic for trichomoniasis but is visible without colposcopy in only about 2% of infected patients.

For patients of all ages, the diagnosis is made easily and rapidly if characteristically motile, flagellated trichomonads are seen in a saline suspension of discharge examined microscopically within about 15 minutes after the specimen has been obtained (Fig. 94.7). If a longer delay occurs, the organisms will gradually lose their mobility and normal shape, making them much more difficult to identify. The false-negative rate for wet mount examinations can be as high as 40%. More sensitive methods for detecting trichomonal infection are culture and colorimetric probes for trichomonal DNA.

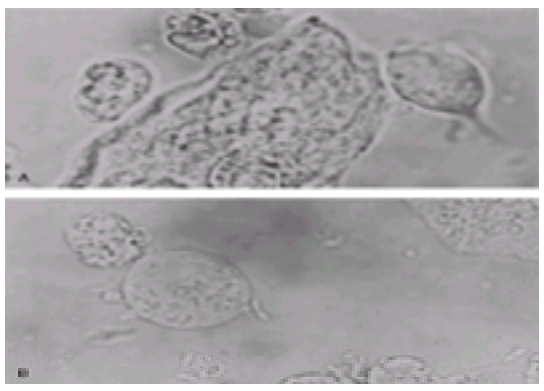

FIGURE 94.7. A. Trichomonad in the vaginal discharge of a 17-year-old patient with gonococcal pelvic inflammatory disease. The flagellated protozoan is elliptical and somewhat larger than the adjacent polymorphonuclear leukocytes (×225 magnification). **B.** After suspension in saline solution for microscopy, trichomonads gradually become swollen and immobile. This balloon-shaped trichomonad is barely recognizable (×225 magnification).

Management Metronidazole is effective for the treatment of vaginal trichomoniasis. The dosage for infants is 15 mg/kg per day orally in three divided doses for 7 days. A single oral dose (2 g) is prescribed for adolescents. Because trichomoniasis is sexually transmitted, the adolescent patient's partner(s) must also be referred for treatment.

Nausea and an unpleasant taste are common side effects of metronidazole. Alcohol should be avoided during treatment to prevent the occurrence of more severe abdominal pain, vomiting, flushing, and headache (disulfiram reaction). Recent data indicate that metronidazole is not a teratogen, but many clinicians prefer to postpone treatment of pregnant patients until the second trimester. Intravaginal clotrimazole (2 intravaginal tablets at bedtime for 7 days) can provide symptomatic relief for pregnant patients but will cure only 10 to 20%.

Shigella Vaginitis

Clinical Manifestations Shigella flexneri, S. sonnei, S. boydii, and *S. dysenteriae* can produce vaginal infections in infants and children but do not appear to cause genital disease after puberty. The vaginitis is characterized by a white to yellow discharge that is bloody in three-quarters of cases. Associated pruritus and dysuria are uncommon. One-third of patients have diarrhea that precedes, accompanies, or follows the vaginal discharge. On inspection, the vulvar mucosa is often inflamed or ulcerated. The diagnosis is established by culture of a specimen of vaginal discharge. Rectal cultures are positive in some cases.

Management Patients with *Shigella* vaginitis should be treated with oral antibiotics chosen on the basis of sensitivity testing. If the antibiotic sensitivity is unknown, trimethoprim–sulfamethoxazole (8 mg/kg per day orally of trimethoprim in two doses for 5 days) should be used.

Streptococcal Vaginitis

Clinical Manifestations S. pyogenes can be identified in cultures of vaginal specimens taken from about 14% of prepubertal girls with scarlet fever. Most of these vaginal infections produce either no symptoms or minor discomfort, but a few patients develop outright vaginitis with a purulent discharge. Streptococcal vaginitis can accompany or follow symptomatic pharyngitis and occurs uncommonly in girls with neither symptomatic pharyngitis nor scarlet fever. Most of these latter patients are pharyngeal carriers of the organism. Streptococcal vaginitis causes genital pain or pruritus and can mimic candidal or gonococcal vaginitis. A swab of the patient's discharge should be cultured to verify the clinical diagnosis, as well as to exclude gonococcal infection.

Management As for any other infection with group A b-hemolytic streptococci, penicillin is the preferred antibiotic. Intramuscular benzathine penicillin G is an alternative if poor compliance with oral treatment is anticipated. Oral erythromycin ethylsuccinate or azithromycin can be prescribed for children who are allergic to penicillin (see Table 94.2 for dosages).

Table 94.2. Treatment of Vaginal Infections

Candida Vulvovaginitis

Clinical Manifestations C. albicans frequently colonizes the vagina after the onset of puberty, when estrogen stimulates local increases in glycogen stores and acidity that both appear to enhance its growth. If the ecologic balance of the vagina is changed either by inhibition of the normal bacterial flora, by impaired host immunity, or by an increase in the availability of nutrients (broad-spectrum antibiotics, immunodeficiency states, corticosteroids, diabetes mellitus, pregnancy), the resulting proliferation of *Candida* will produce symptoms in a fraction of affected patients. However, most patients with candidiasis have no identifiable predisposing risk factor for infection. Because of the importance of estrogen in promoting fungal growth, candidal vulvovaginitis is rare among prepubertal girls.

The most common clinical manifestation of vulvovaginal candidiasis is vulvar pruritus. In severe infections, vulvar edema and erythema can occur. “External” dysuria is produced when urine comes in contact with the inflamed vulva. Vaginal discharge is variable in quantity and appearance. In severe cases, the vaginal vault is red, dry, and has a whitish, watery, or curdlike discharge that may be relatively scanty. Patients with mild disease may have only intermittent itching and an unimpressive discharge.

Microscopic examination of a sample of vaginal discharge suspended in 10% potassium hydroxide solution to clear the field of cellular debris can provide a rapid diagnosis of candidiasis if hyphae are seen (Fig. 94.8). However, in as many as 50% of cases, wet mounts are falsely negative. Gram-stained smears of discharge are somewhat more sensitive because hyphae and yeast cells are Gram positive and more easily visible. Culture can only corroborate or fail to corroborate the clinical impression of candidiasis because the vaginal flora includes *C. albicans* in up to 25% of young women who have no symptoms or signs of infection. Similarly, cultures from patients with classic signs of candidal infection may yield only a light growth of the organism, making heavy growth an inadequate criterion for diagnosis. From these considerations, it is apparent that although the presence of *C. albicans* can be confirmed by laboratory tests, the diagnosis and subsequent treatment of this infection should be guided by the presence or absence of clinical disease.

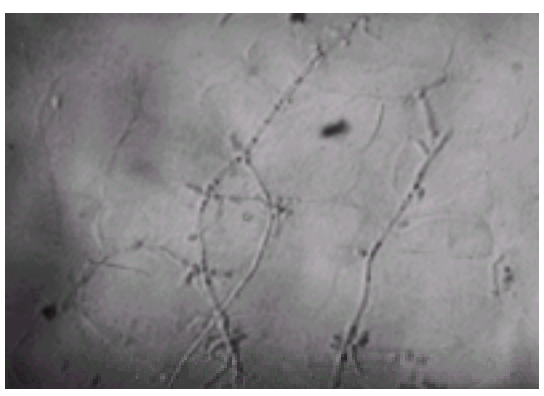

FIGURE 94.8. Branching hyphae of *Candida albicans* in vaginal discharge suspected in 10% potassium hydroxide. Ghosts of vaginal epithelial cells are also visible (×100 magnification).

Management Topical imidazoles will promptly cure 80 to 90% of patients with candidal infections. Most are available without prescription. The creams are packaged with intravaginal applicators, but many premenarchal and virginal girls can be treated adequately and more comfortably by applying cream to the vulva alone. Effective, nonprescription, short-course treatments for patients with mild to moderate candidal vulvovaginitis include butoconazole 2% cream (one full applicator at bedtime for 3 nights); clotrimazole 500-mg tablets (1 tablet intravaginally as a single dose); miconazole 200-mg suppositories (1 suppository at bedtime for 3 nights); and tioconazole 6.5% ointment (1 full applicator as a single dose). For patients with severe discomfort, one of the 5- or 7-day formulations of a topical agent is likely to be more effective. Fluconazole, an oral fungicide, treats candidal vulvovaginitis as effectively as the topical preparations, and many patients prefer oral to topical treatment. However, the potential for promoting fungal resistance and the risks, albeit low, of systemic toxicity and allergy are important disadvantages of oral antifungal agents.

Nonspecific Vaginitis in Children

Clinical Manifestations The term *nonspecific vaginitis,* referring to a disorder of prepubertal girls, encompasses a variety of genitourinary symptoms and signs that are sometimes caused by poor perineal hygiene but that in other cases have no readily identifiable cause. Genital discomfort, discharge, itchiness, and dysuria are relatively common childhood complaints. When a girl with such symptoms has either a normal vulva and vagina or only mild vulvar inflammation on physical examination, a specific vaginal infection is unlikely, and other possible explanations for the complaint—smegma, pinworms, urinary tract infection, a local chemical irritant, or sexual abuse, for example—should be sought with appropriate questions and laboratory tests. (It should be noted that commercially available bubble bath is not often the culprit.) If, on the other hand, a vaginal discharge *is* present on physical examination, the specific vaginal infections discussed in this chapter are diagnostic possibilities, and cultures should therefore be obtained. In reported series of premenarchal girls with vaginitis who have been systematically evaluated, between 25 and 75% are ultimately categorized as having nonspecific vaginitis. The diagnosis should not be made until other entities have been excluded. (A more comprehensive discussion of the differential diagnosis of genital complaints is presented in Chapter 76 and Chapter 77.)

Management General measures to promote cleanliness and comfort should be initiated for the girl with nonspecific vaginitis. Daily soaking in a bath of warm water, either plain or with some baking soda added, gentle perineal cleaning with a soft washcloth, and the use of cotton underwear can be recommended. The girl should be taught to wipe toilet paper anteroposteriorly after having a bowel movement. Using these suggestions, most girls with perineal irritation will be improved within 2 weeks. The remaining patients should be reevaluated to exclude any specific but previously unrecognized disorder. If none is found, these girls may benefit from a brief course of topical estrogen cream (a small amount dabbed onto the vulva nightly for 2 to 4 weeks) to stimulate thickening of the vaginal mucosa so that it is more resistant to local irritation. Parents should be cautioned that estrogen cream is capable of producing breast growth if it is used for a prolonged period of time.

Bacterial Vaginosis

Background Bacterial vaginosis is a syndrome characterized clinically by the presence of three of the following four signs: 1) a homogeneous, white adherent vaginal discharge; 2) vaginal pH above 4.5; 3) a fishy, aminelike odor released when 10% potassium hydroxide solution is added to a sample of the discharge; and 4) the presence of clue cells (Amsel criteria). The syndrome occurs when lactobacilli that normally predominate in the genital tract are displaced by an overgrowth of mixed flora, including *Gardnerella vaginalis, Mobiluncus* species, other anaerobes, and *Mycoplasma hominis.* What accounts for this change in the vaginal microflora is not understood. The high prevalence of the syndrome in sexually active women and in women attending STD clinics suggests that a wide range of epidemiologic and microbiologic factors may contribute to its pathogenesis. Bacterial vaginosis has been implicated as an important cause of endometritis and chorioamnionitis in women and of preterm delivery of low-birth-weight infants.

Clinical Manifestations The symptoms of bacterial vaginosis—malodor and discharge—are not distinctive and can resemble those of trichomonal infection. A complaint of dysuria or pruritus goes against the diagnosis. As many as half of women who have signs of vaginosis are asymptomatic. The vaginal discharge is moderate or copious, grayish-white, and homogeneous. On examination, the vulva, vagina, and cervix are not inflamed, but concomitant infection with trichomonas or gonorrhea can complicate this picture.

Compared with the composite Amsel criteria, use of single tests (e.g., pH, clue cells, or whiff test alone) produces lower positive and negative predictive values for the diagnosis of bacterial vaginosis. When a wet mount of vaginal discharge is examined, epithelial cells are seen to be studded with large numbers of small bacteria and have a granular appearance with shaggy borders (Fig. 94.9). The ratio of epithelial cells to polymorphonuclear leukocytes in the discharge is 1 or higher. Lactobacilli (long rods) are sparse. Gram stain can be used to confirm the presence of clue cells and the scarcity of long Gram-positive rods (lactobacilli). Because 35 to 55% of women without bacterial vaginosis have positive cultures for *G. vaginalis,* culture is not a useful diagnostic test. Trichomonal infection is the major diagnostic alternative for patients suspected of having bacterial vaginosis.

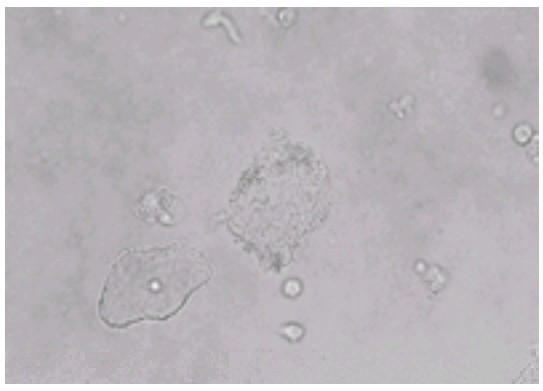

FIGURE 94.9. A clue cell. The vaginal epithelial cell on the right has shaggy borders obscured by coccobacilli (×100 magnification).

Management The standard treatment for bacterial vaginosis is oral metronidazole. Regimens are 500 mg twice daily for 7 days in nonpregnant women and 250 mg three times daily for 7 days in pregnant women. These regimens are moderately effective, yielding a recurrence rate of up to 30% within 3 months. Treatment of patients' sexual partners does not reduce the recurrence rate and is not recommended. Common side effects of metronidazole include GI upset, headache, and a metallic taste. A recent meta-analysis indicated that metronidazole in standard doses is not a human teratogen. However, some clinicians prefer to postpone treatment of pregnant women until the second trimester. Intravaginal clindamycin cream and metronidazole gel are alternative treatments for nonpregnant women but are not recommended during pregnancy. Oral clindamycin (300 mg twice a day for 7 days) is an alternative treatment regimen for pregnant patients with bacterial vaginosis.

Gonococcal Infections

Clinical Manifestations

Prepubertal girls with vaginal gonorrhea uniformly have an obvious whitish to greenish purulent discharge that can be pruritic. Because the child's vaginal flora is normally fairly sparse, a Gram-stained smear of the vaginal discharge can provide a rapid presumptive positive diagnosis if, on microscopic examination, at least eight pairs of typical gonococci can be seen in each of at least two polymorphonuclear leukocytes. However, because the social and legal implications of the diagnosis are major and because this fastidious microorganism can fail to grow in the laboratory, *all management decisions about gonorrhea in a child, including informing the parents of the diagnosis, reporting the case to the state child protective services agency, and instituting antibiotic treatment, should be delayed until after the suspected diagnosis has been confirmed by bacterial culture*.

After puberty, higher estrogen levels stimulate the growth of a thick vaginal mucosa that is relatively resistant to infection by gonococci, and lower genital tract infection is localized to the cervix and/or urethra. A vaginal discharge, excessive menstrual bleeding, or symptoms of cystitis may prompt an infected patient's ED visit, but most infections will produce no symptoms at all. On examination of the cervix, there may be marked central erythema, a purulent discharge, or no abnormality. A culture of a single specimen taken from the endocervical canal with a cotton-tipped swab, plated on a selective medium, and incubated properly will identify about 85% of women with uncomplicated gonorrhea. The remaining 15% includes patients with urethral, rectal, and pharyngeal infections without cervicitis, and those with cervicitis not detected with a single culture.

Management (Table 94.3)

Girls with culture-proven gonococcal vaginitis should be treated with a single intramuscular dose of ceftriaxone. Treatment for *C. trachomatis* should not be given presumptively for children, but rather should be withheld pending the results of screening chlamydial cultures. Pharyngeal and rectal swabs for culture of *N. gonorrhoeae* should be obtained from every child in whom gonococcal vaginitis is confirmed by culture. The finding of gonorrhea in a child mandates detailed psychosocial evaluation and a report to the state child protective services agency for suspected sexual abuse in every case. All household contacts of the child, both children and adults, should be cultured because epidemiologic studies indicate that about 25% of them are likely to have gonorrhea also. Hospitalization of the child may facilitate this investigation in some cases.

Adolescents with uncomplicated genital gonorrhea should receive one of the treatments listed in Table 94.3. The oral treatment regimens have the advantages of easy administration and avoiding both a painful intramuscular injection and the risk of accidental needle stick. Since 1982, the CDC have suggested that every adolescent patient treated for lower genital tract gonorrhea also be treated presumptively for coexisting chlamydial infection because of the substantial likelihood of dual infection.

Every patient with gonorrhea should receive a screening serologic test for syphilis and should be offered screening for HIV infection. None of the treatment regimens for gonorrhea will cure established syphilis, but ceftriaxone is likely to eradicate incubating syphilis. The management of a case of gonorrhea is never complete until the patient's sexual partner(s) has been notified and treated presumptively. Test-of-cure cultures are not indicated because the treatment regimens for gonorrhea are efficacious. However, follow-up remains desirable for adolescents with gonorrhea to review their contraceptive behavior, to counsel them about risk reduction, to identify reinfections, and to obtain Papanicolaou smears.

Chlamydial Infections

Background

Lower genital tract infection with the intracellular bacterium *C. trachomatis* can be acquired at any age by means of sexual contact or during infancy as a result of either direct inoculation from an infected mother during vaginal delivery or spread from the nasopharynx after vertical transmission. Vertically acquired infections may persist in children for a year or more. Chlamydiae infect squamocolumnar epithelial cells and thus can be found in specimens from the urethra, the rectum, the vagina in prepubertal girls, and the cervix after puberty. Infections during childhood are uncommon, usually asymptomatic, and rarely detected. Infections among adolescents and adults are also often asymptomatic but common, occurring in up to 15% of sexually active teenagers. Simultaneous infection with gonorrhea is common in both children and adolescents with lower genital tract chlamydial infection.

Clinical Manifestations

Most prepubertal children with urethral, vaginal, and rectal infections are asymptomatic, although a few complain of dysuria, enuresis, or vaginal discharge. The diagnosis should be suspected in prepubertal girls with vaginal discharge that persists after therapy for a prior gonococcal infection and in girls with urethritis or vaginitis who have had sexual contact. Culture of a urethral or vaginal sample is advisable to confirm the diagnosis in children because the rapid antigen-detection tests can yield false-positive results and because the social and legal implications of a positive test are serious.

In adolescents, *C. trachomatis* can cause dysuria-pyuria syndrome and mucopurulent cervicitis but is often asymptomatic. Untreated lower genital tract infection can result in bartholinitis, perihepatitis, PID, and infertility (see the following section). On speculum examination, the cervix may be erythematous and friable when swabbed. Infected secretions collected from the cervical os may appear yellowish on a cotton swab. The diagnosis in an adolescent should be confirmed by an antigen or DNA detection test of the cervix or urine. These tests have good sensitivity and specificity.

Management

Antibiotic treatment regimens for children and adolescents with lower genital tract chlamydial infections are summarized in Table 94.3. Children should be treated despite the absence of symptoms because complications of the infection may develop after puberty. Adolescents with chlamydial infections should be counseled about the importance of treatment for their sexual partner(s), abstinence until 1 week after all sexual partners have completed treatment, and barrier methods of contraception. Patients should receive follow-up examinations 4 to 6 weeks after treatment to screen for reinfection, coexisting STDs, and cervical dysplasia.

Bartholin Gland Abscess and Cyst

Background

Abscesses and symptomatic cysts of the Bartholin glands are relatively uncommon disorders during adolescence. The Bartholin glands lie at about the 4 and 8 o'clock positions in the vestibule and drain through ducts that open into folds between the hymen and the labia minora. Many Bartholin gland cysts are asymptomatic and need no treatment. The clinical distinction between a symptomatic cyst and an abscess can be arbitrary in some cases.

Clinical Manifestations

The patient with a Bartholin gland abscess presents with a painful, tender, fluctuant mass bulging on the involved side of the vestibule inferior to the labium minus. Pus can sometimes be milked upward from the gland to the duct orifice. Cultures of pus from abscessed glands yield *N. gonorrhoeae* in 10 to 50% of cases. Most of the remaining cases contain mixed growths of facultative, aerobic, and anaerobic organisms, often including *Bacteroides* species. Cultures from a small number of abscesses yield *C. trachomatis,* and in 15 to 30% of cases, the pus is sterile. The patient with a cyst complains of vulvar discomfort; the unilateral mass is typically 1 to 3 cm in diameter and mildly tender. Cyst fluid is usually sterile.

Management

Abscesses and symptomatic cysts are treated similarly, with either placement of a Word catheter, marsupialization, or a “window operation.” Each of these procedures opens the cyst cavity widely and facilitates prolonged drainage. Many experts recommend against simple incision and drainage because of the high recurrence rate associated with this procedure. All patients with abscesses or purulent exudate should be treated for presumed gonorrhea (as outlined in Table 94.3) and their sexual partners referred for concurrent treatment. Complications of Bartholin gland abscess after treatment include slow healing, persistent discomfort, dyspareunia, and recurrence.

Pelvic Inflammatory Disease

Background

Definition

PID is infectious inflammation of the upper genital tract, variably involving the endometrium, fallopian tubes, ovaries, adjacent structures, and the pelvic peritoneum. The following discussion concerns acute PID caused by sexually

transmitted microorganisms ascending from the cervix, and excludes infections associated with childbirth, spontaneous abortion, or pelvic surgery.

Epidemiology

Each year between 1979 and 1988, among American women between the ages of 15 and 44 years, acute PID accounted for more than 165,000 hospitalizations and 1.2 million physician office visits. In 1994, nearly 400,000 women were diagnosed in EDs as having PID. Adolescents account for approximately 16 to 20% of all PID cases in the United States and have the highest age-specific case rates of PID after adjustment is made for the prevalence of sexual activity.

Young age, a large number of sexual partners, and nonbarrier contraceptive methods are risk factors for infection with *N. gonorrhoeae* and *C. trachomatis,* the microorganisms responsible for initiating most cases of acute PID. Recent douching is a risk factor for the development of PID, but the mechanism by which it increases risk is unknown. Overall, reported gonorrhea in the United States has declined steadily since the 1980s. However, teenagers and young adults consistently have the highest age-specific rates of gonorrhea (in 1996, 757 cases per 100,000 women between 15 and 19 years and 523 cases per 100,000 men between 20 and 24 years). In 1994, reported cases of chlamydial infection exceeded reported cases of gonorrhea in the United States for the first time. In 1996, the rate of chlamydial infection for women ages 15 to 19 years was 2,069 per 100,000. In family planning clinic screening programs in 1996, the rate of cervical chlamydial infection in women 15 to 24 years ranged as high as 11%.

Compared with no contraceptive method, barrier methods—male and female condoms, diaphragms, and spermicides—decrease the overall risk of acquiring gonococcal and chlamydial cervicitis. Oral contraceptive pills decrease the likelihood that users with cervical gonorrhea will develop ascending infection. The effect of oral contraceptives on chlamydial disease is less uniform. The increased cervical ectropion produced by oral contraceptives increases the likelihood of chlamydial cervicitis, but the thickened cervical mucus and reduced menstrual flow appear to inhibit ascending infection. A principal reason for strongly discouraging adolescents from using the intrauterine device (IUD) as a contraceptive method is the twofold higher risk of PID associated with IUD use.

The sequelae of PID—chronic and recurrent pelvic pain, dyspareunia, tubo-ovarian abscesses, ectopic pregnancy, and involuntary infertility—affect large numbers of women. It has been estimated that 18% of women with PID will have chronic pelvic pain. The rate of ectopic pregnancy per 1000 reported pregnancies in the United States increased dramatically, from 4.5 in 1970 to 14.3 in 1986, and (based on outpatient as well as inpatient hospital data) to an estimated 19.7 in 1992. It is estimated that half of all ectopic pregnancies result from tubal damage produced by salpingitis. Infertility occurs in about 15% of women who have had a single episode of gonococcal or nongonococcal salpingitis. Repeated bouts of PID substantially increase the likelihood of infertility.

Etiology

Nearly all first episodes of PID in adolescents are the result of gonococcal or chlamydial infection, or both, ascending from the cervix. If lower genital tract infection is not treated, approximately 10 to 40% of women with gonococcal cervicitis and 20 to 40% of women with chlamydial cervicitis will eventually develop PID. *C. trachomatis* is estimated to be responsible for 20 to 50% of all PID cases in the United States.

Subsequent episodes of PID may be produced either by repeated gonococcal or chlamydial lower genital tract infections or by endogenous genital or respiratory flora (most notably *Peptostreptococcus, Prevotella,* and *Bacteroides* species and *Hemophilus influenzae*). Tubal damage caused by concurrent or previous gonococcal or chlamydial infection probably contributes to secondary, polymicrobial PID involving endogenous microorganisms. *M. hominis* produces parametritis and salpingitis experimentally in grivet monkeys and has been isolated from the upper genital tracts of women with PID, but its role in the etiology of PID remains uncertain. Tuberculous PID is fortunately rare in the United States.

Pathophysiology

C. trachomatis was first isolated from the fallopian tubes of patients with acute salpingitis in 1976. The development of salpingitis in grivet monkeys whose cervices were inoculated with *C. trachomatis* confirmed the pathogenesis of this obligate intracellular bacterium. Both chlamydiae and gonococci infect columnar epithelial cells and reach the fallopian tubes by ascending from the cervix along the endometrial surface of the uterus. Menstrual blood facilitates this extension of the infection. In acute chlamydial infection, a polymorphonucleocytic infiltrate occurs, but during repeated or persistent infection, plasma cell endometritis is a prominent feature. An autoimmune response to repeated infection, involving the 60-kD heat shock chlamydial protein, seems likely to account for the severe tubal and peritubal scarring that is particularly associated with chlamydial PID.

Gonococci attach themselves to mucosal secretory cells and invade the submucosal connective tissue, stimulating a marked inflammatory reaction. In the tubal lumen, gonococcal lipooligosaccharides stimulate the production of tumor necrosis factor, endotoxin is released, and IgM–lipopolysaccharide immune complexes activate complement. In either chlamydial or gonococcal infection, pus may spill out from the fimbriated ends of the tubes, producing peritoneal symptoms and signs.

Clinical Manifestations

Although the constellation of symptoms and signs associated with PID—abdominal pain, irregular uterine bleeding, abnormal vaginal discharge, and lower abdominal and pelvic tenderness—is well known, no single symptom or sign or combination of symptoms and signs is both sensitive and specific. Clinical findings that improve the specificity of the diagnosis of PID (i.e., increase the likelihood that the diagnosis is correct) do so only at the expense of sensitivity (i.e., exclude patients who do in fact have PID). Minimum, additional, and definitive criteria for the diagnosis of PID suggested by the CDC are shown in Table 94.4. However, it is noteworthy that approximately one-fourth of women who have pelvic

pain but who do not meet the CDC's minimum criteria have been shown nevertheless to have PID on laparoscopy or endometrial biopsy.

Minimum criteria	Lower abdominal tenderness
	Tenderness produced by motion of the cervix
	Bilateral adnexal tenderness
Additional criteria	Oral temperature >38°C (100.4°F)
	Abnormal vaginal discharge on examination
	Erythrocyte sedimentation rate >15 mm/hr
	Elevated C-reactive protein
	Documented gonococcal or chlamydial cervical infection
Definitive criteria	Fallopian tube visible or fluid-filled on ultrasonography
	Tubo-ovarian abscess on ultrasonography
	Laparoscopic abnormalities consistent with pelvic inflammatory disease
	Endometritis on endometrial biopsy

Adapted from Centers for Disease Control and Prevention. 1998 Guidelines for treatment of sexually transmitted diseases. MMWR 1998;47(RR-1):80; and Case definitions for infectious conditions under public health surveillance. MMWR 1997;46(RR-10):52.

Table 94.4. Minimum, Additional, and Definitive Criteria for the Diagnosis of Pelvic Inflammatory Disease

In patients with suspicious symptoms and signs, a fever higher than 38° C (100.4°F) is about 80% specific for PID but will incorrectly exclude the diagnosis in about 60 to 75% of patients who do have it (25 to 40% sensitivity). A peripheral white blood cell count of more than 10,000/mm^3 is approximately 90% specific but will incorrectly exclude the diagnosis of PID in about 40% of patients with PID (60% sensitivity). A C-reactive protein greater than 5 mg/dL and an erythrocyte sedimentation rate greater than 15 mm/hour are each approximately 50 to 80% specific for PID but will each incorrectly exclude the diagnosis in about 10 to 30% of patients who have it. Perihepatitis (Fitz-Hugh–Curtis syndrome), consisting of right upper quadrant pain and tenderness produced by inflammation of the liver capsule in association with PID, occurs in 5 to 10% of patients with either chlamydial or gonococcal PID. On transvaginal ultrasonography, about one-third of patients with PID will have visible fallopian tubes, and about one-fifth will have a demonstrable tubo-ovarian abscess (Fig. 94.10).

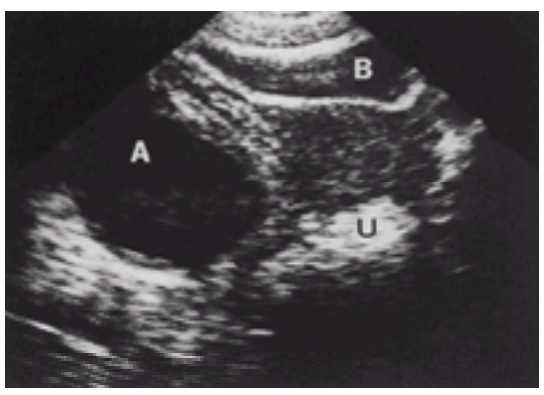

FIGURE 94.10. Transverse real-time sonogram of the pelvis of a 15-year-old patient with gonococcal salpingitis, demonstrating a 6 × 8 cm right tubo-ovarian abscess *(A)* containing a fluid-debris level. *U,* uterus; *B,* bladder.

A complication of PID that warrants prompt diagnosis is ruptured tubo-ovarian abscess. About 15% of tubo-ovarian abscesses rupture spontaneously. The symptoms and signs of a ruptured abscess may be mild if only a small amount of pus has leaked out, but the usual clinical picture includes peritonitis and shock. A pelvic mass is palpable in fewer than one-half the cases. Prompt surgical intervention can be lifesaving.

Laparoscopy confirms the diagnosis of PID in only about 60% of all patients who are suspected, either by gynecologists or by primary care physicians, on clinical grounds of having the disease. Conditions most often mistaken for PID are acute appendicitis, endometriosis, hemorrhagic and nonhemorrhagic ovarian cysts, and ectopic pregnancy. In up to 25% of women judged clinically to have PID, no abnormality can be identified laparoscopically.

The emergency physician must consider the possibility of pregnancy in adolescents with presumed PID for two reasons. First, ascending genital tract infection is rare during pregnancy. As a result, alternative diagnoses to PID, including ectopic pregnancy, should be considered, and hospitalization of the patient is recommended (see the following sections). Second, treatment with fluoroquinolones should be avoided during the first trimester of pregnancy. (Pregnant patients may receive metronidazole for PID because, in a recent meta-analysis, first-trimester exposure was not associated with an increase in the rate of major congenital malformations among live-born infants.)

An important pathophysiologic irony is the observation that tubal occlusion is associated more often with a relatively unimpressive clinical presentation of PID (i.e., long duration of symptoms, no signs of peritonitis, normal peripheral leukocyte count) than with “hot” clinical disease (i.e., short duration of symptoms, fever, peritoneal signs, leukocytosis). Similarly, chlamydial PID is associated with both a longer duration of pain at patient presentation and a higher risk of infertility than is gonococcal PID. Thus, if the diagnosis of PID is allowed to depend substantially on patients' appearance—as either “well” or “sick”—clinicians may be tempted to reject the diagnosis of PID and to withhold antibiotic treatment from those patients at highest risk of subsequent ectopic pregnancy and infertility.

The Kahn approach to the clinical diagnosis of PID is recommended for the emergency physician (Fig 94.11). This

strategy emphasizes diagnostic sensitivity for women with relatively mild illness, encouraging clinicians to err on the side of providing rather than withholding antibiotic treatment, and diagnostic specificity for women with relatively severe illness, focusing on the consideration of major competing diagnoses.

FIGURE 94.11. Strategy for diagnosis of pelvic inflammatory disease. Minimal laboratory evaluation should include tests for gonococcal and chlamydial cervicitis. Expanded laboratory investigation may include, in addition to the minimal evaluation, complete blood count, C-reactive protein or erythrocyte sedimentation rate, and pelvic or transvaginal ultrasonography. (Adapted from Kahn JG, Walker CK, Washington E, et al. Diagnosing pelvic inflammatory disease. JAMA 1991;266:2594–2604.)

Management

The CDC guidelines for the treatment of PID (1998) are summarized in Table 94.5. The antibiotics listed were selected for their effectiveness in combination against *N. gonorrhoeae, C. trachomatis,* and the aerobes and anaerobes responsible for polymicrobial PID. Principal differences between the 1998 treatment guidelines and previous versions of these guidelines are 1) ultrasonographic findings of fallopian tube fluid and thickening are included as definitive criteria for the diagnosis of PID; 2) the previous recommendation that all adolescents with PID be hospitalized is eliminated; 3) 24 hours, rather than 48 hours, of parenteral treatment is recommended after clinical improvement; 4) clindamycin is omitted as an alternative to metronidazole in the oral ofloxacin/metronidazole treatment regimen; and 5) repeat evaluation for *N. gonorrhoeae* and *C. trachomatis* 4 to 6 weeks after the completion of therapy is presented as optional.

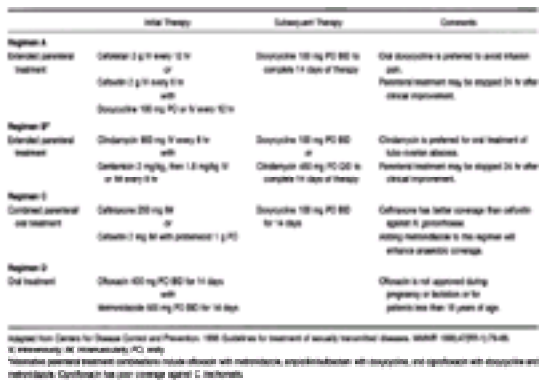

Table 94.5. Treatment Regimens for Pelvic Inflammatory Disease

Hospitalization is recommended for any patient with PID whose diagnosis is uncertain, particularly if ectopic pregnancy or appendicitis seems likely, for patients with severe clinical illness, including those with fever or suspected pelvic abscess, and for patients who are either immunodeficient or pregnant. Parenteral treatment, on either an outpatient or an inpatient basis, is recommended for patients likely to fail a course of oral antibiotics because of either poor compliance or vomiting and for those whose illnesses have not responded to prior oral antibiotics.

The follow-up of outpatients should include a return visit after about 3 days of treatment. The average duration of symptoms among women with gonococcal salpingitis treated with oral antibiotics is 3 to 4 days; the corresponding interval for nongonococcal salpingitis is 4 to 6 days. A poor response to therapy should alert the physician to the possibilities of inadequate compliance, abscess formation, or an alternative diagnosis.

Follow-up for all patients should include reexamination at the end of antibiotic therapy to check for residual pelvic tenderness and adnexal masses. To identify patients with persistent or repeated infection resulting from noncompliance with antibiotics or an untreated sexual partner, follow-up tests for gonococcal and/or chlamydial cervicitis should be scheduled 3 to 4 weeks after the end of treatment. The importance of identifying and treating sexual partners of women with PID cannot be overemphasized. About 25% of such men have asymptomatic urethritis and are unlikely to seek treatment on their own. If contact tracing fails, these men become part of the reservoir of undetected carriers of STDs. All patients with gonococcal and chlamydial infections should be counseled about the HIV and offered serologic screening for both syphilis and HIV infection.

Genital Warts

Background

Genital warts, or *condylomata acuminata,* are multicentric, exophytic tumors on anogenital skin (Fig. 94.12) caused by the DNA-containing human papillomavirus (HPV), most commonly by HPV types 6 and 11. Although HPV infections are not reportable, many venereologists believe they are the most common STDs in the United States. National Disease and Therapeutic Index survey data show that consultations with private physicians for genital warts numbered approximately 60,000 visits in 1966, peaked at nearly 360,000 visits in 1987, and totaled 253,000 visits in 1995. The HPV types that produce most anogenital warts are considered to have low potential for malignant change. HPV infection of the uterine cervix, which is associated with cervical dysplasia and cancer, occurs at an annual incidence of 9 to 20% in college-age women.

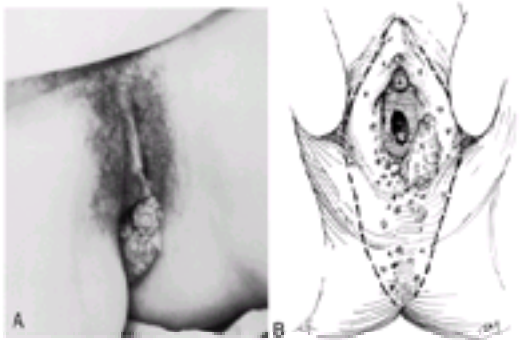

FIGURE 94.12. A. Large vulvar and perianal genital warts in a 15-year-old patient. **B.** In females, genital warts are most commonly located along the posterior margin of the introitus, inside the vagina, and on the labia minora.

Although HPV type 2 (associated with cutaneous, common warts) has been identified in anogenital warts in children, suggesting autoinoculation or heteroinoculation, nearly all genital warts in adolescents and adults, and some in children, are transmitted from person to person by sexual contact. The time from contact with an infected partner to the appearance of genital warts is estimated to be 1 to 3 months. However, the concept of an incubation period does not apply readily to the large number of infections that remain subclinical for long periods.

Pathophysiology

Grossly, genital warts are hyperplastic lesions that occur on squamous epithelium. On microscopic examination, the stratum granulosum contains foci of vacuolated cells. Acanthosis, parakeratosis, and hyperkeratosis are characteristic findings. The presence on Papanicolaou smear of koilocytes—intermediate, often multinucleated squamous cells with perinuclear halos, pyknotic nuclei, and dense peripheral cytoplasm—indicates cervical HPV infection.

Clinical Manifestations

Most patients with genital warts either have no complaint or report noticing “bumps” in the genital area. Uncommonly, large perianal warts can be painful and interfere with defecation. Prepubertal girls with vulvovaginal warts may have a bloody vaginal discharge. Because HPV infection in males is so consistently asymptomatic, most female patients are not aware of their exposure to an infected partner.

Warts can occur anywhere on the perineum, but their growth seems to be encouraged by moisture. The most common locations in females are the posterior fourchette, adjacent areas of the labia minora and majora, and the lower vagina (Fig. 94.12). Single warts 1 cm or more in diameter and clusters of seedlings, each a few millimeters across, are both common. Warts can be velvety and flat or papillomatous. Large warts often contain distinct cauliflowerlike lobulations. On the cervix, acetowhite infected areas are usually seen only with colposcopy. Most visible lesions in men involve the penile frenulum or coronal sulcus. Immunodeficient patients are particularly susceptible to extensive or severe disease with an increased risk of malignant change. Genital warts must be differentiated from *condylomata lata,* a contagious manifestation of secondary syphilis (Fig. 94.13), *molluscum contagiosum,* and, in men, from pearly penile papules.

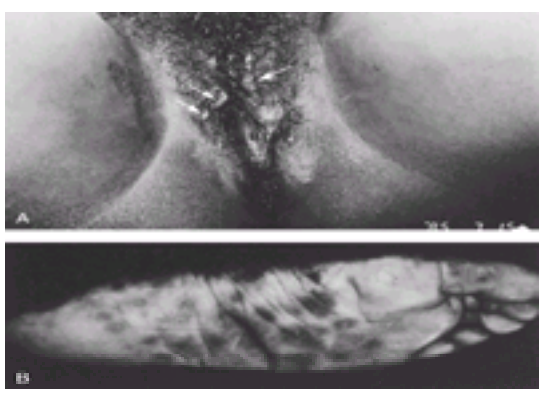

FIGURE 94.13. A. Vulvar condylomata lata of secondary syphilis in a 15-year-old patient. **B.** Macular rash on sole of foot of same patient.

Management

The diagnosis of genital warts is easy to make in patients with obvious lesions but can be more difficult in patients with flat warts or “microwarts” of the vulva. A magnifying lens or colposcope can be used to inspect suspicious areas that have been soaked in 5% acetic acid for 5 minutes. Infected skin, areas of nonspecific inflammation, and skin treated with podophyllin will turn white after soaking. To exclude syphilis, patients should also receive serologic screening.

Although anogenital warts in young children can result from vertical transmission or nonsexual contact with common warts, sexual abuse is another possible source of infection. The management of a child with genital warts should include either consultation with an expert in child abuse and neglect or a report to the state child protective service agency (see Chapter 128). Parents of children with genital warts should be examined for both common and genital warts. Excisional biopsy is preferred to ablative treatment for warts in children because histologic examination of the biopsied tissue can confirm the clinical diagnosis. Viral typing of anogenital warts in children may suggest abuse if a condylomatous HPV type is identified but cannot exclude sexual contact if a cutaneous type is found because fondling is a common manifestation of child sexual abuse.

The goal of treatment is the removal of bothersome tissue. Eradicating visible lesions does not end the viral infection. Whether it reduces contagiousness is uncertain. Spontaneous improvement or resolution of genital warts occurs in a minority of patients. Each of the several available treatment methods has advantages and disadvantages, none is more than about 50 to 60% effective, and recurrences are common. Podophyllin resin and trichloroacetic acid (TCA) are destructive agents that are applied topically. Podophyllin resin, in solutions of up to 25% concentration in tincture of benzoin, and TCA 80% solution are applied by the clinician. Podofilox in a 0.5% gel or solution and 5% imiquimod cream, an immune response modifier that induces cytokines, are available for self-application by patients.

Systemic absorption of podophyllin can produce bone marrow suppression, peripheral neuropathy, coma, and death. It is a teratogen and has been associated with stillbirths. Podophyllin should not be used during pregnancy or on warts that are large, bleeding, or located on mucosal surfaces. Safe maximum doses of 10% podophyllin solution are 4 mL for patients weighing more than 40 kg, and 0.1 mg/kg for children. TCA can be applied to mucosal surfaces and can be administered to pregnant patients. However, TCA has a viscosity lower than water and can spread to unaffected skin rapidly, producing patient discomfort during application more often than does podophyllin. Imiquimod commonly produces local itching, erythema, and burning but is generally tolerated well by patients.

For extensive or recurrent disease or when repeated applications of podophyllin, TCA, or imiquimod are not successful, alternative treatments include surgical removal, cryotherapy, and intralesional interferon. All women with genital warts should be referred to a primary care clinician for gynecologic care, including Papanicolaou screening.

---

[1] All 50 states have acknowledged the confidential nature of communications between an adult and a physician. This right of confidentiality is extended to minors seeking treatment for certain sex-related problems. All states allow adolescents to receive outpatient treatment for STDs without parental consent or notification (limitation: if 14 years or older in Hawaii, Idaho, New Hampshire, North Dakota, and Washington). In 1977, the Supreme Court ruled that minors have a right to contraceptive privacy (Carey *v.* Population Services International). This ruling has been extended both by federal agencies that provide contraceptive services and by many states to permit minors to obtain prescription contraceptives without parental consent or notification (exceptions: if 14 years or older in Hawaii, if patient has ever been pregnant in Oklahoma). Many states require minors to obtain parental consent or approval from a judge to receive an abortion. Emergency physicians should familiarize themselves with the relevant current laws of their own states.

ACUTE RESPIRATORY FAILURE

Background

Respiratory disease accounts for almost 10% of pediatric emergency department (ED) visits. Of all pediatric hospital admissions, approximately 20% result from respiratory illness in children. Respiratory illnesses continue to be a major cause of mortality (Table 95.1). Fortunately, newborn mortality from respiratory illness secondary to prematurity, which was as high as 10,000 deaths per year in the 1980s, has decreased in the last decade. New illnesses such as human immunodeficiency virus (HIV) have accounted for a small but significant increase in mortality as shown in Table 95.1.

Age (yr)	<1	1–4	5–9	10–14	15–19	All

Respiratory failure	15	14	7	3	10	49

From Centers for Disease Control and Prevention, US Health Statistics 1995—ICD9 code by age. (1995 Mortality Tables on Web Site).
SIDS, sudden infant death syndrome; *RDS*, respiratory distress syndrome; *HIV*, human immunodeficiency virus.
*Pulmonary infection includes viral pneumonia, bronchiolitis, influenza, pneumococcal infection, others, and nonspecified pulmonary infection.
†Other includes assorted alveolar disease, pneumothorax, and unspecified pulmonary causes of death.
‡Suffocation includes choking on foreign body or food and mechanical suffocation.

Table 95.1. Deaths from Pediatric Respiratory Disorders, 1995

Many different diseases may lead to respiratory failure (Table 95.2), including disorders outside the respiratory tract. This section discusses the pathophysiology and clinical manifestations of respiratory failure as well as a general approach to treatment. Management of specific disorders can be found in subsequent sections of this chapter as well as in Chapter 84, Chapter 92, and Chapter 119, and other areas of the text.

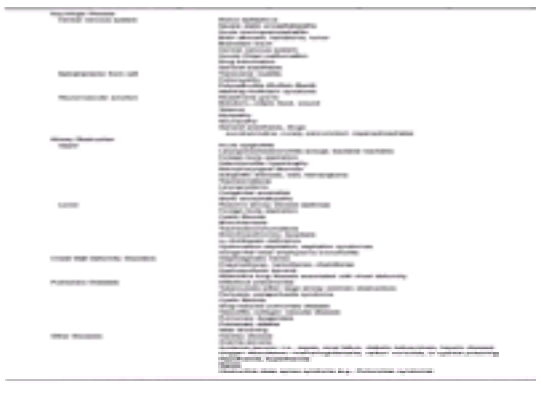

Table 95.2. Causes of Acute Respiratory Failure in Children

Pathophysiology

Acute respiratory failure may occur through a variety of mechanisms. By definition, failure indicates an inability of the respiratory system to provide sufficient oxygen for metabolic needs or to excrete the CO_2 produced by the body. Table 95.2 describes the causes of acute respiratory failure by anatomic location. The most common causes of respiratory failure are related to premature birth, with acquired pneumonitides second.

The neurologic system plays a major role in the control and maintenance of respiration. Children may suffer from either reversible or irreversible causes of central nervous system (CNS) respiratory failure. CNS disease may depress either the respiratory drive or the protective airway reflexes. Alternatively, neurologic disease may directly affect the peripheral nerves or muscles, impairing normal gas exchange through obstruction, fatigue, or ventilation-perfusion mismatch.

Most causes of upper airway obstruction in children are reversible but may lead to respiratory failure if untreated. The treatment approach should be both diagnostic and therapeutic because relief may be simultaneous in many instances (e.g., epiglottitis or aspirated foreign bodies). High-risk patients, such as those with severe static encephalopathy or anatomic head and neck problems but who usually maintain a patent airway when well, may have a partially reversible obstruction during respiratory infection, a seizure, or other acute medical problems.

Lower airway disease is a common cause of acute respiratory failure. Asthma accounts for the largest percentage of this group, but infections such as bronchiolitis or viral pneumonia are also common. Foreign body aspiration can involve the lower airway and continues to be a continued significant problem.

Chest wall deformities and mechanical impairments often play a role in respiratory failure. These entities act by diminishing the vital capacity in a restrictive pattern. The extra energy expended by the inefficient respiratory pattern may lead to both hypoxemia and hypercapnia. Often, children with mechanical problems (e.g., scoliosis) develop significantly increased effort to maintain normal minute ventilation during even mild upper respiratory infection.

Pulmonary parenchymal disease is often the cause of acute respiratory failure. Most children with acute parenchymal disease that causes respiratory failure are less than 1 year of age. In the presence of underlying cardiopulmonary disease, acute pulmonary infection may induce respiratory failure. This correlation is important in children with conditions such as bronchopulmonary dysplasia, congenital heart disease, cystic fibrosis, or other chronic lung processes.

In addition, numerous nonrespiratory diseases may precipitate respiratory failure. The pathophysiologies of the diseases listed in Table 95.2 are varied, but each alters the balance of O_2 consumption and CO_2 production such that they cannot be maintained by the respiratory system, leading to secondary respiratory failure.

Clinical Manifestations

Acute respiratory failure represents the severe end of the spectrum of respiratory distress; it signifies an imbalance of O_2 consumption and CO_2 production. Table 95.3 outlines the clinical findings and laboratory abnormalities. Few clinical manifestations appear early in the progression of respiratory failure. It is important to remember that prevention of the "blood gas"–proven respiratory failure should be the goal of the emergency physician. Therefore, in many cases, therapy should be initiated before the laboratory criteria have been fulfilled.

Clinical findings
Vital signs: tachycardia, tachypnea
General appearance: cyanosis, diaphoresis, confusion, restlessness, fatigue, shortness of breath, apnea, grunting, stridor, retractions, decreased air entry, wheezing
Blood gas abnormalities
$Paco_2$ ≥50 with acidosis (pH <7.25)
$Paco_2$ ≥40 with severe distress
Pao_2 <60 (or Sao_2 <90%) on 0.4 Fio_2
Pulmonary function abnormalities
Vital capacity (<15 mL/kg)
Inspiratory pressure (<25–30 cm H_2O)

Table 95.3. Diagnosis of Acute Respiratory Failure from Pulmonary Causes in Children

Management

Table 95.4 outlines a plan for management of acute respiratory failure. Resuscitation and basic life support are discussed in Chapter 1. The therapeutic approach must relieve or modify alveolar hypoventilation or arteriolar hypoxemia, while the physician simultaneously strives to establish an etiologic diagnosis.

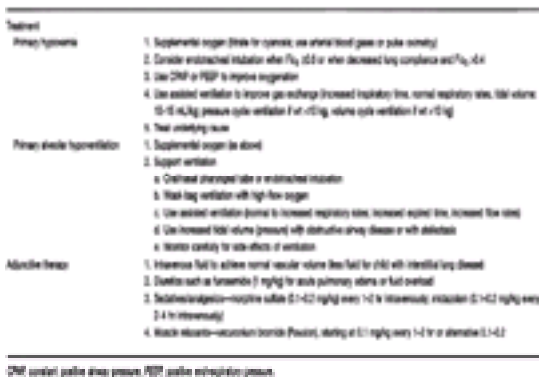

Table 95.4. Management of Acute Respiratory Failure

Treatment of respiratory failure is divided into three categories (Table 95.4). First, the physician should always assume that hypoxemia is present and should give sufficient supplemental oxygen (starting at 1.00 Fi O_2 in severe situations) to improve arteriolar oxygen levels. The goal of this procedure should be to achieve a minimal acceptable Pa O_2 of 60 mm Hg (SaO_2 greater than 90%) in newborns and 70 mm Hg (SaO_2 greater than 93 to 95%) in older children. If hypoxemia persists after adequate supplemental oxygen is administered, assisted positive-pressure ventilation should be initiated (mask bag reservoir, then proceeding to endotracheal intubation) to improve the efficiency of gas exchange. The amount of ventilation provided should be that which produces adequate chest wall expansion and delivery of gas. Usually, this will be achieved with a tidal volume of 10 to 15 mL/kg and a respiratory rate appropriate for the child's age (i.e., 20 to 30 breaths/minute in the young infant and 12 breaths/minute in the adolescent). Inspiratory flow rates need to be set to control the inspiratory:expiratory (I:E) ratio, which is normally around 1:2. Using a manometer in the endotracheal tube reservoir circuit may assist in determining whether unduly low or high airway pressures are generated with each artificial breath. When the patient has a stiff respiratory system or collapse of airways (atelectasis), higher pressures must be generated to sufficiently ventilate the child. If air trapping occurs (i.e., asthma, severe bronchiolitis, or bronchopulmonary dysplasia), the tidal volume and inflating pressure must be increased to adequately ventilate the alveoli. Although past practice strove to achieve normocapnia, more recent practice dictates a pressure-limited ventilation with peak pressures at 35 to 40 mm Hg to minimize the risk of barotrauma. This process maintains oxygenation while allowing varying degrees of permissive hypercapnia and is a safe alternative if the pH is maintained in a reasonable range. When the lung volume is diminished (i.e., neurogenic disease, hyaline membrane disease, interstitial pneumonia in immunocompromised hosts), positive end-expiratory pressure (PEEP) or constant positive airway pressure (CPAP) is indicated. This procedure will increase the end-expiratory lung volume (functional residual capacity) to a position on the compliance curve that allows easier alveolar ventilation.

In general, pressure-cycle or pressure-limited ventilators are used for children who weigh less than 10 kg (most children with acute respiratory failure). The machine settings should replicate the manual settings that produce adequate chest movement and alveolar ventilation. The I:E ratio is set in accordance with the type of disorder. Increased I:E ratios of 1:5 to 1 are used in alveolar-interstitial disorders to improve oxygenation. A normal or decreased I:E ratio is used in lower obstructive airway disease to improve exhalation time to excrete CO_2. From the emergency physician's perspective, the goal is to improve respiratory function, delivering oxygen and minimizing acidosis, without creating significant risk of the complications of ventilation.

Intravenous fluids should be titrated to maintain normal vascular volume as determined by observation of heart rate, blood pressure, peripheral perfusion, and urine output. In severely ill children who require more prolonged therapy in the ED, the measurement of central venous pressure may provide a more exact guide. Children with severe pulmonary interstitial involvement or pulmonary-capillary leak may benefit from a decreased vascular volume. This condition may reduce the need for high FiO_2 concentrations and CPAP and improve the mechanics of the ventilator. At other times, intravenous fluids may need to be transiently increased to improve cardiac filling, which has decreased secondary to reduction in venous return from elevated transpulmonary pressure.

The efficient use of assisted ventilation may require the use of sedation even in the early phases of emergency management. If the child is neurologically depressed, sedation may be contraindicated. In other cases, morphine sulfate 0.1 to 0.2 mg/kg every 1 to 2 hours may be given. A benzodiazepine is also a useful alternative if additional sedation is required. Midazolam 0.1 to 0.2 mg/kg intravenously can be given. Additional doses can be given as needed, generally on a 2- to 4-hour basis. Muscle relaxants are occasionally required to optimally ventilate children with severe respiratory failure. This treatment may be necessary for children with stiff lungs (e.g., severe interstitial pneumonia) or stiff chest wall (e.g., status epilepticus). Muscle relaxants improve chest wall compliance and reduce oxygen consumption. Vecuronium may be given initially in doses of 0.1 mg/kg every 1 to 2 hours (see Chapter 5).

BRONCHOPULMONARY DYSPLASIA

Background

Bronchopulmonary dysplasia (BPD) is a chronic lung disorder that may follow moderate to severe hyaline membrane disease (HMD) (Fig. 95.1) or other acute lung insults around birth. Children with apnea, complex congenital heart disease, or other illnesses requiring prolonged ventilation in the first weeks of life are at risk. The term *BPD* should be limited to children with neonatal lung pathology who are more than 28 days of postnatal age and who have significant clinical, radiologic, or blood gas abnormalities. The overall rate of BPD has dramatically decreased with the advances in newborn care and use of surfactant. In most industrialized nations, BPD is exceedingly rare in infants more than 32 weeks' gestation, but it remains common in infants who are very immature and weigh less than 1000 g at birth. Etiologic

factors have not been proven, but the following have been implicated: lung immaturity, oxygen therapy, positive-pressure ventilation (lung stretch), infection and inflammation, abnormal nutrition, and lung healing.

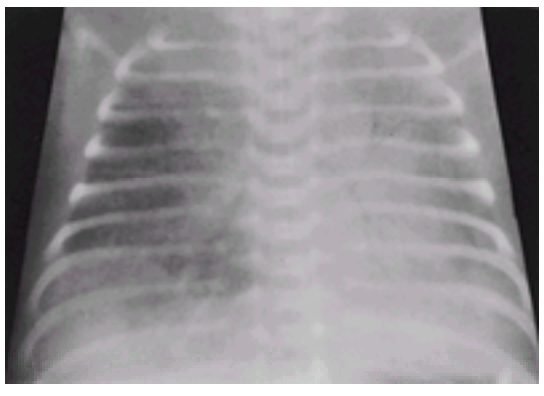

FIGURE 95.1. Hyaline membrane disease. This is one of twins born at 31 weeks' gestation. The chest film shows hypoaeration, diffusely opaque lung fields, air bronchograms, and loss of normal vascular shadows.

Clinical Manifestations

Typically, infants with BPD are discharged from the nursery initially at 3 to 6 months of age for home therapy, although more severely affected patients may require assisted ventilation for much longer intervals. These children have tachypnea and retractions at rest or during the mildest respiratory infections or fever. Their lungs are hyperinflated (increased anteroposterior chest diameter), and they may have crackles, wheezes, or decreased breath sounds in areas of the thorax. Some patients will manifest dyspnea and moderate to severe failure to thrive. Arterial blood gas (ABG) tensions show Pa_{O_2} less than 60 mm Hg (Sa_{O_2} less than 90 to 92%) and/or Pa_{CO_2} more than 45 mm Hg in room air, often despite respiratory rates of greater than 60 to 80 breaths/minute. Chest roentgenograms (Fig. 95.2) demonstrate varying amounts of hyperinflation; several patterns occur, including cystic areas with signs of fibrosis, which are often confused with congenital lobar emphysema; severe cystic fibrosis; and new infiltrates when previous radiographs are not available for comparison.

FIGURE 95.2. Bronchopulmonary dysplasia. This 2-month-old child was treated with mechanical ventilation during the first days of life for hyaline membrane disease. The chest film shows generalized overaeration and coarse modularity with multiple cystlike areas throughout both lung fields.

Management

Emergency physicians most often will evaluate children with BPD accompanied by acute respiratory infections. More than 50% of infants with BPD require admission within a year of their diagnosis for respiratory illness. Of particular importance is respiratory syncytial viral (RSV) infection, which occurs most often in winter months. RSV infections can lead to a deterioration in respiratory status or manifest with apnea only without significant acute pulmonary change. Management is primarily limited to supportive care: ensuring oral or intravenous intake, providing relief of hypoxemia, and when necessary, providing assisted ventilation for hypercarbia and acidosis. Although infants with BPD can often be treated as outpatients, care must be taken to determine the severity of the episode. Pulse oximetry can be beneficial in assessing the degree of oxygen saturation and may obviate the immediate need for arterial puncture in mild illness (in general, A saturation 90% or greater is equivalent to a Pa_{O_2} more than 60). ABG is always necessary when signs and symptoms may be the result of hypercapnia or when cyanosis, respiratory distress, or deterioration from baseline cannot be easily reversed. ABGs may be misleading in that decreases in Pa_{O_2} may reflect hypoxia from crying rather than from worsening pulmonary function. A chest radiograph is helpful in most episodes but often merely corroborates clinical changes. Indications for admission include a respiratory rate above 70 to 80 breaths/minute (or significant change from baseline), increasing hypoxia or hypercarbia, poor feeding associated with respiratory symptoms, apnea, or new pulmonary infiltrates. Parental fatigue or stress are also important factors to consider. If the acute exacerbation is mild, outpatient therapy may be indicated. Home therapy may include supplemental oxygen, bronchodilators, and corticosteroids. Most children with BPD have had trials of b-agonists. Nebulizer delivery is favored as it may be easier to use during the infant's sleep time. Some children benefit from diuretic therapy and have a need for increased oxygen supplementation during the acute illness. Antibiotic therapy should be considered when the risk of bacterial infection appears higher. Studies have demonstrated that seasonal use of RSV immunoglobulin may reduce the clinical picture in the most

high-risk infants with BPD.

Interstitial Pneumonia

Background

The group of pulmonary diseases best known collectively as interstitial pneumonia (often with pulmonary fibrosis) is categorized by cause in Table 95.5. The multiple causes, often associated with no known insults, may result in end-stage lung disease requiring lung transplant for cure. Patients may have a disorder that includes multiple cystic areas in the periphery of the lung fields, separated by fibrosis of connective tissue. Usual interstitial pneumonia (UIP—cryptogenic or idiopathic fibrosing alveolitis) is uncommon in children and requires a biopsy for diagnosis. Desquamative interstitial pneumonitis (DIP) may also occur rarely in children. It is not diminishing in frequency as it is in adults and has a familial form. Pathologically, the difference is seen on biopsy; cellular infiltrates predominate in DIP, whereas fibrosis predominates in UIP. Lymphoid interstitial pneumonia (LIP), with a lymphocytic infiltrate, is somewhere between UIP and DIP pathologically and is more recently associated with HIV infection in up to 30% of perinatally transmitted disease (see Chapter 85). The prognostic implications are crucial to the differences among the disorders. DIP is usually sensitive to corticosteroids, with dramatic clinical improvement of pulmonary disease.

Environmental irritants	Sarcoidosis
Inorganic dusts	Inherited disorders
Organic dusts (hypersensitivity)	Neurofibromatosis
Noxious gases	Miscellaneous causes
Drugs	Celiac disease
Radiation	Whipple's disease
Collagen vascular disease	Weber-Christian disease
Rheumatoid arthritis	Histocytosis
Scleroderma	Hermansky-Pudlak syndrome
Systemic lupus erythematosus	

Table 95.5. Causes of Interstitial Lung Disease

Clinical Manifestations

Interstitial pneumonias are rare in children but may manifest in older patients or in immunocompromised children initially with dyspnea on exertion and later at rest. Children often have a concomitant nonproductive cough, and systemic symptoms, including weight loss, anorexia, and fatigue, may occur. Occasionally, hemoptysis or a “spontaneous” pneumothorax may be the first event. Physical findings may include tachypnea and tachycardia, with shallow excursions and bibasilar end-inspiratory rales. In severe cases, digital clubbing and cyanosis may be present. The chest roentgenogram (Fig. 95.3 and Fig. 95.4) may be normal or may show a diffuse reticulonodular infiltrate, especially in the lower lobes. Eventually, the restrictive disease will progress with decreased lung volume and a cystic “honeycomb” appearance. Pulmonary function testing reveals reduced vital capacity with reduced forced expiratory volume in 1 second (FEV_1) but normal FEV_1:FVC (forced vital capacity) ratio. ABG tensions or oxygen saturation predict severity by initial reduction during exercise and with progression during rest. The $PaCO_2$ usually remains normal until late in the course. Polycythemia may be present secondary to hypoxemia in severe cases.

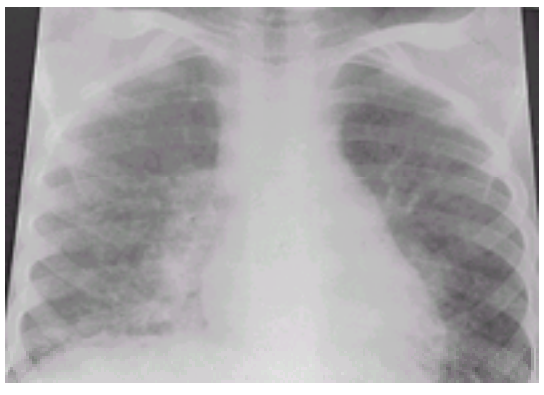

FIGURE 95.3. Sarcoid. A 9-year-old child with hepatosplenomegaly but no pulmonary complaints. The chest film shows interstitial lung disease with hilar adenopathy.

FIGURE 95.4. Idiopathic interstitial pneumonia. An 18-year-old boy with chronic granulomatous disease, after bone marrow transplant, with insidious onset of shortness of breath. The chest film shows bilateral interstitial disease in the lower lung field more on left side.

Management

Because the diagnosis requires biopsy to separate the entities, clinical concerns include 1) how to manage the new patient with suspected UIP, DIP, or LIP and 2) how to manage the child with known interstitial disease and acute illness. The child with characteristic history and physical findings will need admission to the hospital and assurance that the oxygen saturation is satisfactory at rest (by ABG or pulse oximetry). Referral to a pediatric pulmonologist should be made. The workup will usually include pulmonary functions (with diffusion capacity and exercise testing). High-resolution computed tomography (CT) has become an important adjunct because it produces much greater detail on abnormal lung morphology than does a routine chest radiograph. A ventilation-perfusion scan is often obtained, and in some instances, a cardiology consultation may be beneficial. Transthoracic lung biopsy (now often done by thoracoscopy) is the preferred procedure to establish the diagnosis and begin therapy. The older child with only mild impairment may not have to be admitted immediately but does need close follow-up and initial ABG and complete blood count (CBC) (to detect polycythemia), as well as studies, such as antinuclear antibody (ANA) and serum immunoglobulins, to detect vasculitis. Of concern in the differential diagnosis with presumed LIP would be the possibility of an immunocompromised host or HIV infection, which may necessitate a bronchoalveolar lavage to rule out infection, such as *Pneumocystis carinii.* In general, therapy consists of low-flow oxygen and a trial of systemic corticosteroids. Final data on use of other immunosuppressants are still pending, although in many cases, the results appear promising.

The child who presents in relapse of a diagnosed interstitial pneumonia should be assessed in a similar fashion. The physician should test for hypoxemia and treat it. The specific history revealing premature discontinuation of steroids in DIP may account for an acute relapse. Unfortunately, these diseases may progress despite aggressive therapy. Admission for supportive therapy may be helped by use of gallium scan or bronchoalveolar lavage, which measure severity of disease through the finding of active quantitative results of macrophage activation. Patients with active interstitial disease require close follow-up by a pediatric pulmonologist.

Aspiration Pneumonia

Background

Pneumonia is an inflammation of the lung tissue that may follow either a noninfectious or infectious insult, often involving the pathogens entering directly down the respiratory tract. The common infectious causes of pneumonia are discussed in Chapter 84. Although the pathophysiology of these pneumonias may directly involve aspiration of various pathogens, the term *aspiration pneumonia* has become commonly associated with the consequences of inhalation of oropharyngeal or stomach contents. In contrast to episodic pneumonia in an otherwise healthy child, aspiration pneumonia is most common in children with debilitation, altered consciousness, and CNS disorders that impair normal swallowing or protective airway reflexes. Other important causes of aspiration pneumonia are disorders of esophageal motility or problems with gastric emptying, and obstructive lesions such as tracheoesophageal fistula or, rarely, duodenal stenosis. Institutionalized children are often afflicted with this disorder. However, aspiration pneumonia can also occur in healthy children who have full stomachs when undergoing emergency procedures, in otherwise healthy children following seizures, or in children with decreased intestinal motility caused by pain, trauma, or analgesic administration.

Pathophysiology

Wynee and Modell have comprehensively reviewed the pathophysiology of aspiration pneumonias, which may be classified in two groups, based on the pH of the aspirate. A critical pH (2.5), below which severe lung damage is likely to occur, has been described.

Acid Aspiration

Aspirations in humans are considered acidic if the pH of the aspirate is less than 2.5. Experimentally, as the pH decreases below this level, the severity of lung injury increases. The volume and distribution of the aspirate are also important: large, poorly localized aspirates are most damaging. Likewise, aspirates with high bacterial content, such as those in patients with bowel obstruction, are associated with high morbidity. Acid aspiration causes a severe chemical pneumonitis with direct injury to alveolar-capillary membranes. A hemorrhagic, granulocytic, necrotizing reaction generally follows.

Hypoxia from multiple causes can occur within minutes of acid aspiration. These causes include reflex airway closure;

destruction of surfactant, resulting in atelectasis; interstitial and alveolar edema after exudation of fluid and protein across damaged membranes; and alveolar hemorrhage and consolidation.

Nonacid Aspiration

Nonacid aspirates (pH greater than 2.5), such as from the oropharynx or with mixed aspiration, can cause either transient or sustained pulmonary damage. Many of the early effects seen after acid aspiration may also result from nonacid aspiration. Pulmonary edema, endothelial cell alteration, and peribronchial neutrophilic infiltration have all been described. However, alveolar neutrophilic infiltration and necrosis are minimal. The exact nature and extent of lung damage from nonacid aspirates depend greatly on the composition of the aspirate. In contrast to the rapid resolution of nonacid, clear liquid (saline, water) aspiration, a prolonged pathologic response follows aspiration of partially digested meat, vegetable, or dairy products in which small food particles may be present. Unlike the neutrophilic response to acid aspiration, a widespread mononuclear and granulomatous reaction is seen in these cases. When repeated aspirations of irritating food particles occur over an extended period, roentgenograms may show granuloma formation similar to that of miliary tuberculosis.

Infection

The role of infection in the pathogenesis of aspiration pneumonia is unclear. Most physicians agree that infection plays little or no role in the initial pulmonary complications as a result of aspiration. However, following acid aspiration, the injured lung is potentially vulnerable to bacterial infection. Bacterial pulmonary infection is a complication in up to half of these cases. Why most patients do not develop pulmonary infection is not well understood. Although normal gastric contents contain few, if any, bacteria, oropharyngeal secretions may contain up to 10^8 bacteria/cm^3. It is conceivable that bacteria in oropharyngeal secretions either do not always gain access to susceptible areas or are diluted by the aspirate to concentrations that can be cleared by local defense mechanisms.

Two distinct patterns of infection are seen in patients who aspirate. A localized necrotizing bacterial pneumonia, abscess, or empyema may result from a heavily infected inoculum. In nonhospitalized children, anaerobic organisms are generally responsible for these infections; in hospitalized patients, facultative anaerobes and aerobic organisms are more common. The second pattern of infection is that which follows large aspirates, usually of the acid type. Aerobic, rather than anaerobic, organisms predominate here; Gram-negative organisms such as *Pseudomonas aeruginosa* and Gram-positive organisms such as staphylococci are often isolated. Of particular risk are children with bowel obstruction who develop aspiration syndromes.

Clinical Manifestations. Aspiration pneumonia should be suspected in any at-risk child who has signs of respiratory distress. The actual aspiration is often witnessed or vomitus is present in the immediate vicinity, suggesting the possibility of aspiration.

The clinical manifestations of pneumonia are discussed in Chapter 84. Most often, after the aspiration of gastric contents, a brief latent period occurs before the onset of respiratory signs and symptoms. More than 90% of patients are symptomatic within 1 hour, and almost all patients have symptoms within 2 hours. Fever, tachypnea, and cough are usually seen. Hypoxia is common. Apnea and hypotensive shock are less common. Sputum production is usually minimal.

The physical findings in patients with aspiration pneumonia are not dissimilar from those in patients with pulmonary infections resulting from either bacterial or viral causes. Diffuse crackles and wheezing are common; cyanosis appears with progression of the diseases. Chest roentgenograms (Fig. 95.5A and Fig. 95.5B) may show either localized or diffuse infiltrates, which are often bilateral. The chest roentgenogram of a patient who has aspirated stomach contents may evolve suddenly from normal to complete bilateral opacification within 8 to 24 hours.

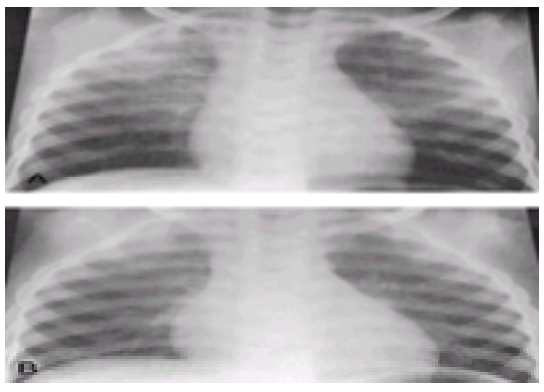

FIGURE 95.5. A. Blood aspiration. A 3-year-old boy with tachypnea 1 day after surgery for enlarged adenoids/tonsils. Chest film shows an infiltrate in the right upper lobe and left lower lobe. **B.** Blood aspiration (see **A**). The chest film 2 days later shows clearing of the infiltrate in the right upper lobe and left lower lobe.

Management. The suspicion of aspiration should be confirmed with a chest radiograph. Children with a significant aspiration pneumonia (lobar infiltrates, moderate to severe respiratory distress) require admission to the hospital. Table 95.6 outlines therapeutic modalities that may be useful. Some children who aspirate may have radiographs that are significantly abnormal in the face of minimal clinical symptoms. A common example is that of mild hydrocarbon aspiration.

Proven measures	Optional modalities
Suction	Corticosteroids
Airway protection	Antibiotics
Oxygen	

Table 95.6. Initial Treatment of Aspiration Pneumonia

In the acute-care setting, children who aspirate stomach contents require primarily supportive care. Specifically, prevention of further aspiration by adequate oropharyngeal suctioning and proper positioning should be the rule. The pulmonary signs and symptoms associated with aspiration of stomach contents may resolve quickly with supportive care or progress to respiratory failure, with the subsequent development of bacterial superinfection over a period of days. Intubation of the trachea is indicated if the airway reflexes are inadequate or if respiratory failure ensues. Supplemental oxygen should be administered, as determined by pulse oximetry or direct measurement of oxygenation with an ABG. The management of subsequent bacterial infection is addressed in the following section.

The use of corticosteroids in the treatment of aspiration pneumonia is controversial. Because experimental evidence indicates at best minimal benefit from steroids in acid aspirations and because these drugs may be contributing factors in the development of secondary bacterial pneumonia, their administration is not indicated in the ED.

Another consideration in the therapy of aspiration pneumonias is the role of prophylactic antibiotic administration. Because fever, purulent sputum, leukocytosis, and pulmonary infiltrates all may result from chemical pneumonitis alone and because no strong data exist that support the use of prophylactic antibiotics in children who acutely aspirate stomach contents, a reasonable initial approach is to defer antibiotic treatment in favor of careful observation.

Assuming that prophylaxis is not given following the aspiration of stomach contents, and clear signs of infection later develop, the choice of antibiotics can be guided by both the clinical setting and the results of properly obtained specimens for culture. Community-acquired pneumonias generally involve anaerobes and are adequately treated with penicillin, whereas nosocomial infections require antibiotics effective against both aerobes (including *Staphylococcus aureus* and Gram-negative bacilli) and anaerobes. A combination such as clindamycin and gentamicin is often used. In neurologically impaired children, with either aspiration or tracheostomy-associated pneumonia, antibiotics effective against penicillin-resistant anaerobic bacteria (i.e., clindamycin or ticarcillin-clavulanate) have been shown to produce clinical and microbiologic responses superior to those associated with agents less effective against these organisms.

Pulmonary Embolism

Background

Pulmonary embolism is largely a disease of adults, afflicting more than 500,000 patients per year in the United States. In autopsy series, the reported incidence of this disorder ranges from 1 to 4% in children and up to 8% in teenagers. In the adolescent population, the incidence of pulmonary embolism is reportedly approximately 1 case per 1,300 hospital admissions. In Cincinnati, over a 20-year period, a retrospective review identified only 20 cases, with an average patient age of 18 years (range, 10 to 20 years).

Perhaps one reason for the uncommon occurrence of pulmonary embolism in children is that generally healthy individuals are rarely afflicted. Major risk factors identified in children include ventriculoatrial shunt(s), trauma, congenital heart disease, infection (e.g., bacterial endocarditis), neoplasia, central venous catheters, prolonged immobilization, surgery, and severe dehydration. Adolescents have a unique set of risk factors for pulmonary embolism, which are a mixture of those for younger children and for adults. They include oral contraceptive use, trauma (particularly spinal injury), elective abortion, surgery, prolonged immobilization, infection, collagen vascular disease, intravenous drug abuse, rheumatic heart disease, severe dehydration, obesity, and renal transplantation.

Pathophysiology

Embolism is not a primary phenomenon, but it is by definition a complication of thrombosis elsewhere in the body. In adult populations, approximately 90 to 95% of pulmonary emboli originate within the deep venous systems of the pelvis and thigh. In contrast, the associated venous thromboses described in autopsy series in children are more commonly located in the chambers of the right side of the heart, mesenteric and cerebral vessels, or the inferior or superior vena cava. In adolescents, deep vein thrombosis is a common concomitant physical finding. In addition to venous thrombi, pulmonary emboli can arise from tumor cells, amniotic fluid, air, or fat (following fractures).

Obstruction of the pulmonary arteries by an embolus affects the pulmonary and bronchial circulation, the airways, and the function of the right and left sides of the heart. The degree of hemodynamic compromise correlates with the extent of arterial obstruction in patients without preexisting cardiopulmonary disease. In patients with underlying heart or lung disease, lesser degrees of obstruction may trigger severe pulmonary hypertension or cardiovascular collapse.

The cause of acute hypoxemia, which is seen in more than 80% of patients with pulmonary embolism, is not well defined.

Alveolar hypoventilation, intrapulmonary shunting, decreased diffusion capacity, and alveolar collapse secondary to a reduction in surfactant may all contribute.

Clinical Manifestations

The classic presentation of massive pulmonary embolism with severe circulatory compromise is easily recognized. However, most patients have nonspecific signs and symptoms and no pathognomonic laboratory abnormalities (Table 95.7). The most common presenting abnormalities in children and adolescents are pleuritic pain (which may radiate to the shoulders), dyspnea, cough, and hemoptysis. Additional findings may include apprehension, nonproductive cough, fever, sweats, and palpitations.

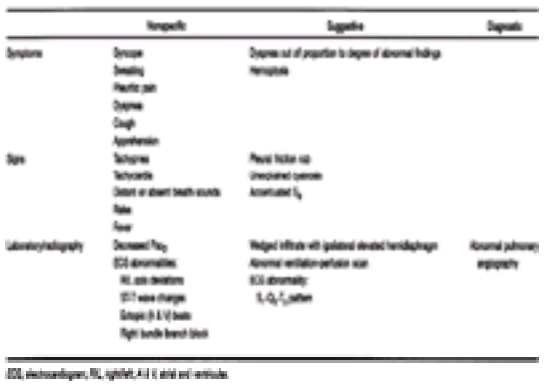

Table 95.7. Clinical Manifestation of Pulmonary Embolism

Aside from tachycardia, abnormalities on physical examination are often lacking. If a sufficiently large associated infarction is identified, there may be decreased resonance over the lung fields and a pleural friction rub. Breath sounds may be distant or absent, and rales may be heard. The presence of hypoxemia not completely explained by the underlying disease process or clinical state should suggest the possibility of pulmonary embolism.

The diagnosis of pulmonary embolism can be established with high probability based on ventilation-perfusion lung scan findings. The characteristic pattern is normal ventilation of poorly perfused areas of lung. Many physicians consider pulmonary angiography to be the preferred diagnostic method in previously healthy individuals. However, the reliability of this method diminishes with time after the acute embolism. The electrocardiogram (ECG) is neither a specific nor a sensitive indicator of pulmonary embolism. The S_1-Q_3-T_3 pattern that has been described with pulmonary embolus may be seen in other conditions, including a pneumothorax. Although the presence of a pulmonary infiltrate with an ipsilateral elevated hemidiaphragm is suggestive of a pulmonary embolism, there are no pathognomonic radiographic signs in the acute-care setting. ABGs generally indicate a decreased partial pressure of oxygen. However, about 15% of patients have a PaO_2 greater than 80 mm Hg and 5%, greater than 90 mm Hg. In one series, all patients had a decreased A-a gradient, if measured.

Management

In all patients strongly suspected of having a pulmonary embolism, a chest radiograph, ECG, and ABG should be obtained. If the clinical suspicion is high, regardless of the results, the patient should be admitted for initiation of definitive treatment. When the patient is vaguely suspected of having pulmonary embolism, all the aforementioned tests are normal, the patient's clinical condition permits, and the likelihood of pulmonary embolism appears low, the patient may be discharged with close follow-up. When abnormalities are uncovered, further diagnostic workup (i.e., ventilation-perfusion scan) and admission to the hospital should be considered.

Initial therapy includes supplemental oxygen, ventilatory support as indicated, and achievement of venous access. Intravenous heparin remains the mainstay of definitive therapy for pulmonary embolism because its onset of action is immediate and it is rapidly metabolized. However, it should be kept in mind that heparin is a common cause of in-hospital drug-related deaths in reasonably healthy adults, and it has been cited as a source of in-hospital complications in adolescents. The initial dosage is 500 units/kg daily given as a continuous intravenous infusion, which is adjusted to maintain the partial thromboplastin time (PTT) at 1.5 to 2 times the baseline value. Warfarin sodium is the orally administered anticoagulant usually used to maintain long-term anticoagulation. This drug may be initiated either at the time of initial treatment with heparin or 1 to 2 days thereafter. The required daily dose varies, depending on concomitant medical illness and other drug ingestion. In adults, the dose is adjusted to maintain the prothrombin time (PT) at twice normal. Warfarin is usually continued for 2 months beyond the time of diagnosis. However, the role of fibrinolytic agents in the treatment of children has not been established.

Pulmonary Edema

Background

Pulmonary edema refers to the abnormal accumulation of fluid within the alveolar spaces and bronchioles. Alterations of normal intravascular and interstitial hydrostatic and colloid osmotic pressures, changes in the permeability characteristics of the fluid-exchanging membranes in the lungs, and impairment of lymphatic drainage have been found to be instrumental in the generation of this condition. Pulmonary edema may occur in a variety of disorders, including adult respiratory distress syndrome (ARDS), left-sided heart failure, congenital heart malformations such as ventricular septal

defects, severe malnutrition, extensive burns, nephrosis, upper airway obstruction, asthma, bronchiolitis, pneumonia and other infections, hypervolemia, and poisoning with barbiturates, narcotics, alcohol, paraquat, epinephrine, hydrocarbons, and gases such as oxides of sulfur and nitrogen, hydrocyanic acid, and smoke.

Pulmonary edema can also develop in some highland dwellers who return home after a brief stay at sea level and in some sea-level dwellers soon after arriving at high altitude. This “high-altitude” pulmonary edema characteristically affects young people who are exposed to altitudes above 2700 m.

Pathophysiology

As previously noted, fluid accumulation in the lung is largely determined by the balance of vascular and interstitial hydrostatic and colloid osmotic pressures, vascular permeability, and lymphatic drainage. Edema may develop following the alteration of one or more of these factors, which vary according to the disease state involved. Many disorders are associated with increased pulmonary vascular bed hydrostatic pressures, resulting from elevation of vasculature pressures distal to the lung. These disorders include congenital conditions such as hypoplastic left heart syndrome, cor triatriatum, mitral stenosis, and left-sided heart failure, which may be seen with severe aortic stenosis, coarctation of the aorta, large arteriovenous fistulas, or myocardial disease. Left-to-right vascular shunting as seen in patent ductus arteriosus, ventricular septal defects, or iatrogenic shunts (e.g., Waterston) may lead to edema via increasing pulmonary vascular blood flow. Hydrostatic pressures are also raised by overaggressive administration of intravenous fluids.

A breakdown in the alveolar-capillary barrier with accumulation of protein-rich fluid in the interstitium and alveoli is the major and the initial manifestation of ARDS. This increased capillary permeability edema is the result of an assault on the pulmonary vasculature by various inflammatory cells. Cellular enzymes, metabolic products, and cytokines seem to be the major factors responsible for tissue destruction.

Decreased plasma colloid osmotic pressure is associated with pulmonary edema. This condition is seen in children with significantly lowered levels of plasma proteins, such as those with nephrosis, protein-losing enteropathies, massive burns, and severe malnutrition.

In patients with upper airway obstruction (Fig. 95.6A, Fig. 95.6B, Fig. 95.6C), exaggeration of the transmural pulmonary vascular hydrostatic pressure gradient is the most likely pathogenic mechanism. The highly negative pleural pressures that accompany upper airway obstruction tend to increase venous return (causing increased pulmonary vascular volumes), impair ejection of left ventricular blood, and cause highly negative pulmonary interstitial pressures, all of which contribute to transudation of fluid across pulmonary capillaries. In some patients, increased lung volumes may mask pulmonary edema on radiograph. The latter becomes manifest when lung volumes decrease following relief of the obstruction.

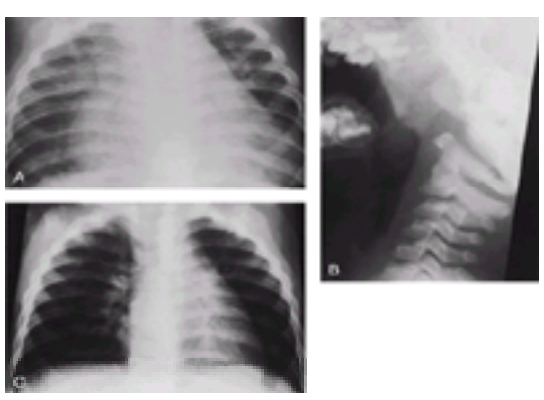

FIGURE 95.6. Cor pulmonale secondary to upper airway obstruction. **A.** This is a 2-year-old boy with tachypnea and dyspnea. The chest film show a large hematoma and mild interstitial edema. **B.** The lateral view of the neck shows obstructing enlarged adenoids and tonsils. **C.** The chest film 2 days after adenoidectomy shows a decreased heart size and improvement in interstitial edema.

A variety of clinical conditions are thought to alter the permeability of the alveolar-capillary membrane, presumably by damage to epithelial or endothelial cells. In some disorders, chemical mediators such as prostaglandins, histamine, and bradykinin may be influential in the genesis of pulmonary edema. Such is the case with asthma, hypersensitivity pneumonitis, Goodpasture's syndrome, and systemic lupus erythematosus. Pulmonary edema caused by denaturation of proteins and cellular damage is seen after the inhalation of several noxious gases, particularly those generated during fires. The inhalation of herbicides (i.e., paraquat) has also been associated with development of pulmonary edema. Other entities that alter alveolar-capillary membrane permeability include circulating toxins, such as snake venom and endotoxins from Gram-negative sepsis, and perhaps severe salicylate poisoning. The mechanism responsible for pulmonary edema that may accompany intracranial pathology is not entirely understood. Acute sympathetic discharge has been documented after head injury or sudden increases in intracerebral pressure. This reaction results in profound generalized vasoconstriction, increasing pulmonary-capillary pressure. The same mechanism might account for the pulmonary edema occasionally reported after seizures in children.

Clinical Manifestations

The onset of pulmonary edema is variable but may be rapid. Tachypnea, cough (often producing frothy, pink-tinged sputum), dyspnea, shortness of breath, and chest pain are commonly seen. Grunting often occurs in an effort to prevent lung collapse. On physical examination, the child may appear pale or cyanotic and have a rapid pulse. Decreased breath

sounds and moist (“bubbly”) rales are the most common auscultatory findings. However, these are generally absent with small increases in lung fluid. Indeed, auscultatory and roentgenographic findings may not manifest until the interstitial and extravascular fluid has doubled or tripled in volume.

Unless it is massive, acute fluid accumulation may not be detectable by chest roentgenogram. Lymphatic and interstitial fluid accumulations may be visible as Kerley A and B lines (septal lines) (Fig. 95.7). These lines represent interlobular sheets of abnormally thickened or widened connective tissue tangential to the radiograph beam. The A lines are located near the hilum of the lung, and the B lines lie in the periphery. Although other processes may produce these lines, when transient they are usually caused by edema. Flattening of the diaphragm on radiograph may also be a finding with pulmonary edema. This is presumably caused by air trapping that results from airway narrowing as a result of bronchiolar fluid collections.

FIGURE 95.7. Interstitial fluid from volume overload. This is a 2-year-old child with paraspinal sarcoma removed 6 months earlier. Before chest radiation he received a large fluid load. The chest film shows interstitial edema with Kerley's lines and bilateral small pleural effusions.

It should be kept in mind that if pulmonary edema is superimposed on another pulmonary process, the clinical and roentgenologic findings may be obscured by those of the primary illness. Similarly, once pulmonary edema is severe enough, it may be difficult to separate edema, atelectasis, and inflammation on the roentgenogram.

Management

The management of patients with pulmonary edema should ultimately be directed toward correction of the primary disorder. Initial efforts (Table 95.8) should be directed toward reversal of hypoxemia by the administration of oxygen and by mechanical ventilation if necessary. The latter has several beneficial effects, including reduced oxygen consumption through reduced work of breathing, improved oxygenation by prevention of alveolar collapse, and reduced fluid filtration in the lung by decreased pulmonary vascular volume and pressure from the positive intrathoracic pressures generated. CPAP therapy delivered via face mask has also been shown to be effective in some patients. In addition to satisfying the patient's oxygen demands, reversal of hypoxemia is often useful in relieving chest pain and is important to the metabolism of vasoactive mediators that affect microvascular permeability.

Oxygen	Venodilation
Diuresis	Morphine 0.1 mg/kg IV
Furosemide 1 mg/kg IV	Digitalis (see Table 82.7, for dosage)

Table 95.8. Treatment of Pulmonary Edema

Other therapeutic measures should be tailored somewhat to fit the patient's individual needs. When heart failure is the cause of pulmonary edema, in addition to oxygen and ventilation, diuretics (to decrease plasma volume), digitalis (to improve contractility), and bronchodilators (to improve contractility and afterload and to produce bronchodilation) are useful. Morphine dilates the venous system and may be helpful in relieving anxiety and dyspnea. In patients with ARDS, clinical studies have shown that the use of methylprednisolone does not improve outcome and may in fact increase the mortality and incidence of secondary infections.

The ability of mammalian lungs to gradually absorb instilled fluid has been known for some time. The process responsible for fluid removal has been identified as active sodium transport by alveolar epithelium. Alveolar fluid clearance can be augmented with b-adrenergic agonists, which enhance sodium transport. Long-acting b-adrenergic agonists have been demonstrated to increase alveolar fluid clearance in animals. When decreased plasma colloid osmotic pressure is an issue, albumin administration may be helpful. To minimize initial rises in vascular pressures,

colloids should be infused slowly, usually in conjunction with diuretics.

Pulmonary Hemorrhage

Background

Bleeding into the lung manifests clinically with hemoptysis, or coughing up blood, and pathologically with pulmonary hemosiderosis, the presence of hemosiderin in lung macrophages. Although hemoptysis is uncommon, it has many possible causes, some of which may manifest in a dramatic and life-threatening manner. Table 95.9 provides a differential diagnosis for pulmonary hemorrhage by category. The cause of hemorrhage should be sought to provide a specific diagnosis. Children with recurrent hemorrhage may have isolated cow's milk allergy or an idiopathic cause. Rarely, isolated hemangiomatosis manifests with hemorrhage. Airway and parenchymal causes include infection, infarction, and congenital anomalies.

Primary	Associated with Other Organ Dysfunction	Secondary	Airways	Parenchymal
Cow's milk allergy	Nephritis	Congestive heart failure	Bronchitis	Trauma
Idiopathic	Wegener's granulomatosis	Clotting disorders	Bronchiectasis/cystic fibrosis	Infection—tuberculosis, other
Hemosiderosis	Vasculitis—Henoch-Schönlein purpura	Malignancy	Airway anomalies	Infection
	Collagen vascular disease	Alveolar injury	Vascular anomalies, including hemangiomatosis	Neoplasm
		Drug	Foreign body	Cavitary lesion
		Radiation		
		Smoke injury		
		Acid aspiration		

Modified from Boat TF. Pulmonary hemorrhage and hemoptysis. In: Chernick V, Boat TF, eds. Kendig's Disorders of the Respiratory Tract in Children. 6th ed. Philadelphia: WB Saunders, 1998:53.

Table 95.9. Causes of Pulmonary Hemorrhage in Children

Clinical Manifestations

The hallmark of pulmonary hemorrhage is recurrent intrapulmonary bleeding with lung injury and secondary depletion of body iron stores. Therefore, the symptoms and signs include hemoptysis, recurrent pneumonias (manifest by fever, tachypnea, tachycardia, and coarse or fine crackles), and pallor. Emesis of blood arising in the pulmonary tree may mislead the clinician to investigate the gastrointestinal tract. Associated symptoms of fatigue and poor weight gain are common.

Laboratory findings after recurrent hemorrhage most characteristically include a microcytic, hypochromic anemia with low serum iron. Leukocytosis and eosinophilia may be present, and the stool usually tests positive for blood. Roentgenograms (Fig. 95.8) may show alveolar infiltrates that may be transient, localized processes or that may be diffuse and chronic. Cardiorespiratory embarrassment ensues in children with severe anemia. Severely affected patients may develop secondary restrictive lung disease with retention of CO_2.

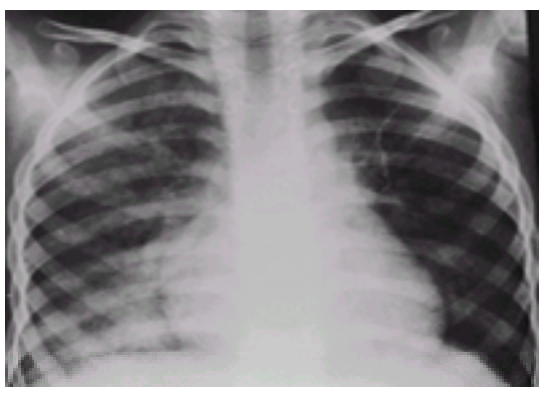

FIGURE 95.8. Idiopathic pulmonary hemosiderosis. A 5-year-old child with repeated bouts of pulmonary hemorrhage. The chest film shows diffuse radiopacities throughout both lungs (more on right side), with a well-defined alveolar opacity in the right lower lobe. Note the surgical sutures in left upper lobe.

A presumptive diagnosis can be made by finding siderophages (iron-laden microphages) in nasogastric washings; these macrophages will stain blue with the Prussian blue reaction (i.e., potassium ferrocyanide and hydrochloric acid). More definitive diagnosis requires the identification of typical macrophages obtained by bronchial lavage or lung biopsy.

Pulmonary function testing may reveal an obstructive pattern secondary to bronchial irritation from blood and, over time, a restrictive pattern from scarring and fibrosis.

Management

Most children with pulmonary hemorrhage have a chronic disease requiring supportive therapy for hypoxia and anemia in

the form of blood transfusions and supplemental O_2. Occasionally, pulmonary hemorrhage is so severe that it causes respiratory insufficiency or hypotension. Positive-pressure ventilation with PEEP is the preferred treatment in this situation; bleeding is usually not rapid or well enough localized to be identified and controlled by bronchoscopy. In allergic, vasculitic, and idiopathic hemorrhage, the use of corticosteroids is indicated as either methylprednisolone (2 mg/kg per day) or hydrocortisone (8 mg/kg per day) intravenously in three to four divided doses. When hemorrhage is caused by infection, especially tuberculosis, antimicrobial therapy should be instituted and steroids avoided. Admission is necessary to support the child until the cause of the process has been determined or acutely until the hemorrhage has been controlled. Bronchoscopy can be useful diagnostically to determine infectious causes and may localize bleeding sites. Occasionally, when the bleeding is brisk as in bronchiectasis with erosion to a bronchial vessel as in cystic fibrosis, embolization of vessels may be needed to stop the bleeding.

Pleuritis

Background

Pleuritis or pleurisy refers to inflammation of the pleural membranes, usually as a result of diseases elsewhere in the body. This inflammation may be associated with minimal or considerable accumulation of liquid in the pleural cavity, and remains a major cause of pulmonary morbidity in children. Specific references to the incidence of pleural effusions in various respiratory infections are made in Chapter 84. The surgical approach to pleural effusions is reviewed in Chapter 119.

The causes of pleural inflammation are varied (Table 95.10). Viral (e.g., coxsackievirus, Epstein-Barr virus, herpes zoster), mycoplasmal, bacterial (e.g., *S. aureus, Streptococcus pneumoniae, Haemophilus influenzae,* group A streptococcus, *Mycobacterium tuberculosis*), and fungal (e.g., histoplasmosis, coccidioidomycosis) infections from pulmonary, subdiaphragmatic, or more distant sites may all eventually involve the pleura. Neoplastic involvement may be primary or metastatic and may result in obstruction of lymphatic drainage, thereby promoting the accumulation of pleural fluid. Pulmonary embolism may cause pleural inflammation with or without effusion as a result of focal parenchymal necrosis. Trauma, both accidental and following diagnostic and therapeutic procedures in the chest, can irritate the pleura and lead to secondary infection. Pleuritis with or without effusion is seen in more than half of patients who have a systemic vasculitis such as systemic lupus erythematosus or sarcoidosis.

Transudative Pleural Effusions	Gastrointestinal diseases
Congestive heart failure	Pancreatitis
Cirrhosis	Esophageal rupture
Nephrotic syndrome	Subphrenic abscess
Acute glomerulonephritis	Hepatic abscess
Myxedema	Whipple's disease
Peritoneal dialysis	Diaphragmatic hernia
Hypoproteinemia	Peritonitis
Meigs' syndrome	Trauma
Sarcoidosis	Hemothorax
Vascular obstruction	Chylothorax
Ex vacuo effusion	Drug hypersensitivity
Exudative Pleural Effusions	Nitrofurantoin
Infectious diseases	Methysergide
Tuberculosis	Miscellaneous diseases
Bacterial infections	Asbestos exposure
Viral infections	Pulmonary and lymph node sarcoidosis
Fungal infections	Uremia
Parasitic infections	Postmyocardial infarction syndrome
Neoplastic diseases	Trapped lung
Mesothelioma	Congenital abnormalities of the lymphatics
Metastatic disease	Postradiation therapy
Collagen vascular diseases	Drug reactions
Systemic lupus erythematosus	
Rheumatoid pleurisy	
Pulmonary infarction/embolization	

From Light RW. Pleural effusions. Med Clin North Am 1977;61:1339.

Table 95.10. Differential Diagnosis of Pleural Effusion

Pathophysiology

The pleura is a double-layered, thin membrane that separates the lung from the chest wall, diaphragm, and mediastinum. The parietal pleura (outer layer) is adherent to the chest wall, and the visceral pleura (inner layer) completely covers the lungs except at the hili. In the healthy child, the two layers of pleura are in apposition, separated by only a thin layer of serous fluid. Fluid seems to enter the pleural space from a parietal pleura and to exit via the lymphatics and vasculature of the visceral pleura.

Several mechanisms have been linked by cause to abnormal pleural fluid accumulation, including changes in hydrostatic or oncotic pressures and diseases of the pleural surface that alter capillary permeability or affect lymphatic reabsorption of protein. On the basis of these mechanisms, pleural effusions can be classified as either transudates or exudates. Transudates occur as a consequence of altered capillary hydrostatic pressure or colloid osmotic pressure, as seen in congestive heart failure or hypoproteinemic states. Exudates result from any disease of the pleural surface that produces increased capillary permeability or lymphatic obstruction, such as pleural infection or tumor.

The determination of the nature of pleural fluid may be helpful from a diagnostic standpoint (Table 95.10). Traditionally, an effusion has been classified as an exudate if the total protein concentration exceeds 3.0 g/dL. However, use of this parameter alone results in inaccurate classification of more than 10% of effusions. Better separation of transudates and exudates can be made by comparing the concentrations of total protein and lactate dehydrogenase (LDH) in serum and pleural fluid. Although several investigators have tested modified versions, the criteria of Light et al. have been the most reliable in distinguishing exudative from transudative effusions. These criteria include a pleural fluid:serum protein ratio greater than 0.5, a pleural fluid:serum LDH ratio greater than 0.6, and a pleural LDH concentration more than two-thirds normal upper limit for serum. If any one of these critical values is exceeded, the effusion is an exudate.

Clinical Manifestations

The hallmarks of pleural disease are pain, shortness of breath, fever, and an abnormal chest roentgenogram. Inspiratory

chest pain from pleural inflammation is the most characteristic symptom.

In “dry” pleurisy, which is caused by a minor pulmonary infection, the patient is febrile with an irritating, nonproductive cough. The symptoms often follow an upper respiratory infection and often last only a few days. Patients are acutely ill appearing, with grunting respirations as a result of pain. Pressure over the involved area elicits tenderness. Upon palpation, a coarse vibration may be felt.

A pleural friction rub is most apt to be heard in pleural inflammation that is associated with little or no effusion. The sound has been variously described as low pitched with either a grating or squeaking quality. It is usually loudest on inspiration, but often it is also audible during expiration. Sometimes, the rub is confused with a low-pitched, nonmusical wheeze (rhonchus) produced by secretions partially blocking the airway. A vigorous cough will eliminate these secretions and sounds but will not affect the pleural friction rub.

Although symptoms of pleural effusion are varied and relate to the primary cause of the effusion, most patients complain of some degree of dyspnea. Pleuritic chest pain is also a common complaint and can occur before the accumulation of fluid. Characteristic physical findings include restriction of movement of the chest wall on the affected side, flatness to percussion, diminished to absent tactile and vocal fremitus, and decreased to absent breath sounds.

The physical findings of atelectasis of an entire lung and large pleural effusion are similar with one exception: both conditions produce dullness to percussion and absent transmission of voice and breath sounds. However, pleural effusion decreases the size of the hemithorax, causing the trachea to deviate away from the diseased side. On the other hand, atelectasis causes the trachea to deviate toward the diseased side.

Pleural effusion is the most common radiographic manifestation of pleural disease. The first roentgenographic sign of a pleural effusion is usually blunting of the costophrenic angles, producing wedgelike menisci that extend upward along the lateral chest wall. Similar collections are seen in the posterior costophrenic angles on lateral views. Larger effusions may be seen to extend up the entire lateral chest wall or retrosternally.

Pleural effusions may alternatively present with what at first appears to be unusual prominence or thickening of the interlobar fissures, or by wedge-shaped accumulations of fluid at either end of these fissures. The latter may appear as focal infiltrates or segmental atelectasis on some views. Although small effusions are easily overlooked on radiograph, with the proper technique, effusions as small as 5 to 25 mL can be demonstrated. In adults, pleural effusions are visible as a meniscus on lateral chest radiograph at a volume of approximately 50 mL. At a volume of 200 mL, the meniscus can be identified on the posteroanterior radiograph, whereas at a volume of 500 mL, the meniscus obscures the hemidiaphragm.

Management

The management of pleural disease is aimed at determining the cause, treating the primary disorder, and relieving associated functional disturbances. When no effusion is present, relief of chest pain is one of the most pressing issues. Analgesics, bed rest, and/or mild sedatives may be indicated. It should be kept in mind that irritability and restlessness may be a result of pain, which, in dry pleurisy, can occur with every phase of respiration.

The accumulation of pleural fluid usually provides relief from pain. Thoracentesis is indicated when fluid accumulation is extensive enough to cause dyspnea and/or for diagnostic purposes (Figure 95.9). Sonographic guidance can simplify and enhance the success of this procedure with small effusions. The complications of thoracentesis include pneumothorax, hemothorax, reexpansion pulmonary edema, and rarely, air embolism. The recommended technique for thoracentesis is given in Section VII, and details of management of fluid in the pleural space are reviewed in Chapter 119.

FIGURE 95.9. Approach to pleural effusion. [a]Consider simultaneous placement of small gauge (8–10 F) chest tube by Seldinger technique for large, free-flowing effusions.

Thoracentesis is the most commonly used method of external drainage of pleural fluid, but other techniques are also available. These techniques include image-guided catheter drainage, thoracostomy tube placement (which may be performed using the Seldinger technique), thoracotomy with debridement and directed chest tube placement, open pleural decortication, and video-assisted thoracoscopic pleural surgery (pleuroscopy). Of these available techniques, image-guided catheter drainage is the only one that might be routinely performed in the ED.

Image-guided percutaneous transthoracic drainage of infected pleural collections can be used in patients who have a diagnostic thoracentesis showing frank empyema. Fluoroscopy, sonography, CT, or any combination of these techniques

can accurately guide catheter placement. Image-guided catheter drainage is most effective in patients with short duration of symptoms, free-flowing or unilocular effusions, absence of thick pleural peel on CT scans, and fluid that can be easily aspirated by needle.

Pleuroscopy, another procedure generally not performed in the ED, may be used either as a diagnostic or a therapeutic procedure. Among the therapeutic purposes of pleuroscopy are 1) lysis of pleural adhesions in the management of pleural effusions, 2) removal of blood after trauma, and 3) performance of pleural toilet in the fibrinopurulent stage of empyema.

Diagnostic tests of pleural fluid should include gross and microscopic examination; Gram stain; and protein, glucose, LDH, and pH determinations. Cytology should also be performed if malignancy is known or suspected. On gross examination, empyema fluid is opaque and viscous, fluid high in cholesterol has a characteristic satinlike sheen, and chylous effusions are milky white. A clear or slightly yellow pleural fluid is generally a transudate; however, exudates may also appear clear. Concomitant blood and pleural fluid protein and LDH determinations can help physicians make the distinction, as previously discussed. The more protein and cells, the deeper the color and the more turbid the fluid.

Although pleural fluid pH measurements have not been reported in series of empyema in pediatric patients, these measurements have been found to be valuable in the management of adults. Pleural fluid pH values of greater than 7.2 to 7.3 are generally found in sterile fluids not requiring drainage. In adults, a pleural fluid pH of less than 7.3 limits the differential diagnosis to empyema, malignancy, collagen vascular disease, tuberculosis, hemothorax, or esophageal rupture; a pH of less than 7.0 is seen only in empyema, collagen vascular disease, or esophageal rupture. One notable exception to the previous statement is empyema caused by *Proteus mirabilis,* which causes an elevated pleural fluid pH. It is also important to remember that pleural fluid pH will be lowered in the face of systemic acidosis. Therapeutically, in adults, a pleural fluid pH of less than 7.2 suggests that the effusion will not resolve spontaneously and will require chest tube drainage. Pleural fluid should be collected anaerobically in a heparinized syringe and transported to the laboratory on ice to ensure proper pH measurement.

A pleural fluid:serum glucose ratio less than 0.5 has a similar differential diagnosis as low pleural fluid pH. In animal studies, both leukocytes and bacteria have been shown to use glucose anaerobically, resulting in reduced glucose concentration, increased carbon dioxide and lactate levels, and decreased pH. Diseases known to depress pleural fluid glucose (less than 60 mg/100 mL) include infectious causes, collagen vascular diseases, malignancies, and esophageal rupture.

Most commonly performed, but least helpful, is the white blood cell count. Although counts are generally higher (greater than 10,000/mL) in children with purulent effusions and lower (less than 1,000/mL) in clear transudates, values overlap considerably. In large series of both adult and pediatric patients, pleural fluid white blood cell counts have not been helpful in narrowing the differential diagnosis or in determining the need for or duration of closed chest tube drainage.

Needle biopsy of the parietal pleura, although easily performed at the bedside, is not generally performed in the ED. Complications include pneumothorax, hemothorax, and rarely, spread of infection or tumor to the chest wall.

Obstructive Sleep Apnea

Background

Obstructive sleep apnea (OSA) is often discussed in adult medical journals but receives little attention in pediatric literature. Although the cause of this disorder is incompletely understood, OSA is most likely a multisystemic result of respiratory failure, involving airway structure and dynamics, autonomic nervous system function, the cardiovascular system, and other systems. Because of this systemic interaction, OSA could fall within the confines of several chapters within this text. It is reasonable to suggest that OSA in infants represents an example of a mixed apnea syndrome, with a significant central component. As experience with this disorder in older children increases, understanding of its cause and management should improve.

The sleep apnea syndrome is one with a rich history of description in both the medical and lay literature. The term *Pickwickian* was coined by William Osler in 1918, referring to obese, hypersomnolent patients. This association stems from the description of an incredibly fat boy with persistent somnolence in Charles Dickens' *Posthumous Papers of the Pickwick Club.*

Numerous other accounts of sleep apnea associated with obesity have since appeared in international literature. Individual descriptions of afflicted patients resulted in a profusion of named syndrome types. Confusion in nomenclature and incomplete understanding of the pathophysiology of these disorders have thwarted the accumulation of good epidemiologic data regarding this syndrome in older patients. Obesity-hyperventilation is a rarely reported syndrome in children. The recent literature contains few large reviews. Larger series of OSA patients have appeared.

OSA that fulfills the accepted criteria for apnea (cessation of air flow at the nose and mouth for 10 seconds or longer despite continued respiratory effort) can occur in children. The exact incidence is unknown, but it is likely that OSA in children is more common than previously suspected. The wide range and frequent absence of symptoms in the awake child can make the diagnosis of OSA in this age group difficult.

Pathophysiology

Three main types of apnea have been described: central, mixed, and obstructive. Apnea affecting infants is discussed in Chapter 10. In older patients, a central sleep apnea syndrome may develop into a mixed or obstructive syndrome during the natural evolution of the disorder.

As mentioned previously, the exact pathophysiology of OSA is unclear. Diaphragmatic electromyelographic (EMG) studies of obese patients have shown inhibition of activity during initial segments of apnea. In obstructive cases, increased diaphragmatic activity has been noted after one or two breaths. Partial obstruction also stimulates the autonomic and central nervous systems, resulting in disturbed sleep. Partial obstruction causes the diaphragm to work harder to maintain normal air exchange. In children, these increased inspiratory efforts may result in daytime complaints and nighttime symptoms.

Children with craniofacial anomalies are at higher risk for obstruction shortly after birth and can develop obstructive sleep disorders and OSA. In children whose craniofacial anomalies reduce the size of the nasal cavity, nasopharynx, or oropharynx, the normal pharyngeal tissues or minimal hyperplasia of the lymphoid tissue of Waldeyer ring can cause varying degrees of obstruction, including sleep apnea.

Other children with abnormal neuromuscular systems are also prone to obstruction and sleep apnea. In these children, the pharyngeal tissues from the nasopharynx to the hypopharynx may collapse during sleep. Children with neuromuscular disorders often have chronic pulmonary disease and impaired ability to clear pharyngeal secretions, which further complicates their evaluation and management.

Clinical Manifestations

Because a child's age will influence the interpretation of certain complaints, symptoms associated with different diseases can be difficult to quantify. Guilleminault et al. were able to review a large group of children diagnosed with OSA and report their presenting features. Interestingly, many of their referrals came from school teachers and other others who were not the parents charged with the children's daytime care. Most (73%) were noted to have abnormal daytime sleepiness. Other commonly associated behavioral abnormalities included hyperactivity, continuous fighting with peers, crying easily (especially in younger children), short attention span, and quick shifts from hyperactivity to excessive somnolence and withdrawal behavior.

Older children complained of sleepiness, tiredness, and fatigue. Decreased school performance, especially with regard to language acquisition, was seen in some children. One-fourth of patients reported morning headaches, and more than half demonstrated signs of failure to thrive. Severe symptoms included massive obesity in 11%, hypertension in 8%, and acute cardiac or cardiorespiratory failure in 17%.

Disordered sleep is the most common symptom of OSA. All children report continuous snoring, which is interspersed with pauses and snorts. More than 80% have disrupted nocturnal sleep (e.g., nightmares, night terrors, sleepwalking), and 90% sweat profusely during the night. Intermittent or nightly enuresis is also commonly noted (26%). Chronic nighttime cough may also be observed as a result of intermittent aspiration of small amounts of pharyngeal secretions and may aggravate other chronic conditions such as asthma.

Adult patients generally complain of daytime tiredness, fatigue, and sleepiness. Other common symptoms include deterioration of memory and judgment, nausea, headaches, mood swings, and neurotic behavior. Polycythemia, hypertension, cardiac arrhythmias, anoxic seizures, gastroesophageal reflux, and esophagitis are less common associated serious consequences. Two-thirds of one group of adult patients were reported to be overweight (more than 20% over estimates of ideal weight). This presentation is occasionally seen in children, but most are not obese. Because it is difficult for affected children to eat and breathe at the same time, they are often in the lower 25th percentile by weight and appear to have failure to thrive.

Management

Any child with a definite history of apnea must be managed with caution and concern. Hospitalization in a monitored setting is the rule. At the time of presentation, children might not appear in extremis, by definition, during nonwakeful periods. However, these children run the risk of repeated apnea and the related complication of subsequent hypoxemia. As always, acute obstruction should be managed according to Advanced Cardiac Life Support (ACLS) protocols. The determination of the exact cause of disease is of secondary importance.

In addition to a thorough general medical evaluation, children with OSA generally require otolaryngologic consultation for airway evaluation and, if needed, planning for relief of obstruction. Many children with OSA have preexisting anatomic airway abnormalities (e.g., facial dysmorphia syndromes or enlarged lymphoid tissue) that require the expertise of an otolaryngologist.

Polysomnography is an accepted method for evaluating apnea; however, it is inconvenient and expensive. This method of evaluation is generally reserved for the most severely obstructed patients. Roentgenograms of the neck taken with the child lying on his or her back can be helpful, but are not a definitive method of diagnosis. Both radiographs and physical examination of the pharynx have similar limitations in that the dynamics of the tissues at night cannot be observed. Standardized recordings of breathing sounds can also be taken either in the hospital or in the patient's home. These tapes can be evaluated for the quality of respiratory noise and presence of interrupted breathing. The lack of measurement of respiratory effort is usually not a problem because most older children with OSA have associated loud snoring respirations.

Numerous methods of management of OSA have been suggested and studied. Patients with obesity-hypoventilation syndrome (Pickwickian syndrome) may benefit from maintained weight reduction. Unfortunately, weight loss in these patients often is either difficult to achieve or only temporarily successful. For some such patients, nasally administered CPAP successfully alleviates hypoventilation. Trials of progesterone and protriptyline have also been reported to have some degree of success. Occasionally, patients require artificial airway placement and/or supplemental ventilation.

Patients with hyperplasia of the tonsils and adenoids as their only cause for obstruction will often have dramatic relief of symptoms following tonsillectomy and adenoidectomy. Patients with craniofacial anomalies and with neuromuscular disorders also usually have significant improvement after adenotonsillectomy. Other surgical procedures can be helpful in relieving obstruction in children with craniofacial anomalies or neuromuscular degenerative disorders.

Unfortunately, patients with obesity-hypoventilation syndrome often have multiple system dysfunction. By the time many patients present for treatment, they have significant airway and weight disorders, as well as coexistent motor, learning, and psychological dysfunction. Successful therapy depends on coordinated psychiatric, medical, and rehabilitative services.

In adults with primary snoring or OSA, oral appliances have been shown to improve snoring and reduce apnea and hypopnea. The appliances modify the upper airway by changing the posture of the mandible and tongue. Although appliances are generally tolerable, oral discomfort probably decreases compliance rates, which vary from 50 to 100%. Nevertheless, in adults, oral appliances seem to present a useful alternative to CPAP, especially for those patients who cannot tolerate CPAP or who are not candidates for tonsillectomy, adenoidectomy, craniofacial surgery, or tracheostomy.

CHAPTER 96

Cystic Fibrosis

THOMAS F. SCANLIN, MD

Department of Pediatrics, The University of Pennsylvania School of Medicine, and Cystic Fibrosis Center, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Cystic fibrosis (CF) is the most common lethal inherited disease among Caucasians in the United States. CF is a generalized defect in all of the exocrine gland secretions. CF is inherited as an autosomal recessive condition. The CF gene and the most common mutation that causes CF have recently been identified. Most homozygotes for the disease have the “classical triad” of clinical findings: 1) chronic pulmonary disease, 2) malabsorption secondary to pancreatic insufficiency, and 3) elevated concentration of sweat electrolytes. However, it must be emphasized that the severity and the course of the disease vary greatly.

Whether CF is mild or severe, its course is generally a chronic progression of the pulmonary disease, and the severity usually correlates with the rate of progression. Many more CF patients are now surviving to adulthood and are leading active and productive lives. Several factors contribute to this improving survival rate, including more effective antibiotics, earlier diagnosis, and comprehensive care in CF centers. Another important factor in the improving outlook for CF patients is the prompt recognition and aggressive treatment of the serious, acute complications that can occur in this chronic disease.

Because CF affects the exocrine glands distributed throughout the body, it is understandable that such a wide variety of symptoms in several different organs can be associated with a single disease entity. It is impossible to discuss all features of the disease here, many of which are chronic rather than acute. However, several of the more common and severe symptoms of CF that are likely to be seen by a physician in an emergency department are listed in Table 96.1. A discussion of the clinical manifestations and treatment of these complications of CF form the basis of this section. If any of these conditions are present in a patient not previously diagnosed as having CF, the patient should be referred for diagnostic evaluation after treatment of the acute episode. The evaluation should include a sweat test performed using the quantitative pilocarpine iontophoresis method.

Meconium ileus	Pneumothorax
Rectal prolapse	Hemoptysis
Intestinal obstruction	Pulmonary exacerbation
Hypoelectrolytemia with metabolic	Cor pulmonale
alkalosis	Respiratory failure

Table 96.1. Common Manifestations of Cystic Fibrosis Requiring Emergency Interventions

PATHOPHYSIOLOGY

The exocrine glands, each of which performs a specialized function, are primarily affected in CF. Although the CF gene has been identified, the precise function of the gene product remains to be elucidated; therefore, it is not yet possible to describe precisely the pathogenesis of this complex disorder. Although it involves an enormous oversimplification, it is useful to consider the pathogenesis of symptoms in two large categories. First, viscous secretions result in obstructive phenomena in the respiratory and gastrointestinal tracts. Second, altered reabsorption results in electrolyte losses in the sweat glands.

The abnormally viscous mucous secretions and the chronic colonization of the respiratory tract with bacterial pathogens, predominantly *Staphylococcus aureus* and *Pseudomonas aeruginosa*, appear to be the major contributing factors in the progressive deterioration of pulmonary function that is characteristic of CF. The interplay of these two factors, mucous plugging and infection, produces a variable amount of hyperinflation, bronchiectasis, and atelectasis. Increasing ventilation-perfusion abnormalities and structural changes lead to chronic pulmonary insufficiency. Most CF patients

eventually die of respiratory failure complicated by cor pulmonale.

Pancreatic insufficiency occurs with the obstruction and dilation of pancreatic ducts and the production of viscous, low-volume, bicarbonate and enzyme-deficient pancreatic secretions. Abnormal intestinal mucins and biliary tract secretions have also been implicated in the intestinal malabsorption and obstruction seen in CF.

The high concentrations of sodium and chloride in the sweat of CF patients can lead to acute or chronic electrolyte depletion. The elevated sweat electrolytes are the most important criteria for establishing the diagnosis of CF.

Clinical Manifestations

Presentation

Patients who have CF but who have not yet been diagnosed with CF may present with a variety of chronic symptoms. Failure to thrive and a history of chronic respiratory and/or gastrointestinal symptoms are fairly typical. The respiratory symptoms may vary from a mild but persistent cough to recurrent pneumonia and atelectasis. Expiratory rhonchi and low-pitched wheezes are sometimes found on auscultation of the chest in CF patients. The atypical asthmatic who has digital clubbing, bronchiectasis, or a cough productive of purulent sputum may also have CF.

Frequent passage of pale, bulky, loose, and excessively foul-smelling stools is characteristic of CF. Patients with this presentation are often misdiagnosed as having chronic diarrhea or a milk allergy. The loose stools often prompt repeated formula changes for young children. Edema and hypoproteinemia may develop in children with CF and especially in those who are receiving a soy protein formula. In addition, a hemorrhagic diathesis resulting from vitamin K malabsorption has been reported.

In contrast to those patients with the more acute manifestations listed in Table 96.1, many patients with chronic symptoms will not require emergency treatment. However, proper management requires that they be referred for further evaluation, which should include a quantitative pilocarpine iontophoresis sweat test.

Meconium Ileus

CF often presents as intestinal obstruction secondary to meconium ileus in the neonatal period. A typical history is that after the first few feedings the infant develops abdominal distension and begins vomiting. The child usually has a history of passing little or no meconium stool. In addition to the obvious abdominal distension, peristaltic waves may be seen on the abdomen and a mass may be palpable. Three-view radiographic examination of the abdomen should be obtained promptly. The typical findings of uncomplicated meconium ileus include dilated loops of bowel and a bubbly, granular density in the lower abdomen. In many cases, air–fluid levels will not be seen (Fig. 96.1A). If associated signs of intestinal perforation are apparent, such as calcifications or free air in the abdomen, a laparotomy will be necessary. If no signs of perforation exist, a radiographic examination following contrast enema will typically show a microcolon of disuse and impacted meconium in the terminal ileum (Fig. 96.1B). Other abnormalities or complications such as volvulus can usually be seen on the barium enema. If complications exist or if the physician has some doubt about the diagnosis, laparotomy should be performed.

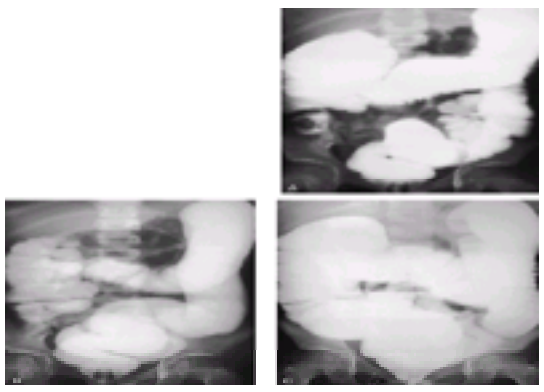

FIGURE 96.1. Distal intestinal obstruction syndrome (DIOS). **A.** Presenting Gastrografin enema of a child who had crampy abdominal pain and a right lower-quadrant mass. Fecal impaction with intussusception is demonstrated. **B.** Partial resolution of the obstruction after Gastrografin administration. **C.** Complete resolution of the intussusception and fecal impaction.

In cases of uncomplicated meconium ileus, an enema with diatrizoate methylglucamine (Gastrografin) can be used to clear the obstructing meconium, and surgery may not be necessary.

Rectal Prolapse

Rectal prolapse occurs most commonly in children less than 3 years old. Although several other conditions may cause a rectal prolapse, the association with CF is common and a sweat test should be performed on a child who has had rectal prolapse. In a child who is known to have CF, rectal prolapse usually results when pancreatic enzyme therapy has been inadequate. Although it may be frightening in appearance, the prolapse can easily be reduced by placing the infant in a comfortable position and using a lubricated glove for manual reduction. It is only in the unusual situation when an

intussusception is responsible for the prolapse that bowel strangulation may occur.

Intestinal Obstruction

Acute or chronic crampy abdominal pain is common in CF patients, and an associated fecal mass in the right lower quadrant is often present. Some patients with this history may present with signs and symptoms of intestinal obstruction, and roentgenograms of the abdomen may show dilated loops of bowel with air–fluid levels. Intestinal obstruction occurring beyond the neonatal period in patients with CF is often referred to as meconium ileus equivalent. It has been suggested that the abnormal intestinal mucus in CF patients causes a decreased motility that, combined with a decreased amount of abnormal pancreatic and biliary secretions, results in dry, puttylike stool that cannot pass from the terminal ileum to the cecum. In its mildest form, this situation may be responsible for intermittent abdominal pain. Eventually the fecal mass may cause an obstruction or serve as a leading edge for either an intussusception or a volvulus.

When the roentgenogram of the abdomen shows signs of obstruction, such as dilated loops of bowel and air–fluid levels, a barium or diatrizoate methylglucamine enema must be performed. If a nonreducible volvulus or intussusception is seen, emergency surgery is necessary. In some cases, an associated intussusception may be reduced by using diatrozoate methylglucamine as the contrast agent (Fig. 96.1A,Fig. 96.1B,Fig. 96.1C). If only a fecal mass is present without an associated volvulus or intussusception, medical management using diatrizoate methylglucamine and saline enemas usually results in dissolution of the impacted feces. Because diatrizoate methylglucamine has a very high osmolarity, the infant must be well hydrated before, during, and after the procedure. Fluid balance and serum electrolytes must be monitored closely. A useful technique is to instill a small amount of the diatrizoate methylglucamine as a bolus followed by the diluting water. This procedure often achieves a good result while using a lower total osmotic load. If some progress is made with the first diatrizoate methylglucamine enema, the procedure may be repeated. Pressure (other than hydrostatic) should not be exerted to instill the diatrizoate methylglucamine. External pressure to the infant's abdomen is also contraindicated. These procedures should be performed in consultation with a surgical team so that they may be prepared to intervene. In cases of fecal impaction without complete obstruction, enemas and oral administration of mineral oil and *N*-acetylcysteine (30 mL in 30 mL of cola) have been reported to be effective.

Hypoelectrolytemia and Metabolic Alkalosis

Especially during periods of hot weather, the increased loss of sodium and chloride in the sweat of patients with CF may lead to severe and symptomatic electrolyte depletion. Examples of the electrolyte abnormalities that were seen in two infants are shown in Table 96.2. The first patient was known to have CF. An intercurrent upper respiratory tract infection occurred during hot weather, and a decrease in oral intake was followed by profound lethargy. Several features of the electrolytes are characteristic of the abnormalities seen in CF. The extremely low chloride and elevated bicarbonate combined with a less severe hyponatremia probably reflect a renal compensation for the increased salt loss in the sweat of CF patients. The second patient presented with a history of an upper respiratory tract infection that progressed to bilateral upper lobe pneumonia and atelectasis during a period of warm weather. Again, an abrupt decrease in oral intake was followed by lethargy. In this second patient who was not previously diagnosed as having CF, the electrolytes provided an important clue for the subsequent diagnosis. In these patients, prompt fluid replacement with isotonic saline is critical; 20 to 30 mL/kg should be given within 15 minutes if signs of shock are present or within 1 hour in less severely ill patients. Potassium chloride should be administered as soon as urine output is established. However, the concentration of potassium should not exceed 40 mEq/L. Frequent determinations of serum electrolytes will be necessary to guide further therapy until correction is complete.

		Serum Electrolytes (mEq/L)				
Patient	Age (mo)	Na	K	Cl	CO_2	Serum pH
1	9	123	2.2	49	48	7.60
2	6	125	2.4	55	41	7.63

Table 96.2. Hypoelectrolytemia with Metabolic Alkalosis in Cystic Fibrosis Patients

Pneumothorax

Sudden onset of chest pain often referred to the shoulder and sometimes associated with the acute onset of increasing dyspnea and cyanosis is most likely the result of a pneumothorax in the CF patient. Rupture of a subpleural bleb introduces air into the pleural space. This complication is reported with frequency in older CF patients. It is important to realize that recurrences are very common and that tension pneumothorax has been reported in as many as 30% of these cases.

CF patients with a pneumothorax of larger than 10% of the area of the hemithorax should be treated with tube thoracostomy. This procedure should be performed promptly, but care should be taken to prepare the patient and surroundings properly and to consult an experienced physician, if one is available.

Needle aspiration of the pneumothorax should be avoided unless the patient's condition is rapidly deteriorating as the result of developing a tension pneumothorax (Fig. 96.2).

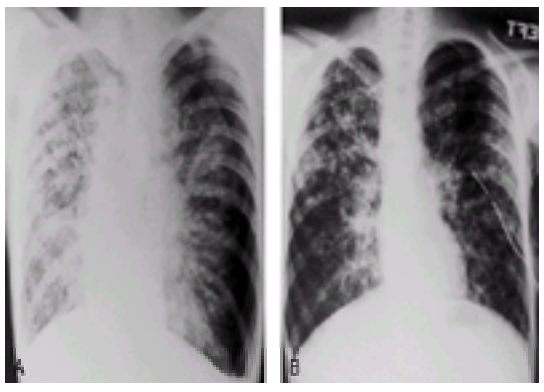

FIGURE 96.2. A. Chest roentgenogram showing a large left-sided pneumothroax with some shift of mediastinal structures of the right. **B.** Reexpansion of the left lung after tube thoracostomy and suction.

Hemoptysis

The expectoration of a small amount of blood, usually seen as bloodstreaking of the sputum, is a fairly common occurrence in CF patients. Although the first such episode may be very alarming to the patient and the parents, the patient's usual home care regimen does not need to be altered other than considering an appropriate course of antibiotic therapy to treat any intercurrent pulmonary infection.

Significant hemoptysis has been arbitrarily defined as the expectoration of at least 30 to 60 mL of fresh blood. The mechanism proposed to explain this event is the erosion of an area of local bronchial infection or bronchiectasis into a bronchial vessel. Hospitalization for observation is indicated for significant hemoptysis. Blood should be sent for a type and crossmatch in addition to hematocrit and prothrombin time determinations. Intravenous antibiotics against *Staphylococcus* and *Pseudomonas* are usually started. An intravenous line also provides an opportunity for rapid administration of saline or blood products if bleeding becomes more severe. If the patient is dyspneic, oxygen should be administered. If the prothrombin time is prolonged, vitamin K (5 mg initially) should be given. If bleeding persists, guidelines for replacement are essentially the same as for blood loss from other causes (see Chapter 59). Although it is less common, some patients with CF may have bleeding from esophageal varices secondary to advanced cirrhosis with portal hypertension. It is therefore important to establish whether the source of bleeding is from the respiratory or gastrointestinal tract. The treatment of bleeding esophageal varices is discussed in Chapter 30 and Chapter 93.

CF patients occasionally present with an episode of massive hemoptysis with volumes of blood loss ranging from 300 to 2500 mL. Massive hemoptysis represents a life-threatening situation, and in addition to instituting the measures already described, the skilled intervention of a team, including a bronchoscopist, anesthesiologist, and thoracic surgeon, may be necessary to maintain an airway and to locate and ligate the bleeding vessel. Bronchial artery embolization has been described for CF patients, and although potentially serious complications may result, this procedure may be valuable when conservative measures fail and surgery is not feasible.

Pulmonary Exacerbation

CF patients who experience an increase in respiratory symptoms such as cough and the rate and effort of breathing require careful evaluation. These symptoms often will occur after the onset of a mild upper respiratory tract infection. On physical examination, the patient will be tachypneic with intercostal retractions and may be cyanotic. Auscultation may reveal areas of coarse rales. A chest roentgenogram should be taken to determine whether pneumothorax, effusion, or local consolidation or atelectasis is present. However, in many cases, the roentgenogram will show only diffuse peribronchial thickening with a varying amount of fluffy infiltrates and hyperinflation. The roentgenogram is most helpful in assessing the degree of acute change if comparison can be made with previous roentgenograms and if medical personnel who are familiar with the patient's previous course can be contacted for advice. The establishment of the network of CF centers by the CF Foundation for the comprehensive care of CF patients has helped to ensure that such information will be available even on an emergency basis. If such guidance is not available and if lobar atelectasis, significant respiratory distress, or hypoxia (Pa O_2 less than 60 mm Hg) is present, the patient should be treated in a hospital setting with vigorous chest physiotherapy and antibiotics effective against *S. aureus* and *P. aeruginosa* (until results of sputum culture are available). Oxygen therapy should be guided by arterial blood gas determination or pulse oximetry.

Diffuse expiratory wheezing and prolonged expiration in a patient with CF suggest the possibility of coexisting asthma. A history of respiratory allergy with a good response to bronchodilators provides further support for this diagnosis. If these findings are present or if the patients show an improvement after a dose of epinephrine (1:1000, 0.01 mL/kg subcutaneously) or an inhaled bronchodilator (Albuterol 0.5%, 0.01–0.03 mL/kg 2 mL saline), therapy should be administered as outlined under Asthma in addition to treating for CF.

Cor Pulmonale

Patients with CF who have moderately severe pulmonary insufficiency and some degree of hypoxia will eventually develop right ventricular hypertrophy secondary to pulmonary hypertension. However, this condition is often not detected

by a standard electrocardiogram. Increased hypoxia during an exacerbation of pulmonary symptoms in such patients may precipitate an episode of congestive heart failure. In addition to cyanosis, tachypnea, and tachycardia, other associated signs are an enlarged, tender liver and in some patients a gallop rhythm, peripheral edema, and ascites. Most of these patients will have pronounced digital clubbing, which reflects the severity of their pulmonary disease. Rather than the elongated, narrow cardiac silhouette usually seen in the patient with CF, the chest roentgenogram will now show some cardiac enlargement with a prominence of the pulmonary vasculature. Oxygen and diuretics (furosemide 1 mg/kg given intravenously as an initial dose) have been most helpful in addition to starting treatment for the underlying pulmonary disease. Digitalis and pulmonary vasodilators have not been shown to be of proven benefit. However, many CF centers use digitalis during an acute episode of congestive failure and in selected CF patients (e.g., those with recurrent episodes of congestive heart failure and/or significant left ventricular dysfunction in addition to right ventricular dysfunction on echocardiography).

Some consideration must be given to the course of the patient's disease before the current episode when anticipating the response to therapy. The patient with a first episode of congestive heart failure precipitated by an acute exacerbation of the pulmonary disease may improve appreciably. However, in a patient in whom the congestive heart failure is superimposed on a course of inexorable deterioration in pulmonary status, a dramatic response is unlikely.

Respiratory Failure

When a CF patient presents with respiratory failure (i.e., hypercarbia—Pa CO_2less than 60 mm Hg) in addition to hypoxia, the management decisions become extremely difficult. CF patients in general do not respond as well to and have more complications from mechanical ventilation when compared with patients with other forms of chronic obstructive pulmonary disease.

If an acute episode such as viral pneumonia or status asthmaticus precipitates respiratory failure in a CF patient who had a history of good pulmonary function before the episode, mechanical ventilation should be considered. Factors in this decision include the patient's level of activity and pulmonary function before the episode, the course of the patient's disease, and the expectations of the patient and parents. Adequate, objective guidelines are not currently available, but one large retrospective study found that a history of hypercarbia indicated a poor prognosis. It seems reasonable that good pulmonary function before the acute episode provides an opportunity for a good result. However, when mechanical ventilation is used for a patient with CF, a skilled intensive care team must be prepared for a potentially difficult course.

When respiratory failure with increasing hypercarbia occurs in a CF patient after a course of progressive pulmonary insufficiency despite adequate medical therapy, mechanical ventilation is not indicated. However, consultation with the physicians providing long-term care for the patient is important before choosing this course. This consultation should include a determination of whether or not, and for how long, a patient has been listed for lung transplantation.

CHAPTER 97

Endocrine Emergencies

DANIEL E. HALE, MD

Department of Pediatrics, The University of Texas Health Science Center at San Antonio, and Pediatric Endocrinology, Santa Rosa Children's Hospital, San Antonio, Texas

Because the symptoms and signs of endocrinologic disease are associated with a wide range of nonendocrinologic diseases, many endocrine conditions are not recognized in the emergency department (ED). However, to achieve a favorable outcome, endocrinologic causes should be included in the differential diagnosis of ill children and appropriate testing should be performed. In many cases, the results of specific diagnostic tests will not be available on an emergency basis, and management will have to be initiated based on a probable diagnosis. In this chapter, emphasis is placed on the clinical and laboratory findings that are helpful in recognizing endocrinologic emergencies and in effectively treating those emergencies. Table 97.1 summarizes the major clinical features, recommended investigations, and treatments of pediatric endocrine emergencies.

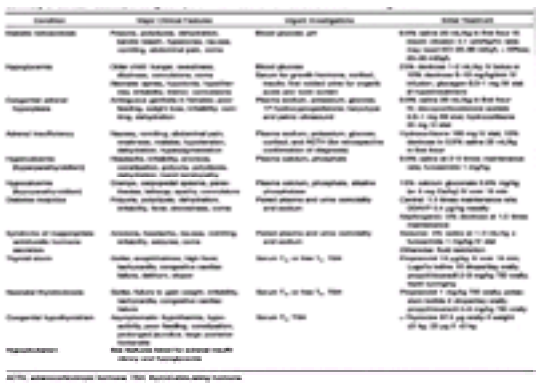

Table 97.1. Summary of Clinical Features, Investigations, and Initial Treatment of Pediatric Endocrine Emergencies

DIABETIC KETOACIDOSIS

Background

Severe ketoacidosis is a life-threatening complication of diabetes that is present in 20 to 40% of newly diagnosed juvenile-onset diabetic patients; it accounts for 65% of all admissions of diabetic patients less than 19 years old. The mortality rate for diabetic ketoacidosis (DKA) in children is less than 2% but still greater than ideal. Clinically, dehydration and acidosis are the serious immediate risks to the child. Characteristic biochemical findings include hyperglycemia and metabolic acidosis. DKA may be precipitated by acute infection, inadequate quantities of endogenous or exogenous insulin, or emotional factors. Recurrent or frequent episodes should lead to careful evaluation for this latter possibility. Nonketotic hyperosmolar coma, although rare in children, can be managed adequately using the principles outlined in the following sections.

Pathophysiology

Insulin deficiency is accompanied by elevations of the counterregulatory hormones, glucagon, catecholamines, corticosteroids, and growth hormone. These hormonal changes lead to hyperglycemia by reducing peripheral glucose use and increasing hepatic gluconeogenesis. Hyperglycemia promotes an osmotic diuresis and results in dehydration. Insulin deficiency also causes increased release of free fatty acids from adipose tissue; these fatty acids are subsequently converted into ketoacids in the liver. Ketoacids readily dissociate in the blood to produce free hydrogen

ions, and metabolic acidosis ensues. This reaction is partially compensated for by a respiratory alkalosis (hyperventilation), with a resultant lowering of P CO_2 and plasma bicarbonate (HCO^-_3).

Intracellular potassium is depleted because of transcellular shifts of this ion brought about by the acidosis and extracellular dehydration. Protein catabolism secondary to insulin deficiency causes a negative nitrogen balance and results in additional efflux of potassium from cells. The potassium is then lost in the urine during the osmotic diuresis. Volume depletion causes secondary hyperaldosteronism, which further promotes urinary potassium excretion. Thus, total body depletion of potassium occurs, although the plasma potassium concentration may not reflect the loss at the time of presentation.

Clinical Manifestations

In cases of new-onset diabetes, the child usually has a history of polyuria and polydipsia for a few days or weeks before the acute decompensation. A prolonged history of polyuria, or hyperglycemia without acidosis, should raise the possibility of type 2 diabetes, particularly in obese children from ethnic and racial minorities. Significant weight loss often occurs despite a vigorous appetite. In children known to have diabetes, the prodrome may be less than 24 hours and precipitated by an intercurrent illness, inappropriate sick-day management, or omission of insulin doses. Patients may complain of nausea, vomiting, and abdominal pain, and the parents may have noticed increasing listlessness. Fewer than 10% of children are in coma at the time of hospital admission, although a higher percentage have an altered state of consciousness. The history and physical examination usually suggest the diagnosis; however, particularly in the patient with new-onset diabetes, presenting clinical features can be misdiagnosed, especially in the infant or young child. For example, abdominal pain may be misinterpreted as appendicitis; hyperpnea may be mistaken as a sign of pneumonia or asthma; and polyuria may be incorrectly diagnosed as a urinary infection. Enuresis, polydipsia, and irritability are sometimes wrongly categorized as behavioral problems.

On physical examination, particular attention should be paid to the degree of dehydration, including skin turgor and dryness of mucous membranes. In severe cases, the child may exhibit signs of shock, including a thready pulse, cold extremities, and hypotension. The smell of ketones on the breath and the presence of deep sighing (Kussmaul) respirations reflect the ketoacidosis. The patient's consciousness level, which may range from full alertness to deep coma, should be noted. The child may have exquisite abdominal tenderness with guarding and rigidity, which can mimic an acute abdomen. The ears, throat, chest, and urine should be examined because infection is often a precipitating factor. The presence of hyperpigmentation (acanthosis nigricans) on the posterior neck should alert the clinician to the possibility of non–insulin-dependent diabetes.

Typical laboratory findings include a serum glucose greater than 200 mg/dL (usually 400 to 800 mg/dL), the presence of glucose and ketones in the urine, acidosis (venous pH less than 7.3 and HCO^-_3 less than 15 mEq/L), high or normal plasma potassium, and a slightly elevated blood urea nitrogen. Occasionally, DKA can occur with normoglycemia when persistent vomiting and decreased intake of carbohydrates are accompanied by continued administration of insulin. The serum sodium is usually low or in the low-normal range. Leukocytosis may be noted but does not necessarily signify an underlying infection. Hyperglycemia in the absence of acidosis should cause the clinician to consider additional possibilities (see subsequent section on Hyperglycemia).

Management

Careful clinical assessment and judgment is required. This section primarily focuses on the child who is significantly dehydrated, acidotic, and unable to take oral fluids because of vomiting or altered level of consciousness. Many cases of mild DKA can be managed with rehydration, either orally or intravenously, and with supplemental insulin either at home or in the ED. This possibility is addressed at the end of this section. For the severely dehydrated child, initial treatment is directed toward rapid expansion of intravascular volume and correction of the acidosis because these conditions are life-threatening. Subsequent treatment is directed at the normalization of all biochemical parameters by the use of insulin. Medical intervention carries significant risks of hypokalemia and cerebral edema (Table 97.2 and Table 97.3).

Table 97.2. Principles of Management of Diabetic Ketoacidosis

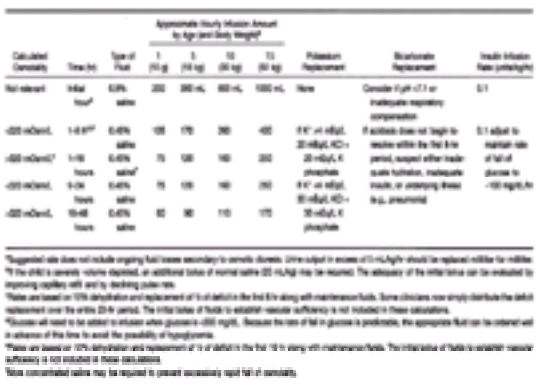

Table 97.3. Guide to Treatment of Severe Diabetic Ketoacidosis

Fluid and Electrolyte Replacement

Fluid replacement should be instituted promptly. In the first hour, isotonic (0.9%) saline should be infused intravenously at 20 mL/kg per hour to establish an adequate vascular volume and to improve tissue perfusion. This procedure may need to be repeated if the pulse rate and capillary refill rate do not decrease. Once adequate intravascular volume is established, the fluid deficit can be replaced over the next 24 to 48 hours, depending on the degree of hyperosmolality; however, once the child is able to drink, rehydration may occur enterally. It can be assumed that the fluid deficit is 10% of the body weight in children with DKA. Dehydration may actually be greater than that estimated on clinical appearance because of the hyperosmolar state. The volume of fluid given should replace the deficit (100 mL/kg), provide daily maintenance fluids (see Chapter 18 and Chapter 86), and replace ongoing urinary losses in excess of 5 mL/kg per hour (osmotic diuresis). For the child whose calculated osmolality is less than 320 mOsm/L, the deficit can be replaced over 24 hours, but a longer period (36 to 48 hours) should be used for children with higher osmolalities.

The Na^+ deficit is approximately 10 mEq/kg body weight and Na^+ maintenance is 3 mEq/100 per mL of maintenance fluid. From a practical point of view, half-normal (0.45%) saline can be started after the initial bolus of normal saline. The serum sodium should rise with initiation of therapy. If the initial serum sodium is less than 135 mEq/L, a falling serum sodium is an indication to use a more concentrated sodium stock and to increase monitoring, as well as to consider the possibility of the syndrome of inappropriate antidiuretic hormone.

All children with DKA are total body potassium depleted (5 mEq/kg body weight); therefore, potassium replacement is an important part of therapy. If the initial serum K^+ is greater than 4 mEq/L, 40 mEq/L of potassium is added to the infusion after vascular competency has been established and the child has urinated. Generally, K^+ is provided as potassium chloride (or acetate) and potassium phosphate in equal amounts. If the initial serum K^+ is less than 4 mEq/L, potassium replacement should be initiated promptly; doses of K^+ of 60 mEq/L or greater may be necessary. If the K^+ initial concentration is low, electrocardiographic (ECG) monitoring is indicated.

Phosphate depletion is almost universal in patients with DKA; however, the clinical significance of this reaction remains uncertain. As noted earlier, half of the K^+ replacement is with potassium phosphate.

Alkali

The most essential steps for the correction of acidosis are volume repletion and insulin. The use of sodium bicarbonate for correction of acidosis remains controversial because of the potential for paradoxical acidosis of the central nervous system (CNS) and resultant cerebral depression. Paradoxical acidosis occurs because administered HCO^-_3 combines with excess H^+ ions in the bloodstream to form H_2O and CO_2. Because the blood–brain barrier is relatively more permeable to CO_2 than to HCO^-_3, CO_2 accumulates in the CNS, resulting in further exacerbation of acidosis in this compartment, while acidosis is being corrected systemically. Most children will correct their acidosis during rehydration and initiation of insulin therapy without recourse to alkali. Bicarbonate therapy is generally reserved for children with an initial arterial pH of less than 7.1, and for those who are unable to compensate for their acidosis by hyperventilation. The adequacy of compensation can be evaluated if an PCO_2 and the serum $[HCO^-_3]$ are known. If the PCO_2 is in excess of $(1.5 \times HCO^-_3) + 8$, respiratory effort is inadequate for the degree of acidosis, and bicarbonate is required. The amount of bicarbonate needed may be calculated using the formula:

$$\text{Amount of bicarbonate (mEq)} = \text{Base deficit (mEq/L)} \times \text{Body weight (kg)} \times 0.6 \text{ (distribution factor for bicarbonate)}$$

Half of this amount is given intravenously over 2 hours. Biochemical studies are then repeated; the need for continued bicarbonate is reevaluated, and if necessary, a new dose of bicarbonate is calculated and administered. Alternatively, 1 to 2 mEq/kg may be given intravenously every hour until the pH is more than 7.25 and the HCO^-_3 is more than 15 mEq/L.

Insulin

Regular insulin is used for the treatment of ketoacidosis. Insulin is initially necessary to stop ongoing ketone body production, the primary cause of the acidosis. Insulin should be started at the same time as initial fluid expansion to correct the acidosis and may be either infused intravenously or injected intramuscularly at hourly intervals. Subcutaneous

injections of insulin should be avoided because of the uncertainties of absorption in a dehydrated patient. The starting dose of insulin for continuous infusion is 0.1 unit/kg per hour, which is normally infused by a regulated pump. The rate of insulin infusion should be adjusted to sustain a fall in the blood glucose of about 100 mg/dL per hour. Failure of the glucose to decrease in response to insulin suggests improper insulin preparation, inadequate hydration, or serious underlying disease (e.g., appendicitis with resultant significant increases in counterregulatory hormones). It is unnecessary to give an initial bolus of insulin. The dose for the hourly intramuscular injection is 0.25 unit/kg as a priming dose followed by 0.1 unit/kg per hour. Once the blood sugar is less than 300 mg/dL, glucose should be added to the intravenous (IV) fluids. As long as the child remains acidotic, insulin infusion should never be stopped; instead, the amount of glucose in the IV infusion should be increased and the insulin infusion adjusted to maintain the blood sugar between 100 and 200 mg/dL. When the child is able to eat and is no longer significantly acidotic, IV infusion of insulin can be discontinued. Because IV insulin is metabolized rapidly, subcutaneous insulin must be given promptly after the infusion is stopped. The initial dose of regular insulin should be about 0.25 unit/kg. If hourly intramuscular injections are used, they should be continued until the blood sugar is below 300 mg/dL and acidosis is correcting. By this time, perfusion is reestablished and subcutaneous insulin can be administered four times a day.

Monitoring

Close monitoring is mandatory, and a well-organized flow sheet ensures that all parameters are being observed. Admission to an intensive care unit is advisable if the patient is less than 1 year of age, has a Glasgow Coma Scale score of less than 12, has an initial calculated osmolality of more than 320 mOsm/L, has an initial [Na^+] of more than 145 mEq/L, or has an initial [K^+] of less than 4 mEq/L. The patient's blood pressure, pulse rate, respiratory rate, and the level of consciousness should be observed regularly. Careful neurologic examination, with particular attention to arousability and pupillary reactivity, should be performed frequently. The fluid input and output must be reviewed hourly to ensure that appropriate rehydration is occurring. The IV fluids should be checked frequently so that pump failure or fluid leakage into the subcutaneous tissues can be corrected quickly. In the severely ill child, an ECG monitor is advisable to detect arrhythmias associated with hyperkalemia or hypokalemia.

The serum glucose should be measured hourly until the blood glucose is stable and below 300 mg/dL and as long as the child is on an insulin infusion. Glucose measurement may be less frequent once the patient has been changed to subcutaneous insulin. Serum K^+ needs to be measured every 3 to 4 hours until the acidosis and hyperglycemia are normalized, or more frequently if hypokalemia is encountered or bicarbonate therapy is used. An arterial pH should be obtained before treatment and repeated if bicarbonate therapy is used or contemplated.

When the child is better hydrated and the acidosis resolves, mental alertness will improve and symptoms of nausea, vomiting, and abdominal pain should remit. If they do not resolve, an abdominal disorder should be considered. Some patients complain of blurred vision, which is caused by lens distortion resulting from fluid shifts of rehydration and correction of hyperglycemia. Twelve hours after initiation of treatment, most patients are able to tolerate oral fluids, at which point rehydration can be continued orally.

Mild Ketoacidosis

Some children with new-onset diabetes may also have hyperglycemia without ketoacidosis or with only mild acidosis. Generally, these patients are hospitalized for at least 12 to 24 hours to allow time to educate the family and stabilize the insulin dosage. These children require rehydration (as described in the next section) similar to patients with known diabetes and mild ketoacidosis. Insulin therapy can be initiated subcutaneously, at a total daily dose of 0.25 to 0.5 units/kg per day for the prepubertal child and 0.5 to 0.75 units/kg per day for the adolescent. Two-thirds of the total daily dose is administered in the morning, and one-third before dinner; two-thirds of the morning dose and one-half of the evening dose should be as an intermediate duration insulin (NPH, Lente).

Children with known diabetes often develop mild ketoacidosis during the course of intercurrent illness, especially gastroenteritis, or secondary to omission of insulin doses. Even the mildly dehydrated (5%) child with slight acidosis who presents to the ED benefits from a fluid bolus (20 mL/kg of normal saline); furthermore, this bolus will be given while awaiting laboratory test results. Once the laboratory results are available, the physician must decide whether to hospitalize the child, continue treatment in the ED, or send the child home. For purposes of definition, *mild DKA* is defined as a pH of more than 7.3, a bicarbonate of more than 15 mEq/L, and a calculated osmolality of less than 320 mOsm/L. Children who are significantly acidotic or hyperosmolar should be hospitalized and managed as outlined in the earlier section of this chapter. Several factors must be considered before sending a child home:

1. Is the child conscious and alert?
2. Can the child drink and retain oral fluids?
3. Can home glucose monitoring be done and are all related supplies available in the home?
4. Will the child have competent supervision at home?
5. Does the family have access to both a telephone and transportation?
6. Is there a physician available with whom the family can communicate by telephone?
7. Is the family comfortable with managing the mild acidosis at home?

If all of these questions can be answered in the affirmative, the child may be sent home.

Recommendations should be made to the family regarding fluid intake, insulin administration, and monitoring. Specific recommendations may vary with the age of the child and the experience of the family, but the following scheme may be helpful. Oral intake should be about the same as would be given intravenously to resolve the deficit and provide maintenance (e.g., the 10-year-old child would normally get about 260 mL/hour during the first 8 hours intravenously if he or she was hospitalized; therefore, the physician should suggest that the family try to get in about 8 ounces of liquid every hour for the next 6 to 8 hours). It is best if this liquid is taken in as sips. Additional insulin will be required. In the ED, two decisions will need to be made regarding insulin: First, how much should be given to the child before dismissal?

Usually, an amount equal to 10% of the child's usual daily dose will be adequate (e.g., a child normally takes 12 units R and 6 units N in the AM and 6 units R and 6 units N in the PM. The total daily dose is 30 units. Ten percent of 30 = 3 units. Therefore, 3 units of regular insulin would be given to the child before discharge). Second, how much should be given at home and with what frequency? Once home, the preceding 10% rule is generally applicable. If the blood glucose has not come down within 1 to 2 hours, consultation with the child's physician is recommended. If the blood glucose has decreased but is still more than 250 mg dL, a second dose of similar size is indicated. If a third home dose is contemplated, consultation with the child's physician is required. Many children have insulin adjustment algorithms for premeal adjustments from their endocrinologist. The family can begin using this algorithm once the child is able to return to a normal intake. Last, hourly monitoring of blood glucose, urine output, and ketones is recommended with the expectation that the blood glucose should decline, the urine output should fall, and the urine ketones should begin to clear.

HYPERGLYCEMIA

Background

According to new American Diabetes Association guidelines, a fasting glucose of greater than 125 mg/ dL or a random glucose greater than 199 mg/dL is highly suggestive of diabetes in an otherwise healthy person. These guidelines were developed primarily by specialists in adult diabetes and may not be completely applicable to the pediatric population, especially not infants and young children who are ill as well as distressed by the trauma of phlebotomy.

Therefore, it is essential that any elevated glucose level be evaluated within the context of the ill child and that other factors, such as simultaneous medication administration, be considered.

Pathophysiology

As noted in the previous section on diabetes and the following section on hypoglycemia, glucose homeostasis reflects the balance between glucose input (from gut absorption, hepatic glycogen breakdown, or gluconeogenesis) and disposal (via storage or oxidation). With the exception of gut absorption, this process is largely regulated by insulin, although counterregulatory hormones have a significant effect as well. Furthermore, tissue factors and medication also impact on the insulin effect.

Clinical Manifestations

Blood glucoses in the 200 to 300 mg/dL range rarely result in symptoms. This level of hyperglycemia may be accompanied by intermittently increased frequency of urination; however, parents are rarely aware of their child's frequency of urination once the child is toilet-trained unless the frequency becomes disruptive (e.g., the child begins having “accidents” at school). Children and adolescents have no sense of what is the normal frequency of urination, so they rarely complain, unless the frequent urination is accompanied by dysuria. Higher levels of glucose (greater than 300 mg/dL) may be associated with subtle clinical findings such as blurring of vision or dryness of oral membranes.

Significant hyperglycemia may occur without significant symptoms and can be tolerated for a prolonged period without clinical signs. In the ED, hyperglycemia is likely to be seen in several different situations. First, the child may be known to have diabetes and present with an intercurrent illness or traumatic injury. Both illness and injury result in increased counterregulatory hormones, which may lead to relative insulin resistance and hyperglycemia. The second presentation is the child for whom diabetes is suspected because of classical symptoms of polyuria, polydipsia, and polyphagia accompanied by weight loss. Almost half of children with new-onset diabetes mellitus present to their pediatrician or to the ED in this way. Third, some medical conditions are associated with persistent hyperglycemia, such as recurrent urinary tract infections and vaginal yeast infections. Furthermore, type 2 diabetes is increasingly being reported in minority adolescents; in many, hyperpigmentation of the posterior neck and axilla (acanthosis nigricans) may be noted. Fourth, a laboratory panel obtained for some other reason (e.g., abdominal pain) may reveal hyperglycemia.

Management

In the child with diabetes, unless the child is clinically dehydrated or is unable to take oral fluids, hyperglycemia is not a crisis. Oral fluids should be encouraged, and supplemental insulin may be required (usually 10% of the child's total daily dose, given as either regular insulin or the rapid-acting lispro insulin). Failure to respond to these simple measures, whether in the ED or at home, should lead to a consultation with the child's endocrinologist. If oral fluids must be restricted (e.g., a child with traumatic injury requiring surgery), IV fluids without glucose should be used and glucose should be monitored frequently. Supplemental insulin may be required, depending on when the child last received insulin and the response to simple hydration.

Clearly, the child with classic symptoms merits further evaluation to determine whether the child is dehydrated, hyperosmolar, or acidotic. If the child is simply hyperglycemic, hospitalization is often required for initiation of treatment and diabetes-related education; however, IV fluid resuscitation and intensive care are not indicated.

In children with signs or symptoms that may reflect hyperglycemia, a serum glucose should be obtained. If this test reveals hyperglycemia, as defined by the American Diabetes Association, the child should be referred for further evaluation and treatment.

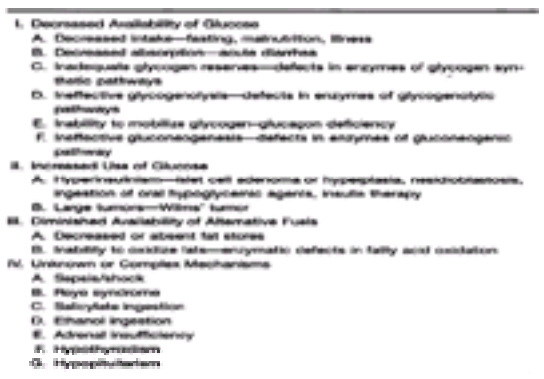
Last, if hyperglycemia is a coincidental finding, the diagnosis requires thoughtful consideration. How traumatic was the blood draw? How upset was the child? What medications or IV fluids were given to the child just before the phlebotomy? What was the child drinking while waiting to see the physician? Are the symptoms in any way related to the hyperglycemia? Three simple evaluations are helpful in determining whether the hyperglycemia is circumstantial or suggestive of diabetes. Brief hyperglycemia resulting from a stress response to phlebotomy or secondary to oral intake

rarely results in significant glucosuria; therefore, a urine dip for glucose is often helpful. Second, in the absence of ongoing stress or input, glucose tends to fall over time. A fingerstick glucose is rarely stressful. Therefore, repeating a glucose measurement by fingerstick 1 to 2 hours after the original sample was sent is useful in separating disease from nondisease. Third, hyperglycemia secondary to these factors is usually mild (150 to 250 mg/dL). More significant hyperglycemia should raise the suspicion of diabetes or glucose intolerance.

HYPOGLYCEMIA

Background

Hypoglycemia is defined as serum glucose of less than 50 mg/L, regardless of whether symptoms are present. Hypoglycemia is a chemical finding that should lead to a diligent search for a cause. A differential diagnosis of hypoglycemia, as it may present in the ED, is provided in Table 97.4.



I. Decreased Availability of Glucose
A. Decreased intake—fasting, malnutrition, illness
B. Decreased absorption—acute diarrhea
C. Inadequate glycogen reserves—defects in enzymes of glycogen synthetic pathways
D. Ineffective glycogenolysis—defects in enzymes of glycogenolytic pathways
E. Inability to mobilize glycogen—glucagon deficiency
F. Ineffective gluconeogenesis—defects in enzymes of gluconeogenic pathway
II. Increased Use of Glucose
A. Hyperinsulinism—islet cell adenoma or hyperplasia, nesidioblastosis, ingestion of oral hypoglycemic agents, insulin therapy
B. Large tumors—Wilms' tumor
III. Diminished Availability of Alternative Fuels
A. Decreased or absent fat stores
B. Inability to oxidize fats—enzymatic defects in fatty acid oxidation
IV. Unknown or Complex Mechanisms
A. Sepsis/shock
B. Reye syndrome
C. Salicylate ingestion
D. Ethanol ingestion
E. Adrenal insufficiency
F. Hypothyroidism
G. Hypopituitarism

Table 97.4. Causes of Childhood Hypoglycemia

Hypoglycemia may be secondary to insulin therapy for diabetes. Excluding this category, almost all hypoglycemia in children occurs during periods of decreased or absent oral intake, often coupled with increased energy demand (e.g., viral gastroenteritis with fever). Postprandial hypoglycemia is unusual in children, except in those who have had prior gastrointestinal surgery.

Pathophysiology

Because glucose is necessary for cellular energy production in most human tissues, the maintenance of an adequate blood glucose is important for normal function. The serum glucose reflects a dynamic balance among glucose input from dietary sources, glycogenolysis and gluconeogenesis, and glucose use by muscle, heart, adipose tissue, brain, and blood elements.

The liver plays a unique role in glucose homeostasis because it stores glucose as glycogen. With fasting, this glycogen is degraded to glucose, which is released into the bloodstream. In addition, the liver synthesizes new glucose from glycerol, lactate, and certain amino acids. During fasting, lipolysis occurs and the resultant fatty acids are used for the production of both energy and ketones (acetoacetate and b-hydroxybutyrate) by the liver. The energy generated from the metabolism of fatty acids is essential to sustain maximal rates of gluconeogenesis and ureagenesis in the liver. The ketones are an important auxiliary fuel for most tissues, including the brain.

Muscle contains significant quantities of glycogen and protein. Under fasting conditions, the glycogen is degraded and used endogenously but is not released as free glucose into the bloodstream. Certain amino acids, particularly alanine and glycine, are released from the muscle and subsequently used by the liver for gluconeogenesis. Muscle derives an increasing proportion of its energy requirement from fatty acids as fasting proceeds.

Brain tissue is highly dependent on glucose for its energy requirements. Under certain circumstances, it can extract a limited proportion of its energy requirement from other substrates (e.g., glycerol, ketones, lactate), although this process requires a period of adaptation and does not negate the need for a constant supply of glucose.

Insulin is the primary hormone that regulates the blood glucose level. Insulin stimulates the uptake of glucose and amino acids into skeletal, cardiac, and adipose tissue and promotes glycogen and protein synthesis. It inhibits lipolysis and glycogenolysis. The net effect of insulin action is to accelerate the removal of glucose and gluconeogenic substrates from the bloodstream. Opposing or modulating the effects of insulin are cortisol, glucagon, epinephrine, and growth hormone. The effects of these hormones include inhibition of glucose uptake by muscle, mobilization of amino acids for gluconeogenesis, activation of lipolysis, inhibition of insulin secretion, and induction of gluconeogenic enzymes. The net effect is to increase the availability of gluconeogenic substrates to the liver, and to increase the accessibility and use of nonglucose fuels by other tissues.

Clinical Manifestations

Prompt recognition of hypoglycemia is important because brain damage may result if the hypoglycemia is prolonged or recurs frequently. The acutely ill child warrants a glucose determination if the level of consciousness is altered because hypoglycemia may accompany an illness that interferes with oral intake. Historical evidence may aid in establishing the cause of hypoglycemia. Because hypoglycemia in children occurs after a period of fasting, a careful chronology of dietary

intake during the preceding 24 hours should be obtained. The possibility of ingestion should be considered because ethanol, propranolol, and oral hypoglycemic agents are in common use.

The symptoms and signs of hypoglycemia are nonspecific and are often overlooked, especially in the infant and young child. The clinical findings of hypoglycemia reflect both the decreased availability of glucose to the CNS and the adrenergic stimulation caused by a decreasing or low blood sugar. Adrenergic symptoms and signs include palpitations, anxiety, tremulousness, hunger, and sweating. Irritability, headache, fatigue, confusion, seizure, and unconsciousness are neuroglycopenic symptoms. Any combination of these symptoms should lead to a consideration of hypoglycemia. Any child presenting with a seizure or unconsciousness should have a serum glucose determination.

Management

If hypoglycemia is suspected, blood should be obtained, if at all possible, before treatment. An extra tube (3 mL, red top) should be obtained and refrigerated until the laboratory glucose is known. Rapid screening should be performed using a portable glucose monitor while awaiting definitive laboratory results. Therapy should be instituted if this screen is suggestive of hypoglycemia. This method may lead to some overtreatment because the primary error with the chemically treated strips is underestimation of the serum glucose value; however, treatment holds minimal risk. It is preferable to overtreat than to allow a child to remain hypoglycemic until definitive laboratory results are available. If the laboratory glucose confirms that the blood glucose was less than 50 mg/dL, the reserved serum can be used for chemical (b-hydroxybutyrate, acetoacetate, free fatty acids, carnitine), toxicologic, and hormonal (insulin, growth hormone, cortisol) studies and may provide the correct diagnosis without extensive additional testing.

The first voided urine after the hypoglycemic episode should be saved for toxicologic and organic acid evaluation. In the ED, the urine can also be tested immediately for ketones. With hypoglycemia, ketones should be large. Failure to find large ketones in the presence of hypoglycemia strongly suggests either that fats are not being mobilized from adipose tissue, as might occur in hyperinsulinism, or that the fats cannot be used for ketone body formation, as might occur in enzymatic defects in fatty acid oxidation. The urine should be sent for organic acid analysis and toxicologic investigations. Both the urine and the serum results will be useful in determining the underlying cause of hypoglycemia.

The preferred treatment for hypoglycemia is 0.25 g of dextrose/kg body weight (2.5 mL/kg of 10% dextrose/kg, 1.0 mL/kg of 25% dextrose/kg) rapidly. The serum glucose should then be maintained by an infusion of dextrose at a rate of 6 to 8 mg/kg per minute. Generally, this goal can be accomplished by providing 10% dextrose at 1.5 times maintenance rates. Glucagon (1 mg intramuscularly) may be used to treat hypoglycemia that is known to be caused by hyperinsulinism but is not indicated as part of the routine therapy of hypoglycemia. Cortisol should not be used because it has minimal acute benefit and may delay identification of the cause of hypoglycemia.

The adequacy of therapy should be evaluated both chemically and clinically. The serum glucose should be monitored frequently until a stable level above 70 mg/dL is attained. Adrenergic symptoms should resolve quickly. The resolution of CNS symptoms may be prolonged, particularly if the child was initially seizing or unconscious. Seizures that do not respond to correction of hypoglycemia should be managed with appropriate anticonvulsants (see Chapter 83). The mild acidosis (pH 7.25 to 7.35) usually seen in hypoglycemia will correct without specific intervention. Marked acidosis (pH less than7.10) suggests shock or serious underlying disease and should be managed appropriately (see Chapter 3). Any child with documented hypoglycemia not secondary to insulin therapy should be hospitalized for careful monitoring and diagnostic testing.

HYPOPITUITARISM

Background

The term *hypopituitarism* generally applies to any condition in which more than a single pituitary hormonal deficiency is present. This condition may include deficiencies resulting from a lack of hypothalamic-releasing factors, as well as deficiencies of anterior and posterior pituitary hormones. Diabetes insipidus, the lack of antidiuretic hormone (ADH), may occur alone or in association with other hormonal defects and is discussed in a subsequent section.

Pathophysiology

Adrenocorticotropic hormone (ACTH) primarily affects adrenal glucocorticoid production; generally, it does not affect mineralocorticoid synthesis, which is primarily regulated by the renin–angiotensin system. A deficiency of ACTH production manifests as cortisol deficiency. Because cortisol plays a role as an insulin counterregulatory hormone, a lack of either ACTH or cortisol may result in hypoglycemia. Because the only identified role for thyroid-stimulating hormone (TSH) is the stimulation of thyroid hormone production, a deficiency of TSH is most likely to manifest as hypothyroidism. Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are involved in gonadal maturation and the regulation of gonadal functions. LH and FSH play an important role in testicular descent and penile growth in the fetus, as well as affecting the onset of puberty in the adolescent. The circulating levels of these two pituitary hormones are low in children and have no demonstrable function. Prolactin is primarily involved in the maintenance of lactation and is of minimal significance in childhood. Growth hormone is a principal regulator of linear growth and an important insulin counterregulatory hormone. The absence of growth hormone may be associated with hypoglycemia, particularly in infants and young children.

Clinical Manifestations

The symptoms and signs of hypopituitarism depend on which hormones are missing. Isolated growth hormone deficiency is most likely to present with poor linear growth, although occasionally, an infant or young child will present with hypoglycemia. The acute presentation of hypopituitarism is most likely to occur when the child is stressed by injury, illness, or fasting. The presentation may involve either an unusually rapid decompensation, reflecting the role of cortisol

in adaptation to stress, or as hypoglycemia, mirroring the role of both cortisol and growth hormone in opposing the effects of insulin. In the older child, no specific symptoms or signs indicate a lack of LH and FSH. An association between a lack of these hormones and anosmia has been noted (Kallmann's syndrome). In the adolescent, a deficiency of LH and FSH may be evidenced as pubertal delay. No specific signs or symptoms have been associated with a deficiency of prolactin in childhood.

In the neonatal male, hypopituitarism may be accompanied not only by hypoglycemia but also by micropenis (less than 2 cm, stretched length). This condition echoes the role of LH and FSH in stimulating testicular function in utero. Significant liver dysfunction in the neonatal period may be associated with congenital hypopituitarism. Hypopituitarism is seen with various midline structural anomalies, including optic nerve hypoplasia, cleft palate, absence of the septum pellucidum, and spina bifida.

In the older child, intracranial mass lesions, particularly with craniopharyngioma and other pituitary abnormalities, may cause hypopituitarism. The presence of visual field abnormalities may aid in localizing the site of the lesion. A history of severe head trauma, surgery for CNS tumors, or CNS irradiation should increase the suspicion of hypopituitarism.

Management

The child with hypopituitarism may require any or all of the following therapies. Adequate cortisol replacement is an absolute necessity in children with known or suspected secondary adrenal insufficiency (ACTH deficiency). Cortisol replacement under stress conditions (e.g., trauma, fever) should be the equivalent of 50 mg of hydrocortisone/m^2 per day (hydrocortisone semisuccinate, constant IV infusion; cortisone acetate 50 mg/m^2 intramuscularly every 24 hours; methylprednisolone 7.5 mg/m^2 per 24 hours every 8 hours). Because both cortisol and growth hormone are insulin counterregulatory hormones, children with hypopituitarism are prone to hypoglycemia. If oral intake is interrupted for prolonged periods, glucose should be supplied intravenously. Blood glucose should be monitored to ascertain the adequacy of therapy. Both adrenal insufficiency and diabetes insipidus can lead to fluid and electrolyte abnormalities; therefore, electrolytes should be determined at presentation and followed closely. Changes in IV therapy should be based on serum electrolytes. Judicious use of 1-desamino8- D-arginine vasopressin (DDAVP) may be helpful in managing diabetes insipidus, as outlined subsequently; however, this treatment is usually unnecessary at the time of acute presentation.

Although both thyroid hormone and sex hormone(s) may need to be replaced, this treatment is not required in the ED.

Because hypopituitarism often results from intracranial lesions, the demonstration of a pituitary or a hypothalamic mass, or a history of a significant cranial insult, should lead to a diligent search for hormonal deficits. Similarly, documented pituitary deficits should lead to a thorough radiologic investigation of the cranial cavity.

ACUTE ADRENAL INSUFFICIENCY

Background

Acute adrenal insufficiency occurs when the adrenal cortex fails to produce enough glucocorticoid and mineralocorticoid in response to stress. Patients at risk of this life-threatening event include individuals with primary adrenal disease and those who have adrenal insufficiency secondary to hypothalamic-pituitary suppression (Table 97.5). This emergency has become increasingly common with the widespread use of suppressive doses of corticosteroids in the treatment of chronic disease (e.g., nephrotic syndrome, acute lymphoblastic leukemia, asthma). Infection, trauma, or surgery in the susceptible patient generally precipitates the acute crisis. The diagnosis must be based primarily on clinical suspicion because prompt commencement of therapy is mandatory for survival and definitive diagnostic test results may not be available for weeks. Congenital adrenal hyperplasia is a unique form of adrenal insufficiency that is discussed in a subsequent section of this chapter.

I. Primary Adrenal Insufficiency
A. Congenital adrenal hyperplasia
B. Autoimmunity
C. Tuberculosis
D. Meningococcal septicemia
E. Adrenal hemorrhage
II. Secondary Adrenal Insufficiency
A. Suppression of adrenocorticotropic hormone by pharmacologic doses of glucocorticoid administration
B. Pituitary or hypothalamic tumors
C. Central nervous system surgery or irradiation
D. Structural abnormalities (septooptic dysplasia)
E. Congenital hypopituitarism

Table 97.5. Common Causes of Acute Adrenal Insufficiency in Children

Pathophysiology

Because the production of corticosteroids by the adrenal cortex is under pituitary and hypothalamic control, adrenal insufficiency can result from either an adrenal (primary) or hypothalamic–pituitary (secondary) disorder. Specific adrenal problems resulting in adrenal insufficiency include inborn errors of hormonal biosynthesis (discussed in the subsequent section on Congenital Adrenal Hyperplasia), autoimmune destructive processes, adrenoleukodystrophy, and adrenal

hemorrhage. Hypothalamic–pituitary causes include CNS tumors, trauma, and radiation therapy for a variety of neoplastic disorders. Exogenous administration of glucocorticoids also suppresses the adrenal–pituitary axis, an effect that often lasts well beyond the cessation of corticosteroid therapy.

Glucocorticoids are essential for withstanding stress; therefore, adrenal insufficiency is most likely to be manifested during an intercurrent infection or after trauma. Mineralocorticoids, especially aldosterone, play an important role in salt and water homeostasis by promoting salt resorption in the distal renal tubules and collecting ducts. Mineralocorticoid production is primarily regulated by the renin–angiotensin system; thus, adrenal insufficiency resulting from hypothalamic–pituitary causes is rarely associated with a lack of aldosterone. On the other hand, aldosterone deficiency is a common feature in primary adrenal insufficiency. Because of the nature of the pituitary–adrenal axis, primary adrenal insufficiency is accompanied by significantly elevated ACTH levels.

Clinical Manifestations

The historical information suggestive of adrenal insufficiency depends on the cause. Children with a primary adrenal defect are more likely to have had a gradual onset of symptoms, such as general malaise, anorexia, fatigue, and weight loss. Salt craving and postural hypotension may also have been noted. A child with secondary adrenal insufficiency is more likely to have a history of neurosurgical procedures, head trauma, CNS pathology, or chronic disease necessitating the prolonged use of glucocorticoids.

Findings on physical examination are more likely to be characteristic of the precipitating illness or trauma rather than specifically suggestive of adrenal insufficiency. Although a lack of glucocorticoid and aldosterone can be associated with hypotension and dehydration, a better clue to the possibility of adrenal insufficiency is inappropriately rapid decompensation in the face of metabolic stress. Hyperpigmentation may be present in primary adrenal insufficiency, especially of long duration.

Biochemical evidence suggestive of adrenal insufficiency includes hyponatremia, hyperkalemia, hypoglycemia, and hemoconcentration. Mild metabolic acidosis and hypercalcemia may be present. The definitive diagnosis depends on the demonstration of an inappropriately low level of cortisol in the serum. Blood should be obtained for the measurement of both cortisol and ACTH if the diagnosis is suspected, but results are unlikely to be available on an emergency basis.

Management

Treatment of adrenal crisis is based on rapid volume expansion and the administration of glucocorticoids. Immediate management consists of 50 to 100 mg of hydrocortisone intravenously. Subsequent management is hydrocortisone 50 mg/m^2 per 24 hours given continuously intravenously or methylprednisolone (Solu-Medrol) 7.5 mg/m^2 per 24 hours divided and administered every 8 hours intravenously. Volume expansion is accomplished with normal saline (20 mL/kg) in the first hour, followed by fluids appropriate for maintenance and replacement. Additional Na^+ may be needed in primary adrenal insufficiency because of ongoing urinary Na^+ losses. These fluids should contain 10% dextrose and should not contain potassium until the serum potassium is within the normal range. Mineralocorticoid therapy is rarely important in the acute phase, provided fluid therapy is adequate; however, patients with primary adrenal insufficiency may need replacement with a mineralocorticoid for long-term management. Specific therapy directed toward correction of the hyperkalemia is rarely required unless cardiac arrhythmias are present. Hypoglycemia is remedied by the use of dextrose and by the hyperglycemic effects of glucocorticoids. The precipitating factor, such as infection, also requires appropriate therapy.

Improvement in peripheral circulation and blood pressure should occur quickly. Dramatic improvement often occurs in all parameters within hours after the first dose of glucocorticoid. Because adrenal crisis is commonly brought on by another stress such as infection, the symptoms of malaise, anorexia, and lethargy may take longer to resolve. Once instituted, high-dose glucocorticoid therapy should be continued for 48 hours, and adequate hydration should be maintained either orally or intravenously. The patient known to be at risk for adrenal insufficiency should wear an identifying bracelet to alert ED personnel to this possibility.

CONGENITAL ADRENAL HYPERPLASIA

Background

Inborn errors of adrenal steroid biosynthesis are grouped under the term *congenital adrenal hyperplasia* (CAH). Two major modes of presentation occur in early infancy and require prompt diagnosis and treatment: acute salt-losing crisis and ambiguous genitalia (Table 97.6). CAH may also present in children as precocious virilization. This form of CAH warrants investigation, but it does not require emergency management. The most common form of CAH presenting in infancy is 21-hydroxylase deficiency, which is recessively inherited and accounts for 90% of all cases. Clinically apparent salt wasting develops in 30 to 70% of affected patients. In the United States, the incidence of 21-hydroxylase deficiency is about 1 in 15,000 live births.

	Clinical Features				
	Newborn with Sexual Ambiguity				
Enzyme Deficiency	Female	Male	Salt Wasting	Hypertension	Postnatal Virilization
21-Hydroxylase					
Non-salt wasting	+	0	0	0	+
Salt wasting	+	0	+	0	+
11-Hydroxylase	+	0	0	+	+
3β-Hydroxysteroid dehydrogenase	+	+	+	0	0
17α-Hydroxylase	0	+	0	+	0
Cholesterol desmolase	0	+	+	0	0
18-Hydroxylase	0	0	+	0	0
17β-Hydroxysteroid dehydrogenase	?	+	-	-	+

Table 97.6. Clinical and Laboratory Features of Various Forms of Congenital Adrenal Hyperplasia

Pathophysiology

The enzymes 21-hydroxylase, 11a-hydroxylase, 3b-hydroxysteroid dehydrogenase, and 20,22-desmolase are involved in the production of both cortisol and aldosterone (Table 97.6). Because the hypothalamic–pituitary axis is under feedback control by cortisol, the lack of production of this hormone caused by the enzyme deficiency results in a significant increase in ACTH. In turn, ACTH stimulates the adrenal to increase steroid hormone production. Because cortisol synthesis is impaired, the precursors of cortisol accumulate significantly. The symptoms and signs characteristic of each enzymatic deficiency reflect either the absence of cortisol or aldosterone or the accumulation of their precursors.

Impairment of mineralocorticoid synthesis by 21-hydroxylase, 3b-hydroxysteroid dehydrogenase, and 20,22-desmolase deficiency can result in salt wasting. Although 11a-hydroxylase deficiency also blocks aldosterone production, the immediate precursor to the block, desoxycorticosterone, has potent mineralocorticoid activity. Thus, instead of developing salt loss, patients with this enzyme defect often develop hypertension during childhood.

Androgenic compounds accumulate in 21-hydroxylase and 11a-hydroxylase deficiencies. Females with these defects are virilized in utero and are born with ambiguous genitalia; therefore, females are often identified in the newborn period. Some female infants are so virilized that they are mistaken as males with bilateral cryptorchidism. Males have normal genital development; therefore, the diagnosis is generally missed until they present with salt-wasting crisis during infancy or with evidence of precocious puberty during childhood. Deficiency of 3b-hydroxysteroid dehydrogenase leads to underproduction of testosterone. Boys with this deficiency are undervirilized because only weak androgens are produced, whereas girls are mildly virilized because of these weak androgens. Lack of cortisol renders the patient more susceptible to hypoglycemia and reduces the tolerance to severe stress, such as dehydration.

Clinical Manifestations

Initial evidence of CAH may be acquired at birth with the discovery of ambiguous genitalia, between 2 to 5 weeks of age when the baby presents with acute salt-losing crisis, or during childhood with the onset of precocious puberty. The affected child may come to the ED for any of these reasons. Two words of caution are in order regarding newborn screening for CAH. Although many states now screen newborns for CAH, the results may not be available for 3 to 4 weeks and the acute salt-losing crisis may occur before this time. Furthermore, the report of an abnormal test result may precipitate a visit to the ED: unless the child is ill, consultation with the pediatric endocrinologist is highly recommended.

The subsequent discussion deals primarily with the recognition and management of the acute salt-losing crisis, which is-life threatening. Salt wasting is present shortly after birth, but acute crisis usually does not occur until the second week of life. The appearance of symptoms can be insidious, with a history of poor feeding, lack of weight gain, lethargy, irritability, and vomiting. The nonspecificity of symptoms may lead to consideration of diagnoses far removed from CAH and delay initiation of treatment.

Examination of the child should include the vital signs and an assessment of the degree of dehydration. In severe cases, there may be shock and metabolic acidosis. The genitalia should be examined carefully because the degree of ambiguity of the genitalia varies considerably. Virilized females may have an enlarged clitoris and fusion of the labial folds. An undervirilized male may have a small phallus and/or hypospadias. The presence of gonads in the inguinal canals or labioscrotal fold is suggestive of a male karyotype. Hyperpigmentation of the labioscrotal folds and the nipples is occasionally present in the neonatal period; however, it is rarely prominent enough to alert the examiner to the possibility of CAH.

In the ED, the most urgent investigations are plasma electrolytes and blood glucose. The combination of hyperkalemia and hyponatremia is often the first clue to the diagnosis of CAH, especially in males. The plasma potassium is elevated, but in the presence of vomiting and diarrhea, the rise may be blunted. Levels between 6 and 12 mEq/L are commonly encountered, often without any clinical cardiac dysfunction or ECG changes. The plasma bicarbonate level is usually low, reflecting the metabolic acidosis that results from the retention of hydrogen ions in exchange for sodium loss. The blood glucose is usually normal; however, hypoglycemia may occur secondary to the lack of cortisol and the reduced caloric intake during the acute illness. Serum should be drawn for determination of an adrenal steroid profile to include 17-hydroxyprogesterone, dehydroepiandrosterone, androstenedione, and testosterone. Ideally, blood should be obtained for these tests before the administration of hydrocortisone. In the child in crisis, the diagnosis must be based on physical findings and electrolyte abnormalities, and treatment must be instituted before the definitive adrenal steroid profile is available.

Management

Fluid and Electrolyte Replacement

If the child is dehydrated, fluid replacement is urgent. Volume expansion should be effected by the rapid infusion of 20 mL/kg normal saline in the first hour or more rapidly, if needed. Because the dehydration in salt-losing CAH represents urinary losses of isosmotic fluid, replacement should consist of normal saline (0.9%). The volume to be replaced should constitute the child's daily requirements as well as the estimated fluid loss. Fluid input and output should be monitored carefully.

Mineralocorticoid Replacement

Principal management of the mineralocorticoid deficit is by the provision of sodium. In addition, hydrocortisone has some mineralocorticoid effect, particularly at high dosages. For long-term management, the child will require mineralocorticoid replacement (fludrocortisone 0.1 mg/day). Most infants also require oral Na^+ supplements for the first several months of life.

Glucocorticoid Replacement

Hydrocortisone (25 mg) should be given in an IV bolus, followed by hydrocortisone 50 mg/m^2 per 24 hours as a constant infusion. Alternatively, cortisone acetate 25 mg intramuscularly immediately, followed by 25 mg every 24 hours, may be used. Glucocorticoids can suppress ACTH and the precursor steroids production within a few hours of administration, thus making the diagnosis of an enzymatic deficiency more difficult. However, it is better to avoid the possibility of mortality by giving the steroid than to delay treatment for diagnostic purposes.

Correction of Hyperkalemia, Hypoglycemia, and Acidosis

Infants with CAH tolerate hyperkalemia far better than do other children and adults, with potassium levels as high as 12 mEq/L reported without clinical signs. Volume restoration with normal saline is the major and, usually, the only measure needed to lower the potassium. In the presence of arrhythmias, IV 10% calcium gluconate can be given for its membrane-stabilizing properties. Therapy with glucose and insulin is contraindicated because of the danger of precipitating hypoglycemia. If hypoglycemia is found at the time of presentation, it should be treated acutely by the administration of dextrose (0.25 g/kg) intravenously and by the subsequent inclusion of 10% dextrose in the infusate. Acidosis generally does not require specific treatment; however, the low serum bicarbonate may take days to fully correct.

PHEOCHROMOCYTOMA

Background

Pheochromocytomas are functional tumors that arise in chromaffin tissues. In most children, these tumors are in the adrenal medulla, but they may be found in aberrant tissue along the sympathetic chain. Less than 5% of all pheochromocytomas occur in children. They are twice as common in males as in females, with the incidence of malignancy estimated to be 2 to 4%. Most information on pheochromocytoma is derived from adult studies, especially regarding signs and symptoms. Few detailed studies are available on children.

Pathophysiology

Catecholamines are low-molecular-weight substances produced in the CNS, the sympathetic nerves, the adrenal medulla, and the extra-adrenal chromaffin cells. Catecholamines affect metabolic processes in most tissues of the body and have many effects, including accelerated heart rate, increased myocardial contraction, and increased peripheral vascular resistance. Excessive production of catecholamines by a pheochromocytoma results in intensification of the normal physiologic effects.

Clinical Manifestations

The detection of a pheochromocytoma requires expert clinical awareness. Most patients are symptomatic, but the symptoms are nonspecific and, in the child, are likely to be attributed to other disease entities. The symptoms and signs are related to the excess production of catecholamines and can be explained on the basis of the pharmacologic effects of these substances. The most common symptoms are headache, palpitations, and excessive or inappropriate sweating. The headache, characteristically, is pounding and may be severe. The palpitations may be accompanied by tachycardia. Almost all patients will have one of the three symptoms listed, and most will have at least two. Other symptoms may include nervousness, tremor, fatigue, chest or abdominal pains, and flushing.

The most useful screening tool for pheochromocytoma is the blood pressure cuff because most pheochromocytomas are associated with hypertension. Because this hypertension may be continuous or paroxysmal, frequent and repeated blood pressure determinations may be necessary. Hypertension is most likely to be found when the patient is symptomatic. A hypertensive patient who is asymptomatic is unlikely to have a pheochromocytoma. Paroxysmal symptoms and hypertension should lead to consideration of this diagnosis.

The diagnosis of a pheochromocytoma should also be considered in patients with malignant hypertension, in those who fail to respond or respond inappropriately to antihypertensive medications, and in those who develop hypertension during the induction of anesthesia or during surgery. Incidence of pheochromocytomas is increased among patients with

neurofibromatosis and with the multiple endocrine neoplasia syndromes types II and III.

Documentation of excess catecholamine in either the urine or serum confirms the diagnosis of pheochromocytoma. The most readily available and widely used test for this purpose is the measurement of urinary catecholamines or their metabolites (3-methoxy-4-hydroxymandelic acid and total metanephrines) in a 24-hour urine collection. The finding of significant elevations of these substances is adequate confirmatory data. Some false-negative results may occur using urinary catecholamines. When the degree of suspicion is high, repeated specimens may be needed. Plasma metanephrines and normetanephrines, when appropriately collected, have proven to be diagnostically useful.

Once the diagnosis is confirmed, anatomic localization is necessary using either computed tomography or nuclear magnetic resonance imaging. Occasionally, arteriography with selective sampling for epinephrine production is necessary for localization.

Management

Pheochromocytoma is cured by the surgical removal of the tumor. The focus of ED management should be on controlling hypertension and hypertensive crisis that may occur before the surgical procedure. a-Adrenergic blocking agents are useful in controlling hypertension and in minimizing blood pressure fluctuations during the surgical procedure.

Preferred drugs for controlling hypertension are phenoxybenzamine (Dibenzyline) and prazosin (Minipress). Dosage schedules and quantity must be tailored to the individual for adequate control of hypertension. Hypertensive crisis may be appropriately managed with IV phentolamine (Regitine 1 mg intravenously for children; 5 mg for adolescents) or sodium nitroprusside (0.5 to 8.0 µg/kg per minute).

DIABETES INSIPIDUS

Background

Diabetes insipidus (DI) is caused by an inability of the kidneys to concentrate urine and is characterized clinically by polyuria and polydipsia. Either a deficiency of ADH secretion from the hypothalamus and posterior pituitary gland or renal unresponsiveness to ADH can cause this disease (Table 97.7). Most central causes of DI in children are acquired and can present at any age. In contrast, the most common cause of nephrogenic DI in children is X-linked recessive and manifests in males during early infancy. Renal lesions associated with nephrogenic DI can present in later childhood.

I. Antidiuretic Hormone Deficiency
A. Head injury
B. Meningitis
C. Idiopathic
D. Suprasellar tumors and their treatment by surgery and/or radiotherapy
1. Craniopharyngioma
2. Optic nerve glioma
3. Dysgerminoma
E. Septooptic dysplasia
F. Association with midline cleft palate
G. Familial (dominant or sex-linked recessive)
H. Wolfram syndrome (diabetes insipidus, diabetes mellitus, optic atrophy, deafness)
I. Histocytosis X (Hand-Schüller-Christian disease)
II. Nephrogenic Diabetes Insipidus
A. Sex-linked recessive
B. Renal disease
1. Polycystic kidneys
2. Hydronephrosis
3. Chronic pyelonephritis
C. Hypercalcemia
D. Hypokalemia
E. Toxins:
1. Demeclocycline
2. Lithium
F. Sickle cell disease
G. Idiopathic

Table 97.7. Causes of Diabetes Insipidus in Children

Pathophysiology

ADH is synthesized in the supraoptic and paraventricular nuclei of the hypothalamus. It is transported along nerve axons to the posterior pituitary gland, where it is stored. ADH is released in response to increased plasma osmolality, hypernatremia, and decreased right atrial pressure secondary to hypovolemia. The distal convoluted tubules and the collecting ducts of the kidneys respond to ADH by increasing water reabsorption. Lack of ADH (central DI) can result from a wide variety of hypothalamic and pituitary lesions (Table 97.7). Conversely, in nephrogenic DI, ADH levels are normal or elevated because the defect resides in the renal collecting tubules, which are resistant to the action of ADH. In either case, failure of water reabsorption results in polyuria. A normal thirst mechanism contributes toward fluid balance by promoting adequate fluid intake; however, if this balance is not achieved, hypertonic dehydration ensues. If a hyperosmolar state develops abruptly, it may lead to dehydration of neural tissues, which can cause serious neurologic sequelae or result in death.

Clinical Manifestations

Urine excretion is increased in both volume and frequency in the child with DI. This condition may manifest as enuresis in the younger child. Provided the thirst mechanism is intact and fluids are accessible, the child can compensate for the water loss by drinking more. A history may be elicited of the child's awakening in the middle of the night to drink. If fluids are not available or if fluid intake is interrupted because of a viral illness, dehydration rapidly ensues. In the young infant who is not provided with adequate fluids and consequently is chronically dehydrated, the child may fail to thrive or may have a history of intermittent low-grade fevers. On the other hand, if the cries of the infant are interpreted as hunger rather than thirst, the infant with DI may be obese.

Physical examination may be normal, or signs of dehydration, such as dryness of mucous membranes, decreased skin turgor, sunken eyes, and in an infant, a depressed anterior fontanel, may be present. Because of the hyperosmolarity, the degree of dehydration may be underestimated on physical examination. Hypothalamic or pituitary lesions can lead to other endocrine abnormalities such as secondary hypothyroidism and growth failure. A craniopharyngioma or optic nerve glioma may affect the visual fields or cause raised intracranial pressure, which is indicated by papilledema.

DI is diagnosed by demonstrating that the kidneys fail to concentrate urine when fluid intake is restricted. This condition can be difficult to prove in children. Nonetheless, an adequate working diagnosis is usually obtained by finding an elevated serum osmolality (normal less than 290 mOsm/L) and an elevated serum [Na] (normal less than 145 mmol/L) in the presence of dilute urine (normal osmolality more than 150 mOsm/L). Blood glucose and serum creatinine levels are normal.

In many cases, the diagnosis can be ruled out by the demonstration of appropriately concentrated urine and normal serum osmolality on specimens obtained upon awakening. The definitive diagnosis is made by a formal water deprivation test. This test is performed electively in cases in which the diagnosis is uncertain and should never be performed if the child is already dehydrated. The measurement of ADH by radioimmunoassay is available but generally is not useful in the diagnosis of DI.

Management

In most cases, a diagnosis of DI is not known at the time of presentation; therefore, the acute management is directed toward correction of the dehydration and the hyperosmolar state. The treatment of DI is similar to that described for hypernatremic dehydration (see Chapter 18) with the notable addition that the fluid required for the replacement of urinary fluid losses will be far greater. In fact, the high urinary output, despite significant dehydration, often provides the first and most convincing evidence for DI. If the child is hypotensive or if the serum Na^+ is greater than 160 mmol/L, initial volume expansion is necessary, using 20 mL/kg normal saline during the first hour or more rapidly, if needed. Once an adequate intravascular volume has been achieved, further fluid replacement is accomplished slowly because overly rapid volume correction can cause cerebral edema, seizures, and death.

If the child is not hypotensive, or once the hypotension has been corrected, free water replacement is done over 48 hours. Calculations of appropriate fluids must include maintenance requirements, replacement needs, and ongoing urinary losses (see Chapter 18).

If DI is strongly suspected on the basis of discrepant serum and urine osmolality, DDAVP (5 to 20 µg intranasally or 0.2 to 0.4 µg/kg subcutaneously) may be a useful adjunct to IV fluid therapy. If DDAVP is not available or cannot be used for some reason, other antidiuretic agents are available (aqueous pitressin 1 to 5 units intramuscularly or 2 to 3 µU/kg per minute as a constant IV drip). DDAVP acts rapidly to promote tubular resorption of free H_2O; clinically, this reaction is apparent as decreased urinary output with increased osmolality within an hour of administration. Failure to respond to DDAVP suggests the possibility of tubular unresponsiveness to ADH (nephrogenic DI); however, more commonly, failure to respond results from improper administration of the medication or use of DDAVP that has lost its potency. Because of these factors, if cessation of diuresis is not noted within 2 hours of administration of the first dose, a second dose from a different bottle of DDAVP should be tried. The use of an ADH agonist generally simplifies management by reducing the quantity of fluid that must be infused; however, careful monitoring of input and output remains essential. Children who fail to respond to DDAVP are likely to have nephrogenic DI and must be acutely managed with fluid therapy alone. Paradoxically, the thiazide diuretics have proven to be useful in the chronic control of nephrogenic DI.

The child should be closely observed for changes in level of consciousness, pulse rate, and blood pressure. Fluid input and output should be meticulously monitored. Serum osmolality and $[Na^+]$ should be determined every 1 to 2 hours until the rate of their decline can be determined. Urine osmolality should be measured every 1 to 2 hours to determine the responsiveness of the renal tubule to DDAVP. Because large volumes of dextrose-containing fluids are used, the blood glucose should also be followed closely. If the blood glucose exceeds 160 mg/dL, the concentration of dextrose in the infusate should be decreased.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

Background

Excessive secretion of ADH accompanying normal or low plasma osmolality or [Na] is inappropriate because it further depresses the plasma osmolality and [Na]. Symptoms of excessive ADH secretion are not usually apparent until the plasma [Na] falls below about 120 mmol/L. The overall incidence of the syndrome of inappropriate antidiuretic hormone secretion (SIADH) in childhood is unknown, but it is common in certain disease states. More than 50% of children with bacterial meningitis, about 20% of patients on positive pressure ventilation, and about 70% of children with Rocky Mountain spotted fever develop SIADH.

Pathophysiology

ADH secretion is stimulated by hypertonicity of the fluid surrounding the hypothalamic osmoreceptors, by volume receptors in the left atrium, and by ill-defined nervous impulses from higher cortical centers. Disorders of the CNS (Table 97.8) may cause excessive ADH secretion by producing either a local disturbance of the hypothalamic osmoreceptors or some undetermined nervous stimuli. Many intrathoracic conditions are associated with SIADH, probably by stimulating the volume receptors in the left atrium. Physical and emotional stress and severe pain also cause ADH secretion. Excessive secretion of ADH leads to water retention by the collecting tubules of the kidneys, a mechanism mediated by cyclic adenosine monophosphate (cAMP). The retained water expands the intravascular compartment, dilutes all plasma

constituents, and lowers the plasma osmolality.

I. Disorders of Central Nervous System	III. Miscellaneous
A. Infection (meningitis, encephalitis)	A. Pain (e.g., after abdominal surgery)
B. Trauma, postneurosurgery	B. Severe hypothyroidism
C. Hypoxic insults, especially in the perinatal period	C. Congenital deficiency
D. Brain tumor	D. Tumors (e.g., neuroblastoma)
E. Intraventricular hemorrhage	E. Idiopathic deficiency
F. Guillain-Barré syndrome	IV. Drug-Induced
G. Psychosis	A. Increased antidiuretic hormone secretion
II. Intrathoracic Disorders	1. Vincristine
A. Infection (tuberculosis, pneumonia, empyema)	2. Cyclophosphamide
B. Positive-pressure ventilation	3. Carbamazepine
C. Asthma	4. Adenine arabinoside
D. Cystic fibrosis	5. Phenothiazines
E. Pneumothorax	6. Morphine
F. Patent ductus arteriosus ligation	B. Potentiation of antidiuretic hormone effect
	1. Acetaminophen
	2. Indomethacin

Table 97.8. Some Causes of Syndrome of Inappropriate Antidiuretic Hormone Secretion (SIADH) in Children

Clinical Manifestations

Most patients with SIADH are asymptomatic until the plasma [Na] falls below 120 mmol/L. Symptoms associated with hyponatremia range from anorexia, headache, nausea, vomiting, irritability, disorientation, and weakness to seizures and coma, leading ultimately to death. Absence of edema and dehydration are significant clinical findings.

Laboratory investigations for diagnostic purposes must include concomitant serum and urine samples (Table 97.9). Hyponatremia, hypoosmolality (serum), and low blood urea nitrogen will be present. In contrast, the urinary osmolality and [Na] are inappropriately elevated for the hypotonicity of the serum. Radioimmunoassay for ADH is now available and has been helpful in defining this syndrome; however, the results of this test are unlikely to be available on an emergency basis. The underlying cause of the syndrome should be investigated according to the physician's' clinical judgment. In the presence of hyperglycemia, hyperlipidemia, or hyperproteinemia, the serum sodium may be falsely low. Renal salt wasting, secondary to adrenal insufficiency, should be accompanied by hyperkalemia and dehydration. The urine osmolality in water intoxication states is usually low compared with that found in SIADH.

Hyponatremia, reduced serum osmolality
Urine osmolality that is inappropriately elevated (a urine osmolality <100 mOsm/kg usually excludes the diagnosis)
Urinary Na concentration that is excessive in comparison to the degree of hyponatremia (usually >18 mEq/L)
Normal renal, adrenal, and thyroid function
Absence of volume depletion

Table 97.9. Criteria for Diagnosis of Syndrome of Inappropriate Antidiuretic Hormone Secretion (SIADH)

Management

Severely Symptomatic Children

Patients with a persistent seizure attributable to severe hyponatremia and those who are lethargic or comatose need urgent treatment. Hypertonic (3%) saline is the preferred treatment. Infusing small amounts of 3% saline in the range of 3 mL/kg every 10 to 20 minutes until symptoms remit is probably the safest course of treatment. A single dose of furosemide (1 mg/kg) also can be administered intravenously. Close monitoring of fluid balance, plasma and urinary sodium, potassium, and osmolality is essential. Phenytoin (Dilantin) intravenously (5 to 10 mg/kg) inhibits ADH release and may be helpful in the patient with seizures secondary to CNS causes of SIADH. The underlying cause of SIADH, such as meningitis, should be treated when possible; successful treatment is usually accompanied by remission of inappropriate antidiuresis.

Asymptomatic or Mildly Symptomatic Children

Asymptomatic or mildly symptomatic patients are treated by rigorous fluid restriction. If the patient is not vascularly compromised, fluid input should be sharply limited, often below insensible loss, until the [Na] and osmolality begin to rise. If the initial [Na] is less than 125 mmol/L, all fluids must be withheld. Frequent measurements of plasma electrolytes and osmolality, as well as close monitoring of fluid input and output, are essential. As the serum [Na] rises and urine osmolality falls, the rate of fluid administration can be gradually increased. The child with chronic or recurrent episodes of SIADH may require treatment with demeclocycline 10 mg/kg. The underlying cause should be identified, treated, and eliminated, if possible.

HYPERPARATHYROIDISM

Background

Hyperparathyroidism is most commonly recognized during the third, fourth, and fifth decades of life. It is uncommon in children.

Pathophysiology

The parathyroid glands are derived from the third and fourth pharyngeal pouch and are usually embedded in the posterior aspect of the thyroid gland. Occasionally, a gland may be found in the anterior mediastinum. Parathyroid hormone (PTH) is the primary hormone produced by the parathyroid glands. The normal stimulus for PTH synthesis and release is a low calcium concentration. Prolonged hypocalcemia may lead to hypertrophy of the parathyroid glands. PTH acts on the kidney to decrease the excretion of calcium, magnesium, and hydrogen while increasing the excretion of phosphate, sodium, and bicarbonate. Many of the effects are mediated by cAMP, and an increased quantity of cAMP is present in the urine of patients with hyperparathyroidism. PTH also increases the formation of 1,25-dihydroxyvitamin D in the kidneys. PTH may increase intestinal absorption of calcium, although this effect is primarily mediated by 1,25-$(OH)_2D$. Both PTH and 1,25-$(OH)_2D$ affect bone. PTH acts on bone to increase the release of calcium by increasing the number and activity of the osteoblasts, whereas vitamin D decreases calcium use in bone formation by decreasing the number of osteoblasts. The net effect of the actions of PTH and vitamin D is to increase serum calcium by decreasing renal calcium excretion, decreasing new bone formation, increasing intestinal absorption of calcium, and increasing bone resorption.

Clinical Manifestations

Hyperparathyroidism has two common presentations in children. The first presentation is the critically ill infant who is found to have severe hypercalcemia during the course of diagnostic investigations. The serum calcium level may be extremely high. The second presentation is a child in the early to midteens with nonspecific symptoms including nausea, constipation, unexplained weight loss, personality changes, and headaches. Diffuse bone pain or renal colic may be reported, although these symptoms are less common in children than in adults.

The physical findings of hypercalcemia are hypotonia, weakness, and listlessness. Rarely, a palpable mass is located in the parathyroid region. Certain characteristic features have been associated with idiopathic hypercalcemia in infancy, including hypertelorism, broad forehead, epicanthal folds, prominent upper lip, an underdeveloped nasal bridge, and a small mandible. Not surprisingly, these same features have been noted in infants with hyperparathyroidism.

A family history may be helpful because hyperparathyroidism has been associated with both multiple endocrine neoplasia types I and II, which are inherited as autosomal-dominant conditions. Hyperparathyroidism also may occur in infants of hypoparathyroid mothers. Radiologic findings consistent with hyperparathyroidism include evidence of demineralization and bone resorption (Fig. 97.1 and Fig. 97.2). Osteitis fibrosa cystica, although highly suggestive of the diagnosis, is unusual in children.

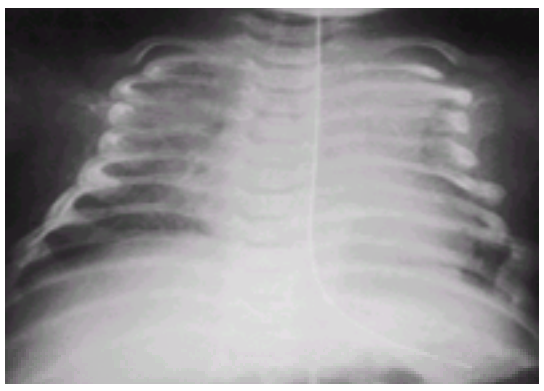


FIGURE 97.1. Primary hyperparathyroidism in a 3-day-old girl. Roentgenogram of the chest shows profound demineralization of the skeleton with loss of a well-defined cortical margin. Cystic changes in rib and subperiosteal bone resorption in humerus are seen. (Courtesy of Soroosh Mahboubi, MD, The Children's Hospital of Philadelphia.)

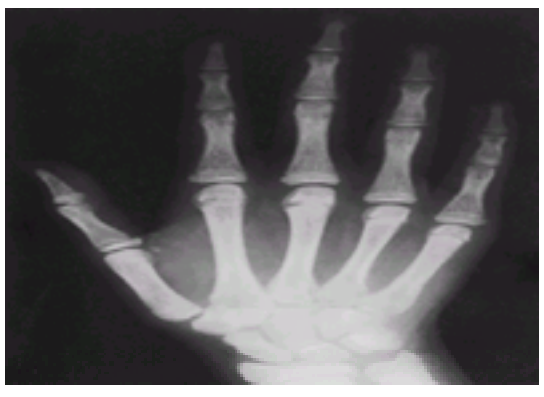

FIGURE 97.2. Secondary hyperparathyroidism in a 12-year-old girl with chronic pyelonephritis. There is moderate subperiosteal erosion on the radial side of the middle phalanges; note a lacy appearance of the periosteum and small-tuft

erosion. Subperiosteal bone resorption is the most significant radiologic finding in hyperparathyroidism; subperiosteal bone resorption and tuft erosion are seen in both primary and secondary hyperparathyroidism. (Courtesy of Soroosh Mahboubi, MD, The Children's Hospital of Philadelphia.)

The clinical laboratory is helpful in the recognition of hyperparathyroidism. Hypercalcemia is usually present but may be subtle or intermittent in mild cases. The serum inorganic phosphate level is usually low but may be normal, especially in patients with decreased renal function. Mild hyperchloremic acidosis may be present. Alkaline phosphates level and urinary hydroxyproline excretion may be elevated secondary to increased osteoclast activity. Because PTH causes a significant increase in cAMP in the kidney tubule, the presence of excess cAMP in the urine is strongly suggestive of excess PTH production. The determination of PTH levels is critical for diagnostic purposes, and elevated levels of PTH, when the patient is hypercalcemic, is a definitive laboratory finding.

Management

Acute management of hyperparathyroidism is essentially the same as management of hypercalcemia (see Chapter 86). The specific management of hyperparathyroidism depends on the level of calcium and on the presence of signs and symptoms. In the asymptomatic patient with a serum calcium of less than 12 mg/dL, careful follow-up with close attention to both bone mass and renal function is recommended. If the child is persistently hypercalcemic, parathyroid surgery is the preferred treatment. In the case of hyperplasia, the common reason for hyperparathyroidism in the infant, subtotal parathyroidectomy is indicated. If an adenoma is present, as is usually the case in the older child, simple removal of the involved parathyroid gland is adequate.

HYPOPARATHYROIDISM

Background

Hypoparathyroidism is rare in children. It may occur sporadically or be part of a familial syndrome consisting of combinations of several autoimmune diseases (e.g., Addison's disease, diabetes mellitus, lymphocytic thyroiditis, pernicious anemia, ovarian failure). Hypoparathyroidism is also associated with thymic aplasia and severe immunologic deficiencies (DiGeorge's syndrome). A transient form of hypoparathyroidism, lasting for as long as a year, has been reported in some infants. Hypoparathyroidism also may result from damage incurred during thyroid surgery or irradiation.

Pathophysiology

The basic actions of PTH are described in the preceding section on hyperparathyroidism. The lack of PTH, regardless of cause, has several deleterious effects on calcium homeostasis. Because PTH has significant effects on 1,25-$(OH)_2D_3$ formation, the absence of PTH is magnified by a consequent reduction in 1,25-$(OH)_2D_3$. The net effect of the lack of PTH (and decreased quantity of vitamin D) is a declining serum level of calcium, primarily caused by decreased intestinal absorption of calcium and decreased renal resorption of calcium.

Clinical Manifestations

The predominant historical features and clinical manifestations of hypoparathyroidism are the same as those of hypocalcemia (see Chapter 86). Unique historical information that may suggest the diagnosis of hypoparathyroidism includes other family members with autoimmune endocrine disease, recurrent episodes of serious infection in the affected child, and previous thyroid manipulations.

Most symptoms and signs of hypoparathyroidism are the same as those related to hypocalcemia. The particular symptoms and signs found depends on the age at onset of the disease, the chronicity of the disease, and the presence of other autoimmune or syndromic phenomena. Papilledema without hemorrhage may be seen during the initial examination and tends to resolve within several days after the initiation of therapy. Lenticular cataracts are common in hypoparathyroidism and are associated with long-standing hypocalcemia of any cause. Psychiatric and neurologic disorders occur in association with hypoparathyroidism. Subnormal intelligence occurs in about 20% of children with the idiopathic form of hypoparathyroidism, and the severity correlates closely with the period of untreated hypocalcemia. Dry, scaly skin is a common finding, as is patchy alopecia. Psoriasis or mucocutaneous candidiasis may be found on occasion. Unusually brittle fingernails and hair are often found. Hypoplasia of tooth enamel may be seen if hypoparathyroidism was present at the time of dental development. Intestinal malabsorption and steatorrhea have been reported in association with hypoparathyroidism.

In most cases, the diagnosis of hypoparathyroidism is first considered when low serum calcium is found. If an elevated phosphate accompanies low calcium, a low or normal serum alkaline phosphate, and normal blood urea nitrogen, hypoparathyroidism is a likely possibility. Finding a low or unmeasurable level of PTH in the presence of hypocalcemia and hyperphosphatemia makes the definitive diagnosis. Because PTH increases cAMP levels in the urine, the excreted amount of cAMP in the urine is low in patients with hypoparathyroidism and rises briskly with the administration of exogenous PTH. The presence of antibodies in other endocrine tissues or organs may help in delineating the cause of the hypoparathyroidism.

Management

The acute management of hypoparathyroidism is essentially the management of the hypocalcemia (see Chapter 86). Long-term management consists of treatment with vitamin D, usually with one of its more active analogs—1,25-$(OH)_2D_3$.

Supplemental oral calcium is almost always necessary. The goals of long-term therapy are to maintain the serum calcium in the lower range of normal and to avoid both vitamin D toxicity and hypercalcemia. Preparations of PTH are not available for the long-term management of hypoparathyroidism.

RICKETS

Background

Rickets describes a characteristic set of clinical features delineated centuries ago, which is now known to be predominantly caused by inadequate dietary vitamin D. With this awareness and the advent of vitamin D supplementation of foods, especially milk, the incidence of rickets has fallen significantly; however, rickets is still seen among certain ethnic groups, premature infants, children with severe malabsorption problems, and patients with serious renal disease.

Pathophysiology

Rickets is caused by the failure of mineralization of bone matrix in growing bone resulting from a lack of vitamin D. Consequently, unmineralized cartilage is excessive, and bone is soft. In addition to inadequate intake of vitamin D, the other causes of rickets are inability to form the active metabolite of vitamin D, excess phosphate excretion, and excess accumulation of acid.

Vitamin D may be obtained from dietary sources (especially animal fat) or synthesized from cholesterol via a complex pathway requiring the interaction of the precursor molecule with sunlight. Further hydroxylation of vitamin D in the liver (25-hydroxylation) and kidney (1-hydroxylation) leads to the formation of the active metabolite 1,25-dihydroxyvitamin D. Therefore, failure to form 1,25-$(OH)_2D_3$ may result from inadequate intake of vitamin D or insufficient exposure to sunlight. This is a particular problem among ethnic groups that eat small quantities of animal meat and that are extensively clothed when outdoors. Because vitamin D is fat soluble, any problem leading to prolonged fat malabsorption can result in rickets. Diseases affecting kidney or liver function may also lead to inadequate production of 1,25-$(OH)_2D_3$. An inherited deficiency of the 1-hydroxylase in the kidney (vitamin D–dependency rickets) is known. Certain drugs, such as phenobarbital and phenytoin, affect liver metabolism of vitamin D and can lead to rickets. Premature infants are particularly prone to vitamin D deficiency because of their minimal stores of vitamin D and their limited capacity for vitamin D synthesis.

Phosphate is a critical component of bone formation. Excess excretion of phosphate may lead to clinical rickets. Conditions that lead to excess phosphate excretion include primary hyperphosphaturia, Lowe's syndrome, and Fanconi's syndrome. Vitamin D–resistant rickets is a misnomer because the primary defect is in the renal tubular resorption of phosphate and not a resistance to vitamin D. Both an X-linked recessive and an autosomal-dominant form of phosphate wasting are known.

Rickets may also occur in conditions leading to chronic acidosis because bone is resorbed to buffer the acid load. This condition is seen in patients with distal renal tubular acidosis and may be partially responsible for the rachitic changes associated with Fanconi's syndrome.

Clinical Manifestations

Children with rickets may come to medical attention because of specific physical abnormalities (bowed legs), limb pain and swelling, seizures, failure to thrive (renal tubular acidosis), biochemical abnormalities (hypocalcemia), or radiographic findings (broadened, frayed metaphysis). A thorough social and dietary history is helpful in delineating the probable cause and in sparing the patient an extensive and expensive evaluation. A family history may be useful in identifying the 1-hydroxylase deficiency or renal phosphate wasting. If the child has previously been treated with vitamin D, the reported response to that treatment may be helpful in identifying the likely site of defect.

The clinical findings in rickets may vary considerably depending on the underlying disorder, the duration of the problem, and the child's age. Most features are related to skeletal deformity, skeletal pain, slippage of epiphyses, bony fractures, and growth disturbances. Muscular weakness, hypotonia, and lethargy are often noted. Failure of calcification affects those parts of the skeleton that are growing most rapidly or that are under stress. For example, the skull grows rapidly in the perinatal period; therefore, craniotabes is a manifestation of congenital rickets. On the other hand, the upper limbs and rib cage grow rapidly during the first year of life, and abnormalities at these sites are more common at this age (i.e., rachitic rosary, flaring of the wrist). Bowing of the legs is unlikely to be noted until the child is ambulatory. Dental eruption may be delayed, and enamel defects are common.

Radiography is the optimal way to confirm the clinical diagnosis because the radiologic features reflect the histopathology. Characteristic findings include widening and irregularity of the epiphyseal plates, cupped metaphyses, fractures, and bowing of the weight-bearing limbs (Fig. 97.3 and Fig. 97.4). The clinical laboratory is often helpful in correctly identifying the cause of rickets. Frank hypocalcemia (less than 7 mg/dL) is unusual in rickets. Calcium levels in the 7 to 9 mg/dL range are common and warrant careful attention because the initiation of vitamin D treatment increases bony deposition of calcium and may lead to a fall in serum calcium. Phosphate levels are often low. An amino aciduria is often present and may lead to some confusion of simple vitamin D deficiency with Fanconi's syndrome. Alkaline phosphatase levels are significantly increased, reflecting extremely active bony metabolism. Although PTH levels are elevated, the results of this test are unlikely to be available at the time initial clinical decisions are made. Chronic acidosis, liver disease, and renal disease should be ruled out.

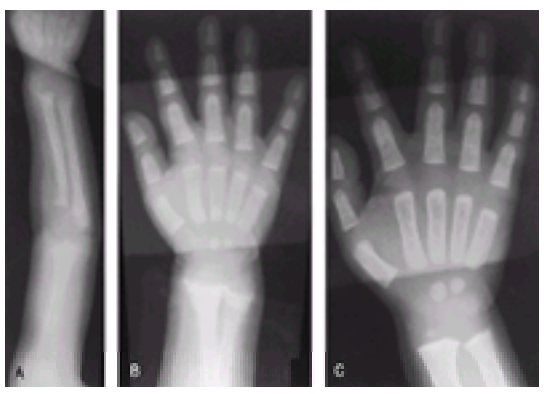

FIGURE 97.3. A. Rickets in an 11-month-old boy, breast-fed since birth. Roentgenogram of the upper extremity shows profound demineralization of the skeleton, with frayed, irregular cupping of the end of the metaphysis and poorly defined cortex. Note retardation of skeletal maturation. **B.** Same patient with some healing 4 weeks after supplemental vitamin D. Severe rachitic changes are noticeable. Periosteal cloaking, both of the metacarpals and of the radius and ulna, is evidence of healing. **C.** Complete healing of the rickets 8 months after treatment. Note the reappearance of the provisional zone of calcification. (Courtesy of Soroosh Mahboubi, MD, The Children's Hospital of Philadelphia.)

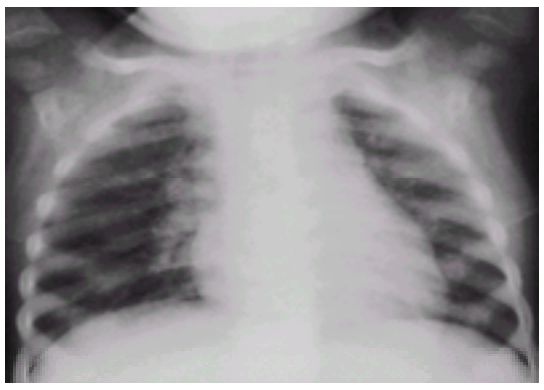

FIGURE 97.4. Rickets in an 11-month-old boy, breast-fed since birth. Roentgenogram of the chest shows demineralization of the skeleton with cupping of the distal end of ribs and humerus. (Courtesy of Soroosh Mahboubi, MD, The Children's Hospital of Philadelphia.)

Treatment

Treatment depends on the nature of the underlying disease. The response to treatment may be helpful in differentiating simple dietary vitamin D deficiency from more complex causes of rickets. In the absence of chronic disease, dietary rickets may be adequately treated with daily doses of 1000 to 2000 IU of vitamin D until healing occurs. Serum phosphate usually returns to normal within 1 to 2 weeks, and radiographic improvement is generally apparent by 2 weeks. Once healing is complete, the child should continue to be treated with 400 IU/day to prevent recurrence. If the initial serum calcium is borderline low or low, supplemental calcium should be initiated 48 hours before the institution of vitamin D, especially in the young child. Otherwise, the institution of vitamin D may cause a further decrease in serum calcium and elicit frank hypocalcemia. Children with symptomatic hypocalcemia or an initial serum calcium of less than 7 mg/dL on presentation warrant hospitalization and frequent calcium determinations. Failure to respond to vitamin D treatment suggests that the child has a more complex cause of rickets, and consultation with a pediatric nephrologist or endocrinologist is recommended.

THYROID STORM

Background

Thyroid storm, or thyrotoxic crisis, is a fulminating intensification of the hyperthyroid state. Because hyperthyroidism uncommonly occurs in children and because thyroid storm occurs in only 1% of patients with hyperthyroidism, thyroid storm is rare in children. Therefore, most information available on thyrotoxic crisis is derived from reports of this condition in adults. Precipitating factors include intercurrent infection, trauma, and subtotal thyroidectomy in an inadequately prepared patient. The mortality rate in adults may be as high as 20%; similar data are not available for children.

Pathophysiology

In thyroid storm, thyroid hormone is suddenly released into the circulation, which results in the uncoupling of oxidative phosphorylation and/or increased lipolysis, both of which contribute to excessive thermogenesis. Insensible fluid loss increases as a result of increased metabolism and sweating. Tachycardia is caused by both the hyperthermia and the direct action of thyroid hormones on the cardiac conduction system.

Clinical Manifestations

Almost all cases of thyroid storm occur in patients with known hyperthyroidism, although occasionally, a patient will present initially with thyroid storm. Most patients will have clinical findings characteristic of hyperthyroidism, including goiter (more than 95%), exophthalmos, tachycardia, bounding pulses, and systolic hypertension. Tremulousness,

restlessness, mania, delirium, or frankly psychotic behavior may be present. A primary feature that distinguishes thyroid storm from uncomplicated hyperthyroidism is the presence of high fever, often as high as 41°C (105.8°F). The marked increase in cardiac work load may result in congestive heart failure, in which case hypotension and pulmonary edema may be seen, rather than more classic hypertension.

Thyroid studies including serum thyroxine (T_4), triiodothyronine (T_3), T_3 resin uptake (T_3 RU), and TSH should be obtained. Many clinical laboratories can now perform T_4 assays on an emergency basis; however, in many cases, therapy must be initiated on the basis of clinical evidence. Furthermore, the T_4 and T_3 values seen in thyroid storm overlap with those found in frank hyperthyroidism without storm. Serum electrolytes should be obtained but are unlikely to reveal any characteristic abnormalities, except for evidence of modest dehydration. A chest radiograph and ECG are helpful in evaluating and following cardiac status as treatment is initiated.

Management

Initial treatment is directed toward lowering the metabolic rate and reducing the cardiac work load. Subsequent treatment is directed toward controlling thyroid hormone production. Because many of the hypermetabolic effects of hyperthyroidism are mediated by the adrenergic system, a blocker (propranolol starting at 10 µg/kg intravenously over 10 to 15 minutes) is useful in the acute management of thyroid storm. ECG monitoring for heart rate and arrhythmias is recommended. Because the metabolic rate is increased about 10% for every degree of body temperature above 36.5°C (97.7°F), lowering body temperature is an effective means of reducing the metabolic rate in the patient with thyrotoxicosis. Tepid sponging, use of a cooling blanket, and administration of acetaminophen can accomplish this task. Aspirin should not be used because it is a potential uncoupler of oxidative phosphorylation that may exacerbate the hypermetabolic state.

Treatment of the hyperthyroidism in thyroid storm is accomplished by the use of iodide and a thiourea derivative such as propylthiouracil. Iodide rapidly terminates thyroid hormone release; however, this effect is overcome after 3 to 5 days of iodide therapy. Lugol's iodide 5 drops once every 8 hours orally or sodium iodide 125 to 250 mg/day intravenously over 24 hours is the usual mode of iodide therapy. Propylthiouracil has at least two beneficial effects: 1) prevention of thyroid hormone synthesis in the thyroid gland and 2) inhibition of the peripheral conversion of thyroxine to its more active form, T_3. The dosage of propylthiouracil is 6 to 10 mg/kg per day, given orally every 6 to 8 hours. Its effects are minimally useful in acute management because the reduction in thyroid levels may take several days. Methimazole 0.6 to 0.7 mg/kg per day divided every 8 hours is an alternative to propylthiouracil, but its usefulness in thyroid storm is subject to the same limitations as propylthiouracil.

Adequate hydration is essential for effective treatment, and the estimate of fluid replacement should include a consideration of the significant increase in fluid requirements caused by fever and an accelerated metabolic rate. Glucocorticoids are useful in the acute situation because they appear to inhibit thyroid hormone release from the thyroid and decrease the peripheral conversion of T_4 to T_3. Dexamethasone (0.2 mg/kg) or hydrocortisone (5 mg/kg) can be given parenterally during the acute phase. Because intercurrent infection may be the precipitating factor, it should be searched for and treated appropriately. Broad-spectrum antibiotics should be considered while awaiting the results of cultures.

Improvement should be seen within a few hours after the initiation of treatment with propranolol, especially in terms of cardiovascular status. Full recovery and adequate control of the underlying thyroid disease will take several days to achieve. For the patient presenting with thyroid storm, serious consideration should be given to permanent treatment of the hyperthyroidism, either by surgery or radioiodide ablation.

NEONATAL THYROTOXICOSIS

Background

Neonatal thyrotoxicosis is a life-threatening condition that may not be correctly diagnosed in the newborn nursery and that may be discovered only when the child presents in extremis in the ED. Neonatal thyrotoxicosis is found in 1 to 5% of infants born to mothers with a history of hyperthyroidism; however, the maternal disease does not have to be active during the pregnancy.

Pathophysiology

Neonatal thyrotoxicosis is caused by excessive thyroid hormone produced by the neonatal thyroid that has been stimulated by maternal thyroid-stimulating antibodies present in the immunoglobulin G (IgG) fraction that have crossed the placenta. TSH, T_4, and T_3 do not cross the placenta in significant quantities. In most cases, the disease is self-limiting, and hyperthyroidism remits within about 6 weeks. Occasionally, the disease may run a protracted course and arise in the absence of maternal thyroid-stimulating antibodies.

Clinical Manifestations

Goiter and exophthalmos are almost always present; however, a goiter may be difficult to appreciate in a small infant with a short neck. The child usually fails to gain weight despite a ravenous appetite. The child may also be irritable and have tachycardia, as well as signs of congestive heart failure. Laboratory investigations should include estimations of serum T_4, T_3, and TSH, and thyroid-binding capacity. Increased concentration of T_4 in the presence of suppressed TSH levels is consistent with the diagnosis. If the mother is taking antithyroid medication, thyroid function tests on the infant may be unreliable in the first days of life because of suppression of the fetal thyroid by transplacental passage of maternal antithyroid medication. The bone age may be advanced. In most cases, treatment must be initiated on the basis of

historical and clinical findings.

For an infant who has an elevated level of T_4 but who has few, if any, symptoms or signs, consultation with a pediatric endocrinologist is strongly recommended. T_4 levels in all infants tend to be higher than those in older children because of increased TBG induced by maternal estrogen that crosses the placenta. Also, an elevated thyroxine may be seen with defects that alter the binding of T_4 to thyroid-binding globulin (TBG) or the end-organ sensitivity to T_4.

Management

Treatment is identical to that outlined for thyroid storm in older children. The duration of treatment is uncertain and should be based on serial thyroid function tests, especially TSH. It is anticipated that treatment need be continued only for 6 to 8 weeks in most cases because the causative agent is a subclass of IgG molecules with a serum half-life of about 2 weeks.

CONGENITAL HYPOTHYROIDISM

Background

Most westernized countries routinely screen infants in the first days of life for congenital hypothyroidism. The incidence of this problem is 1 in 3500 to 5000 live births. On occasion, notification of the parents by the screening program results in significant parental anxiety and leads to a visit to the ED. Emergency physicians should be knowledgeable about congenital hypothyroidism so that they can appropriately educate parents and initiate therapy. Acquired hypothyroidism rarely results in urgent clinical problems that lead to ED visits.

Pathophysiology

The causes of congenital hypothyroidism are numerous. About 20% of patients have ectopic glands, and another 50% have hypoplastic or aplastic thyroid glands. Other causes are less common and include dyshormonogenesis, maternal ingestion of antithyroid medication, hypothalamic–pituitary disorders, and defects in thyroglobulin metabolism. The dyshormonogenic disorders are inherited as autosomal-recessive conditions. Congenital thyroid deficiency may result in impaired neurologic development if not treated before 1 month of age.

Clinical Manifestations

Clinical symptoms and signs of congenital hypothyroidism may be subtle, especially during the first month of life. Severely affected infants may be relatively large at birth, have a large posterior fontanel, manifest hypothermia and hypoactivity, feed poorly, tend to become constipated, and have prolonged jaundice. An enlarged tongue, coarse facies, and a hoarse cry may also be noted but are unusual in the first weeks of life. An umbilical hernia may be present. If treatment is not started, the physical characteristics become more prominent as the child grows older. Thyroid function tests beyond the first 2 days of life are most useful diagnostically. The TSH level is elevated in primary hypothyroidism, and the T_4 level is low or normal for age. A thyroid scan (^{123}I) may be helpful in identifying the particular type of primary hypothyroidism, but treatment should not be delayed to obtain this study. A low T_4 level in the absence of elevated TSH level may result from a deficiency of thyroid-binding globulin, a pituitary deficiency of TSH, or prematurity.

Management

In term infants, treatment with l-thyroxine, 37.5 µg once daily should be instituted as soon as the relevant diagnostic tests are performed. This dosage can be adjusted to maintain a T_4 level between 10 and 14 µg/dL and a TSH value of less than 5.5 µU/mL after a few weeks of treatment. Both undertreatment and overtreatment must be avoided. Careful follow-up on a monthly basis during the first several months, preferably by a physician who is accustomed to dealing with congenital hypothyroidism, is strongly recommended.

CHAPTER 98

Metabolic Emergencies (Inborn Errors of Metabolism)

MARC YUDKOFF, MD

Department of Pediatrics, The University of Pennsylvania School of Medicine, and Child Development, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

The inborn errors of metabolism comprise a group of clinically diverse disorders that usually involve a deficiency of an enzyme or transport system. Consequently, one or more metabolites accumulate in body fluids, often to a concentration that causes serious toxicity of the central nervous system. This chapter focuses on those disorders in which coma and other neurologic signs are major clinical findings. A summary of these diseases, together with suggestions for initial evaluation and treatment, is given in Table 98.1.

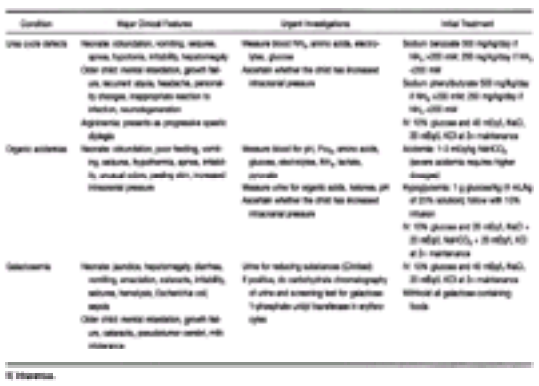

Table 98.2. General Features of Inborn Errors of Metabolism

Failure to make an early diagnosis, when appropriate treatment often can be administered, may lead to irreparable brain injury. Physicians therefore should consider the inborn errors of metabolism in the differential diagnosis of the patient with unexplained neurologic findings. The alert caregiver should request appropriate laboratory tests when indicated by the history and physical findings. The latter are summarized in Table 98.2.

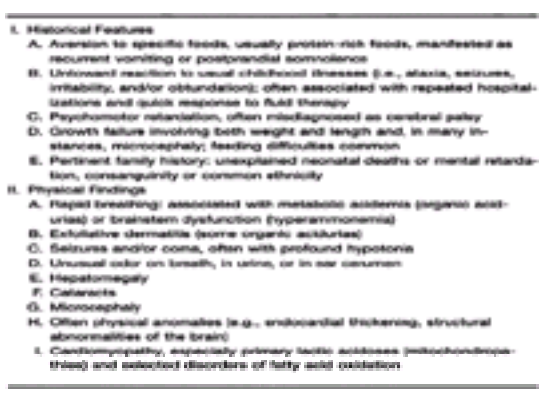

Table 98.1. Summary of Clinical Features, Investigations, and Initial Treatment of Inborn Errors of Metabolism

A careful history is essential. Is the disease episodic? Has an acute attack of obtundation, seizures, and acidosis been preceded by a high intake of protein or an acute infection? Even otherwise trivial infections may precipitate a fulminant syndrome. Parents sometimes report that their child has been admitted repeatedly to the hospital, only to recover after administration of intravenous fluids and glucose. Such a history, especially if coupled with psychomotor retardation and/or growth failure, should always prompt consideration of an inherited metabolic defect.

Many discrete metabolic diseases have been identified. The spectrum of clinical manifestations is broad, ranging from clinically silent biochemical derangements that are detected through a routine screening program to potentially fatal disturbances (e.g., the urea cycle defects, which are characterized by a dramatic clinical presentation entailing sudden

neurologic decompensation).

Metabolic diseases are relatively rare, often occurring perhaps only once in 100,000 or 200,000 live births. A precise estimate is elusive because some cases remain undetected. In addition, the classical phenocopy of a given biochemical defect often is not the only mode of clinical presentation. The literature now abounds with descriptions of variant forms that manifest a later age of onset and a clinical course that is milder than that of the more complete metabolic lesion; the latter usually is described first because of the more dramatic clinical findings that are associated with a pervasive enzymatic deficiency.

UREA CYCLE DEFECTS

Background

All cells produce ammonia as an end-product of nitrogen metabolism. Because high ammonia concentrations are toxic to the brain, various biochemical strategies have evolved for the efficient disposal of this metabolite. Many animals, including humans, convert ammonia to urea via the urea cycle, as shown in Figure 98.1. Waste nitrogen is thereby eliminated as urea, which is excreted into the urine. The most vivid example of the importance of the urea cycle to metabolism is the hyperammonemia that occurs in hepatic failure or a congenital deficiency of one of the urea cycle enzymes (Table 98.3).

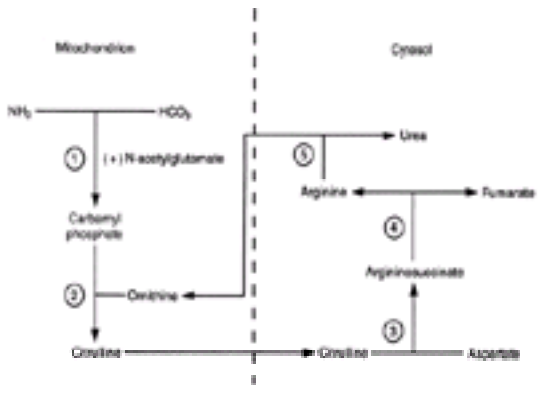

FIGURE 98.1. The urea cycle. Enzymes: *1,* carbamyl phosphate synthetase; *2,* ornithine transcarbamylase; *3,* argininosuccinate synthetase; *4,* argininosuccinate lyase; *5,* arginases. The symbol + indicates that *N*-acetylglutamate is a positive effector for carbamyl phosphate synthetase.

I. Primary Urea Cycle Enzyme Deficiencies	II. Hepatic Amino Acid Transport Defects
A. Carbamyl phosphate synthetase deficiency	A. Lysinuric protein intolerance
B. Ornithine transcarbamylase deficiency	B. Homocitrullinuria, hyperornithinemia, and hyperammonemia
C. Citrullinemia	
D. Argininosuccinic aciduria	
E. Argininemia	

Table 98.3. Inherited Causes of Hyperammonemia

Pathophysiology

The relationship between elevated ammonia levels and impaired neurologic function remains poorly understood. A derangement of energy metabolism may be involved because adenosine triphosphate (ATP) levels can be low, particularly in the brainstem reticular-activating system. Energy metabolism may be compromised by interference with the malate-aspartate shuttle, which is responsible for the transport of reducing equivalents from cytoplasm to mitochondria, thereby permitting the storage of energy released from glycolysis. Other evidence links ammonia toxicity with a derangement of neuronal membrane ion transport, especially chloride conductance. Recently, elevated concentrations of brain glutamine, which is formed from ammonia and accumulates in hyperammonemic conditions, has been shown to lead to a loss in the integrity of the blood–brain barrier and to swelling of brain cells. Ammonia toxicity also may impair the metabolism of brain glutamate, the major excitatory neurotransmitter, as well as the activity of glutamate receptors.

Clinical Manifestations

Signs and Symptoms

A variety of clinical presentations may accompany hyperammonemia. The severity of the clinical syndrome usually reflects the completeness of the inherited enzymatic defect, with milder syndromes being associated with a relative

preservation of enzyme activity.

Neonatal Catastrophe

The infant appears well at birth, although the ammonia level may be high in umbilical blood. The disorder usually manifests during the first few days of life, after the baby ingests protein in infant formula or breast milk. Vomiting is a common early finding, followed by poor feeding, a loss of muscle tone, and a progressive diminution of consciousness culminating in frank coma. Convulsions occur in many cases. Hepatomegaly without liver failure is often observed. If timely treatment is not initiated, ventilatory failure secondary to brainstem involvement develops by the end of the first or second week. Death is common, and the prognosis is poor for complete neurologic recovery among surviving babies. The duration of coma, rather than the severity of the hyperammonemia, best predicts outcome.

Recurrent Coma in the Older Infant and Child with Retarded Psychomotor Development

Urea cycle defects may be the true cause of developmental delay in the older infant or child who is thought to have cerebral palsy. Careful questioning of the parents may elicit a history of vomiting and/or lethargy after ingestion of protein-rich foods. Indeed, many patients intuitively avoid meat, chicken, fish, and so on. The marginal dietary intake may result in growth failure.

An important clinical feature is that minor infections may precipitate hyperammonemia. The reason for this relationship is that infections may evoke a protein catabolic response that leads to increased ammonia production. Affected youngsters may be admitted repeatedly to the hospital before the metabolic defect is appreciated.

Recurrent Vomiting and Ataxia

Frank psychomotor retardation does not occur, but physical development is poor because of inadequate dietary intake. Vomiting, dizziness, ataxia, and obtundation may result in repeated hospitalizations. Patients may be diagnosed incorrectly as having vestibular dysfunction, migraine, or even epilepsy. School performance may be poor. Parents may report that the child often seems listless and has a brief attention span. An aversion to foods rich in protein is common. The acute symptoms improve after treatment with parenteral fluids, but symptoms reappear after a few weeks or months.

Progressive Neurologic Deterioration

These patients seem normal for years, after which intellectual performance and overall neurologic function decline progressively. The pathophysiology associated with an extended period of normal development and subsequent decompensation is unknown.

Laboratory Findings

Blood ammonia levels are usually elevated in the acutely ill child. Infants with near complete enzymatic defects may have levels greater than 1000 µg/dL (normal is less than 50 µg/dL). Lesser increases are often seen in the older infant or child, even when acute symptoms are present. Conversely, a patient occasionally will seem asymptomatic even though the blood ammonia is 100 to 150 µg/dL. The reason for the absence of a strict correlation between the blood [NH_3] and the clinical findings remains uncertain. One possibility is that ammonia is not the only toxin. Thus, some evidence points to a toxic role for glutamine, which the brain forms in large amounts during hyperammonemia. Symptoms may also reflect not only the magnitude of the hyperammonemia but also the rate of rise of the ammonia concentration. The brain of the chronically hyperammonemic child may have adjusted to the metabolic perturbation. An acute neurologic syndrome occurs when the level increases abruptly.

The blood urea may be low, as would be anticipated in a disorder of ureagenesis, but a normal blood urea does not exclude a congenital hyperammonemia syndrome, especially if the child is dehydrated from vomiting and renal urea excretion is consequently diminished. Furthermore, in patients with an incomplete enzymatic defect, enough urea may be produced to bring this metabolite into the low-normal range.

The blood electrolytes, including pH, are usually normal. Although ammonia is a base, the amounts that accumulate are not large enough to cause metabolic alkalosis. Conversely, metabolic acidosis does not occur unless the patient experiences cardiorespiratory arrest. The latter point deserves emphasis; clinicians often erroneously assume that the absence of acidosis is evidence against the existence of an inborn error of metabolism.

The routine urinalysis is normal. However, careful microscopic examination of the urine in the patient with ornithine transcarbamylase (OTC) deficiency, the most common urea cycle defect, may reveal the presence of orotic acid crystals. These long, spindle-shaped crystals are excreted in excess because carbamyl phosphate, a substrate for the OTC reaction, is produced in the liver mitochondria but is not converted to citrulline (Fig. 98.1). The excess carbamyl phosphate spills over into the cytoplasm, where it is used to make orotic acid, a precursor to pyrimidines. Orotic aciduria in OTC deficiency is of diagnostic importance. The peripheral blood count is nondiagnostic.

The cerebrospinal fluid (CSF), glucose, and protein levels are normal unless intraventricular hemorrhage has occurred. Both brain and pulmonary hemorrhage can occur, especially in the fulminant hyperammonemia syndrome encountered in the neonate. The CSF ammonia is elevated. The amino acid concentrations of the CSF will reflect the underlying urea cycle defect. Glutamine is often increased, particularly when the ammonia level is high. Other CSF amino acids (e.g., citrulline, argininosuccinate, arginine) will be elevated depending on the underlying enzymatic defect.

Extreme hyperammonemia may be accompanied by elevation of the blood transaminases and other enzymes marking liver dysfunction. Indeed, the urea cycle defects have been confused with acquired syndromes of hyperammonemia and

liver failure (e.g., Reye syndrome). Differentiation between these disorders may require microscopic examination of a liver biopsy to detect the characteristic microvesicular fat deposition of Reye syndrome.

The blood amino acids are important to diagnosis. As noted in Figure 98.1, an enzymatic defect of one of the three final steps in the urea cycle should produce elevations in blood citrulline, argininosuccinic acid, or arginine, respectively. An increased concentration of one of these amino acids in a hyperammonemic child constitutes a presumptive diagnosis of a specific urea cycle defect. If none of these three amino acids is increased in blood but levels of glutamine and alanine, the primary nitrogen carriers, are increased, an enzymatic block may exist at the level of either carbamyl phosphate synthetase (CPS) or OTC. Quantitation of urine orotic acid, which is high in OTC deficiency and normal or low in CPS deficiency, often differentiates between these two disorders. OTC deficiency is far more common than CPS deficiency.

Definitive diagnosis requires enzymatic assay and/ or analysis of deoxyribonucleic acid (DNA). If a patient dies in the emergency department (ED), the physician should try to secure appropriate postmortem samples of tissue, blood, and urine. Identification of the enzymatic lesion is important for genetic counseling. Liver tissue should be obtained quickly and kept frozen, if possible at –80°C (–176°F), until assay of the urea cycle enzymes can be undertaken.

Management (See Table 98.1)

Blood ammonia must be lowered as quickly as possible because the long-term prognosis depends on the severity and duration of hyperammonemia. Effective management should include a double-pronged attack: 1) minimization of ammonia production and 2) facilitation of ammonia removal. The latter goal has been abetted in recent years by the development of new antidotes to ammonia toxicity and by the increasing use of dialysis in the pediatric population.

Parenteral fluids should be administered to stimulate urine flow and renal ammonia excretion. The infusion of glucose augments tissue anabolism by stimulating secretion of insulin, which promotes protein synthesis and minimizes protein catabolism. The administration of 10% glucose and 45 mEq/L sodium chloride at twice the maintenance fluid rate should be adequate. Brain swelling sometimes occurs, and fluid administration should be adjusted accordingly.

Unless the patient has acidemia, bicarbonate should not be given because alkalinization of the blood favors conversion of NH_4^+ to NH_3, which more readily traverses the blood–brain barrier than does the ionized species. Similarly, maintenance of a relatively low urine pH favors excretion of NH_4.

Dialysis and exchange transfusion have been used to remove ammonia, with the former technique being more effective. Blood ammonia can be reduced dramatically by peritoneal dialysis, hemodialysis, or continuous arteriovenous hemofiltration. This treatment is particularly effective in the neonate with severe hyperammonemia (greater than 500 µg/dL), in whom dialysis for 2 to 3 days lowers blood [NH_3]. The potential risks of short-term dialysis are outweighed by the risks of prolonged hyperammonemia. Clearly, dialysis should only be attempted at centers with the requisite expertise.

Highly effective antidotes to ammonia toxicity have been developed in recent years. These antidotes are compounds that react with amino acids to form acyl conjugates that are rapidly excreted into the urine, thereby providing a mechanism, in addition to urea synthesis, by which excess nitrogen is eliminated.

One such agent is sodium benzoate. As illustrated in Figure 98.2, benzoate and glycine are converted to hippurate, which is excreted readily in the urine. Because glycine nitrogen is derived directly from ammonia, excretion of the latter as hippurate is an effective detoxification mechanism. This treatment has been particularly useful for the management of congenital defects in either of the first two steps of the urea cycle (i.e., carbamyl phosphate synthetase deficiency or ornithine transcarbamylase deficiency). In the ED, it is preferable to administer benzoate (250 to 500 mg/kg per day) as a parenteral (10%) solution. Toxicity associated with benzoate treatment is relatively low.

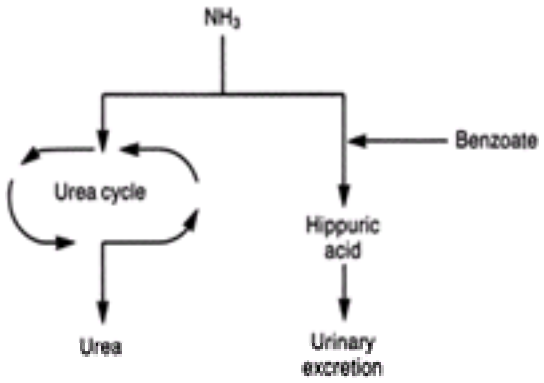

FIGURE 98.2. The benzoate effect.

Benzoate treatment can be supplemented with enteral (oral or nasogastric) sodium phenylbutyrate (250 to 500 mg/kg per day), which the liver converts to phenylacetate. The latter is then conjugated with the glutamine to form phenylacetylglutamine, which is cleared quickly by the kidney. Because glutamine contains 2 atoms of nitrogen, in contrast to the single atom present in glycine, therapy with phenylbutyrate is even more efficient than benzoate treatment in promoting the elimination of waste nitrogen.

For defects involving either of the next two steps of the urea cycle (i.e., citrullinemia or argininosuccinicaciduria),

treatment with arginine (1 to 3 mmol/kg per day) is indicated. Arginine therapy, which can be administered parenterally, reduces blood ammonia by a variety of mechanisms. First, the arginine is cleaved in the liver to urea and ornithine, the latter being a positive effector for the synthesis of *N*-acetylglutamate, which stimulates activity of carbamyl phosphate synthetase, the first step of the urea cycle (Fig. 98.1). In addition, because the patient with either citrullinemia or argininosuccinicaciduria has a relative inability to produce arginine via the urea cycle, overall protein synthesis is diminished. Administration of arginine corrects this deficiency and thereby favors protein anabolism and minimizes catabolism and concomitant production of ammonia. Finally, arginine treatment promotes formation of either citrulline or argininosuccinic acid, both of which are excreted in large amounts, carrying with them NH_3 on an equimolar basis.

If parenteral solutions are unavailable, benzoate, phenylbutyrate, and arginine can be administered by a nasogastric tube. A 10% solution in water is usually convenient. A therapeutic effect, that is, a lowering of blood ammonia, should be noted in about 2 hours.

In addition to the treatments already described, gut sterilization may minimize ammonia formation by enteric urea-splitting bacteria. Absorption of ammonia from the gut can be lowered by giving lactulose (5 mL for infants, 10 to 20 mL for children), a nonabsorbable carbohydrate that acidifies the colon and thereby favors formation of NH_4^+ rather than the more readily absorbed NH_3.

The mainstay of long-term therapy is a low-protein diet. During the first year of life, 1.5 to 2 g/kg per day of protein are necessary to satisfy the growth requirement. Thereafter, an allotment of approximately 1.0 g/kg per day should be sufficient. In most patients, the combination of a low-protein diet and supplemental sodium phenylbutyrate and/or arginine is compatible with reasonable control.

ORGANIC ACIDURIAS

Background

All cells oxidize carbohydrates, fats, and amino acids to yield carbon dioxide, water, and in the case of the amino acids, ammonia. This metabolic interconversion does not occur in a single step, however. Instead, carbohydrates, fats, and amino acids are first converted to metabolic intermediates, many of which are organic acids, as illustrated in Figure 98.3.

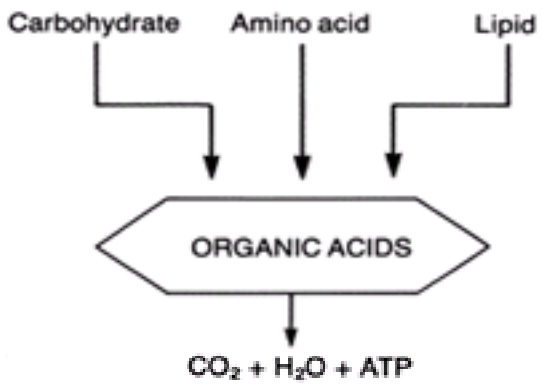

FIGURE 98.3. Formation of organic acids. *ATP,* adenosine triphosphate.

The term *organic aciduria* refers to a class of diseases characterized by excessive accumulation of one or more organic acids in body fluids. This reaction may occur as a secondary phenomenon, as in the lactic acidosis consequent to tissue hypoxia. In this case, lactate cannot be converted to pyruvate because of an increased cytoplasmic NADH:NAD ratio in hypoxic tissue. Another common cause of secondary organic aciduria is the ketoacidosis of diabetes mellitus, in which a lack of insulin leads to increased production of acetoacetate and 3-hydroxybutyrate from fatty acids.

This section focuses on the primary organic acidurias, that is, a group of inherited disorders that are usually caused by the congenital deficiency of an enzyme mediating the metabolism of a particular organic acid. As a result, the acid accumulates, often to toxic levels. As noted in Table 98.4, the number of disorders is large because of the diverse metabolic pathways involved in the oxidation of carbohydrates, fats, and amino acids. The associated clinical presentations are also varied, although sufficient features are shared to warrant consideration as a single group.

I. Disorders of Amino Acid Metabolism
A. Maple syrup urine disease
B. Isovaleric acidemia
C. Propionic acidemia
D. Methylmalonic acidemia
E. β-Ketothiolase deficiency
F. β-Methylcrotonic aciduria
G. Holocarboxylase synthetase deficiency
H. Biotinidase deficiency
I. Glutaric aciduria (types I and II)
J. β-Methylglutaconic aciduria
II. Disorders of Carbohydrate and Energy Metabolism
A. Primary lactic acidosis
1. Pyruvate dehydrogenase deficiency
2. Pyruvate carboxylase deficiency
3. Inherited defects of the tricarboxylic acid cycle
4. Disorders of the electron transport chain
B. Glyceric aciduria
III. Disorders of Fatty Acid Oxidation
A. Medium-chain acyl-CoA dehydrogenase deficiency
B. Long-chain acyl-CoA dehydrogenase deficiency
C. Very-long-chain acyl-CoA dehydrogenase deficiency
D. Carnitine palmitoyltransferase II deficiency
E. Type II glutaric aciduria
F. 3-Hydroxy-acyl-CoA dehydrogenase deficiency
G. Primary carnitine deficiency

Table 98.4. Inherited Organic Acidurias

The occurrence of individual disorders is relatively low, with an incidence of perhaps 1 in 100,000 to 200,000 live births. The collective incidence, of course, is much higher. As awareness of these disorders has increased and the technology necessary for diagnosis has become more available, many more cases have been detected.

Pathophysiology

The central nervous system is usually prominently involved. Untoward concentrations of certain compounds (e.g., methylmalonate) have deleterious effects on cerebral oxidative metabolism. These compounds may also inhibit important hepatic metabolic pathways, such as ureagenesis and gluconeogenesis, thereby causing hyperammonemia or hypoglycemia. Disorders of lactate oxidation (e.g., pyruvate dehydrogenase deficiency, electron transport defects) are usually damaging to the brain; the degree of damage depends on the severity of the block of oxidation of lactate and pyruvate derived from glucose via glycolysis.

Acidosis is a common, although not invariant, feature of the organic acidurias. On rare occasions, the acidosis is the consequence of impaired renal bicarbonate reabsorption and consequent proximal renal tubular acidosis.

A more common kind of acidosis, especially during acute illness, is associated with an anionic gap. This abnormality develops when the positive charges (cations) in the blood (Na^+ plus K^+) significantly exceed the negative charges (anions) (Cl^- plus HCO_3^-). Because blood is electrically neutral, the sum of the positive and negative charges must be equal. As shown in Figure 98.4, the anions of blood are primarily chloride and bicarbonate, with lesser contributions from sulfate, phosphate, and negatively charged proteins. Few negative charges are contributed by the organic acids, which are ordinarily oxidized completely to carbon dioxide and water (Fig. 98.3). However, a congenital deficiency of an enzyme mediating the breakdown of a particular organic acid will increase the contributions such acids make to the anions of the blood.

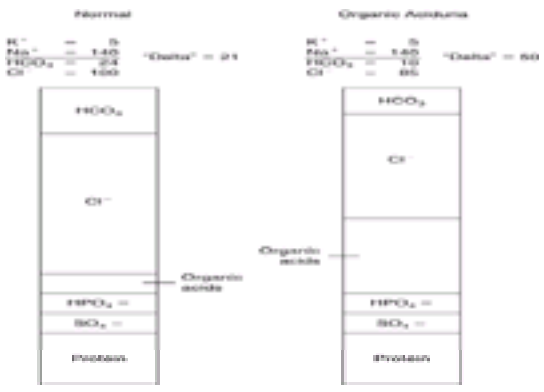

FIGURE 98.4. The anionic gap.

The clinician may infer the presence of a large organic acid concentration by inspection of the routine blood electrolytes. As noted in Figure 98.4, if the total of cationic charges is 145 mEq/L and the sum of chloride plus bicarbonate is only 95 mEq/L, an anionic gap of some 50 mEq/L of negative charges compared with a normal anionic gap of only 15 to 25 mEq/L clearly exists. The unidentified negative charges could have been derived from phosphate or even sulfate rather than from the carboxylate anions, but discriminating clinically among these possibilities is usually not difficult.

In addition to the central nervous system, the toxicity of organic acid accumulation extends to the liver and bone marrow. Hepatic gluconeogenesis and ureagenesis are often impaired. The precise mechanisms are poorly defined, although a likely factor is a depletion of free intracellular coenzyme A, which is consumed rapidly by esterification with the accumulated organic acid. Because these metabolic processes, especially ureagenesis, depend on an adequate supply of coenzyme A, hyperammonemia may supervene.

The bone marrow toxicity reflects an inhibition in the maturation of leukocyte and platelet precursors rather than an inhibition of stem cell formation. Neutropenia and thrombocytopenia result and may cause confusion of the organic acidurias with septicemia.

Clinical Manifestations

The clinical presentations of the organic acidurias resemble those of the urea cycle defects. Indeed, the two groups of diseases can be confused, particularly because hyperammonemia can occur in several of the organic acidurias. However, certain clinical findings should suggest a primary disorder of organic acid metabolism.

Acute Catastrophe in the Newborn Period

This clinical presentation has been noted in association with almost all the disorders listed in Table 98.4. The infant seems well for the first few days or weeks of life, after which he or she becomes increasingly apathetic and irritable. Progression to frank coma can occur abruptly. Symptoms generally do not become apparent until after institution of the first feedings. Intrauterine development is usually normal because organic acids can be metabolized by the mother. Vomiting, mild hepatomegaly, hypothermia, hypotonia, and convulsions occur often. An unusual symptom may be a

bizarre odor in the urine, breath, perspiration, saliva, or ear cerumen. This finding is attributable to the accumulation of organic acid. The repertoire of possible odors is varied, ranging from the sweet smell of branched-chain keto acids in maple syrup urine disease to the “sweaty socks” scent of isovaleric acid encountered in isovaleric acidemia (Table 98.5).

Disorder	Odor
Maple syrup urine disease	Burnt sugar or maple syrup
Isovaleric acidemia	Sweaty socks or cheeselike
Methylmalonic acidemia	Fruity (from ketosis), ammoniacal
Phenylketonuria	Mouse urine, musty
Tyrosinemia	Cabbagelike
Methionine malabsorption	Malt or hops
3-Methylcrotonic aciduria	Tomcat urine
3-Hydroxy-3-methylglutaric aciduria	Tomcat urine
Propionic acidemia	Fruity (ketosis), ammoniacal

Table 98.5. Odors Associated with Organic Acidurias

The long-term outlook is related to the time elapsed before diagnosis. Treatment (see the following) should be started early to realize maximum benefit.

Recurrent Coma in a Child with Mental Retardation and Growth Failure

A subset of patients come to attention because of delayed psychomotor and physical development. Cerebral palsy may have been misdiagnosed. An otherwise trivial infection may cause sudden clinical decompensation, including vomiting, obtundation, and frank coma. Parents often report an intolerance to protein-rich foods and a history of recurrent vomiting. Physical examination discloses a comatose, hyperventilating child whose weight and height are often below average. Both urine and breath should be scrutinized for unusual odors. Convulsions and focal neurologic findings may be present. Several children have had severe choreoathetosis, reflecting basal ganglia involvement. In others, particularly children with the primary lactic acidoses, spinocerebellar degeneration has been noted.

Older Infant or Child with Acute Decompensation and Liver Failure

These children may have mild to moderate mental retardation and/or growth failure. Some may be asymptomatic until severe vomiting and dehydration develop in association with a stress, usually a viral illness. The progression to altered consciousness and coma may be very rapid. A careful history often reveals that these children have been hospitalized previously with vomiting and loss of consciousness. The family history also is important: a similar presentation in siblings suggests an inborn error of metabolism.

A subset of these children have defects of fatty acid oxidation, such as medium-chain acyl-CoA dehydrogenase deficiency or primary carnitine deficiency. The primary clinical findings are coma, hypoglycemia, hyperammonemia, and hepatomegaly. Muscle weakness and cardiomyopathy may occur. Analysis of the urine organic acids usually discloses a typical pattern of metabolite excretion.

Laboratory Findings

Metabolic acidosis may occur during the acute illness when an anionic gap develops. The alkali requirement may be very high, perhaps 10 to 15 mEq/kg per day of HCO^{-}_{3}, to maintain the blood bicarbonate in the low-normal range.

Patients may occasionally demonstrate hyperchloremic metabolic acidosis, particularly if they are dehydrated from vomiting and/or diarrhea. In rare instances, hyperchloremic metabolic acidosis is also seen in patients with primary lactic acidosis or methylmalonic aciduria and secondary renal tubular acidosis.

Ketonuria is common and probably reflects an inhibition of ketone body oxidation by accumulated organic acids. Significant ketonuria is unusual in newborn infants; its presence should alert the clinician to the likelihood that the baby may have an inherited disorder of organic acid metabolism.

Hypoglycemia is common. In some disorders (e.g., maple syrup urine disease, methylmalonic acidemia), the cause is a primary failure of hepatic gluconeogenesis. In certain disorders of fatty acid oxidation (e.g., medium-chain acyl-CoA dehydrogenase deficiency), the hypoglycemia reflects a rate of glucose consumption that exceeds the rate of glucose production.

Hyperammonemia occurs because high levels of organic acids may inhibit ureagenesis. The hyperammonemia sometimes leads to confusion of the primary organic acidurias with the urea cycle defects. Careful inspection of the concentrations of the blood amino acids and urine organic acids should permit discrimination between these two categories of disease.

Neutropenia and thrombocytopenia are common findings. The occurrence of these derangements in the neonate often suggests the diagnosis of septicemia. Infants may be erroneously treated with antibiotics instead of a specific therapy for organic acidurias (see the following).

The plasma lactate and pyruvate levels are usually elevated in children with primary lactic acidosis, caused either by a primary defect of pyruvate oxidation (e.g., pyruvate dehydrogenase deficiency) or by a defect in the respiratory chain (e.g., cytochrome oxidase deficiency). Special care should be exercised in obtaining blood to measure the lactate level, which is often artifactually increased by extended application of a tourniquet. The lactate concentration may also be artifactually raised by the metabolism of erythrocytes if a delay occurs between blood sampling and analysis. Therefore, laboratory guidelines for blood collection should be followed carefully. In a minority of patients, the plasma lactate level is normal, and the diagnosis of primary lactic acidosis requires quantitation of the CSF lactate level.

Analysis of urine organic acids usually points to a specific syndrome. Organic acid excretion is commonly abnormal even when the patient is clinically stable. However, in children with partial enzymatic defects (i.e., those who have some residual capacity to oxidize the organic acid in question), the biochemical abnormality may be detectable only during episodes of clinical decompensation. Therefore, repeated testing is indicated for children at risk in whom initial testing proves negative. Such testing requires gas–liquid chromatography of the urinary organic acids. Because urine is an exceedingly complex mixture, normally containing many hundreds of different compounds, organic acid analysis should be undertaken in laboratories with the requisite expertise, including gas chromatography–mass spectrometry, to identify with certainty the many peaks in the chromatographic effluent.

The plasma aminogram is not necessarily diagnostic, but it provides useful information. Thus, significant elevations of blood glycine are common in methylmalonic aciduria and propionic acidemia, in which the accumulated organic acid inhibits hepatic oxidation of glycine. The levels of leucine, isoleucine, and valine are extremely high in patients with maple syrup urine disease who lack the ability to metabolize these branched-chain amino acids. The blood alanine is high in children with primary lactic acidosis because alanine is formed rapidly from pyruvate via transamination. Patients with primary lactic acidosis also may have increased levels of proline, reflecting an inhibition of proline oxidase activity by high levels of lactate.

The emergency physician will often lack access to specialized laboratory tests such as gas–liquid chromatography. An alternative approach to diagnosis is the use of simple liquid screening tests that can be performed in any ED. Thus, the ferric chloride reaction is grayish green in the urine of children with maple syrup urine disease. The 2,4-dinitrophenol reaction is positive (i.e., a yellowish precipitate forms), in the same disorder. The para-nitroaniline reaction gives a bright emerald green reaction in the urine of patients with methylmalonic aciduria.

Management

The treatment of a child with primary organic aciduria should be directed to three primary goals: 1) correction of abnormalities (e.g., acidosis) that are consequences of the primary metabolic insult; 2) reduction of organic acid production; and 3) if possible, enhancement of organic acid disposal.

The acidosis may be severe. Indeed, when a patient needs high dosages of alkali to control metabolic acidemia, primary organic aciduria must be considered among the diagnostic possibilities.

The rationale for bicarbonate therapy is twofold. First, acidosis impairs normal metabolism and physiology. In addition, a higher pH favors ionization of the carboxylate anion (COO^- versus COOH). The ionized species is more efficiently excreted into urine. Thus, the urine pH should be kept at 6 or higher. The initial dose of bicarbonate should be 1 to 2 mEq/kg, or based on arterial blood gases. A dosage of 1 to 3 mEq/kg per day should be adequate for most children after recovery from acute decompensation. A notable exception is the rare patient whose organic acidemia also causes renal tubular acidosis (e.g., a child with methylmalonic aciduria) and some of the primary lactic acidoses. In the latter group, extremely high dosages of bicarbonate (8 to 13 mEq/kg per day) are sometimes needed.

In addition to metabolic acidosis, hypoglycemia is common during the acute presentation. The hypoglycemia, which may be severe in maple syrup urine disease and methylmalonic aciduria, is caused by defective gluconeogenesis (see previous section). Therefore, clinicians should carefully monitor the blood glucose. Emergency treatment consists of intravenous administrations of 1 g (4 mL)/kg of 25% glucose followed by a 10% glucose infusion.

The administration of intravenous glucose also alleviates the ketoacidemia, which may be severe. This reaction occurs because glucose infusions favor the secretion of insulin, which inhibits the production of ketone bodies from fatty acids.

Organic acid production must be minimized by avoiding the administration of compounds that are precursors to the organic acid in question. Most clinically relevant organic acids are derived from amino acids; therefore, protein intake should be restricted. In the ED, the patient should receive adequate glucose (i.e., a 10% glucose infusion) to provide a source of calories and to minimize endogenous protein catabolism. Such treatment also helps correct the hyperammonemia that often accompanies these disorders (see previous section).

The organic acidurias are best conceptualized as toxicity syndromes, and a specific antidote is often available, as indicated in Table 98.6. Two kinds of antidotes have been developed: 1) a particular vitamin that, at a high dosage, stimulates the congenitally defective metabolic pathway, thereby allowing increased oxidation of the accumulated organic acid, and 2) a compound that reacts with the organic acid to form a conjugate that is excreted more efficiently into the urine. An example of the latter approach is the use of glycine to treat children with isovaleric acidemia. The hepatic enzyme glycine *N*-acylase mediates the formation of isovalerylglycine from glycine and isovalerate. Glycine therapy can safely reduce the concentration of isovaleric acid in many patients.

Thiamine (25–100 mg/day, orally or parenterally)
Maple syrup urine disease
Primary lactic acidosis with megaloblastic anemia
Biotin (10–40 mg/day, orally or parenterally)
Holocarboxylase synthetase deficiency
Biotinidase deficiency
Vitamin B_{12} (2 mg intramuscularly)
Methylmalonic acidemia with homocystinuria
Folic acid (1–5 mg/day, orally or parenterally)
Methylmalonic acidemia with homocystinuria
Lipoic acid (25–50 mg/kg/day, orally)
Primary lactic acidosis secondary to lipoamide dehydrogenase deficiency
Vitamin C (50 mg/kg/day) and vitamin K (0.6 mg/kg/day as menadione)
Primary lactic acidosis secondary to electron transport defect
Glycine (250 mg/kg/day, orally or parenterally)
Isovaleric acidemia
Carnitine (50 mg/kg/day, orally)
Carnitine deficiency
Dichloroacetate (experimental, dose not established)
Primary lactic acidosis

Table 98.6. Specific Treatments for Organic Acidurias

Another therapeutic approach is the administration of L-carnitine. The blood concentration of carnitine, a cofactor for the oxidation of long-chain fatty acids, is significantly diminished in several organic acidurias, perhaps because of increased excretion as carnitine esters. Exogenous carnitine may favor esterification and thereby alleviate the toxicity associated with high free organic acid concentrations.

Detoxification of the child with isovaleric acidemia and other organic acidurias often requires 1 to 2 weeks because much acid is probably sequestered in adipose tissue, from which it is released only slowly. Therefore, initiation of glycine or carnitine treatment is not imperative during the relatively brief interlude most patients spend in the ED.

The organic acidurias that can be managed with either vitamins or conjugating agents are described in Table 98.6.

Recent evidence indicates that dialysis, which efficiently removes ammonia from the body (see previous section), can dramatically reduce organic acid levels in the acutely affected child. Peritoneal dialysis, hemodialysis, and continuous arteriovenous hemofiltration have been used, primarily in the neonate with a fulminant syndrome. The risks of performing such a procedure for 2 to 3 days appear to be less than those of prolonged exposure of the brain to elevated levels of a potentially toxic organic acid. Obviously, dialysis should only be performed by a staff with the necessary expertise.

GALACTOSEMIA

Background and Pathophysiology

Approximately 15% of the calories of human milk are derived from galactose, which together with glucose constitutes the disaccharide lactose. To use this energy, the infant must convert galactose to glucose, which is then oxidized, first via the glycolytic pathway and then in the tricarboxylic acid cycle. The conversion of galactose to glucose is mediated through the uridine nucleotide pathway, as noted in Figure 98.5.

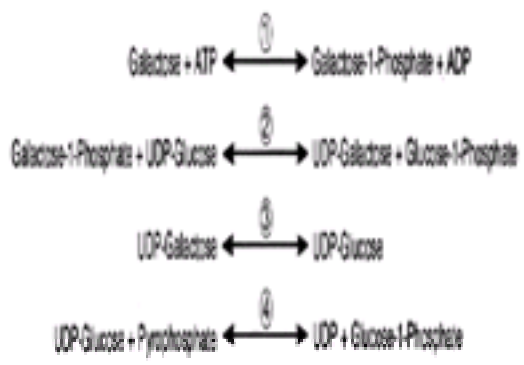

FIGURE 98.5. The uridine nucleotide pathway. *1,* galactokinase; *2,* galactose-1-phosphate uridyltransferase; *3,* epimerase; *4,* UDP-glucose pyrophosphorylase.

Galactosemia is caused by a failure to metabolize galactose to glucose. In most cases, the disease is associated with an inherited deficiency of galactose-1-phosphate uridyltransferase (Fig. 98.5). Rarely, inherited defects of galactokinase or of uridine diphosphate (UDP)-galactose 4-epimerase cause the galactosemia syndrome.

The accumulation of galactose in the body fluids of the transferase-deficient patient affects primarily the brain, liver, eyes, and kidneys. The toxic factor appears to be galactose-1-phosphate, not galactose. Early diagnosis and treatment can attenuate severity of the clinical syndrome.

Clinical Manifestations

Failure to thrive is characteristic and may be the reason for referral. Most affected children also have gastrointestinal problems, particularly vomiting and diarrhea, a few days after exposure to dietary lactose. By the end of the first week of life, the classic patient shows signs of liver disease. Hyperbilirubinemia, which may be intense, is caused by both hepatic dysfunction and hemolysis. Cataracts are present in almost all babies at birth, although a slitlamp examination may be

necessary to visualize an embryonic cataract. Neurologic deterioration with coma ensues in severe cases. The risk of infection is also increased, and death from *Escherichia coli* septicemia is not unusual, often as the initial manifestation of the disorder.

Mental retardation may occur in patients who survive the neonatal period. Indeed, recent data indicate a high incidence of learning disabilities even in children who are treated with a galactose-free diet from an early age. This correlation may reflect either subtle intrauterine injury or an autointoxication syndrome caused by the endogenous production of galactose, which probably continues throughout the life span.

If the toxicity syndrome is not alleviated with a low-galactose diet, patients may develop renal tubular dysfunction with hyperchloremic acidosis and generalized aminoaciduria. Albuminuria is common. Progressive hepatic failure is encountered. Hypergonadotropic hypogonadism is common even in treated female galactosemics. Gonadal function in male patients appears to be normal.

It is important to emphasize that the severity of transferase-deficiency galactosemia varies in different racial groups. Thus, African-American patients tend to have more residual erythrocyte transferase activity than do white patients. The African-American child's tolerance for milk may be correspondingly greater, and the clinical presentation may be delayed until the child is several years of age, at which time hepatomegaly, growth failure, cataracts, and mental retardation become evident. Such patients often receive partial treatment once parents appreciate that the administration of milk evokes vomiting.

Laboratory Findings

A presumptive diagnosis is made by the presence of galactosuria in a symptomatic individual. This diagnosis is accomplished most simply by testing the urine for the presence of a reducing agent. Clinitest tablets are commonly used for this purpose. If a reducing substance is present, the urine should be tested with a paper strip impregnated with glucose oxidase to rule out glycosuria.

Precise quantitation of galactose in the urine or blood requires either enzymatic assay or isolation of the galactose with gas–liquid chromatography.

Most patients have abnormal liver function tests. Jaundice is common, especially in babies who initially develop indirect hyperbilirubinemia followed by direct hyperbilirubinemia 1 to 2 weeks later.

Urine may disclose bicarbonaturia and generalized aminoaciduria. The most important clinical counterpart of the renal tubular dysfunction is hyperchloremic metabolic acidosis.

In some patients, particularly during the newborn period, hemolysis may be prominent and may be so severe that it is confused with erythroblastosis. The hemolysis is a contributing factor to the hyperbilirubinemia.

Definitive diagnosis requires demonstration of the enzyme deficiency in the patient's cells. Erythrocytes are usually used, although the defect is probably present in all tissues. Much simpler, semiquantitative enzyme assays have been developed for screening purposes. These tests can be performed on filter paper impregnated with the patient's blood.

Management

Complete exclusion of dietary galactose is the mainstay of treatment. In the newborn period, this treatment is accomplished by feeding the child a lactose-free formula, such as Nutramigen or Pregestimil. In later life, when patients are able to eat a more diverse diet, parents must avoid all foods that may contain galactose, however trivial the amount.

An important adjunct in monitoring the scrupulousness of diet therapy are erythrocyte levels of galactose-1-phosphate. The goal of diet therapy should be to maintain erythrocyte galactose-1-phosphate levels as close to normal as possible (less than 1 mg/dL erythrocyte volume).

The emergency physician can best aid the galactosemic patient by being mindful of this diagnosis when managing the newborn with a suggestive clinical pattern. Liver failure and electrolyte abnormalities consequent to the renal tubulopathy are of special concern during the acute illness. Because defective bactericidal activity seems to be an intrinsic feature of the syndrome, appropriate cultures should be obtained and antibiotic therapy instituted quickly.

Various agents (e.g., menthol, progesterone) have been used to promote galactose oxidation in humans. Unfortunately, none has proved to be of real clinical benefit. Experimental evidence suggests that high doses of folate can stimulate galactose oxidation in a rat, and this approach may hold promise for some patients.

CHAPTER 99

Dermatology

PAUL J. HONIG, MD

Departments of Pediatrics and Dermatology, The University of Pennsylvania School of Medicine, and Pediatric Dermatology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

ATOPIC DERMATITIS

Background

The definition of atopic dermatitis is confusing. Many alternative terms are used to describe skin inflammation (dermatitis) that is chronic and relapsing. Although the eruption may have a variable appearance (erythema, edema, papules, vesicles, serious discharge, and crusting), its constant feature is unrelenting pruritus. The eruption often has a characteristic distribution, depending on age (Fig. 99.1), and often occurs in allergic (atopic) individuals or those with a family history of allergies (e.g., hayfever, asthma, allergic rhinitis). Although many theories relating to cause exist (e.g., genetic, physiologic, pharmacologic, immunologic), the data are conflicting.

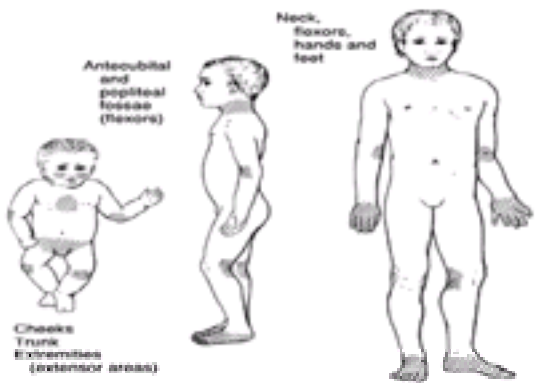

FIGURE 99.1. Distribution of atopic eczema at various ages.

Atopic dermatitis affects about 3% of children, beginning at 1 to 2 months of age. Of children who acquire atopic dermatitis, 60% will do so by the end of their first year of life, 90% by 5 years, 95% by 10 years, and 99% between 10 and 20 years of age. The course of an individual case is difficult to predict, but only 30% of those who develop the problem during the first year continue to have the disease during childhood. Of all children who have atopic dermatitis

during childhood, 90% will be clear by the time they reach adolescence.

Pathophysiology

No single theory explains the initiation and progression of atopic dermatitis. Some evidence suggests that a combination of factors including altered physiologic, pharmacologic, and immunologic mechanisms, is involved in the exaggerated reactivity of the skin.

Various studies have found that patients with atopic dermatitis have dry skin. This reaction may be caused by increased transepidermal water loss and/or decreased quantities of sebaceous gland-derived lipids at the skin surface. Patients also have an increased sweating response to Mecholyl. If this drug is injected into the skin of an individual with atopic dermatitis, it causes blanching rather than the usual erythema. Simple scratching of the skin in an atopic will induce white dermatographism. Finally, the b-adrenergic blockade therapy hypothesizes that reduced function of the b-adrenergic system leads to decreased production of cyclic adenosine monophosphate (cAMP). This reaction results in increased release of the pharmacologic mediators, such as histamines, producing pruritus and inflammation of the skin.

Atopic dermatitis patients have immune system dysregulation, which includes increased production of immunoglobulin E (IgE) by B cells, elevated prostaglandin E_2, abnormal lymphokine secretion profiles, and abnormalities of Langerhans cells. How these changes produce what is called atopic eczema is slowly becoming clearer. cAMP phosphodiesterase is abnormally increased. This response lowers cAMP, producing increased release of histamine, prostaglandin E_2, and other cytokines. This reaction leads to decreases in cell-mediated interferon-g responses and increases in interleukin-4 and interleukin-5 responses. The resulting inflammatory mediators arising from these complex interactions trigger the itch– scratch cycle.

Clinical Manifestations

The patient's age often determines the distribution and appearance of the skin lesions. During infancy, the itch–scratch cycle, which usually begins at 2 to 3 months of age, produces the erythematous, exudative lesions that appear on the cheeks and extensor surfaces. At times, the process becomes generalized. Near the age of 2 years, the more characteristic flexural involvement occurs. Also indicative of atopic dermatitis are 1) varying sized patches of hypopigmentation, especially prominent on the cheeks (pityriasis alba) (Fig. 99.2); 2) patchy or diffuse, fine papules (follicular accentuation) (Fig. 99.3); 3) scaling in the scalp with or without hair loss; and 4) hyperlinear palms and soles (Fig. 99.4), which may show desquamation. Involvement of the feet in such a manner often leads to the misdiagnosis of tinea pedis, which occurs less often in the pediatric population before adolescence. During adolescence, the distribution remains the same; however, a greater incidence of involvement of the face, neck, posterior auricular areas, and the hands and feet occurs. The major physical findings of chronicity, hyperpigmentation, and lichenification are often present (Fig. 99.5).

FIGURE 99.2. Postinflammatory hypopigmentation occurring in a child with atopic dermatitis (pityriasis alba).

FIGURE 99.3. Follicular accentuation in a patient with atopic eczema.

FIGURE 99.4. A patient with atopic eczema who has hyperlinearity of the soles.

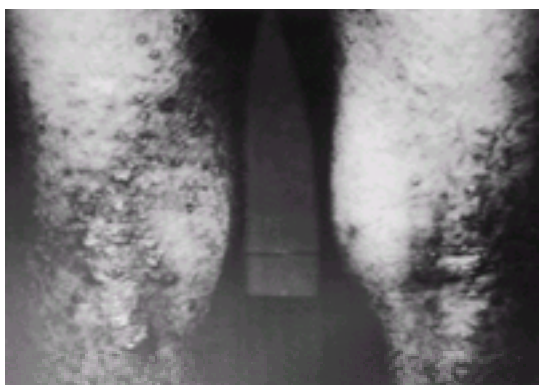

FIGURE 99.5. Chronic changes of hyperpigmentation and lichenification often seen in atopic eczema.

The diagnosis of atopic dermatitis is based on the presence of pruritus, typical morphology, and distribution, as well as a tendency toward chronically relapsing dermatitis. Other possible features are listed in Table 99.1. Unfortunately, laboratory tests are not helpful in the diagnosis of this disorder. Although eosinophilia and elevated serum IgE levels are present, they are not specific for this condition.

Major	Ichthyosis
Typical morphology and distribution	Tendency toward nonspecific hand and foot dermatitis (pseudotinea pedis)
Pruritus	
Chronically relapsing course	Tendency toward repeated cutaneous infections
Personal or family history of atopic disease	White dermographism
Additional Features	Elevated serum immunoglobulin E
Xerosis	*Minor*
Hyperlinear palms and soles	Cataracts
Follicular accentuation	Keratoconus
Pityriasis alba	Dennie-Morgan (infraorbital) fold
Scaling of the scalp	

Table 99.1. Diagnostic Features of Atopic Dermatitis

Differential Diagnosis

Atopic and seborrheic dermatitis may be difficult to differentiate when first appearing in a 1- to 2-month-old infant. Both conditions may cause scaling in the scalp or diaper dermatitis. Clues pointing to seborrheic dermatitis include involvement of the flexural and intertriginous areas in the infant; a salmon-colored eruption with greasy, yellow scaling; and the lack of pruritus. Therapeutic clues include a rapid response to antiseborrheic shampoos and steroids in seborrheic scaling of the scalp. Atopic dermatitis, on the other hand, is often worsened with antiseborrheic shampoos and responds slowly to topical steroids.

Nummular eczema is an eruption that differs from atopic eczema in that the lesions are circular, erythematous, scaling, crusted patches or plaques. The lesions begin as papules and vesicles that spread and coalesce, forming the typical coin-shaped patches. Pruritus is variable. Affected patients do not usually have an atopic background, and IgE levels are generally not elevated. This disorder may be a manifestation of dry skin and, in fact, is aggravated by overwashing, harsh soaps, low temperatures, and low humidity. Decreased bathing, use of mild soaps, and topical steroids are generally helpful.

Xerosis, or dry skin, is a condition that is commonly seen in patients who bathe frequently and use harsh soaps. Low temperatures and humidity will exacerbate this disease. Therefore, it is more common during winter months. The rash is pruritic and appears as rough, red, dry, scaling skin. It is similar in appearance to chapped hands and cheeks seen in cold weather. Decreased bathing, use of mild soaps, and lubrication of the skin are helpful.

Many immune and metabolic disorders are also associated with a rash that is similar in appearance to atopic dermatitis. These disorders are listed in Table 99.2.

Metabolic Disorders	Immunologic Disorders
Phenylketonuria	Ataxia-telangiectasia
Acrodermatitis enteropathica	Letterer-Siwe disease
Histidinemia	Wiskott-Aldrich syndrome
Gluten-sensitive enteropathy	X-linked agammaglobulinemia
Hartnup's syndrome	Hyper immunoglobulin E syndrome
Hurler's syndrome	Selective immunoglobulin A deficiency
	Severe combined immunodeficiency

Table 99.2. Immune and Metabolic Disorders Causing Rash That Resembles Atopic Dermatitis

Complications

Infection of the existing dermatosis is the principle complication in atopic dermatitis. Colonization and infection with *Staphylococcus aureus* is common among atopic children and may account for flare-ups or failure to respond to therapy. Group A b-hemolytic streptococci are also cultured from many individuals with secondarily infected skin.

Viral skin infections also occur more often in patients with atopic dermatitis. Whether this infection is directly correlated to the impaired cellular immunity problem these patients have has not been proven. Eczema vaccinatum, once a dreaded and often fatal complication, rarely occurs now that routine smallpox vaccination has been discontinued. The common causes for what is termed Kaposi's varicelliform eruption are mainly herpes simplex virus (Fig. 99.6) (eczema herpeticum) or, on occasion, coxsackievirus infection. Groups of umbilicated vesicles or areas of increased crusting and ulceration should be cultured for herpes simplex. A diagnostic procedure that may yield a quick answer to the presence of herpes simplex is the Tzanck test (Fig. 99.7). Material from the base of a freshly opened vesicle is scraped for a Giemsa stain. Multinucleated giant cells and balloon cells indicate the presence of herpes simplex. A much more sensitive and specific test is the rapid direct immunofluorescent test (DIF) described in Chapter 67. This virus can also cause localized flare-ups of eczema without dissemination. Leyden described culturally proven recurrent local attacks of herpes simplex virus appearing as discrete punched-out ulcerations. Varicella virus lesions also tend to concentrate in areas of inflamed skin as a result of leakage of virons through dilated vessels. The viruses that cause molluscum contagiosum and warts also infect individuals with atopic dermatitis more often than the average patient (Fig. 99.8).

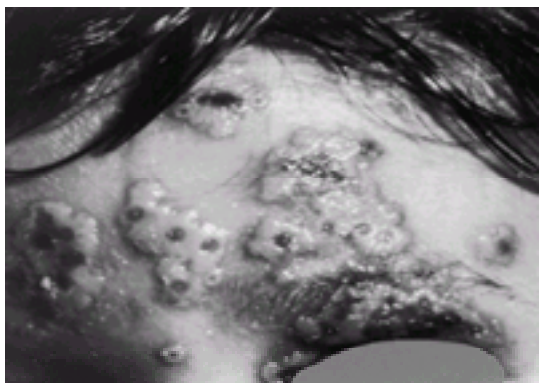

FIGURE 99.6. Eczema herpeticum.

Management (Table 99.3)

Reduction of Pruritus		*Reduction of Inflammation*
Mild soaps	skin care	Skin care
Infrequent washing		Topical steroids (high potency)
Skin lubrication		Systemic steroids (rarely necessary)
Topical steroids (high potency)		*Control of Infection*
Systemic steroids (rarely necessary)		Penicillinase-resistant antibiotics
Antihistamines (children >4 yr old)		

Table 99.3. Acute Treatment of Atopic Dermatitis

Skin tests and hyposensitization are of little value and are rarely indicated. Dietary restrictions may be helpful in certain patients but are difficult to maintain. The four main objectives in the treatment of uncomplicated atopic dermatitis are 1) reduction of pruritus, 2) reduction of inflammation, 3) protection of the skin from unknown irritants, and 4) removal of known irritants. Reduction of pruritus can be accomplished in numerous ways. Most important of these methods is limitation of bathing (at times, to only once per week) and the use of a mild soap (e.g., Dove, Tone, Caress). Lubrication of the skin with Nivea cream, Eucerin cream, or Moisturel (which contains no lanolin or perfumes) ameliorates dryness, which may be a factor in producing pruritus. Antihistamines can be helpful, although, during infancy, the necessity for soporific doses results in their being less helpful therapeutically. Old standbys include diphenhydramine hydrochloride (5 mg/kg per day in three to four divided doses) and hydroxyzine (2 mg/kg per day in three to four divided doses). Newer preparations include topical doxepin and oral cetirizine. Control of inflammation is accomplished with the use of topical steroids (Table 99.4). During the acute phase, potent steroids should be used to bring the situation under control. (At times, systemic steroids are used to bring an acute flare-up under control. Fortunately, this measure is rarely necessary.) Once control is achieved, steroids of mild potency should be used and applied less often. (Note: Steroids should not be used on the face for prolonged periods.) Maintenance with the least potent steroid, applied as infrequently as possible, is advisable. However, continued therapy is usually necessary. After control has been maintained for a fairly prolonged period, an attempt to discontinue steroid therapy can be made. Protection of the skin against unknown irritants is best done by covering it. Long-sleeve polo shirts and leotards are helpful in preventing dust and pollens from coming into contact with the skin. Removal of known irritants is achieved by 1) environmental control (i.e., no stuffed toys, wool clothing or blankets, or pets); 2) avoidance of harsh soaps; and 3) keeping fingernails short. At times, hospitalization for control is advisable and certainly a more desirable alternative than systemic steroids.

Mild	
Hydrocortisone 1%	
Moderate	
Aristocort ointment 0.1% (triamcinolone acetonide)	
Cordran ointment 0.05% (flurandrenolide)	
Synalar cream 0.025%	(fluocinolone acetonide)
Synalar ointment 0.025%	
Valisone cream 0.1% (betamethasone valerate)	
Potent	
Diprosone ointment 0.05% (betamethasone dipropionate)	
Florone ointment 0.05% (diflorasone diacetate)	
Lidex cream or ointment 0.05% (fluocinonide)	
Topicort ointment 0.25% (desoximetasone)	

[a]All the synthetic preparations are fluorinated. Hydrocortisone is not.

Table 99.4. Potency of Topical Steroids [a]

Appropriate antibiotics are important in the treatment of secondary bacterial infections. A child who is not toxic can often be treated orally in the home setting. Because penicillin-resistant staphylococcal organisms are commonly involved,

antibiotics such as erythromycin (40 mg/kg per day) or dicloxacillin (50 mg/kg per day) provide suitable coverage. These antibiotics also treat group A b-hemolytic streptococci that may be present. When a child is toxic, intravenous (IV) therapy is advisable; therefore, hospitalization is necessary. Again, penicillinase-resistant antistaphylococcal drugs should be given.

Eczema herpeticum that is localized and that has not produced toxicity in a child can be treated symptomatically and will usually clear in 2 to 3 weeks. With severe infection, especially in young infants, more aggressive therapy may be necessary. A daily dosage of 700 mg/m^2 per 24 hours of acyclovir, given in a 1-hour IV infusion every 8 hours, is advised. More localized primary or secondary infections can be treated orally at a dosage of 15 to 30 mg/kg per 24 hours in four to five divided doses for 10 days.

Studies evaluating therapy with medications such as Tacrolimus ointment, oral cyclosporine, interferon gamma, as well as many others, are under way.

SEBORRHEIC DERMATITIS

Background

Seborrheic dermatitis is the term given to the salmon-colored patches with yellow, greasy scales occurring primarily in the so-called seborrheic areas (face, postauricular area, scalp, axilla, groin, presternal area). During childhood, seborrheic dermatitis is seen in infants or adolescents. Its onset occurs during the first 3 months of life and generally disappears shortly thereafter, only then reappearing in adolescence.

Pathophysiology

Although sebaceous gland dysfunction is often cited as a cause, the definite cause of this disorder has not been established. In fact, surface fat levels are normal in seborrheic dermatitis, but their ratio is altered. The presence of seborrheic dermatitis correlates strongly to concomitant emotional stress or neurologic disorders.

Clinical Manifestations

The two common locations of skin involvement during infancy are the scalp (“cradle cap”), as shown in the infant with seborrheic dermatitis in Figure 99.9, and diaper area. Most commonly, yellow, greasy scales are found over the anterior fontanel. Scaling is concentrated in this location because of the fear some mothers have about rubbing or scrubbing over the fontanel. Many times the scaling is limited to this area; however, occasionally, the scaling is spread to the forehead, eyebrows, nose, ears, and neck. The intertriginous and flexural areas may also become involved. This reaction is especially seen in the diaper area (see Fig. 99.15). The child is not irritable, and pruritus does not seem to be present. The prognosis for clearing is excellent, and resolution usually occurs within several weeks to months.

FIGURE 99.9. Seborrheic dermatitis.

FIGURE 99.15. Infant with seborrheic diaper dermatitis.

Between the periods of infancy and adolescence, scaling of the scalp usually indicates causes other than seborrheic dermatitis (atopic dermatitis or tinea capitis). In fact, true seborrheic dandruff does not appear until puberty, when

excessive production of sebum occurs. Most commonly, scaling before puberty and after infancy indicates the presence of atopic dermatitis or tinea capitis (especially Trichophyton tonsurans). Differentiation is aided by clinical appearance, cultures, and response to therapy. Atopic dermatitis is often worsened with harsh shampoos and responds slowly to topical steroids. The diagnosis of tinea capitis is best made with cultures. If steroids are used in the presence of tinea capitis, scaling of the scalp often increases secondary to suppressed local immunity of the skin and increased growth of the fungus. Seborrheic dermatitis of the scalp during the adolescent period is similar in nature to the condition in adults. Scaling in the scalp appears, and the seborrheic areas are variably involved. Erythema and scaling occur between the eyebrows, on the eyelid margins, and in the nasolabial creases, sideburns, beards, mustache, posterior auricular areas, and aural canals. Rarely, the patient may develop a secondary infection with monilia or bacteria.

Management

Seborrheic dermatitis of the scalp responds readily to antiseborrheic shampoos (i.e., selenium sulfide) and topical steroids such as fluocinolone acetonide or betamethasone valerate (Table 99.4). In infants, loosening of the scales with a soft toothbrush or fine-toothed comb before shampooing often hastens clearing of the cradle cap. Topical steroids are effective in the treatment of seborrheic dermatitis. Because hairy locations are commonly involved, steroid preparations in the form of lotions or gels are advisable. The strength of the steroid and the frequency of application is determined by the response to therapy. Steroids should not be used for prolonged periods on the face because of potential damage to the skin in that area. Secondary infection with bacteria can be treated with appropriate antibiotics. If *Candida albicans* secondarily invades the lesions, topical clotrimazole cream, applied twice a day, is useful.

ALLERGIC CONTACT DERMATITIS

Background

Allergic contact dermatitis is a cell-mediated reaction to antigenic material in contact with the surface of the skin. The incidence in children is about 1.5%, a considerably lower value than that given for adults. Children less than 1 year of age rarely respond to contactants and, until nearly 3 years of age, have a reduced incidence of contact dermatitis.

Pathogenesis

An allergen penetrates the stratum corneum (facilitated by trauma at times) and combines with a carrier protein to form the foreign substance that is responsible for initiating the sensitization process. This complex is carried via lymphatics to the regional lymph nodes where processing by macrophages occurs. Recognition by T lymphocytes follows; these cells then leave the node, enter the bloodstream, and migrate into the skin. When the antigen again comes in contact with the skin, sensitized T lymphocytes combine with the specific foreign material and release inflammatory lymphokines. The characteristic dermatitis occurs 6 to 18 hours later.

Clinical Manifestations

The acute onset of linear or geometric areas of erythema, edema, eczematization, and papulovesiculation usually indicates the presence of allergic contact dermatitis. Because skin involvement is limited to areas of contact, the distribution, pattern, and shape of the dermatitis provide important clues for the clinician (Table 99.5). Therefore, a round lesion on the back of the wrist would incriminate a wristwatch; a linear pattern encircling the waist points to the rubber in the waistband of a garment; linear lesions on exposed portions of the body indicate brushing against the leaves of a poison ivy plant (Fig. 99.10); and extensive involvement of exposed areas of skin suggests an airborne allergen, as with ragweed or vaporized oil transmitted in the smoke of burning poison ivy (Fig. 99.11). Generally, the scalp, palms, and soles are less permeable to allergens and therefore are less often involved. Involvement of oral mucous membranes is uncommon. As previously mentioned, trauma or nonspecific factors such as pressure, heat, and perspiration may predispose the skin to allergic contact dermatitis.

Head and Neck
Scalp—hair dye, hair spray, shampoo
Ear canal—neomycin
Forehead—hat band
Eyelids—nailpolish, volatile gases, false eyelash cement, mascara, eye shadow/cosmetics
Perioral—dentrifices, bubble gum, chewing gum
Ears—earrings, perfume
Trunk
Axilla—deodorant, clothing dye
Breasts—metal, elastic in bra
Arms
Wrist—cosmetic jewelry (nickel), leather (p-phenylenediamine, chrome)
Abdomen
Waistline—rubber dermatitis from elastic in pants, jockstrap (lower)
Lower extremities
Feet—shoe dermatitis

Table 99.5. Regional Predilection of Various Substances That Cause Contact Dermatitis

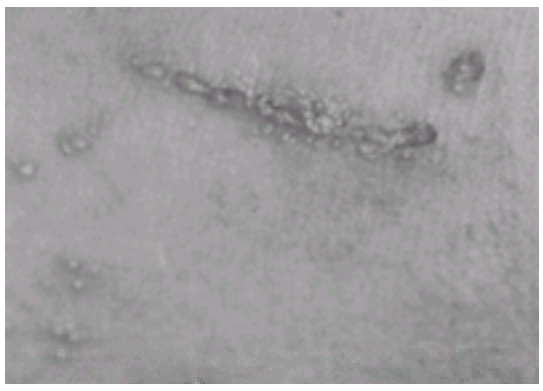

FIGURE 99.10. Typical linear pattern after exposure to the poison ivy plant.

FIGURE 99.11. Facial edema and inflammation in response to exposure to airborne contact allergen (e.g., vaporized oil in smoke of burned poison ivy plants). *Please see the color-tip insert (Color Plate 99.11).*

Fisher states that the most common causes of contact dermatitis in order of frequency are rhus (poison ivy, oak, sumac), *p*-phenylenediamine, nickel, rubber compounds, and the dichromates. Although these conclusions are based on an adult sample, they generally apply to children, except for the substance *p*-phenylenediamine, which is found in hair dyes and is probably at the bottom of the list.

Rhus (Poison Ivy, Oak, Sumac)

Rhus dermatitis is the most common allergen involved in the production of contact dermatitis. The poison ivy plant (Fig. 99.12A) occurs in all parts of the United States as a shrub or vine, often on trees or fences. Poison oak (Fig. 99.12B), an upright shrub, appears only on the west coast. Poison sumac (Fig. 99.12C) grows as a shrub or tree east of the Mississippi. Seventy percent of the population will become sensitized if exposed to the oleoresin, known as urushiol, contained on the leaf, stem, or root of the plant. The active ingredient in this oil is pentadecylcatechol. The oil can be carried on clothing and pets or by the wind.

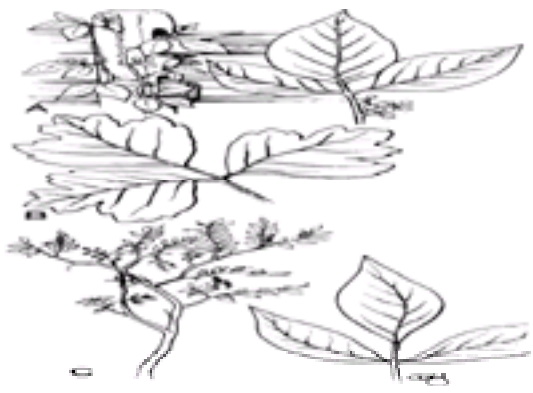

FIGURE 99.12. A. Poison ivy *(Rhus radicans).* **B.** Poison oak *(Rhus toxicodendron).* **C.** Poison sumac *(Rhus vernix).*

Each plant produces an identical redundant eruption. From the time of exposure, the average time to the appearance of the rash is 48 hours. At that time, onset of pruritus, inflammation, and grouped or linear papulovesicles or bullae occurs. With severe exposure, the face and eyelids become uniformly edematous. The eruption can last from 1 to 3 weeks.

Avoidance of exposure is the best prophylaxis in treatment. Topical barrier agents such as the product that is used by forest rangers have been developed to prevent rhus dermatitis in high-risk individuals. However, at times, protection is impossible. Once an individual is exposed, contaminated clothing should be removed and laundered, and the body should be bathed with any soap as soon as possible, preferably within 5 to 10 minutes. Once the oil has been removed, spread does not occur, even from vesicular fluid. Although sequential outbreaks on various parts of the body suggest spread, lesions appearing later in time indicate initial exposure to a lesser dose of the offending oil.

Antipruritic lotions such as calamine are useful. Topical steroids are minimally effective, and topical antihistamines and anesthetics should be avoided because they can be sensitizers. Antihistamines can be helpful. With generalized reactions, oral prednisone 1 to 2 mg/kg once daily for 1 week than tapered over the next week is advisable.

Nickel Contact Dermatitis

Nickel dermatitis is seen commonly in the female in response to nickel-containing jewelry. Earlobes are commonly involved because of the popularity of pierced ears. Most articles of jewelry contain nickel, including those made of gold and silver. Any person wearing these items is at risk. Perspiration begins the process by leaching the nickel from the jewelry around the neck, wrist, or the fingers. Treatment consists of removing the offending object, avoiding further contact with nickel-containing jewelry, and applying topical steroids to the affected areas of skin.

Shoe Contact Dermatitis

Erythema, blistering, weeping, crusting, or lichenification of the dorsal aspects of the toes and instep of the feet, with sparing of the interdigital webs, suggest shoe contact dermatitis. The responsible antigens are usually the rubber, glues, dyes, and tanning agents used in making the shoes. Although not often recognized, the problem is common. Children who sweat freely are more likely to be affected because of the leaching of allergens from the shoes onto the skin. Secondary infection is common, and an “id” reaction, similar to that seen in tinea pedis, can cause involvement of the hands and other areas of the skin distant from the primary site.

Patch testing kits for shoe components are available to determine specific sensitizing substances. This testing should be done only after the skin problem is brought under control, and probably by a dermatologist. Control is achieved by avoiding shoes when possible, treating secondary infection with appropriate antibiotics, and using topical steroids. All antihistamines are helpful for reducing pruritus. An id reaction consisting of huge bullae on the hands and feet can occur. The child is often unable to walk. Hospitalization and the use of systemic steroids (see previous section regarding Rhus) are necessary.

Cosmetics

Many practicing physicians do not know that nail lacquers (containing sulfonamides and formaldehyde resins) or nail hardeners (containing formaldehyde) are a common cause of allergic reactions on the skin of the eyelids. The skin in this area is thin and permeable. Simply rubbing the eyes with fingernails that have polish on them can induce the problem. *p*-Phenylenediamine, which is contained in hair dyes, will also cause eczematous eruptions of the scalp and face.

Management

Elimination and avoidance of the causal antigen is the most effective preventive and therapeutic measure. Topical steroids and antihistamines help with the inflammation and pruritus.

With localized involvement, moderate to high potency topical steroids can be helpful in reducing symptoms while the dermatitis clears. With generalized skin involvement, oral steroids are effective at a dosage of 1 to 2 mg/kg per day over 7 to 10 days then tapered over the next 7 days (rebound less likely). Patch testing should not be done during an acute episode because contact with the allergen may cause worsening of the rash.

DIAPER DERMATITIS

Background

Diaper dermatitis is a general term used to describe skin abnormalities beneath the diaper secondary to a variety of causes. The problem is common in children 2 years of age or younger who require the use of a diaper. It generally disappears after toilet training.

Pathophysiology

The pathogenesis of the problem is multifactorial (Fig. 99.13) and not clearly defined. The possibilities include the concentration of bacteria or fungi, the action of organisms on the urine, and moisture itself.

FIGURE 99.13. Proposed sequence of events producing skin inflammation in the diaper area.

No firm proof exists that bacteria play a major role. However, bacterial overgrowth does occur on moist skin with increasing time. Bacteria have been implicated in liberating ammonia from urine and raising urine pH. The rise in pH increases the activity of fecal proteases and lipases, which can damage skin. Bile salts can potentiate this damage.

C. albicans is found on the skin in 40% of infants with active diaper dermatitis within 72 hours of the appearance of the rash. Because studies show that this organism is present in less than 10% of infants without diaper dermatitis, *C. albicans* may be playing a significant role. Sources of *C. albicans* include the gastrointestinal (GI) tract and secondary implantation from a mother with candidal vaginitis.

Chronic exposure of the skin to moisture, especially under occlusion by the diaper, leads to maceration and alteration of the epidermal barrier with overgrowth of bacteria and *C. albicans.* If one major instigating factor exists, the effect of chronic exposure to moisture is critical to the development of diaper dermatitis.

Another consideration is the predisposition of certain individuals to react more easily and negatively to varying irritants. Generally, infants with an atopic or seborrheic background are at greater risk for the development and persistence of diaper dermatitis.

Clinical Manifestations

Differentiation of the various types of diaper dermatitis is difficult. Clues from the history and physical examination are necessary when characterizing the cause of this problem. The different types of diaper rashes include occlusion dermatitis, atopic dermatitis, seborrheic dermatitis, moniliasis, and mixed or not diagnosable rash.

Occlusion Dermatitis (Fig. 99.14)

FIGURE 99.14. Infant with occlusion diaper dermatitis. *Please see the color-tip insert (Color Plate 99.14).*

Occlusion dermatitis contains two components. The first, friction, occurs mainly on those portions of the diaper area where contact with the diaper is greatest (inner thighs, lower abdomen, and prominent surfaces of the genitalia and buttocks). The rash waxes and wanes and often has a shiny, glazed surface appearance. Occasionally, papules are associated with the rash. The second component, trapped moisture, causes the erythema and maceration that occurs in the intertriginous parts of the diaper area (inguinal, genital, intergluteal, and folds of the thighs). This type of problem is often associated with and precipitated by tightly applied diapers, commercial plastic diapers (especially those made with elastic edges to prevent leakage around the thighs), and rubber pants placed over cloth diapers. Such coverings increase friction and prevent the evaporation of moisture.

Atopic Dermatitis

The appearance of the rash in the diaper area is not different from occlusion dermatitis. It is, however, more chronic and difficult to treat. Examination may disclose lesions on other body surfaces (cheeks, antecubital and popliteal spaces) typical of atopic involvement, and a family history of atopy often exists.

Seborrheic Dermatitis (Fig. 99.15)

Generally, the rash has an erythematous, salmon-colored base that is covered with yellow, greasy scaling. Similar involvement of other seborrheic locations such as the scalp, postauricular area, or other flexures helps to establish the diagnosis. At times, a family history of seborrheic dermatitis exists.

Moniliasis

Moniliasis is the most characteristic of the diaper rashes. The skin in the diaper area has clusters of erythematous papules and pustules that go on to coalesce into an intensely red confluent rash with sharp borders. Beyond these borders are satellite papules and pustules. At times, the infant has concomitant oral thrush. When the problem is chronic and recurrent, seeding from the GI tract or from a mother with monilial vaginitis should be considered.

On rare occasions an id reaction occurs (Fig. 99.16). Beside the primary monilial diaper rash lies an antigenic dissemination with involvement of the intertriginous areas as well as scattered small patches or plaques of scaling

erythema on other parts of the skin surface. Generally, *C. albicans* cannot be cultured from these plaques.

FIGURE 99.16. Infant with monilial diaper dermatitis with id reaction.

Mixed or Not Diagnosable Rash

Mixtures of the above categories of diaper dermatitis are often found on infants. A diagnosis is often difficult to make. Secondary invasion with *C. albicans* is common as mentioned. The potential for secondary bacterial infection exists. If blistering occurs, *S. aureus* infection should be considered.

Management

Treatment is determined by the cause of the dermatitis. In general, proper skin care, which includes decreased frequency of washing, use of mild soaps, and keeping the diaper off as much as possible, will help resolve diaper dermatitis resulting from any cause. With occlusive dermatitis, avoidance of tightly fitting diapers, plastic-covered paper diapers, and rubber pants is important. When atopic dermatitis is present, the use of topical steroids is necessary. It is important to avoid fluorinated or other potent steroids in the diaper area because occlusion by the diaper enhances the steroid effect and is more likely to produce skin atrophy and striae. The newer antifungal–steroid combinations should also be avoided for these same reasons. Therefore, 1% hydrocortisone cream no more than twice daily over a short period is recommended. Hydrocortisone (1%) is also effective for seborrheic diaper dermatitis and can be used intermittently.

With monilial diaper dermatitis, the use of preparations such as econazole twice a day is effective. If thrush is also present, oral nystatin 200,000 units (2 mL) four times a day for 7 days, is advisable. This medication will also be useful if the infant is seeding *C. albicans* from the GI tract onto the skin of the diaper area. Because another potential source of *C. albicans* is from a vaginal infection in the infant's mother, the mother should be questioned for this problem; if a vaginal discharge is present, it should be checked by a gynecologist and treated appropriately. Patients with id reactions, as described before, require oral nystatin, econazole on the diaper and intertriginous areas, and 1% hydrocortisone applied to the plaques. Resolution usually takes 7 to 10 days. Mycolog II cream is recommended by many physicians for monilial diaper rashes; however, the clinician should be cognizant that this preparation contains a fluorinated steroid. Secondarily infected dermatitis, such as bullous impetigo, should be treated with the appropriate systemic antibiotics.

Whether traditional diaper creams and ointments are effective is still unproven. Their ability to provide an effective barrier that reduces irritation remains to be established.

DRUG REACTIONS IN THE SKIN

Background

When a drug is being taken by a child, any reaction of the skin that is not expected should be considered a drug reaction. Hospitalized patients are more likely (30%) to have a reaction to a drug because of multiple exposures. Approximately 2 to 3% of these inpatients have cutaneous reactions. The rate of adverse effects depends on the particular drug. Arndt et al. showed that reactions occur at the rate of 59 per 1000 drug courses for trimethoprim–sulfamethoxazole, whereas with the use of chloralhydrate, only 0.2 reactions per 1000 courses occurred. When considering all drugs, they found reactions at a rate of 3 per 1000 courses of therapy. Penicillins, sulfonamides, and blood products were responsible for most reactions.

When considering penicillin and its derivatives alone, allergies to these substances affect 1 to 10% of the population. Fatal anaphylaxis occurs in approximately 2 of 100,000 patients taking penicillin. Penicillin reactions appear less often in children, as is the case with any drug reaction. An increased risk for the development of anaphylactic reactions to penicillin is present in atopic individuals.

Pathophysiology

The pathogenesis of such reactions can be on an immune or nonimmune basis. When occurring on an immune basis, any of the four types of immunologic mechanisms (IgE-mediated, immune complex, cytotoxic, cell-mediated) can be involved. However, reactions also occur on the basis of overdosage, specific toxicity, common side effects of a particular drug, and unusual drug interactions. Pathogenic mechanisms in specific situations often cannot be identified.

Clinical Manifestations

The appearance of drug reactions is nonspecific and may mimic almost any known dermatosis. Therefore, the clinician cannot make a diagnosis of a drug reaction based on the appearance of the rash alone because the skin can react only in a limited number of ways to many different stimuli. However, certain patterns should raise suspicion of the presence of an adverse reaction.

Laboratory analysis is usually not helpful in the diagnosis of drug eruptions. Peripheral eosinophilia, thought to occur commonly with adverse drug reactions, is actually uncommon. Skin biopsy can be helpful.

Specific Reaction Patterns

Urticaria. Urticaria constitute the most common expression of drug sensitivity. Most commonly, reactions occur within 1 week of drug exposure. When an individual is on multiple agents and has a reaction, the clinician should suspect those agents that were most recently introduced or those medications that are known to be commonly associated with drug reactions (Table 99.6) When questioning for the use of medications, it is important to ask not only about prescription items, but also about over-the-counter preparations. Occasionally, patients who use aspirin, acetaminophen, laxatives, or ear, nose, or eye drops do not consider these substances to be medications or drugs.

Trimethoprim-sulfamethoxazole	Cephalosporins
Ampicillin	Dipyrone
Semisynthetic penicillins (carbenicillin, cloxacillin, dicloxacillin, methicillin, nafcillin, oxacillin)	Nitrazepam
	Barbiturates
Sulfisoxazole	Nitrofurantoin
Penicillin G	Glutethimide
Gentamicin	Indomethacin

Table 99.6. Drugs Most Commonly Associated with Allergic Skin Reactions

Maculopapular Eruptions Similar to Those of a Viral Exanthem. Maculopapular eruptions are the second most common of all drug-induced rashes and may be caused by many different agents. These eruptions are symmetric and consist of erythematous macules and papules with areas of confluence. Variable involvement of the palms, soles, and mucous membranes, as well as purpura may occur. The presence and severity of pruritus is variable. Ampicillin is a medication often associated with this type of skin reaction, particularly in patients with infectious mononucleosis.

Erythema Multiforme. Erythema multiforme is an acute and often recurrent inflammatory syndrome often secondary to drugs (e.g., penicillins, sulfonamides, hydantoins, barbiturates) or infections. Recent observations suggest that a significant portion of idiopathic erythema multiforme cases may be caused by herpes simplex virus. The skin findings include macules, papules, vesicles, and pathognomonic target or iris lesions (Fig. 99.17) that tend to be more or less symmetrically distributed. Bullous lesions may also be present. In the more severe cases, constitutional symptoms occur; when mucous membranes are involved, the term *Stevens-Johnson syndrome* is used (Fig. 99.18 and Fig. 99.19). Erythema multiforme consists of two lesion types: macular-urticarial and vesicular-bullous. There is a predilection for the backs of the hands, palms, soles, and extensor surfaces of the limbs. The lesions may begin at these sites and then spread diffusely or they may begin generalized. In 25% of the patients, the mucous membranes are involved and, in fact, can be the sole site of involvement. The usual sites of mucous membrane involvement are the lips, buccal mucosa, palate, conjunctivae, urethra, and vagina. With severe involvement, the pharyngeal, tracheobronchial, and esophageal mucous membranes are also affected. Less common sites are the anal and nasal mucosa. When the eyes are involved, there may be simple conjunctivitis, severe keratitis, or panophthalmitis. These changes may lead to blindness in 3 to 10% of these patients. Therefore, close attention to involvement of the eyes is necessary. Lesions may continue to erupt in crops for as long as 2 to 3 weeks. Death occurs in 3 to 15% of patients.

FIGURE 99.17. Iris or target lesions pathognomonic of erythema multiforme.

FIGURE 99.19. Same child as seen in Figure 99.18. Note photo distribution of lesions. *Please see the color-tip insert (Color Plate 99.19).*

Vasculitis. The classic lesions of vasculitis are palpable purpura. Although these lesions are characteristic, vasculitis may be manifest by erythematous macules, papules, urticaria, and hemorrhagic vesicles and bullae (Fig. 99.20). The diagnosis is made by a skin biopsy, which shows leukocytoclasis, endothelial cell necrosis, and destruction of dermal vessels.

FIGURE 99.20. Hemorrhagic bulla in patient with vasculitis. *Please see the color-tip insert (Color Plate 99.20).*

Erythema Nodosum. The lesions of erythema nodosum appear as deep, tender, erythematous nodules or plaques of the extensor surfaces of the extremities (Fig. 99.21). They are thought to be hypersensitivity phenomena secondary to infections (e.g., streptococcal pharyngitis, tuberculosis, coccidioidomycosis, histoplasmosis), inflammatory bowel disease, sarcoidosis, malignancies, and occasionally, drugs. The exact immunologic mechanism has not been clarified.

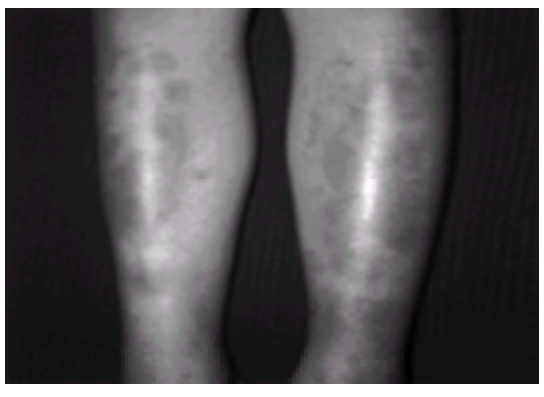

FIGURE 99.21. Extensor surface involved with lesions of erythema nodosum. *Please see the color-tip insert (Color Plate*

99.21).

Photosensitive Cutaneous Eruption. When a drug causes an exaggeration of the sunburn response, a phototoxic eruption should be considered. However, photoallergic eruptions usually do not occur on first exposure to a medication because immunologic induction must first occur. Because a hypersensitivity reaction is also involved, the eruption, although concentrated most heavily on sun-exposed areas, can also occur on non–sun-exposed areas. Tetracycline and sulfonamides can be involved in this reaction.

Toxic Epidermal Necrolysis. Drug-induced toxic epidermal necrolysis (TEN) must be differentiated from an illness caused by a circulating staphylococcal exotoxin. If a child who has TEN has been taking drugs long term or shortly before onset of the rash, is over 6 years of age, or has a mixed rash (i.e., areas with the appearance of erythema multiforme as well as toxic epidermal necrolysis), a biopsy must be performed to distinguish between the two disorders. With drug-induced TEN, dermal–epidermal separation is visible on histologic examination. If epidermolytic toxin has been released by staphylococci, epidermal cleavage occurs in the granular layer (see Fig. 99.24). With extensive exfoliation of skin, fluid and electrolyte disturbances may occur, and the potential for bacterial sepsis is present.

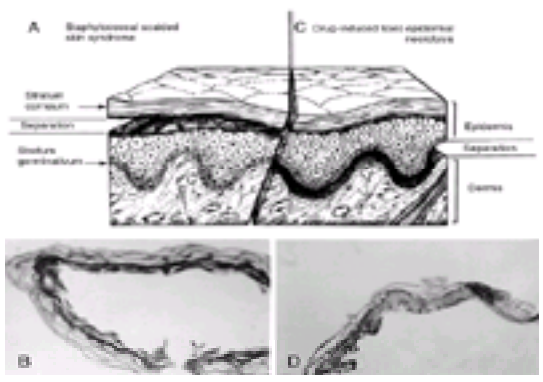

FIGURE 99.24. A. and **B.** Pathology in staphylococcal scalded skin syndrome (SSSS). **C.** and **D.** Pathology in drug-induced toxic epidermal necrolysis.

Fixed Drug Eruption. Fixed drug eruption refers to a localized round or oval dermatitis that tends to recur at the same location each time there is exposure to the offending drug. The lesions are generally erythematous and may or may not contain vesicles. They disappear over 7 to 10 days after cessation of the drug, leaving various shades of postinflammatory hyperpigmentation in their place. The discoloration may persist for months or years. Initially, lesions are solitary but then can become multiple; they often involve the palms, soles, glans penis, and lips.

Management

Vital to the management of any suspected drug reaction is the identification and removal of the offending drug. Pruritus can be controlled with antihistamines, and open lesions are responsive to compressing with Burow's solution and topical silver sulfadiazine. When extensive exfoliation occurs, attention to fluid and electrolyte balance and secondary infection is essential. Any patient with mucous membrane involvement should have an ophthalmologic examination to rule out the presence of corneal involvement. Hospitalization should be considered in any patient who has severe involvement of the skin, is toxic, or has extensive exfoliation.

The literature suggests that steroid therapy of Stevens-Johnson syndrome and drug-induced toxic epidermal necrolysis is of no value, will prolong hospital stays, and may in fact be harmful. Steroids (i.e., an equivalent of prednisone 1 to 2 mg/kg per day) must be started within the first 2 days of the eruption to be effective. Progression of the reaction after 5 days of steroid therapy indicates that the medication is ineffective and should be discontinued. If skin denudation is greater than 20% of the child's body surface area steroid therapy should be avoided. If denudation progresses to greater than 25% of body surface area the child should be transferred to a burn unit.

STAPHYLOCOCCAL SCALDED SKIN SYNDROME

Background

The term *toxic epidermal necrolysis* is often used indiscriminately. Because the gross dermatologic changes are the same despite different causes, this term should be used to indicate only the visible changes. In this way, the physician will approach patients with an open mind and be more likely to consider the alternative possibilities: although rare, a drug-induced TEN in children and bacteria-induced TEN in adults. *Staphylococcus*-induced disease, or the staphylococcal scalded skin syndrome (SSSS), is presented in this section. Included under the heading of SSSS are bullous impetigo (staphylococcal pustulosis), in newborns, scarlatiniform rashes induced by *S. aureus,* and the generalized exfoliative syndrome caused by *S. aureus* seen in newborns (Ritter's disease) or in children (Lyell's syndrome).

Pathophysiology

The mechanism of these reactions was described by Mellish and Glasgow. They injected coagulase-positive phage group II staphylococci into newborn mice, producing erythema and a positive Nikolsky sign (denudation of skin with gentle rubbing) in 12 to 16 hours, followed by bullae and extensive exfoliation in 16 to 20 hours. Since that time, phage group I and III staphylococci have also been implicated. The disease is believed to occur primarily in children because they lack antibodies against the organism and are unable to metabolize and excrete the toxin as well as adults.

Clinical Manifestations

The illness begins with malaise, fever, and irritability. The irritability is often caused by significant tenderness of the skin when touched. Mothers will relate that their infant does not want to be held and cries when handled. A “sunburn” erythema follows, which first begins and is most intense around the neck, the intertriginous areas, and periorifically (especially the eyes and mouth). The erythema spreads to varying portions of the skin surface, and the child may be very toxic. With mild involvement of the skin, superficial desquamation (flaking) then follows similar to the reaction that occurs after an ordinary sunburn (Fig. 99.22). With severe involvement, large sheets of skin shear away, leaving a denuded, oozing surface similar to the reaction that occurs after a burn (Fig. 99.23). The skin can often be rubbed off (Nikolsky's sign). Vesicles, pustules, and bullae can also occur during the exfoliative phase. Often, a purulent discharge emits from the eyes, but no conjunctival injection is present. Mucous membranes are not involved. Most children do well, and clearing of the skin occurs in 12 to 14 days, leaving no residua.

FIGURE 99.22. Desquamation of the skin of the face in the staphylococcal scalded skin syndrome (SSSS).

FIGURE 99.23. Denudation of skin of nose in child with staphylococcal scalded skin syndrome (SSSS).

The complete blood count (CBC) and urinalysis are not helpful in the evaluation of such children. Although blood cultures should be done, they are usually negative, as are cultures of intact vesicles or bullae. At times, *S. aureus* can be grown from exfoliating skin, the umbilicus, circumcision wounds, throat, eyes, ears, nose, or rectum. Histologic examination of the skin distinguishes between changes caused by staphylococci or a drug. In SSSS, skin clippings or a punch biopsy show separation of the superficial layer of the epidermis subcorneally (Fig. 99.24A and Fig. 99.24B). Patients who have drug-induced TEN will have dermal–epidermal separation (Fig. 99.24C and Fig. 99.24CD). Children taking medications long term or shortly before the eruption of the rash, children older than 6 years of age, or children with a mixed rash (i.e., areas of TEN and erythema multiforme) should have a skin biopsy taken for differentiation.

Causes other than *S. aureus* or drugs may produce a similar clinical picture. These conditions include certain fumigants, lymphomas, aspergillosis, irradiation, and graft-versus-host reaction. More recently, the toxic shock syndrome has been described (Table 99.7).

Fever	Sterile pyuria
Toxic epidermal necrolysislike rash	Elevated bilirubin and enzymes
Desquamation (after 10 days)	Low platelets
Hypotension	Disorientation or alteration in consciousness
Vomiting/diarrhea	
Hyperemia of the mucous membranes	

Table 99.7. Toxic Shock Syndrome

Management

Most of the time, SSSS is a self-limited disorder. Antibiotics probably ameliorate the course of the disease, but steroids have no beneficial effects. In fact, steroids may exacerbate the dermatitis by increasing the ability of the organisms to proliferate and produce greater amounts of epidermolytic toxin.

Neonates and children less than 1 year of age should be admitted to the hospital and started on IV antistaphylococcal antibiotics (cefazolin, oxacillin) after blood cultures are obtained. In addition, any older child who is toxic or who has severe skin involvement with significant denudation should be admitted. Close attention should be paid to the child's state of hydration and electrolyte imbalances when a significant amount of skin is lost. Secondary infection, similar to a patient with a major burn, is an important consideration.

Older children with mild involvement limited to dry desquamation, who are not toxic, can be managed on an outpatient basis. These children can be started on oral dicloxacillin or erythromycin (depending on local sensitivities) or cephalexin and followed closely. Skin care is nonspecific unless extensive denudation occurs, then the use of Silvadene cream is warranted.

BITES AND INFESTATIONS (SEE ALSO CHAPTER 91)

Children are often bitten by insects (especially mosquitoes and fleas) and at times are infested by parasites. The papules, urticaria, blisters, and hemorrhagic lesions produced are commonly misdiagnosed. The season of the year, area of the country, grouping and appearance (central punctum) of the lesions, and distribution on exposed surfaces provide the clues necessary for diagnosis.

Mosquitoes and Fleas

Mosquitoes are probably the most common cause of insect bites in children, followed closely by fleas (Fig. 99.25). Mosquito bites are generally limited to the warm months of the year. On the other hand, flea bites, which predominate from spring to fall, can also occur during the winter months as a result of cats and dogs living indoors. At times, flea bites occur without an animal living in the household. Generally, the clinician should ask for a history of visits to a household that has pets or whether the patient's family has recently moved into a home in which the prior owners had pets. In the latter situation, fleas can live in carpeting for a long time.

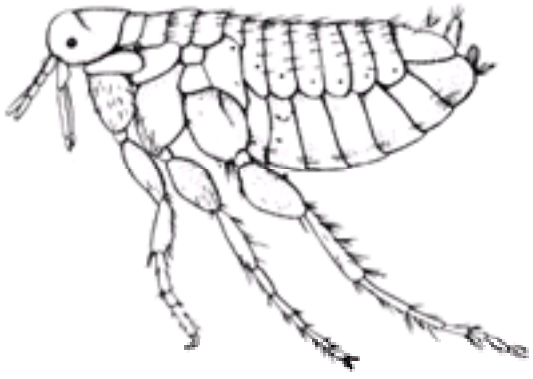

FIGURE 99.25. Flea *(Pulex irritans).*

The distribution of lesions is a valuable clue in making the diagnosis of mosquito or flea bites. Insect bites generally involve the exposed surfaces of the head, face, and extremities. The lesions are usually urticarial wheals that occur in groups or along a line on which the insect was crawling. On occasion, both mosquito bites and flea bites can cause blistering lesions. These lesions are not caused by secondary infection but rather by a violent immune response to the bite. Certainly, excoriation with resulting secondary infection with *S. aureus* or group A streptococci can complicate a simple bite.

A recurrent papular eruption called papular urticaria can occur in young children who become sensitized to insect bites.

Although the lesions tend to occur on exposed parts of the body, with sensitization they may appear at sites distant from the primary bite.

Unfortunately, no specific treatment exists for insect bites. Antihistamines, calamine lotion, or topical steroids have a limited or temporary effect. Prevention by the prophylactic use of insect repellents offers the best solution. Obviously, elimination of the biting insects by treatment of the homes with insecticides or treatment of the infested animals is important.

Tick Bites

Tick bites usually cause only local reactions. Rarely, they are associated with significant systemic illness, including Rocky Mountain spotted fever, tick paralysis, and Lyme arthritis.

When ticks are removed, it is important not to leave fragments of the mouth parts in the skin or to introduce body fluids containing infectious organisms. Various methods have been recommended for removal of ticks from the skin. The only safe method is to use a blunt curved forceps, tweezers, or fingers protected by rubber gloves. The tick is grasped close to the skin surface and pulled upward with a steady even force. The tick must not be squeezed, crushed, or punctured. If mouth parts are left in the skin, they should be removed.

Spider Bites

Loxosceles reclusus, or the brown recluse (Fig. 99.26), found most commonly in the south central United States, is responsible for most skin reactions caused by the bite of a spider. This spider is small, the body being only 8 to 10 mm long, and bears a violin-shaped band over the dorsal cephalothorax. The venom contains necrotizing, hemolytic, and spreading factors. The initial symptoms include mild stinging and/or pruritus. A hemorrhagic blister then appears, which can develop into a gangrenous eschar. Severe bites can cause a generalized erythematous macular eruption, nausea, vomiting, chills, malaise, muscle aches, and hemolysis. Treatment includes oral steroids within 6 to 12 hours after the bite, antibiotics to prevent secondary infection, and surgical removal of the necrotic area to prevent spread of the toxin. An antivenom has been developed at the Vanderbilt School of Medicine.

FIGURE 99.26. Brown recluse spider *(Loxosceles reclusus).*

Scabies Infestation

The cardinal symptom of any infestation with scabies is pruritus. Infants and children excoriate themselves to the point of bleeding. Two clues should be considered when attempting to make this diagnosis: 1) distribution (concentration on the hands, feet, and folds of the body, especially the finger webs) and 2) involvement of other family members. It is important not only to ask other family members if they have pruritus but also to examine their skin. In contrast to adults, infants may develop blisters and also exhibit lesions on the head and face.

The diagnosis is made by scraping involved skin and looking for mites under the ×-10 microscope objective (Fig. 99.27). The materials necessary to examine the skin for scabies are a glass slide, immersion oil, and a No. 15 scalpel blade. A drop of immersion oil should be placed on the glass slide and the No. 15 blade edge dipped into this oil. The best areas to scrape are the interdigital webs of the hands or tiny linear lesions that represent burrows caused by the mite. A recently described procedure involves the use of fountain pen ink applied to the suspected area of skin. After the surface ink is cleaned away, the mite burrows can be identified by means of the ink that has trickled into them.

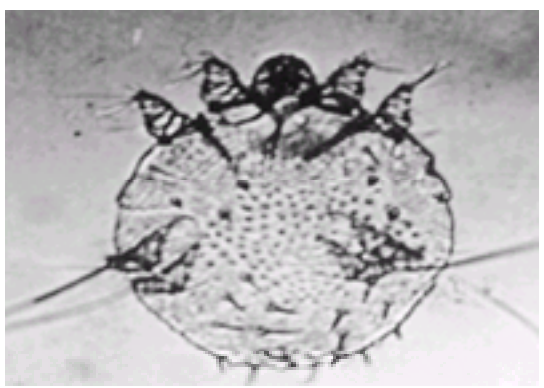

FIGURE 99.27. Mite that causes scabies *(Sarcoptes scabiei).*

Once an infestation occurs, it usually takes 1 month for sensitization and pruritus to develop. The introduction of 5% permethrin cream (Elimite) has obviated the need for lindane and its potential risks. This cream should be applied from head to toe and left on for 8 to 14 hours. The preparation is then washed off with soap and water. Its safety for use in pregnant females has not been proven. All family members and close contacts (e.g., baby-sitters, grandparents) should be treated simultaneously.

Louse Infestation

Three forms of lice infest humans: 1) the head louse, 2) the body louse, and 3) the pubic or crab louse (Fig. 99.28). The major louse infestation in children involves the scalp and causes pruritus. The female attaches her eggs to the hair shaft. The egg then hatches, leaving behind numerous nits (Fig. 99.29) that resemble dandruff. Secondary infection can occur from vigorous scratching. Body lice generally reside in the seams of clothing and lay their eggs there. They go to the body to feed, particularly the interscapular, shoulder, and waist areas. Red pruritic puncta that become papular and wheal-like then occur. Pubic lice occur in the genital area, lower abdomen, axillae, and eyelashes. Transmission is usually venereal. Blue macules (maculae caeruleae) that are 3 to 15 mm in diameter can be seen on the thighs, abdomen, or thorax of infested persons. These macules are secondary to bites.

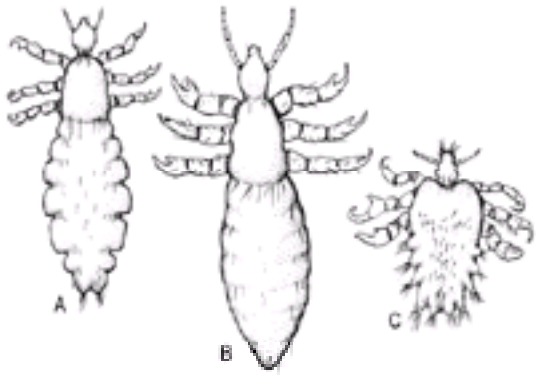

FIGURE 99.28. A. Head louse (*Pediculus humanus var.Capitis*). **B.** Body louse (*Pediculus humanus var. Corporis*). **C.** Pubic louse (*Phthirus pubis*).

FIGURE 99.29. Nits in the hair of a child with head lice.

Because the body louse resides in clothing, therapy consists mainly of disinfecting the clothing with steam under pressure. Pediculosis capitis is most effectively treated with 1% permethrin creme rinse (Nix). The patient's hair should be shampooed, rinsed, and toweled dry. Enough permethrin to saturate the hair and scalp is applied. The medication is washed out after 10 minutes. Pediculosis pubis is best treated with the same preparation. Any nits are removed with a fine-toothed comb. The safest treatment for lice in the eyelashes is the application of white petrolatum twice daily for 8 days. The lice stick to the Vaseline, cannot feed, and die. Another less safe therapy is physostigmine ophthalmic ointment.

SUPERFICIAL FUNGAL INFECTIONS OF THE SKIN

Tinea Corporis

Tinea corporis (Fig. 99.30) is characterized by one or more sharply circumscribed scaly patches. The center of the circular patch generally clears as the leading edge spreads out. The leading edge may be composed of papules, vesicles, or pustules. The lesions are most commonly confused with nummular eczema. The diagnosis can be made by scraping the active outer rim of papules and examining the scales with a potassium hydroxide (KOH) preparation under the microscope (Fig. 99.31). These lesions do not fluoresce under the Wood's light. The most common offending fungi

are Trichophyton tonsurans and Microsporum canis. Treatment with topical antifungal agents such as clotrimazole, miconazole, or econazole produces clearing in 7 to 10 days. Therapy should be maintained for 2 weeks. If improvement does not occur, treatment with griseofulvin (15 mg/kg per day in two divided doses) will usually resolve the problem.

FIGURE 99.30. Child with tinea corporis.

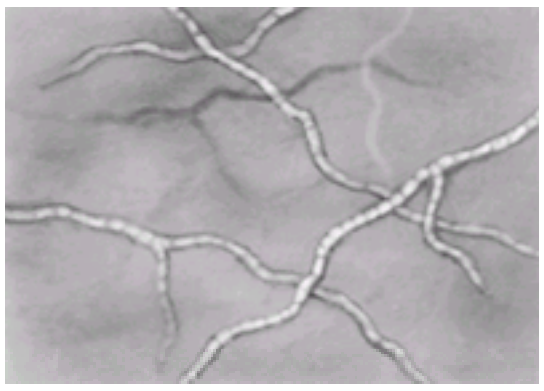

FIGURE 99.31. Characterization of a positive potassium hydroxide (KOH) preparation demonstrating branching hyphae running across the microscope field.

Tinea Capitis

Although tinea capitis was commonly caused by the *Microsporum* species in the past, it usually results now from infection by *Trichophyton tonsurans.* The two forms have different clinical appearances. The *Microsporum* species (Table 99.8) generally causes round patches of scaling alopecia (Fig. 99.32). Illumination of a lesion with a Wood's lamp gives a blue–green fluorescence. Kerion formation can occur as a swollen, boggy abscess. The *Trichophyton* species (Table 99.9) usually causes scattered alopecia, not always oval or rounded; the alopecia is irregular in outline with indistinct margins. Normal hairs grow within the patches of alopecia. At times, the hairs break off at the surface of the scalp, leaving a “black dot” appearance (Fig. 99.33). Diffuse scaling may simulate dandruff, and although minimal hair loss is present, it is not perceived. Wood's light examination of the lesion does not produce fluorescence. The organism can cause a folliculitis suppuration and kerion formation (Fig. 99.34). Diagnosis is made by culturing the affected scalp area (Fig. 99.35). The clinician should consider the presence of tinea capitis when a nonresponsive seborrheic or atopic dermatitis of the scalp is present, black dots are seen, or increased scaling follows the use of topical steroids. With the use of dermatophyte test media (DTM), a color change occurs in the media (yellow to red) in the presence of a growing dermatophyte. If a kerion is present, the swelling (allergic reaction to the fungus) can be controlled by a combination of prednisone and griseofulvin.

Round patches of scaling alopecia
Fluoresce blue-green
Kerion formation

Table 99.8. Tinea Capitis *Microsporum* Species

Partial scattered alopecia—not always oval or rounded	Black dots, diffuse scaling ("dandruff")
Alopecia irregular in outline with indistinct margins	Nonfluorescent
Normal hairs growing within patch of alopecia	Folliculitis, suppuration, kerion formation

Table 99.9. Tinea Capitis *Trichophyton* Species

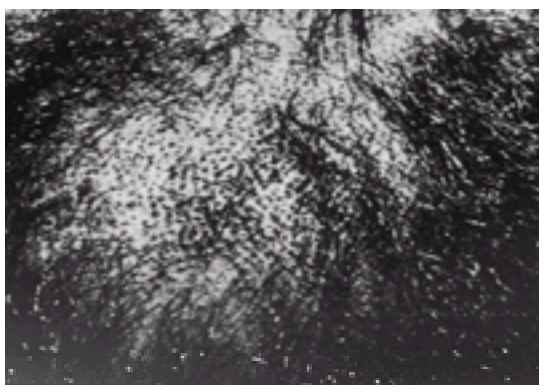

FIGURE 99.33. "Black-dot" appearance of scalp infection with *Trichophyton tonsurans.*

FIGURE 99.34. Patient with tinea capitis and multiple kerions.

FIGURE 99.35. Toothbrush implants of scalp brushing that are growing fungus.

In the differential diagnosis of patchy hair loss, as is seen in tinea capitis, the clinician should consider alopecia areata (Fig. 99.36). However, with alopecia areata, no inflammation or scaling of the scalp occurs. *Trichotillomania,* the term given to the habit children develop of rubbing, twirling, or playing with their hair to the point that the hair breaks and is lost in irregular patches, should also be considered. Traction alopecia occurs with certain hair styles. Hair is lost at the margins of the hairline with the ponytail style or frequent use of hair rollers. Tight braiding or corn-rowing can cause hair loss on any area of the scalp. At times, papules or pustules occur where the skin has been disrupted by the traction. Infants who are left on their backs for long periods may lose hair at the occiput from the constant friction in that area.

FIGURE 99.36. Child with alopecia areata.

Treatment for tinea capitis consists of orally administered griseofulvin 15 to20 mg/kg per day in two divided doses with a glass of milk for 6 weeks. Adjunctive therapy includes the use of 2.5% selenium sulfide shampoo twice weekly. With the use of this shampoo, shedding of spores is decreased within 1 to 2 weeks. Two newer oral medications, itraconazole and terbinafine, are currently under study and may eventually replace griseofulvin as the preferred medication.

Tinea Cruris

Tinea cruris begins as a small, red, scaling rash in the groin that spreads peripherally and clears centrally. The edges are sharply marginated and scalloped, extending down the thighs. Generally, the scrotum is not noticeably involved. This fungal infection is most common in semitropical regions where heat and high humidity are prevalent. Tight-fitting clothes also contribute to the problem by preventing evaporation. Other conditions to consider are seborrheic dermatitis (which usually can be differentiated by involvement of other areas of the body such as the ears, scalp, and eyelids), intertrigo (generally secondary to friction and maceration), contact dermatitis, candidiasis (which usually involves the inner thigh and causes the scrotum to appear bright red), and erythrasma. The clinician should always check the feet to make sure there is not fungal involvement in that area as well. In general, this condition affects only postpubertal children. Diagnosis is made by KOH preparation. Nonspecific measures for treatment include loose-fitting clothing, reducing the amount of perspiration by using dusting powders, and decreasing intake of caffeine-containing foods. Clotrimazole, miconazole, tolnaftate, and econazole are useful as topical antifungal agents. Oral griseofulvin may be needed in severe cases.

Tinea Pedis

Tinea pedis is generally caused by *Trichophyton rubrum* or *T. mentagrophytes.* It occurs most commonly in postpubertal children. The cracking and peeling of the skin suggestive of tinea pedis in prepubertal children more often indicates the presence of atopic eczema or hyperhidrosis. Tinea pedis is a penalty of civilization in that it occurs only in those individuals who wear shoes. KOH preparation will demonstrate hyphae, especially when samples are taken from between the fourth and fifth interspaces of the toes. Clinically, the skin has a dry, white, hazy appearance and is often pruritic. When secondary bacterial infection is present, an odor occurs. At times, an inflammatory type of lesion (caused by *T. mentagrophytes*) causes blistering. The presence of an id reaction indicates dissemination of antigen to other parts of the body, especially the hands.

The differential diagnosis of tinea pedis includes simple maceration, contact dermatitis, and atopic eczema. Treatment consists of drying the feet thoroughly after washing; wearing dry, clean socks; avoiding caffeine-containing foods to decrease sweating; keeping shoes off as much as possible; and walking barefoot or in sandals. Topical antifungal agents (see the previous section on Tinea Cruris) and/or oral griseofulvin are used to treat this condition. Newer medications (see the previous section on tinea capitis) are on the horizon.

Tinea Versicolor

Tinea versicolor refers to a superficial infection of the skin caused by *Pityrosporum orbiculare,* which produces color changes of the skin, hypopigmentation, hyperpigmentation, and redness (Fig. 99.37). Wood's light examination usually shows yellowish brown fluorescence. Because moisture promotes growth of the organism, exacerbations occur in warm weather or in athletes who sweat excessively. The infection is difficult to eradicate and recurs frequently. A KOH

preparation shows large clusters of spores and short, stubby hyphae, often called meatballs and spaghetti.

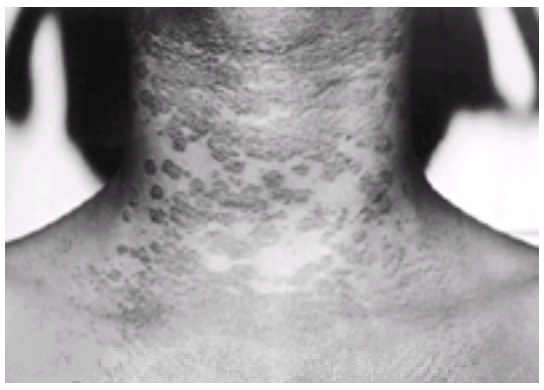

FIGURE 99.37. Adolescent with tinea versicolor.

Treatment consists of lathering the entire body with selenium sulfide shampoo (2.5% concentration) after wetting the skin surface in a shower. The lather is left on for 20 minutes and is then showered off. This procedure is carried out multiple times during the first week, with decreasing frequency over the ensuing weeks. Maintenance therapy is advisable because of the high incidence of recurrence. Localized areas of involvement can be treated with topical antifungal agents (e.g., econazole, ketoconazole topically). Adolescents can be treated with 400 mg of ketoconazole initially and then 200 mg at monthly intervals during the warm summer months or during a sports season when the child sweats frequently.

PYOGENIC GRANULOMAS

Pyogenic granulomas (Fig. 99.38) are vascular nodules that develop rapidly at the site of an injury such as a cut, scratch, insect bite, or burn. The histologic picture is that of proliferating capillaries in a loose stroma. Although this lesion was previously believed to be caused by infection of a small wound, the definite cause has not been established. Pyogenic granulomas occur commonly in children and young adults, usually on the fingers, face, hands, and forearms.

FIGURE 99.38. Pyogenic granuloma on the cheek of a child.

Clinically, the lesions are bright red to reddish brown or blue–black. The vascular nodules are pedunculated, ranging from 0.5 to 2 cm in size. Their surfaces are glistening, or raspberrylike, often becoming eroded and crusted. They bleed easily. Generally, they are asymptomatic. Because spontaneous disappearance is rare, the lesions must be removed by excision, electrosurgery, or cryosurgery.

URTICARIA

Background

Urticaria as a symptom complex is often encountered in the pediatric population, occurring in 2 to 3% of all children. In most cases, no cause is identified. A small number of cases are caused by allergic reactions from the ingestion of drugs or foods (e.g., nuts, eggs, shellfish, strawberries). Urticaria also follow viral (e.g., Epstein-Barr virus, hepatitis), bacterial (streptococcal), or parasitic infections. Physical factors, including dermographism, cholinergic stimulation (induced by heat, exercise, and emotional tension), cold (acquired and familial), and solar exposure, can induce urticaria. Finally, urticaria may be caused by factors producing a vasculitis and substances causing degranulation of mast cells (radiocontrast material). Episodes of urticaria that last less than 6 weeks are termed transient or acute. The most common causes of urticaria are infection, insect bites, drugs, and foods. Chronic urticaria are defined as those that last more than 6 weeks. No cause is found in 90% of children. These cases include the physical urticarias or urticarial vasculitis.

Pathophysiology

The lesion itself follows vasodilation and leakage of fluid and red blood cells from involved vessels. The vascular damage can be caused by mediators such as histamine complement and immune complexes. IgE can attach to and cause

degranulation of mast cells in sensitized individuals with resulting histamine release. Urticarias are usually acute and transient, but at times become chronic and recurrent.

Clinical Manifestations

The typical urticarial lesions are familiar to all physicians. They can be localized or generalized (involving the entire body). At times, the lesions are giant with serpiginous borders. Individual wheals rarely last more than 12 to 24 hours. Most commonly, the lesions appear in one area for 20 minutes to 3 hours, disappear, and then reappear in another location. The total duration of an episode is usually 24 to 48 hours; however, the course can last 3 to 6 weeks.

Management

Acute relief can be accomplished with subcutaneous epinephrine (1:1000) 0.01 mL/kg and intramuscular diphenhydramine 1 mg/kg. Prolonged sympathetic effect can be maintained with Sus-Phrine 0.005 mL/kg. Oral antihistamines are useful for maintenance therapy for transient urticaria. Hydroxyzine hydrochloride (2 mg/kg per day in three to four divided doses) or diphenhydramine hydrochloride (5 mg/kg per day in three to four divided doses) should be prescribed for at least 10 days. Newer long-acting antihistamines include terfenadine (dose varies by age) or loratadine (10 mg once per day).

PITYRIASIS ROSEA

Pityriasis rosea can occur in all age groups but is seen predominantly after 10 years of age and only rarely under 5 years of age. The cause is unknown; however, a viral cause is suspected. Less than 5% of cases occur in multiple family members. In 80% of children, a large, oval, solitary lesion known as the herald patch appears on the trunk (Fig. 99.39) before the eruption of subsequent lesions. Individual lesions are oval and slightly raised, pink to brown, with peripheral scaling. Because the lesions follow the cleavage lines (Fig. 99.40) of the skin, the backs of patients have a “Christmas tree” appearance. Generally, the face, the scalp, and distal extremities are spared. On occasion, an inverse distribution occurs (lesions on the face and extremities with truncal sparing). The rash is pruritic early in the course but then becomes asymptomatic. It lasts 4 to 8 weeks.

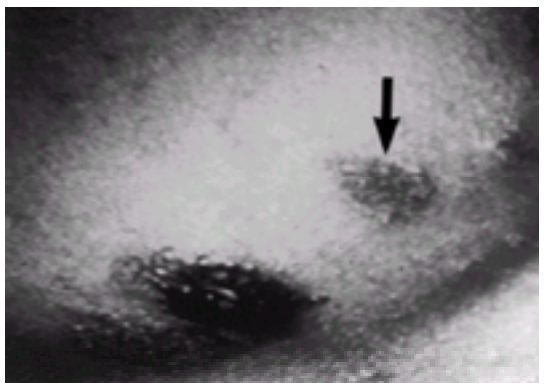

FIGURE 99.39. Herald patch *(arrow)* in adolescent with pityriasis rosea.

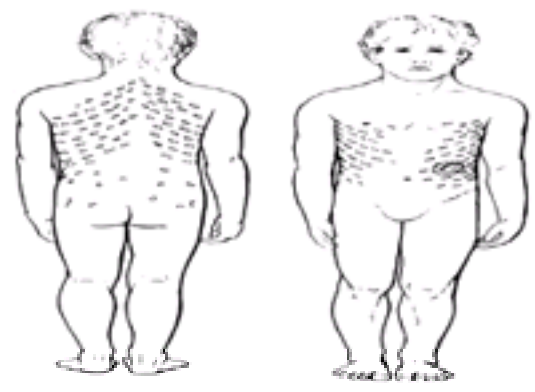

FIGURE 99.40. Typical distribution of pityriasis rosea.

The herald patch can be mistaken for tinea corporis, but a KOH preparation eliminates that possibility. When pityriasis rosea appears in adolescence, it must be differentiated from secondary syphilis. Clinical clues are helpful (Table 99.10), but serologic testing is necessary.

	Pityriasis Rosea	Syphilis
Herald patch	+	-
Ovals follow dermatomes	+	-
Lymphadenopathy	-	+
Mucous membrane lesion	-	+

Table 99.10. Differential Diagnosis

Treatment is symptomatic. Antihistamines and topical emollients can help the pruritus.

PANNICULITIS

Erythema Nodosum

Erythema nodosum seems to be a hypersensitivity reaction to infection (streptococci, tuberculosis, coccidioidomycosis, histoplasmosis), inflammatory bowel disease, sarcoidosis, and drugs. The exact immunologic mechanism has not been clarified. The entity occurs predominantly in adolescents during the spring and fall. Females are affected more often than males.

The lesions of erythema nodosum appear as deep, tender, erythematous nodules or plaques on the extensor surfaces of the extremities (Fig. 99.21). The sedimentation rate is generally elevated and usually returns to normal with disappearance of the eruption unless an underlying disease is present. The reaction usually lasts 3 to 6 weeks. Treatment should be directed toward the cause when and if established; otherwise, it is symptomatic (aspirin and antihistamines). Hospitalization is unnecessary. Corticosteroids should not be used except in severe cases after an underlying infection has been ruled out.

Cold Panniculitis

Cold panniculitis is secondary to cold injury to fat. During the cold of winter, infants and some older children develop red, indurated nodules and plaques on exposed skin, especially the face. The subcutaneous fat in infants and some children solidifies more readily at a higher temperature than that of an adult because of the relatively greater concentration of saturated fats. Infants who hold ice popsicles in their mouths are also susceptible to this phenomenon (Fig. 99.41). The lesions gradually soften and return to normal over 1 or more weeks. Treatment is unnecessary.

FIGURE 99.41. Infant with popsicle panniculitis of the cheek. *Please see the color-tip insert (Color Plate 99.41).*

WARTS AND MOLLUSCUM CONTAGIOSUM

Warts

Warts affect 7 to 10% of the population and are one of the most common dermatologic problems encountered in pediatrics. The peak incidence is during adolescence. Sixty-five percent of common warts disappear spontaneously within 2 years, and 40% of plantar warts disappear within 6 months in prepubertal children. However, immunosuppressed patients may have extensive spread of the lesions.

The common wart resembles a tiny cauliflower. The shape of the wart varies with its location on the skin. They may be long and slender (filiform) on the face and neck or flat (verruca plana) on the face, arms, and knees. When located on the soles, they are called plantar warts, and when in the anogenital area, they are referred to as condyloma acuminata.

The tendency for recurrence of warts makes the treatment of this condition frustrating. Because most warts disappear spontaneously with time, procedures that are least traumatic for the child should be attempted first (Table 99.11). The

simple, nontraumatic method of airtight occlusion with plain adhesive tape for 1 month has been shown to be successful on many occasions. Topical application of salicylic acid in flexible collodion (Duofilm; Table 99.12) is good for home use, as are some of the over-the-counter preparations (e.g., Compound W). When simple methods are unsuccessful, touching the warts with liquid nitrogen for 20 to 30 seconds or surgical removal can be attempted. Both procedures are painful.

Decrease irritation—cover with tape (1–2 months)
Over-the-counter preparations such as Compound W (1 month)
Salicylic in collodion (Duofilm) (1 month)
Refer to dermatologist

Table 99.11. Management of Warts

1. Soak wart for 5 min.	5. Cover with tape.
2. Dry.	6. Repeat twice a day.
3. Surround with petroleum jelly.	7. Pare dead skin.
4. Apply Duofilm (let dry for few minutes).	

Table 99.12. Use of Duofilm

Plantar warts can be treated with 40% salicylic acid plaster. Circular pieces, slightly larger then the plantar wart, are cut from a sheet of this material. They are placed on the wart and kept in place continuously with adhesive tape for 1 to 2 weeks. At that point, the dead tissue is carefully pared away. Treatment is continued until normal skin is seen in place of the wart.

Anogenital warts are treated with 20% podophyllin. This medication is carefully applied to the wart only and washed off in 4 to 6 hours (see Chapter 94). Severe burning of the skin occurs if the material is not completely removed. Child abuse should be considered in any child with genital warts.

Molluscum Contagiosum

The lesion, produced by the common poxvirus, is a papule with a white center (Fig. 99.42). It occurs at any age during childhood. It is more common in swimmers and wrestlers. Patients with atopic eczema are especially susceptible. Most lesions resolve in 6 to 9 months, but some may persist for more than 3 years. Spread is by autoinoculation.

FIGURE 99.42. Molluscum contagiosum. Papules with white centers that contain the virus.

Lesions can be single or numerous and favor intertriginous areas such as the groin. They are usually 2 to 5 mm in diameter, but several can coalesce and form a lesion 1.5 cm in diameter. They may become inflamed, which sometimes heralds spontaneous disappearance. At times, an eczematous reaction occurs around some lesions, and they can

become secondarily infected.

Treatment should be gentle. Removal of the white core will cure the lesion. This treatment can be performed by applying eutectic mixture of local anasthetics (EMLA) cream under occlusion to the lesion 1 to 2 hours before treatment. This procedure will anesthetize the area and allow the physician to prick the skin open over the core with a 26-gauge needle, and squeeze the core out with a comedome extractor. Multiple light touches with liquid nitrogen can also be effective. With widespread lesions, nonpainful procedures are preferable. Application of 0.1% retinoic acid one to two times daily may induce enough inflammation to hasten the host's immune response or cause extrusion of the central core. Multiple painful treatments will cause great fear in the patient and make future visits to a physician difficult for the family.

CONGENITAL HERPES SIMPLEX VIRUS

Congenital herpes simplex virus (HSV) infection encompasses a broad clinical spectrum ranging from localized cutaneous and mucosal lesions to life-threatening central nervous system and internal organ involvement. Studies have shown that the prevalence of HSV-2 infection has increased by 30% from 1976 to 1994. The greatest increases occurred in white teenagers and white women in their twenties. The risk of acquiring HSV during pregnancy was 2% in susceptible women. The risk of acquiring the infection is similar in each trimester. Less than 10% of those who were seropositive gave a history indicating genital herpes infection. Other patients noted nonspecific genital urinary symptoms such as dysuria, leukorrhea, hematuria, and pelvic pain. If seroconversion occurs in the mother before delivery, the risk to the infant is small. However, if a primary infection occurs shortly before labor, neonatal HSV infection can occur in up to 50% of newborns. Whereas most infections are transmitted by direct contact with the infected birth canal during the second stage of labor, some evidence supports transplacental infection of the fetus.

The incubation period of congenital HSV infections ranges from 2 to 30 days after exposure. Lesions present at birth or shortly thereafter have been explained by transplacental passage of the virus. The clinical manifestations of congenital HSV infection are diverse, but more than 50% of infected neonates present with external involvement. In vertex deliveries, the scalp is a common site for the vesicles. Conversely, infants delivered by breech often develop lesions of the buttocks and perianal area initially. The lesions are not unlike those seen in older children or adults in that they are grouped tense vesicles arising on an erythematous base. However, the infection may present on the skin as individual vesicles, pustules, bullae, or denuded skin. Unfortunately, when infants have disease limited to the integument, HSV infection is often not considered as a possibility. Instead, these children are treated for “impetigo.” The correct diagnosis may not be considered until constitutional symptoms such as fever, hypothermia, poor feeding, irritability, lethargy, and vomiting have appeared. By then, dissemination of the disease has occurred.

Diagnosis of congenital HSV infection should be suspected in any infant less than 1 month of age who has a vesicular eruption on an erythematous base. A Tzanck preparation of the base of an unbroken vesicle is an easy and rapid diagnostic tool to aid in the recognition of this potentially lethal disease (Fig. 99.7). Giemsa, Papanicolaou, or hematoxylin-eosin stains of the smeared preparation of vesicles infected with HSV will reveal multinucleated giant cells, intranuclear inclusions, ballooning degeneration, or margination of nuclear chromatin. Rapid slide tests, using monoclonal antibodies, are also available for rapid diagnosis. Viral culture still remains the gold standard for proving that HSV is present.

The differential diagnosis of vesiculopustular lesions in the newborn includes bullous impetigo, congenital cutaneous candidiasis, congenital syphilis, neonatal pustulomelanosis, and cytomegalovirus infection. Differentiation of these entities requires the use of Gram stains, KOH scrapings, serologic studies for syphilis, and appropriate cultures. Although many serologic tests are currently available to detect the presence of HSV antibodies, none of these studies is valuable in arriving at an early diagnosis of congenital infection. Direct culture of the herpes virus from a lesional vesicle takes 24 to 48 hours for identification.

All infants with suspected congenital HSV should be treated with IV acyclovir, which is the preferred drug. Acyclovir is should be given at a dosage of 30 mg/kg per day, divided every 8 hours (10 mg/kg per dose), in a 1- to 2-hour IV infusion.

DISORDERS OF PIGMENTATION

Hypopigmentation

A dominant form of partial albinism occurs, in which localized areas of skin and hair are devoid of pigment. Ocular albinism is also seen. Two syndromes with albinism are Waardenberg's syndrome (white forelock, heterochromia of the iris, sensorineural hearing loss) and Chediak-Higashi syndrome (immunodeficiency, leukocytes with giant granules).

Loss of pigmentation can be a result of absence of melanocytes as in vitiligo and halo nevi. Vitiligo is a symmetric, patchy loss of pigmentation. Hair located in areas of vitiligo is often white. Vitiligo can be associated with alopecia areata, pernicious anemia, Addison's disease, hypothyroidism, diabetes mellitus, hypoparathyroidism, and other endocrine disorders. Vitiligo and some of the diseases associated with it may be autoimmune disorders. Antibodies directed against melanocytes have been detected.

Suppression of melanocytic pigment production can cause loss of pigmentation as in postinflammatory hypopigmentation. An example of this condition is the white patch of hypopigmentation and scaling often seen on the face, trunk, or extremities of children with atopic eczema. The ash-leaf macule is a flat, hypopigmented (whitish) spot that is present in more than 90% of patients with tuberous sclerosis. In white patients, they are more easily seen by shining a Wood's lamp on the skin.

Hyperpigmentation

Diffuse hyperpigmentation is associated with Addison's disease, acromegaly, and hemochromatosis.

Pigment deep in the dermis appears gray or blue at the surface of the skin. Mongolian blue spots are an example. The nevus of Ota is dermal pigment in the distribution of the ophthalmic branch of the fifth nerve; this pigmentation can involve the sclera and palate as well.

Certain syndromes, including neurofibromatosis, are associated with pigmented skin lesions. Patients with this disease have café-au-lait spots, which are flat, nonpalpable, coffee-colored lesions of varying size and shape. When six or more lesions are present, greater than 0.5 cm in size, neurofibromatosis should be considered. The Peutz-Jeghers syndrome is a dominantly inherited condition that includes frecklelike lesions of the lips, nose, buccal mucosa, fingertips, and subungual areas associated with polyps in the small intestine, stomach, or colon. Melena and intussusception are the chief complications that may develop, usually in the second decade of life. Albright's syndrome should be suspected when unilateral café-au-lait spots with irregular borders occur in the lumbosacral area. Included in this syndrome are bony abnormalities and precocious puberty.

Single or multiple red–brown papules or nodules occurring on the extremities or face of children may have a confusing tissue structure. Although the lesions are benign, they have commonly been misdiagnosed as malignant melanoma. Therefore, the name *benign juvenile melanoma* has been assigned to this condition. Other names include *Spitz tumors* or *spindle-cell epithelioid nevi.* True malignant melanomas are rare in children. They usually arise from congenital pigmented nevi.

CHAPTER 100

Oncologic Emergencies

MICHAEL D. HOGARTY, MD and BEVERLY LANGE, MD

Department of Pediatrics, The University of Pennsylvania School of Medicine, and Division of Oncology and Pediatric Oncology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Each year only 1 child in 10,000 develops cancer. Yet, next to accidents, cancer remains the leading cause of death in children 100older than 1 year of age. Fortunately, with carefully planned therapy, more than half the children diagnosed with cancer can now be expected to become healthy, productive members of society.

Not so much because cancer is potentially fatal, but because it is potentially curable, pediatric oncology concerns all physicians who see children. The pediatrician or the emergency physician must first consider cancer as a diagnosis and must decide which child needs a complete blood count (CBC), radiograph, or biopsy. Children who develop cancer complain of the same things that bother most children: fatigue, fever, headache, or pain. After a history, physical examination, and appropriate laboratory tests, the emergency physician may already have sufficient information to make a presumptive diagnosis of cancer. His or her role in the management of the child may consist of sharing this information with the family and then referring the child to a specialist who is qualified to confirm the diagnosis and undertake the care of pediatric cancer. On some occasions, however, the emergency physician must begin supportive therapy that is potentially lifesaving or care for a child who has a complication of cancer therapy.

This chapter is divided into two sections. The first section describes the presentation and initial care of children with cancer. Leukemia is described first and in greatest detail because it is often diagnosed in the emergency department (ED); the lymphomas and histiocytic diseases are discussed separately because they may present in a variety of locations. Soft tissue and bone sarcomas are discussed separately for the same reason. Other solid tumors, including central nervous system (CNS) tumors, are presented by location because signs, symptoms, and potential emergencies are related to the surrounding anatomy.

Common problems of children undergoing cancer therapy or with progressive tumor are discussed in the second section. During treatment, the most common problems relate to 1) the risk of hemorrhage, anemia, and infection as a result of bone marrow suppression; 2) metabolic derangement caused by tumor lysis or the side effects of chemotherapy; 3) the compression of a vital organ by progressive tumor growth; or 4) damage to a vital organ as a result of cancer therapy.

Pain is associated with cancer at diagnosis, at the time of painful procedures, and when the disease has failed to respond to therapy. The pain of cancer is often severe and can qualify as an emergency. This topic is discussed briefly in the second section (see also Chapter 4).

DIAGNOSIS AND INITIAL CARE OF PATIENTS WITH CANCER

The early symptoms and signs of cancer can be indistinguishable from the initial manifestations of more common childhood illnesses. Table 100.1 reviews common symptoms and signs associated with pediatric malignancies. The history and physical examination often suffice to rule out cancer. In general, any mass in the abdomen of a child should be considered possibly malignant. Multiple cytopenias must be considered a sign of malignancy until a bone marrow examination proves otherwise or until other evidence establishes the cause. The primary care or emergency physician should remember that, except in the rare circumstance when the need for emergency care is clear, the diagnostic workup of a malignancy should be completed in a pediatric oncology center where all tests required by modern treatment protocols are available. Tissue for diagnosis should be obtained at the institution that will undertake the child's care. Today, for almost all diseases, viable tissue is essential for categorizing diseases and determining treatment; histologic slides and cell blocks may not be sufficient.

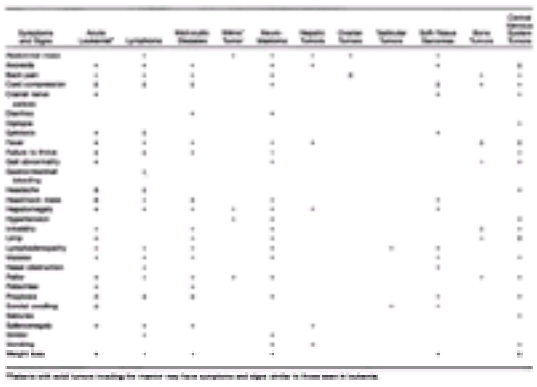

Table 100.1. Common Presenting Symptoms and Signs of Pediatric Malignancies

Leukemia

Background

Definition

In leukemia, excessive numbers of immature malignant white blood cells (WBCs), “leukemic blasts,” replace normal marrow hematopoietic cells. Leukemic blasts leave the marrow, circulate in the peripheral blood, and infiltrate lymph nodes, liver, spleen, meninges, and soft tissues. Leukemia manifests as bone marrow failure and by infiltration into extramedullary sites.

Classification

Leukemia is a group of diseases. The various types of leukemia are classified according to whether the disease is acute or chronic and according to the morphology of the leukemic blasts. Acute leukemia is characterized by the rapid onset of bone marrow failure. Untreated, the disease is fatal within a few weeks to several months from the onset of symptoms. Most childhood leukemia is acute. Chronic leukemia, in contrast, evolves over months to years; initially, peripheral blood granulocytes of all stages of maturation increase, but ultimately, blasts predominate (“blast crisis”) and marrow failure ensues.

Morphologic classification of leukemia defines two discrete types according to the appearance of the blasts: 1) lymphoblastic (lymphoid, lymphocytic, lymphatic) and 2) myelogenous (myeloid, myelocytic, myeloblastic, acute nonlymphoblastic). The distinction is based on the superficial resemblance of the lymphoid blasts to immature or transformed lymphocytes and of the myeloid blasts to normal myeloblastic, promyelocytic, or monocytic precursors. These two types of leukemia are further classified by immunologic surface markers and chromosomal abnormalities. A small percentage of leukemic blasts have features of both types. Unlike normal myeloid and lymphoid precursors, the leukemic blasts do not have the ability to mature and differentiate *in vivo,* do not obey the signals that regulate proliferation of normal cells, and make no contribution to the body's immune system.

The distinction between acute myelogenous and lymphoblastic leukemia is important: childhood acute lymphocytic leukemia (ALL) responds to different therapy and has a substantially better prognosis than acute myelogenous leukemia (AML). About 75% of childhood leukemia is lymphoblastic.

Epidemiology

Leukemia is the most common childhood malignancy in the United States. The yearly incidence is about 4 cases per 100,000 children. The peak incidence is between 3 and 6 years.

Physical agents (e.g., ionizing radiation) and chemical agents (e.g., benzene) can cause leukemia in humans, and certain DNA viruses and RNA retroviruses are associated with leukemia in laboratory animals, but the cause of most childhood leukemia is unknown. Certain groups are at especially high risk of developing leukemia: 1) an identical twin of an infant with leukemia; 2) children with Down's syndrome, Bloom's syndrome, ataxia telangiectasia, or neurofibromatosis type 1; or 3) rarely, children who have previously received radiation and chemotherapy for another tumor. When

discussing the possibility of a child having leukemia, the emergency physician should reassure the parents that the cause is unknown in most cases, that the parents could not have prevented its occurrence, and that the disease is treatable.

Clinical Manifestations and Pathophysiology

The symptoms of acute leukemia are the symptoms of marrow failure and tissue infiltration. Marrow failure leads to anemia, thrombocytopenia, and leukopenia. Anemia causes pallor, fatigue, and irritability. Thrombocytopenia causes spontaneous bruising, epistaxis, and oozing from gums. Patients with myelogenous leukemia, especially hypergranular promyelocytic leukemia, are prone to CNS hemorrhage.

Infiltration of the marrow with leukemic cells can cause bone pain. Joint pain and dactylitis also occur, but their cause is obscure. Some children have a limp because of bone or joint pain. Leukemic infiltration of the reticuloendothelial system can cause adenopathy, hepatosplenomegaly, and mediastinal mass, especially in T-cell leukemia. In myelogenous leukemia, gingival hypertrophy is seen, and in monocytic leukemia, subcutaneous and soft tissue collections of leukemic blasts, called chloromas, are not uncommon. Leukemic cells invading the CNS can be clinically silent or can produce a meningitic syndrome or spinal cord compression. Extreme leukocytosis can also cause CNS symptoms. A high WBC count, CNS disease, and the presence of a mediastinal mass are unfavorable prognostic signs.

Table 100.2 shows the clinical and laboratory presentation of 1637 children with ALL. Although most patients have some hematologic abnormalities, many do not show such profound leukocytosis that a diagnosis of leukemia is certain from the peripheral count. Strikingly abnormal blood counts can also be seen in aplastic anemia, infectious mononucleosis, cytomegalovirus (CMV) infection, pertussis or parapertussis infection, chronic myeloid leukemia, and leukemoid reactions to bacterial or viral infections. Isolated thrombocytopenia is unusual in leukemia and is usually indicative of immune thrombocytopenic purpura (ITP). Anemia, reticulocytopenia, and neutropenia may be seen in transient erythroblastopenia of childhood (TEC). However, the neutropenia is usually mild in TEC and the WBC morphology is normal (see Chapter 87 for a discussion of ITP and TEC).

Clinical		Laboratory	
Characteristic	Percentage	Characteristic	Percentage
Age (yr)		Hemoglobin (g/100 mL)	
< 2	9	< 7	44
2–6	61	7–10	36
7–10	15	> 10	20

WBC, white blood cell.

Table 100.2. Acute Lymphocytic Leukemia: Presentation of 1637 Children from 1972 to 1977, Children's Cancer Study Group

Although an experienced hematologist can usually differentiate blasts from atypical mononuclear cells on the peripheral smear, the diagnosis of leukemia is made by marrow aspiration or biopsy. The leukemic marrow is hypercellular and contains a monotonous population of blasts. Normal precursors are rare or absent. Performing the marrow examination in an ED is not advisable because diagnosis and current management of acute leukemia require karyotyping, immunophenotyping of surface markers, and special histochemical stains; these studies need to be arranged by the physician who will assume responsibility for the management of the patient.

Management

In many instances, confirmation of the diagnosis of leukemia is not made in the ED. However, when leukemia is the probable diagnosis or the only tenable diagnosis (e.g., WBC count of 100,000/mm ^{3} with a predominance of blasts), the emergency physician or pediatrician should discuss the possibility that a child's disease is leukemia. This practice is accepted provided the physician has laboratory evidence to support the diagnosis, can take time to explain the reasons for concern, and can reassure the family that leukemia is no longer an untreatable disease. After the physician has begun appropriate supportive care, he or she should arrange admission to the hospital or referral of the child to a pediatric oncologist. Referral to a pediatric oncologist is important because survival is generally better when a child is treated at a pediatric cancer center or is managed by a specialist according to a current protocol.

Specific treatment of leukemia with chemotherapy should not be undertaken in the ED. Immediate antileukemic therapy in a child with a large tumor burden can precipitate massive tumor lysis, hyperkalemia, hypocalcemia, renal failure, and possibly death (see the following section on metabolic complications). Definitive therapy requires medical and emotional support and use of chemotherapeutic protocols designed for specific subsets of leukemia. The goals of therapy are to achieve a marrow “remission” (i.e., a normal bone marrow within 1 or 2 months of intensive “induction” therapy) and then to maintain the remission. Induction is followed by a period of prevention or treatment of occult CNS disease and then maintenance therapy. Treatment is changed if the disease recurs in the marrow or appears in the CNS or testes. Treatment is stopped after months or years of continuous remission.

Table 100.3 outlines the initial care of patients with acute leukemia. Fortunately, most patients require only general supportive care. However, some patients require immediate intervention for specific life-threatening problems. All

patients and their families require emotional support and sensitivity to deal with the fear and disorientation they feel when confronted with the diagnosis of cancer.

Table 100.3. Emergency Department Care of the Patient with Probable or Certain Acute Leukemia

Hematologic Complications

The emergency physician should take special care to inform the blood bank that a patient may have acute leukemia. Current blood bank practices for the patient with acute leukemia include 1) initial complete red blood cell (RBC) antigen typing to facilitate future crossmatches if the patient develops anti-RBC antibodies; 2) the use of CMV-negative products for potential bone marrow transplant patients, all patients with myeloid leukemia, and CMV-seronegative patients with lymphoblastic leukemia; 3) the use of in-line leukocyte-depletion filters in many types of acute leukemia; and 4) irradiation to 1500 cGy or greater of all blood products used in oncology patients. Some or all of these practices are followed in major pediatric oncology centers, but transfusion of an acutely ill patient should not be delayed to follow these recommendations.

Anemia. At the time of diagnosis, most children with leukemia are anemic. If the hemoglobin is less than 8 g/dL, administration of packed blood cells is advisable (Table 100.3) because the child is unlikely to have the ability to produce erythrocytes for several weeks; however, if the child is not having symptoms or showing signs of severe anemia, transfusion does not need to take place in the ED. If, in the absence of hemorrhage, the child has profound anemia (i.e., hemoglobin, 1 to 4 g/dL), transfusions at the usual rate can precipitate heart failure. Blood should be replaced slowly, at 3 to 5 mL/kg over 4 hours, and supplemental oxygen should be given to enhance oxygen delivery to tissues. Furosemide (1 mg/kg) can help avoid fluid overload or heart failure; however, if the WBC count is greater than 100,000/mm ^{3}, diuretics should be withheld because intravascular dehydration encourages sludging and thrombosis. Exchange transfusion has been advocated by some physicians in these exceptional circumstances. When hemorrhage is the cause of a low hemoglobin, transfusion therapy should be carried out quickly to replace losses.

Hemorrhage. Hemorrhage is the second most common cause of death in leukemia. Spontaneous bleeding can occur at platelet counts less than 10,000 to 20,000/mm^3, although spontaneous bruising is seen at higher levels in some patients. Other factors contributing to a bleeding tendency include 1) infection with associated disseminated intravascular coagulation (DIC); 2) consumptive coagulopathy in acute promyelocytic leukemia, monoblastic leukemia, and T-cell ALL; 3) antibiotic therapy, which causes hypoprothrombinemia; and 4) aspirin, which interferes with platelet function.

In most newly diagnosed leukemic children, bleeding problems can be controlled with local measures alone (i.e., pressure and topical thrombin for epistaxis), or in conjunction with platelet transfusions (0.2 unit/kg platelets). Epistaxis is sometimes a serious problem that may last for hours and may fail to respond to pressure. If local measures (see pp. 1177–1178 and Chapter 23) and platelets fail, packing is a necessary but uncomfortable therapy. Sedation and analgesia may be helpful in controlling the anxiety associated with severe bleeding.

In some patients with AML, especially those with hypergranular promyelocytic leukemia and some with monoblastic leukemia, a bleeding diathesis may occur at presentation or upon initiation of therapy. Bleeding is generally refractory to platelet transfusion. Patients show prolonged prothrombin and partial thromboplastin times, elevated fibrin split products, and drastically shortened fibrinogen half-life. The most common form of bleeding in this situation is in the CNS; it may be fatal in the first few days of illness. Fresh-frozen plasma (10 mL/kg) and cryoprecipitate can help maintain levels of fibrinogen and clotting factors. Platelet transfusions (0.2 unit/kg) are given to correct thrombocytopenia. Although no controlled study has been conducted to demonstrate the benefit of prophylactic heparin, heparinization (loading dose, 50 units/kg; then 5 to 10 units/kg per hour to maintain the partial thromboplastin time at approximately 1.5 times normal) is often given to patients who show no improvement with aggressive blood product support.

Extreme Leukocytosis. Extreme leukocytosis with a WBC count of greater than 200,000/mm^3 occurs at diagnosis in about 5% of patients with acute leukemia and in those with chronic myelogenous leukemia (CML). In acute leukemia, extreme leukocytosis predisposes patients to early bleeding and thrombosis in the CNS. It has been suggested that patients with WBC counts greater than 200,000/mm^3 should receive prompt cranial irradiation or leukocytopheresis, but these therapies are unproven. Patients with CML may also have the problem of sludging and thrombosis seen in AML when they have a predominance of blasts or when their WBC counts are greater than 200,000/mm ^{3}. Hydration and alkalinization often result in a substantially lower WBC count (Table 100.3).

Leukopenia. *Leukopenia* is defined as a WBC count of less than 3000/mm^3 and *neutropenia,* in children, as less than 500 neutrophils/mm^3. Leukopenia per se is not life-threatening, but it can predispose patients to life-threatening

infections (see the following).

Infectious Complications

Infection remains the leading cause of death in acute leukemia. The patient with acute leukemia has quantitative and qualitative cellular immune dysfunction. Leukopenia and neutropenia are common at diagnosis. Even if the absolute neutrophil count is more than 500/mm^3, as may be the case in a patient with a WBC count of 50,000/mm^3 and 1% neutrophils, defective chemoattraction and killing have been documented in patients with acute leukemia. Therefore, any patient with newly diagnosed leukemia, especially those with AML, should be considered at increased risk for infection. In the ED, handwashing by staff, strict asepsis for drawing blood and performing other procedures, and protection of the patient from airborne infections (e.g., measles and varicella) must be enforced.

Although fever is a symptom of leukemia in 25% of patients, more often it indicates infection. In the leukemic patient, significant fever is defined by three temperature elevations of 38.0°C (100.4°F) or higher over 4 hours or a single temperature higher than 38.4°C (101.1°F). There are exceptions to the association between fever and infection. A leukemic patient in septic shock may have no fever or may be hypothermic.

Management of fever begins with a thorough physical examination to search for localizing signs of infection. Even an apparently minor swelling or a tear in the skin or a mucosal surface can be a source of disseminated infection. Blood and urine cultures should be obtained. All leukemic patients should have baseline chest radiograph films taken. Thereafter, chest radiograph is needed only if the child has respiratory symptoms or signs. Bacterial meningitis is rare in leukemia, but if symptoms of meningitis are found, spinal fluid should be sent for bacterial, fungal, and viral culture and for cytology to rule out CNS leukemia.

After the appropriate cultures are obtained, intravenous broad-spectrum antibiotics should be started in a patient with leukemia and fever. The choice of antibiotic combinations is reviewed in Figure 100.7. Most patients do not have invasive fungal disease. However, oral candidiasis sometimes occurs in a patient who has been treated with antibiotics before the diagnosis of leukemia. Thrush should be treated with oral Mycostatin, fluconazole, or clotrimazole troches.

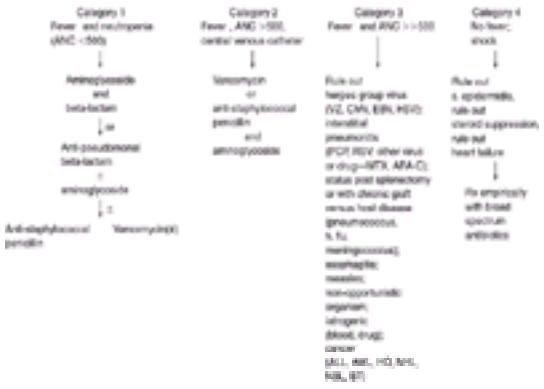

FIGURE 100.7. Initial management of the child with cancer and presumed infection. *ANC,* absolute neutrophil count; *VZ,* varicella-zoster; *CMV,* cytomegalovirus; *EBV,* Epstein-Barr virus; *HSV,* herpes simplex virus; *PCP, Pneumocystis carinii* pneumonia; *RSV,* respiratory syncytial virus; *MTX,* methotrexate;*ARA-C,* cytarabine; *ALL,* acute lymphoblastic leukemia; *AML,* acute myelogenous leukemia; *HD,* Hodgkin's disease; *NHL,* non-Hodgkin's lymphoma;*NBL,* neuroblastoma; *BT,* brain tumor. [a]Fever: temperature 38°C × 3 or >38.4°C × 1. [b]Use of vancomycin or anti-staphylococcal penicillin varies according to prevalence and resistance patterns of institutional Gram-positive bacteria. NB: Aminoglycoside alone is not adequate Gram-negative coverage in the neutropenic patient.

Infection can cause septic shock in a patient with leukemia. Treatment consists of aggressive measures to maintain intravascular volume and blood pressure (see Chapter 3) and broad-spectrum antibiotics. Because the patient with leukemia is commonly anemic at diagnosis, bolus infusions of packed RBCs can be useful when treating shock.

Metabolic Complications

Uric Acid Nephropathy. Some patients with acute leukemia have an elevated serum uric acid caused by spontaneous breakdown of leukemic cells. The excess uric acid precipitates in the renal tubules. Antileukemic therapy accelerates breakdown of leukemic cells; more urates are formed and renal failure can occur. To prevent urate nephropathy, all children with leukemia should receive the xanthine oxidase inhibitor allopurinol (150 mg/d orally in three daily doses for those 6 years old or younger; 300 mg/d orally in three daily doses for those older than 6 years) for at least 24 hours before starting therapy. Hydration at the rate of twice maintenance and alkalinization of urine to pH between 6.5 and 7.5 with sodium bicarbonate (40 mEq/L) facilitates dissolution of uric acid crystals. Once the serum uric acid level is normal and the child is adequately hydrated and producing a dilute urine, specific antileukemic therapy may begin. Bicarbonate is stopped at this time to avoid development of hypoxanthine nephropathy.

Hypercalcemia. Hypercalcemia occurs in about 2% of patients with acute leukemia. Hypercalcemia is caused by destruction of bone by malignant cells, by ectopic production of parathormone by the leukemic cells themselves, or by elevated levels of peripheral plasma prostaglandin E_2, vitamin D–like substances, or osteoclast-activating factors. The serum calcium can reach levels high enough to cause anorexia, nausea, vomiting, constipation, lethargy, confusion, coma, tachycardia or bradycardia, and renal failure. The ultimate therapy of leukemic hypercalcemia is treatment of the leukemia. Interim supportive management consists of hydration with normal saline (200 mL/m^2 per hour), followed by diuresis with furosemide (1 to 2 mg/kg intravenously every 4 to 6 hours). Monitoring of the cardiovascular status is

essential. For indications for corticosteroids, calcitonin, gallium nitrate, or dialysis in symptomatic hypercalcemia (usually greater than 12 to 15 mg/dL), see Chapter 86. Phosphorus has no role in the emergency treatment of the patient who has leukemia and an acute elevation of serum calcium. Malignant hypercalcemia may require management in an intensive care setting.

Tumor Lysis Syndrome. In a patient with a large tumor burden, especially patients with leukemia and massive organomegaly or with high WBC counts, or in patients with non-Hodgkin's lymphoma, antineoplastic therapy can cause a potentially fatal tumor lysis syndrome that consists of a rapid rise in serum potassium and phosphorus, a precipitous fall in serum calcium, and elevations of the serum uric acid, blood urea nitrogen (BUN), and creatinine. These abnormalities may occur despite appropriate hydration and allopurinol therapy. Hyperkalemia, the most dangerous abnormality, demands prompt treatment with Kayexalate, insulin and glucose infusion, or dialysis (see Chapter 86).

Other Complications

Spinal Cord Compression. Spinal cord compression occurs in leukemia because of epidural or subarachnoid collections of leukemic cells. Symptoms include radicular pain, back pain, difficulty with urination, paresis, and paralysis. Physical examination can be unremarkable or may show percussion tenderness over spinous processes, weakness, hyperactive (or later, absent) deep tendon reflexes, absent superficial reflexes, inability to walk on the toes or heels, and a sensory level. Radiographs may show a collapsed vertebral body, but they are often normal. Magnetic resonance imaging (MRI) with and without gadolinium confirms the diagnosis; therapy consists of immediate corticosteroid administration (dexamethasone 0.25 to 0.5 mg/kg every 6 hours), prompt irradiation, or both. Leukemia and lymphoma of the spinal cord respond to steroids or radiation therapy and do not require laminectomy.

Central Nervous System Leukemia. Leukemia can present or relapse in the CNS as diffuse subarachnoid disease or as localized deposits of cells. Symptoms include headache, stiff neck, malaise, cranial nerve palsy, and rarely, fever. Diagnosis is made by finding greater than 5 leukemic blasts/mm^3 in the spinal fluid. Spinal fluid should be examined by cytospin preparation. Treatment consists of intrathecal chemotherapy and craniospinal irradiation, as well as reinstitution of systemic chemotherapy in the case of CNS relapse.

Testicular Leukemia. Clinically apparent testicular disease is rarely present at diagnosis, but the first site of relapse may be the testes. A painless, hard swelling is seen in one or both testes. Treatment consists of reinduction therapy and irradiation. Testicular relapse may be a harbinger of marrow relapse.

Non-Hodgkin's Lymphomas

Background

Definition

Non-Hodgkin's lymphomas (NHL) are malignant tumors that originate in lymphatic tissues: lymph nodes, Waldeyer's ring, the appendix, mesentery, Peyer's patches, or rarely, the spleen. Sometimes NHL arises in extralymphatic sites such as bone, ovaries, or the nervous system. In contrast to NHL in adults, which often remains indolent and localized for years, NHL in children has a tendency to proliferate rapidly and spread outside the primary lymphatic area in weeks or months. Often, it metastasizes to bone marrow, the CNS, or both. When extensive marrow replacement occurs, the distinction between NHL and acute leukemia is difficult.

Classification

No disease classification is more controversial than that of NHL. The NHLs are classified according to histology, cytology, and immunology. The types of lymphoma seen in children are almost always poorly differentiated and diffuse (as opposed to the nodular NHL common in adults), and they efface entirely the architecture of the tissue of origin. In children, the malignant cells are often B lymphoblasts or T lymphoblasts (lymphoblastic NHL), undifferentiated stem cells, Burkitt-type B-cells, or histiocytelike cells (nonlymphoblastic NHL). NHLs are also classified according to stage. Stage reflects the tumor burden and extent of spread. A small tumor burden that is confined to the tissue or region of origin usually confers an excellent prognosis. However, most pediatric NHL is widely disseminated.

Epidemiology

NHL usually occurs before puberty or in early adolescence. The incidence in childhood is 0.5 per 100,000. There is a male predominance of 1.4:1. Patients with immunodeficiency diseases have an exceptionally high incidence of NHL. The inherited immunodeficiency states associated with NHL include severe combined immunodeficiency, variable immunodeficiency, X-linked hypogammaglobulinemia, IgA deficiency, IgM deficiency, X-linked lymphoproliferative syndrome (Duncan's disease), ataxia telangiectasia, and Wiskott-Aldrich syndrome. In addition, NHL occurs with increased frequency in patients with acquired disorders of immunity, including rheumatoid arthritis, systemic lupus erythematosus, sarcoidosis, celiac disease, and acquired immune deficiency syndrome (AIDS). NHL develops with increased frequency in renal and cardiac transplant patients, in patients receiving long-term immunosuppressive therapy, and in patients with Hodgkin's disease treated with radiation and chemotherapy.

Clinical Manifestations and Pathophysiology

Localized NHL

About 25% of childhood NHL presents as localized disease. Presentations include swelling in the cervical or inguinal nodes, nasopharyngeal masses, mediastinal masses, and bone pain and swelling. Primary disease in the abdomen may

be confused with acute appendicitis or intussusception. Gastrointestinal (GI) hemorrhage can result from tumor infiltration of the bowel and may be the presenting symptom.

B-Lymphocyte NHL (American Burkitt's Lymphoma)

American Burkitt's lymphoma usually causes generalized abdominal enlargement, pain, nausea, vomiting, constipation, and in about half of patients, malignant ascites. In these circumstances, the primary tumor is either in the ovaries or retroperitoneal nodes, but kidneys and sometimes bowel are involved. Jaw tumors occur in only 20% of American cases and cervical node primary tumors in about 15%.

Burkitt tumor cells proliferate exceedingly rapidly. Tumors grow quickly and tend to extend locally over several days to weeks, causing ascites, pleural effusion, and renal failure. They often metastasize to the marrow and meninges. Untreated, American Burkitt's lymphoma is rapidly fatal, usually because of renal failure.

Mediastinal NHL

Mediastinal NHL occurs most often in males in late childhood or early adolescence and, untreated, metastasizes to marrow, nervous system, and testes. The symptoms and signs of mediastinal NHL may be those of leukemia or other thoracic tumors. Mediastinal NHL sometimes causes life-threatening superior vena cava (SVC) syndrome or tracheal compression (see the following section about thoracic tumors).

Management

Localized NHL

When localized NHL is suspected, the node or mass should be biopsied promptly and ideally at an institution that has the facilities to provide phenotyping and the necessary genetic studies on the malignant cells. Open biopsy is mandatory to evaluate node architecture. Before biopsy, it is advisable to obtain a chest radiograph and blood count to ensure that no large mediastinal mass or unsuspected leukemic process is present. When localized NHL is treated with surgery and chemotherapy, with or without irradiation, the prognosis is excellent. Complete surgical resection should not be attempted when extensive disease is present.

Burkitt's Lymphoma with Extensive Abdominal Involvement

When the primary tumor is abdominal, the disease usually constitutes a medical emergency because the tumor grows day by day and rapidly encroaches on vital organs, especially the kidneys. Spontaneous tumor lysis causes metabolic abnormalities, discussed in the previous section about tumor lysis syndrome.

The role of the emergency physician who suspects intra-abdominal Burkitt's lymphoma is to ascertain the hematologic and metabolic status of the child with the following studies: CBC, BUN, creatinine, uric acid, electrolytes, calcium, phosphorus, and liver function tests. Hydration (3000 mL/m^2 per day of D5W/0.25 NS), alkalinization, and allopurinol (150 mg/d orally in three daily doses for those 6 years old or younger; 300 mg/d orally in three daily doses for those older than 6 years) should be started immediately. If renal failure is present, determining whether it is from uric acid nephropathy, tumor infiltration, or obstructive uropathy is necessary. An ultrasound examination can detect infiltration or compression by tumor. Catheterization may be necessary to establish whether the kidneys are forming urine and to rule out bladder obstruction. Treatment of renal failure and secondary hypertension varies with the cause (see Chapter 88). Antineoplastic therapy should be directed by a pediatric oncologist.

Mediastinal Lymphoma

When the chest radiograph reveals a mediastinal mass and no obvious congenital abnormality or infectious cause is apparent, cancer must be ruled out. Sometimes it is possible to diagnose NHL by the combination of an abnormal blood count or bone marrow examination and a mediastinal mass. Other times, biopsy of a peripheral node or the mass itself is necessary. Often, open biopsy is a straightforward procedure, but it can be life-threatening. For a discussion of mediastinal masses, see the following section about thoracic tumors. Mediastinal NHL is responsive to combinations of chemotherapy and irradiation and most patients are now long-term survivors.

Hodgkin's Disease

Background

Definition

Like NHL, Hodgkin's disease is a malignancy of the lymphatic tissues. It usually begins in a cervical node and spreads in a predictable and orderly sequence from one lymph node region to the next; untreated, it progresses to involve organs outside the lymph nodes. In contrast to NHL, spread to the marrow or CNS is rare. The malignant cell in Hodgkin's disease is the Reed-Sternberg cell, which is believed to originate from either a B lymphocyte or a histiocyte precursor.

Classification

Hodgkin's disease is classified according to the extent of disease at presentation, the stage, and the histology of the involved lymph node. Unlike most other malignancies, Hodgkin's disease is multicellular (i.e., more than one cell type is present, and the interaction of these cells comprises the malignant process). The accepted histologic classification is a modification of the Rye, New York, classification based on the number of lymphocytes, the number of “reactive” cells, the

number of Reed-Sternberg cells, and the amount of fibrosis. The four histologic types are 1) lymphocyte predominant, 2) nodular sclerosing, 3) mixed cellularity, and 4) lymphocytic depletion. Two-thirds of pediatric patients have the nodular sclerosing type.

Epidemiology

The incidence of Hodgkin's disease is similar to that of NHL, 0.6 per 100,000 per year. Although Hodgkin's disease has been reported in infants, it is rare in children less than 5 years of age; there is one peak in adolescence and a later peak in the sixth decade. In the United States, Hodgkin's disease tends to occur more often in the higher socioeconomic classes. The cause is unknown.

Clinical Presentation and Pathophysiology

Hodgkin's disease most often presents as a mass in the neck; about 4% of patients have masses in the groin. The mass may have been present for days, months, or years. Some patients complain of adenopathy localized to a few lymph node regions; others note generalized adenopathy. Anterior mediastinal masses occur in 50% of patients. Hodgkin's disease rarely occurs in Peyer's patches, Waldeyer's ring, or epitrochlear nodes. Large mediastinal Hodgkin's tumors can cause the same cardiovascular or respiratory symptoms as mediastinal NHL (see the following section about thoracic tumors). Most Hodgkin's disease patients are well, but 30% have fever, involuntary weight loss, or both. At diagnosis, the fever may be low or high grade. The Pel-Epstein fever, a high, debilitating fever followed by a drenching sweat, is usually a sign of advanced disease. Incapacitating pruritus, seen in about 15% of adults, is uncommon in children.

Patients with Hodgkin's disease manifest defects of cellular immunity early in the course of their disease. B-lymphocyte function remains relatively intact, but almost all patients have impaired T cell–mediated immunity that results in increased susceptibility to fungal, viral, and certain bacterial infections. Complete anergy to recall antigens does not usually occur until the disease is advanced.

Hodgkin's disease is classified by stage according to the extent of disease and the presence of symptoms: stage I, one lymph node region; stage II, two lymph node regions on the same side of the diaphragm; stage III, lymph node involvement (including spleen) on both sides of the diaphragm; stage IV, lymph node disease plus lung, liver, marrow, or bone involvement. “A” patients have no symptoms; “B” patients have fever and weight loss. The clinical stage is that which is determined by physical examination and radiograph studies, including lymphangiogram, retroperitoneal computed tomography (CT) scan, or both. The pathologic stage refers to the stage as determined by laparotomy with splenectomy and surgical sampling of abdominal lymph nodes, liver, and bone marrow.

Management

The first step in treating Hodgkin's disease is to obtain a tissue biopsy using the same guidelines and precautions as for NHL. The second step is to determine the stage of the disease by either clinical or pathologic staging. In the past, most patients with Hodgkin's disease underwent pathologic staging, including splenectomy. Those with stages IA to IIIA were treated with large fields of irradiation, and those with more advanced disease were treated with chemotherapy combinations (MOPP: nitrogen mustard, vincristine (oncavin), prednisone, and procarbazine; AVBD: adriamycin, vinblastine, bleomycin, and 5-(3, 3-dimethyltriazeno)imidazole-4-carboxamide [DTIC]; or other combinations). With the advance of these therapies, most Hodgkin's disease patients can be cured. However, splenectomy carries a high risk of hyperacute pneumococcal infection in children with Hodgkin's disease. Furthermore, irradiation causes major growth disturbances in children less than 18 years old and some risk of secondary sarcomas 10 to 20 years after treatment. On the other hand, chemotherapy and large-field irradiation predispose to the development of leukemia and NHL in about 5% of patients. Awareness of these complications is leading many pediatric oncologists to investigate staging without laparotomy and to use different combinations of chemotherapy and lower dosages and smaller fields of irradiation.

The issues regarding biopsy and SVC syndrome in patients with Hodgkin's disease are presented in the following section on thoracic tumors. Infections and other special problems seen during therapy for Hodgkin's disease are discussed in the following section about complications of therapy and progressive disease.

Histiocytic Diseases

Background

Histiocytic diseases include a heterogeneous group of benign and malignant disorders. With some of these diseases, determining whether the histiocytes are benign or malignant is difficult because they may appear histologically benign and yet metastasize; conversely, they can appear histologically malignant and behave with relative benignity.

Clinical Manifestations and Pathophysiology

Histiocytic diseases are best classified according to their disease functions into lipid storage diseases, reactive diseases, and neoplastic diseases. Among the reactive disorders are those diseases formerly called histiocytosis X and hemophagocytic lymphohistiocytosis. Some reactive disorders tend to behave in a malignant fashion. Among the neoplastic group, acute monocytic leukemia and malignant histiocytosis are seen in children and adolescents. Three of the disorders, which behave in a malignant fashion regardless of cause or disease function, are discussed: 1) the spectrum of eosinophilic granulomas, 2) familial and nonfamilial hemophagocytic lymphohistiocytosis, and 3) malignant histiocytosis. Monocytic leukemia is considered a form of AML (see previous section about leukemia).

Eosinophilic Granuloma Syndromes

A solitary eosinophilic granuloma presents as a painless or mildly painful swelling in the skull, long bones, ribs, pelvis, or vertebra. Radiograph films show a lytic lesion with well-defined borders. Multiple eosinophilic granulomas can arise over weeks, months, or years. They can be confined to the long bones or may be distributed in the skull in a manner that causes proptosis, diabetes insipidus, cholesteatomas, and loss of teeth (Hand-Schüller-Christian disease). Rare cases of paraplegia caused by vertebral lesions have been described.

Widespread eosinophilic granulomas of bone and soft tissue in an infant constitute Letterer-Siwe disease. Symptoms and signs include failure to thrive, diarrhea, chronic seborrhea, chronic otitis media and otorrhea, purpuric rash, generalized adenopathy, and hepatosplenomegaly. The chest radiograph may show interstitial pneumonitis. The blood count may be normal, but marrow involvement or massive splenomegaly can lead to pancytopenia.

Familial and Nonfamilial Erythrophagocytic (Hemophagocytic) Lymphohistiocytosis

Familial erythrophagocytic lymphohistiocytosis is an autosomal-recessive systemic disease presenting in early infancy with fever, vomiting, anorexia, irritability, and occasionally (25%) with seizures, cranial nerve abnormalities, and aseptic meningitis. Nonfamilial forms have been reported, and some cases have followed infection with Epstein-Barr virus (EBV) or similar viruses. Generalized adenopathy and hepatosplenomegaly are common, and a purpuric rash sometimes occurs. Laboratory abnormalities include hypofibrinogenemia, hypertriglyceridemia, elevated liver enzymes, and hypogammaglobulinemia or hypergammaglobulinemia. Biopsy of involved tissues or bone marrow aspiration in advanced disease shows diffuse infiltration by morphologically benign histiocytes and prominent erythrophagocytosis. Thymic and lymphoid tissue is depleted.

Malignant Histiocytosis (Histiocytic Medullary Reticulosis)

Malignant histiocytosis presents with fever, adenopathy, hepatosplenomegaly, pancytopenia, or leukocytosis. The mean age at presentation is 31 years but the age range is from 1 to 71 years. Biopsy of involved tissues reveals infiltration with malignant histiocytes of all stages of maturation. Infiltrates are prominent in the medullary zone of lymph nodes.

Management

The role of the emergency physician in the management of the histiocytic disorders is to suspect them, recognize their presentations, refer those patients who require chemotherapy or irradiation, and handle the complications of the diseases and therapy. Eosinophilic granulomas can cause diabetes insipidus (see Chapter 86 and Chapter 97), pathologic fracture, or rarely, paraplegia. Letterer-Siwe disease can be suspected from the clinical findings but must be differentiated from severe combined immunodeficiency. The complications of pancytopenia are the same as in leukemia. Massive organomegaly can cause respiratory embarrassment. Irradiation and chemotherapy usually restore adequate ventilation.

Specific therapy depends on the extent of the disease. Isolated eosinophilic granulomas are cured with surgical curettage. If the lesion is inaccessible and in a critical area (e.g., pituitary fossa), low-dose irradiation can be used. The disease often arrests spontaneously with prolonged observation. Disseminated histiocytosis requires multiagent chemotherapy under the direction of a pediatric oncologist.

Familial and nonfamilial erythrophagocytic lymphohistiocytosis and malignant histiocytosis are usually fatal, but remissions have been achieved using multiagent chemotherapy and bone marrow transplantation. Plasmapheresis and immunotherapy have been used to achieve remission in several patients with erythrophagocytic lymphohistiocytosis. The major complications are marrow failure that predispose the patient to infection and hemorrhage and respiratory failure as a result of massive hepatosplenomegaly and ascites.

Thoracic Tumors

Anterior Mediastinum

Hodgkin's disease and NHL are the most common malignant tumors of the anterior mediastinum. Other tumors include thymoma, thymic cyst, thymic hyperplasia, teratoma, ectopic thyroid, thyroid carcinoma, sarcomas, neuroblastoma (rarely), lymphangiomas, and inflammatory processes such as sarcoid. Half of anterior mediastinal masses are benign. However, almost all large tumors and masses that cause compromise to the great vessels or cause pleural effusions are malignant.

Large tumors in the anterior mediastinum can cause tracheal narrowing, SVC syndrome, or both. Tracheal compression causes tracheal deviation, stridor, cough, dyspnea, and orthopnea. Compression of the vena cava by tumor may cause headache, dyspnea, orthopnea, syncope, or cardiovascular collapse. Physical examination may be unremarkable or may show venous distension, plethora, cyanosis, and edema anatomically confined to the head, neck, thorax, and arms. When the arm is involved, the veins will remain full when the arm is raised. Conjunctival and retinal vessels may be engorged. Children with SVC syndrome are often anxious and diaphoretic and will resist efforts to place them in a supine position. When these findings are present, narcotics, sedatives, and any drugs that interfere with venous return are contraindicated. Chest radiograph reveals a mass in the anterior mediastinum (Fig. 100.1). If a tumor is ausing SVC syndrome in a child or adolescent, the diagnosis is almost certain to be NHL or Hodgkin's disease.

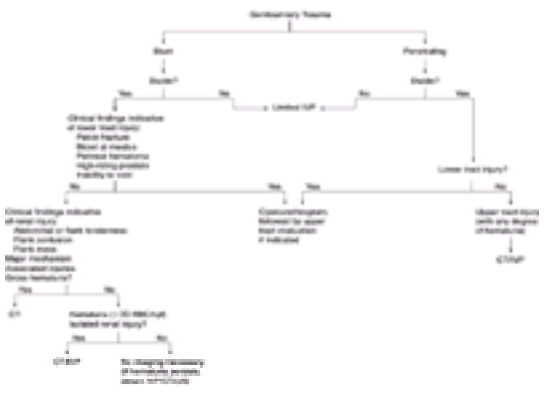

FIGURE 100.1. Management guidelines for children with an anterior mediastinal mass who are at risk for superior vena cava syndrome. (Modified with permission from Kelly KM, Lange B. Oncologic emergencies. Pediatr Clin North Am 1997;44:809–831.)

SVC syndrome is life-threatening. It may be ill-advised to try to obtain a histologic diagnosis under general anesthesia because these patients tolerate procedures poorly. Even placing the patient in the CT scanner can cause cardiorespiratory decompensation. If both arms are involved, intravenous infusions should be started in the feet, provided that venous return is good in the lower extremities. Infusions in an affected arm can cause respiratory distress, thrombosis, or phlebitis. In the unstable patient with SVC syndrome, empiric therapy with radiation (50 to 100 cGy to the midplane for 2 or 3 days), corticosteroids (hydrocortisone 2 mg/kg every 6 hours), or both may alleviate symptoms. Either treatment may make later interpretation of histology difficult; however, studies of tissue obtained a day or two after initiation of emergent treatment have documented that the initial clinical impression of the treating oncologist is usually correct. If the patient can tolerate procedures, effusions should be drained, a bone marrow aspirate should be taken as early as possible (to rule out NHL), and a biopsy should be performed on an accessible peripheral node under local anesthesia.

Middle Mediastinum

Most tumors of the middle mediastinum are benign. Malignant tumors include Hodgkin's disease of the hilar nodes or pericardium, NHL or metastatic tumors such as neuroblastomas (less commonly), and sarcomas (rarely). Many large anterior mediastinal tumors extend into the middle mediastinum. Rarely, these large tumors may cause cardiovascular compromise by compression of the vagus nerve, coronary vessels, or pericardial invasion. Spontaneous syncope or syncope with a Valsalva maneuver are clues to vagal involvement. Similar to the rare patients with SVC syndrome, patients with a history of syncope are poor surgical risks. They require hospitalization and supportive care.

Posterior Mediastinum

Most tumors in the posterior mediastinum are of neurogenic origin: neuroblastoma, neurofibrosarcoma, ganglioneuroblastoma, ganglioneuroma, and neurofibroma (Fig. 100.2). Only the first two tumor types have malignant potential. The more slowly growing tumors are often detected on chest films taken for other purposes. Larger, rapidly growing tumors can cause pain and neurologic deficits.

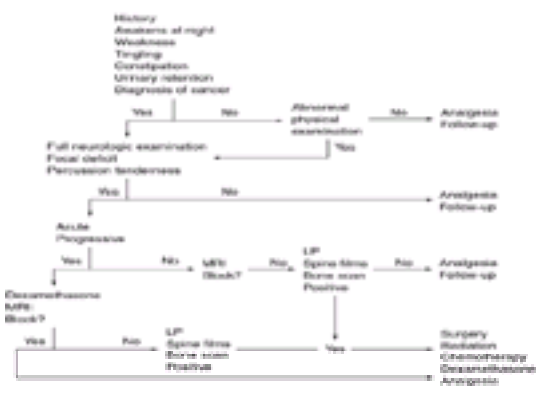

FIGURE 100.2. Approach to back pain in children at risk for spinal cord compression. (Modified with permission from Kelly KM, Lange B. Oncologic emergencies. Pediatr Clin North Am 1997;44:809–831.)

Pulmonary Parenchyma

Nodules (“coin” lesions or “cannonball” lesions) in a child with a solid tumor are usually metastases. In the everely compromised host, they may be fungal legions. Rarely, bacteria such as staphylococci may cause coin lesions; in this case, the patient is usually acutely ill.

Abdominal, Genitourinary, and Retroperitoneal Tumors

Intra-abdominal tumors manifest themselves as discrete masses or as generalized abdominal enlargement. Wilms' tumor and neuroblastoma are the most common intra-abdominal malignant tumors in young children. Wilms' tumor presents as a large flank mass in a well child, and abdominal neuroblastoma, following the newborn period or infancy, as a midline or

flank mass in an ill child. Hepatic tumors are sometimes associated with systemic illness. Pelvic sarcomas, teratomas, neuroblastomas, or lymphomas may first cause neurologic deficits or abdominal pain. (Pelvic sarcomas are discussed in the following section about soft-tissue sarcomas.)

For most of these tumors, staging usually depends on the amount of tumor that has been surgically removed. Stage I tumors are those that have been completely removed. If microscopic or gross residual tumor or spread to regional nodes occurs, the tumors are stage II or stage III. The most advanced stage (IV) is defined by the presence of distant metastases. Each tumor category also has a classification based on histology, which is prognostically important.

Wilms' Tumor

Background

Definition

Wilms' tumor (nephroblastoma), the most common intrarenal malignancy of childhood, is an embryonal neoplasm of mixed tissue structure. About 5% of Wilms' tumors are bilateral.

Classification

The accepted classification of Wilms' tumor is based on extent of disease after surgery and on tumor histology. The grouping system of The National Wilms' Tumor Study Group (NWTS), a multi-institutional cooperative, is as follows: a stage 1 tumor has been resected entirely, stage 2 has microscopic residual, stage 3 has gross residual, stage 4 has metastatic disease, and stage 5 has bilateral tumors. The most favorable histology has a high degree of differentiation of the epithelial elements. Histologically unfavorable tumors are sarcomatous, anaplastic, clear cell, or rhabdoid.

An intrarenal tumor that is clinically similar in presentation to Wilms' tumor but that is morphologically distinct is congenital mesoblastic nephroma. Mesoblastic nephroma occurs in children younger than 1 year of age, is composed primarily of mesenchymally derived cells, and lacks the malignant elements of Wilms' tumor. It is treated by nephrectomy alone.

Epidemiology

Wilms' tumor occurs in 0.78 per 100,000 children less than 15 years of age. In children less than 5 years old, it is the fourth most common malignancy; 65% of children presenting with Wilms' tumor are younger than 5 years of age.

A significant association exists between Wilms' tumor and congenital anomalies, including aniridia, hemihypertrophy, genitourinary anomalies, hemangiomas, hamartomas, cardiac anomalies, and Beckwith-Wiedemann syndrome. There are reports of familial cases of Wilms' tumor, as well as reports of families in which some of the members had the congenital anomalies previously listed and other members had Wilms' tumor.

Clinical Manifestations and Pathophysiology

Most patients with Wilms' tumor have an abdominal mass that is discovered accidentally by the parents while bathing or clothing a child or by a physician during a routine physical examination. The mass is deep in the flank and can be either firm or soft. Abdominal pain, fever, anorexia, malaise, vomiting, and weight loss are rare presenting complaints. Gross hematuria occurs in less than 25% of patients. Some institutions report hypertension in up to 15% of patients. Hypertension is thought to result from increased renin secretion secondary to compression of the renal artery. By a related mechanism, polycythemia occasionally occurs in patients with Wilms' tumor. More often, anemia results from bleeding into the tumor. When performing a physical examination, the physician should be particularly attentive to the size of the liver and spleen, the site and size of the mass, the patient's blood pressure, and the presence of the previously listed congenital anomalies. Laboratory evaluation should include CBC, BUN, and creatinine. Abdominal radiograph (kidney, ureter, bladder [KUB]) may reveal a mass displacing bowel. Intravenous pyelogram (IVP) demonstrates an intrarenal mass distorting the calyces. Ultrasound, when available, is the preferred imaging technique for initial localization of these tumors (Fig. 100.3).

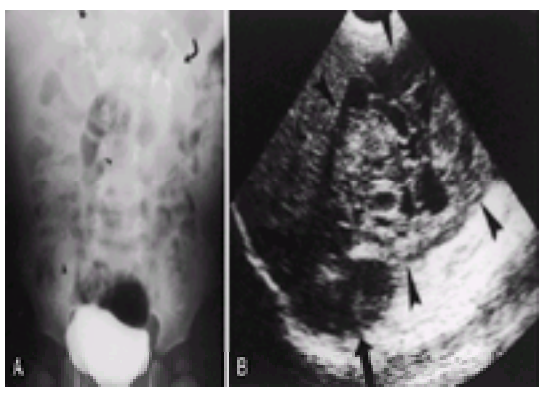

FIGURE 100.3. A. Wilms' tumor. Intravenous pyelogram demonstrates a normal left kidney *(curved arrow).* There is upward displacement and splaying of the right renal collecting system *(arrow)* by a large nonopacified mass *(arrowhead).* **B.** Wilms' tumor. Right parasagittal sonogram shows the liver *(L),* the right upper renal pole *(arrows),* and a large complex mass *(arrowheads)* arising from the midpole of the right kidney. The hypoechoic areas represented necrosis within the tumor. (Courtesy of Dr. Henrietta Kotlus Rosenberg, Director, Division of Ultrasound, Children's Hospital of

Philadelphia.)

Management

Children with a presumed Wilms' tumor should be referred to a surgeon experienced in the diagnosis and treatment of this tumor. Definitive therapy for localized disease with favorable histology consists of complete resection and chemotherapy. Surgery, chemotherapy, and irradiation are used in patients with advanced disease or unfavorable histology. The chemotherapeutic agents with proven efficacy are vincristine, actinomycin D, and doxorubicin.

Wilms' tumor exemplifies the advances made in pediatric oncology with multimodal therapy: disease-free survival of all patients approaches 90%. Even patients with metastatic disease, bilateral tumors, or unfavorable histology can be treated successfully.

Delayed complications from the combined use of radiation and chemotherapy can occur months or years after treatment. They include inflammation and then fibrosis of lung, liver, or kidneys. Postradiation hepatitis is often associated with thrombocytopenia. The complications can be either debilitating or fatal; fortunately, they are rare.

Neuroblastoma

Background

Definition

Neuroblastoma is a malignant tumor that arises from the sympathetic tissue in the adrenal medulla or in the sympathetic chain along the craniospinal axis in the neck, in the posterior mediastinum (see previous section on thoracic tumors), intra-abdominally, or in the pelvis. The tumor is composed of small, round cells with scant neurofibrillar cytoplasm. The cells may form rosettes. Neuroblastoma commonly metastasizes to bone, bone marrow, liver, skin, lymph nodes, and uncommonly to lungs or to the CNS.

Classification

Several staging systems have been in use for neuroblastoma. To provide a uniform nomenclature, the International Committee for Neuroblastoma Staging has proposed a staging system based on extent of disease and the completeness of surgical resection. Recently, factors other than stage have been shown to be important for predicting outcome. These factors include the Shimada-Chatten histology, the child's age, serum ferritin, amplification of the *MYCN* oncogene in tumor tissue, and the DNA content of the tumor cells.

Epidemiology

After CNS tumors, neuroblastoma is the most common solid tumor in childhood. About 50% occur before the age of 2 years and about 80% are found in children less than 5 years old. Neuroblastoma occurs in approximately 1 per 100,000 children less than age 16 each year.

Clinical Manifestations and Pathophysiology

About two-thirds of patients have widespread metastases. Symptoms and signs include irritability, anorexia, weight loss, pallor, and subcutaneous nodules. Adrenal neuroblastoma as well as nonadrenal intra-abdominal tumors can cause an abdominal mass that is palpable on routine physical examination. Involvement of the cervical sympathetic ganglia can cause Horner's syndrome or hoarseness by compressing the recurrent laryngeal nerve. Neuroblastoma arising from the sympathetic ganglia and extending into and out of the intravertebral foramina (“dumbbell tumor”) can cause symptoms and signs of compression of the spinal cord. Skeletal lesions lead to bone pain or pathologic fractures. Periorbital metastases cause proptosis and periorbital ecchymosis (“raccoon eyes”). Patients with black eyes can be mistaken for attered children (Fig. 100.4). Rare presentations include opsoclonus-myoclonus, hypertension, tachycardia, skin flush, and chronic diarrhea from excess catecholamine secretion.

FIGURE 100.4. Neuroblastoma with “black eyes” that may be mistaken for child abuse. (Courtesy of Dr. Audrey Evans, Department of Pediatrics, Children's Hospital of Philadelphia.)

An intriguing characteristic of neuroblastoma is its ability to undergo spontaneous regression or to undergo maturation to more benign lesions, ganglioneuroblastoma, and ganglioneuroma. Whether all ganglioneuromas were once neuroblastoma is unclear, but it is generally agreed that they have the same cellular origin.

Stage 4S (formerly IVS of the Evans classification) encompasses a unique group of patients with metastatic disease: generally well-appearing infants whose primary tumor is small, with metastases limited to liver, skin, and marrow. Most of these patients have spontaneous regression of tumor, even when the tumor burden is massive. Infants with stage 4S appear to have a tumor that is biologically distinct from the tumor of older patients with stage 4 disease metastatic to bone and bone marrow. Patients with stage 4S present in the first few months of life with gross hepatomegaly or skin nodules. The primary tumor may not be obvious. The emergency physician who notes massive hepatomegaly in an infant who otherwise looks healthy should consider stage 4S neuroblastoma in the differential diagnosis.

Management

Evaluation of patients with suspected neuroblastoma should include a CBC, ultrasound, chest radiograph, skeletal survey, bone scan, and bone marrow aspiration and biopsy. Radiographs of painful areas in bones may show symmetric lytic lesions of the metaphyses of the long bones. Cortical destruction is seen in flat bones. Skull films may show increased soft tissue over the involved orbit in a child with proptosis. Abdominal radiographs reveal a retroperitoneal mass displacing normal structures. Adrenal primaries commonly have fine calcifications. Ultrasound can show a suprarenal mass that displaces the kidney down and away from its normal axis. All patients with suspected neuroblastoma should have quantitative evaluation of serum ferritin and urinary catecholamines including homovanillic acid (HVA) and vanillylmandelic acid (VMA). Evaluation requires several days and is most efficiently performed at a pediatric oncology center. The primary tumor is examined for the amount of stroma and number of mitoses, and viable tissue is assayed for amplification of *MYCN*, a cellular oncogene of prognostic importance in this tumor.

Treatment of neuroblastoma is directed toward both the tumor itself and complications of the tumor. The choice of treatment is based on several prognostic factors: age, stage, initial ferritin, histology, and *MYCN* oncogene amplification. Most low-stage tumors are associated with a good prognosis and are treated with surgical excision. Patients with poor-prognosis disease are treated with combined modalities, including bone marrow transplantation. Radiation may be used to reduce tumor bulk and for palliation, especially to treat painful bone lesions. Chemotherapeutic agents used to treat advanced neuroblastoma include vincristine, cyclophosphamide, doxorubicin, DTIC, VP-16, and cisplatin. Even though most poor-prognosis patients initially respond to therapy, many eventually die of recurrent or progressive disease.

Emergency physicians need to recognize special conditions in neuroblastoma.

1. Massive hepatomegaly in a neonate or infant can cause hepatic failure or respiratory embarrassment. These children need to be admitted for supportive care.
2. Dumbbell tumors can cause cord compression. These children need immediate evaluation. The acute onset of paraplegia in a child less than 5 years of age should be considered neuroblastoma unless another cause has been proven. Treatment may consist of chemotherapy, laminectomy, surgical removal, and irradiation.
3. Rarely, airway obstruction can result from large mediastinal tumors.
4. Extensive marrow disease can cause pancytopenia. Children with neuroblastoma and fever and neutropenia need to be managed similarly to children with leukemia.
5. Opsoclonus-myoclonus (dancing eyes, dancing feet) can resemble a toxic drug reaction or neuromuscular disease. This disorder is usually seen in children with limited surgically resectable disease; however, surgery may not cure the neurologic disorder.

Hepatic Tumors

Background

Definition

The two major primary liver tumors in children are hepatoblastoma and hepatocellular carcinoma. iver tumors originate most commonly in the right lobe of the liver. The common sites of metastases are lung and intra-abdominal lymph nodes and viscera. Bone and bone marrow spread is unusual.

Epidemiology

The incidence of primary hepatic tumors in children is 0.2 per 100,000 each year. Hepatoblastoma usually occurs before the age of 3 years. Incidence of hepatocellular carcinoma peaks around 4 years of age and again around 15 years.

A strong association exists among the appearance of cirrhosis, prior hepatitis B virus infection, and the development of hepatocellular carcinoma, although the association in children is not as strong as it is in adults. Metabolic diseases that cause cirrhosis (von Gierke's disease, Niemann-Pick disease, galactosemia, and chronic hereditary tyrosinuria) can progress to hepatic cancer. Patients who have received anabolic steroid therapy are at risk for developing benign hepatic neoplasms, and a few cases of hepatocellular carcinoma after androgen therapy or long-term hyperalimentation have been reported.

Clinical Manifestations and Pathophysiology

The most common presentation of a hepatic tumor is an enlarging abdomen, an abdominal mass, and symptoms and

signs resulting from the mass—anorexia, weight loss, vomiting, pain, fever, diarrhea, and irritability. Jaundice is uncommon, but pallor as a result of chronic disease is seen. Virilization, which may result from production of chorionic gonadotropin, is rare.

Management

The evaluation of patients with suspected liver tumors includes roentgenographic examination of the abdomen, which may show an enlarged liver and occasionally hepatic calcifications; a chest roentgenogram should be taken to look for metastases. CT scan shows lucent areas with increased vascularity after contrast. Initial laboratory tests should include a CBC and liver function tests (although they are often normal) and serum a-fetoprotein. Further evaluation necessitates admission to the hospital.

Tumors of the Female Genitalia

Background

Definition

Tumors of the female genitalia include primary ovarian tumors and vulvar, vaginal, and intrauterine tumors. Most ovarian tumors are cystic and histologically benign. Malignant ovarian tumors are solid, and in children, they are usually derived from the germ cells. Malignant tumors of the vulva are usually sarcomas; vaginal tumors are either sarcoma botryoides in younger girls or adenocarcinomas in adolescents.

Classification

The ovarian tumors seen in children are dysgerminomas, embryonal carcinomas, endodermal sinus tumors, teratomas, choriocarcinomas, and mixed germ-cell tumors. The staging system is based on the extent of tumor spread.

Epidemiology

Malignant ovarian tumors are uncommon, accounting for only about 1% of malignant neoplasms in girls less than 17 years old. Incidence increases with age, with approximately 20% occurring between 0 and 4 years, 30% between 5 and 9, and 50% between 10 and 14. Menarchial hormonal factors may play a role in development of ovarian tumors.

Female offspring of mothers who received diethylstilbestrol (DES) during pregnancy are at risk for developing vaginal adenocarcinoma.

Presentation and Pathophysiology

Ovarian tumors are usually large and may be mistaken for pregnancy. They can cause painful ovarian torsion or an acute abdomen, especially if hemorrhage or rupture of a cyst occurs; right-sided ovarian tumors may mimic acute appendicitis.

Stromal tumors may produce hormones, causing precocious puberty, vaginal bleeding (granulosa cell tumors), or masculinization (arrhenoblastoma). Ovarian tumors spread by direct extension along the adnexal structures to lymph nodes and the peritoneal surface of the bladder, uterus, sigmoid colon, liver, diaphragm, and small intestine. Rarely, these tumors metastasize to lung, liver, and bone. Ascites and pleural effusion are seen with fibroid tumors (Meigs' syndrome); however, fibroids are rare in children and adolescents.

Vaginal sarcomas may present as exophytic masses. Vaginal adenocarcinoma is detected by a routine Papanicolaou smear or by the presence of a mass or bleeding.

Management

Girls with suspected genital neoplasms need a thorough physical examination, including careful inspection of the external genitalia, bimanual pelvic examination, and evaluation of pubertal status. This evaluation should be performed by a physician experienced in pediatric and adolescent gynecology. Abdominal radiograph may reveal displacement of bowel, calcifications, teeth or other aberrant tissue structures, and ascites, but abdominal and pelvic ultrasound is the preferred imaging technique. A chest radiograph should be taken to look for metastatic disease. Laboratory examinations for ovarian tumors should include measurement of a-fetoprotein, which is produced by embryonal carcinoma and endodermal sinus tumor, and human chorionic gonadotropin, produced by embryonal carcinoma and choriocarcinoma.

Tumors of the Male Genitalia

Background

Tumors of the male genitalia include testicular, paratesticular, and prostatic tumors. Germ-cell tumors comprise about 75% of the primary testicular tumors. Leukemia can metastasize to the testes. Paratesticular and prostatic tumors are usually rhabdomyosarcomas.

A relatively high incidence of germ-cell testicular tumors occurs in infancy. The incidence decreases after age 4 years and begins to rise again in puberty, with a continued increase into early adulthood. A cryptorchid testis has a 30 to 50 times greater risk of developing a neoplasm; 10 to 20% of all testicular cancers arise from a cryptorchid testis. Sarcomas of the male genitalia occur mostly between the ages of 2 and 10 years.

Clinical Manifestations

Most testicular tumors present as slowly growing scrotal masses. Occasionally, a patient may have pain. About 25% of the patients have either an associated hydrocele or an inguinal hernia. Testicular and paratesticular tumors most commonly metastasize to lungs or spread to regional lymph nodes.

Management

Patients with solid testicular or paratesticular masses should be referred to a urologic surgeon with experience in removing pediatric neoplasms. For germ-cell tumors, treatment usually consists of orchiectomy with high ligation of the spermatic cord. Sarcomas require chemotherapy and irradiation in addition to surgery.

Tumors of the Head, Neck, and Extremities

Tumors of the head, neck, and extremities include those that present as masses in the brain (brain tumors) or near the brain (parameningeal tumors), in the eye (retinoblastoma), and in the neck or extremities. Most malignant tumors of the nasopharynx, middle ear, or behind the eye are rhabdomyosarcomas. In the neck, lymphomas are most common; sarcomas, neuroblastomas, thyroid carcinomas, and metastatic tumors also occur. Soft-tissue sarcomas and bone sarcomas are the most common malignant tumors of the extremities.

Retinoblastoma

Background

Retinoblastoma is the most common primary intraocular malignancy in children. Retinoblastoma arises from the nuclear layer of the retina and is of neurologic origin. Most cases of retinoblastoma are cured by enucleation. Retinoblastoma occasionally metastasizes hematogenously to bone marrow, bones, lymph nodes, and liver. It can also spread by direct extension via the optic nerve to the meninges and into the spinal fluid. The staging system for retinoblastoma is based on size, number, and location of lesions in the retina and vitreous.

Retinoblastoma occurs in 1 in 23,000 births. Most patients are diagnosed by 2 years of age. Two patterns of retinoblastoma occur: 1) a hereditary form that is autosomal dominant with about 90% penetrance, and 2) a sporadic form. Approximately 35 to 45% of retinoblastomas are hereditary. Bilateral cases are almost always hereditary. Patients with retinoblastoma are at risk for developing osteosarcoma or pineal tumors (i.e., trilateral retinoblastoma) later in life.

Clinical Manifestations

Two-thirds of children with retinoblastoma have a white pupil (leukocoria or “cat's eye”), often detected by the parents (Fig. 100.5). The white pupil is actually the tumor itself, as seen through the vitreous. Other symptoms and signs include strabismus (see Chapter 25); a unilateral, fixed, and dilated pupil (see Chapter 26); decreased visual acuity; a red, painful eye (see Chapter 24) caused by glaucoma; spontaneous hyphema; proptosis; and heterochromia iridis. In families with known hereditary forms of retinoblastoma, most tumors are detected while they are asymptomatic because of careful and frequent ophthalmologic examinations.

FIGURE 100.5. Leukocoria in a child with retinoblastoma of the left eye. (Courtesy of Dr. Anna Meadows, Department of Pediatrics, Children's Hospital of Philadelphia.)

Management

All children who present with a white pupil or with suspected retinoblastoma need a thorough ocular examination under general anesthesia by an experienced ophthalmologist. The ophthalmologist must be able to differentiate other causes of leukocoria (nematode endophthalmitis, persistent hyperplastic primary vitreous, Coats' disease, coloboma, idiopathic retinal detachment, and congenital cataract) from a neoplasm. Treatment is usually enucleation; more ecently, insertion of radioactive plaques or use of laser in small tumors has been under investigation. Chemotherapy is reserved for metastatic disease or for bilateral disease.

Thyroid Cancer

Background

Thyroid cancers are carcinomas, usually arising in the thyroid gland and less commonly in ectopic thyroid tissue. Thyroid cancer is divided into four histologic subtypes: papillary, follicular, medullary, and anaplastic. Papillary carcinoma accounts for approximately 70% of cancers, and follicular carcinoma comprises 20%.

Thyroid cancer is uncommon in children. Exact figures regarding the incidence in childhood are difficult to obtain. The disease is approximately twice as common in females as in males.

A well-documented association exists between previous low-dose head and neck irradiation and the development of thyroid cancer. This association was discovered when the histories of many patients with thyroid cancer revealed that they had received irradiation for conditions such as acne, tonsil enlargement, or thymic enlargement. All persons with previous neck irradiation should have careful neck examinations every 1 to 2 years, and all palpable nodules should be evaluated.

Clinical Manifestation and Pathophysiology

Thyroid cancer usually presents as one or more firm, painless nodules in the neck. Occasionally, patients will have symptoms of dysphagia or hoarseness. Thyroid cancer commonly spreads to cervical lymph nodes and less commonly to lungs and bones. Local invasion of the trachea, larynx, or esophagus can also occur. Any patient suspected of having a thyroid nodule should have a radioisotope study of the thyroid with either iodine-123 or technetium-99 pertechnetate. Thyroid scan usually reveals a “cold” nodule, although “hot” nodules can also be malignant. The evaluation should also include radiographs of the chest and neck, radionuclide bone scans, and measurement of triiodothyronine (T_3), thyroxine (T_4), and thyroid-stimulating hormone (TSH).

Soft-Tissue Sarcomas

Background

Definition

Soft-tissue sarcomas are derived from mesenchymal tissue: muscle, tendon, nerve, fat, and endothelium. Rhabdomyosarcoma arises from muscle and is the most common member of this group in children. Less common are Ewing's sarcoma (PNET), fibrosarcoma, neurofibrosarcoma, synovial sarcoma, mesenchymoma, malignant fibrous histiocytoma, and leiomyosarcoma.

Classification

Soft-tissue sarcomas are classified according to the apparent tissue of origin. Rhabdomyosarcoma is further subdivided according to histologic subtype (embryonal, alveolar, or pleomorphic) and the extent of disease after surgery.

Epidemiology

Soft-tissue sarcomas can occur at birth. Their incidence peaks at 2 to 6 years of age. Sarcoma botryoides of the bladder, prostate, or vagina tend to occur in infants; paratesticular sarcomas occur in childhood or adolescence. Soft-tissue sarcomas occur at an annual rate of 0.84 per 100,000 in white children and 0.39 per 100,000 in African-American children. They account for approximately 6% of all neoplasms in children.

Clinical Presentation and Pathophysiology

A sarcoma usually presents as a lump in the soft-tissues. The lump may be painless or painful. Specific symptoms depend on the location of the tumor.

Orbital tumors cause rapidly developing unilateral proptosis. Nasopharyngeal tumors can present with recurrent epistaxis, chronic sinusitis, chronic nasal obstruction, or dysphagia. Middle ear rhabdomyosarcoma can cause a chronic otitis media, ear pain, cranial nerve palsies, and rarely, sarcomatous meningitis. Neck tumors can cause dysphagia, hoarseness, or simply a painless mass in the posterior cervical triangle. Tumors of the bladder or prostate lead to acute urinary tract obstruction or constipation. Sarcoma botryoides of the vagina present with bleeding or as a polypoid mass protruding from the introitus. Extremity sarcomas usually appear as painless masses.

Management

The role of the emergency physician is to include cancer in the differential diagnosis of masses in the soft tissues of children and to refer children for prompt biopsy of the mass when a benign cause has been ruled out. Definite therapy consists of surgery, chemotherapy, and usually radiotherapy.

Bone Tumors

Background

Definition

A variety of neoplasms, many of which are benign, occur in bones. The malignant tumors are sarcomas arising from the cells of the cortical or cancellous bone (osteogenic sarcoma), cartilaginous bone (chondrosarcoma), periosteum (periosteal sarcoma), or reticuloendothelial cells of the marrow (Ewing's tumor).

Classification

Malignant bone tumors are classified according to the cell of origin. The two malignant bone tumors that are of practical importance are osteogenic sarcoma and Ewing's tumor.

Epidemiology

Osteogenic sarcoma and Ewing's tumor are more common in adolescents than in children. However, both tumors have been described in infants. Sixty percent of osteogenic sarcomas occur just above or below the knee. Both osteogenic sarcomas and Ewing's tumor show a male:female predominance of 1.6:1. The incidence of osteogenic sarcoma in the United States is approximately 0.5 per 100,000 children and that of Ewing's tumor is 0.1 per 100,000. Osteogenic sarcoma shows no racial predilection; Ewing's tumor, in contrast, is exceedingly rare in African-Americans.

Considerable epidemiologic data have accumulated to show that ionizing radiation causes osteogenic sarcoma. Despite the extensive epidemiologic data linking radiation and osteogenic sarcoma, most adolescents with osteosarcoma have had no excessive exposure to sources of radiation. Likewise, the cause of Ewing's tumor is unknown.

Clinical Presentation and Pathophysiology

Patients with malignant bone tumors complain of pain or a painful lump. The pain commonly occurs after a well-remembered episode of trauma and has often been present for weeks to months. Traumatic hemorrhage into the tumor may call attention to a lesion. Often, the pain is more intense at night and may awaken the patient. Patients with osteogenic sarcoma are almost always well. About one-third of patients with Ewing's tumor have a history of systemic symptoms, including fever, weight loss, anorexia, and malaise.

When the tumor is in an extremity, physical examination may reveal a hard, tender mass. Large tumors may feel warm and may have obviously increased vascularity. Disuse muscular atrophy may occur in the affected limb.

Trunk lesions, especially those of the pelvis, are difficult to diagnose. Often the mass is buried in gluteal tissue and cannot be appreciated on routine physical examination or on routine radiographs. A meticulous neurologic examination with particular attention to bladder and bowel function and the lower extremities is mandatory.

Diagnosis of a malignant bone tumor requires a radiograph and a biopsy of the lesion. Radiographs will reveal changes associated with a destructive process in bone. Early changes include loss of soft-tissue fat planes and periosteal elevation (Codman's triangle). Later, an “onionskin” periosteal reaction caused by repetitive episodes of the lesion pushing out the periosteum and the periosteum responding by laying down calcium is visible. Further along in disease development, normal trabeculation disappears, and areas of lysis are seen. No defined sclerotic margin is visible around the area of destruction, and the tumor's precise limits are impossible to determine. Eventually, the tumor breaks through the cortex, weakening bone and predisposing the patient to pathologic fracture. The “sunburst” phenomenon of osteosarcoma occurs as the tumor blood vessels grow perpendicularly to the shaft of the bone and malignant osteoblasts lay down bone along the vessels (Fig. 100.6). Almost all osteosarcomas are seen on plain radiographs. Some Ewing's tumors may not be obvious; if the history and physical examination suggest that trauma alone cannot account for the pain, a bone scan is the next radiologic study to order. Sometimes, pelvic Ewing's tumors may be difficult to see on plain radiographs; CT scan is helpful in delineating the full extent of these tumors. In osteosarcoma and Ewing's tumor, MRI may help delineate the extent of disease, but it is rarely needed to make the initial diagnosis. Other studies that may be useful are a CBC, sedimentation rate, serum lactate dehydrogenase (LDH) in Ewing's tumors, and serum alkaline phosphatase in osteosarcoma. If a presumed malignant tumor is seen, a plain chest radiograph should be taken to determine whether obvious metastases are present.

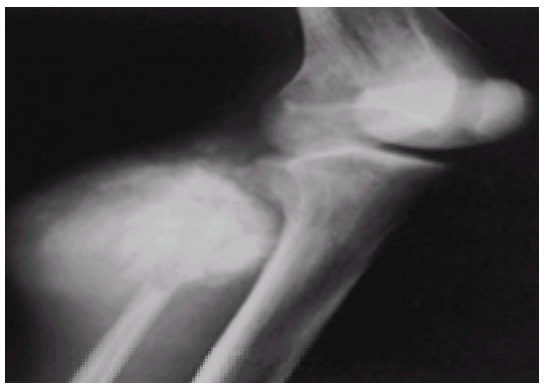

FIGURE 100.6. Osteosarcoma in the fibula in a 14-year-old girl. Radiograph shows lytic bone destruction, malignant new bone formation, cortical breakthrough, and massive extraosseous tumor.

Management

If the clinical findings suggest osteomyelitis, blood culture and culture from the lesion are necessary. If the clinical presentation is more suggestive of tumor, a biopsy is indicated. Ideally, biopsy of a Ewing's tumor or osteosarcoma should be performed by an orthopedic surgeon who has expertise in the management of eoplastic bone lesions. A large lesion with a thin cortex in a weight-bearing bone may require immediate immobilization to prevent pathologic fracture.

Before 1970, patients with osteogenic sarcoma or Ewing's tumor succumbed to pulmonary metastases within months or years. Since the early 1970s, adjuvant chemotherapy has been combined with surgery (amputation or en bloc resection for osteogenic sarcoma) or high-dose irradiation (Ewing's tumor). Agents used to treat osteogenic sarcoma include vincristine, high-dose methotrexate with leucovorin rescue, Adriamycin, and cisplatin. Agents used to treat Ewing's tumor include vincristine, Adriamycin, cyclophosphamide, actinomycin D, VP-16, and ifosfamide. Current projected survival rate for patients with these tumors is roughly 50%.

The major complication of osteogenic sarcoma therapy that may bring a patient to the attention of an emergency facility is methotrexate toxicity. Patients treated with high-dose methotrexate can develop life-threatening mucositis, renal compromise, or cerebral vascular changes.

Rarely, patients with osteosarcoma develop pneumothoraces. This condition is usually an indication that a subpleural metastasis has broken through the pleura. No immediate intervention is warranted unless the pneumothorax causes respiratory distress.

Patients with Ewing's tumor who have received irradiation and chemotherapy are prone to develop pathologic fractures. These fractures may occur silently or may cause pain and dislocation. Treatment consists of external immobilization. Many fractures eventually require internal fixation.

Central Nervous System Tumors

Background

Definition

Primary CNS tumors, whether histologically benign or malignant, arise in the brain, meninges, or spinal cord. This group of diseases includes many histologic variants, but only the relatively common primary neoplasms are discussed. In the past, metastatic brain tumors were relatively uncommon in children, but as chemotherapy changes the natural history of some tumors, cerebral or epidural metastases of some tumors (rhabdomyosarcoma, Ewing's sarcoma, osteogenic sarcoma, and lymphomas) are becoming more common.

Classification

Several classification systems have been used for characterization of brain tumors, based on histology, benignancy or malignancy, and location. For the clinician, a more useful classification is one based on the location of the tumors because lesions at specific locations produce corresponding specific neurologic deficits. In contrast to adult brain tumors, most pediatric brain tumors are infratentorial. Histologically, the most common brain tumors are gliomas. Astrocytomas, a subset of gliomas, comprise about one-third of all brain tumors. Astrocytomas are graded according to the degree of malignancy: grade 1 astrocytoma is histologically benign and grade 4, glioblastoma multiforme, is the most malignant. More than half of astrocytomas are infratentorial, predominantly cerebellar in location. Brainstem gliomas are usually regarded as a separate subset of astrocytomas. Astrocytomas and ependymomas are the common low-grade spinal cord gliomas.

Primitive neuroectodermal tumors (PNETs), the most common of which was formerly called medulloblastoma, are the second most common histologic types of brain tumor. They mostly occur in the cerebellum, arising from germinative cells of the external granular layer, and grow predominantly from the vermis.

Epidemiology

Brain tumors occur in 4 of 100,000 children yearly and are the most common group of solid tumors in children. They can occur at any age, but their incidence peaks from ages 5 to 10 years. Gliomas are more common in children less than 5 years old, and PNETs are most common around age 8 years, with a striking male predominance of 4:1. Certain constitutional disorders are associated with an increased risk of development of brain tumors. Most notable is neurofibromatosis type 1 (NF-1) in which optic pathway, hypothalamic, and brainstem gliomas are common; in addition, MRI screening programs have identified benign, sometimes transient unidentified bright objects (UBOs) in young children with NF-1. Many brain tumors in patients with NF-1 do not require treatment. Patients with NF-2 may develop acoustic neuromas and meningiomas. Other associations of brain tumors with constitutional disorders are tuberous sclerosis with subependymal giant cell astrocytoma, von Hippel-Lindau disease with retinal or brainstem hemangioblastomas as well as renal neoplasms, and nevoid basal cell carcinoma syndrome with PNETs.

Clinical Presentation and Pathophysiology

Most brain tumors cause symptoms and signs of increased intracranial pressure (see Chapter 13, Chapter 78, Chapter 83, and Chapter 125). In fact, brain tumors are now a relatively common cause of increased intracranial pressure because the incidence of other causes, such as brain abscess, is decreasing. The symptoms of increased intracranial pressure vary with age. Infants show personality changes, vomiting, lethargy, loss of previously acquired motor skills, seizures, and symptoms of obstructive hydrocephalus. In older children, headache is the most common complaint. Early in the course, headaches are usually intermittent. A history of headache on arising in the morning should alert the

emergency physician to the possibility of a CNS tumor. Morning vomiting, with or without nausea, is also a common presenting symptom. Other early anifestations include diplopia, ataxia, hemiparesis, speech disturbance, stiff neck, dizziness, lethargy, and coma.

Specific tumors cause specific focal neurologic changes. Brainstem gliomas cause cranial nerve deficits usually in the order of VI, VII, IX, and X. Facial palsies and dysphagia are presenting symptoms; ataxia and hemiparesis follow. Localizing symptoms often occur before increased intracranial pressure. PNETs and cerebellar astrocytomas, because of their midline location, cause truncal ataxis and an unbalanced reeling gait. If PNETs “drop” metastases to the cord, cord compression may occur (see p. 1183 and Chapter 83). Cerebellar astrocytomas that occupy one hemisphere cause ipsilateral hypotonia and a tendency to fall to the side of the lesion. Herniation of a cerebellar tonsil causes head tilt and neck stiffness. Tumors near the third ventricle (craniopharyngiomas, germinomas, optic gliomas, and hypothalamic and pituitary tumors) cause visual impairment, increased intracranial pressure, and hydrocephalus. Tumors of the chiasmatic/hypothalamic region may produce the diencephalic syndrome (failure to thrive, wasting, and inappropriate alertness) in infants and young children. However, these tumors may cause major deficits in visual acuity and reduction in visual fields that are difficult to detect in young children. Pineal tumors obstruct the aqueduct of Sylvius, producing increased intracranial pressure and Parinaud's syndrome (upward gaze paralysis, convergence nystagmus, and decreased pupillary response). Cerebral astrocytomas, ependymomas, and oligodendrogliomas cause seizures and hemiparesis.

Spinal cord tumors cause pain at the site of the tumor and neurologic deficits. The tumor is sometimes localized by tenderness of the overlying vertebral segments. Depressed motor function, sensory deficit, hyperreflexia below the lesion, and a Babinski sign may be present. Later, paralysis, areflexia, and loss of bladder and bowel control may occur.

Management

The long-term management of CNS tumors requires a team approach that includes the participation of a pediatric neurologist, neurosurgeon, oncologist, radiation therapist, and psychosocial support staff. The role of the emergency physician in the management of CNS tumors is one of recognizing CNS lesions, performing the initial diagnostic procedures to establish the presence of the lesion, and stabilizing the patient who has a life-threatening increase in intracranial pressure or spinal cord compression. When an intracranial lesion is suspected, a complete neurologic evaluation, including an eye examination and developmental assessment, is mandatory. CT scanning is the most rapid way to establish the presence of a mass lesion. The mass will show enhancement with the use of contrast material. Definitive localization of intracranial and spinal cord tumors is now accomplished using MRI. Myelography and angiography are reserved for those patients in whom the neurosurgeon needs further information for planning the surgical approach.

Lumbar puncture is rarely useful in the initial evaluation of a child with a CNS tumor. If focal neurologic signs or signs of increased intracranial pressure are present, a CT scan should precede any attempt to perform a lumbar puncture. If an immediate lumbar puncture is deemed necessary to rule out meningitis, the protocol outlined in Chapter 12 should be followed.

Increased intracranial pressure may be treated with the administration of dexamethasone (0.5 to 1.0 mg/kg per day in four divided doses) and diuretics such as mannitol (1 to 2 g/kg over 30 to 60 minutes). Depending on the severity of the neurologic findings, intubation and hyperventilation may be indicated. (See Chapter 13 and Chapter 83 for additional discussions of increased intracranial pressure.)

The patient should be examined carefully for signs of spinal cord compression. Tumors that cause spinal cord compression, whether intrinsic to the cord, such as astrocytomas, ependymomas, or chordomas, or extrinsic to the cord, such as metastatic PNETs, lymphomas, or sarcomas, demand immediate attention by a pediatric neurosurgeon and oncologist. (See the following section on cord compression, p. 1183.)

Definitive diagnosis of a CNS tumor should be made by biopsy. Surgical resection is becoming increasingly important because surgery in the hands of experienced pediatric neurosurgeons appears to improve the prognosis for CNS tumors. An operative procedure that removes as much of the tumor as possible is a goal that must be weighed against the risk of neurologic deficits. Tumors that are deep in the dominant hemisphere or in the brainstem are not usually amenable to aggressive surgical resection.

Definitive therapy for CNS tumors depends on the patient's age, the location of the tumor, tumor histology, and the extent of the surgical resection. Radiation therapy (4500 to 6500 cGy) has improved survival in most children with unresectable CNS tumors, especially PNETs, ependymomas, and low-grade astrocytomas. However, the dosages used may be devastating to children less than 5 years of age, and chemotherapeutic regimens are now being used in this group of patients. Adjunctive chemotherapy and bone marrow transplantation in patients with CNS tumors are under investigation. Many patients are now receiving multimodal therapy with surgery, radiation therapy, and multiagent chemotherapy. Chemotherapeutic agents used for CNS tumors include lomustine (CCNU), carmustine (BCNU), cyclophosphamide, vincristine, cisplatin, carboplatin, ifosfamide, prednisone, VP-16, procarbazine, and thiotepa.

COMPLICATIONS OF THERAPY AND PROGRESSIVE DISEASE

Children with cancer have many problems that are no different from those of normal children. However, the ffects of their disease and of the surgery, chemotherapy, and radiation used to treat their disease create problems unique to these patients. This section reviews the most common problems that are unique to children with cancer. These problems generally arise from 1) bone marrow suppression, 2) metabolic derangements caused by the primary disease or chemotherapy, and 3) major organ damage caused by treatment or progressive disease.

The evaluation of a patient with cancer who presents to the ED begins with establishing the patient's history. Table 100.4

lists the basic data needed to evaluate a cancer patient. Knowledge of the most recent course of therapy is important because it establishes the potential for bone marrow suppression at the time of the visit.

I. Primary diagnosis	IV. Central venous access device
A. Disease	A. Type
B. Primary and metastatic sites	B. Previous infections
C. Date of diagnosis	V. Current medications
D. Status of disease (remission, relapse, completed therapy)	A. Corticosteroids
II. Surgical history	B. Chemotherapy
A. Date	C. Trimethoprim-sulfamethoxazole prophylaxis
B. Extent of resection	D. Growth factors (e.g., g-CSF, erythropoeitin)
III. Last treatment	VI. How is the child acting?
A. Chemotherapy	VII. Has the problem occurred before?
1. Drugs	VIII. What does the parent believe to be the problem or the cause of the problem?
2. Date	
B. Radiation therapy	
1. Dosage	
2. Fields	
3. Date	

Table 100.4. Basic Historical Data Needed for Evaluation of a Cancer Patient in the Emergency Department

In general, the first few months of cancer therapy are intensive. During this time, oncologists are particularly cautious about the risk of infection associated with bone marrow suppression. Early in the course of therapy a patient may be admitted to the hospital for observation on the basis of ill appearance alone, even if the neutrophil count is adequate and the patient is afebrile.

The parents of children with cancer are often uncomfortable in the ED because of the absence of doctors and nurses with whom they are familiar, the perceived risk that their child will be exposed to communicable diseases, and the need to recite their child's complex history. However, the parents of oncology patients usually acquire a great deal of sophistication about their child's illness and the symptoms that their child manifests when ill. Cancer chemotherapy can cause unusual side effects and can mask some of the symptoms and signs of illness; therefore, soliciting the parents' impression of their child's problem is important. The emergency physician must also recognize the parents' concerns that an acute problem may represent relapse of their child's cancer.

Except for patients who are still on mask precautions after bone marrow transplant, oncology patients do not need to be isolated in private rooms. However, they do need separation from patients who have contagious illnesses, especially varicella or measles infection. Strict handwashing by all personnel is mandatory.

Hematologic Complications

Anemia

Anemia is common in children being treated for cancer and is usually well tolerated. Most often, anemia is a result of the suppression of normal hematopoiesis by chemotherapy. Other causes, such as nutritional deficiencies, chronic blood loss, infection, and hemolysis, should be ruled out if the anemia is problematic. After induction therapy, routine transfusion for a hemoglobin in the range of 7 to 10 g/dL is not advisable unless the anemia is causing symptoms or blood loss is continuous. If the child is a potential candidate for bone marrow transplant, blood products from family members should not be used.

Guidelines for the use of packed RBCs are reviewed on p. 1160 and in Table 100.3. If there is a question about the need for CMV-negative blood, the child's oncologist or the blood bank director should be consulted. RBC products should be irradiated to 1500 cGy before transfusion. Leukodepletion filters should be used. It is useful to write “oncology patient” on blood bank requests so that the product can be properly prepared.

Some cancer patients may receive recombinant human erythropoietin to ameliorate the effects of chemotherapy-induced anemia. A patient who receives erythropoietin should not receive a packed RBC transfusion without his or her oncologist being consulted.

Hemorrhage

After infection, hemorrhage is the second most common serious complication of cancer therapy. Often the hemorrhage is minor (mild epistaxis, gum bleeding), but when the platelet count is below 10,000 to 20,000/mm ^{3}, spontaneous intracranial hemorrhage or GI bleeding becomes more likely. See the previous section on hemorrhage in the discussion of leukemia and Table 100.3 for treatment guidelines.

Two special circumstances require a high index of suspicion of hemorrhage. Patients who have had a resection of a CNS tumor are at particular risk for bleeding into the tumor bed. Also, many cancer patients taking high dosages of corticosteroids must be considered at increased risk of GI hemorrhage.

For epistaxis or bleeding of the oral mucosa, local measures to control the bleeding should be tried before blood products are used. Local pressure should be applied to the bleeding site or to the nasal bridge; the use of 2 to 3 drops of phenylephrine (0.25 or 0.5%) is ften helpful in epistaxis. One or two vials of topical thrombin (1000 units/vial, as the powder) may be applied after the large unstable clot is removed. Desmopressin (DDAVP, 10 µg/m ^{2} intravenously) has been used successfully in thrombocytopenic patients with mucosal bleeding that is unresponsive to local measures and

platelet transfusion.

Leukocytosis/Leukopenia

Leukocytosis is discussed in the previous section on leukemia. Infection in the leukopenic patient is discussed in the following section.

Infectious Complications

Despite advances in supportive care, infection remains a major cause of morbidity and mortality in cancer patients. As chemotherapy regimens have become more aggressive, periods of neutropenia and mucositis have become more severe and prolonged. The disruption of mechanical barriers to infection and the quantitative neutrophil defect place the cancer patient at increased risk of opportunistic infection. Indeed, even a minor infection can overwhelm the compromised immune system of a cancer patient. (See infectious complications in the previous section on leukemia, p. 1162, for a discussion of problems seen in patients with newly diagnosed leukemia.) A general approach to infection in the child with cancer is presented in Figure 100.7.

Febrile Neutropenic Patient

The most important variable in determining the outcome of infection is the degree of neutropenia caused by the disease itself and by many cytotoxic agents. In adults, *neutropenia* is defined as fewer than 1000 neutrophils/mm^3. In practice, children tolerate neutropenia better than adults, and most can remain free of infection with counts of more than 500 neutrophils/mm^3. However, with fewer than 500 neutrophils/mm^3, the risk of infection increases; at less than 200/mm^3, it becomes more likely. If the neutrophil count is on its way down from 200 to 0, the risk of infection becomes even greater. Duration of neutropenia is also significant. Infection is less likely if neutropenia represents a transient dip in the neutrophil count after a large dose of chemotherapy, and recovery is likely within a few days. If infection occurs in this setting, the patient's own defenses can usually be of aid in time. If, on the other hand, the neutropenia is of several weeks' duration, overwhelming infection is more of a threat.

Management of fever and presumed infection begins with a careful history. This historical information is important because the neutropenia and cytotoxic therapy can mask signs of illness and cause a physician who does not know the child well to underestimate the potential seriousness of the illness.

A thorough physical examination sometimes uncovers the source of fever. In addition to examining the common sites of infection in children (the buccal mucosa, perianal area, and nail beds), muscles, joints, bones, and former sites of intravenous infusions should be evaluated. In a patient undergoing treatment for cancer, just as in the patient with newly diagnosed leukemia, an apparently minor swelling or a tear in a mucosal surface or the skin can be a source of disseminated infection. Perirectal abscesses, commonly seen in patients with AML, may cause pain and discoloration but no edema. Seemingly insignificant paronychia may be the source of significant bacteremia. Blood and urine cultures should be obtained and a chest radiograph should be taken in patients with respiratory symptoms, but a lumbar puncture is not indicated unless signs of meningitis are present; for unknown reasons, infectious meningitis is rare in children with cancer.

The accepted practice in treating a febrile neutropenic patient is to begin empiric antibiotic therapy with combinations of intravenous broad-spectrum antibiotics. The choice of antibiotic combination depends on the prevailing patterns of infection and antimicrobial resistance in the area. First-line combinations currently in use are listed in Figure 100.7. These choices are based on experience; most infections in neutropenic patients arise from the patient's endogenous flora and are caused by invasion of skin (*Staphylococcus aureus* and *Staphylococcus epidermidis*) or intestinal *flora (Escherichia coli, Pseudomonas, Klebsiella, Enterococcus, Serratia). S. epidermidis* is a common cause of sepsis in children with indwelling Broviac or Hickman catheters. Antibiotics should be started if the child appears toxic or the neutrophil count is less than 500/mm^3. When possible, the primary physician should be contacted for advice.

Most patients with cancer do not present to the ED with invasive fungal disease unless they are in relapse or have been recently discharged from the hospital after a protracted course of antibiotics or hyperalimentation. Corticosteroids and indwelling catheters also predispose cancer patients to fungal disease. Fungal overgrowth can present as esophagitis, cellulitis, pneumonitis, sinusitis, meningitis, urinary tract infection, septicemia, or fever of unknown origin. Mucositis and esophagitis are discussed in the following sections about GI and genitourinary complications and pneumonitis is discussed in the following section about interstitial pneumonitis. In general, invasive fungal infections must be treated with intravenous amphotericin B. However, initiation of therapy with amphotericin B is not usually indicated in the ED.

Bacterial, viral, or fungal infections can cause septic shock in the neutropenic patient. Treatment consists of aggressive measures to maintain intravascular volume and blood pressure (see Chapter 3), broad-spectrum antibiotic therapy appropriate for neutropenic patients, and hematologic support with red cells, platelets, and plasma. Stress doses of corticosteroids should be given to patients who have been on adrenal-suppressive doses of prednisone or dexamethasone for more than 10 days.

Patients with Central Venous Catheters

Many children with cancer have central venous catheters. These catheters may be of the Hickman/Broviac type, which have an external portion, or of the subcutaneous port type, which are completely internal. Patients with these devices are at increased risk of three types of infection: 1) bacteremia or sepsis related to an indwelling catheter, particularly with *S. epidermidis, Streptococcus viridans,* and Gram-negative enteric organisms; 2) local infection along the tunnel tract from the central vessel to the exit or port site or surrounding the port, usually with *S. aureus* or *S. epidermidis;* and 3) infection

at the exit site of externalized catheters.

Patients with central venous catheters and significant fever (38°C [100.4°F] × 3 or 38.4°C ([101.1°F] or higher × 1) require admission and intravenous antibiotics, after blood cultures are obtained. Blood cultures must be drawn from each lumen of the catheter. The choice of antibiotics depends on the patient's absolute neutrophil count (Fig. 100.7, Category 1 and Category 2). Fever, headache, nausea and vomiting, or chills that occur within 20 to 45 minutes after a central venous catheter is flushed indicate bacteremia related to catheter infection. The patient with erythema, swelling, or tenderness along the tunnel tract or around the port should be treated with intravenous antibiotics (Fig. 100.7, Category 1 or 2) even if fever is not present, and a pediatric surgeon familiar with central venous access devices should examine the patient. Catheters may become obstructed by blood clot formation. This may act as a nodus for infection.

Patients with erythema around the exit site of an externalized catheter, no fever, and an absolute neutrophil count of more than 500/mm^3 may be treated with conservative measures. Dressing changes should be increased to once or twice per day; mupirocin ointment may be added to the dressing change routine. During warm weather, fungal dermatitis under the catheter dressing is common. Frequent dressing changes and the use of clotrimazole cream twice daily will usually result in rapid resolution of this problem.

Interstitial Pneumonitis

Interstitial pneumonitis in the oncology patient may be caused by a wide range of infectious agents or may be a result of chemotherapy or radiation therapy. Therefore, it occurs in patients with different primary diagnoses and in different clinical settings. A patient often presents with interstitial pneumonitis when the eutrophil count is normal and when the primary disease is under control.

Before the advent of effective prophylaxis with trimethoprim–sulfamethoxazole (TMP-SMZ given at a dosage of 2.5 to 5 mg/kg per dose of TMP twice daily on 2 to 3 consecutive days per week), *Pneumocystis carinii* pneumonia (PCP) presented a special problem for patients with ALL. PCP was the most common cause of death in ALL patients in remission before the use of TMP-SMZ. PCP has been virtually eliminated from this population since the advent of effective prophylaxis.

However, ALL patients who are unable to take TMP-SMZ because of sensitivity to the drug or drug-induced myelosuppression are still at risk for PCP, even if they are treated with inhaled pentamidine. Several cases of PCP have been reported during the use of inhaled pentamidine. These cases tend to be milder and localized to lung segments not reached by an aerosolized drug (e.g., the right upper lobe). Patients who have had lung, mediastinal, or spinal irradiation, who are receiving high-dose corticosteroids, or who are receiving severely myelosuppressive chemotherapy are also at risk for PCP if not given adequate prophylaxis.

Now that the risk of PCP has been lessened with adequate prophylaxis, other causes of interstitial pneumonitis must be considered. Causative microorganisms include 1) atypical bacteria-- *Mycoplasma* and*Legionella* species; 2) viruses—EBV, CMV, varicella, respiratory syncytial virus (RSV), and influenza species; and 3) fungi, especially *Candida* and *Aspergillus* species. Interstitial pneumonitis may also be a direct result of chemotherapy with bleomycin, cyclophosphamide, methotrexate or cytosine arabinoside, or irradiation of the lungs.

PCP presents with fever, cough, tachypnea, and hypoxemia. The degree of hypoxemia is often out of proportion to the adventitial sounds heard on chest examination. Initially, the chest radiograph may be normal in PCP, but a diffuse increase in interstitial markings is usually evident by 24 hours after the onset of symptoms (Fig. 100.8). *Mycoplasma* or viral infection may present in a similar manner, although a history of upper respiratory tract symptoms suggests these diagnoses.*Mycoplasma* and RSV infection in infants may be associated with wheezing. Aspergillus infection can present as a diffuse interstitial pneumonia in the neutropenic patient or with a fungus ball (Fig. 100.9) and hemoptysis in a patient who has had an adequate number of neutrophils to localize the infection. Pleuritic chest pain is sometimes present in fungal pneumonia, probably a result of the presence of pleural-based lesions.

FIGURE 100.8. *Pneumocystis carinii* pneumonitis in a 6-year-old boy with a 24-hour history of fever and cough. Chest radiograph shows bilateral alveolar infiltrates most prominent at the hila. (Courtesy of Dr. Spencer Borden, Department of Radiology, Children's Hospital of Philadelphia.)

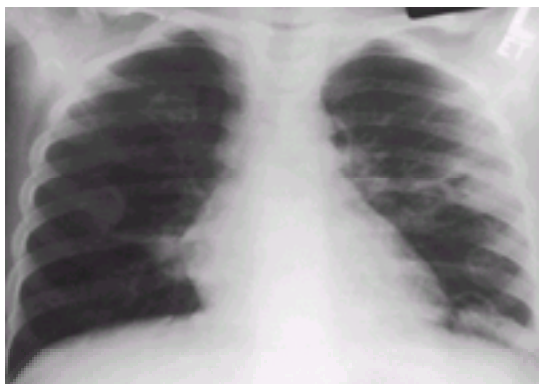

FIGURE 100.9. Fungal pneumonitis in a 6-year-old boy with acute lymphoblastic leukemia; he had received 60 mg/m ^{2} per day of prednisone and broad-spectrum antibiotics and had persistent fever. Physical examination was remarkable for hepatosplenomegaly and normal heart and lungs. Chest radiograph shows bilateral cavitary lesions. (Courtesy of Dr. Spencer Borden, Department of Radiology, Children's Hospital of Philadelphia.)

Interstitial pneumonitis may be a manifestation of bacterial pneumonia in the severely neutropenic patient. It may also follow septicemia by 24 to 48 hours and be a harbinger of adult respiratory distress syndrome.

The evaluation of the oncology patient with interstitial pneumonitis should include a CBC with differential, liver function tests in patients suspected of having disseminated viral infections, blood culture, and sputum culture when feasible. Pulse oximetry should be used to monitor for hypoxemia. CMV and fungi may be grown from urine; urine viral and fungal cultures should be sent if these organisms are suspected. Serologic testing for specific viruses, such as CMV and EBV, may be useful.

Varicella and herpetic pneumonia are rare in the absence of skin or mucosal lesions. When skin lesions are present, scrapings from the base of a vesicle should be submitted for Tzank prep, viral culture, or rapid immunologic detection tests. If no diagnosis is evident from initial noninvasive tests, early bronchoscopy with bronchoalveolar lavage is indicated. Open lung biopsy or thoracoscopic biopsy is indicated when no diagnosis is evident following bronchoscopy.

In the neutropenic patient, initial evaluation and therapy should be directed toward the identification and treatment of presumptive bacterial infection. Treatment guidelines are presented in the previous section on the febrile neutropenic patient. Additional treatment of the neutropenic patient, and initial treatment of the nonneutropenic patient, should be directed toward the most likely organism. If a patient is at risk for PCP and is not receiving systemic prophylaxis, TMP-SMZ (20 mg/kg per day of TMP) should be given. Prednisolone 2 mg/kg per day given intravenously or orally has proven beneficial as an adjunct to anti-*Pneumocystis* therapy in patients older than 13 years of age with human immunodeficiency virus (HIV) infection and Pa_{O_2} less than 70 mm Hg on room air. Intravenous acyclovir is given when herpes (750 mg/m^2 divided every 8 hours) or varicella (1500 mg/m^2 divided every 8 hours) virus is evident or suspected. Ganciclovir (2 to 5 mg/kg every 8 hours) and intravenous gamma-globulin are used for proven CMV infection or when CMV is highly suspected, as in patients who had a bone marrow transplant 1 to 3 months prior. Early treatment with erythromycin is rarely contraindicated.

Supplemental oxygen should be used when transcutaneous oxygen saturation is less than 96%. Packed RBC transfusion is indicated in the setting of hypoxemia and anemia. Ventilatory support should be provided, except when its use is precluded by prior discussions with the family of a terminally ill patient.

Chemotherapy-induced and radiation therapy–induced pneumonitis are diagnoses of exclusion. The emergency physician should concentrate on the identification and treatment of possible infectious causes.

Varicella and Herpes Virus Infection

Up to half the children with Hodgkin's disease develop varicella-zoster during or after therapy. About 1% develop lethal visceral dissemination. In patients with ALL, varicella has replaced PCP as the most common cause of death during remission. Acyclovir 1500 mg/m^2 per day intravenously divided every 8 hours can shorten the course of the illness and lessen the risk of dissemination in the immunocompromised patient.

Any immunocompromised patient who has a vesicular rash should be admitted for intravenous treatment with acyclovir. Oral treatment is inadequate. All chemotherapy should be discontinued. On admission, an appropriate diagnostic test (viral culture or rapid detection test) should be done because herpes simplex virus (HSV) can present as a vesicular skin eruption in the immunocompromised host; for HSV, a lower dosage of acyclovir is used (750 mg/m^2 per day divided every 8 hours). Interstitial pneumonitis may occur in these patients, so a chest radiograph should be obtained when respiratory signs and symptoms are present. Initial liver function tests, to detect evidence of viral hepatitis, and renal function tests as a baseline for monitoring acyclovir toxicity, should be obtained.

Hodgkin's disease and ALL patients are at the highest risk for varicella infection, but any patient with significant immunosuppression and evidence of varicella infection should be treated in the manner previously described. Patients with intraoral or labial HSV infection may also require intravenous acyclovir if they are leukopenic and ill with their infection. Oral acyclovir is sometimes used to suppress HSV reactivation during times of severe leukopenia in patients with a history of HSV infection.

Care should be taken to isolate oncology patients from other ED patients with active varicella or a history of exposure to

the virus. If a child without a history of previous varicella infection or documented titers before treatment is exposed to varicella, varicella-zoster immunoglobulin (VZIG) should be given (125 units/10 kg to a maximum of 625 units) by intramuscular injection. VZIG is most effective if given within 96 hours of exposure. The patient's oncologist should be consulted regarding discontinuation of chemotherapy during the postexposure period.

Postsplenectomy Sepsis

Laparotomy with splenectomy is a part of the diagnostic evaluation of Hodgkin's disease in many pediatric oncology centers. All patients should be given pneumococcal and *Haemophilus influenzae* type b vaccines before splenectomy. However, many patients do not respond adequately to these vaccines. Although penicillin or erythromycin prophylaxis (250 mg orally twice daily) is prescribed for these patients, sepsis from encapsulated organisms not covered by the vaccines or the prophylactic antibiotics can be life-threatening.

In the past, hyperacute infection occurred in as many as 10% of children with Hodgkin's disease. Most of these children had advanced disease, had experienced multiple relapses, or had received no prophylaxis. Hyperacute infection is less common today. Children with hyperacute infections develop high fever and cardiovascular collapse, followed by death in at least half the patients. If a patient who has undergone splenectomy or who has had more than 3600 cGy of splenic irradiation suddenly develops high fever and appears acutely ill, blood and urine cultures should be obtained, and cefotaxime (100 mg/kg per day) should be started immediately. Careful attention should be given to maintenance of adequate perfusion see Chapter 3). If the patient is neutropenic as a result of therapy, antibiotic coverage should be administered as described in the previous section about the febrile neutropenic patient.

Common Childhood Infections

Children with cancer acquire common pediatric viral and bacterial infections. For the child who is receiving maintenance therapy for ALL, or who is not neutropenic from therapy for other malignancies, diseases such as otitis media, urinary tract infection, streptococcal pharyngitis, impetigo, infectious mononucleosis, mumps, influenza, and the ubiquitous upper respiratory tract infections may be managed as they would be in an otherwise healthy child. However, varicella and measles (rubeola) infection are dangerous in oncology patients regardless of the status of their disease. Varicella should be treated as described in the previous section on varicella and herpes virus infection.

Measles outbreaks have become more prevalent in recent years, placing oncology patients at higher risk of exposure to the disease. Measles can result in fatal pneumonia in the immunocompromised host, gamma-globulin (0.1 mL/kg intramuscularly) provides some protection from measles and should be given to an exposed patient. Measles vaccine is contraindicated during therapy, although patients who were adequately vaccinated before therapy usually retain their immunity.

Measles–mumps–rubella vaccine may be used safely in the contacts of immunocompromised patients; its use should be encouraged in families with a child who is being treated for cancer. Families of children with cancer should also be encouraged to get an influenza vaccination during the course of their child's treatment.

Neurologic Complications

Neurologic complications of cancer therapy may be caused by the compression of vital structures of the CNS by growing tumor or the effects of therapy. Radiation therapy to the brain or spinal cord may have direct effects on CNS function. Chemotherapy may act directly to cause seizures or encephalopathy, or indirectly by causing electrolyte imbalance or a predisposition to thrombosis. In addition, other drugs used during the course of cancer treatment may cause alterations in CNS function: antiemetics may cause extrapyramidal symptoms, headache, or encephalopathy; amphotericin B can cause severe electrolyte imbalance, which may result in CNS symptoms.

Seizures

Seizures in a child with cancer should be evaluated and treated in much the same way as outlined in Chapter 70. A careful history should be taken to see whether the child has a ventriculoperitoneal shunt, what medicines the child is taking, and whether the child has had radiation to or surgery on the brain or spinal cord.

Metabolic abnormalities account for 7% of seizures in children with cancer. Cisplatin, ifosfamide, and amphotericin B can all cause renal wasting of electrolytes, especially potassium, phosphorus, magnesium, and calcium. A rapid assessment of potassium, calcium, and magnesium levels is essential in patients who have received these drugs.

Vincristine, intrathecal methotrexate, and cytosine arabinoside may directly cause seizures. L-Asparaginase predisposes cancer patients to CNS thrombosis, which may result in seizures. Therefore, knowing the child's recent chemotherapy history is essential.

A child in whom a shunt malfunction or primary or metastatic tumor in the CNS is a possibility must have imaging studies performed to localize the problem. Infectious meningitis is rarely a problem except in the child who has a CNS foreign body or who has had a recent lumbar puncture.

Altered Mental Status

A few unique circumstances must be considered when evaluating the cancer patient with coma or encephalopathy. Progressive disease must always be considered in the differential diagnosis. The emergency physician must be concerned with a cerebrovascular accident in those with thrombocytopenia, DIC, or a thrombotic tendency secondary to L-asparaginase use. Viral encephalitis with HSV or varicella is of particular concern in the immunocompromised host.

Ifosfamide, BCNU, 5-fluorouracil, thiotepa, high-dose cytosine arabinoside, and high-dose methotrexate may cause acute coma or encephalopathy.

Phenothiazines are often used as antiemetics and may cause extrapyramidal symptoms, somnolence, or coma. Occasionally, a patient who is using a scopolamine patch for control of emesis will leave a patch in place long enough to cause encephalopathy. Removal of the patch reverses the problem over a few hours.

Many terminally ill patients are maintained on home infusions of opioid narcotics or are taking high-dose oral narcotics for cancer pain. Care should be taken not to rapidly reverse the effects of these drugs with naloxone because acute withdrawal symptoms can be precipitated. Supportive care and gradual withdrawal of the opioid is indicated if coma or encephalopathy occur.

Cerebrovascular Accidents

In children with cancer, a cerebrovascular accident (CVA) may result from direct or metastatic spread of tumor, the effects of chemotherapy or radiation, or as a result of a bleeding diathesis associated with thrombocytopenia or DIC (secondary to leukemia or sepsis). Patients with acute leukemia and hyperleukocytosis are at risk of CVA secondary to leukostasis. The treatment of hyperleukocytosis is discussed in the previous ection on leukemia. Acute promyelocytic leukemia and acute monocytic leukemia predispose to stroke by causing DIC. Treatment with fresh-frozen plasma is discussed in the previous section on leukemia.

L-Asparaginase has a direct effect on anticoagulant factor production. Patients who are receiving the drug three times per week during induction therapy for ALL must be considered at high risk for thrombotic stroke. If stroke occurs, antithrombin III, protein S, and protein C levels should be measured and the patient should then be given 10 mL/kg of fresh-frozen plasma twice daily until the patient is able to produce normal amounts of these factors.

Spontaneous hemorrhagic stroke secondary to thrombocytopenia is rare when the platelet count is maintained at greater than 20,000/mm^3 using platelet concentrates. If intracranial hemorrhage does occur in the thrombocytopenic patient, the platelet count should be raised to greater than 80,000/mm^3 with platelet concentrates. Platelet-refractory patients present a difficult problem. Plasmapheresis, intravenous gamma-globulin, and human lymphocyte antigen (HLA)-matched platelets have varying success in maintaining an adequate platelet count.

CT scan with contrast should be taken for all oncology patients suspected of having a CVA. Although CT may not reveal an early stroke, it will identify bleeding or a progressive tumor that may be the cause of neurologic symptoms. A CT scan repeated at 7 to 10 days after the acute event usually identifies the lesion. If the patient is stable enough to complete the examination, MRI will often be able to identify a stroke that is not apparent on CT scan. MRI offers the advantage of magnetic resonance angiography, which may obviate the need for invasive angiography.

Spinal Cord Compression

Spinal cord compression is almost always a result of direct invasion of tumor into the spinal canal. Occasionally, a patient taking high-dose corticosteroids may develop nerve root compression after the collapse of an osteopenic vertebral body. Radiation-induced spinal cord injury is rare but should be considered in the differential diagnosis if the patient received more than 4500 cGy to the cord.

Careful neurologic examination should include an assessment of sacral nerve function (anal tone and anal wink, postvoiding bladder residual). A spinal sensory level should be sought. A spinal cord lesion may often be localized by percussion tenderness or pain over the involved vertebral segment(s). MRI is the best technique for definitive localization of the lesion.

Spinal cord compression is treated with surgery (see Fig. 100.2 and Chapter 125), radiotherapy, or chemotherapy. The choice of treatment is determined by the type of tumor and the duration and severity of symptoms. Dexamethasone should be given to all patients at an initial dose of 1 to 2 mg/kg intravenously. The restoration of bowel and bladder continence can have a profound impact on quality of life. Therefore, even in a terminally ill patient, spinal cord compression should be considered an emergency.

Gastrointestinal and Genitourinary Complications

Mucositis and Esophagitis

Chemotherapy, especially with methotrexate, high-dose cytosine arabinoside, and anthracyclines can cause mucosal injury throughout the GI tract. Breaks in the mucosal barrier, added to the effects of myelosuppression, predispose patients to fungal and viral infections of the oral and GI mucosa. Radiation therapy to the head, neck, and mediastinum also commonly results in oral or esophageal mucositis. Oral and esophageal mucositis may interrupt normal nutrition and require hospitalization for intravenous fluids, hyperalimentation, and pain relief. Treatment strategies for acute stomatitis are outlined in Table 100.5. *Candida* and HSV should be suspected and treated aggressively if found.

1. Cleanse 2–3 times/day with gauze or disposable sponge brush; use ½ tsp of sodium bicarbonate/cup of water.
2. Use 0.1% chlorhexidine gluconate mouthwash after each cleansing.
3. Avoid commercial mouthwashes.
4. Topical agents used 3–4 times/day:
• Dyclonine HCl 0.5% applied on a cotton applicator or as a spray
• Diphenhydramine or hydroxyzine applied on a cotton applicator (using maximum dose appropriate for age)
• 1:1 mixture of Maalox and diphenhydramine or hydroxyzine swish and spit or applied with cotton applicator
5. Individual lesions: Apply Orabase with benzocaine or Kenalog as needed.
6. Admit for intravenous fluids, hyperalimentation, and analgesia if intake inadequate.
7. Culture suspicious lesions for HSV; KOH preparation for yeast.
8. Treat oral candidiasis (mycostatin, fuconazole) and HSV (acyclovir) aggressively.

HSV, herpes simplex virus; *KOH*, potassium hydroxide.

Table 100.5. Treatment of Acute Stomatitis

Esophagitis presents with dysphagia and substernal chest pain. Fever and acute stomatitis may or may not be present. The diagnosis may be confirmed with barium swallow (Fig. 100.10) or endoscopy. Endoscopy offers the advantage of definitive diagnosis of candidal or herpetic lesions and the ability to examine the gastric and duodenal mucosa during the same procedure.

FIGURE 100.10. Esophageal candidiasis in a 16-year-old boy with acute lymphocytic leukemia who was receiving corticosteroids and broad-spectrum antibiotics. Barium swallow shows ulceration and dissection of mucosa of distal esophagus. (Courtesy of Dr. Spencer Borden, Department of Radiology, Children's Hospital of Philadelphia.)

Esophagitis in an otherwise well patient who can still swallow may be treated using oral ketoconazole (3.3 to 6.6 mg/kg per day) or fluconazole (100 to 200 mg/day). Patients who are neutropenic, febrile, or unable to maintain adequate oral intake should be admitted for intravenous fluids, alimentation, and a 7 to 10 day course of amphotericin B.

Abdominal and Rectal Pain

Abdominal pain is a common complaint in children with cancer. Pain may be caused by inflammation in ny part of the abdominal viscera. Acute abdominal pain may be caused by the usual disorders seen in childhood (e.g., gastroenteritis, appendicitis), but some problems deserve special consideration in oncology patients. Table 100.6 lists these problems, the clinical setting in which they are seen, and the appropriate course of action to be taken.

Problem	Clinical Setting	Action
Stomach pain	Chemotherapy-induced gastritis Corticosteroid-induced gastritis	Trial of oral antacid
Small bowel obstruction	Progressive tumor Postoperative adhesions	Abdominal radiographs Nasogastric drainage Surgical consultation
Right lower quadrant pain/typhlitis	Severe myelosuppression, especially acute myelogenous leukemia	Abdominal radiographs (look for pneumatosis) Nothing-by-mouth status and nasogastric drainage Antibiotics (Gram negative, anaerobic, and fungal coverage) Surgical consultation
Anorectal pain/perirectal abscess	Severe myelosuppression	Rectal examination by pediatric surgeon Antibiotics (Gram negative and anaerobic coverage) Sitz baths
Abdominal pain, vomiting hypotension, and increased amylase/lipase (pancreatitis)	L-Asparaginase use Corticosteroid use	Ultrasound examination Nothing-by-mouth status and nasogastric drainage
Constipation/ileus	Vincristine use, hypokalemia Narcotic-induced	Increased fluids Oral stool softeners and laxatives Suppository/enema if no results with oral therapy (consult oncologist before giving enema) Check serum potassium

Table 100.6. Abdominal Pain in Children with Cancer

Gastritis caused by chemotherapy or corticosteroid use is common in oncology patients. Oral antacids usually provide symptomatic relief. Small bowel obstruction is rare in patients with cancer, but it occasionally results from progressive tumor or postoperative adhesions.

Patients who are receiving weekly doses of vincristine are prone to ileus and constipation. Hypokalemia caused by renal electrolyte loss also causes constipation in the patient who has had cisplatin, ifosfamide, or amphotericin B. Pain can be

severe, and the risk of infection is increased in the patient with severe ileus or obstipation. Stool softeners (e.g., docusate sodium), increased fiber in the diet, and increased fluid intake help prevent constipation. However, if severe ileus or obstipation occurs, rapid resolution with oral laxatives or enemas is important. Enemas should be used only in the most recalcitrant cases and only after consultation with the patient's oncologist.

Typhlitis and perirectal abscess are seen in the setting of neutropenia. Typhlitis is a necrotizing colitis of the cecum seen almost exclusively in patients with AML. It presents with right lower quadrant pain, tenderness on palpation, and fever. Plain films of the abdomen may show ileus, thickened bowel wall, and air in the bowel wall. Ultrasound examination will confirm thickening of the cecal wall. The mortality rate ranges from 50 to 100% regardless of treatment. A patient suspected of having typhlitis should be allowed nothing by mouth and be placed on broad-spectrum antibiotic coverage that includes coverage for anaerobic bacteria.

Perirectal abscess presents with anorectal pain, pain on defecation, a frank abscess on external or rectal xamination, or perirectal cellulitis and fever. Therapy is antibiotics, including coverage for anaerobic bacteria, and sitz baths. Stool softeners should be used to ease the pain of defecation and to help prevent future episodes. Although a pediatric surgeon should be consulted, many patients improve with medical therapy.

Pancreatitis must be considered in a patient taking L-asparaginase or corticosteroids who presents with abdominal pain and vomiting. Determination of the amylase and lipase and ultrasound examination will confirm the diagnosis. The treatment is the same as for any patient with acute pancreatitis.

Hemorrhagic Cystitis

Hemorrhagic cystitis is a complication of treatment with ifosfamide and high dosages of cyclophosphamide. The metabolism of these drugs produces an acrolein dye that is excreted in the urine. Contact between the dye and the bladder wall may lead to mucosal inflammation and resultant bleeding. Hemorrhagic cystitis has become much less common with the use of the uroprotectant MESNA (sodium 2-mercaptoethane sulfonate).

A child with hemorrhagic cystitis presents with pain on voiding and either microscopic or gross hematuria. Lower abdominal pain, when present, represents bladder wall irritation or spasm. Occasionally, the patient passes large clots. Urinary tract infection should be ruled out, especially in the febrile or neutropenic patient. The platelet count and clotting times should be checked and corrected if abnormal.

Initial treatment of microscopic or uncomplicated gross hematuria consists of hydration with 1.5 to 2 times maintenance fluids and frequent voiding. A pediatric urologist should be consulted to remove large clots and to assist with further management if bleeding does not abate with medical therapy. Belladonna and opium suppositories or oral oxybutynin chloride (Ditropan 5 mL twice daily in children older than 5 years of age) will help control bladder spasm and pain. MESNA has no role in the treatment of established hemorrhagic cystitis.

Metabolic Complications

Electrolyte Abnormalities

Patients receiving certain chemotherapeutic agents or amphotericin B may have renal wasting of electrolytes, which requires acute treatment. Tumor lysis syndrome is discussed in the previous section on leukemia (Table 100.3).

Amphotericin B commonly causes moderate to severe hypokalemia. Cisplatin causes loss of calcium, phosphorus, and magnesium. Renal wasting is the mechanism of electrolyte loss for both of these drugs. Patients who are being treated with these drugs are usually taking oral electrolyte supplementation. However, decreased oral intake or noncompliance, especially in adolescent patients, can result in symptomatic electrolyte disturbances.

Hypokalemia can cause symptomatic ileus or cardiac arrhythmias. Bolus intravenous doses of potassium should be reserved for the patient with electrocardiogram (ECG) changes. Otherwise, potassium should be replaced by increased oral supplementation or constant intravenous infusion.

Of the electrolyte problems that cisplatin causes, hypocalcemia is most often associated with symptoms. If tetany or cardiac arrhythmias occur, intravenous calcium should be given (calcium gluconate 100 mg/kg per dose every 6 hours) until the ionized calcium is normal. Cisplatin also causes magnesium wasting; magnesium must also be corrected in the patient with symptomatic hypocalcemia. In these patients, hypomagnesemia and hypophosphatemia are rarely symptomatic before the onset of symptomatic hypocalcemia.

Hyperglycemia

L-Asparaginase or corticosteroids may cause hyperglycemia. L-Asparaginase inhibits production of insulin; corticosteroids stimulate glucose production through catabolic pathways. During induction therapy for ALL, L-asparaginase and corticosteroids are often used in combination, and hyperglycemia is common. Conservative dietary measures—small, frequent meals and decreased concentrated sugar—usually control the transient, mild hyperglycemia most often seen with these drugs. However, when the serum glucose is greater than 250 g/dL or glycosuria or ketonuria are found, a diabetic diet should be instituted.

Patients who are unresponsive to dietary management require insulin. Initial insulin doses should be small because some insulin reserve exists. After a small dose of insulin is given, the patient should be monitored for the recurrence of urine glucose/ketones or a rise in the blood glucose above 250 g/dL before subsequent doses are administered. A single, small dose often provides reasonable control for many hours. Tight diabetic control is not the goal in these

patients because the problem is transient, and overtreatment can result in hypoglycemia. Diabetic ketoacidosis is rare; it should be treated in the usual manner if it occurs (see Chapter 97).

Syndrome of Inappropriate Antidiuretic Hormone

In children with cancer, the syndrome of inappropriate antidiuretic hormone (SIADH) occurs for reasons unrelated to therapy (e.g., stress, pulmonary disease, primary CNS disease) or is a side effect of vincristine or cyclophosphamide treatment. In patients with CNS tumors or renal tubular damage, salt-wasting syndromes must be considered. Hypotonic dehydration must be considered in the differential diagnosis in young children with severe diarrhea. The mainstay of treatment is fluid restriction (see Chapter 97).

Cardiovascular Complications

Superior Vena Cava Syndrome

SVC syndrome occurs in patients with anterior mediastinal tumors. This problem is discussed in the previous section on thoracic tumors.

Cardiac Failure and Rhythm Disturbances

Anthracyclines (adriamycin and daunomycin) can cause rhythm disturbances, cardiomyopathy, and cardiac failure. These problems are related to total dose and increase in frequency with total doses of more than 450 to 500 mg/m ^{2}. Radiation alone or in combination with anthracycline may contribute to cardiac damage. Arrhythmias and conduction abnormalities are the most common acute toxicities of anthracyclines, but carditis-pericarditis syndrome and congestive failure are also seen. Myocardial and pericardial fibrosis may follow large doses of radiation. Chronic cardiomyopathy may be mild or severe; patients may be asymptomatic for many years and then present with congestive failure.

In the anthracycline-treated patient who is in shock and who does not respond to initial fluid resuscitation, cardiogenic shock must be considered. The initial treatment in the acutely ill patient is with oxygen, afterload reduction with diuretics or vasodilators (e.g., furosemide or nitroprusside), and inotropic agents (e.g., dobutamine, amrinone).

In patients who have anthracycline-induced heart damage, hypokalemia or hypocalcemia may exacerbate the problem. Patients who have not had anthracyclines may still have rhythm disturbances on the basis of potassium or calcium abnormalities. The severity of the rhythm disturbance determines the rate at which the electrolyte disturbance is corrected.

Post-Bone Marrow Transplantation

Bone marrow transplantation is increasingly used to treat many hematologic, oncologic, or immunologic diseases. In hematologic malignancies (leukemias), allogeneic marrow transplantation may follow initial remission induction or disease relapse. This approach requires the use of a histocompatible related or unrelated donor. The patient's own marrow is ablated using chemotherapy alone or with radiotherapy, and donor marrow is transfused to reconstitute the hematopoietic system. Allogeneic transplant may result in the complication of graft-versus-host disease.

Graft-versus-host disease (GVHD) may develop as newly engrafted immune cells of the donor react against tissue antigens of the recipient which are perceived to be “foreign.” GVHD risk increases for donor grafts which are less tissue compatible but can occur even in HLA-identical allografts. Acute GVHD causes skin, gastrointestinal, and liver disease and generally has onset at the time of engraftment during hospitalization. Therapy is primarily immunosuppressive using corticosteroids and/or cyclosporine. The ER physician should be aware of these complications as patients may present with exacerbations of acute GVHD. Chronic GVHD involves dermal, hepatic, ocular, pulmonary, gastrointestinal, and neuromuscular systems. Children with chronic GVHD have severe immunologic dysfunction and are at risk of acute hyperinfection with encapsulated organisms (see Postsplenectomy Sepsis, above).

Children with solid tumors which are high-risk for conventional treatment failure, or who have recurrent or refractory disease, may benefit from autologous transplantation. The patient's own marrow is harvested and used to reconstitute their hematopoietic system (bone marrow rescue) following myeloablative chemotherapy. Since the patient's own bone marrow is reinfused, there is no risk of graft-versus-host disease.

Infectious complications of marrow transplantation result from the extreme immunosuppression achieved by myeloablation, the cutaneous and mucosal barrier damage, and the immunologic immaturity of the transplanted marrow. Patients are at risk of exogenous and reactivated endogenous viral infections, including cytomegalovirus or herpes pneumonitis, varicella-zoster, and Epstein-Barr posttransplant lymphoproliferative disease. Adenovirus and cryptosporydium may cause severe diarrhea. Hyperacute pneumococcal sepsis may occur in the first posttransplant year.

Chemotherapy

Table 100.7 lists antineoplastic agents, their uses, and side effects. Most of these agents and irradiation cause some myelosuppression or immunosuppression, and most, except corticosteroids, vinca alkaloids, and bleomycin, cause nausea and vomiting.

Table 100.7. Cancer Chemotherapy

Attempts to control nausea and vomiting are made at the time of drug administration. Ondansetron (0.15 mg/kg intravenously or orally given 30 minutes before and 2 and 6 hours after chemotherapy) is a new serotonin antagonist that provides effective prevention of emesis without sedation. The phenothiazines (promethazine or chlorpromazine 0.25 to 0.50 mg/kg per dose every 4 to 6 hours orally, intravenously, or rectally) and metoclopramide (1 to 3 mg/kg per dose intravenously) are useful in the prevention and control of emesis, but they cause sedation and extrapyramidal symptoms. Diphenhydramine or hydroxyzine (1.0 to 1.25 mg/kg per dose orally or intravenously) are used to control extrapyramidal symptoms.

Pain Management

Pain in children with cancer may be acute and may be the first symptom of the disease or of recurrence of disease. When pain is acute, it is most appropriately managed by diagnosing its cause and treating the cause specifically with surgery, chemotherapy, or irradiation. If a delay in diagnosing the cause and initiating therapy occurs, analgesics are necessary to treat the pain.

Chronic pain in a child with cancer is often difficult to manage, but a child with cancer should never be allowed to suffer. Chronic pain may be caused by several mechanical problems: compression of a nerve by a mass or edema, spasm or compression around a vessel, obstruction of a viscous organ, or distension of the marrow space and subperiosteal hemorrhage. These physical components of pain are complicated by the psychologic experience. Pain itself is frightening, and many children with cancer and their families are frightened both by the suffering and by the association of cancer pain with cancer death. The physician can relieve some of the anxiety by explaining that she or he will look for the cause of the pain and will make every attempt to relieve the pain within a short time. Relaxation and hypnotic techniques are successful in managing chronic pain, but emergency facilities are not often prepared to provide impromptu services of this sort. As with acute pain, a specific cause should be sought. Compression of a nerve may be relieved with corticosteroids or radiation and, if the child is not terminally ill, possibly by surgery. The pain of pathologic fractures can be relieved by immobilization but usually requires narcotic analgesia. Obstruction of a viscous organ may require surgery, unless it appears to be an imminently fatal event in a child who is known to be terminally ill. The extent to which specific measures are appropriate should be clarified with the patient's physician and the family.

If no analgesics have been used and the pain is mild, acetaminophen is usually the preferred analgesic. Aspirin is contraindicated in most cancer patients because it interferes with platelet function. If acetaminophen alone is insufficient, acetaminophen plus codeine (3 mg/kg per day) should be tried for moderate pain. Patients should be warned about the constipating effects of codeine, morphine, or morphine analogues. The dosages, routes of administration, and duration of action of analgesics are listed in Table 100.8. These recommendations are standard; however, they are often considerably less than the dosages needed to relieve pain in a terminally ill cancer patient. Tolerance is acquired rapidly, and pain often breaks through previously successful dosages. Studies of pain management in cancer patients invariably show that physicians use too little medication because of fear of causing addiction and because of conservative recommendations in the available literature. Addiction is not a problem in the terminally ill patient. The most important rule in the management of cancer pain is that the dose of narcotic necessary to relieve the pain is that which relieves it successfully.

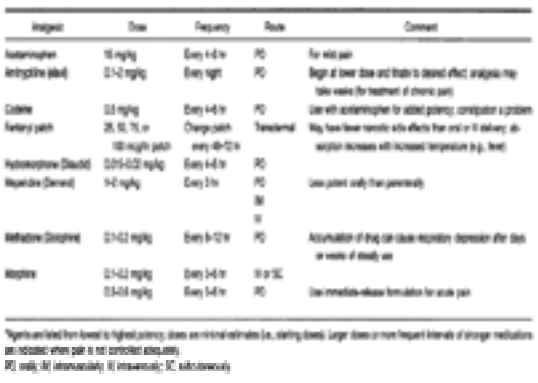

Table 100.8. Analgesics for Use in Acute and Chronic Cancer Pain[a]

If a child is in severe pain, he or she should not be discharged from the ED without control of the pain or without a plan

for means to control the pain. The plan may require admission for titration of narcotics, sedatives, and antiemetics, or consideration of nerve blocks, intrathecal morphine, or even rhizotomy or chordotomy. Alternatively, the plan may involve communication with a hospice facility in the child's home town. Hospice facilities vary in their willingness and capacity to deal with dying children, but in the recent past, many have been able to care for the dying child at home in a medically compassionate and philosophically appropriate way. See Chapter 126 for a discussion of the psychosocial aspects of pain.

CHAPTER 101

Rheumatologic Emergencies

ROBERT P. SUNDEL, MD

Department of Pediatrics, Harvard Medical School; Rheumatology Program, Children's Hospital, Boston, Massachusetts

JUVENILE RHEUMATOID ARTHRITIS

Background

Juvenile rheumatoid arthritis (JRA) is now the most common rheumatic disease of children in the developed world, having replaced acute rheumatic fever during the past 20 years. JRA occurs in all races and ethnic groups and, in the United States alone, may affect as many as 100,000 children.

The American College of Rheumatology criterion for diagnosing JRA is persistent unexplained arthritis of 1 or more joints lasting more than 6 weeks in children less than 16 years of age. The JRA diagnostic category thus includes a disparate group of syndromes characterized by chronic synovitis. Because no laboratory abnormalities are specific for JRA, the diagnosis is made clinically after exclusion of other conditions associated with chronic synovitis.

The cause of JRA is unknown. Although it has been reported to occur after trauma or systemic infections, extensive investigations attempting to correlate JRA with specific viral, bacterial, or mycoplasmal agents have not been conclusive. The presence of rheumatoid factor (RF) in the serum of some children with JRA, a lowered level of complement in the synovial fluid, and activated lymphocytes in the synovial tissue, suggest that immunologically mediated injury plays a role in the pathogenesis of this disease. There may also be genetic factors, as suggested by the association of JRA with particular histocompatibility antigens and cytokine alleles.

Pathophysiology

The pathogenesis of JRA may be divided into an initiating phase and a perpetuating phase. It appears that a variety of events, particularly viral infections, may trigger the articular inflammation. For unknown reasons, a process that is self-limited in most children leads to ongoing inflammation in genetically susceptible hosts. This inflammation is characterized by abnormal tissue and circulating levels of proinflammatory cytokines (including interleukin-1 [IL-1], interleukin-6 [IL-6], tumor necrosis factor [TNF], and interferon-g [IFN-g]), leading to activation of lymphocytes and infiltration of synovium.

Pathologically, vasculitis is prominent in early lesions. In established cases of arthritis, light microscopy of the synovium shows fibrin deposits, hyperplasia and hypertrophy of synovial lining cells, and an inflammatory cell response. Increased secretion of synovial fluid results in joint effusions. In uncontrolled and persistent arthritis, synovial villi project into the joint. Fronds of synovium may spread from the edges of the joint and overgrow the articular cartilage (pannus), causing destruction of the cartilage and eventually of the underlying bone.

Clinical Manifestations

A wide variety of demographic and clinical features may accompany the arthritis of JRA, so the condition has been divided into subtypes based on these factors and on the pattern of the disease during the first 6 months after onset. Until better means of classifying and distinguishing these subtypes of JRA become available, what is likely to be several discrete conditions will continue to be grouped on the basis of purely clinical features (Table 101.1).

Subgroup	% of JRA	Sex Ratio	Age at Onset	Joints Affected	Serologic and Genetic Test*	Extra-articular Manifestations	Prognosis
Rheumatoid positive polyarticular	10%	90% female	Late childhood	Any joints (typically hands, wrists	ANA 70% RF 100%	Low-grade fever, anemia, nodules, rheumatoid nodules	>50% severe arthritis
Rheumatoid negative polyarticular	20%	70% female	Younger onset	Any joints	ANA 80% RF negative	Low-grade fever, mild anemia, nodules, growth retardation	20-40% severe arthritis
Type I Pauciarticular	40%	90% female	Early childhood	Few large joints (hips and sacroiliac joints spared)	ANA 90%, RF negative	Few constitutional complaints, chronic iridocyclitis in 50%	Severe arthritis uncommon; 10-20% ocular damage from iridocyclitis if un-treated
Type II Pauciarticular	5%	90% male	Late childhood	Few large joints (hip and sacroiliac involvement common)	ANA negative, RF negative HLA-B27 70%	Few constitutional complaints, acute iridocyclitis in 5-10% during childhood	Clinically similar to spondyloarthritis
Systemic onset	20%	50% female	Any age	Any joints	ANA negative, RF negative	High fever, rash, or lymphadenopathy, polyserositis, hepatosplenomegaly, growth retardation	20% severe arthritis

*Modified with permission from Schaller J. In: Franklin EC, ed. Clinical Immunology. Update. New York: Elsevier North Holland, 1979.
ANA, antinuclear antibody; RF, rheumatoid factor; HLA-B27, histocompatibility antigen B27.

Table 101.1. Subgroups of Juvenile Rheumatoid Arthritis

Pauciarticular arthritis is defined as arthritis involving four or fewer joints. Type I pauciarthritis occurs more often in young girls and is the most common subtype of JRA, accounting for approximately half of all cases. Typically, it involves one or more large joints with swelling, pain, and limitation of movement. Antinuclear antibodies (ANAs) are detectable in the sera of more than 50% of these children, and its presence correlates with a higher risk for developing iridocyclitis.

Type II pauciarticular JRA occurs more often in preadolescent boys. Although they are often classified as having JRA, the predilection for axial involvement is more typical of spondyloarthritis. In fact, some of these children may develop ankylosing spondylitis on long-term follow-up. Typical of spondyloarthritis, the risk for developing chronic iridocyclitis is negligible, but 5 to 10% of these children may develop acute anterior uveitis.

Polyarticular arthritis (both RF positive and RF negative) occurs more commonly in girls than in boys. It is characterized by the insidious onset of symmetric synovitis in both large and small joints, accompanied by low-grade fever, morning stiffness, and malaise (Fig. 101.1). The presence of antibodies to native immunoglobulins in the serum (RF) corresponds to an increased risk of severe, erosive arthritis, as well as to the development of vasculitic complications and subcutaneous nodules. Cervical spine involvement occurs in approximately 30 to 50% of patients with this variety of arthritis, resulting in neck pain, stiffness, and torticollis. Unlike pauciarticular JRA, in which ocular involvement is the cause of the most significant morbidity, polyarticular disease may result in severe musculoskeletal disability. Thus, involvement of the temporomandibular joint may result in restricted ability to open the mouth, involvement of the hips may permanently affect ambulation, and small joint arthritis of the hands may compromise manual dexterity.

FIGURE 101.1. Symmetric involvement of large and small joints of the hands in a child with polyarticular arthritis.

The least common subtype of JRA is systemic-onset, or Still's disease. This subtype occurs most often in boys less than 5 years of age, although it has been reported even in adults. Clinically, these children often present with a fever of unknown origin; they may have high spiking temperatures (39° to 41°C [102.2° to 105.8°F]) for several weeks or months. Although the child often feels stiff and does not move normally, arthritis may not be a prominent feature at the onset of the disease. Diagnosis therefore generally involves excluding infectious and malignant conditions, especially sepsis, leukemia, and neuroblastoma. A characteristic salmon-pink evanescent maculopapular rash (Fig. 101.2), diffuse lymphadenopathy, and hepatosplenomegaly may also be present in the early stages, offering clues to the diagnosis. Arthralgias and myalgias are common, and pericarditis occurs most typically in this subtype of JRA. With time, systemic features of the disease become less prominent, and polyarticular arthritis becomes the major focus of management.

FIGURE 101.2. Macular rash in a child with systemic type of juvenile rheumatoid arthritis.

Laboratory and Radiologic Features

No laboratory test is diagnostic of JRA. JRA is a clinical condition diagnosed on the basis of characteristic findings on history and physical examination, although some laboratory studies may be suggestive of the diagnosis. In polyarticular JRA, one subgroup shows RF in the serum; no other pediatric rheumatologic disease typically has this marker. Mild to moderate anemia is common in all subtypes, particularly the systemic type. The white blood cell (WBC) count is often elevated, again most typically in the systemic type, in which leukemoid reactions may be seen. Platelet counts are often elevated, and urinalysis is usually normal. Levels of acute-phase reactants in the serum are elevated, often in proportion to the number of joints involved, and most prominently in systemic-onset disease. Complement levels may be normal or elevated, whereas immunoglobulins may be increased, leading to a reversal of the albumin:globulin ratio. ANA in the serum, particularly in children with pauciarticular arthritis, is an important marker for increased risk of developing iridocyclitis.

Radiographic features of JRA include soft-tissue swelling and periarticular osteopenia adjacent to affected joints. Later, narrowing of the joint space, bony cysts, erosions, subluxation, and ankylosis may be seen. In rare children in whom physical examination is difficult or inconclusive, ultrasonography may confirm the presence of a joint effusion, and magnetic resonance imaging (MRI) may show both synovial proliferation and increased fluid in the joint space.

Management

General Management

The major goal of therapy of children with JRA is to help the child and his or her family maintain as normal a life as possible. Emotional support, including the information that most children with this disease recover with minimal residual problems, provides reassurance. Simple measures, such as warm tub baths and the use of electric blankets at night, help control morning stiffness. For children with minimal joint involvement, regular daily activities, including participation in physical education classes, are to be encouraged, although high-impact activities should be avoided. In the presence of muscle wasting, weakness, or restricted range of motion in any joint, an active physical therapy program is indicated. Splinting may be used to rest actively inflamed, painful joints and to prevent worsening of deformities.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are now the mainstay of therapy for children with JRA. Aspirin, formerly the preferred agent, has fallen into disfavor because of concerns about Reye syndrome, as well as the need for dosing four times daily. Agents that are approved for use in children include naproxen, ibuprofen, and tolmetin sodium (Table 101.2). These and other drugs in this class share similar toxicity profiles, with gastrointestinal (GI) disturbances being both the most common and the most troublesome.

Drug	Dosing Frequency	Dosage Range	Side Effects
Ibuprofen (Motrin, Advil, Pediaprofen)	TID-QID	Anti-inflammatory doses are 37.5–40 mg/kg/day	Gastric irritation, chemical hepatitis
Indomethacin	TID	Start at 0.5 mg/kg/day; increase to 2.5 mg/kg/day	Gastric irritation, headache, hematuria
Naproxen (Naprosyn)	BID	10–20 mg/kg/day; maximum daily dose, 1000 mg	Gastric irritation, behavioral changes, headache, rash
Tolmetin sodium (Tolectin)	TID-QID	Start at 15 mg/kg/day; increase to 30 mg/kg/day; maximum daily dose, 1800 mg	Gastric irritation, headache, hematuria

Table 101.2. Nonsteroidal Anti-Inflammatory Drugs

For children who respond inadequately to NSAIDs, so-called disease-modifying antirheumatic drugs (DMARDs) are generally added to the regimen. Several agents, including sulfasalazine, hydroxychloroquine, and methotrexate, are available. Practitioners choose among these agents based on a child's age, the severity of the synovitis, and the subtype of arthritis. Methotrexate is the most commonly used agent in both juvenile and adult rheumatoid arthritis, and it appears to be the most effective drug at preventing or reversing joint damage. Sulfasalazine is most often used in children with inflammatory bowel disease but also is effective in various forms of arthritis. It is typically administered at a dosage of 40 to 70 mg/kg per day divided two to three times daily.

Hydroxychloroquine is an antimalarial agent with mild immunomodulatory effects. Dosages should never exceed 7 mg/kg per day to avoid ocular toxicity, including corneal deposition and macular degeneration.

Corticosteroids must be used judiciously in JRA because of the significant toxicity associated with their use. Systemic steroids are typically reserved for children with severe cardiac or pulmonary symptoms, during brief flare-ups of severe arthritis, or while waiting for slower-acting agents to take effect. Topical steroids are also effective for localized manifestations of JRA. Intra-articular steroids may be used in patients with pauciarthritis, or in children with polyarticular

disease in whom selected joints require particularly aggressive management. Ocular steroids are the linchpin of therapy for iridocyclitis.

Management of Complications and Emergencies (Table 101.3)

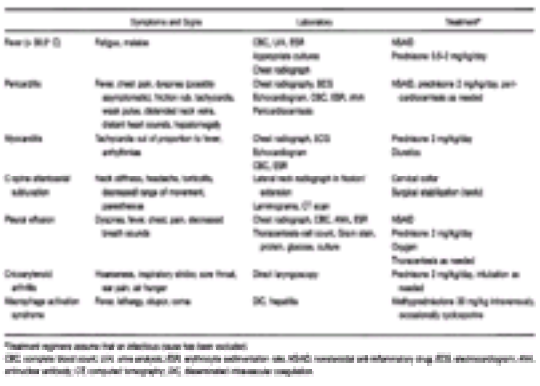

Table 101.3. Complications in Juvenile Rheumatoid Arthritis

Fever

Marked elevation of body temperature is characteristic of systemic JRA, whereas a lower-grade fever often accompanies polyarticular disease. The diagnosis of systemic JRA is one of exclusion, and fever is a common symptom, so diligent efforts should be made to rule out infectious diseases and malignancies. This may require hospitalization for a diagnostic evaluation, particularly in infants and young children. Appropriate cultures, including cultures of cerebrospinal fluid (CSF) if indicated, should be obtained. A bone marrow examination to rule out malignancy is necessary in many patients with systemic JRA.

In a patient being treated for known systemic JRA, the appearance of fever is always of concern. Fever may represent recurrence of JRA, or it may be caused by an intercurrent infection. Fevers in Still's disease typically follow the classic double quotidian pattern, with two peaks above 39°C (102.2°F) daily, as well as periods at or below normal without use of antipyretic medications. The child may be treated for a presumed JRA flare-up if there are no localizing signs of infection; if the complete blood count (CBC) shows the leukocytosis, thrombocytosis, and anemia typical of JRA; and if the urinalysis is normal. If the fever results from a specific infection (e.g., otitis media, urinary tract infection), appropriate antibiotics should be used. If the patient has received corticosteroids for more than 4 weeks within the previous 12 months, appropriate coverage with stress dosages (three times the physiologic dose) is indicated during the period of treatment of the infection.

Fever in systemic JRA, especially within 6 months of onset of disease, may rarely be caused by macrophage activation syndrome (MAS). This life-threatening complication is marked by disseminated intravascular coagulopathy (DIC) with diffuse microthromboses, hepatic inflammation, and central nervous system (CNS) changes progressing to seizures or coma. The cause of MAS is unknown, but it occurs more commonly during intercurrent viral illnesses, as well as in those taking NSAIDs or DMARDs (particularly sulfasalazine) as treatment. Differentiation from sepsis or a flare-up of JRA may be difficult, although a sudden rise in hepatic enzymes or a sudden drop in platelets, red blood cells, or erythrocyte sedimentation rate (ESR) (because of consumption of cellular elements and fibrinogen) are suggestive. Early diagnosis and a high level of suspicion are essential. Treatment with pulse dose methylprednisolone and/or cyclosporine, as well as general support measures for DIC, usually in an intensive care unit (ICU) setting, often lead to full recovery. Delayed diagnosis, on the other hand, is accompanied by a reported mortality rate of 20 to 50%.

Pericarditis, Myocarditis, and Cardiac Tamponade

Cardiac involvement is an important feature of systemic onset JRA but is uncommon in other subtypes of juvenile arthritis. Pericarditis (Fig. 101.3), like other systemic manifestations of Still's disease, most often occurs during the first 2 years of the illness. Common symptoms are fever, chest pain, dyspnea, and inability to lie flat in bed, although at times pericardial effusions may be asymptomatic. On physical examination, a parasternal pericardial friction rub may be heard over the left second and third intercostal spaces, especially with the patient supine. If the child has a moderate to large effusion, the clinician may not hear the friction rub but should look for the following signs of pericardial fluid: edema, tachycardia, weak pulse, distended neck veins, distant heart sounds, palpation of the apical impulse within the border of cardiac dullness, and hepatomegaly. Occasionally, the effusion may be massive, leading to cardiac tamponade as suggested by a pulsus paradoxus greater than 20 mm Hg.

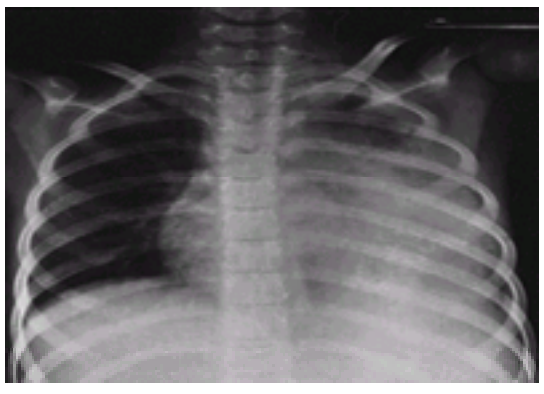

FIGURE 101.3. Pericardial and pleural effusions in a child with systemic type of juvenile rheumatoid arthritis.

Other types of cardiac involvement are unusual. Valvulitis is not typical of JRA and should suggest the possibility of acute rheumatic fever or bacterial endocarditis. Myocarditis is rare but may be seen. Tachycardia out of proportion to the elevation of temperature, arrhythmias, and congestive heart failure (CHF) are the usual clinical indicators of myocarditis.

If pericarditis or myocarditis is suspected, the child should be admitted and observed closely. Diagnostic studies should include electrocardiogram (ECG), chest radiograph, and echocardiogram. In pericarditis, the usual changes noted on ECG are tachycardia, elevated ST segment, and inverted T waves. Radiographs of the chest may show straightening of the left border of the heart and cardiac enlargement. Echocardiogram should be performed to confirm the presence of a pericardial effusion, as well as to quantify ventricular function, particularly if cardiac tamponade or myocarditis is suspected.

Bed rest and therapy with one of the NSAIDs should be adequate for the treatment of mild to moderate pericarditis. Corticosteroids (prednisone 1 to 2 mg/kg per day) are indicated for the treatment of myocarditis, for massive pericarditis causing compromise of cardiac output, or if significant symptoms persist despite therapy with NSAIDs. In the presence of tamponade or progressive deterioration, pericardiocentesis provides temporary relief while anti-inflammatory medications are used to prevent reaccumulation of fluid. If the child is acutely ill, requiring intravenous (IV) fluid support, care should be taken to avoid fluid overload, and diuretics should be added to the regimen.

Pulmonary Emergencies

Pleural effusions are a recognized complication of systemic JRA. Other pleuropulmonary manifestations include pneumonitis, diffuse interstitial disease, lymphoid bronchiolitis, and pulmonary arteritis. Occasionally, pleural fluid collections may be massive, resulting in respiratory distress. The usual clinical features of pleural effusion are chest pain, cough and dyspnea. On physical examination, there is dullness to percussion and diminished breath sounds on auscultation over the area of fluid. Chest radiographs, including lateral decubitus views (involved side down), may be used to document the extent of the effusion. Thoracentesis is indicated for diagnostic purposes, especially to rule out infectious processes, and in severe cases removing pleural fluid may help relieve respiratory compromise. Otherwise, treatment is aimed at the underlying disease process, primarily involving control of inflammation with NSAIDs or corticosteroids. Children with this complication often require admission for the overall severity of systemic features of the disease, rather than for the pleural effusion alone.

Iridocyclitis

Iridocyclitis (inflammation of the iris and ciliary body) occurs in approximately 10 to 20% of all children with JRA. This can be of acute or chronic onset. The chronic type of iridocyclitis occurs primarily in young girls with type I pauciarticular JRA, and it is virtually universal in girls with pauciarthritis and a positive ANA. In contrast, acute iridocyclitis occurs most often in older boys with pauciarticular disease.

The onset of chronic iridocyclitis is insidious and asymptomatic. Late signs are decreased visual acuity, unequal pupils, and band keratopathy. These reflect irreversible damage to the eye, however, and represent a missed opportunity for prevention. Therefore, all children with JRA, particularly those at high risk for iridocyclitis, should have a routine eye examination as soon as the diagnosis is made and at 3- to 6-month intervals thereafter. The emergency physician may be able to recognize evidence of established iridocyclitis such as posterior synechiae or cataracts using a +8 or +10 diopter lens in the ophthalmoscope, but slitlamp examination is required to recognize early inflammation.

Acute iridocyclitis, on the other hand, is characterized by sudden onset of redness, tearing, pain, and photophobia, and urgent management is crucial. Consultation with an ophthalmologist is essential. The usual treatment includes topical corticosteroids and mydriatics.

Flare-Up of a Single Joint in a Patient with JRA

In a patient known to have JRA who is taking anti-inflammatory medication, acute swelling with pain and limitation of range of movement of a single joint raises a major management problem. The differential diagnosis of this situation includes an acute flare-up of JRA versus infectious arthritis, and careful attention to physical examination and historical features are essential to avoid misdiagnosis.

Physical findings characteristic of infection of the joint are extreme pain, tenderness, erythema, and warmth over the joint. The affected joints of JRA may be swollen, warm, and stiff, but they are rarely red. There is usually a pronounced limitation of range of movement of the joint in infectious arthritis; the slightest movement may cause severe pain and muscle spasm. In contrast, some range of motion (5 to 10 degrees) is usually possible even with severely inflamed joints of JRA. If the patient is taking one of the corticosteroid preparations, physical findings of inflammation and/or infection may be masked.

If infection cannot be excluded with confidence, joint fluid must be aspirated, and the fluid sent for cell count, Gram stain, and culture. If there is any doubt about the diagnosis, it is best to obtain a blood culture as well and to initiate treatment for septic arthritis. For the acute swelling and pain in a single joint as a result of JRA, resting for 2 to 3 days and splinting the involved joint may be adequate. Local injection of the joint with a topical steroid preparation such as triamcinolone

hexacetamide (10 to 20 mg) is sometimes indicated after infection has been excluded.

Ruptured Popliteal Cyst

There are six bursae around the knee joint. Of these, the gastrocnemius-semimembranosus bursa is the one that most often communicates with the synovial space. Consequently, in the presence of effusion in the knee joint, fluid may enter the bursa and produce a popliteal cyst (Baker's cyst). Patients with popliteal cysts have a palpable and visible enlargement in the popliteal area, which is best seen in extension.

Rupture of a popliteal cyst with drainage of fluid into the calf muscles may present as an emergency. Affected patients complain of sudden pain in the calf associated with swelling in the leg. On physical examination, they have induration, erythema, warmth, and tenderness of the calf, as well as ankle edema. An effusion in the knee joint and evidence of synovial thickening are often present. Homan's sign may be positive, but other signs of thrombophlebitis, including palpable venous cords, dilation of collateral veins, and arterial spasm, are usually absent.

Differentiation of a ruptured popliteal cyst from thrombophlebitis may be difficult. Imaging techniques such as ultrasonography or MRI may be needed to establish the diagnosis. Intra-articular administration of steroids (triamcinolone hexacetamide, 10 to 20 mg) is the recommended initial treatment. If the response is inadequate or if the syndrome is chronic, surgical excision of the cyst may be necessary.

Cervical Spine Involvement

Cervical spine involvement usually is seen in children with established severe polyarticular JRA. Although this complication is known to occur in 30 to 50% of patients with JRA, atlantoaxial subluxation (AA subluxation) and subluxation of the lower cervical spine are less common in children than in adults, up to half of whom have AA subluxation. Clinical evidence of pressure on the spinal cord is seen in 23 to 65% of adults with radiologic evidence of AA subluxation. Similar figures are not available for children.

Neck stiffness that is worst in the morning is the most common symptom of cervical spine involvement in JRA. Occasionally, torticollis may be the presenting manifestation of cervical arthritis. Severe pain in the neck and referred pain over the occipital and retroorbital areas also may occur. The pain has a dull, aching quality and is often aggravated by neck movement. On physical examination, torticollis and/or loss of lordosis of the cervical spine and limitation of range of movement of the neck are the typical findings.

Paresthesia of the fingers is the most common symptom of spinal cord compression. Weakness of the arms and legs and inability to control the bladder are other complaints that should suggest spinal cord compression. During the initial stages, exaggerated deep tendon reflexes and an extensor plantar reflex are noted. Chronic myelopathy results in muscle atrophy and loss of deep tendon reflexes. Lateral radiographs of the neck in flexion and in extension are required for complete evaluation of the cervical spine. The patient should be asked to actively and slowly flex and extend the neck to tolerance without discomfort; care should be taken not to force these movements. Tomograms and an open-mouth view of the odontoid process may be helpful. On some occasions, computed tomography (CT) or MRI may be indicated.

The distance between the anterior surface of the odontoid and the posterior surface of the anterior arch of atlas when measured in a lateral flexion film is usually 4 mm or less. In the presence of AA subluxation, this may be as wide as 10 to 12 mm (Fig. 101.4). Other radiologic abnormalities characteristic of cervical spine involvement in JRA include loss of curvature, osteoporosis, erosions and sclerosis of joints, disc space narrowing, and altered height:width ratio of the vertebral bodies.

FIGURE 101.4. Atlantoaxial subfixation in a child with juvenile rheumatoid arthritis. (The distance between the anterior arch of the atlas and the odontoid process in the original radiograph was 5 mm.)

Although most children with AA subluxation do not have evidence of spinal cord compression, the physician must be wary of its occurrence with excessive movement, as for endotracheal intubation. Regular use of a light plastic cervical collar is often all that is required to relieve pain and prevent excessive anterior flexion, particularly during automobile rides. In the presence of spinal cord compression with muscle weakness and atrophy, surgical stabilization may be required.

Cricoarytenoid Arthritis

The cricoarytenoid joint is a diarthrodial joint with a synovial membrane. In patients with known polyarticular JRA, cricoarytenoid arthritis may rarely lead to acute airway obstruction. Clinical features of cricoarytenoid arthritis include stridor and hoarseness. The inspiratory stridor may wax and wane and may be present only when the patient is asleep. Some of these patients also may complain of pain in the throat while swallowing and pain in the ears. Many of these symptoms and signs are similar to those of severe acute laryngotracheobronchitis, which at times may be excluded only by direct laryngoscopy. Redness and swelling of the arytenoid eminences may be observed in cricoarytenoid arthritis, rather than the airway inflammation of croup.

Increasing airway obstruction with severe inspiratory retractions demands urgent treatment with respiratory support. High dosages of corticosteroids (methylprednisolone, 2 mg/kg per day intravenously) may control acute inflammation of the joints, avoiding emergency tracheostomy. If significant obstruction occurs, intubation should be attempted to establish an airway until swelling decreases; occasionally, emergency tracheostomy may be necessary. Even if tracheostomy is done, corticosteroid therapy is indicated so that the tracheostomy may be closed as quickly as possible.

Drug Toxicity

Almost all drugs used for the treatment of JRA have the potential for serious toxicity. If a child with JRA is being treated and develops a new symptom, drug toxicity must always be considered as one of the possible causes. Table 101.2 lists the common adverse reactions reported with NSAIDs. GI toxicity is the most common side effect, but significant NSAID gastropathy is actually unusual in children, and gastric or intestinal perforations, a significant problem in older adults, are rare. Nonetheless, children remain at risk for these complications, and only prostinoids such as misoprostil provide true gastroprotection. Antacids and H_2 blockers, although they ameliorate symptoms, do not actually reduce the risk of GI complications.

NSAIDs may cause a variety of other side effects as well. Reversible CNS complaints, particularly headaches, dizziness, and fatigue, occur in about 5% of children. Hepatotoxicity, manifested primarily as elevation of transaminases, and nephrotoxicity, including proteinuria and renal papillary necrosis, are rare but potentially dangerous if overlooked. Friability of the skin and a porphyrialike blistering of sun-exposed areas may be seen with these agents, especially in fair-skinned children taking naproxen.

Unlike salicylates, NSAIDs rarely cause tinnitus or hyperventilation. Reye syndrome, although far less common than with salicylates, has been reported in children taking NSAIDs; therefore, it is prudent to consider suspension of these agents in children with influenza or varicella. Salicylates must be carefully avoided in children who are even exposed to these viruses. Reye syndrome should be considered in the differential diagnosis of any child taking salicylates or other NSAIDs who presents with pernicious vomiting and/or alteration in mental status.

Each of the second-line agents used in the treatment of JRA also has the potential to cause specific forms of toxicity. More than 100,000 Americans now receive low-dose methotrexate for the treatment of arthritis, so questions of potential side effects are most likely to involve this drug. Doses used for JRA are much lower than those employed for treating malignancies—typically 0.3 to 1 mg/kg per week—and the degree of immunosuppression, although controversial, appears to be minimal. Live viral vaccines are nonetheless generally avoided in children receiving methotrexate, but reported cases of opportunistic or unusually severe infections are rare.

Despite its favorable therapeutic profile, methotrexate is an antimetabolite with the potential to cause oral ulcers, nausea, and abdominal pain. These may be minimized by supplementation with folic acid. Children must be monitored regularly for evidence of hepatic toxicity, and persistent elevation of hepatic transaminases identifies those at risk for hepatic fibrosis or cirrhosis. Methotrexate may also cause lymphopenia, especially with prolonged use, or even pancytopenia caused by bone marrow suppression. Concurrent use of other dihydrofolate reductase inhibitors, such as trimethoprim–sulfamethoxazole, potentiates this risk, and should be avoided.

Rarely, use of methotrexate is associated with the development of pulmonary hypersensitivity. This most commonly occurs during the first 6 to 12 months of use and may be marked by dyspnea, cough, fever, and fluffy infiltrates on chest radiograph. Although such symptoms may be conclusively distinguished from viral pneumonitis only by lung biopsy, suspicion of this complication necessitates discontinuation of methotrexate and institution of treatment with systemic corticosteroids. Failure to stop the drug or rechallenge with methotrexate may cause fatal respiratory failure.

Sulfasalazine is a sulfa drug, and its most severe toxicity is typical of this class of medications. Headache and GI upset, especially with preparations that are not enterically coated, are the most common side effects. Rarer, although more concerning, are bone marrow suppression, agranulocytosis, photosensitive eruptions, and hypersensitivity reactions, including Stevens-Johnson syndrome. Sulfasalazine is contraindicated in children with known intolerance of sulfa drugs, as well as in children less than 2 years of age in whom neurotoxicity may occur.

Antimalarial agents such as hydroxychloroquine must be administered judiciously because they can cause irreversible ocular toxicity at high dosages. Even at lower dosages, children may develop rashes, gastric upset, or reversible visual disturbances secondary to altered accommodation. Finally, children with glucose-6-phosphate deficiency who receive hydroxychloroquine may develop hemolytic anemia, especially during intercurrent infections.

The long list of potential side effects of systemic corticosteroids is enumerated elsewhere. In the acute-care setting, immunosuppressive effects of systemic steroids have the greatest impact on clinical management of JRA. It is important to remember that these agents most dramatically increase susceptibility to herpesviruses (especially disseminated varicella) and intracellular pathogens such as *Mycobacteria* and *Listeria*. Although they have little effect on susceptibility to other bacterial infections, their anti-inflammatory effects tend to mask clinical signs of infection, accentuating the need for vigilance on the part of clinicians.

A variety of other agents are rarely used in the United States, although occasionally, patients taking intramuscular or oral gold or d-penicillamine, may still present for evaluation. The major side effects from gold compounds are skin rash, bone marrow suppression with cytopenias, and proteinuria. D-penicillamine may cause skin rash, bone marrow suppression, nephrotoxicity, myasthenia gravis, and Goodpasture's syndrome. In view of their low risk:benefit ratios and prolonged duration of action, these agents should be discontinued if toxicity is suspected. If subsequent investigations identify another explanation for an apparent drug reaction, the drug may be restarted after a hiatus of days or weeks with little effect on control of the underlying arthritis.

SYSTEMIC LUPUS ERYTHEMATOSUS

Background

Systemic lupus erythematosus (SLE) is a multisystem disease that is both pleomorphic in its presentation and variable in its clinical course. The annual incidence of this disease has been reported to be 7.6 per 100,000 in adults, and it is estimated that there are approximately 10,000 to 15,000 children with SLE in the United States. The prevalence of SLE is greater among women between the ages of 15 and 64 years (1 in 700), particularly among African-American women (1 in 245).

The diagnosis of SLE is based on classification criteria established by the American College of Rheumatology (ACR). The 1971 preliminary criteria were revised in 1982 to include the presence of ANA and antibodies to native DNA; in 1997, a subcommittee of the ACR recommended inclusion of antiphospholipid antibodies as well. Table 101.4 lists the revised criteria and definitions. A patient should meet (any) 4 or more of the 11 criteria, simultaneously or in sequence, during any period of clinical follow-up to be diagnosed as having SLE. It is nonetheless important to remember that these criteria are intended for classification, not diagnosis, so patients may have SLE and not fulfill criteria, or they may meet criteria despite having another illness. Thus, pediatricians experienced in the care of children with SLE should participate in the diagnosis and management of all pediatric lupus patients.

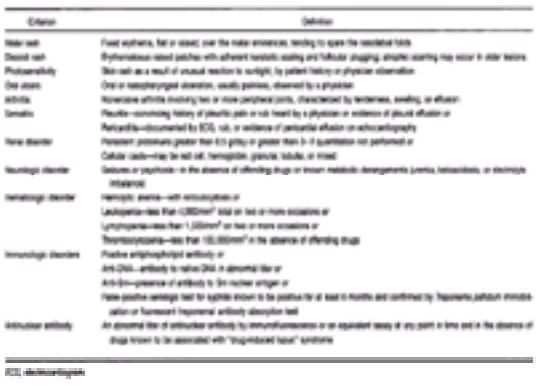

Table 101.4. Criteria for Classification of Systemic Lupus Erythematosus

Pathophysiology

The great variation in manifestations of SLE suggests that several discrete conditions may fall within the overall diagnostic category. A 7-year-old boy with arthritis, positive ANA, photosensitive eruption, and oral ulcerations appears to have little in common with a multiparous woman with seizures, pericarditis, renal failure, and high-titer anti-dsDNA antibodies. In fact, several different animal models for SLE have been developed, and they vary both in their clinical characteristics and in the underlying defect causing disease. The final common pathway unifying all cases of SLE is abnormal production of autoantibodies directed against a variety of antigens, including double-stranded DNA. The resultant circulating and in situ immune complexes deposit in tissues and activate the complement cascade. Release of activation products of complement, such as C5a, as well as other chemotactic, opsonic, and proinflammatory mediators, ultimately leads to tissue damage.

Current concepts of the pathogenesis of SLE envisage an interplay of environmental and genetic factors. Exposure to sun or to certain drugs (e.g., procainamide), and various types of infections (especially Epstein-Barr virus [EBV]), precipitate or exacerbate SLE in a predisposed host. On the other hand, family clusters of SLE, the occurrence of lupuslike syndromes with certain types of complement deficiencies, and the association between SLE and specific human leukocyte antigen (HLA) haplotypes, support a genetic component to the pathogenesis. The net result of these factors is functional abnormalities of both T and B cells, including diminished T-cell proliferative and stimulatory responses, polyclonal B-cell activation, defects in lymphocyte apoptosis, immunoglobulin isotype derangements, and defective cytokine production and response.

Histopathology of affected tissues reflects these mechanisms. In the skin, lesions vary from nonspecific vasculitis in the maculopapular variety of rash, to deeper lesions showing thinning of the epidermis, disruption of the dermal–epidermal junction, edema of the dermis, lymphocytic infiltration, and fibrinoid degeneration of the connective tissue. On immunofluorescent staining, localization of immunoglobulins and complement in the dermal–epidermal junction of the skin is seen in more than 75% of patients, although these findings may be present in other collagen vascular diseases as well.

Joints affected by arthritis show synovitis with fibrinoid degeneration of connective tissue but no pannus formation or cartilage destruction. Histologic features of lupus nephritis, even in the absence of clinical renal involvement, include

cellular proliferation and crescent formation, leukocyte and mononuclear cell infiltrates, and hyaline thrombi, as well as more chronic changes such as interstitial fibrosis and glomerular sclerosis. Analogous lesions in the CNS include microinfarcts and perivascular lymphocytic accumulation, as well as true vasculitis with inflammatory cells infiltrating vessel walls. Microhemorrhages into the subdural space have been documented as well.

Clinical Manifestations

The onset of SLE may be insidious or acute. The initial presentation usually includes constitutional features such as fever, malaise, and weight loss, in addition to features of specific organ involvement such as rash, pericarditis, arthritis, and seizures. Because virtually any part of the body may be affected by SLE, lupus may present with a bewildering variety of signs and symptoms. Although many of these are nonspecific, the examiner's level of suspicion for possible SLE should increase as the number of involved organ systems increases. Furthermore, although SLE is indeed a protean disease, most pediatric cases present with a typical spectrum of findings marked by musculoskeletal, renal, cutaneous, and hematologic involvement.

Arthritis in SLE is usually symmetric, involving both large and small joints. Swollen joints may be painful, but they are usually not erythematous. Patients may lose function because of tendon involvement, but the erosive synovial proliferation seen in JRA is uncommon.

Cutaneous lesions are present in more than 85% of patients with SLE. The typical malar erythematous rash with butterfly distribution occurs in about half of patients at the time of diagnosis. Discoid lesions are less common in children but, when seen, are characteristic of SLE (Fig. 101.5). Vasculitic skin lesions over the extensor surface of the forearm and on the fingertips are reported in about 20% of patients. These lesions are tender and may ulcerate. Nodules are less common. Mucosal lesions (macular and ulcerative) may involve the nose or the mouth, particularly the palate (Fig. 101.6) and are usually painless. Rarer types of mucocutaneous lesions in SLE include livedo reticularis, urticaria, erythema multiforme, and alopecia.

FIGURE 101.5. Adolescent girl with discoid lesions in malar distribution.

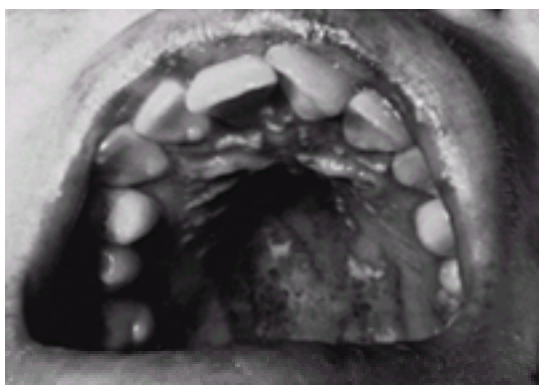

FIGURE 101.6. Mucosal lesions (macules and ulcers) of the palate in an adolescent girl with active lupus.

Evidence of renal disease is present in approximately 50% of children with SLE at the time of presentation. Nearly 90% of affected children will develop some degree of renal involvement during the course of their disease. Lupus nephritis is usually asymptomatic, although occasionally edema or hypertension may be clues to involvement of the kidney. Despite significant improvements in treatment, the extent of renal involvement remains the single most important determinant of prognosis in SLE. Most children will therefore require a renal biopsy before a therapeutic regimen may be established.

Clinical evidence of CNS involvement may occur at onset or later in the disease course. Symptoms and signs referable to the CNS include headache, seizures, polyneuropathy, hemiparesis/hemiplegia, ophthalmoplegia, hallucinations, memory alterations, and psychosis. Chorea is the most common movement disorder and may be a presenting sign; Lyme disease and rheumatic fever must also be considered in such cases. Cranial nerve palsies most commonly involve the optic nerve, trigeminal nerve, and nerves controlling the extraocular muscles. Myasthenia gravis should be excluded if any extraocular muscles are involved.

Pericarditis is the most prevalent form of cardiopulmonary involvement in SLE. Myocarditis occurs less often but is seen more often in SLE than in JRA. Heart murmurs caused by valvular lesions are uncommon, but asymptomatic vegetations

on valve leaflets are seen at autopsy in most patients (Libman-Sachs endocarditis). These do provide a potential nidus for bacterial superinfection, and in fact, patients with SLE are at increased risk of developing subacute bacterial endocarditis.

Pleuropulmonary involvement in SLE occurs in more than 50% of cases. Patients with pleuropulmonary manifestations commonly complain of chest pain, dyspnea, cough productive of small amounts of sputum, and fever. Pleural rub is the most common physical finding; dullness on percussion of the chest and/or diminished breath sounds on auscultation indicate the presence of a pleural effusion. Unilateral or bilateral pleural involvement may occur, with or without pleural effusion. For any SLE patient with pleuropulmonary manifestations, exclusion of intercurrent infection, CHF, aspiration pneumonia, and renal failure are critical for care. Although uncommon, pulmonary hemorrhage also occurs in children with SLE. It is potentially lethal and requires early recognition.

Common GI manifestations include nausea, vomiting, and anorexia. Persistent localized abdominal pain should suggest specific organ involvement, such as pancreatitis or gastric ulcer—both of which may occur from the disease or associated with steroid therapy. Generalized abdominal pain in SLE is not always related to the underlying disease but may stem from other causes such as appendicitis, ruptured ovarian cyst, or pelvic inflammatory disease. Manifestations of any of these conditions may be masked by the corticosteroids most patients receive. Malabsorption syndrome may be an occasional manifestation of SLE. Melena should suggest bleeding from the GI tract and requires immediate evaluation and treatment.

Laboratory Features

Mild to moderate anemia is common in patients with SLE. Hemolytic anemia associated with a positive Coombs' test is most characteristic. An acute decrease in the hemoglobin or hematocrit should alert the physician to the possibility of internal hemorrhage or massive hemolysis. Autoimmune thrombocytopenia, even in the absence of offending drugs, is commonly seen in SLE. Leukopenia and lymphopenia are additional hematologic abnormalities characteristically seen in SLE; few other conditions in children lead to lymphocyte counts under 1000/mm $_3$.

Circulating antibodies to specific clotting factors, deficiencies of one or more clotting factors, and abnormal platelet function may lead to abnormal hemostasis in SLE. A specific circulating anticoagulant, the “lupus anticoagulant,” has been described in up to 10% of patients with SLE. The antibody is so named because in vitro assays of coagulation are prolonged in its presence. In vivo, this antibody predisposes to arterial or venous thrombosis.

Proteinuria, hematuria, and cellular casts are the usual urinary abnormalities. Renal failure is suggested by decreased urine output, elevated levels of blood urea nitrogen (BUN) and creatinine, and reduced creatinine clearance. Nephrotic syndrome is best documented by a 24-hour urine collection for quantitation of protein excretion, although a spot urinary protein:creatinine ratio is a useful screening tool for proteinuria.

The most important single test in children suspected of having SLE is the ANA. Up to 2% of normal children have low to intermediate titers of ANA at any time; in most cases, these antibodies are transient cross-reacting immunoglobulins triggered by a viral infection. In SLE, the titer is often high--1:512 or greater—and is accompanied by antibodies to double-stranded DNA, a more specific marker for the lupus. Nonetheless, it must be remembered that SLE may be diagnosed only in the presence of evidence of multiple organ system involvement, so no laboratory study is pathognomonic.

Total serum hemolytic complement (CH_{50}) is often decreased in patients with active disease; therefore, it may aid in differentiating disease flare-ups from intercurrent illnesses. An elevated level of anti-DNA antibody with hypocomplementemia particularly correlates with active renal disease. Acute-phase reactants are elevated in the serum during active phases of the disease, whereas serum protein analysis may demonstrate elevation of immunoglobulins.

Management

General Management

No specific treatment exists for SLE. Rather, type and intensity of therapy are dictated by the particular organ systems affected. Patients with mild disease (fever and/or arthritis) without nephritis generally receive one of the NSAIDs (e.g., tolmetin sodium 20 to 40 mg/kg per day) (Table 101.2). Severe systemic features usually require treatment with oral or IV corticosteroids, with doses divided three or four times daily in the most florid cases. As disease activity subsides, steroids may be carefully tapered; tapering too rapidly often results in a flare-up of the disease process. Steroids are generally first consolidated into a single morning dose, then the total daily dose is gingerly tapered over weeks to months. Ultimately, when possible, patients are weaned to alternate-day therapy in an attempt to minimize side effects.

Patients with life-threatening disease, particularly those with severe renal or CNS involvement, may require so-called pulse doses of corticosteroids (IV methylprednisolone 30 mg/kg per day), plasmapheresis, or an immunosuppressive agent (especially azathioprine or cyclophosphamide). Symptomatic management may be necessary for the treatment of seizures, psychosis, or acute renal failure. Most patients also receive hydroxychloroquine, which has been shown to prolong disease-free remissions once signs and symptoms of active lupus are controlled. In any event, close follow-up is mandatory to detect clinical and serologic clues to exacerbations as rapidly as possible and to monitor drug toxicity. Finally, as with all chronic diseases, total management should include emotional support for patients and their families.

Management of Complications and Emergencies (Table 101.5)

Table 101.5. Complications of Systemic Lupus Erythematosus

Infections in SLE. Management of emergencies in patients with SLE first and foremost involves distinguishing primary disease manifestations from secondary complications. Infection is the major cause of mortality in children with SLE. Defective phagocytosis, decreased leukocyte chemotaxis, lymphocytotoxic serum factors, hypocomplementemia, and functional asplenia, contribute to the increased susceptibility of these patients to opportunistic infection. Gram-negative bacilli (especially *Salmonella*), *Listeria, Candida, Aspergillus, Cryptococcus, Toxoplasma, Pneumocystis,* and the varicella-zoster virus are some of the organisms associated with severe infections in SLE. Patients with SLE who are taking corticosteroids or cytotoxic drugs are at even higher risk for developing viral, mycotic, and other opportunistic infections. Most of these infections are diagnosed at autopsy, so clinicians must maintain a high level of suspicion in all children with SLE.

All patients with lupus and suspected infection need not be admitted. However, acutely ill children, those with an absolute neutrophil count of less than 1000/mm_3, and those with pneumonia or the possibility of meningitis require hospitalization for IV antibiotics while awaiting culture results. Patients with minor infections who are not acutely ill or neutropenic may be treated with appropriate antibiotics given orally along with frequent follow-up visits. The dosage of corticosteroids should also be increased to provide stress coverage (at least three times the physiologic need) in any acutely ill child who has received more than 20 mg of prednisone for more than 1 month.

Fever. Each febrile episode in a child with SLE represents a potential emergency. It is difficult to determine whether the fever is secondary to infection, to a flare-up of the primary disease, or to a combination of both. A complete physical examination should be performed. A CBC, including total and differential WBC counts and platelet count, urinalysis, Westergren sedimentation rate, quantitative C-reactive protein (CRP), CH_{50} (or C4), C3, ANA, and anti-dsDNA antibody titers, should be obtained. Cultures of blood and urine are mandatory, and clinicians should have a low threshold for culturing CSF and other fluids when indicated. These cultures are particularly critical if no source of fever is apparent after a complete physical examination. In most cases, children with SLE who develop fever without a readily apparent source should be given antibiotics pending culture results; abnormal splenic function places them at increased risk of rapid development of bacteremia and overwhelming sepsis.

Renal Complications. Renal disease is a major cause of morbidity in patients with SLE, so its presence and severity must be established at the time of diagnosis and renal function regularly monitored thereafter. Clinical manifestations of lupus nephritis are often minimal. Gross hematuria or headache resulting from hypertension may be warning signs. In the presence of nephrotic syndrome, the child may be edematous. Laboratory evidence of renal disease includes proteinuria, hematuria, hyposthenuria, casts, and elevated levels of BUN and creatinine. The presence of these findings in a patient with known SLE requires a more thorough investigation, including estimation of the protein in a 24-hour urine collection, creatinine clearance, measurement of C3, ANA, and anti-dsDNA antibodies, and renal biopsy. In a patient with SLE and documented renal disease, hospitalization is necessary only in the presence of rapidly worsening renal status, acute renal failure, hypertensive crisis, or severe complications of therapy.

Treatment of renal disease is aimed at preserving renal function while minimizing medication toxicity. Active disease may often be managed with the usual dosages of corticosteroids (prednisone 1 to 2 mg/kg per day). In the presence of progressive renal failure, the patient should be hospitalized for more aggressive therapy. This generally includes divided doses of IV corticosteroids with or without an immunosuppressive agent such as cyclophosphamide. “Pulse” therapy with methylprednisolone (30 mg/kg in 50 mL of D5W) may be indicated in the presence of rapidly progressive renal disease. Plasmapheresis has been used in the treatment of severe lupus nephritis, especially in patients who fail to respond to conventional therapy with corticosteroids and cytotoxic agents. Although this modality appears to have little effect on long-term outcome, acute disease flare-ups may be rapidly controlled by removing pathogenic autoantibodies, immune complexes, and cytokines. Each of these therapies is associated with significant toxicity, so their use should be limited to centers experienced in the care of acutely ill children with SLE.

Hematologic Complications. Anemia is common in SLE and may have many causes. The most common type is the normocytic, normochromic anemia of chronic disease. Anemia from GI blood loss may be secondary to vasculitis or caused by irritation of the GI tract. These patients often have symptoms of GI distress and occult blood in the stool. They require further investigation, but the urgency depends on the severity of the bleeding.

Hemolytic anemia in SLE may be related to the disease itself (antierythrocyte antibodies) or to medications. Patients with hemolytic anemia often present with pallor, fatigue, jaundice, splenomegaly, and dark-colored urine. Occasionally, these patients develop symptoms of cardiorespiratory distress and CHF after severe hemolysis and a rapid fall in hemoglobin. Laboratory investigation of anemia in SLE should include CBC, reticulocyte count, and examination of the blood smear for red cell size and shape, nucleated red cells, and fragmented red cells. Serum levels of iron, iron-binding capacity, free erythrocyte protoporphyrin, and bilirubin should be obtained. The antibody responsible for autoimmune hemolytic

anemia is of the “warm” variety, most commonly of the IgG type; IgM type antibody is present in only a small percentage of cases. These red cell–bound antibodies may not be demonstrated by the standard Coombs' test, so more sensitive assay systems may have to be used.

Mild to moderate anemia of any cause may be managed using oral iron preparations and by treatment of the primary disease. Children with a hematocrit of less than 20% or compromised cardiac function often require admission to the hospital. Corticosteroids are the most effective agents for the control of autoimmune hemolytic anemia in SLE. Prednisone at 2 mg/kg per day is the preferred initial treatment. Transfusion may be needed for children with a rapidly dropping hemoglobin concentration or CHF.

Leukopenia occurs in about 50% of patients with SLE. It may be caused by a reduction in granulocytes, lymphocytes, or both. Granulocytopenia may be secondary to drugs used in the treatment of SLE or, less commonly, to disease-related destruction of granulocytes. Febrile children with absolute granulocyte counts of less than 1000/mm $_3$ should be admitted for empiric antibiotic coverage, pending results of further studies because they are at higher risk of severe infections.

Thrombocytopenia occurs in approximately 25% of patients with SLE; conversely, more than 5% of children presenting with idiopathic thrombocytopenic purpura (ITP) eventually develop SLE. The usual causes of thrombocytopenia are circulating antibodies to platelets or drug-induced bone marrow suppression. Infection should always be considered as a possible cause. The presence of purpura and ecchymoses requires immediate investigation. Hemorrhage into one of the internal organs, a sudden drop in hemoglobin, and platelet counts of less than 20,000/mm $_3$ are the usual indications for admission to the hospital. Studies should include CBC, examination of the peripheral blood smear, and appropriate cultures. At times, bone marrow examination and testing of serum for antiplatelet antibodies may be helpful in determining the cause of reduced platelet counts.

Patients with SLE are at risk of bleeding from any mucosal surface because of vasculitic ulceration, impaired hemostasis, thrombocytopenia, or a combination of these factors. Patients with life-threatening *epistaxis* may require local packing and platelet replacement in addition to high-dose corticosteroids. Severe pulmonary hemorrhage may necessitate general supportive measures such as transfusions, ventilatory assistance and bronchial lavage, as well as treatment of the underlying pathologic condition with high-dose corticosteroids, immunosuppressive agent, and plasmapheresis.

Although rare, *DIC* may occur in patients with SLE, with or without an associated infection. Therefore, patients with thrombocytopenia and severe bleeding should be investigated with prothrombin time (PT), partial thromboplastin time (PTT), fibrin split products, and examination of the peripheral smear. Lupus appears to predispose patients with SLE to a particularly malignant form of thrombotic thrombocytopenic purpura. Reported mortality rates are extremely high despite general support in ICUs, as well as aggressive treatment with pheresis and immunosuppression.

The presence of a circulating *lupus anticoagulant* does not lead to a bleeding diathesis unless associated with significant thrombocytopenia; on the contrary, these patients are at increased risk of deep venous or arterial thromboses. Prolongation of PTT and chronic false-positive serologic test results for syphilis are the usual clues to the presence of these autoantibodies. Specialized studies such as mixing assays and the Russell viper venom test (RVVT) may confirm the diagnosis. Significant thrombosis or pulmonary embolus in a child with SLE is an indication for immediate anticoagulation with heparin, followed by oral warfarin or subcutaneous low-molecular-weight heparin, pending assays for these circulating anticoagulants.

Neurologic Complications. *Seizures* (see Chapter 70) and altered states of consciousness (see Chapter 13 and Chapter 83) are the most common manifestations of CNS involvement in SLE. Other possible causes of seizures in patients with SLE include hypertension (from the disease itself or as a complication of corticosteroid therapy), infection (acute or indolent meningitis or abscess), and uremia. Coma is not a primary manifestation of SLE but may result from meningitis or CNS hemorrhage secondary to thrombocytopenia. Therefore, patients with SLE who develop seizures or altered states of consciousness require admission for evaluation, which should include a thorough examination with special attention to blood pressure and neurologic findings, as well as the following investigations: CBC with differential and platelet counts, electrolytes, BUN, creatinine, urinalysis, and lumbar puncture (including measurement of opening pressure and CSF cultures). The CSF should be sent for routine studies and for special stains to look for opportunistic organisms such as fungi and acid-fast bacilli.

No study is perfectly sensitive for detecting lupus cerebritis. Measurement of the IgG index [(CSF IgG/Serum IgG) (CSF Albumin/Serum Albumin)] may allow estimation of IgG synthesis within the blood–brain barrier; although this is increased in a variety of chronic infections, it also typically rises in active CNS lupus. In addition, an electroencephalogram (EEG), MRI study, and CT scan with contrast may facilitate elucidation of the cause of CNS signs in children with lupus.

IV diazepam (0.2 to 0.3 mg/kg) is the preferred drug for the initial management of seizures, followed by phenytoin for maintenance of seizure control. Phenytoin is preferred over phenobarbital because the latter may alter mental status acutely. If CNS manifestations are considered to be secondary to active vasculitis, IV corticosteroid therapy should be initiated. In the presence of deteriorating mental function, “pulse” methylprednisolone (30 mg/kg in 50 mL of D5W), IV cyclophosphamide, or plasmapheresis may be beneficial.

Other manifestations of CNS involvement, such as psychosis, also may need inpatient evaluation. *Listeria monocytogenes* may cause an indolent meningitis that is clinically indistinguishable from organic brain syndromes. Similarly, it may be difficult to determine whether psychosis is secondary to corticosteroid therapy, especially because steroids are most likely to induce psychiatric symptoms in patients with underlying psychiatric disease. Clinicians should not hesitate to aggressively pursue a diagnostic evaluation, including lumbar puncture and imaging procedures, so that appropriate therapy may be instituted as expeditiously as possible. When psychosis resulting from SLE is suspected, psychotropic drugs (e.g., haloperidol 0.025 to 0.05 mg/kg per day in divided doses) may be used along with large doses of corticosteroids for 1 to 2 weeks. If no improvement is seen, the steroid dosage may be reduced gradually in an attempt

to rule out steroid-induced psychosis.

Transverse myelitis is a rare complication of SLE thought to result from vascular compromise of the spinal cord. Patients note acute onset of pain and weakness, and they may develop incontinence. Physical examination is remarkable for weakness or flaccid paralysis below the level of the functional transection. In a high percentage of cases, the process is associated with a circulating lupus anticoagulant or antiphospholipid antibodies. Prognosis is related to the duration of symptoms before initiation of therapy, and favorable outcomes are possible only with urgent intervention. Thus, once infection, epidural abscess, and hematoma are excluded with appropriate imaging procedures and lumbar puncture, pulse doses of IV methylprednisolone (30 mg/kg over 1 to 2 hours) plus anticoagulation with IV heparin are begun. Early addition of potent immunosuppressive agents such as IV cyclophosphamide (500 to 750 mg/m_2 intravenously) is often essential.

Pulmonary Complications. Pleural effusion is the most common pulmonary manifestation of SLE. However, pulmonary infections and hemorrhage present more acute management issues. *Pleural effusion* is often bilateral and small, although occasionally, it may be massive. The child is often ill with acute manifestations of systemic disease, such as fever, fatigue, and poor appetite. Symptoms may be minimal (cough, chest pain, and mild tachypnea) or absent. Chest pain aggravated by deep breathing or coughing is suggestive of pleurisy, although pain may be absent. In the presence of a moderate or large effusion, the patient may have dyspnea and tachypnea. On auscultation, a pleural rub may be heard. A radiograph is essential to determine the extent of the effusion.

If the physician knows the child and has no concerns about infection, hospitalization may not be necessary. Increasing the corticosteroid dosage or adding indomethacin (0.5 to 2 mg/kg per day) or tolmetin sodium (20 to 40 mg/kg per day) may be adequate therapy, but arrangements must be made for close follow-up. If the cause of a pleural effusion is in doubt, pleural fluid should be aspirated. Usually, pleural effusions caused by SLE are exudates that show elevated protein levels and cell counts, and decreased levels of lactic dehydrogenase. The presence of fluid is easily demonstrated clinically (diminished breath sounds and dullness to percussion), and the radiograph of the chest establishes the extent of the effusion. Patients with large effusions should be admitted to the hospital for further observation and management. Thoracentesis is often necessary 1) to relieve symptoms, 2) for diagnosis, and 3) to reveal any underlying lesions obscured by the effusion.

Pulmonary hemorrhage is a potentially catastrophic complication of SLE, particularly in the pediatric age group. Early recognition and treatment are critical. A hemorrhage may be related to the disease itself (e.g., pulmonary vasculitis), to the treatment (e.g., drug-induced thrombocytopenia), or to an infection (e.g., aspergillosis). Clinical features of patients with pulmonary hemorrhage include hemoptysis, tachypnea, tachycardia, and dyspnea; rapid deterioration may result in asphyxia within 24 to 48 hours.

Evaluation of patients with unexplained respiratory symptoms should include a chest radiograph. In cases of pulmonary hemorrhage, this shows fluffy infiltrates resembling pulmonary edema. CBCs often reveal a dramatic drop in hemoglobin and a low platelet count. Diagnosis of a pulmonary hemorrhage may be confirmed by pulmonary function testing, including diffusing capacity of carbon monoxide (DL_{CO}). Intra-alveolar blood increases CO absorption and therefore is one of the few conditions that results in an abnormally *high* DL_{CO}. Bronchoalveolar lavage or lung biopsy still may be needed in some patients in whom *Pneumocystis* or *Aspergillus* infection remains a concern.

Management should include transfusions and high dosages of IV corticosteroids. If bleeding is related to thrombocytopenia, platelet transfusion is indicated. Tracheal lavage with epinephrine, oxygen therapy, and intubation with positive end-expiratory pressure (PEEP) ventilation may be needed, depending on the severity and progression of the process.

Occasionally, children with lupus may develop interstitial pneumonitis. Such patients are often ill with high fever, chest pain, cough, and dyspnea. On examination, rales may be heard throughout the chest. Radiographs show a diffuse alveolar infiltrate, unilateral or bilateral, with or without effusion. Cultures of the blood and respiratory secretions, bronchial washings, transtracheal aspirate, or lung biopsy may be necessary to exclude infection. Supportive therapy should include increased concentrations of oxygen, adequate pulmonary toilet, and antipyretic drugs. Measures used to control other manifestations of SLE, including corticosteroids or immunosuppressive agents, may lead to dramatic improvement.

Gastrointestinal Complications. Peritonitis and GI hemorrhage are emergencies associated with SLE. Drug-induced gastric ulcer and pancreatitis also occur. The nature of an intra-abdominal catastrophe is often difficult to determine. Plain radiographs of the abdomen, ultrasonogram, MRI, CT scanning, peritoneal aspiration, and rarely, even exploration may be required to rule out surgical conditions.

Peritonitis may be a feature of the disease itself (serosal inflammation) or may be caused by secondary infection or visceral perforation. Patients with SLE and peritonitis should be admitted at once. Symptoms and signs associated with peritonitis are pain in the abdomen, fever, vomiting, diarrhea, abdominal distension, diffuse tenderness, rigidity of the anterior abdominal wall, and hypoactive or absent bowel sounds on auscultation. However, all of these findings of peritoneal irritation may be masked by corticosteroid therapy.

A radiograph of the abdomen may show dilation of intestinal loops with edema of the wall of the intestines, free air in the peritoneal cavity, or evidence of ileus or obstruction. Aspiration of the peritoneal fluid under strict aseptic conditions is essential if the cause of the peritoneal effusion is in doubt. The fluid should be sent for Gram stain and culture. Cell counts of more than 300/mm_3 should be considered indicative of infection. Peritonitis secondary to GI perforation should be treated aggressively with surgery and IV antibiotics. Peritonitis of the serous type (a feature of SLE) may be treated with one of the NSAIDs; corticosteroids may be added if the response to the anti-inflammatory medication is inadequate or if there is additional evidence of active systemic disease. Prolonged use of both NSAIDs and corticosteroids may lead

to more problems from gastric irritation and/or ulceration.

An acute abdomen in SLE may be the result of bowel ischemia, infarction, or perforation, in addition to the occasional unrelated complication such as intussusception or appendicitis. Symptoms of an acute abdomen include sudden onset of abdominal pain, vomiting, and diarrhea that may be bloody, although corticosteroids may obscure all signs and symptoms. The patient may go into shock rapidly. Localized abdominal tenderness, guarding, and rigidity with absent bowel sounds are often present. Rectal examination must be performed to localize tenderness, palpate any masses, and obtain stool for occult blood testing. The patient should be well hydrated and shock promptly treated in an intensive care setting. A CBC, serum electrolytes, and serum amylase determination should be obtained at once. A plain radiograph of the abdomen may show air–fluid levels or free air under the diaphragm. Abdominal ultrasound or CT may allow greater diagnostic precision. Paracentesis is essential to rule out infection or hemorrhage secondary to perforation. Gram stain and culture of peritoneal fluid, in addition to blood culture, should be obtained immediately. Infection should be treated aggressively, and the ischemic or perforated area of intestine surgically repaired.

Pancreatitis must be considered in children with SLE and abdominal symptoms. SLE is the most common medical cause of pancreatitis in children, and corticosteroids are the medication most often associated with this complication. If the serum amylase is normal and pancreatitis is suspected, one should obtain an amylase clearance. An amylase:creatinine clearance ratio of greater than 5 suggests pancreatitis. If pancreatitis is secondary to SLE, corticosteroid therapy is used. If it is secondary to medications, attempts should be made to withdraw them gradually. During this slow process, the patient may have to be maintained on parenteral hyperalimentation.

GI hemorrhage may be secondary to NSAIDs (stomach), vasculitis of the GI tract (small intestines), or thrombocytopenia. Symptoms include abdominal pain, hematemesis and melena if the bleeding is in the upper GI tract, and abdominal pain with hematochezia or occult blood in the stool if bleeding is from the lower GI tract. The patient may develop massive bleeding, leading to shock. Immediate studies to be obtained in the emergency department include hematocrit, CBC, serum electrolytes, and blood type and crossmatch. Stool obtained by rectal examination should be tested for occult blood even if the stool appears frankly bloody. If bleeding from a gastric ulcer is suspected, endoscopy can confirm the diagnosis. Therapy for a bleeding gastric ulcer includes volume replacement, hourly antacid administration, and H_2 blockers (e.g., cimetidine 20 to 40 mg/kg per day, maximum 1200 mg/day).

If active bleeding caused by vasculitis is suspected, celiac axis angiography or endoscopy with deep intestinal biopsies are required for confirmation. GI vasculitis is rare in pediatric lupus, and most commonly occurs in the setting of chronically active disease. Children typically have an associated peripheral neuropathy, as well as chronic weight loss, anorexia, and inanition.

Cardiac Complications. Pericarditis and myocarditis are two of the important cardiac complications of SLE that may require emergency care. The features of pericarditis are similar to those described in JRA and include chest pain, dyspnea, inability to lie flat in bed, and pericardial friction rub. In the presence of cardiac tamponade, additional signs supervene (weak pulse, distended neck veins, distant heart sounds, and pulsus paradoxus of more than 20 mm Hg). Pericarditis without significant hemodynamic effects may be managed with NSAIDs or corticosteroids. Massive effusion leading to tamponade requires pericardiocentesis in addition to treatment with corticosteroids, which may be injected directly into the pericardium at the time of pericardiocentesis.

Myocarditis is characterized by resting tachycardia out of proportion to fever, cardiomegaly without an effusion, CHF, ST-T wave changes on ECG, and arrhythmias. These patients should be on strict bed rest with monitoring. In addition to treatment of the basic disease, digoxin and diuretic therapy are often indicated.

Raynaud's Phenomenon. Raynaud's phenomenon (RP) is characterized by triphasic color changes of the extremities upon exposure to cold. These color changes proceed from cyanosis to blanching because of microcirculatory compromise and resolve with erythema caused by reactive hyperemia. Severe episodes of RP may cause excruciating pain in the extremities or even digital ulceration and autoamputation. Poor circulation impairs wound healing and clearing of infections, so patients with paronychia or digital cellulitis may require admission for IV antibiotics.

Prophylactic techniques to improve digital circulation (avoidance of cold exposure, biofeedback) are the cornerstones of treatment of RP. Calcium channel blockers (e.g., slow-release nifedipine 30 to 180 mg/day) may decrease the frequency and severity of attacks, whereas oral and topical vasodilator drugs (e.g., prazosin, nitroglycerin) or medical or surgical sympathetic blockade may be necessary during severe episodes. Cases of impending gangrene may also be treated with prostacyclin analogs such as Iloprost. These medications may cause dramatic vasodilation and result in pulmonary edema or cardiac arrhythmias; therefore, they should be used by experienced clinicians only.

Hypertension. Hypertension may be a result of effects of SLE on systemic vasculature, a concomitant of renal involvement, or secondary to steroid therapy. Mild to moderate hypertension is usually controlled by combinations of diuretics, vasodilators, and a- or b-blockers, whereas angiotensin-converting enzyme (ACE) inhibitors are effective for renovascular hypertension. Diazoxide (5 mg/kg) given intravenously as rapidly as possible as a single bolus is the preferred drug for the treatment of hypertensive encephalopathy.

Ocular Complications. Children with SLE may develop blurring or loss of vision. When this is accompanied by headache and vomiting, the differential diagnosis includes meningitis (both septic and aseptic), hypertension, and pseudotumor cerebri. An ophthalmologic consultation should be obtained to exclude other complications such as retinal vasculitis or retinal vascular occlusion. The patient should have an exhaustive neurologic evaluation, and examination of the spinal fluid should be performed with great caution after an emergency CT scan has been obtained. Gradual periodic release of CSF pressure is the treatment of choice for pseudotumor cerebri. High-dose corticosteroid therapy should be added if the intracranial hypertension is believed to result from SLE, whereas it should be tapered if the pseudotumor is secondary to steroid toxicity.

JUVENILE DERMATOMYOSITIS

Background

Juvenile dermatomyositis (JDMS) is a rare rheumatic disorder characterized by inflammation of the skin and striated muscle. The disease has a wide spectrum, from a mild form involving mainly the skin to a severe vasculitic type with a rapidly fulminating course. JDMS may be conceptualized as passing through four overlapping phases that typically last for 2 to 5 years but may persist indefinitely: 1) a prodromal phase of nonspecific aches and pains, 2) a phase of progressive muscle weakness, 3) a phase of persistent active disease, and 4) an indolent phase with development of contractures and calcinosis. The goal of therapy is to compress this natural history into a shorter time period that ends before irreversible sequelae occur.

As with other idiopathic rheumatic diseases of childhood, diagnosis of JDMS depends on fulfillment of clinical criteria. Bohan and Peter's criteria for dermatomyositis (DM)/polymyositis (PM) in adults are typically used for diagnosing this condition, and they are given in Table 101.6. In fact, the condition in children differs significantly from that in adults; it includes a more prominent degree of vascular inflammation and scantier evidence of circulating autoantibodies, and it rarely accompanies malignancies. Furthermore, in children, the appearance of inflamed muscle and soft tissues on MRI is essentially pathognomonic, eliminating the need for muscle biopsy or electromyogram (EMG) to confirm the diagnosis (Fig. 101.7). Nonetheless, in the absence of alternative criteria, Bohan and Peter's scheme remains the gold standard for classification of children with inflammatory myopathies.

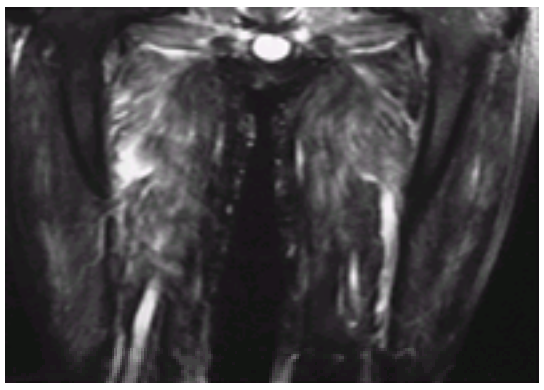

FIGURE 101.7. Coronal fast multiplanar inversion recovery image of the thighs shows areas of increased signal intensity, especially in the adductor muscle groups, in a patient with dermatomyositis.

1. Symmetric weakness of the proximal limb muscles and of anterior neck flexors	
2. Evidence of necrosis of type I and II fibers on muscle biopsy	
3. Elevation of serum levels of skeletal muscle enzymes—creatine phosphokinase and aldolase	
4. Short, small, polyphasic motor unit potentials with fibrillation; insertional irritability; and high-frequency repetitive discharges on electromyography	
5. Skin rash—characteristic heliotrope rash, scaly erythematous rash over extensor aspects of the joints, and periungual erythema	
Definite:	4 criteria (PM) 3 or 4 criteria + rash (DM)
Probable:	3 criteria (PM) 2 criteria + rash (DM)
Possible:	2 criteria (PM) 1 criterion + rash (DM)

From Bohan A, Peter JB: Polymyositis and dermatomyositis. N Engl J Med 1975;292:344.

Table 101.6. Criteria for the Diagnosis of Dermatomyositis (DM)/Polymyositis (PM)

Pathophysiology

Microscopically, the skin in JDMS shows dermal atrophy, obliteration of appendages, and lymphocytic infiltration. Characteristic lesions in the muscle include a mixture of degenerating and regenerating muscle fibers, variations in muscle fiber size, perivascular lymphocytic infiltration, and perifascicular atrophy of muscle fibers. Angiopathy involving small arteries, venules and capillaries of the skin, muscle, fat, and GI tract is characteristic of childhood DM. Viral infections, particularly coxsackie B, vasculitis caused by immune complex deposition, and cell-mediated cytotoxicity against muscle fibers, have all been implicated in the pathogenesis of JDMS. Associations of juvenile DM with the presence of HLA-B8/DR3 antigens have also been reported. Theories of pathogenesis thus center on an as yet unexplained perpetuation of muscle inflammation in susceptible hosts following what is generally a self-limited illness in most children.

Clinical Manifestations

The onset of JDMS is often insidious, with aches and pains in the limbs, low-grade fever, general weakness, and edema of the hands, feet, and eyelids. A diffuse and nonspecific rash may be seen. This prodromal stage evolves into the acute phase, when the characteristic features of JDMS become evident. Classical skin manifestations include a violaceous heliotrope rash in the periorbital region and occasionally on the forehead; dusky red or atrophic lesions over the extensor aspects of the knees, elbows, and knuckles (Gottron's papules); and periungual erythema (Fig. 101.8). Skin findings may

precede or follow the onset of muscle weakness.

FIGURE 101.8. Atrophic, hypopigmented lesions overlying extensor surfaces of interphalangeal joints, with periungual erythema typical of juvenile dermatomyositis.

The muscular involvement is characterized by pain, tenderness, and weakness of proximal muscles in a symmetric fashion with prominent involvement of the anterior neck flexors and sparing of the facial muscles. The disease may progress to involve the muscles of the palate and pharynx, resulting in regurgitation, nasal voice, and aspiration. Involvement of the respiratory muscles may lead to a poor cough, pneumonia, and respiratory failure. Risk of GI hemorrhage and perforation are increased at this stage and are associated with abdominal pain, hematemesis, and melena.

The clinical course of JDMS is variable. Traditionally, patterns such as “limited” or “monocyclic,” with a single period of disease activity, were differentiated from a “chronic” or “polycyclic” pattern of exacerbations and remissions. It now appears that these distinctions are an artifact of inadequate therapy, however, and with newer approaches to treatment, disease manifestations may be controlled within a few months in most patients.

Children who continue to have florid or smoldering muscle inflammation for more than 6 to 12 months are at risk of developing late complications of JDMS. These complications include pronounced muscle wasting, contractures, lipodystrophy, and pigmentary changes of the skin. The rash over the extremities often becomes dry, scaly, and atrophic. Subcutaneous calcifications have historically occurred in up to 30 to 40% of children during this phase, although aggressive treatment of inflammation from the onset of JDMS dramatically lowers this figure. Calcifications are most typically discrete nodules around large joints, but a diffuse encasement of the soft tissues by a shell of calcium, called calcinosis universalis, may occur. Occasionally, children pass through the early stages insidiously and come to the attention of the physician with contractures and calcinosis.

Laboratory Features

Weakness is a consistent manifestation of JDMS, but it is a late, variable, and subjective clinical sign. Objective evidence of muscle inflammation should also be sought by measuring serum levels of muscle enzymes that are released into the circulation when myocytes are injured. A wide variety of enzymes may be elevated in JDMS, including creatine kinase (CK), aldolase, lactate dehydrogenase (LDH), and transaminases (ALT and AST). Interpretation of these markers must be done with caution, however, because none is specific for muscle. Elevated levels may be derived from damage to a variety of other tissues, including hepatocytes, brain cells, and the GI tract. Furthermore, for unknown reasons, many children do not reliably demonstrate elevated muscle enzymes despite significant myositis. This is particularly true during later stages of the disease, when LDH and aldolase may rise during a disease flare-up, but CK levels often remain normal.

Because JDMS is a microangiopathic process, disease activity may also be demonstrated through the presence of elevated levels of factor VIII–related antigen (von Willebrand factor antigen), which is released by damaged endothelial cells. On the other hand, evidence of systemic inflammation may be absent, and acute phase markers (including ESR and CRP) and CBCs may be normal. In particularly difficult cases, MRI of the thighs may be the most sensitive method of documenting muscle inflammation (Fig. 101.7). Evidence of cardiac involvement should also be sought, particularly with an ECG and an echocardiogram. Serologic markers of myocardial involvement are unreliable because both the CK MB fraction and troponin level are often elevated in JDMS due to myoblast proliferation in skeletal muscles.

Management

General Management

The sine qua non of treating JDMS is aggressively controlling muscle inflammation. The more rapidly markers of myocyte damage, such as CK and aldolase, can be normalized, the less the chance that acute and chronic complications will occur. During the initial evaluation of JDMS, it is essential to monitor the function of the palatopharyngeal and respiratory muscles; palatal weakness increases the risk of aspiration. Eating only in the upright position, frequent suctioning, or placement of a nasogastric tube may be necessary to avoid aspiration. Support of weak muscles (e.g., wearing a soft neck collar while riding in automobiles) may also be necessary to avoid complications until children regain their strength.

Recognition of the importance of expeditious disease control is leading to modifications in the medical management of JDMS. Thus, virtually all children with clinical or biochemical evidence of muscle inflammation begin treatment with prednisone at a dosage of 1 to 2 mg/kg per day in two or three divided doses as they traditionally have. If muscle

enzymes, weakness, or GI symptoms do not rapidly improve, however, or if significant steroid toxicity develops, other agents are introduced within 4 to 8 weeks. IV methylprednisolone (30 mg/kg, maximum 1.5 g) infused over 1 to 2 hours ("pulse therapy") is the agent of choice, even when high oral dosages of corticosteroids are ineffective. This drug may prove effective because it bypasses the GI tract, where absorption of orally administered medications may be impaired because of vasculitis.

In more recalcitrant cases, it may be necessary to add cytotoxic drugs such as cyclophosporine (2 to 7 mg/kg per day), azathioprine (1 to 3 mg/kg per day), or methotrexate (0.5 to 1.0 mg/kg weekly). Plasmapheresis may be beneficial in particularly severe cases. Under all circumstances, the goal is to rapidly control disease activity while minimizing toxicity from medications. Fortunately, active disease generally does not recur if a complete remission can be induced and maintained for 1 to 2 years.

Management of Complications and Emergencies (Table 101.7)

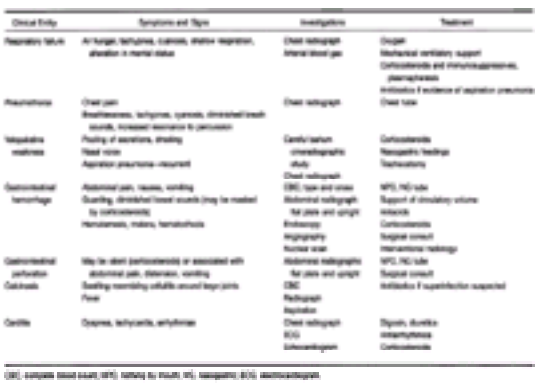

Table 101.7. Complications of Juvenile Dermatomyositis

The most serious emergencies in JDMS relate to the respiratory and GI tracts. In addition, complications occur as a result of therapy with corticosteroids (e.g., infection, GI hemorrhage).

Respiratory Complications. Respiratory emergencies seen in childhood DM have diverse causes. Entities to be considered include 1) aspiration pneumonia secondary to weakness of velopalatine muscles; 2) atelectasis and pneumonia secondary to difficulty in clearing secretions as respiratory muscles become involved; 3) respiratory failure secondary to profound involvement of respiratory musculature, including the diaphragm; 4) progressive interstitial lung disease; and 5) opportunistic infection (tuberculosis, fungi, viruses, or *Pneumocystis*) in the immunocompromised host.

The history should provide clues for differentiating between these possibilities. On physical examination, the child with a respiratory complication is often acutely ill with an elevated temperature. Because fever also may occur with active DM, fever caused by infection must be differentiated from fever caused by underlying disease. The patient with respiratory complications is often dyspneic and tachypneic and has a weak cough with impaired production of sputum. Pooling of secretions in the mouth and a nasal voice should suggest the presence of palatal weakness. Each breath is shallow, with poor air entry on auscultation. The child cannot complete a sentence in one breath and often pauses between words. On auscultation, crackles may be heard. Cyanosis and alteration of consciousness imply impending respiratory failure.

Children with JDMS who develop respiratory problems are usually hospitalized for observation and diagnosis. Those at risk of developing respiratory failure should be cared for in an ICU. Preliminary investigations should include a CBC, urinalysis, serum electrolytes, measurement of muscle enzymes (including CK, aldolase, and LDH), and chest radiograph. Depending on the seriousness of the symptoms and the cooperativeness of the child, blood gas analysis and pulmonary function studies may be obtained. These latter studies should be compared with baseline pulmonary function tests (PFTs) on an individual basis because more than two-thirds of children with DM show restrictive disease and a diffusion abnormality.

If the cause of the respiratory deterioration remains in doubt, more sensitive tests of disease activity, including factor VIII–related antigen and MRI, may be necessary to determine whether more aggressive control of the underlying myositis is necessary. Corticosteroids are the preferred treatment for weakness of respiratory muscles and interstitial lung disease. If the weakness seems to be worsening, maximum efficacy may be obtained with pulse dose methylprednisolone 30 mg/kg (maximum of 1.5 g) in a single IV bolus dose of 50 mL of D5W over 1 to 2 hours. During this pulse therapy, blood pressure and cardiac rhythm should be monitored and the infusion stopped if sudden hypertension or hypotension or a rhythm disturbance occurs. Plasmapheresis is reserved for children who deteriorate even after pulse steroid therapy. Frequent suctioning, nasogastric feeding, and occasionally, tracheostomy may be necessary to avoid aspiration pneumonia.

Aspiration pneumonia can be recognized on a clinical and radiographic basis. A chest radiograph with a severe interstitial or reticulonodular pattern may indicate progression of underlying lung disease or opportunistic infection. Lung biopsy may be helpful in such situations. If pulmonary problems are suspected to result from infection, treatment with IV antibiotics should be initiated after appropriate cultures are obtained. In addition, sufficient corticosteroids (three times physiologic need) are given to cover the child for iatrogenic adrenal insufficiency if he or she has recently received high dosages of steroids.

Pneumothorax is another complication known to occur during the course of childhood DM. The usual symptoms are sudden onset of chest pain and tachypnea. Physical examination shows deviation of the trachea to the opposite side of

the chest, and increased resonance and diminished breath sounds on the affected side. A radiograph of the chest shows air in the pleural cavity. A chest tube should be placed and connected to underwater seal.

Gastrointestinal Complications. Vasculitic changes characterized by intimal hyperplasia, and arteriolar occlusion by fibrin thrombi, are characteristic of severe or poorly controlled JDMS. Arteries and veins of the skin, muscles, and GI tract may be involved. Resultant ulcerations and perforations may occur anywhere from the esophagus to the large intestine, and they may disrupt the integrity of the integument. Symptoms and signs of these complications depend on the site of the lesion. For example, bleeding from the esophagus is uncommon, but perforation may cause mediastinitis. On the other hand, bleeding from ulceration of the stomach or duodenum typically leads to abdominal pain with vomiting and melena. If the bleeding is severe, hematemesis with a sudden drop in the hemoglobin will be the presenting manifestation. Laboratory studies to be obtained include a CBC, electrolytes, and BUN. Endoscopy may prove useful in locating the site of bleeding. Treatment of upper intestinal hemorrhage includes support of circulatory volume and hematocrit, antacids, and H_2 blockers (e.g., cimetidine 20 to 40 mg/kg per day, maximum 1200 mg).

Evidence of bleeding from the lower portion of the GI tract includes abdominal pain, vomiting, a distended abdomen, and melena or bright red blood in the stool. The hematocrit can fall precipitously, and radiographs of the abdomen may show free air in the peritoneum. If bleeding is active, a technetium scan to locate the area of hemorrhage is the initial step. This may be followed by an angiogram to localize the actual vessel that is bleeding. The details of the management of hemorrhage from the GI tract are discussed under SLE and in Chapter 93.

In a patient with JDMS, intestinal perforation may go unnoticed and present with pneumatosis intestinalis. This finding may also precede clinical perforation and pneumoperitoneum. Thus, any patient with JDMS and persistent abdominal pain should be examined radiographically for the presence of pneumatosis intestinalis. In the presence of acute perforation, usual physical findings are abdominal tenderness, guarding of the abdominal wall, and distant or absent bowel sounds. It should be stressed that corticosteroids may mask these physical findings. Supine and erect abdominal radiographs are indicated to demonstrate intramural gas or subdiaphragmatic air. Patients with this diagnosis require admission to the hospital and emergent surgical evaluation.

Calcinosis. During the period of formation of subcutaneous calcification, children with JDMS may develop high fever, chills, and one or more areas of swelling under the skin. The inflammation caused by the subcutaneous calcium deposit may be indistinguishable from that of cellulitis or abscess formation, with warmth, erythema, and tenderness. Eventually, the lesion may spontaneously extrude calcium, at which time the fever often subsides. Although this is the natural history of subcutaneous calcifications, it is often hard to exclude an infectious cause for the swelling. If doubt exists, needle aspiration of the site may be performed and the fluid examined for calcium crystals and organisms. In the face of uncertainty, it is best to treat for infection with antibiotics until culture reports are available. Incision and drainage or surgical debridement should be avoided, however, because the inflamed skin rarely heals satisfactorily.

Cardiac Emergencies. One of the less common complications of childhood JDMS is myocarditis, although ECG abnormalities may be seen in up to 50% of children. Tachycardia out of proportion to fever may be the earliest evidence of this complication. Involvement of the conduction system by edema and fibrosis leads to electrical abnormalities and arrhythmias. All patients with myocarditis should be admitted for an evaluation that includes an ECG, chest radiograph, and echocardiogram. Supportive management includes judicious and careful use of diuretics and cardiotonic drugs while aggressively treating the primary disease.

SCLERODERMA

Background

Systemic sclerosis (SS) is an uncommon disorder occurring in 2 to 12 adults per million per year. It is even less common in children. Morphea and linear scleroderma are more likely to be seen than SS in this age group. Various conditions included under the term scleroderma are given in Table 101.8.

I. Systemic Sclerosis
  A. With diffuse skin thickening
  B. With limited skin thickening (including CREST syndrome)
  C. With overlapping manifestations of other connective tissue disease, including systemic lupus erythematosus, dermatomyositis, rheumatoid arthritis
II. Chemically Induced Conditions
  A. Systemic syndromes seen with vinyl chloride, bleomycin, trichloroethylene
  B. Localized syndromes seen with eosinophilia-myalgia, toxic oil, pentazocine, graft-versus-host disease
III. Localized Scleroderma
  A. Morphea
  B. Linear (includes "en coup de sabre")
  C. Eosinophilic fasciitis
IV. Pseudosclerodermа
  A. Edematous as associated with diabetes mellitus, myxedema
  B. Indurative as in porphyria cutanea tarda, phenylketonuria, acromegaly
  C. Atrophic as in progeria, acrodermatitis chronica atrophicans

Modified with permission from Medsger TA Jr, Steen V. Systemic sclerosis and related syndromes. In: Schumacher HR, ed. Primer on the Rheumatic Diseases. 10th ed. Atlanta, Arthritis Foundation;1993.
CREST, calcinosis, Raynaud's esophageal dysfunction, sclerodactyly, and telangiectasia.

Table 101.8. Classification of Scleroderma and Related Conditions

Pathophysiology

The most characteristic microscopic feature of affected areas of the skin is increased thickness and density of collagen in the dermis. In addition, flattening of rete pegs, mononuclear cell infiltrate around small blood vessels, obliteration of skin

appendages, and hyalinization and fibrosis of arterioles are seen.

The cause of this disease is unknown. Increased collagen production by fibroblasts, perhaps in response to disordered immune regulation and cytokine release, appears to be a final common pathway for a clinical entity with numerous genetic and environmental triggers. Similarities between this disorder and graft-versus-host disease after bone marrow transplantation, and to chronic Lyme disease (acrodermatitis chronica atrophicans) have suggested many areas of research. However, clear understanding of the underlying abnormalities in scleroderma remains elusive.

Clinical Manifestations

Localized scleroderma is more common in children than in adults. The lesions may be one of three types. Morphea is a focal ivory-white patch with a violaceous or erythematous rim; it is often a single lesion on the trunk, although generalized morphea also occurs in children. The linear form of scleroderma causes scarring, fibrosis, and atrophy (not corresponding to dermatomes) of involved skin with firm binding of the subcutaneous tissues to deeper structures ("hidebound" appearance). It may extend to involve an entire extremity (Fig. 101.9) and to affect underlying muscle and bone, leading to flexion contractures, leg-length discrepancies, and atrophy of an extremity. A variant affecting the forehead is called scleroderma en coup de sabre.

FIGURE 101.9. Linear scleroderma involving left lower extremity in a 12-year-old girl.

SS often presents with cutaneous changes such as RP (90% of patients), edema, induration, increased pigmentation, and tightening of the skin. Some of these children also may develop arthritis resembling JRA, muscle weakness resembling JDMS, and nodules along tendon sheaths. If these features are seen, the clinician should consider the possibility of undifferentiated or mixed connective tissue disease, in which features of SLE, SS, JDMS, and JRA overlap.

Serious illness and death can occur in SS. Severe, uncontrolled hypertension and rapidly progressive renal failure (scleroderma renal crisis) have been a major source of mortality, although introduction of ACE inhibitors has dramatically improved short-term survival. Primary myocardial disease with conduction disturbances, pericarditis, and intractable CHF, as well as pulmonary hypertension secondary to fibrosis, remain significant sources of morbidity and mortality. Additional complications of SS include 1) digital gangrene and nonhealing ulcers most often involving the fingers, elbows, and malleoli secondary to vascular occlusion; 2) disordered motility of the distal esophagus with dysphagia and reflux esophagitis (60% of affected children); 3) malabsorption syndrome; 4) thrombocytopenia with subsequent cerebral hemorrhage; 5)interstitial lung disease; and 6) cranial nerve involvement with trigeminal sensory neuropathy, facial weakness, and tinnitus.

Management

General Management

Specific therapy for SS is nonexistent at present. Virtually every medication, from antihistamines to potent immunosuppressives, has been used in patients with this disease, although none has been shown to offer clear benefit. During the inflammatory, prefibrotic stages of interstitial lung disease and pulmonary vascular involvement, corticosteroids (prednisone 2 mg/kg per day or the equivalent) are indicated. Cyclophosphamide appears to forestall pulmonary fibrosis if added early to the treatment regimen. If the esophageal sphincter is involved, patients should be advised to sleep with the head comfortably elevated, and an antacid may be prescribed. Minor episodes of Raynaud's syndrome are managed with prophylactic measures such as the avoidance of cold exposure and the use of warm clothing. Biofeedback training and calcium channel blockers such as nifedipine may be helpful in decreasing the frequency of attacks. Aggressive physical therapy is indicated to prevent contractures and maintain normal function. Despite these measures, linear scleroderma with involvement of deep structures may lead to contractures of the extremities requiring surgery, whereas the mortality rate of systemic scleroderma appears to approach 50% at 7 years.

Management of Complications and Emergencies (Table 101.9)

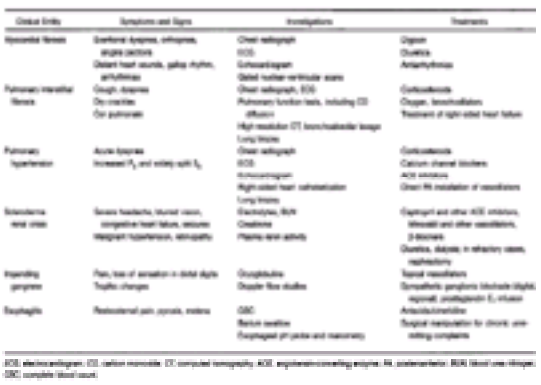

Table 101.9. Complications of Systemic Sclerosis

Cardiac Complications. Signs and symptoms of myocardial fibrosis are essentially those of a cardiomyopathy with dyspnea, orthopnea, and fatigue. Angina pectoris and myocardial infarction also occur. Fibrosis of the conduction system may result in arrhythmias, presenting as palpitations, syncope, or sudden death. Pericarditis is usually silent and valvular involvement in scleroderma is rare. Even in the absence of symptoms or physical findings, cardiac involvement eventually develops in most patients with systemic sclerosis, and sensitive imaging or functional studies reveal some cardiac involvement early in the course of disease in most cases. Management of cardiac dysfunction is symptomatic, including inotropic support and afterload reduction. Extensive diuresis should be avoided because of potential adverse effects on renal cortical perfusion. No specific drugs are available to arrest the progress of cardiac involvement.

Pulmonary Complications. Pulmonary involvement in SS may have three manifestations: pleurisy, interstitial lung disease, or pulmonary artery fibrosis. Diffuse interstitial lung disease is often asymptomatic. A dry cough may be the earliest symptom. Early in the course of the disease, even before symptoms appear, PFTs in these patients show a restrictive pattern and diffusion abnormalities. Later, radiographs of the chest show increased reticulation, a so-called honeycombed appearance, mainly basilar and bilateral. Other diagnostic modalities, including high-resolution CT scanning, bronchoalveolar lavage, and lung biopsy may identify earlier, prefibrotic states of disease more responsive to anti-inflammatory therapy. With progression of the disease, cough and dyspnea become prominent. On examination, crackles over both sides of the chest, particularly over the infrascapular area, may be the only finding. With the onset of right-sided heart failure, these patients may have increasing dyspnea, although edema of the lower extremities may not be appreciated because of hidebound skin. Patients with right-sided heart failure require admission and symptomatic management.

Patients with irreversible pulmonary fibrosis and chronic respiratory failure also may need admission. If such patients contract intercurrent respiratory infections, they should be treated promptly. Supplemental oxygen, bronchodilators, and corticosteroids may be helpful. If residual inflammation is demonstrable after further investigations such as those previously noted, these patients should receive corticosteroids (prednisone 2 mg/kg per day) for 6 to 8 weeks, although the value of this therapy is doubtful in established fibrosis. In addition, treatment of right-sided overload is indicated.

Pulmonary hypertension is the most common cause of dyspnea in patients with SS. On auscultation, the pulmonic component of the second heart sound is accentuated, and there is a wide or fixed splitting of the second heart sound. The ECG shows right ventricular hypertrophy. Echocardiography and catheterization of the right side of the heart are often indicated to document the etiology of respiratory deterioration. Corticosteroids and cyclophosphamide (50 mg/day orally or 500 to 750 mg/m_2 by monthly IV infusion) are the treatment of choice in patients without established interstitial fibrosis, in addition to supportive measures. Calcium channel blockers, ACE-inhibitors, and prostaglandin analogs may provide temporary symptomatic improvement in individual cases.

Renal Complications. Sclerodermatous involvement of the vessels of the kidney is the most common cause of renal failure in adults with SS. Proteinuria, hypertension, rapid progression of skin thickening early in the illness, anemia, pericardial effusion, and CHF are all markers of the patient at risk for renal scleroderma. The development of a microangiopathic hemolytic anemia suggests imminent renal failure. These complications appear to be less common in children than in adults.

Renal failure may develop gradually or acutely in a patient with known renal disease, and use of corticosteroids may precipitate its appearance. The combination of rapidly progressing azotemia with malignant hypertension (scleroderma renal crisis) requires hospitalization and urgent management. Characteristically, a patient displays a sudden rise in blood pressure to levels as high as 150 to 200 mm Hg diastolic, often without symptoms or heralded only by headache. Evaluation reveals hypertensive retinopathy (flame hemorrhages, cotton wool exudates, and papilledema), elevated plasma renin activity, and rapid deterioration of renal function. Immediate investigation should include urinalysis, measurement of urine output and urinary electrolytes, serum electrolytes, BUN, creatinine, and plasma renin level.

A major advance in the pharmacologic management of scleroderma renal crisis has been the use of ACE inhibitors such as captopril. Patients who fail to respond to this drug may still respond to potent vasodilators such as minoxidil, along with b-blockers and diuretics; regimens involving multiple drugs may also be necessary (see Chapter 35). Renal dialysis and, rarely, bilateral nephrectomy may be indicated in hypertension unresponsive to pharmacologic therapy. Maintenance of blood volume is an essential part of management of these patients.

Peripheral Vascular Complications. RP often can be incapacitating, particularly in cold weather. Symptoms include severe pain in the extremities and loss of sensation in the tips of the digits. Treatment with calcium channel antagonists such as slow-release nifedipine (30 to 180 mg/day) may decrease the frequency or severity of attacks. In urgent cases with impending gangrene, systemic or topical vasodilators (e.g., nitroglycerin paste or intra-arterial reserpine) or

sympathetic ganglion block may be tried, although these forms of therapy have not been validated in well-constructed studies. They also may be associated with complications, so these procedures should be performed only with intensive monitoring. If gangrene has set in, it is best left alone if no infection is present. Spontaneous separation of the tips of the digits will occur and carries less risk and morbidity than surgical amputation.

Gastrointestinal Complications. Abnormal esophageal motility with reflux may result in esophagitis. The major symptom of this condition is retrosternal pain that is made worse by certain foods and recumbent positioning. The pain may be severe and incapacitating. Although children with the complaint of retrosternal pain do not require admission to the hospital, they need an evaluation of their lower esophageal sphincter with esophageal manometry. Those with mild pain and objective manifestations of reflux (lower esophageal sphincter pressure of less than 10 mm Hg, evidence of esophagitis on endoscopy) are usually treated with simple measures such as antacids 1 hour after meals and 1 hour before bedtime, and elevation of the head during sleep. If symptoms are severe, H_2 blockers such as cimetidine (20 to 40 mg/kg per day, maximum daily dosage 1200 mg) may be prescribed.

VASCULITIS

Background

Vasculitis is rare in children, and one result of this has been insubstantial and inconsistent data on the classification and prognosis of childhood vasculitides. Classification schema useful in adults have limited applicability to children because certain illnesses are unknown in the young (e.g., temporal arteritis, Churg-Strauss disease), whereas other vasculitides occur only in children (e.g., Kawasaki disease). Classification is hampered further by a paucity of pathogenetic data on the vasculitides; distinction between the entities is based instead on a combination of clinical and histologic criteria. Finally, the recent discovery that antineutrophil cytoplasm antibodies (ANCA) are central to several forms of vascular inflammation has caused many old categorization schema to become outdated. One classification that is suitable for use in children is shown in Table 101.10. The most common of the life-threatening vasculitides (polyarteritis nodosa [PAN] and Kawasaki disease) are discussed here.

Leukocytoclastic vasculitis	Polarteritis nodosa
Henoch-Schönlein purpura	Systemic
Hypersensitivity vasculitis	Cutaneous
Allergic granulomatous angiitis	Kawasaki disease
Churg-Strauss syndrome	Giant cell arteritis
ANCA-positive vasculitis	Temporal arteritis
Wegener's granulomatosis	Takayasu's arteritis
Microscopic periarteritis	Isolated central nervous system angiitis
Pauci-immune glomer-	Vasculitis associated with rheumatic
ulonephritis	disease

ANCA, antineutrophil cytoplasm antibody.

Table 101.10. Necrotizing Vasculitis

Polyarteritis Nodosa

Background

The annual incidence of PAN in adults is approximately 0.3 per 100,000; no comparable data are available for children. Before the introduction of corticosteroids for the treatment of PAN, mortality rates as high as 100% were reported; today, fewer than 1 in 5 cases is believed to have a fatal outcome.

Pathophysiology

PAN is characterized by focal, panmural, necrotizing inflammation of small- and medium-sized muscular arteries. Sites of bifurcation are particularly prone to involvement, presumably because of hemodynamic turbulence at these points. Biopsies reveal a cellular infiltrate initially predominated by polymorphonuclear leukocytes and fibrinoid necrosis. As lesions mature, mononuclear cells, thrombosis, and recanalization mark the healing process.

The cause of PAN is unknown, although it is considered an archetype of immune complex–mediated vascular damage. Most children with PAN have serologic evidence of an antecedent streptococcal infection; up to one-third of adults have PAN associated with hepatitis B or C, including chronic antigenemia with viral proteins demonstrable in the circulating and fixed immune complexes. The incidence of hepatitis-associated PAN in children is significantly lower.

Clinical Manifestations

Childhood PAN occurs in both cutaneous and generalized forms, and distinguishing between them may be difficult. Both types display systemic manifestations, including fever, malaise, and myalgias. However, generalized PAN is significantly more likely to also involve the renal, GI, and central nervous systems. Common to both are rashes, although these are more likely to be nodular or lacy (so-called livedo reticularis) in the cutaneous form, and urticarial, petechial, or ischemic in the systemic form. Renal involvement (including proteinuria, abnormal urinary sediment, and hypertension), abdominal pain (often a manifestation of gut vasculitis), arthritis, mononeuritis multiplex, and CNS involvement (seizures, hemiparesis) typify generalized PAN. Less commonly, children may have cardiac disease (pericarditis, cardiomegaly,

ECG changes, myocardial infarction) or pulmonary involvement (diffuse infiltrates, pulmonary hemorrhage, or hemothorax). A rare subtype of PAN, Cogan's syndrome, is characterized by interstitial keratitis and sensorineural hearing loss.

Laboratory Features

Laboratory findings in polyarteritis are nonspecific. Most children have WBC counts greater than 15,000/mm $_3$, hemoglobin less than 10 g/dL, broadly elevated acute-phase reactants, and hypergammaglobulinemia. Complement levels are usually normal or increased, and ANA and rheumatoid factor levels are elevated only slightly if at all. Some children have evidence of ANCA, although other autoantibodies are usually absent.

Diagnosis of PAN generally requires tissue confirmation. Acute necrotizing inflammation of small and medium arteries is demonstrable in renal, cutaneous, muscular, or GI tissues. At times, biopsy may not be practical, and angiographic visualization of aneurysms may provide an alternative to tissue samples. Prognosis seems to improve if treatment is initiated early, so absence of tissue confirmation should not delay therapy. Vasculitis in general, and PAN in particular, is a pleomorphic condition with no diagnostic laboratory findings. Clinicians must have a high level of suspicion and be willing to subject their patients to invasive diagnostic procedures to avoid significant morbidity from delayed diagnosis.

Management

General Management

The initial management of PAN should include corticosteroids (generally divided doses of prednisone 2 mg/kg per day to a maximum of 80 mg/day). Rash and constitutional symptoms improve first, followed by control of end-organ involvement. Pulse doses of methylprednisolone (30 mg/kg in 50 mL of D5W by IV infusion over 1 to 2 hours, maximum dose 1500 mg) may offer an alternative for the treatment of acute exacerbations, provided that blood pressure and cardiac rhythm are closely monitored.

Cutaneous PAN may require lower dosages of steroids to suppress disease activity, or alternative agents such as dapsone or colchicine may adequately control the rash. On the other hand, children with systemic PAN may not tolerate a reduction in their steroid dosage or may not respond adequately to steroids. In such cases, addition of cytotoxic agents (e.g., oral or IV cyclophosphamide) may improve the outcome. Other modalities, including NSAIDs for fever and arthritis, anticonvulsants, antihypertensives, and physical therapy, should be used when appropriate.

Management of Complications and Emergencies (Table 101.11)

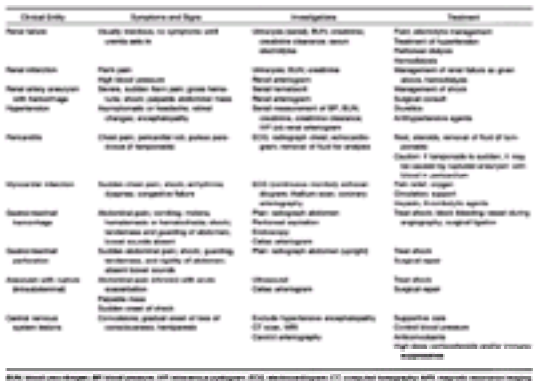

Table 101.11. Complications of Polyarteritis Nodosa

The most serious emergencies in childhood polyarteritis are 1) renal insufficiency; 2) severe hypertension; 3) cardiac complications such as CHF, myocardial infarction, and arrhythmias; 4) GI vasculitis resulting in bowel infarction, intestinal perforation, or cholecystitis; and 5) CNS manifestations, such as seizures and cranial nerve palsies.

Renal Emergencies. Although medical management of PAN has resulted in a significantly improved prognosis, azotemia and hypertension at the time of diagnosis continue to identify children with extremely aggressive disease. Arteritis of medium-sized vessels of the kidney may lead to renal infarction and ischemia or to glomerulonephritis manifested by hematuria, hypertension, and uremia. Sudden flank pain associated with gross hematuria, falling blood pressure, and an expanding abdominal mass suggest the possibility of aneurysmal dilation and rupture, with renal artery hemorrhage.

Serial urinalyses, measurements of BUN and creatinine levels, and determination of creatinine clearance are essential components of the investigation of all patients with PAN. Management of renal failure includes correction of fluid and electrolyte abnormalities, as well as high dosages of corticosteroids to control the underlying disease process (e.g., prednisone 2 mg/kg per day). Rupture of a renal artery aneurysm initially is managed with treatment of shock and replacement of volume, followed by surgical repair of the aneurysm once the patient is stabilized.

Hypertension. A mild to moderate elevation of blood pressure is noted in more than 90% of children with generalized PAN. Diuretics, hydralazine, and b-blockers are preferred drugs for the management of hypertension. Severe hypertension associated with encephalopathy or CHF requires inpatient management.

Cardiac Emergencies. Pericarditis may be asymptomatic. Alternatively, chest pain (particularly in the recumbent

position), shortness of breath, pericardial friction rub, and pulsus paradoxus may be present. The ECG may reveal depression of the ST segment and T-wave inversion, and chest radiograph may demonstrate globular enlargement of the cardiac silhouette. However, echocardiographic demonstration of pericardial fluid is the most sensitive means of confirming the presence of pericarditis.

Chest pain with tachycardia, arrhythmia, and dyspnea may herald the occurrence of myocardial infarction in a patient with PAN. Pericardial tamponade caused by a ruptured coronary aneurysm may present similarly. Occasionally, a patient with coronary disease may present with CHF. Characteristic ECG changes (deep Q waves) and areas of ischemia on myocardial nuclear scanning may be seen. Echocardiogram is indicated to study the function of the myocardium and the status of the valves. Coronary arteriography is essential to establish the size, location, and extent of aneurysms and occlusions.

Patients with CHF, myocardial ischemia, and arrhythmias will require continuous monitoring and urgent management in an intensive care setting. Patients with pericarditis without effusion may be treated with bed rest, careful monitoring, and corticosteroids. Pericardiocentesis is indicated in the presence of tamponade. Patients with myocardial infarction need careful monitoring, pain relief (morphine), treatment of shock, antiarrhythmic agents, and treatment of CHF. A radiograph of the chest, ECG, and echocardiogram should be obtained as soon as possible; thallium scan and coronary angiography may be indicated in certain patients.

Supportive medical management includes careful monitoring of cardiorespiratory status, judicious use of IV fluids, diuretics, and cardiotonics when needed. Treatment of the primary disease with steroids and cytotoxic agents should be continued as described. If hypertension does not respond to diuretic therapy, other antihypertensive agents may have to be added. Serum electrolytes should be monitored because most patients will be taking high dosages of steroids, diuretics, and antihypertensive agents, and electrolyte imbalances increase the risk of toxicity.

Gastrointestinal Complications. Abdominal pain is the most common manifestation of GI involvement in PAN. It may be diffuse and nonspecific or localized and severe. Hematemesis and melena suggest ulceration and hemorrhage. Patients with persistent abdominal pain, hematemesis, and melena require immediate admission.

Visceral perforation should be suspected in cases of active systemic disease and unrelenting abdominal pain. Tenderness on palpation of the abdomen, guarding of the abdominal wall, and absent bowel sounds are the usual physical findings, although they may be masked by steroid therapy. Arteritis of specific organs may lead to cholecystitis, pancreatitis, appendicitis, and hepatitis. These complications are generally manifested by vomiting and localized abdominal pain and tenderness.

Mesenteric thrombosis with infarction of the bowel may present with sudden abdominal pain, vomiting, hematemesis or hematochezia, and shock. Exquisite tenderness of the abdomen and absent bowel sounds are the major findings. Hemorrhage from a ruptured aneurysm (mesenteric, hepatic, or renal) with hemoperitoneum is heralded by sudden onset of severe pain, vomiting, tachycardia, and shock. The abdomen is tender and tense, and bowel sounds are diminished or absent.

Initial management of each of these GI catastrophes includes volume replacement, gastric decompression, and stress doses of corticosteroids. All such patients will require measurement of intake and output and serial determination of hematocrit, BUN, and electrolytes. Abdominal radiographs (supine and upright), abdominal ultrasound, technetium scan, angiography of the celiac axis vessels, and peritoneal aspiration may be indicated in some cases. In selected instances, direct examination of the GI tract by endoscopy may yield valuable information concerning the nature, location, and extent of lesions. Surgical consultation should be obtained immediately, and in the presence of bleeding aneurysms or infarcted bowel, surgical exploration is mandatory.

Central Nervous System Complications. Clinical signs of CNS disease are less common than those of peripheral nervous system involvement. Seizures and hemiparesis are the most common manifestations of CNS involvement in PAN and require immediate hospitalization. A complete neurologic evaluation, including measurement of blood pressure, and funduscopic examination for evidence of hypertension or intracranial bleeding, should be performed. CT and/or carotid angiography may help localize the lesion.

Management of hypertensive encephalopathy and increased intracranial pressure are described elsewhere (see Chapter 35 and Chapter 83). Surgical correction of a ruptured aneurysm should be undertaken if the bleeding vessel can be localized and is accessible.

KAWASAKI DISEASE

Background

Mucocutaneous lymph node syndrome was first described by a Japanese pediatrician in 1967, and it has become known as Kawasaki disease in his honor. In fact, the condition certainly predates this description: a preserved heart from the 19th century shows pathologic changes characteristic of Kawasaki disease, and the entity of “infantile polyarteritis” probably represents the same syndrome. Kawasaki disease is an idiopathic vasculitis of small- and medium-sized vessels, which has become a leading cause of acquired heart disease in children in the United States. Characteristically, children with Kawasaki disease have fever, conjunctivitis, rash, mucosal inflammation, lymphadenopathy, and extremity changes. However, the major morbidity of Kawasaki disease occurs in the heart. Coronary artery aneurysms or ectasia develop in approximately 15 to 25% of untreated children and may lead to myocardial infarction, sudden death, or chronic coronary artery insufficiency. IV gamma-globulin decreases the incidence of coronary artery aneurysms by threefold to fivefold if given within 10 days of disease onset. Therefore, management of children with suspected Kawasaki disease requires accurate and expeditious diagnosis and close monitoring of the cardiovascular system.

Pathophysiology

In Kawasaki disease as in other vasculitides, blood vessel damage appears to result from an aberrant immune response leading to endothelial cell injury and vessel wall damage. Humoral factors, such as antiendothelial cell antibodies or circulating immune complexes, may be critical. On the other hand, a direct cell-mediated attack on endothelial cells that are infected with an as yet unidentified infectious agent may underlie the vascular injury. For unknown reasons, Kawasaki disease has a predilection for the coronary arteries.

The pathologic changes of coronary arteries in Kawasaki disease have been classified by Fujiwara and Hamashima into four stages, depending on the duration of illness at the time of examination (Table 101.12). Initially, endothelial swelling is accompanied by a neutrophilic infiltrate. Lymphocytes and plasma cells replace polymorphonuclear cells by the subacute stage (beginning 2 weeks after onset), accompanied by destruction of the internal elastic lamina; coronary artery aneurysms characteristic of Kawasaki disease first become apparent at this time. Finally, during the convalescent state of Kawasaki disease, healing of the vascular lesions occurs with fibroelastic proliferation and scar formation, along with expansion of aneurysms caused by hemodynamic forces.

Stage I—Disease duration <10 days
Acute perivasculitis of coronary arteries
Microvascular angiitis of coronary arteries and aorta
Pancarditis with pericardial, myocardial, endocardial inflammation
Inflammation of the atrioventricular conduction system
Stage II—Disease duration 12–28 days
Acute panvasculitis of coronary arteries
Coronary artery aneurysms present
Coronary obstruction and thrombosis
Myocardial and endocardial inflammation less intense
Stage III—Disease duration 28–45 days
Subacute inflammation in coronary arteries
Coronary artery aneurysms present
Myocardial, endocardial inflammation much decreased
Stage IV—Disease duration >50 days
Scar formation, calcification in coronary arteries
Stenosis and recanalization of coronary vessel lumen
Myocardial fibrosis without acute inflammation

From Melish ME. Kawasaki syndrome. Pediatr Rev 1980;2:111.

Table 101.12. Pathology of Kawasaki Disease (Adapted from Fujiwara)

The cause of Kawasaki disease is unknown, although many lines of evidence point toward an infectious origin. The fact that the disease often occurs in epidemics, that boys are more susceptible than girls, and that studies in Japan suggest that household contacts of children with Kawasaki disease are at increased risk for developing the disease, all point to a transmissible agent. Nonetheless, although many putative causes have been proposed during the past three decades, suggestions that certain viruses (EBV, parvovirus, human immunodeficiency virus [HIV]-2) or bacterial toxins (streptococcal erythrogenic toxin, staphylococcal toxic shock toxin) account for most cases have not been substantiated. Many researchers now believe that Kawasaki disease represents a final common pathway of immune-mediated vascular inflammation after a variety of inciting infections.

Clinical Manifestations

Kawasaki disease is a clinical syndrome diagnosed on the basis of fever and four of five signs of mucocutaneous inflammation (Table 101.13). These guidelines were established by Tomisaku Kawasaki in 1967, and they remain the sine qua non for diagnosing Kawasaki disease. Nonetheless, as with all clinical criteria, these should be regarded as imperfect guidelines with less than 100% sensitivity and specificity. Children who do not meet criteria may indeed have Kawasaki disease, and some children with other conditions may nonetheless manifest 5 or 6 criteria of Kawasaki disease.

I. Fever ≥5 days unresponsive to antibiotics If the fever disappears because of intravenous gamma-globulin (IVGG) therapy before the fifth day of illness, a fever of <5 days' duration fulfills fever criterion for case definition.
II. At least four of the five following physical findings with no other more reasonable explanation for the observed clinical findings: 1. Bilateral conjunctival injection 2. Changes in the oropharyngeal mucous membranes (erythematous and/or fissured lips, strawberry tongue, injected pharynx) 3. Changes of peripheral extremities, including erythema and/or edema of the hands or feet (acute phase) or periungual desquamation (convalescent phase) (Fig. 101.12) 4. Polymorphous rash, primarily truncal; nonvesicular 5. Cervical lymphadenopathy ≥1.5 cm diameter

Modified from Centers for Disease Control and Prevention. Kawasaki disease—New York. MMWR 1990;39 (RR-13):17–18.

Table 101.13. Diagnostic Criteria for Kawasaki Disease

Fever is probably the most consistent manifestation of Kawasaki disease. It reflects the elevated levels of proinflammatory cytokines (e.g., TNF, IL-1), which are also thought to mediate the underlying vascular inflammation. A diagnosis of Kawasaki disease should be considered in all children with prolonged, unexplained fever, irritability, and laboratory signs of inflammation, especially in the presence of mucocutaneous inflammation. Conversely, the diagnosis must be suspect in the absence of fever.

The remaining cardinal manifestations of Kawasaki disease vary considerably in frequency. Up to half of children with Kawasaki disease do not have cervical lymphadenopathy, especially children under 2 years of age. When present, lymphadenopathy tends to involve the anterior cervical nodes overlying the sternocleidomastoid muscle. Diffuse lymphadenopathy, as well as other signs of reticuloendothelial involvement such as splenomegaly, should prompt a search for an alternative diagnosis.

Bilateral, nonexudative conjunctivitis is present in more than 90% of patients. A predominantly bulbar injection typically begins within days of the onset of fever, and eyes eventually develop a brilliant erythema, which spares the limbus. Children are also commonly photophobic, and five of six patients have evidence of anterior uveitis during the first week of illness. Consequently, in ambiguous cases, slitlamp examination may be helpful in confirming a diagnosis of Kawasaki disease.

Cracked, red lips and a strawberry tongue are characteristic of the mucositis typically seen during the first week of Kawasaki disease (Fig. 101.10). Discrete oral lesions, such as vesicles or ulcers, and tonsillar exudate, suggest a viral or bacterial infection rather than Kawasaki disease. The cutaneous manifestations of Kawasaki disease are polymorphous. The rash typically begins as perineal erythema and desquamation, followed by macular, morbilliform, or targetoid lesions of the trunk and extremities. Vesicular or bullous lesions are rare. Changes in the extremities are generally the last clinical manifestation of Kawasaki disease to develop. Children demonstrate an indurated edema of the dorsum of their hands and feet, and a diffuse erythema of their palms and soles (Fig. 101.11). In addition, one-third of children develop arthritis. This is typically a small joint polyarthritis during the first week of illness, followed by a large joint pauciarthritis. During the convalescent phase of Kawasaki disease, sheetlike desquamation that begins in the periungual region of the hands and feet, and linear nail creases (Beau's lines) are characteristic (Fig. 101.12).

FIGURE 101.10. Cracked, erythematous lips and “strawberry” tongue in Kawasaki disease.

FIGURE 101.11. Brawny edema of dorsum of hand and small joint polyarthritis in Kawasaki disease.

FIGURE 101.12. Peeling of the skin over the thumbs in Kawasaki disease.

Kawasaki disease is most commonly confused with exanthematous infections of childhood (Table 101.14). Measles, echovirus, and adenovirus may share many of the signs of mucocutaneous inflammation, but they typically have less

evidence of systemic inflammation and generally lack the extremity changes seen in Kawasaki disease. Toxin-mediated illnesses, especially b-hemolytic streptococcal infection and toxic shock syndrome, generally lack the ocular and articular involvement typical of Kawasaki disease. Finally, drug reactions such as Stevens-Johnson syndrome or serum sickness may mimic Kawasaki disease but with subtle differences in the ocular and mucosal manifestations.

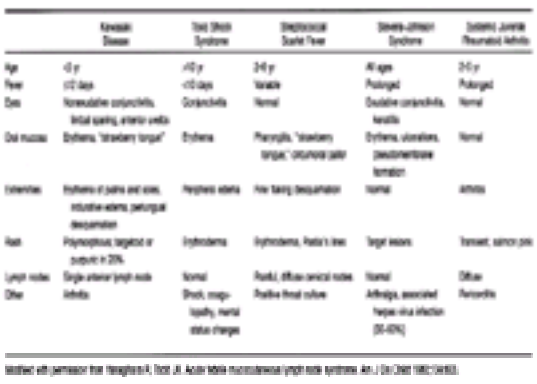

Table 101.14. Differential Diagnosis of Kawasaki Disease

The conventional diagnostic criteria are particularly useful in preventing over diagnosis, but they may result in failure to recognize incomplete forms of the illness. Clinical manifestations of Kawasaki disease tend to be most incomplete and atypical in the youngest patients, the subgroup at highest risk for development of coronary artery abnormalities. Thus, Kawasaki disease should be considered in any infant with prolonged, unexplained fever. On the other hand, alternative explanations for the child's symptoms must be carefully excluded before treating empirically with intravenous immunoglobulin (IVIG). Consideration should be given to referring such children to a regional Kawasaki disease center for further evaluation.

Laboratory Features

No laboratory studies are included among the diagnostic criteria for Kawasaki disease, but certain findings may support the diagnosis. Most characteristic is the systemic inflammation, with widespread elevation of acute-phase reactants (including CRP and ESR), leukocytosis, and a shift to left in the WBC count. By the second week of illness platelet counts rise as well, reaching 1,000,000/mm_3 in the most severe cases.

Children with Kawasaki disease often present with a normocytic, normochromic anemia; hemoglobin concentrations more than 2 standard deviations below the mean for age are noted in approximately half of patients within the first 2 weeks of illness. Urinalysis commonly reveals WBCs on microscopic examination; the cells are mononuclear and therefore are not detected by dipstick tests for leukocyte esterase. They also originate in the urethra, so they will be missed on urinalyses obtained by bladder tap or catheterization. Measurement of liver enzymes often reveals elevated transaminase levels or mild hyperbilirubinemia caused by intrahepatic congestion. In addition, a minority of children may develop obstructive jaundice from hydrops of the gallbladder. If sampled, other body fluids demonstrate inflammation as well: CSF typically displays a mononuclear pleocytosis (less than 100 cells/mm_3) with normal glucose and protein concentrations, whereas arthrocentesis of involved joints demonstrates 50 to 300,000 WBCs/mm_3, primarily neutrophils.

Management

General Management

IVIG has truly revolutionized the care of children with Kawasaki disease; treatment within 10 days of onset significantly shortens disease duration and minimizes the incidence of complications. Overall, prompt diagnosis and appropriate therapy prevent aneurysm formation in approximately 95% of children and result in rapid symptomatic improvement in about 90%. Use of anti-inflammatory medications, such as aspirin or NSAIDs, improves patient comfort and complements the disease-modifying effects of IVIG.

Studies in Japan were the first to suggest relative protection from coronary artery aneurysms when IVIG is administered early in the course of Kawasaki disease. Since then, further trials in the United States and Japan have confirmed this finding and documented the safety of high-dose infusions of immunoglobulin. Most recently, a single large infusion of IVIG (2 g/kg) administered over 8 to 12 hours has become the standard of care for Kawasaki disease. This is somewhat more effective, and equally as safe, as traditional 4-day infusions, and significantly shortens the duration of hospitalization as well.

Therapy with IVIG also has other benefits. Treatment results in a reduced prevalence of giant aneurysms, the most serious form of coronary abnormality caused by the disease, and accelerates normalization of abnormalities of left ventricular systolic function and contractility. Finally, high-dose IVIG reduces fever and laboratory indices of inflammation, suggesting a rapid, generalized anti-inflammatory effect in addition to specific cardioprotective effects. Several different preparations of IVIG are currently available, but data are insufficient to determine whether all are equally effective.

Despite its advantages, IVIG is an expensive and potentially toxic intervention. The greatest long-term concern is of transmission of bloodborne pathogens. Elaborate sterilization procedures, including lyophilization, pasteurization, and addition of solvent detergents, are generally effective in rendering the product free of infectious agents. Nonetheless,

technical errors apparently led to more than 100 cases of hepatitis C in recipients of a single brand of IVIG in 1994, although none were children with Kawasaki disease. Overall, however, significant toxicity is rare, and benefits clearly outweigh risks in children with confirmed Kawasaki disease.

Aspirin

Aspirin was the first medication to be used for treatment of Kawasaki disease, both for its anti-inflammatory and its antithrombotic effects. High-dose (more than 80 mg/kg per day) and lower-dose regimens (30 mg/kg per day) are still used in conjunction with IVIG during the acute phase of the illness, despite the fact that aspirin has no known effect on development of coronary artery aneurysms. Once fever resolves, patients are generally switched to antiplatelet doses of aspirin (3 to 5 mg/kg per day). Unless coronary artery abnormalities are detected by echocardiogram, aspirin is discontinued once laboratory studies return to normal, usually within 2 months of the onset of Kawasaki disease.

The risks of aspirin appear to be similar to those reported in other settings: transaminitis, chemical hepatitis, transient hearing loss, and rarely, Reye syndrome. These risks may even be increased in Kawasaki disease: 1) Aspirin-binding studies have suggested that the hypoalbuminemia of children with Kawasaki disease predisposes them to toxic free salicylate levels despite measured (bound) values within the therapeutic range. 2) At least one case of Reye syndrome has been reported after 6 days of aspirin therapy for Kawasaki disease. 3) Alternative antipyretic and anti-inflammatory agents, such as ibuprofen, may be used for prolonged or debilitating fever, and aspirin should be rapidly discontinued on exposure to or signs of varicella or influenza.

Cardiovascular Complications and Emergencies

Cardiac abnormalities dominate the pathology of Kawasaki disease. Clinical examination is often remarkable for tachycardia and gallop rhythms that are more prominent than expected from the degree of fever and anemia. The ECG in acute Kawasaki disease may show mild abnormalities consistent with myocarditis, most commonly a prolonged P-R interval and nonspecific ST- and T-wave changes. Echocardiographic evaluation of myocardial function early in the course of the disease often reveals reduced left ventricular function and contractility. Rarely, myocardial inflammation may progress to frank CHF. The severity of myocarditis does not correlate with the risk of coronary artery aneurysms or with the pericardial effusion that may develop during the second week of illness. The effusion only rarely progresses to tamponade and resolves spontaneously in most instances. Valvulitis presenting as either aortic or mitral regurgitation is seen in a percentage of children during the early phases of Kawasaki disease. Late-onset mitral regurgitation, from papillary muscle dysfunction or myocardial infarction, may also complicate the clinical course.

Most characteristic of Kawasaki disease is inflammation of the coronary arteries. This progresses to ectasia or aneurysm formation in 15 to 25% of untreated children. Male gender, age less than 1 year, prolonged fever, dramatic elevation of CRP and absolute band count, and pronounced depression of albumin level identify children at greatest risk for developing coronary artery aneurysms. Dilation of coronary arteries may be detected by echocardiography as early as 6 days after the appearance of fever and usually peaks 3 or 4 weeks after onset of illness. Cardiac catheterization need not be performed in patients with normal echocardiograms and ECGs throughout the disease course because the likelihood of finding unsuspected lesions is negligible.

Coronary aneurysms in early Kawasaki disease usually occur in the proximal segments of the major coronary vessels; abnormalities that occur distally are almost always associated with proximal coronary dilation. Aneurysms may also occur in arteries outside the coronary system, most commonly the subclavian, brachial, axillary, iliac, or femoral vessels, and occasionally in the abdominal aorta and renal arteries. Therefore, abdominal aortography and subclavian arteriography are often performed in patients undergoing coronary arteriograms for Kawasaki disease. However, visceral vessels are almost never involved.

Management of Complications and Emergencies

Myocardial infarction caused by thrombotic occlusion of an aneurysmal and/or stenotic coronary artery is the principal cause of death in Kawasaki disease (Fig. 101.13 and Fig. 101.14). Mortality resulting from Kawasaki disease has decreased from almost 2% to less than 0.1% as a result of improved treatment. Nonetheless, most deaths continue to occur during the first 6 months after disease onset, when myocardial and coronary artery inflammation are greatest. A Japanese registry of 195 children with myocardial infarction revealed that almost 40% infarcted within 3 months of disease onset, and 74% had their infarctions during the first year after onset of Kawasaki disease. About two-thirds of myocardial infarctions were associated with symptoms (shock, crying, chest or abdominal pain, vomiting, dyspnea, or arrhythmia), but only three patients had a history of antecedent angina.

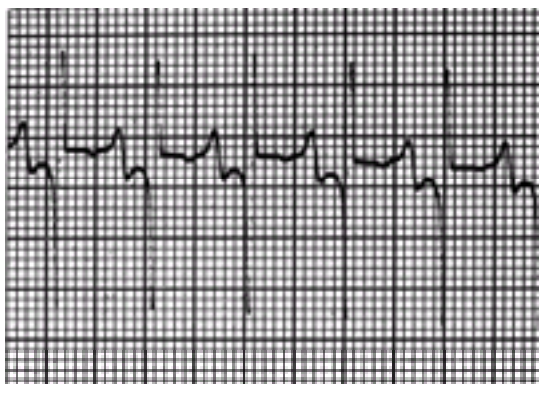

FIGURE 101.13. Lead III from an electrocardiogram on a 15-month-old boy showing deep Q waves in Kawasaki disease.

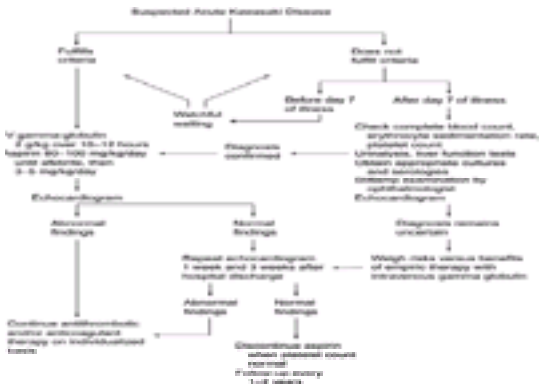

FIGURE 101.14. Algorithm for evaluation of patients with suspected Kawasaki disease. (Modified with permission from Sundel RP, Newburger JW. In: Cooke JP, Frohlich ED, eds. Current Management of Hypertensive and Vascular Diseases. St Louis: Mosby,1992:258.)

Treatment with thrombolytic agents in adults with myocardial infarction has been demonstrated to decrease mortality and improve function. In children with Kawasaki disease and coronary artery thrombosis, thrombolytic agents—mainly urokinase and streptokinase, either IV or intracoronary—have been used with variable success. Thrombolytic therapy for coronary artery thrombosis is most effective if begun within 3 to 4 hours of symptom onset. Immediately after clot lysis, systemic heparin is begun in combination with aspirin. Maintenance of reperfusion then requires long-term oral antithrombotic therapy (e.g., warfarin with dipyridamole), although the ideal regimen has not been established.

CHF may rarely complicate the acute phase of Kawasaki disease. When this is caused by myocarditis, routine treatment with IVIG generally results in rapid clinical improvement. Although IVIG therapy involves infusing large volumes of isotonic solution-- 2 g/kg of 5% IVIG delivers 40 mL/kg over 8 to 12 hours—improvements in myocardial contractility compensate for the volume load, and treatment rarely leads to circulatory deterioration. By the second week of illness, and especially in children with coronary artery dilation, ischemia or infarction must be excluded as causes of new myocardial dysfunction. Characteristic ECG and echocardiographic changes allow this distinction to be made rapidly in most patients.

Vascular Obstruction

Children with severe Kawasaki disease, especially infants or those in whom treatment is delayed, may develop other complications related to arterial occlusion. Peripheral obstruction leads to ischemia and gangrene; this complication generally accompanies other manifestations of critical disease such as giant coronary artery aneurysms and aneurysms in peripheral arteries. Various therapies have been attempted to restore circulation, although control of vascular inflammation with sufficient IVIG and/or corticosteroids is an essential prerequisite to arterial reperfusion. Thereafter, treatments may include thrombolytic therapy if arterial thrombosis is present or vasodilators if tissue viability is primarily threatened by vasospasm. Peripheral arterial obstruction may be corrected by thrombolysis with urokinase, streptokinase, or tissue-type plasminogen activator, after which perfusion is maintained with heparin followed by a long-term oral anticoagulant regimen.

Other Complications

Arthritis occurs in approximately one-third of children with Kawasaki disease and may add supportive evidence for the diagnosis in ambiguous cases. The arthritis tends to involve the small joints of the extremities during the acute phase of illness, and the large joints during the second and third weeks. The arthritis of Kawasaki disease is always nondeforming and self-limited, generally resolving within 30 days. Anti-inflammatory medications such as ibuprofen are usually effective in relieving symptoms until spontaneous resolution occurs.

Kawasaki disease may recur in 1 to 2% of children within 12 months of diagnosis, and an additional 5 to 10% may respond poorly to IVIG treatment during the initial bout of illness. In fact, patients who fail to respond completely to IVIG pose the greatest therapeutic dilemma. Prolonged fever itself correlates with increased risk of developing coronary artery abnormalities, and fever lasting for more than 14 days identifies a group of children at risk for developing giant coronary artery aneurysms (internal diameter larger than 8 mm), the group at highest risk for infarction and sudden death.

In cases of persistent, recurrent, or recrudescent Kawasaki disease, most clinicians repeat treatment with IVIG 2 g/kg over 8 to 12 hours. The risk of additional IVIG seems to be minimal, and several studies show a dose response to IVIG in Kawasaki disease. However, it is extremely important to confirm the diagnosis; failure to respond to IVIG might indicate that the child has a bacterial or viral infection or systemic JRA.

Approximately two-thirds of children with Kawasaki disease who fail to respond to an initial dose of IVIG improve with a second course. A small number seem to be resistant to IVIG, and approaches to these children vary. One regimen that appears to be safe and effective is the use of pulse doses of methylprednisolone, as used in PAN and other vasculitides.

LYME DISEASE

Background

Current knowledge of Lyme disease is the result of discoveries that have spanned most of the 20th century. Afzelius in Sweden first described the chronic migrating erythematous skin rash of Lyme disease in 1909, in association with an Ixodid tick bite. Twenty-one years later, Bannworth reported a tickborne syndrome of lymphocytic meningitis, neuritis, radicular pain, and an expanding erythematous rash (erythema migrans). In 1975, an outbreak of arthritis in Lyme, Connecticut, allowed identification of the tick vector associated with late disease. Finally, in 1981 the spirochete that is transmitted by ticks and causes the illness, *Borrelia burgdorferi,* was characterized.

Lyme disease is now the most common tickborne illness in the United States. More than 16,000 cases were reported in 1996, and outbreaks have been documented in 48 of the United States. Endemic foci are located in the New England, Middle Atlantic, Upper Midwest, and Western regions, as well as in Canada, Europe, China, Japan, and Russia. Most cases of Lyme disease occur between April and October, and up to 40% of cases occur in children.

Clinical Manifestations

Symptoms of *B. burgdorferi* infection may be classified into three stages, similar to the progression of syphilis. Stage 1 or early infection consists of a localized erythema migrans rash (Fig. 101.15). This begins as a small, red, indurated papule at the site of the tick bite, and then expands centrifugally for days or weeks. Lesions ultimately may reach an average diameter of 15 cm and may be accompanied by mild flulike symptoms, including fever, regional lymphadenopathy, and malaise.

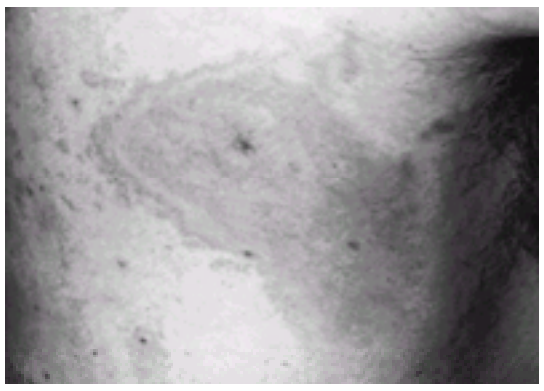

FIGURE 101.15. Primary erythema chronicum migrans lesion. (Courtesy of James Leyden, MD.)

Stage 2 of Lyme disease results from hematogenous dissemination of the spirochete. Integumental, musculoskeletal, and central nervous systems are most commonly affected. Approximately half of patients develop secondary annular skin lesions similar to erythema migrans but smaller and without central punctae. Debilitating fatigue may accompany myalgias and migratory arthralgias, followed in somewhat more than 50% of patients by a large-joint oligoarthritis. Severe headache and meningismus, cranial neuritis (especially Bell's palsy), and peripheral radiculoneuropathy may supervene. Finally, approximately 5% of patients demonstrate cardiac involvement, including conduction abnormalities or, more rarely, pancarditis. These symptoms generally resolve within weeks or months, but they may recur or persist.

Stage 3 disease is characterized by persistent infection and symptoms of prolonged latency. A sclerodermalike skin rash, acrodermatitis chronica atrophicans, is seen most commonly in Europe. A potentially erosive chronic oligoarthritis may be seen months to years after the tick bite. Subtle neurologic findings, including peripheral neuropathies and organic brain syndromes, may become apparent long after other manifestations of spirochete infestation have resolved.

Laboratory Features

B. burgdorferi is extremely difficult to grow in culture, and spirochetes generally cannot be identified in infected tissues. Diagnosis of Lyme disease therefore is made on the basis of characteristic clinical features accompanied by confirmatory serologic markers. Two caveats accompany serologic testing for Lyme disease. First, these tests are relatively difficult to perform, and standardization has been difficult to achieve. Many laboratories are plagued by both false-positive and false-negative results, so only experienced reference labs, preferably state or regional centers, should be used. Second, serologic tests for LD depend on the patient's antibody response. Titers may not be measurable until the second month after a tick bite in up to 85% of cases, and they may be abrogated by early antibiotic therapy. Early Lyme disease is thus a clinical condition based on a typical erythema migrans rash, and serology should not be relied on to confirm the diagnosis.

Current recommendations for testing use a two-tiered approach to optimize efficiency and accuracy. Patients are screened using an enzyme immunoassay (EIA) or immunofluorescent assay (IFA). If these tests are negative, generally no further testing is indicated. Positive results by these methods, however, require confirmation because a variety of viral illnesses and autoimmune conditions may cause false-positive results.

The second level of serologic evaluation involves Western or immune blotting. Any positive or equivocal antibody screening study should be confirmed by demonstrating the presence of at least five IgG bands directed against discrete *B. burgdorferi* proteins. This test is not foolproof, and false-positive studies may be seen in the setting of EBV and HIV infections and in SLE. In addition, up to 10% of residents of endemic regions have positive Lyme titers without evidence of true infection. Consequently, only those with compatible clinical findings, as well as positive serologies, require treatment.

Other laboratory data are not specific for Lyme disease. Hemoglobin, WBC counts, and platelet counts are generally normal. The ESR is elevated in approximately 50% of cases. ANA and RF are negative. Serum IgM is elevated in one-third of cases and correlates with the severity and chronicity of illness; IgM cryoglobulins are similarly associated. Immune complexes may be demonstrated in serum and synovial fluid.

In Lyme arthritis, synovial fluid analysis typically reveals elevated leukocyte counts ranging from 2,000 to 100,000 cells/mm_3. Polymorphonuclear leukocytes usually predominate, but Lyme disease is one of the few conditions in which a significant number of eosinophils may be identified in the synovial fluid. Total protein is elevated. Synovial biopsy reveals nonspecific synovial hypertrophy and mononuclear cell infiltration. In cases of neuroborreliosis, CSF analysis may reveal a mononuclear pleocytosis ranging from 25 to 500 cells/mm_3. At times, however, CSF may be entirely normal despite the presence of neurologic symptoms; even polymerase chain reaction (PCR) testing might fail to reveal evidence of borrelial DNA. In such cases, MRI of the brain might be useful, although other causes of the symptoms must also be considered. Suspected cardiac involvement may be confirmed by ECG, which reveals varying degrees of atrioventricular block and nonspecific ST-T wave changes.

Management

General Management

The cornerstone of treatment of Lyme disease is antibiotics. Oral antibiotic therapy is beneficial in early stages of the infection, whereas IV medications have a lower failure rate in chronic Lyme disease. Late manifestations of Lyme disease may represent a host autoimmune response rather than direct effects of the spirochete, but antibiotics may nonetheless be beneficial.

Current treatment guidelines are shown in Table 101.15 Clinical trials have resulted in the recommendation that patients with erythema migrans be treated with 14 to 21 days of doxycycline (100 mg twice daily). Children less than 8 years old should receive amoxicillin (25 to 50 mg/kg per day, maximum 2 g). Erythromycin (30 mg/kg per day) is reserved for allergic patients. Therapy of early constitutional symptoms is supportive and includes bed rest, analgesics, and antipyretics. As with other spirochetal infections, a Jarisch Herxheimer reaction may be seen after initial antibiotic therapy.

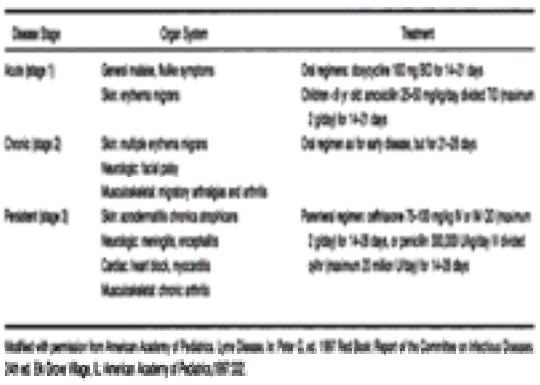

Table 101.15. Treatment of Lyme Disease

Management of Complications and Emergencies (Table 101.15)

Neurologic Complications. The presentation of neuroborreliosis is varied and may be categorized according to duration of infection. Early neurologic involvement, occurring during the first month after exposure, is seen in approximately 15% of untreated patients. Symptoms of aseptic meningitis and encephalitis, including severe headache, stiff neck, nausea and vomiting, photophobia, lethargy, and poor memory, are most notable. Kernig's and Brudzinski's signs are generally negative.

Facial nerve palsy is the most common cranial neuropathy of early neuroborreliosis. This is most often unilateral but may be bilateral. An isolated facial nerve palsy often presents difficult diagnostic decisions. With a history of tick exposure or erythema migrans rash, the diagnosis may be clear. More often, however, families will not recall such specifics, in which case facial nerve involvement caused by *B. burgdorferi* must be distinguished from that of viral, autoimmune, and idiopathic Bell's palsy.

Lyme-induced facial nerve symptoms tend to resolve spontaneously, but oral antibiotics are recommended to prevent dissemination and late sequelae. Because similar CSF findings may be seen regardless of the cause, lumbar puncture is generally not recommended in cases of isolated facial nerve palsy thought to result from Lyme disease. When a lumbar puncture is performed, CSF typically shows a lymphocytic pleocytosis with or without elevated protein. A CSF index, obtained by comparing the ratio of albumin to Lyme antibodies centrally and peripherally, is currently the most sensitive marker of neuroborreliosis. Evidence of intrathecal production of antiborrelial antibodies may be found in 80 to 90% of patients with Lyme meningoencephalitis and is treated with parenteral ceftriaxone or penicillin for 14 to 21 days.

Months or years after infection, some patients may develop late or chronic peripheral neuropathies. These manifest as paresthesias, symmetric or asymmetric; radicular pain and muscle weakness are generally less intense than in early

neuroborreliosis. Treatment with IV antibiotics, generally for 2 to 4 weeks, usually results in gradual improvement.

Most vexing of the late neurologic sequelae of Lyme disease is chronic Lyme encephalopathy. Symptoms are largely nonspecific, including debilitating fatigue, cognitive slowing, memory impairment, sleep disturbances, and depression. Distinction from idiopathic chronic fatigue syndrome or psychiatric conditions is extremely difficult. In cases attributable to Lyme disease on the basis of positive serologic markers of borrelial infection in addition to antibody, PCR, or MRI evidence of CNS involvement, symptoms often improve gradually with IV antibiotic therapy.

Cardiac Complications. Lyme carditis may present weeks to months after the initial infection in 5 to 10% of untreated children. Atrioventricular (AV) block is the most common manifestation; pericarditis, intraventricular conduction disturbances, and heart failure also may be seen. Patients may be asymptomatic with low-grade AV block, or they may complain of dyspnea, chest pain, palpitations, dizziness, or syncope with higher-grade disturbances. Physical signs include those of CHF with gallop rhythm, bibasilar crackles, and hepatojugular reflux, or those of pericarditis with friction rub and pulsus paradoxus (greater than 10 mm Hg). The heart rate may be elevated in the face of myocarditis or CHF; bradycardia as low as 30 beats/minute can be seen in patients with conduction abnormalities. ECG reveals varying degrees of AV block and ST-T wave changes. Chest radiographs may reveal cardiomegaly. Echocardiography is useful in documenting small pericardial effusions and ventricular dysfunction.

Treatment decisions are made on the basis of the severity of the carditis. Symptomatic patients or those with high-grade conduction disturbances should be admitted to the hospital for close monitoring with telemetry. This course should also be considered for those with significant prolongation of the P-R interval. Placement of a temporary pacemaker may be necessary in patients with complete heart block. There is no evidence that antibiotic therapy speeds recovery from Lyme carditis, but these agents are nonetheless used to eradicate infection and prevent additional complications. Oral antibiotics are used in early or mild cases, whereas IV regimens are indicated for more severe or chronic disease. Anti-inflammatory therapy with either aspirin (80 to 100 mg/kg per day) or occasionally prednisone (1 to 2 mg/kg per day) is recommended in cases of cardiomegaly, high-grade block, or significantly prolonged P-R interval (more than 300 ms) caused by Lyme disease.

Arthritis. Lyme arthritis occurs in more than 50% of untreated children, making it the most common late manifestation of infection. The classic presentation is a pattern of intermittent episodes of joint swelling beginning weeks to months after exposure. Less typical presentations of Lyme arthritis may also be seen. Patients may develop an apparent septic arthritis, with the acute onset of fever and joint pain, swelling, and erythema. Alternatively, synovitis might be migratory, simulating serum sickness or a postinfectious process, or chronic and persistent as in JRA. There is a propensity for large joint involvement, and often there is relatively little discomfort for the degree of swelling. The knee is affected in approximately 90% of cases, but more than two joints, or joints other than the knee, hip, ankle, or wrist, are involved in fewer than 10% of cases.

Lyme arthritis is clinically indistinguishable from JRA, septic arthritis, and postinfectious reactive synovitis, and it should be diagnosed only in the presence of convincing serologic evidence of borrelial infection. Current guidelines recommend initial treatment with oral antibiotics. Joint symptoms may only gradually improve over several weeks, but if joint pain and swelling persist for more than 2 months despite treatment, patients should be changed to IV therapy. Adjunct treatment with NSAIDs and physical therapy are important means of minimizing disability and accelerating recovery from Lyme arthritis.

CHAPTER 102

Problems of the Very Early Neonate

***GEETA GROVER, MD and †BENJAMIN K. SILVERMAN, MD**

**Department of Pediatrics, †Emergency Services, Harbor/UCLA Medical Center, and Children's Hospital of Orange County, Orange, California*

No aspect of the medical system's transition to shortened inpatient hospital stays has received more attention than that of early discharge to home of the postpartum mother with her newly delivered offspring. Discharge often occurs before the parents have received adequate instruction in care and before they have established a level of comfort and rapport with their baby. As a result, even experienced parents may feel inadequate in determining whether their newborn is ill or has a significant defect.

If a primary care contact has not yet been established, immediate access to medical evaluation is provided only by a visit to the hospital emergency department (ED). Thus, ED physicians are seeing increasing numbers of very early neonates who, in prior years, would still have been housed in the newborn nursery. This chapter serves as a guide to evaluating

and managing the parents' concerns during the first week to 10 days with their new baby.

Many of the problems will be insignificant and can be dealt with by judicious reassurance, but it must be kept in mind that seriously ill newborns may present with only subtle, nondescript symptoms. The parent's expressed complaint may be only a clue to a serious problem far removed from their area of concern, so a relevant perinatal history should be queried and, in most instances, a thorough physical examination performed.

The chapter is structured to allow the physician quick access to the complaint that precipitated the emergency visit. For conciseness and for easier access to information, the description of the presenting complaints is divided into subsections, based on physical, behavioral, and etiologic concerns. In most subsections, there is a delineation of those findings that are normal variants, those that might need further evaluation, and those that call for immediate attention. References are made to other chapters in this book where the more complicated problems are discussed in greater detail.

HISTORY

The emergency physician must be able to elicit relevant information needed to make decisions regarding diagnosis and management within a relatively short period. Time constraints, level of acuity within the ED, and the absence of long-term relationships can make communication in this setting particularly challenging. In the newborn period, not only is it essential to evaluate the health and physiologic stability of the baby, but often it is equally important to assess the psychosocial, emotional, and physical well-being of the mother; her ability and confidence in caring for her baby; the adequacy of support systems for the mother and family; and the access to follow-up care.

Because current concerns may have their origins in issues related to pregnancy or parturition, knowledge of the immediate history, a review of the events of labor and delivery, history of prior and current pregnancies, and a review of the family history are all essential components of the newborn history. Neonatal mortality is defined as the death of an infant between birth and 1 month of age. The leading causes of neonatal mortality—congenital anomalies, disorders related to short gestation and low birth weight, respiratory distress syndrome, and maternal complications of pregnancy—all have an association with pregnancy or parturition. Disclosure or identification of certain maternal, pregnancy, or infant-related factors (Table 102.1) place the newborn at increased risk and alert the practitioner of the potential for morbidity and mortality.

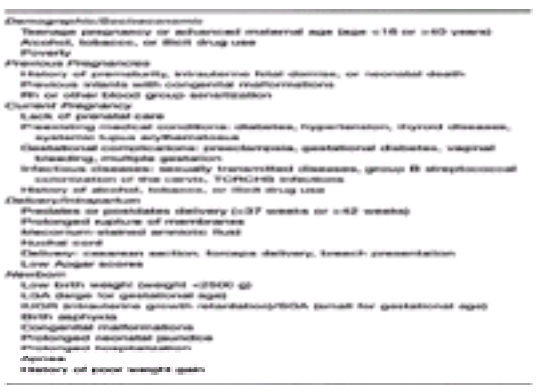

Table 102.1. High-Risk Factors for Neonatal Morbidity and Mortality

Certain points should be included in the history of all newborn infants, regardless of the presenting complaint. Always query regarding the infant's gestational age because size of an infant at birth does not necessarily reflect gestational age. An infant who is born “small for gestational age” (SGA) or with “intrauterine growth retardation” (IUGR) is at higher risk for morbidity and mortality than an infant of the same gestational age who is “appropriate for gestational age” (AGA). An infant whose birth weight is below the 10th percentile for gestational age is SGA. SGA infants have a more than fourfold increase in perinatal mortality than AGA infants of the same gestational age. Conversely, an infant whose birth weight is above the ninetieth percentile for gestational age is “large for gestational age” (LGA). The most common causes for LGA infants are familial, infants of diabetic mothers, and overgrowth syndromes such as the Beckwith-Wiedemann syndrome. Hypoglycemia, hyperbilirubinemia, hypocalcemia, and polycythemia are all associated acute complications that may be seen in the macrosomic infant. The clinician should inquire regarding the infant's general level of alertness, diet, and elimination patterns. Inadequate alimentation or infrequent urination may be clues to more serious problems. Parental concern about excessive crying or inability to soothe their infant requires attention because this excessive fussiness may have an underlying organic origin (see Chapter 17). Nonspecific complaints such as increased crying, sleepiness, and decreased appetite are sometimes the only symptoms of serious illness in the newborn.

Additional history should be guided by and focused specifically on the presenting complaint. Relevant suggestions are included in each of the “presenting complaint” subsections.

VITAL SIGNS

Growth

Weight gain serves as an important indicator of general well-being during the newborn period. Failure of a newborn to gain weight appropriately may be a sign of underfeeding or significant underlying illnesses such as heart disease,

metabolic problems, or malabsorption. Similarly, gaining weight according to age-specific norms can be one of the best indicators that the infant is well, despite nondescript symptoms such as fussiness.

The average newborn infant weighs 7.7 lb (3.5 kg), is about 20 inches (50 cm) long, and has a head circumference of 14 inches (35 cm). The newborn will lose about 5 to 10% of his or her birth weight during the first several days of life and then regain this weight by 10 to 14 days of age. Thereafter, the newborn should gain about 25 to 35 g/day (roughly 1% of the birth weight per day). The average newborn takes 2 to 3 ounces of formula (about 10 minutes on each breast) every 2 to 3 hours and has 10 to 12 wet diapers and 1 to 2 bowel movements (as often as once after each feeding for breast-fed infants) per day. Because breast milk is easier to digest and passes out of the stomach quicker than formula (on average 1½ hours versus up to 4 hours for formula), the breast-fed infant will want to feed more frequently, with an increased number of nighttime feedings as well, than the formula-fed infant.

Temperature

The young infant's immature autonomic thermoregulatory responses, larger body surface area to mass ratio, immature sweating response, and limited ability to move away from or modify adverse environments all limit his or her thermoregulatory ability. Temperature instability, either *hypothermia* or *hyperthermia,* may be the only sign of significant infectious illness. It is unusual to see high temperatures in the newborn. Even a septic newborn may develop only a slight elevation in temperature or temperature instability. Therefore, any temperature greater than 38°C (100.4°F) should be regarded as a fever in the newborn and receive appropriate evaluation (see Chapter 28 and Chapter 84).

Heart Rate (see Chapter 82)

Normal resting heart rate is between 120 to 160 beats/minute. It varies with respiration (increasing with inspiration) and activity (increasing significantly with crying and appreciably slower during sleep). Cardiac output in the infant is primarily increased by increasing the heart rate rather than stroke volume. Sinus *tachycardia* (heart rate greater than 180 beats/minute) is a common response to many types of stress, such as pain, hypovolemia, fever, or cardiac disease (see Chapter 74). *Sinus tachycardia* must be differentiated from *paroxysmal supraventricular tachycardia (SVT)* (see Chapter 82) when the electrocardiogram (ECG) demonstrates a narrow QRS complex tachycardia with a P wave preceding each QRS complex. SVT is usually associated with a more rapid heart rate (usually greater than 220 beats/minute) than is sinus tachycardia. Infants may tolerate SVT for a variable period, but eventually they develop irritability, tachypnea, poor feeding, and poor perfusion. The development of *bradycardia* (heart rate less than 80 beats/minute) usually signals the presence of significant cardiorespiratory compromise and is an ominous sign that requires immediate attention (see Chapter 2 and Chapter 3).

Respiratory Rate

Normal resting respiratory rate is usually between 40 to 60 breaths/minute. During sleep, most newborn infants will exhibit some degree of *periodic breathing,* in which normal respiration is interrupted with short pauses. This breathing pattern is especially common in premature infants. Periodic breathing must be differentiated from *pathologic apnea* (see Chapter 10). In the simplest of terms, apnea is an absence of respiration that can have a central, obstructive, or mixed cause. Short periods of central apnea (less than 15 seconds) can be normal at all ages. However, pathologic apnea is a prolonged respiratory pause (more than 20 seconds) or a shorter pause associated with cyanosis, pallor, bradycardia, or hypotonia. Underlying disorders that must be considered in the evaluation of the apneic infant, even the premature infant, include septicemia, severe anemia, intracranial hemorrhage, seizures, gastroesophageal reflux, metabolic disturbances such as hypoglycemia, or infant or maternal ingestion of narcotics or other central nervous system (CNS) depressants.

Varying degrees of *expiratory grunting, chest retractions, nasal flaring, crackles,* or *rales* are all signs of respiratory distress in the newborn. In addition to a primary pulmonary cause, respiratory distress in the newborn can also be a presenting sign of *congestive heart failure.* Among term infants, especially those born by cesarean section, a common cause of respiratory distress presenting within the first 24 hours, usually beginning between 2 to 6 hours after birth, is *transient tachypnea of the newborn* (TTN). TTN is believed to be caused by a delay in the absorption of the normal fetal lung fluid. The differential diagnosis of TTN includes meconium aspiration pneumonitis, respiratory distress syndrome (unlikely in the term newborn), pneumonia, and bronchiolitis. Symptoms of TTN typically resolve within 72 hours.

Blood Pressure

Normal systolic blood pressure in the term newborn after the first few days of life ranges between 60 to 90 mm Hg. Blood pressure is lower during the first few days of life and in premature infants is related to weight and gestational age. Congenital renal abnormalities, renal tumors, and complications of umbilical artery catheters are some of the more common causes of *hypertension* (see Chapter 35) in the neonatal period. *Coarctation of the aorta* may be diagnosed by the combination of increased upper extremity blood pressure with low blood pressure or diminished pulses in the lower extremities.

COLOR CHANGES

Normal Variants

The skin of a normal Caucasian early neonate is a pink, flushed color. This in itself may be a cause for alarm to some parents but can be dismissed with reassurance if the remainder of the history and physical examination is not remarkable. A hemoglobin or hematocrit determination offers assurance that the baby is not abnormally polycythemic. Racial and ethnic factors may result in variation of the baby's skin color, but this usually can be determined by comparing the baby with the parent's pigmentation.

Alterations of the flushed appearance to blue, deep yellow, orange, or pale may precipitate an ED visit. Evaluation and

management of these changes are discussed here.

Cyanosis/Acrocyanosis (see Chapter 16)

The presenting complaint may be that “the baby is blue.” Relevant questions to be asked include the following: When was the blueness first noted? Is it persistent or does it come and go? Does it involve all of the body or only the distal extremities and lips? Does it increase or lessen with crying or feeding? Is there emesis or diarrhea?

Physical examination should be complete. The distribution of the blueness should be carefully noted; particularly, check the color of the tongue. Does the intensity of the blueness decrease or increase with crying or with effort? Are the vital signs normal for a neonate? Is the baby responsive to stimulation? Is mottling present? Is there a cardiac murmur? Are respirations labored? Are the lungs clear? Is the liver enlarged? Are the femoral pulsations palpable?

The degree of cyanosis should be documented by pulse oximetry. The more likely causes are discussed in the following sections.

Acrocyanosis

An otherwise healthy baby has cyanosis confined to the hands, feet, and lips. The tongue is pink; pulse oximetry is normal. It may be associated with cool ambient temperature. Disposition: Parent(s) should be reassured that the acrocyanosis is self-limited.

Cyanotic Congenital Heart Disease (see Chapter 16, Chapter 33, and Chapter 82)

Cyanosis is diffusely distributed and increases with crying. Pulse oximetry shows diminished saturation at rest, worsening with crying; cyanosis responds only minimally to oxygen therapy. A cardiac murmur is usually, but not necessarily, present. ECG and echocardiography, if accessible, should be performed. Neonates with cyanotic heart disease only rarely go into cardiac failure. Disposition: Very early neonates with a strong suspicion of cyanotic cardiac defect should be admitted if cardiac consultation is not readily available.

Congestive Cardiac Failure (see Chapter 33 and Chapter 82)

Cyanosis is diffusely distributed, and pulse oximetry shows desaturation but improves somewhat with oxygenation. The infant is tachypneic, possibly with retraction. Rales may be apparent in lung fields. Cardiac murmur may be present or femoral pulsations may be absent. The liver is enlarged. Disposition: Emergency treatment and admission are indicated.

Respiratory Disease (see Chapter 16, Chapter 68, and Chapter 95)

Respiratory disease is associated with tachypnea and possibly retractions. Pulse oximetry shows desaturation but usually improves significantly with rest, crying, and oxygenation. The clinician should think of respiratory infection or congenital intrathoracic defect. A chest radiograph should be done. Disposition: After appropriate emergency treatment, the patient should be admitted.

Hypovolemia, Acidosis, and Shock (see Chapter 3 and Chapter 69)

Hypovolemia, acidosis, and shock are characterized by cyanosis accompanied by mottling in an extremely lethargic, hypotonic baby with marked tachycardia and possibly hypotension. Pulse oximetry is desaturated. Disposition: After appropriate emergency workup and treatment, the patient should be admitted.

Methemoglobinemia (see Chapter 16 and Chapter 87)

Methemoglobinemia is characterized by cyanosis diffusely distributed in the absence of cardiac or pulmonary disease. There may be a recent history of gastroenteritis. Pulse oximetry gives factitiously normal readings. A drop of blood on filter paper remains reddish brown, even after oxygenating it by waving in room air. Disposition: Emergency and laboratory evaluation to determine the intensity of involvement are indicated; treatment with methylene blue and admission should be considered.

Blue Sclerae

Blue color confined to the sclerae may be associated with osteogenesis imperfecta. The neonate's sclerae commonly may be normally blue, although the intensity is less. If in doubt, the clinician should take a careful family history and examine for fractures of the extremities, ribs, and pelvis.

Jaundice

The parent may be concerned because the newborn appears yellow or orange. Because this *may be a normal variant* in Pacific rim or Native American racial or ethnic groups, the parents' coloring should be compared with the baby's.

Bilirubin is formed by the catabolism of hemoglobin and may accumulate when there is either excessive hemolysis, failure of conjugation with glucuronic acid in the liver, or inadequate excretion through the liver canaliculi or the bile ducts. Bilirubin that has not been conjugated in the liver tests as indirect and is related to excessive hemolysis of red cells; conjugated bilirubin is reported as direct and is elevated when excretion is obstructed.

If jaundice is identified, relevant questions to be asked should include the following: When was the jaundice first noticed?

What is the color of stools and urine? What type of feeding is being used (breast or formula)? Are feedings adequate? What are the mother's and baby's blood types, if known? Has the infant vomited? Is there a family history of jaundice? Is the mother diabetic?

The most precise way of determining whether the color change is truly jaundice is by examining the sclerae—yellow color of the sclerae is jaundice. A complete physical examination should be performed, with emphasis on vital signs, intensity and distribution of icterus, presence of cephalohematoma, or hepatosplenomegaly.

The intensity of jaundice is determined by the level of bilirubin in the blood and by its distribution. As a rule, jaundice is not discernible in infants at levels less than 5 mg/dL. Jaundice is usually first discerned in the face and becomes more obvious caudally as the total serum bilirubin (TSB) level increases. In each patient, a TSB level and a complete blood count (CBC) with blood smear should be performed. If subsequent TSB levels are indicated in the baby, the direct bilirubin level should be determined at least once.

Physiologic Jaundice (see Chapter 41)

Physiologic jaundice is icterus that is not pathologic. Discernible jaundice in the first 24 hours of life of a healthy term newborn is probably pathologic, so a cause must be sought and therapy inaugurated. Beyond the first day, however, if the CBC and smear are not abnormal and the physical examination is not remarkable, a moderate degree of jaundice can be assumed to be physiologic. Infants of diabetic mothers and babies with congenital hypothyroidism or those with resorption from large cephalohematomata may have higher levels of icterus than one would expect physiologically.

Management and disposition can be governed by the recommendations in Table 102.2 and will vary with the baby's age and the bilirubin level. Babies with TSB nearing the levels at which therapy is suggested should be followed with at least one repeat determination within 24 hours to get a sense of the rate of rise.

Age (hr)	Consider Phototherapy[b]	Phototherapy	Exchange Transfusion if Intensive Phototherapy Fails[c]	Exchange Transfusion and Intensive Phototherapy
<24	—	—	—	—
25–48	≥12 (170)	≥15 (260)	≥20 (340)	≥25 (430)
49–72	≥15 (260)	≥18 (310)	≥25 (430)	≥30 (510)
>72	≥17 (290)	≥20 (340)	≥25 (430)	≥30 (510)

Adapted from the report of the Committee for Quality Improvement of the American Academy of Pediatrics. Pediatrics 1994;94:558–565.
TSB, total serum bilirubin.
[b]TSB level, mg/dL (μmol/L).
[c]Phototherapy at these TSB levels is a clinical option, meaning that the intervention is available and may be used on the basis of individual clinical judgment.
[d]Intensive phototherapy should produce a decline of TSB of 1–2 mg/dL within 4–6 hr, and the TSB level should continue to fall and remain below the threshold level for exchange transfusion. If this does not occur, it is considered a failure of phototherapy.

Table 102.2. Management of Hyperbilirubinemia in the Healthy Term Infant According to TSB and Baby's Age[a]

Breast Milk Jaundice (see Chapter 41)

In breast-fed babies, jaundice may be initiated by inadequate caloric intake and the dehydration that may occur before there is sufficient milk. It usually begins in the early neonatal period and may continue for weeks. If TSB is not approaching levels at which phototherapy needs to be considered, breast-feeding should be continued and even encouraged more frequently. Higher TSB levels should be followed with at least one additional determination.

Blood Type Incompatibility (see Chapter 41 and Chapter 87)

If the TSB level is at or near levels requiring therapy (Table 102.2) and particularly if the jaundiced baby has a lower hemoglobin than expected, direct Coombs' test should be done. Mother and baby should be blood typed for ABO and Rh factors. If there is an incompatibility and if the bilirubin is rising rapidly despite phototherapy, blood should be prepared for possible exchange transfusion. Rh incompatibility is uncommon in those mothers who have had ongoing obstetric care. ABO incompatibility is usually more insidious in onset and less severe than Rh.

Sepsis (see Chapter 69 and Chapter 84)

Sepsis need not be a consideration in the alert, well-appearing, jaundiced newborn. If the jaundiced baby is lethargic or extremely irritable, hypotonic, or tachycardiac and has been feeding poorly, sepsis and/or urinary tract infection should be considered. The bilirubin may be indirect or direct.

Congenital Red Cell Defects (see Chapter 41 and Chapter 87)

Careful examination of the blood smear may provide a clue to red cell membrane defects. These babies may have indirect bilirubinemia and anemia and may have a positive family history for spherocytosis or elliptocytosis. More severe forms of glucose-6-phosphate dehydrogenase deficiency also may present with early jaundice and anemia, especially if the mother has received possibly precipitating drugs during late pregnancy. Elevated reticulocytes with a negative Coombs' test would make one suspicious.

Other Congenital Problems (see Chapter 41 and Chapter 42)

The group of congenital infections that falls under the acronym of TORCHS (TOxoplasmosis, Rubella, Cytomegalovirus, Herpes virus, Syphilis) may present with jaundice. These should be thought of in the baby with elevated direct bilirubin who presents with microcephaly, jitteriness, seizures, organomegaly, or petechiae. Elevated direct bilirubin also may be an early manifestation of galactosemia and cystic fibrosis. Babies with the severe form of the enzymatic defect of Crigler-Najjar syndrome may present with extremely high levels of unconjugated bilirubin, which may rise despite phototherapy.

Pallor

The neonate may be brought to the physician because he or she appears pale to the parents. A careful history and physical examination should be done to consider the possibilities of septic or cardiogenic shock, severe chemical or electrolyte imbalance, or significant anemia.

Questions should be asked regarding the mother's perinatal history, the baby's suck and feeding, the occurrence of vomiting or diarrhea, fever, and the baby's responsiveness. Physical examination should include thorough evaluation of the vital signs. Is the baby extremely lethargic? The clinician should look at the inner palpebral conjunctivae, and check the skin for petechiae or rashes. Is there a large cephalohematoma? Is there hepatosplenomegaly?

A CBC should be done and consideration given to a stat glucose and electrolyte panel and total serum bilirubin level. Normal levels at this age for hemoglobin are in the range of 13 to 20 g/dL with a mean of 16; for hematocrit, 42 to 65% with a mean of 50%. Diagnostic considerations include the topics discussed in the following sections.

Fair Complexion

If the vital signs and the physical examination are normal and the CBC does not indicate anemia, the presenting concern probably relates to the baby's normal fair-skinned coloring. Offer appropriate explanation and discharge home.

Anemia (see Chapter 59 and Chapter 87)

Anemia in the neonate is not usually recognized as pallor until the hemoglobin falls below 10 g/dL. It is most commonly, but not necessarily related to excessive hemolysis of the red blood cells and often is accompanied by jaundice. The more common etiologies might include the following:

- *Hemolytic disease of the newborn:* Complete maternal and neonate blood typing should be done, as well as a Coombs' test. Depending on the degree of anemia and the baby's functional status, crossmatching for possible packed cell or exchange transfusion should be inaugurated.
- *Congenital erythrocyte membrane defects:* These defects can usually be suggested by careful evaluation of the blood smear.
- *Malignancy:* Congenital leukemia is a rare entity that should be discernible on the blood smear.
- *Congenital and aplastic anemias:* Diamond-Blackfan syndrome, transient erythroblastopenia of childhood, sickle cell disease, and Fanconi's syndrome do not usually appear in the early neonatal period.
- *Blood loss:* Blood loss can occur through the gastrointestinal tract (Meckel's; clotting disorder) and should be suspected if a stool is positive for blood. Imaging evaluation is indicated. Significant blood loss can also occur into a large cephalohematoma or an intracranial hemorrhage in an infant.
- *Disseminated intravascular coagulopathy (DIC):* DIC may occur in association with bacterial sepsis, viremia, and shock, accompanied by petechiae and purpura. Platelet count is significantly diminished in these ill children. Evaluation is directed at finding a cause and therapy at replacing deficient elements (see Chapter 3, Chapter 65, and Chapter 87).

Ill Children (see Chapter 3)

Pallor may be the most striking presenting complaint in the neonate who is ill. Children in septic or cardiogenic shock may appear pale because of poor perfusion, without necessarily being anemic. Hypoglycemic infants and those with severe electrolyte disturbances may also present with pallor. Rapid diagnosis and emergency administration of glucose and volume restoration are essential.

Mottling

Mottling in the neonate is the patchy appearance of the body surface, resulting from prominent dilation of the superficial veins showing through the thin skin and causing a mosaiclike, patchy appearance. Mottling may be a normal variant when it appears in an otherwise normal baby, undressed in a cool ambient temperature. It is more likely to appear in a preterm baby with thin skin.

However, mottling can be an ominous diagnostic sign in a neonate. It may be indicative of hypovolemia and poor perfusion in a baby in shock or a septic baby. A careful history and complete physical examination with cautious evaluation of the vital signs need to be done. If there is doubt about the baby's status, an electrolyte panel and stat glucose should be drawn. Treatment of the underlying cause and restoration of hemodynamic stability should be inaugurated in the ED.

SKIN FINDINGS

The quality of the newborn's skin varies with gestational age. The premature infant's thin, almost translucent skin is in sharp contrast to the dry, cracked, peeling skin of the postterm infant. The term infant's skin is usually pale pink in color

with some diffuse superficial peeling noted at several days of age. Normal peeling of the superficial layers of the skin should be differentiated from the full-thickness skin loss that is associated with *staphylococcal scalded skin syndrome*. *Excoriations* when noted in an irritable or jittery infant, especially when they are located primarily on the nose or knees, may be a sign of withdrawal in an infant exposed to narcotics prenatally.

Seborrheic dermatitis (see Chapter 99) is a localized scaling or crusting eruption that most commonly involves the scalp ("cradle cap"), forehead, and area behind the ears. Occasionally, the diaper area may be involved. The eruption may have a greasy appearance and the lesions are generally nonpruritic.

Hair

Soft, downy, fine body hair, *lanugo,* located primarily on the back and shoulders, is a normal finding. However, a tuft of coarse, dark hair located in the midline lumbosacral region may be associated with spina bifida occulta.

Papular Rashes (see Chapter 62 and Chapter 63)

A variety of papular rashes may be observed in the healthy newborn. Characteristic body distribution patterns and age at appearance of these typical rashes may help differentiate them from more worrisome conditions.

Milia are small 1 to 2 mm ivory or yellow papules located primarily on the forehead, nose, and cheeks of the newborn. Milia are keratin retention cysts that require no treatment because they will spontaneously rupture and disappear during the first 3 to 4 weeks of life.

Erythema toxicum is a more generalized eruption of small papules or pustules on an erythematous base that may occur anywhere on the body. Usually presenting during the first 3 to 4 days of life, these lesions may be noted as late as 2 weeks of age. Herpes simplex infections, although usually vesicular, and impetigo, usually pustular or crusted, may be entertained in the differential diagnosis of this eruption. If the diagnosis is in question, a smear of the papular contents will show a predominance of eosinophils with a relative absence of neutrophils and no organisms.

Erythematous papules or pustules (rarely comedones) confined primarily to the cheeks, chin, and forehead are characteristic of *neonatal acne.* Lesions are secondary to the influence of circulating maternal hormones and usually appear at 3 to 4 weeks of age and disappear within a few weeks.

Vesicular Rashes (see Chapter 67)

The most important condition to consider when evaluating a vesicular eruption is a herpes simplex virus (HSV) infection because it has the most significant associated morbidity and mortality. Most neonatal *HSV infections* are caused by HSV type 2. Although transplacental transmission of HSV can occur, most neonatal disease is acquired from infection of the maternal genitourinary tract. Primary maternal infection at the time of delivery is associated with a 40 to 50% risk of disease transmission to the newborn, whereas recurrent disease has a much lower risk of transmission (less than 5%). Clinical disease in the newborn may range from localized infection of the CNS, skin, eyes, or oropharynx to disseminated viremia with multisystem involvement. The infant generally appears well at birth but then becomes ill about day 4 to 7, at which time a vesicular eruption may be noted. Unfortunately, not all HSV-infected infants have the typical vesicular eruption, making early diagnosis difficult. Small (1- to 2-mm) vesicles on an erythematous base, which may become pustular in 24 to 48 hours, are the most common lesions. At times, only 1 or 2 vesicles may be present; lesions are noted most often on the scalp and face, the presenting part of the infant in a normal delivery. Early diagnosis and prompt initiation of antiviral therapy can improve morbidity and mortality.

Neonatal varicella may develop when maternal varicella infection occurs during the last 2 to 3 weeks of pregnancy or the first few days postpartum. The severity of neonatal disease depends on the timing of the maternal infection. If maternal disease onset is 5 or more days before delivery, the infection in the newborn is usually mild because of the transplacental passage of maternal varicella IgG antibody. In contrast, if maternal disease onset is within 4 days before delivery or within 48 hours after delivery, the neonate is at risk of developing severe infection with up to a 30% mortality usually caused by pulmonary or visceral involvement. Diagnosis can usually be made by the history and the characteristic rash, vesicles on an erythematous base (dew drops on a rose petal). The primary differential diagnosis includes HSV-1 or HSV-2 infection. Acyclovir may be considered for moderate or severe cases of neonatal varicella. Varicella-zoster immunoglobulin (VZIG) is recommended for uninfected infants born to mothers whose onset of chickenpox was within 5 days before to 2 days after delivery.

Incontinentia pigmenti is an X-linked dominant disorder with both skin and systemic lesions (affecting the eyes, CNS, and bone). It presents at birth or shortly thereafter with an inflammatory vesicular or bullous rash that develops in crops over the trunk and extremities. The cutaneous lesions have four phases (inflammatory vesicles or bullae, verrucous lesions, whorled hyperpigmentation, and hypopigmented patches) that may overlap and occur in an irregular sequence. Suspected cases should be referred to a dermatologist for evaluation because of the potential for systemic involvement.

Miliaria, or neonatal prickly heat, is caused by sweat retention and is characterized by easily ruptured, tiny (1- to 2-mm) vesicles located primarily on the face, chest, and back.

Impetigo appears as superficial vesicular, pustular, or bullous lesions on an erythematous base. In the newborn, lesions tend to occur primarily in the diaper area, folds of the neck, or axillae.

Vascular Lesions

The *salmon patch (nevus simplex)* is the most common vascular lesion of infancy. It is a pale pink macular lesion that is

found most commonly on the nape of the neck (often called a stork bite), forehead, nasolabial region, or upper eyelids. With the exception of the lesions on the nape of the neck, most will fade within the first year of life.

Nevus flammeus (port-wine stain) consists of mature dilated dermal capillaries and presents at birth as pink to purple macular lesions that can vary tremendously in size, sometimes involving a significant portion of the body (Klippel-Trenaunay-Weber syndrome should be considered when the port-wine stain involves a lower limb). Unilateral facial port-wine stains in a trigeminal nerve distribution may be associated with the Sturge-Weber syndrome (seizures, intracranial calcifications, and hemiparesis). These lesions generally will not fade with time.

Although *capillary hemangiomas (strawberry hemangioma)* may be present at birth, most develop during the first few weeks of life. Lesions may occur anywhere on the body and typically begin as small, well-demarcated telangiectatic macules that subsequently develop into raised bright red or purple tumors with distinct borders. Most lesions will go through a period of rapid growth over the first 6 months of life, followed by a static period and then spontaneous involution, usually by 5 years of age.

Cavernous hemangiomas are deep-seated capillary hemangiomas that usually present at birth as a diffuse swelling with little change in the color of the overlying skin or a bluish hue. Most involute spontaneously with time.

Hemangiomas that may require intervention during the neonatal period are those that by location or size may compromise vital structures such as the eyes, nares or auditory canals; lesions that by their size or location (e.g., perianal or labial lesions) are susceptible to trauma, ulceration and secondary infection; and large, rapidly enlarging hemangiomas associated with thrombocytopenia and a consumption coagulopathy (Kasabach-Merritt syndrome).

Pigmentary Changes

Mongolian spots are poorly circumscribed blue–black, gray, or brown large macular lesions generally located over the lumbosacral region, buttocks, and lower limbs in over 80 to 90% of African-American, Native American, Hispanic, or East Asian infants. The incidence is less than 10% in Caucasian infants. Lesions will usually fade during the first few years of life.

Café-au-lait macules are round or oval, brown macular lesions varying in size from less than 1 cm to greater than 20 cm. Although normal individuals may have these lesions, they may be a sign of neurocutaneous disease, most commonly neurofibromatosis.

Ash-leaf macules are irregular hypopigmented macules often with an oval or “ash-leaf” appearance found in 70 to 90% of individuals with tuberous sclerosis. This is an autosomal-dominant condition characterized by CNS lesions, seizures (infantile spasms), retinal lesions, cardiac rhabdomyomas, and renal lesions (hamartomas or cystic kidneys).

HEAD AND NECK PROBLEMS

Head Size and Shape

Shape, size, and symmetry are all factors that must be considered in the evaluation of the neonate's head. *Microcephaly* refers to a head circumference that is less than 2 standard deviations below the mean, or less than the 3rd percentile for age and sex. Microcephaly is usually a sign of a severe underlying abnormality of brain growth or development and is often associated with mental retardation. It may be secondary to a variety of causes, including Down syndrome, congenital TORCHS infections, and fetal alcohol syndrome. *Macrocephaly* is a head circumference that is greater than 2 standard deviations above the mean, or greater than the 97th percentile for age and sex. An excessively large head may be familial or suggestive of hydrocephalus, storage disease, or intracranial hemorrhage.

Molding of the skull bones during the vaginal delivery process is a common cause of temporary asymmetry and scalp edema, *caput succedaneum.* Caput succedaneum is an ill-defined generalized swelling of the soft tissues of the scalp that extends across suture lines. Generally, both caput succedaneum and skull molding spontaneously resolve by 7 to 10 days of age. Trauma during the birth process may produce a *cephalohematoma,* a subperiosteal hemorrhage, distinguished from a caput by the fact that the swelling never crosses suture lines. However, the diagnosis can be difficult in the immediate newborn period if overlying scalp edema is present. Most commonly, a cephalohematoma is unilateral, but it can be bilateral. Cephalohematomas resolve slowly over 4 to 6 weeks with possible calcification and the formation of a hard bump on the scalp that is often a source of great concern to parents. Occasional complications resulting from the breakdown and resorption of large hematomas are anemia or jaundice.

Overriding cranial sutures, caused by the pressures exerted on the skull during its descent through the pelvis, may be noted for the first several days of life. Overriding sutures that are palpable beyond this time may be a sign of underlying brain pathology and deserve further evaluation. Ridging or prominence of cranial sutures may be a sign of *craniosynostosis,* a premature fusion of cranial sutures. Overriding sutures are ballottable, but if the sutures are rigid and have a heaped-up solid closure, radiographs or even a computed tomography (CT) scan should be done to rule out craniosynostosis. Soft areas, *craniotabes,* are occasionally found on palpation of the parietal bones during the first several days of life, especially in premature infants. Soft areas noted in the occipital region may be suggestive of osteogenesis imperfecta or other syndromes and should be investigated.

At birth, the newborn has two *fontanels*. The anterior fontanel, situated at the junction of the coronal and sagittal sutures, usually measures about 2 × 2 cm (can be up to 5 to 6 cm in its largest diameter), and normally closes between 9 to 18 months. The posterior fontanel, situated at the junction of the lambdoidal and sagittal sutures, generally measures between 0.5 to 1 cm (may be closed at birth in some cases), and usually closes to palpation by 3 to 4 months of age. Enlarged fontanels may be associated with a variety of conditions, including prematurity, hypothyroidism, or hydrocephalus. Increased intracranial pressure produces a full or bulging fontanel, whereas dehydration produces a

depressed fontanel. A fontanel that appears full while the infant is supine or crying should be reassessed while the infant is held upright and sleeping or feeding before it is determined to be full or bulging.

Face

Facial asymmetry is usually secondary to in utero position. Commonly, when the face and neck are pressed against the shoulder in utero, a characteristic flattening of the face and angle of the jaw is noted on that side because of displacement of the mandible. This facial asymmetry will resolve spontaneously in a few weeks.

Neck (see Chapter 45 and Chapter 46)

Congenital muscular torticollis is a positional abnormality of the neck resulting in abnormal tilting and rotation of the head. It is believed to be secondary to intrauterine positioning or trauma to the soft tissues of the neck during delivery, with resulting ischemia of the sternocleidomastoid muscle secondary to venous occlusion. This leads to edema and degeneration of the muscle fibers with eventual fibrosis of the muscle body. Although congenital muscular torticollis may be noted at birth, it usually manifests at 2 to 4 weeks of age. The incidence is increased in breech presentations and difficult deliveries. Unilateral contracture and fibrosis of the sternocleidomastoid muscle results in a characteristic head tilt toward the affected side and the chin pointing toward the opposite side. On examination, a firm, nontender mass may be felt within the body of the sternocleidomastoid muscle. Treatment consists of passive stretching exercises of the neck and repositioning toys and mobiles in the crib to stimulate the infant to look toward the side opposite the preferred gaze. Occipitocervical spine anomalies, such as the Klippel-Feil syndrome (congenital fusion of two or more cervical vertebrae; clinical triad of short neck, limited neck motion and low occipital hairline), are rare causes of torticollis that present in the newborn period.

Congenital neck lesions may present during infancy or sometimes much later in childhood. The most common lesions include, *thyroglossal duct cysts* (midline in the neck and inferior to the hyoid bone), *branchial cleft cysts* (along the lateral neck), and *cystic hygromas* (usually located behind the sternocleidomastoid muscle in the supraclavicular fossa; two-thirds of cystic hygromas are present at birth).

Redundant skin on the back of the neck or webbing in a female infant are suggestive of *Turner's* syndrome and may be associated with lymphedema of the dorsum of the hands and feet in the newborn.

EYE PROBLEMS

The newborn is very nearsighted at birth, with a visual acuity of about 20/400. The eyelids are closed most of the time, and any attempt to force them open usually meets with marked resistance and causes blepharospasm. Holding the infant upright and gently swaying him or her from side to side or up and down often induces the eyes to open spontaneously. Common neonatal ophthalmologic concerns include leukokoria, neonatal conjunctivitis, excessive tearing, scleral and subconjunctival hemorrhages, and uncoordinated eye movements.

Leukokoria

The pupillary light reflex is a simple test that takes only moments and should be performed on all newborns. In the normal newborn, a “red reflex” is seen when the ophthalmoscope is held 10 to 12 inches in front of the eyes. A white pupillary light reflex, or leukokoria, is never normal in the newborn. Leukokoria may be a sign of several conditions of variable severity and prognosis such as colobomas, cataracts, retinal detachment, retinopathy of prematurity, or retinoblastoma (the most common signs are leukokoria [60%] and strabismus [20%]). Therefore, all infants with an abnormal pupillary light reflex should be referred to an ophthalmologist for a prompt evaluation.

Conjunctivitis (see Chapter 24 and Chapter 120)

The major causes of *neonatal conjunctivitis, or ophthalmia neonatorum,* are chemical, chlamydial, bacterial, and viral. The time of onset of symptoms after birth can help identify the causative agent. Mild inflammation of the conjunctivae that begins 12 to 24 hours after birth is typically caused by the prophylactic eye drops instilled at birth. This *chemical conjunctivitis* usually resolves by 48 hours of age. *Neisseria gonorrhoeae* conjunctivitis generally appears 2 to 5 days after birth, whereas conjunctivitis caused by *Chlamydia trachomatis* presents between 5 to 14 days after birth because of its longer incubation period. Gonococcal infection may be delayed beyond 5 days of age because of partial suppression by the prophylactic drops instilled at birth. Gonococcal infection usually manifests as marked inflammation of the eyelids, chemosis, and copious purulent discharge. Presentation of chlamydial infection, which is primarily localized to the palpebral conjunctiva, can vary from mild inflammation to severe swelling of the eyelids with copious discharge. Of neonates with chlamydial conjunctivitis, 10 to 20% have chlamydial pneumonia, which can either occur simultaneously with the eye infection or up to 4 to 6 weeks later. Gonococcal conjunctivitis is considered a medical emergency because the infection can spread to the cornea, producing corneal ulceration and perforation. HSV is a less common cause of neonatal conjunctivitis. The presence of characteristic skin lesions can help in the diagnosis. Gram stain and cultures are essential in the evaluation of neonatal conjunctivitis. Treatment is discussed in detail in Chapter 24 and Chapter 120.

Excessive Tearing (see Chapter 24 and Chapter 120)

Congenital obstruction of the nasolacrimal duct, dacryostenosis, is the most common cause of excessive tearing in the newborn. Dacryostenosis should be differentiated from *congenital or infantile glaucoma,* a serious but fortunately rare cause of excessive tearing. Most cases of infantile glaucoma presenting during the first 3 months of life are bilateral, whereas dacryostenosis is usually unilateral.

Increased wetness of the affected eye relative to the normal eye, excessive tearing, mucoid eye discharge, and crusting

along the eyelid margins are the usual presenting symptoms of dacryostenosis. Gentle pressure along the medial canthal region over the lacrimal sac may produce a reflux of tears or purulent material onto the surface of the eye, confirming the diagnosis. In addition to excessive tearing, infants with glaucoma also present with rhinorrhea, photophobia, and corneal haziness. The cornea may be inspected after instillation of fluorescein dye to rule out a *corneal abrasion* as the reason for the excessive tearing. Uncomplicated cases of nasolacrimal duct obstruction should be managed with gentle cleansing of the eyes with warm water followed by local massage of the nasolacrimal duct several times per day. Topical antibiotic ointments should be prescribed if there is associated conjunctivitis or purulent discharge. Suspected cases of infantile glaucoma require immediate ophthalmologic evaluation.

Scleral and Subconjunctival Hemorrhage

Scleral and subconjunctival hemorrhage are often noted in the newborn secondary to birth trauma. These lesions are common and spontaneous resolution within 1 to 2 weeks is the rule. If the funduscopic examination is performed, similar hemorrhages may be noted on the retina in about 25% of newborns. The presence of retinal hemorrhages should also raise the possibility of intentional trauma. Specifically, the *shaken baby syndrome* has been associated with flame-shaped retinal hemorrhages and subdural hematomas.

Transient Neonatal Strabismus (see Chapter 25)

Intermittent esotropia or exotropia may be noted in normal infants during the first 2 to 3 months of life. These deviations are believed to be secondary to neuromuscular immaturity and generally resolve spontaneously by 4 months of age. If such eye deviations are constant instead of intermittent, the infant should be referred for an ophthalmologic examination. In many infants, a broad, flat nasal bridge and prominent epicanthal folds may obscure a portion of the sclera near the nose and create the appearance of esotropia. This *pseudostrabismus,* or apparent deviation of the eyes, is an illusion that can be dispelled by the finding of symmetric bilateral pupillary light reflexes.

MOUTH PROBLEMS (SEE CHAPTER 49)

Normal Findings

Common normal findings in the oropharynx include natal teeth and benign gingival cysts. The incidence of *natal teeth* (teeth present at birth) is about 1 in every 3000 live births. The mandibular central incisors are the most commonly affected teeth. Because most natal teeth are primary teeth that have erupted early, they should be extracted only if they are loose and pose a danger of aspiration, cause discomfort to the mother or child during nursing, or are confirmed to be supernumerary by radiographic examination.

Benign gingival cysts (see Chapter 124) are found in 75% of newborns. *Epstein's pearls* are usually single, small, white, keratin-filled cysts found along the midline of the palate. *Bohn's nodules* are mucous gland cysts that appear as multiple, firm, grayish white lesions along the gums and occasionally on the palate. *Dental lamina cysts* are formed by remnants of dental lamina epithelium and appear as small, cystic lesions along the crests of the mandibular and maxillary mucosa. They are usually larger and more lucent than either Epstein's pearls or Bohn's nodules. These cysts generally disappear by 4 weeks of age.

Thrush

Thrush is caused by *Candida albicans.* Diagnosis may be based on clinical examination. Creamy white plaques located on the buccal mucosa or tongue that are difficult to remove and may cause bleeding when scraped are characteristic of candidiasis. Treatment consists of local application of nystatin suspension four times a day. Topical application of nystatin ointment to the mother's nipples may be indicated in recurrent or refractory cases if the infant is breast-feeding.

CHEST AND BACK FINDINGS

This section discusses those external lesions on the thorax and back of the neonate for which a parent may bring the baby to emergency care. Intrathoraciclesions and diseases which present with secondary symptomatology are discussed in detail in other contexts elsewhere in this book (see Chapter 68, Chapter 95, and Chapter 119).

Normally, the term newborn's thorax is symmetric and barrel-shaped. It is graced with two nipples anteriorly, each about 10 mm in diameter and slightly elevated and stippled. Respiratory excursion should be symmetric and accompanied by simultaneous movement of the abdomen. In the midline of the back, the tips of the vertebrae can be palpated but not visualized. The rib cage is not flared or depressed. There are a number of variations of this normal anatomy, some normal and some not, which may be striking enough for a parent to bring the child to the ED.

Respiratory Excursion (see Chapter 68, Chapter 84, and Chapter 95)

Intrathoracic disease or anomaly may be suggested by variations in the normal symmetric excursion of the thorax. If thoracic excursion is asymmetric or if there is significant tachypnea or retraction accompanied by grunting and either excessive or paradoxic excursion of the abdomen, a chest radiograph is warranted and pulse oximetry should be checked.

Fractured or Absent Clavicle(s)

In the course of vaginal delivery, the clavicle may be fractured, resulting in asymmetry at the shoulder girdle area. Palpation of the clavicle may reveal a “drop-off” in the continuity of the bone and possible crepitation when gentle pressure is applied. A confirmatory radiograph should be taken and appropriate reassurance offered for the healing

process. Much more rarely, clavicles may be absent bilaterally with resultant low positioning of the shoulders. This positioning may be indicative of the dominant genetic defect known as cleidocranial dysostosis and requires orthopedic and genetic evaluation.

Pectus Excavatum

Relative depression of the lower sternum and rib cage is usually a normal variant unless accompanied by signs of respiratory distress.

Xiphoid Process

Parents may feel a firm small mass in the midline at the distal end of the sternum. This is the xiphoid process, angled outwardly, and is a normal variant.

Breast (see Chapter 12 and Chapter 84)

Supernumerary Nipples

A round, possibly slightly elevated or slightly depressed lesion, about 10 mm in diameter, lighter in shade than the nipple and located about 2 to 3 cm below, is a supernumerary nipple. This is a normal variant and will remain permanently. Uncommonly, these may be associated with renal lesions, but that possibility need not be investigated in a child who is otherwise well.

Enlarged

- *Breast buds:* Prominent, nontender breast tissue in the neonate of either sex is a normal variant, probably related to maternal estrogen. This subsides with time, and no therapy is indicated. Often, colostrumlike material can be extruded, but efforts to do this should be gentle and conducted under hygienic conditions.
- *Breast cellulitis/abscess:* Breast tissue that is hypertrophied, reddened, and tender is probably infected. The child may or may not be febrile. Warm compresses and intravenous antibiotic treatment, including coverage for probable staphylococcal origin, should be inaugurated after appropriate cultures are taken. The baby should be admitted for continuing therapy.

Absent

An absent nipple may be associated with an ipsilateral absent pectoralis muscle. Chest radiograph should be taken and the baby referred for genetic and orthopedic evaluation.

Spinal Column Defects

Spina Bifida

A grossly apparent spina bifida lesion, complete with lower extremity flaccidity and meningeal extrusion in the midline of the back, obviously should not have been missed in the hospital nursery. The baby delivered at home however, may be referred into the ED for initial management. Sterile, moist dressing should be applied and the baby admitted for neurosurgical, orthopedic, and urologic management. If the home delivery occurred under less than sterile conditions, cultures should be taken and inauguration of appropriate antibiotic therapy considered.

Sacral Dimple

A midline dimple of the lower back, with or without a tuft of hair, or a lipomatous intracutaneous or subcutaneous lesion in that area may be clues to the presence of spina bifida occulta, a less obvious form of spina bifida. This may or may not be associated with lower extremity deformity. The dimple may also be the external manifestation of a sinus tract connecting to the intradural space without vertebral anomaly, which would leave the infants susceptible to meningeal infection. On the other hand, the dimple may be a normal skin indentation. If in doubt, scheduling of magnetic resonance imaging and neurosurgical referral should be considered.

ABDOMINAL AND PERINEAL FINDINGS

The neonatal abdomen is full but is neither distended nor scaphoid. The liver is normally palpable 2 to 3 cm below the right costal margin; the spleen is not usually palpable; the lower edges of the kidneys may be felt with deep palpation. There should be no palpable extraneous masses. Constipation, meconium passage, and vomiting are discussed in Chapter 14, Chapter 78, Chapter 96, and Chapter 118. This section discusses those external findings in the abdomen and perineum that might cause a parent to bring the new baby to the ED.

Umbilicus

The umbilical cord is tied or clamped at the time of delivery and usually sloughs off by the tenth day. Careful umbilical care consists of gentle hygienic measures and cleansing with isopropyl alcohol several times a day. Still, the umbilical area may be a source of concern for the parents, who may appear in the ED with their neonate.

Discharge

Discharge from the umbilical area may occur and is benign if it is clear or yellow-tinged and thin. Reassurance and instruction in hygienic measures are all that is necessary. A thick, purulent discharge, accompanied by intense redness and apparent tenderness, however, suggests infection. The discharge should be cultured and treated vigorously with antibiotics because the umbilical vessels are potential entry points for systemic invasion.

Granuloma

Granulation tissue, lumped into a small ball about 1 cm across and attached in the umbilical area, can be cauterized with a silver nitrate stick. The parents should be forewarned that the area will turn transiently black. Often, this treatment has to be repeated in a week or so.

Umbilical Hernia

Umbilical hernia is a result of incomplete merging of the recti muscles at the ring through which the cord had been protruding. It is often accompanied by a larger rectus diastasis extending superiorly, sometimes to as high as the xiphoid process. The size can vary from as little as a few millimeters to as much as 4 or 5 cm. It is covered by skin. With crying or straining, portions of the intestine and omentum can be palpated, but not visualized, within the hernia. No treatment is necessary in the neonatal period because these almost always close as the baby becomes ambulant and strengthens the rectus muscles. Abdominal bandages are unnecessary. Rarely, at a later age, an umbilical hernia may strangulate and require surgery.

Omphalocele

An omphalocele is essentially a large hernia into the base of the cord, but it is covered only by peritoneum, not skin. It contains a significant amount of intestine and, rarely, a lobe of the liver. The child should be admitted for early surgery.

Genital Area

The penis should be at least 1 cm in length with a urethral opening at the tip. The testes are usually palpable within the scrotal sac. The labia majora overlie and cover the labia minora.

Vaginal Discharge and Bleeding (see Chapter 76 and Chapter 77)

White mucoid discharge, which may be thick, in the vaginal opening is a normal finding. Vaginal bleeding after the first day or two and during the first week is also a normal occurrence. It is the result of postpartum estrogen withdrawal.

Inguinal Mass

A mass palpable in the scrotum may be an inguinal hernia or a hydrocele or a combination of the two. Hernias are usually easily reducible in the neonate. Hydroceles are fluid-filled and transilluminate readily. A mass within the labia majora is most likely ovary or intestine that has passed through an inguinal hernia. These are somewhat more likely to incarcerate than male hernias.

Hypospadias

When the urethral opening is not at the tip of the penis but on the glans, the baby has first-degree hypospadias. When the opening is on the shaft, it is second degree and on the perineum, third degree. Infants with second- and third-degree hypospadias should be referred for urologic evaluation and imaging of the genitourinary tract.

Ambiguous Genitalia

The possibility of ambiguous genitalia should be considered in a male if the apparent penis is small and there is third-degree hypospadias with a cleft in the scrotum; in the female, genitalia are ambiguous if there appears to be an unusually long clitoris with partial or complete fusion of the labia majora and if there is a firm mass in the labia. In the female, but not in the male, such pseudohermaphroditism may be associated with *congenital adrenal hyperplasia,* with or without “salt-losing” symptomatology (see Chapter 97). To establish gender identity and to evaluate for the possibility of congenital adrenal hyperplasia, electrolyte, imaging, and chromosomal studies need to be done early in the child's neonatal period under the supervision of a urologist and geneticist and possibly an endocrinologist.

Imperforate Anus

An imperforate anus may not be obvious on external examination. The finding of an anus that appears to be located considerably more anteriorly than expected might suggest a fistula from the lower rectum to the skin, detouring around the anus. Meconium may actually pass through this fistula, simulating normal rectal passage. The area should be examined carefully, looking for the normal perianal–anal puckering, which will not be present if the anteriorly placed opening is a fistula. The rectal examination should be carefully performed. The clinician should consider imaging studies and surgical referral.

ORTHOPEDIC CONCERNS (SEE CHAPTER 123)

Most neonatal orthopedic problems are deformities secondary to intrauterine positioning. Some problems (e.g., metatarsus adductus) require only parental reassurance and expectant management, whereas others (e.g., congenital

clubfoot and hip dysplasia) require early orthopedic attention.

Developmental Hip Dysplasia

Developmental dysplasia of the hip (DDH) applies to a range of hip pathology, ranging from instability to frank dislocation, that may either be present at birth or develop during infancy. The Ortolani and Barlow maneuvers may be used in the neonatal period to evaluate for hip instability. Both tests are performed with the infant in a supine position and the hips and knees flexed to 90 degrees. Each leg is examined separately, not simultaneously. In the Ortolani maneuver, gentle abduction and lifting of the femoral head anteriorly produces a palpable “thunk” or “clunk” as the examiner relocates a dislocated hip. Nonpathologic processes such as ligamentous snapping can produce hip clicks that differ from the pathologic “clunk” associated with DDH. In the Barlow maneuver, the examiner attempts to dislocate the hip by gentle adduction and posterior axial pressure on the thigh. Confirmatory radiographs should be taken and orthopedic consultation obtained in a timely manner.

In-Toeing

The differential diagnosis of in-toeing is guided by the age at presentation. In the newborn period, the most common causes of in-toeing are metatarsus adductus and clubfoot. *Metatarsus adductus* is a functional deformity, resulting from intrauterine positioning, in which the forefoot is in adduction with respect to the hindfoot. Most cases resolve spontaneously by 3 to 4 months of age. If the forefoot cannot be brought into the neutral position either by stroking the lateral border of the foot or by gently straightening it, referral to an orthopedic surgeon for cast correction is indicated.

Congenital clubfoot is a pathologic deformity consisting of three components: forefoot varus; heel varus; and ankle equinus. Clubfoot may be either an isolated deformity or seen in association with other neuromuscular anomalies such as arthrogryposis, cerebral palsy, myelomeningocele, or amniotic band syndrome. Orthopedic treatment should begin in the first week of life.

Brachial Plexus Injuries (see Chapter 36)

Lateral traction on the head and neck during delivery can result in injury to the brachial plexus. Clinical signs relate to the site of the traumatic injury. *Erb's palsy,* the most common birth injury of the brachial plexus, results from injury to the upper plexus affecting the C5 and C6 roots, the upper trunk, or its divisions. The affected arm is held with the shoulder adducted and internally rotated, the elbow in extension and pronation, and the wrist in flexion (“waiter's tip posture”). On examination, the Moro reflex (allowing the infant's head to drop back suddenly results in abduction and upward movement of the arms followed by adduction and flexion) is asymmetric; there is weakness of shoulder abduction, flexion, and supination; the biceps reflex is decreased; and there is slight weakness of wrist and finger extensors. In addition, when the C4 root is involved, ipsilateral hemidiaphragmatic paralysis may be appreciated by fluoroscopic examination.

Klumpke's paralysis results from injury to the lower plexus affecting the C8 and T1 roots, the lower trunk or its divisions. The injury primarily affects the muscles of the hand. The infant presents with clawing of the affected hand (hyperextension at the metacarpophalangeal [MCP] joints and flexion of the interphalangeal joints), the elbow is held in flexion and the wrist is usually held in extension, unless there is injury to the middle trunk. On examination, the palmar grasp is decreased, and the triceps reflex is decreased.

Treatment consists of immobilization and appropriate positioning to prevent contractures. Orthopedic referral is indicated.

NEUROLOGIC CONCERNS

Neonatal Seizures (see Chapter 70 and Chapter 83)

Neonatal seizures may be difficult to recognize clinically because it is rare for newborns to have symmetric, generalized tonic-clonic convulsions. It is much more common to see seizure episodes that present as focal abnormalities or as subtle findings. Subtle seizures can be difficult to distinguish from the normal spectrum of newborn behaviors, jitteriness, or benign myoclonic movements. Benign myoclonic movements are isolated jerky movements of an extremity that occur primarily during sleep. Jitteriness may be differentiated from seizures by its disappearance when the affected extremity is touched or held (Table 102.3).

Clinical Characteristic	Seizure	Jitteriness
Stimulus sensitive	No	Yes
Movement ceases with restraint	No	Yes
Accompanied by autonomic changes	Yes	No
Speed of movements	Slower	Faster
Abnormal eye movements	Common	No

Table 102.3. Clinical Differentiation of Neonatal Seizures from Jitteriness

Four clinical seizure types are recognized in the newborn (Table 102.4): subtle, tonic, clonic, and myoclonic. Generalized tonic-clonic seizures tend not to occur in the first month of life because the newborn's immature nervous system is unable to produce and sustain this type of activity. Not all neonatal seizure types are associated with electroencephalogram (EEG) seizure activity (Table 102.4). It has been hypothesized that these seizures may be originating from areas of the CNS that cannot be detected by surface electrodes (e.g., brainstem or spinal cord).

Seizure Type	Electroencephalogram Seizure Correlation
Subtle	
Sucking or chewing motion	Uncommon*
Lip smacking	
Bicycling of legs	
Apnea	
Eyelid fluttering	
Eye deviations	
Laughter	
Tonic posturing	
Tonic	
Focal	Common
Generalized	Uncommon
Clonic	
Focal	Common
Multifocal	Common
Myoclonic	
Focal	Uncommon
Multifocal	Uncommon
Generalized	Common

*Except for tonic eye deviation, which often has an electroencephalographic correlation.

Table 102.4. Classification of Neonatal Seizures

Subtle seizures, perhaps the most common type of neonatal seizures, are stereotypical repetitive movements such as eye blinking, eye deviations, chewing motions, lip smacking, and bicycling or pedaling movements. Most subtle seizures, especially in term infants, are not consistently associated with EEG seizure activity.

Focal *tonic seizures* present as sustained posturing of a limb, whereas generalized tonic seizures are characterized by either tonic extension of all extremities or, occasionally, flexion of the upper extremities with extension of the lower extremities, mimicking decerebrate or decorticate posturing, respectively. These seizures are often seen in association with severe hypoxic brain injury or with intraventricular hemorrhage, which is most common in premature infants but may also be seen in term infants.

A *clonic seizure* involves rhythmic jerking of one or more parts of the body. Clonic seizures can be focal (affecting only one extremity or both the upper and lower extremity on one side of the body) or multifocal (clonic activity in one extremity that randomly migrates to another part of the body—e.g., left arm jerking followed by right leg jerking). Although focal clonic seizures can result from focal brain lesions, they can also be caused by a generalized metabolic disturbance such as hypoglycemia.

Benign myoclonic jerks are often noted in sleeping infants, especially premature infants, during the first 6 months of life. Unlike this benign sleep-related phenomena, *myoclonic seizures* occur during waking and are single or repetitive rapid jerks of either the entire body or a particular extremity. They are distinguished from clonic seizures by their more rapid speed and a predilection for flexor muscle groups. These seizures usually indicate severe underlying brain pathology or injury such as hypoxic brain injury. Infants with these seizures may later develop infantile spasms. Focal myoclonic seizures typically involve the upper extremity. Multifocal myoclonic seizures are characterized by asynchronous twitching of several areas of the body while generalized myoclonic seizures present as bilateral flexion jerks of the upper extremities and sometimes also the lower extremities.

Although there are a variety of causes for neonatal seizures (Table 102.5), only a few causes (perinatal asphyxia, intracranial hemorrhage, metabolic disturbances, and infection or malformations of the brain), account for most cases. Benign or idiopathic neonatal seizures occur, but this diagnosis should be made only after other causes are thoroughly investigated.

First 24 Hours
Hypoxic-ischemic encephalopathy
Infection (meningitis, TORCHS infection, sepsis)
Direct drug effects (inadvertent anesthetic injection)
Metabolic (hypoglycemia, hypocalcemia)
Intracranial hemorrhage (preterm-intraventricular hemorrhage; term-subdural/subarachnoid hemorrhage)
Pyridoxine dependency
>24 Hours
Infection (meningitis, sepsis, herpes simplex virus)
Intracranial hemorrhage
Metabolic (inborn errors of metabolism, hypocalcemia [dietary])
Intracranial malformations
Drug withdrawal

Table 102.5. Common Causes of Neonatal Seizures by Gestational Age

Perinatal asphyxia is the most common cause of neonatal seizures. During the first several days to weeks of life, signs of acute *hypoxic-ischemic encephalopathy (HIE)* are lethargy, hypotonia, and decreased spontaneous movements. Mild asphyxia is often marked by a transient state of hyperalertness and irritability. Seizures, if they occur, generally begin within the first 24 hours of life and may be difficult to control. The diagnosis of HIE should be strongly considered in a

hypotonic infant with increased deep tendon reflexes.

Intracranial hemorrhage is the second most common cause of neonatal seizures. Intraventricular hemorrhages are seen primarily in premature infants, whereas subarachnoid or subdural hemorrhages are most often seen in large term infants and are caused by birth trauma.

A variety of metabolic disturbances are associated with neonatal seizures. SGA infants and infants of diabetic mothers are at risk for hypoglycemia during the first 24 hours of life. These infants may have a variety of findings, ranging from jitteriness to seizures. Infants of diabetic mothers are also at risk for hypocalcemic seizures during the first 24 hours. Premature infants and infants with perinatal asphyxia are also at risk for early-onset (within the first 2 days of life) hypocalcemia. Late-onset hypocalcemic seizures (after day 2 to 3 of life) may be caused by an imbalance in dietary intake (e.g., cow's milk–based formula), hypomagnesemia, or hypoparathyroidism. Inborn errors of metabolism, pyridoxine dependence, and mitochondrial disorders are less common metabolic causes of seizures in the newborn. Inborn errors of metabolism should be suspected when seizures are associated with vomiting, failure to thrive, hepatomegaly, and altered tone or consciousness.

Several bacterial and viral CNS infections can cause seizures in the newborn. Common bacterial causes are group B *Streptococcus* and *Escherichia coli* infections. HSV encephalitis is an important viral source that must be considered. A newborn with a history of a seizure associated with fever requires a comprehensive evaluation for the cause and should not be diagnosed with simple febrile seizures.

The evaluation of newborn seizures should include a detailed history of prenatal, perinatal, and postnatal events. The examination should be directed toward identifying treatable causes such as infectious or metabolic disturbances. Minimal laboratory evaluation for all newborns with seizures includes a CBC; both bedside and laboratory measurement of serum glucose; serum electrolytes, including calcium, phosphorus and magnesium; blood culture; and cerebrospinal fluid analysis and culture. Cranial ultrasound is especially useful in identifying suspected intraventricular hemorrhages. Measurements of serum ammonia, serum amino acids, and urine organic acids should be obtained if a metabolic defect is suspected. Urine testing with the Clinitest reaction (detects excess excretion of galactose and glucose) can screen for galactosemia.

Appropriate *medical management* includes correction of any metabolic abnormalities and institution of empiric antibiotic therapy. If the results of serum glucose and calcium measurements will not be available in a timely manner, empiric therapy may be instituted if the infant is actively seizing. Hypoglycemia (serum glucose less than 40 mg/dL) is treated with a 2 to 3 mL/kg bolus over 20 minutes of a 10% dextrose solution. Treat symptomatic hypocalcemia (serum calcium less than 8 mg/dL) with 1 to 2 mL/kg of elemental calcium as a 10% calcium gluconate solution by slow intravenous drip. If the infant is actively seizing, a trial of pyridoxine (50 to 100 mg intravenously) may be considered. If the seizures are still not controlled, empiric anticonvulsant therapy may be instituted before consultation with a neurologist. Subtle seizures should not be treated with anticonvulsants before consultation with a neurologist. The anticonvulsant of choice in neonates is phenobarbital and is generally given as an initial intravenous loading dose of 20 mg/kg of body weight. Phenytoin is the secondary drug of choice and may be added if the phenobarbital fails to stop the seizures. Prognosis of neonatal seizures is related to the cause.

Hypotonic Infant (see Chapter 83)

A healthy term newborn normally moves his or her extremities spontaneously and has a dominance of flexor tone. Compared with the term newborn's tone, the premature infant's tone is relatively hypotonic, so corrected gestational age must be taken into consideration during evaluation.

Decreased spontaneous movements, poor head and trunk control, and a preponderance of extensor tone are all characteristics of the hypotonic infant. The healthy term newborn when supported by the trunk in an outstretched prone position, also known as ventral suspension, will flex all extremities against gravity, keep the back straight, and support the head in a neutral position with relation to the rest of the body. In the hypotonic infant, the forces of gravity will allow the back and head to droop downward and the extremities to hang in extension. When held by the axillae in vertical suspension, the hypotonic infant will “slip through” the hands of the examiner instead of contracting the upper extremities to maintain position. Because weakness is often associated with hypotonia, the newborn may present with resultant weak cry, poor suck, or respiratory effort. Weakness should also be suspected if the infant does not briskly withdraw a limb that is subjected to a painful stimuli.

The causes of hypotonia depend on the level of the nervous system that is affected (Table 102.6). Motor dysfunction at any level from the CNS to the muscle itself may result in hypotonia. Central hypotonia involves pathology of the cerebral cortex down to the level of the lower motor neuron or can be caused by systemic disease affecting motor function. Neuromuscular disease can be caused by dysfunction at any of four anatomic sites: anterior horn cell (lower motor neuron), peripheral nerve, neuromuscular junction, and muscle.

Central Nervous System Disease
Perinatal asphyxia (hypoxic-ischemic encephalopathy)
Intracranial hemorrhage
Infection
Hyperbilirubinemia
Neonatal drug withdrawal
Metabolic diseases
Organic and aminoacidemias
Hypercalcemia
Chromosomal abnormality
Down syndrome
Prader-Willi syndrome
Neuromuscular Disease
Anterior horn cell diseases (lower motor neuron)
Type I spinal muscular atrophy (Werdnig-Hoffman disease)
Neonatal poliomyelitis
Type II glycogen storage disease (Pompe's disease)
Peripheral nerve diseases
Leukodystrophies
Guillain-Barré syndrome
Neuromuscular junction diseases
Infantile botulism
Neonatal myasthenia gravis (congenital or acquired transient myasthenia)
Muscle diseases
Congenital myopathies
Mitochondrial myopathies
Glycogen storage disease
Hypothyroidism

Table 102.6. Differential Diagnosis of Neonatal Hypotonia

Central Hypotonia

If muscle weakness is not a significant accompanying feature, a central source for the hypotonia should be considered. Features characteristically associated with central hypotonia include a decreased level of alertness, seizures, and a weak cry; muscle bulk is normal, and deep tendon reflexes are either normal or increased. Perinatal asphyxia and intracranial hemorrhage are the two most common CNS causes of hypotonia that presents in the neonatal period. Depressive symptoms are usually present during the first 1 to 2 days of life in these conditions. An infant who is normal at birth and then develops lethargy, hypotonia, or seizures at several days of age after ingestion of milk protein and carbohydrate may have an inborn error of metabolism. Metabolic diseases should always be taken into consideration in the evaluation of the hypotonic infant, especially when the clinical presentation does not readily fit into any distinct diagnosis or if any unusual odors (see Chapter 47) of the infant or urine are noted (e.g., mustiness—phenylketonuria PKU], sweaty feet—isovaleric acidemia, maple syrup—maple syrup urine disease).

Disorders of the Lower Motor Neuron

Disorders of the lower motor neuron are characterized by hypotonia, muscle weakness, and hypoactive to absent deep tendon reflexes in an otherwise alert infant. Werdnig-Hoffman disease is the most common of the lower motor neuron diseases. In the classic, early-onset form of the disease, infants may present at birth or during the first several weeks of life with generalized weakness; absent deep tendon reflexes; muscle atrophy; fasciculations; and cranial nerve abnormalities, including disordered sucking and swallowing. Infants have a characteristic posture with flaccid tone, abducted limbs, and little spontaneous movement. Respiratory distress may be present. The disease is unfortunately rapidly progressive, and death usually occurs in most patients by 2 years of age.

Disorders of the Neuromuscular Junction

Disorders of the neuromuscular junction are important to recognize because supportive and therapeutic interventions are available. Infants with neuromuscular disorders have hypotonia and weakness like infants with lower motor neuron disease, but infants with neuromuscular disease have normal muscle bulk and normal deep tendon reflexes. Infantile botulism (see Chapter 84) is a toxic abnormality of the neuromuscular junction that is seen in infants under 12 months of age. It is caused by the ingestion of *Clostridium botulinum* spores (from soil, honey, or corn syrup), which germinate in the gastrointestinal tract and produce botulinum toxin. Early symptoms include constipation and poor feeding as a result of poor sucking and swallowing. A descending paralysis develops over the next several days with loss of head control, weak cry, flat facial expression, and eventually, generalized hypotonia. Treatment consists primarily of supportive care; ventilatory support may be required for respiratory failure.

Disorders of Muscle

A variety of primary muscle disorders may present during the neonatal period with the nonspecific features of hypotonia, weakness, decreased muscle bulk, and normal to decreased deep tendon reflexes. Metabolic myopathies are caused by abnormal energy metabolism in the muscle and include disorders of the mitochondria and carnitine metabolism. A mitochondrial myopathy should be considered in a hypotonic infant with lactic acidosis.

Laboratory evaluation of hypotonia is guided by the level of the nervous system believed to be affected. If CNS disease is suspected, brain imaging, an EEG, and endocrine and metabolic determinations may be appropriate. When neuromuscular disease is suspected, muscle enzyme determinations, nerve conduction velocities, electromyography, and nerve or muscle biopsies can be done on a scheduled basis.

Most importantly, the possibility that the hypotonia is really lethargy related to shock or sepsis should be considered.

CONGENITAL INFECTIONS

There are a group of transplacentally transmitted congenital infections often referred to jointly by the acronym TORCHS, which vary in their postpartum presentation according to the time during the pregnancy when they were acquired and with the intensity of the inoculum. These include toxoplasmosis, rubella, cytomegalovirus (CMV), herpes virus infections (herpes simplex and varicella), and syphilis.

Fetal infection with these agents acquired in midpregnancy may result in a neonate born with a complex of findings that may include low birth weight or SGA; jaundice, purpura, and thrombocytopenia; hypotonia; microcephaly; cataracts; microphthalmia; chorioretinitis; hepatosplenomegaly; intracerebral calcifications; congenital heart disease; hypoplastic limbs; hearing loss; cicatricial scarring of the skin; and seizures. Obviously, not all, not even most, of these findings will be present in any one affected infant, but their presence should at least arouse suspicion for the TORCHS syndrome.

Clinically, it is often difficult to distinguish one of these infections from the other. Rubella is more likely to be associated with cataracts and cardiac lesions; toxoplasmosis with chorioretinitis and cerebral calcifications; herpes simplex and varicella with vesicular or cicatricial skin lesions; CMV with hearing loss; and syphilis with bone lesions, snuffles, and palm and hand bullae. However, symptoms overlap. The essentials in management include a careful maternal history and appropriate serologic testing and culturing of both mother and infant.

However, the clinician should keep in mind the possibility that aspects of this symptom complex, particularly purpura and jaundice in a hypotonic baby, may be associated with an active acute septic infection.

MISCELLANEOUS CONCERNS

Neonatal Drug Withdrawal

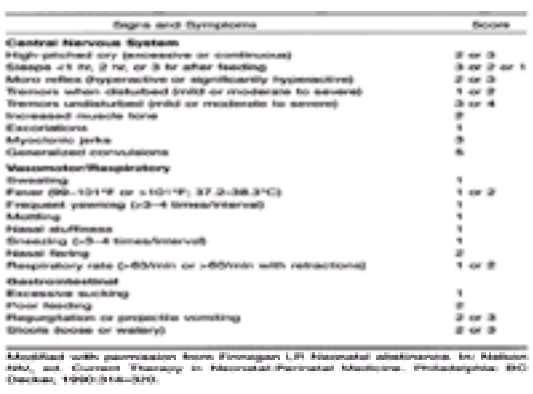
Maternal substance abuse during pregnancy places the newborn at risk for a variety of medical, developmental, behavioral, and psychosocial problems. The particular effects on the newborn infant depend on the type of drug or drugs, the timing of the exposure during gestation, and the frequency of the exposure. Many infants are exposed to cigarettes and alcohol in addition to illicit drugs.

- *Narcotics:* Prenatal exposure to heroin and methadone results in physiologic addiction in the newborn. The symptoms of withdrawal are nonspecific and may not be detected in the newborn nursery, especially when the maternal history of drug abuse is unknown or when the infant is discharged home within 24 hours of delivery. Narcotic antagonists such as naloxone may precipitate withdrawal and should not be used at the time of delivery. Heroin has a short serum half-life, so clinical signs of withdrawal are generally apparent on the first day of life, whereas clinical signs of methadone withdrawal seldom occur before 24 to 48 hours of age because of its long half-life. Symptoms of narcotic withdrawal include irritability, jitteriness, tremors, seizures, disorganized suck and poor feeding, vomiting, diarrhea, sweating, and sneezing. Additional signs of withdrawal that may be noted in the older infant include failure to gain weight and abraded marks along the nose, shins, or occiput caused by the infant's tremulousness and inability to comfort himself or herself.
- *Cocaine:* In utero cocaine exposure has been associated with an increased incidence of abruptio placentae, low birth weight, and preterm delivery. Classically, the cocaine-exposed infant is not so much jittery as he or she is disorganized in sleeping and feeding. These infants are lethargic and poorly responsive but are easily overstimulated and become irritable when alert, making feeding a challenge for many of them. Gavage feeding may be necessary in some instances. Any history of feeding intolerance, vomiting, or abdominal distension needs to be investigated because necrotizing enterocolitis has been noted in term, cocaine-exposed infants. Stool occult blood may be positive secondary to bowel necrosis caused by the vasoconstrictive actions of cocaine. Small CNS bleeds have been described in the basal ganglia and frontal lobes.
- *Amphetamines*: Methamphetamine-exposed infants are often described as being too quiet and may need to be awakened regularly for feedings. Prolonged sleep, depression, and voracious appetite when awakened are characteristic of amphetamine withdrawal.

Evaluation

In general, toxicologic screening can be performed on infants on medical grounds without parental consent. Metabolites of cocaine can be detected for 1 to 2 days after use in the adult and 5 to 7 days in the newborn; amphetamine is present for 1 to 2 days in the adult; and marijuana can be detected in the urine for up to 7 days after use. Most urine toxicology screens use immunoassays and are inexpensive and sensitive but not specific (e.g., antihistamines can cross-react with amphetamines). Newer methods using hair or meconium samples to check for the presence of illicit drugs, especially cocaine, provide a broader window on drug use during pregnancy and are able to document the presence of drugs in the time before delivery.

The Neonatal Abstinence Score (NAS) developed by Finnegan is an objective way of assessing the severity of narcotic withdrawal symptoms (Table 102.7). Infants should be scored at 4-hour intervals for the first several days of life. Three consecutive scores greater than 8 or two scores greater than 12 are an indication for pharmacologic therapy. The NAS can also be used to guide pharmacologic therapy.



Signs and Symptoms	Score
Central Nervous System	
High-pitched cry (excessive or continuous)	2 or 3
Sleeps <1 hr, 2 hr, or 3 hr after feeding	3 or 2 or 1
Moro reflex (hyperactive or significantly hyperactive)	2 or 3
Tremors when disturbed (mild or moderate to severe)	1 or 2
Tremors undisturbed (mild or moderate to severe)	3 or 4
Increased muscle tone	2
Excoriations	1
Myoclonic jerks	3
Generalized convulsions	5
Vasomotor/Respiratory	
Sweating	1
Fever (98–101°F or >101°F; 37.2–38.3°C)	1 or 2
Frequent yawning (>3–4 times/interval)	1
Mottling	1
Nasal stuffiness	1
Sneezing (>3–4 times/interval)	1
Nasal flaring	2
Respiratory rate (>60/min or >60/min with retractions)	1 or 2
Gastrointestinal	
Excessive sucking	1
Poor feeding	2
Regurgitation or projectile vomiting	2 or 3
Loose (loose or watery)	2 or 3

Table 102.7. Neonatal Abstinence Score

Management

Swaddling and minimizing sensory stimulation are two of the simplest and most effective techniques in managing neonatal drug withdrawal. A blanket or sheet can be draped over the infant's bed to minimize light exposure. Often, these infants do well when placed in a “snugly or front pack” over the mother's chest and abdomen. The mother's regular, monotonous cardiorespiratory sounds can be soothing. Demand feeding with hypercaloric formula (24 to 27 calories per

ounce) may be necessary to maintain weight.

Medications, such as phenobarbital, may be used for narcotic withdrawal if the symptoms do not respond to the above techniques and the infant has significant irritability interfering with sleep and/or feeding. Pharmacologic therapy is generally not required when cocaine or amphetamines are the only drugs of abuse. Phenobarbital is especially good for controlling irritability and insomnia. It requires an initial loading dose of 20 mg/kg. A blood level should be obtained in 24 hours and the maintenance dose adjusted according to the infant's symptoms. The usual maintenance dose is 2 to 6 mg/kg per 24 hours divided every 12 hours. Once a maintenance dose has been established, the dosage is decreased approximately 10% per day based on the NAS.

Prognosis

Drug-exposed infants are at increased risk for abuse and neglect because of a combination of environmental (chaotic family environments, limited financial resources, and limited parenting skills because of the impact of the substance abuse) and infant risk factors (poor attachment, high-pitched cry, irritability, difficult to console, and poor feeding).

CHAPTER 103

An Approach to the Injured Child

***RICHARD M. RUDDY, MD and †GARY R. FLEISHER, MD**

**Department of Pediatrics, University of Cincinnati College of Medicine, and Division of Emergency Medicine, Children's Hospital Medical Center, Cincinnati, Ohio; †Department of Pediatrics, Harvard Medical School, and Division of Emergency Medicine, Children's Hospital, Boston, Massachusetts*

Physicians delivering care in an emergency department (ED) must be prepared to treat injured children. Although pediatric trauma victims have needs distinguishing them from adults, it is only in the past decade that investigators have begun to systematically look at the care of the injured child. It is the intent of this chapter to help prepare physicians in the ED for the triage, assessment, and initial care of children with the spectrum of injury from minimal to life-threatening.

Among children aged 1 to 19 years, injuries cause more deaths than all diseases combined. In 1995, more than 20,000 children up to age 19 years died from trauma in the United States. The pyramid of injuries includes more than 500,000 hospitalizations in children and 20 to 30 times as many ED visits. Injuries remain the major factor in 40% of the deaths among children 1 to 4 years of age, and 70% from 5 to 19 years. Of all hospitalizations in pediatrics, 20% result from trauma. An estimated 30,000 children who are injured experience permanent disabilities annually. The economic cost of trauma in childhood is $5 to $8 billion annually in the United States. Although death rates for injuries have declined 25% among children in the last quarter century, those for diseases have decreased by 56%.

The most common cause of traumatic death during childhood is motor vehicle crashes, which account for close to half. Unlike adults, a large proportion of the children injured by automobiles are pedestrians. Overall, homicide and suicide rank second and third as causes of mortality from trauma in the first 19 years of life. Among minority male teenagers, homicide from gunshot wounds is the leading cause of death. More than 5000 of the reported deaths from trauma in children during 1995 were from gunshot wounds.

The approach discussed here provides a framework to decrease morbidity and mortality and is aimed at secondary prevention—after the “impact” has occurred. Secondary prevention is performed in the field by emergency medical services (EMS) providers or after arrival at the hospital. Injury severity scales have been developed to assist in the care of the trauma patient. The two most commonly quoted are the Revised Trauma Score and the Pediatric Trauma Score. These scales have served as useful tools to assess the appropriateness of care provided to injured children. Because both scales are similarly predictive of severity, many recommend use of the Revised Trauma Score because it is suitable for both children and adults. However, the approach to the injured child requires more than the use of a scale for retrospective evaluation.

SPECTRUM OF TRAUMA AND INITIAL TRIAGE

Trauma causes injuries that run the gamut from minimal to fatal, from the splinter lodged in the sole of the foot to the multiply injured victim of an automobile crash. To assist in the initial sorting or diagnostic process, several categorizations of injury are useful: 1) extent—multiple or local; 2) nature—blunt or penetrating; and 3) severity—mild, moderate, or severe (Table 103.1).

Local	Multiple
Blunt	Penetrating
Mild	Severe

Table 103.1. Categorization of Trauma

Trauma can be multiple or local. From a surgical point of view, multiple trauma defines significant injury to two or more body areas: the head and abdomen, the chest and extremities, or other combinations. Although this definition serves a useful purpose in comparing outcomes retrospectively among various centers, it does not suit the needs of emergency physicians who must evaluate and treat children before all diagnostic information has become available. For the purpose of triage in the ED, *multiple trauma* is defined as apparent injury to two or more body areas. Thus, the child who fell from a bicycle, sustaining a forehead laceration and a forearm fracture would be classified in the ED as having multiple trauma (head and extremity), even though the completed evaluation may not uncover any additional or serious injuries.

Localized trauma involves only one anatomic region of the body: head, neck, chest, abdomen/pelvis, or extremities. Again, the designation of local trauma is assigned initially on the basis of even superficial injuries in a given anatomic area, despite the fact that subsequent evaluation might not detect any deeper involvement.

The initial diagnostic task confronting the emergency physician is to decide whether trauma is local or multiple. In some cases, the distinction between local and multiple trauma is obvious. The 13-year-old boy who twisted his ankle coming down with a rebound has a local musculoskeletal injury. The 2-year-old boy who is cyanotic, pulseless, and apneic after a plunge from a ninth story window has sustained critical multiple trauma.

At times, however, the distinction between local and multiple trauma may not be straightforward. A 7-year-old girl who flies over the handlebars of her bicycle onto the sidewalk and is brought to the ED covered with blood, who is thrashing and screaming at every touch, may be judged initially to have serious multiple trauma. After complete and rapid assessment, she may instead have only a superficial forehead laceration and an acute anxiety reaction. The next child with the same history and constellation of symptoms may have a concussion and a ruptured spleen. A third child in a similar scenario may have a rib fracture leading to a pneumothorax; a fourth child may have a buckle fracture of the radius and a depressed skull fracture.

The distinction between local and multiple trauma may be difficult to ascertain initially because 1) some serious injuries are occult in their early phase; 2) some children are difficult to examine because they are nonverbal, uncooperative, frightened, or in pain; and 3) some parents will have played a role in the trauma (i.e., child abuse) and will try to conceal the extent of the injury. Differentiation between local and multiple trauma is thus a dynamic process, and the emergency physician's first impression may change as new evidence accumulates. Generally, it is best to consider trauma multiple until proved otherwise; when the skin is contused over several body parts, the patient is categorized as having multiple trauma until it is known that all the injuries are superficial.

Once it has been decided that multiple trauma has not occurred, the emergency physician should then focus on the specific anatomic region or regions involved. For each region, it is important to ascertain whether the injury is the result of blunt or penetrating trauma and to determine the severity of the wound.

Trauma may be caused by either blunt or penetrating forces. Although most civilian injuries, particularly in childhood, result from blunt trauma, as much as 15% of serious trauma in some centers is related to gunshots, stabbings, and other penetrating wounds. The distinction between these two mechanisms of injury is an important one because it will determine the evaluation based on the expected internal injuries. In this chapter, the management of blunt and penetrating trauma is reviewed for each specific anatomic region.

Finally, the seriousness of injury may vary from mild to severe. Table 103.2 reviews a classification of severity based on history and physical examination, as well as a general schema for disposition of the child with trauma, based on the number of laboratory tests required to diagnose or manage the trauma. Whereas only a few patients with penetrating injuries are considered to have mild wounds, most of the more common blunt injuries seen in the ED are minor. The first categorization by severity depends initially on the history of the incident and the physical examination. An important factor is that a history of a significant or critical force applied during impact increases the index of severity. The schema varies somewhat for each anatomic region; thus, Table 103.2 provides only a general overview. Assessment of severity is essential in the ED because it will determine whether the child is discharged after an examination, receives further observation, undergoes a diagnostic evaluation, or requires immediate intervention. The more laboratory studies required to assess and care for trauma victims, the more likely a child will need admission.

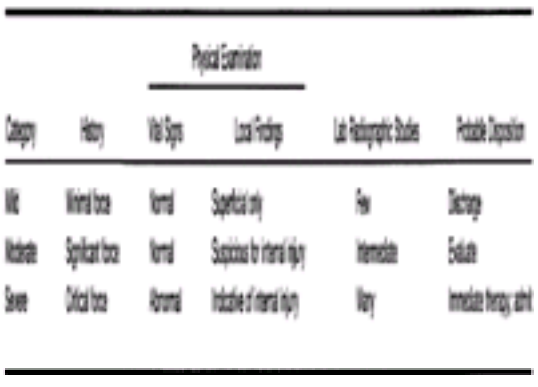

Table 103.2. Classification and Disposition of Trauma by Severity

GENERAL PRINCIPLES OF MANAGEMENT

The child who has sustained more than a trivial injury must be considered at risk of dying; thus, an immediate decision must be made regarding the severity of the trauma (Table 103.2). The clinical approach includes primary assessment, resuscitation (initial treatment), secondary assessment, and definitive care. This approach provides a set of principles for efficiently diagnosing and treating life-threatening conditions without neglecting less severe but important injuries. The primary assessment includes the vital signs and a quick review of the essential functions of all organs; the emphasis is on uncovering treatable injuries and preventing complications (e.g., paralysis from an unstable cervical spine fracture). Concomitantly, resuscitation (initial treatment) attempts to normalize vital functions and prevent further deterioration such as hypoxia or blood loss. Primary assessment and resuscitation occupy the first 5 to 10 minutes of the encounter in most cases. As soon as possible, reassessment of the entire patient (secondary assessment) should take place to fine-tune the details of management. The secondary assessment includes the use of radiographs and laboratory tests. To be effective, physical examinations must be repeated serially and then compared. Although resuscitation of unstable patients is critical and requires a strong team approach, the close surveillance of the apparently stable patient at risk of single or multiorgan trauma may be even more demanding. Definitive care includes stabilization of specific local injuries, preparation of the patient for the operating room, and surgery, as indicated. At the completion of care for trauma patients, a tertiary survey is performed. This is a last thorough check for occult injuries. It is done upon discharge, when a patient goes home after assessment, or in the light of day for admissions.

MULTIPLE TRAUMA

Classification

Multiple trauma (see Chapter 104), as defined for the emergency physician, may vary from mild to severe (Table 103.3). The child with a history of an injury caused by minimal force and a physical examination that shows only superficial lesions in two or more areas of the body would be assigned to the mild category—for example, a 7-year-old child who fell while running and is found to have an abrasion on the forehead and right elbow and tenderness of the right flank. The discovery on examination of signs suggestive of deeper injury places the child in at least the moderate category. Detection of a serious injury or abnormal vital signs (unrelated to anxiety alone) make for classification as severe. Unfortunately, classification of injury by mechanism alone is not a uniformly useful predictor in blunt trauma in children or adults.

		Physical Examination	
Category	History	Vital Signs	Local Findings
Mild	Minimal force	Normal	Abrasions/contusions
Moderate	Significant force	Normal	Refer to Tables 103.7 to 103.9 by anatomic region
Severe	Critical force	Abnormal	Refer to Tables 103.7 to 103.9 by anatomic region

Table 103.3. Severity of Multiple Trauma

Management

Mild Multiple Trauma

The major goal in the management of a child with apparent mild multiple trauma is to confirm the initial impression of lack of severity. If there is any question of more severe injury, a large-bore peripheral intravenous line should be inserted and blood studies obtained, including a complete blood count (CBC) and type and crossmatch. However, in cases that obviously seem to involve minimal trauma, the physician can proceed directly to the examination. Initially, the vital signs should be obtained. Subsequent examination includes a complete assessment with special attention to the level of consciousness; tenderness or limitation of motion of the cervical spine; auscultation of the heart and lungs; palpation of the abdomen, back, and pelvis; and extremities tenderness. The complete physical examination should include vital signs with capillary refill; Glasgow Coma Scale score; inspection and palpation of the head for injuries, pupillary reactions, extraocular muscle function, nasal tenderness, and dental/oral trauma; cervical spine motion (if the child is alert, not in a cervical collar, and without complaint and tenderness); neck vein distension; auscultation of the breath and heart sounds; inspection and palpation of the chest; evaluation of bowel sounds; inspection and palpation of the abdomen; palpation and inspection of the back, flank, and pelvis; rectal and genital examination; evaluation of extremities for deformity or tenderness; palpation of peripheral pulses; neurologic evaluation; and careful survey of the skin and soft tissues.

Laboratory evaluation of a child with a history of minimal multiple trauma and a normal examination may require no studies. If there is any concern, a CBC and urinalysis should be obtained. No other laboratory or radiographic studies are routine.

Moderate Multiple Trauma

The child with multiple trauma categorized as moderate requires immediate intervention, as well as a thorough diagnostic evaluation. A child in this category has an obvious history of involvement of several areas of the body, but initially may have only evidence of musculoskeletal or several superficial local injuries. A 3-year-old child who has been hit by an

automobile and has a significantly deformed femur and a few ecchymoses on the upper extremities, or an older child who fell off a second-story roof but appears well, may fit this group. As a first step, a minimum of one large-bore peripheral intravenous catheter should be placed. If the child is in respiratory distress, supplemental oxygen should be administered. Any suggestion of cervical spine injury mandates immobilization of the neck with a semirigid collar or sandbags. If the vital signs and primary survey are normal for age, the physician then should proceed with a thorough examination, as outlined in mild multiple trauma.

Most patients with moderate multiple trauma require ancillary studies in addition to a urinalysis. These might include a CBC and radiographs of the chest and cervical spine or abdomen. A type and screen for red blood cells is indicated. In fully awake patients, a completely normal examination may be relied upon to exclude the need for all screening studies. Many patients in this category require admission to the hospital. However, an older child with a history of a moderately severe impact, who has an unremarkable examination and normal studies, may be discharged from the ED after observation for several hours.

Severe Multiple Trauma

The management of the child with severe multiple trauma demands immediate action. The initial approach assumes either obvious life-threatening injury or a reasonable likelihood that such an injury exists. An alteration of vital signs (hypotension, tachycardia), diaphoresis, or depressed consciousness automatically categorizes the injury as severe. Although helpful as an initial guide, mechanism alone (e.g., a fall from a two-story building) is not a highly accurate predictor of risk. To adequately manage the child with severe multiple trauma, the physician must understand the need to institute treatment before completing a full examination and to continually intersperse detailed reassessments into an intensive treatment protocol. Table 103.4 provides an outline for organizing the initial approach to severe multiple trauma in the ED. It uses a four-pronged strategy: assessment, treatment, monitoring, and diagnostic testing. The protocol is laid out over time in an idealized fashion; obviously, limitations in the number of personnel or unusually difficult technical procedures may slow the progression.

Table 103.4. Management of Severe Multiple Trauma

LOCALIZED HEAD TRAUMA

Classification

Head trauma (see Chapter 38 and Chapter 105) can be divided into penetrating and nonpenetrating. Cases that involve penetration of the cranial vault entail severe injuries and often require operative intervention. Nonpenetrating head trauma can be classified as mild, moderate, or severe (Table 103.5).

		Physical Examination	
Category	History	Vital Signs	Local Findings
Mild	Minimal force No/momentary LOC	Normal	Glasgow =15 Abrasions/contusions
Moderate	Significant force LOC 1–5 min	Normal	Glasgow ≥13 Drowsiness
Severe	Critical force LOC >5 min	Abnormal	Glasgow ≤12 Focal neurologic abnormalities

LOC, loss of consciousness.

Table 103.5. Severity of Blunt Head Trauma

Management

Penetrating Trauma

Wounds limited to the scalp and not entering the cranial vault are appropriate for primary repair in the ED. Minor wounds

from sharp objects, when the likelihood of penetration is high, should have radiologic evaluation and local exploration before primary closure. All other penetrating injuries require initial stabilization and neurosurgical consultation, as discussed under severe blunt head trauma. Protruding objects should be left in place until definitive management.

Blunt Trauma—Mild

Most children seen in the ED have sustained mild head trauma and have at most momentary loss of consciousness (less than 1 minute), arrive awake, and primarily need a thorough physical examination. The head should be palpated for evidence of local injury, assessing for evidence of a depressed fracture. Bruises around the eyes or behind the ear or a hemotympanum suggest a basilar fracture. The pupils will be equal and reactive and the extraocular muscle function intact, unless the severity of injury has been misjudged. Ideally, the fundi should be visualized; however, this is not essential in most cases. Almost never will an alert child have any significant funduscopic pathology from trauma, nor will visualization of the fundi always be possible in uncooperative infants and young children. In general, papilledema is a late sign of increased intracranial pressure. Although the finding of focal neurologic abnormalities is unlikely, a careful neurologic examination is mandatory. Skull radiographs and computed tomography (CT) are generally unnecessary, but either may be indicated in selected situations, such as palpation of a potentially depressed fracture (see Chapter 38).

Patients with minor head trauma may be discharged from the ED with specific instructions to watch for changes indicative of increased intracranial pressure or hemorrhage. Albeit unlikely, these symptoms include depression of mental status, progressive vomiting (greater than 4 hours from the trauma), visual disturbances, ataxia, or seizures. Postconcussion seizures are unusual but may occur within a few days of mild head injury. In general, they are not prognostic for recurrent seizures.

Blunt Trauma—Moderate

The child with moderate head trauma has sustained a concussion or, perhaps, a cerebral contusion. Moderate head injury includes any clear-cut prolonged loss of consciousness (1 to 5 minutes) or a history suggesting a severe injury, even without specific physical findings to confirm it. Once again, a thorough examination is required to search for signs of intracranial hemorrhage. The most important feature of the examination is a serial evaluation such as the Glasgow Coma Scale. The initial score serves as the baseline for the detection of subsequent deterioration. Radiographs are reserved for the same indications as for mild trauma; CT scanning is often but not necessarily performed in awake patients upon arrival, but it becomes mandatory upon deterioration in mental status or in the presence of focal abnormalities. Because of the small chance of subsequent intracranial hemorrhage or worsening cerebral edema, prolonged observation in the ED or admission is warranted in many cases with moderate injury.

Blunt Trauma—Severe

The child with severe head trauma is at risk for sudden intracranial catastrophe, acute respiratory insufficiency, or a secondary insult (e.g., brain swelling) to the central nervous system. After initial steps to assess the adequacy of respiration and circulation, these functions should be supported as necessary. The cervical spine should be stabilized with a semirigid collar or sandbags. At times, gentle opening of the airway with maintenance of the head in the neutral position will allow adequate ventilation. If intubation is required immediately, extension of the neck should be avoided, and an assistant should stabilize the cervical spine during the procedure. In less urgent situations, intubation may be deferred until a cross-table lateral radiograph of the cervical spine is obtained. In all cases, supplemental oxygen should be administered and two intravenous cannulas inserted. Most children with serious head injury will hyperventilate spontaneously if their airway is patent and decrease their cerebral blood flow, which will help maintain normal intracranial pressure. Intubated, apneic children should be hyperventilated manually to achieve a $PaCO_2$ of 30 to 35 mm Hg. Ideally, continuous noninvasive end-tidal CO_2 monitoring with an arterial blood gas to maximize accuracy should be the goal in the ED. An arterial catheter can be placed as needed. If the patient has an isolated head injury, parenteral fluid administration should be no greater than two-thirds of the daily maintenance rate unless there is evidence of hypovolemia. Corticosteroids are not recommended by most authorities. Osmotic agents are not used prophylactically, but mannitol (0.5 to 1.0 g/kg of a 20% solution) occasionally is necessary to decrease intracranial pressure when acute herniation is suspected or proved.

Standard skull radiographs are time consuming and provide little useful information in the patient with serious head injury. More efficient management calls for an immediate CT to evaluate the intracranial space. Rarely, neurosurgical intervention must precede imaging of the cranial contents. See Chapter 105 for more specific management.

LOCALIZED NECK TRAUMA

Classification

Within the confined anatomic space of the neck pass the larynx and trachea, the carotid arteries, the jugular veins, the spinal cord, and the esophagus. Thus, both penetrating and nonpenetrating insults can cause devastating injuries. All penetrating trauma, with the exception of tangential wounds superficial to the platysma muscle, should be considered serious and be referred promptly for surgical evaluation and possible exploration. Weapons or objects protruding from the neck should be left in place. Children with neck trauma (see Chapter 106) should be carefully examined in the ED for thoracic injuries, such as pneumothorax.

Isolated blunt trauma to the neck does not occur often in children. However, the potential for major disruptions of the airway or large vessels demands a thorough evaluation. Particularly, the examiner should palpate for crepitus, unequal carotid pulses, expanding hematomas, and cervical spine tenderness. Based on the history and physical findings, an estimate of the severity of the injury can be made (Table 103.6). A thorough neurologic examination, with particular

emphasis on spinal cord disruption, is essential.

		Physical Examination	
Category	History	Vital Signs	Local Findings
Mild	Minimal force	Normal	Abrasions/contusions
Moderate	Significant force	Normal	Refusal to move head
			Cervical spine tenderness
Severe	Critical force	Abnormal	Crepitus
			Expanding hematoma
			Unequal carotid pulse
			Paralysis or sensory loss

Table 103.6. Severity of Blunt Neck Trauma

Management

Penetrating Trauma

Wounds clearly superficial to the platysma muscle are appropriate for repair in the ED. Children with penetrating injuries deep to the platysma require stabilization and subsequent surgical evaluation. Initial measures are directed at establishing a patent airway, providing adequate ventilation, tamponading hemorrhage, and restoring the circulation. Protruding objects should be left in place by the physician in the ED.

Blunt Trauma—Mild

If the history is one of a minimal force and no physical findings are indicative of trauma to the deeper structures, the child is symptomatically treated and discharged from the ED. Exceptions might be patients with underlying illnesses such as hemophilia, who are at risk for delayed complications. Follow-up after discharge should be defined clearly to ensure that intervention occurs before compromise to internal structures.

Blunt Trauma—Moderate

The child with an apparent moderate injury to the neck by definition has no evidence of respiratory or vascular compromise. However, either the history of the amount of force involved or the local findings may raise the possibility of cervical spine or other injuries. Such patients require immobilization of the cervical spine with a semirigid collar or sandbags and a meticulous neurologic examination. As a first step, a cross-table lateral radiograph of the cervical spine should be obtained with the child immobilized, usually in the ED. If this first radiograph shows all seven cervical vertebrae to be intact and properly aligned, a complete radiologic evaluation of the cervical spine can be performed, which may include anteroposterior, oblique, and open-mouth views. The discovery of a bony or ligamentous injury requires consultation with appropriate specialists. Spinal cord injury without radiographic abnormality may be present and should be pursued, when symptoms or signs are suggestive. The neurologically intact child with a normal cervical spine evaluation and no other neck trauma who remains well on repeat physical examination may be discharged after observation.

Moderate trauma to the anterior neck requires careful evaluation for possible disruption of the major vessels, trachea, and esophagus. Cervical spine radiographs may outline the airway adequately. However, it is important to pay attention to the alignment of the larynx and trachea and to check for air in the soft tissues from a tear in the airway or esophagus. The carotid triangle must be palpated carefully. If there is a hematoma or abnormality of the pulse, referral for possible arteriogram should be made.

Blunt Trauma—Severe

Classification of blunt neck trauma as severe indicates concern for overt injury to the airway, the major vessels, or the spinal cord. The initial goals of management are establishment of a patent airway, stabilization of the cervical spine, and intravenous access. The first choice for establishment of the airway is orotracheal intubation, with maintenance of the head in the neutral position. The inability to intubate a critical airway requires an immediate surgical approach to the trachea. Blood should be sent for a type and crossmatch; if vascular injury is suspected, multiple units of blood should be available. A surgical consultant should decide whether to proceed with an exploration in the operating room or to rely on further diagnostic studies such as bronchoscopy, arteriography, or esophagoscopy.

LOCALIZED THORACIC TRAUMA

Classification

Penetrating chest injuries (see Chapter 107) are extremely relevant to physicians in the ED because they may be rapidly life-threatening if untreated, yet usually respond to fairly straightforward therapeutic maneuvers. Any object that enters the thoracic cavity will result in significant injury. Patients with large open wounds or instability of vital signs should be considered to have sustained life-threatening trauma.

Blunt chest trauma is seen more often than penetrating injury in civilian practice in general and in children in particular. Although there are no studies on the percentage of chest injuries classified as mild in childhood, statistics are available for older patients. Newman et al. found that 53% of chest injuries sustained by adults in motor vehicle accidents were merely bruises or abrasions. As with trauma to other anatomic regions, blunt thoracic trauma can be divided into mild, moderate, and severe categories (Table 103.7).

		Physical Examination	
Category	History	Vital Signs	Local Findings
Mild	Minimal force	Normal	Abrasions/contusions
Moderate	Significant force	Tachypnea	Splinting
		Normal pulse and blood	Bony tenderness
			Decreased breath sounds
Severe	Critical force	Abnormal pulse or blood pressure	Flail chest
			Distant heart tones
			Absent breath sounds

Table 103.7. Severity of Blunt Chest Trauma

Management

Penetrating Trauma

Patients with mild injury, in which the wound clearly entered only the superficial tissues and not the thoracic cavity, may need only ED management. However, for any knife or gunshot injuries, it is advisable to have an experienced physician explore the wound and to obtain radiographs to determine the extent of injury.

Patients with deeper wounds require chest radiography, CBC, and type and crossmatch. An arteriogram may be necessary in the stable patient with a suspected aortic injury. Tube thoracostomy should be performed to drain a hemothorax or pneumothorax. Hemorrhage can be managed starting with crystalloid, followed by blood replacement. For the child sustaining a cardiopulmonary arrest in the ED after a penetrating thoracic injury, immediate resuscitative thoracotomy may be lifesaving.

Blunt Trauma—Mild

The child with a history of a minimal blow to the chest, normal vital signs, and no local signs of trauma other than abrasions or contusions has sustained a mild injury. The absence of bony tenderness, tachypnea, or decreased breath sounds obviates the need for radiologic evaluation of the thoracic cage or its contents.

Blunt Trauma—Moderate

If the history indicates significant force, bony tenderness is elicited, or there is a question of decreased breath sounds, a chest radiograph, electrocardiogram (ECG), and CBC are often helpful. Particularly in children, a pneumothorax may follow blunt injury with or without a rib fracture. Widening of the mediastinum on chest radiograph suggests disruption of the aorta. The detection of a solitary rib fracture is not important per se because no specific treatment is necessary. However, it raises the suspicion of visceral or vascular disruption. In particular, fracture of the first rib is correlated in adults with injuries to the great vessels. Although the data are scant in pediatrics, an injury to the first rib may require arteriography. The chest radiograph may provide a clue to the diagnosis of pericardial hemorrhage (by showing a slightly enlarged cardiac silhouette), but it is more often normal in this condition. Bleeding into the pericardial space leading to tamponade will invariably manifest on the physical examination at some point; findings include tachycardia, followed by hypotension, distended neck veins, and muffled heart tones. A pulmonary contusion or aspiration may produce a consolidation on chest radiograph. The ECG is obtained as an aid in the diagnosis of myocardial contusion; elevated ST segments are characteristic of this entity.

In the setting of moderate blunt chest injury, it is advisable to achieve venous access and order a type and crossmatch. Sophisticated diagnostic studies, such as CT scan and arteriography, are reserved for children with abnormal findings on the preliminary evaluation. Admission for observation is often warranted; however, the child who shows improvement on examination over the observation interval and does not have an abnormal chest radiograph, ECG, or CBC may often be discharged.

Blunt Trauma—Severe

The child with abnormal vital signs or local findings indicative of internal injuries has sustained an immediate life-threatening injury. Initial therapy includes airway management, the institution of two large-bore intravenous lines, and the administration of supplemental oxygen. Depending on the condition of the child, chest tube insertion may be necessary for treatment of hemopneumothorax before radiographic studies are obtained. In selected circumstances, resuscitative thoracotomy in the ED may be beneficial, although in blunt trauma to the chest the outcome is almost uniformly poor if there has been cardiopulmonary arrest. Admission to the hospital is mandatory, and a full diagnostic

evaluation should be performed to ascertain the need for surgery.

LOCALIZED ABDOMINAL TRAUMA

Classification

Penetrating abdominal injuries (see Chapter 108 and Chapter 109) often cause moderate to severe trauma. However, the physician may cautiously define a small category of mild injuries, depending on the weapon involved.

All gunshot wounds must be considered at least moderate because almost all penetrate the peritoneum. Of those that penetrate the peritoneum, most cause visceral injury. If the vital signs are abnormal after a gunshot, the trauma should be considered severe.

Stab wounds, on the other hand, may be superficial to the peritoneum. The patient with stable vital signs and an apparent superficial stab wound may be judged to have a mild injury if local exploration confirms the clinical impression. Stab wounds that violate the peritoneum should be considered moderately serious and the patient should be referred for surgical consultation. By definition, stab wounds that lead to unstable vital signs have produced severe trauma.

Overall, blunt abdominal trauma is much more common than penetrating injury in children. Most children evaluated in the ED for blunt trauma to the abdomen will have relative minor injuries.

Management

Penetrating Trauma

All gunshot wounds are of at least moderate severity. Thus, these children require two large-bore intravenous lines (preferably inserted above the diaphragm), a nasogastric tube; radiographs of the abdomen and chest; and laboratory studies, including CBC, urinalysis, amylase, AST, ALT, and type and crossmatch. In the child with unstable vital signs, appropriate resuscitation should be initiated and laparotomy urgently considered. Otherwise, an initial CT scan may be preferable to delineate the extent and location of internal injury. All patients will require hospitalization.

Stab wounds produce variable degrees of internal injury, and the approach to management differs among institutions. Patients with abnormal vital signs require stabilization in the ED, including appropriate resuscitative measures, intravenous access, a nasogastric tube, radiographs, and laboratory studies. Transfer to the operating room may be necessary on an urgent basis. Patients whose vital signs are stable are evaluated further by local exploration, lavage, or laparotomy.

Blunt Trauma—Mild

Mild blunt abdominal injuries often occur when there is contusion of the abdominal wall from local trauma (e.g., a fist, a fall). After a careful history and physical examination, including rectal palpation and testing of the stool for blood, usually only a urinalysis for red blood cells is required.

Blunt Trauma—Moderate

Moderate blunt abdominal trauma is often seen in patients with multiple injuries or those in whom there has been an isolated but forceful blow to the abdomen. These patients should have a CBC, amylase, aspartate transaminase (AST), alanine transaminase (ALT), radiographs, and type and crossmatch. At least one intravenous catheter should be inserted, preferably above the diaphragm. A CT scan is often warranted. A diagnostic ultrasound may be useful to reduce the need for immediate CT in some settings. In many cases, hospitalization or prolonged observation in the ED is indicated. Other imaging studies, such as intravenous pyelography, are obtained in selected situations (see Chapter 108 and Chapter 109).

Blunt Trauma—Severe

Severe blunt abdominal trauma usually warrants prompt surgery after an initial stabilization of the vital signs. The issue of whether to perform peritoneal lavage before exploratory laparotomy or whether to do a CT scan is discussed at length in Chapter 108. In general, patients who have stable vital signs after initial fluid resuscitation may be evaluated with CT scanning to define intra-abdominal bleeding. The scans help define the need for surgery, especially if a hepatic or splenic injury producing limited hemorrhage is identified. Peritoneal lavage is usually reserved for children with a decreased level of consciousness, requiring CT scanning of the brain, who experience hemodynamic instability or deterioration in the ED.

In the presence of significant hematuria or strong suggestion of renal injury, a CT scan should be performed (see Chapter 109). In symptomatic patients with severe blunt trauma, the absence of red blood cells in the urine is not by itself sufficient evidence of an intact genitourinary tract. Avulsion of the renal pedicle may occur without hematuria.

EXTREMITY TRAUMA

Classification

Most injuries to the extremities of children (see Chapter 115) seen in the ED are mild. A few injuries are of moderate extent, and occasionally, extremity trauma may be life- or limb-threatening. Both penetrating (Table 103.8) and nonpenetrating trauma (Table 103.9) run the gamut in terms of severity. With penetrating wounds, the major immediate

concern is hemorrhage, although impairment of neurovascular or musculoskeletal integrity with concomitant loss of long-term function is also a consideration. On the other hand, nonpenetrating trauma may cause vascular insufficiency without external bleeding.

		Physical Examination	
Category	History	Vital Signs	Local Findings
Mild	Minimal force	Normal	Laceration
Moderate	Significant force (e.g., stab)	Normal	Laceration of tendon or nerve Significant venous hemorrhage
Severe	Critical force (e.g., gunshot)	Abnormal	Partial/complete amputation of arm or leg Arterial hemorrhage Open fracture

Table 103.8. Severity of Penetrating Extremity Trauma

		Physical Examination	
Category	History	Vital Signs	Local Findings
Mild	Minimal force	Normal	Contusions/point tenderness
Moderate	Significant force Crush injury	Normal	Obvious dislocation of major joint Displaced fracture
Severe	Critical force	Abnormal	Decreased or absent pulses

Table 103.9. Severity of Blunt Extremity Trauma

Management

Penetrating Trauma

The child with mild penetrating trauma requires appropriate wound care and tetanus prophylaxis (see Appendix D) in the ED. A radiograph is indicated if a radiopaque foreign body (including glass) is suspected in the wound. Moderate injuries require careful physical examination and often local exploration to define the extent of the trauma and the degree of functional impairment. At times, prompt surgical consultation or follow-up with a specialist is indicated. Some injuries require repair in the operating room; however, others—even extensive lacerations or extensor tendon disruptions—may be handled, time permitting, in the ED by an experienced physician. Surgical referral is mandatory for children in the severe category, and it is important to proceed as rapidly as possible when vascular damage is suspected.

Blunt Trauma—Mild

Children with mild nonpenetrating injuries often require a radiograph to detect underlying fractures. Particularly when there is tenderness at the end of long bones, careful consideration should be given to radiologic evaluation for growth plate (epiphyseal) injuries, keeping in mind that a normal radiograph does not exclude a nondisplaced Salter-Harris type I fracture.

Blunt Trauma—Moderate

Obvious dislocations should be repositioned as expeditiously as possible, usually after radiographs confirm the diagnosis. Depending on the joint involved, discharge is acceptable after reduction and radiologic reevaluation (e.g., shoulder, patella, metacarpal, phalangeal, or interphalangeal joints). Crush-type injuries may initially manifest with pain and swelling. Of particular concern is the possibility that crush injury may lead to a compartment syndrome over the ensuing 6 to 24 hours.

Blunt Trauma—Severe

Extremity injury associated with hemodynamic disturbances or disruption of the vascular supply are severe. These include de-gloving and crush (i.e., wringer-type) injuries, as well as some long-bone fractures with high energy transfer. Patients with severe extremity injuries should receive a rapid but thorough overall assessment, followed by prompt surgical consultation.

SUMMARY

The approach to the injured child requires great care and clinical acumen to establish the extent of the trauma and

institute appropriate treatment. Loss of life from occult internal hemorrhage, or neurologic sequelae from a missed unstable cervical spine injury, are devastating. Yet, physicians in the ED must also know which children need only a careful physical examination and when laboratory testing or admission is unwarranted. This chapter has described a brief schema for providing appropriate care to children with trauma in such a way that specific issues about management can be approached reasonably by the emergency physician. The subsequent chapters in this section provide a wealth of additional detail for each anatomic area of the body.

CHAPTER 104

Major Trauma

***MORITZ M. ZIEGLER, MD and †JAVIER A. GONZALEZ DEL REY, MD**

**Department of Surgery, Harvard Medical School, and Department of Surgery, Children's Hospital, Boston, Massachusetts; †Department of Pediatrics, University of Cincinnati College of Medicine, and Division of Emergency Medicine, Children's Hospital Medical Center, Cincinnati, Ohio*

Accidents continue to account for close to half of all deaths in children from the ages of 1 to 14 years, exceeding all other causes of childhood mortality and accounting for more than 20,000 deaths per year in children less than 19 years of age in the United States. More than half of these deaths are related to motor vehicle injury. Nearly 22 million children are injured each year in the United States, surpassing all major diseases in children and young adults. Two of three childhood accidents occur in males. The peak accidental age range is between 4 and 12 years, with the highest frequency at age 8 years. Accidental injury also accounts for approximately 30% of infant deaths. The societal impact of years of life lost from childhood mortal accidental injury is staggering.

The mortality rate for children hospitalized after an accident is reported to be low, but that is because 80% of all trauma deaths occur either at the accident scene or in the hospital emergency department (ED). The most common preventable cause of death in injured children is failure to secure the airway. As much as 18% of hospital trauma deaths are avoidable if a correct diagnosis is made and a treatment regimen is instituted. The most common single injury associated with death in injured children is head trauma, which alone or in association with other injuries is responsible for 80% of trauma deaths. Combined thoracoabdominal injuries produce an 82% mortality or condition of extremis upon arrival at the hospital ED. More than 50% of major injuries have associated injuries of the head, chest, and musculoskeletal system. Such multisystem injuries require the use of multiple medical disciplines, with varied diagnostic and treatment modalities, to achieve optimal care. These problems clearly place a large burden on the emergency physician to effect an improvement in outcome from childhood trauma.

A critical factor that influences outcome for the pediatric trauma patient is the recognition that a child's physiologic needs are not the same as those of a small adult. Although the child will usually mount an appropriate physiologic and endocrinologic response to stress, the greater surface area relative to body size results in greater susceptibility to body heat loss and insensible fluid loss. Water, minerals, trace elements, fat, and vitamins are all needed in greater maintenance portions in the child. Critically, the growing child has a significantly higher energy-calorie requirement than that of an adult. Equally important to proper tissue repair are greater total protein and essential amino acid nitrogen requirements, which are age dependent. Whether reversal of the malnourished state will influence morbidity and mortality in childhood trauma is speculative, but if data examining this question for adults are applicable to the child, attention to the patient's nutritional status is certainly important. Despite these concerns, children have amazing recuperative powers and are prime candidates for subsequent medical rehabilitation.

CAUSES OF MAJOR TRAUMA

Motor vehicle crashes account for as many as half of all childhood trauma deaths. Motor vehicle occupant death rates begin to climb steeply at age 13 years and peak at 18 years. Falls from heights and falls against fixed objects account for 25 to 30% of deaths, drownings 10 to 15%, and burns 5 to 10%.

Societal violence as a cause of death in children is increasing at an alarming rate. An estimated 1077 child maltreatment fatalities occurred in the 50 states and the District of Columbia in 1996. Homicide rates in children have two peaks: from age 0 to 3 years and from 14 to 18 years. Death by homicide afflicts African-American citizens most severely. Presently, 1 of every 28 African-American males born today will die as a result of homicide.

In infancy, the most common causes of accidental death are aspiration, suffocation, and motor vehicle crashes. In a 10-year period, more than 50,000 accidental deaths will be reported in children under age 5 years. Annually, there will be more than 70,000 injuries as a result of automobile accidents in the same younger population. Accident mortality statistics show that the youngest occupant in an automobile will be the most vulnerable to injury in the event of a crash.

Children from 5 to 9 years of age are most likely to be pedestrian injury victims, and in this age group, such injuries are

the most common cause of motor vehicle fatalities. Overall, pediatric pedestrian injury accounts for 46% of motor vehicle fatalities. Boys in densely populated urban areas represent the largest group at risk. Injury from bicycle crashes is particularly common in children 6 to 16 years. There are 700 bicycle crash deaths in this age group alone, principally from head injury.

Because the United States is a nation in which vehicles are driven on the right side of the road, injuries to the left side of the pedestrian are the most common. The resulting frequency of injured organs includes, in order, the spleen, genitourinary tract, gastrointestinal (GI) tract, liver, pancreas, pelvis, and major vessels.

The predominant mechanism of major injury in children is blunt trauma, with only 10 to 20% penetrating wounds. This is strikingly different from adult trauma patients, for whom as many as 50% will have a penetrating injury. More than half of the deaths from such blunt abdominal trauma have an associated major liver injury.

ORGANIZATION OF THE TRAUMA SERVICE

The regionalization of trauma care in the United States is still in its evolutionary stage. Hospitals have been designated as Level I, II, or III institutions based both on their capability and on their desire to care for the multiply injured patient. Under the guidance of the American College of Surgeons' Committee on Trauma, the eventual benefit of such a designation plan is to triage Category I–, Category II–, or Category III–injured patients to appropriate, qualified facilities. Because no one hospital can be expected to have in its immediate geographic area the childhood trauma volume necessary to be an independent and freestanding trauma center, regionalization becomes a necessity, using rapid transportation to transport children over distances.

Each institution must develop its own in-house organizational tree for a trauma service. Such a service needs a well-established chain of command with an appropriately designated leader, a responsibility that may change hands as additional personnel arrive at a resuscitation in the ED. The role of this leadership position in a hospital trauma service is to accept responsibility for patient care and organize the multisystem specialists needed to care for the patient with multisystem injury. Such organization begins at the scene of an accident, includes transport, and involves patient triage after initial evaluation and care once the patient arrives in the hospital ED. Subsequently, a decision to transfer the patient to another hospital, admit him or her to an intensive care unit, or take him or her straight to the operating room will be made by the team leader after consultation with the other varied specialists involved. If at this time it is clear that the predominant injury is to a single body system, it is appropriate for the team leader to transfer patient care responsibility to the designated head of a given subspecialty. Figure 104.1 demonstrates a flow diagram of a response to the traumatized child, an example of organizational schema put into action when or before a victim of serious trauma arrives in the ED.

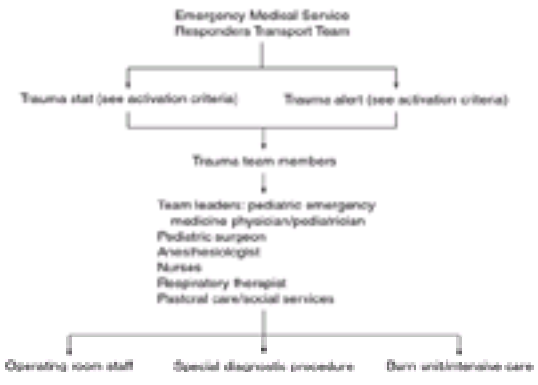

FIGURE 104.1. Sample flow diagram of a response to a traumatized child that is placed into action when or before a victim of serious trauma arrives in the emergency department.

ASSESSMENT AND MANAGEMENT

Initial Evaluation

Guidelines for the street-side evaluation and treatment of accident victims are well documented by the American College of Surgeons. Obviously, a list of priorities needs to be established for the logical approach to the trauma victim—priorities that are no different from those for the severely ill ED or hospitalized patient. It is also imperative that during injury assessment a simultaneous patient management protocol be initiated in a logical sequence. After prehospital evaluation and care of the injured child, the victim is transported to the hospital. A rapid and reproducible schema of immediate, simultaneous, and subsequent evaluation and treatment principles should be applied to every child with major multiple trauma admitted to the ED (Table 104.1). This initial assessment includes a primary survey, resuscitation, a secondary survey, and eventual triage. Two key principles must be followed in the initial assessment of the trauma patient. First, if any physiologic threat to the patient is identified, that threat must be treated immediately. The order of priority is airway, breathing, and circulation (ABCs). For example, relief of a tension pneumothorax takes precedence over intravenous (IV) access. Second, if at any point in the patient's secondary survey or subsequent care there is an unexpected physiologic deterioration, rapidly repeat the primary survey in order of priority (A, B, C). A “trauma stat,” alerting appropriate personnel, should be called upon notification of an impending arrival or simultaneously with an unexpected arrival of a child with multiple injuries in the ED, and all participants of the trauma care team should participate in this initial evaluation and treatment of the patient (Fig. 104.1). The indication for declaring a trauma stat is any one of the criteria listed in Table 104.2. The patient should be admitted to a generously sized area of the ED and placed on a multipurpose stretcher to be undressed and examined. It is important that the same examiners serially assess the patient.

I. Primary survey	C. Intubations—urinary tract, gastrointestinal tract
A. Airway maintenance, cervical spine control	III. Secondary survey
B. Breathing	A. Head
C. Circulation	B. Neck
D. Disability	C. Chest
E. Exposure	D. Abdomen
II. Resuscitation	E. Extremities
A. Oxygenation, airway management, and ventilation	F. Neurologic
B. Shock management	IV. Triage

Table 104.1. Initial Assessment and Management Guidelines for the Injured Child

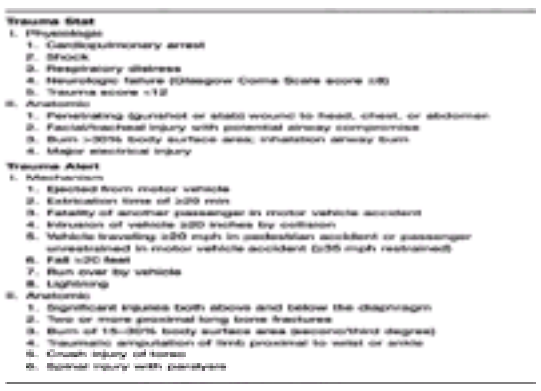

Table 104.2. Declaration of Trauma Stat and Alert

Primary Survey

The first priority in assessment and management is to secure an adequate airway while concomitantly stabilizing the neck to protect the cervical spinal cord from a yet-to-be-diagnosed cervical spine injury. The chin-lift or jaw-thrust maneuver and cleaning the oropharynx of accumulated foreign debris and secretions are the initial steps in establishing an airway. A cervical spine injury should be assumed to be present in all patients with major trauma, especially those injured above the clavicle. Adequate cervical spine radiographs and a normal clinical examination are required to exclude this problem. Therefore, until such films are taken, the head and neck should be neither hyperextended nor hyperflexed during maneuvers to secure the airway. Before any effort at intubation, artificial ventilation may need to be established using a bag-valve-mask device (see Chapter 1). An experienced physician should be able to exclude cervical spine injury clinically only in cases of minor trauma, when a patient is old enough to communicate, or in the absence of a distracting injury.

Breathing is deemed acceptable only in the face of a patent airway and adequate air exchange with normal oxygen saturation and carbon dioxide excretion. Early monitoring with pulse oxymetry is important. Compromise of ventilatory function in an injured child can occur with a depressed sensorium, airway occlusion, restriction of lung expansion, and direct pulmonary injury (see Chapter 95). Compromise of diaphragmatic excursion is a special hazard because of the increased importance of the diaphragm in ventilation in children. Gastric distension, a common event in an injured child, can significantly limit diaphragmatic excursion. In these situations, cricoid pressure should be performed while preparations are made for an artificial airway. This maneuver prevents possible aspiration of gastric content caused by passive regurgitation and/or increased intragastric pressure. Therefore, the early use of a nasogastric or an orogastric tube to decompress the stomach may need to be considered. If the child is obtunded or comatose, ventilation may require use of a bag-valve device that is connected to a mask or endotracheal tube delivering sufficient oxygen-enriched air (approximately 12 to 15 mL/kg) to produce an appropriate rise in the chest and an adequate oxygen saturation. Prompt attention to a hemopneumothorax, especially with mediastinal shift secondary to tension, is essential to the assessment of breathing (see the following section, Secondary Survey).

Circulation is initially assessed by examining the pulse, skin color, and capillary refilling time; from this information the peripheral perfusion and oxygenation may be estimated. A palpable peripheral pulse will generally correlate with a pressure greater than 80 mm Hg; a palpable central pulse indicates a pressure greater than 50 to 60 mm Hg, and a normovolemic patient capillary refilling time, as assessed by color return after blanching, will be within 2 seconds. External hemorrhage should be controlled by direct pressure or pneumatic splints, but the application of extremity tourniquets or hemostats to bleeding vessels is less useful. A mild Trendelenburg position may be of benefit in mild low-perfusion states to restore the central circulation.

To assess patient disability, a rapid neurologic examination is completed to establish the level of consciousness, as well as pupillary size and reaction. Table 104.3 lists the AVPU (alert, verbal stimuli response, painful stimuli response, unresponsive) method of assessing level of consciousness, in addition to pupillary assessment as previously mentioned. The Glasgow Coma Scale (Table 104.4) provides a quantitative measure of the level of consciousness.

A—Alert	P—Responds to painful stimuli
V—Responds to vocal stimuli	U—Unresponsive

Table 104.3. AVPU Method for Assessing Level of Consciousness

	Glasgow Coma Scale	Modified Infant Coma Score	
Eye Opening	Spontaneous	Spontaneous	4
	To voice	To voice	3
	To pain	To pain	2
	None	None	1
Verbal Response	Oriented	Coos, babbles	5
	Confused	Irritable cry, consolable	4
	Inappropriate	Cries to pain	3
	Garbled	Moans to pain	2
	None	None	1
Motor Response	Obeys commands	Normal movements	6
	Localizes pain	Withdraws to touch	5
	Withdraws to pain	Withdraws to pain	4
	Flexion	Flexion	3
	Extension	Extension	2
	Flaccid	Flaccid	1

Table 104.4. Pediatric Coma

To facilitate both assessment and treatment, the patient should be undressed and exposed, while careful attention is paid to the maintenance of body heat. Radiant warmers, air shields, and IV fluid warmers are useful tools in maintaining adequate temperature control in the pediatric patient.

Resuscitation

All patients with major trauma should receive supplemental oxygen therapy. Vascular access is another early necessity in resuscitation, and percutaneous or cutdown cannulation of upper or lower extremity veins should be of first priority, establishing two IV lines to facilitate resuscitation. Although large-bore cannulas are ideal, the size of the available veins should guide the choice of which cannulas to use. In a hypotensive child, the visible veins may be small. Successful placement of a 22- or 20-gauge cannula is preferable to a failed attempt to place a larger cannula. In a small child, one can give large volumes of fluids and blood through a small cannula. Improvement in vascular volume may then permit placement of a larger cannula at an alternative site. Early resuscitation also may be begun by intraosseous infusion into the tibial marrow space by a transtibial needle. We prefer percutaneous cannulation of an antecubital vein plus a saphenous vein at the ankle. In a hypotensive child in whom peripheral access is quickly found to be unsuccessful, the femoral vein provides a safe site for insertion of a central line, often accomplished rapidly using a guidewire technique. Rapid cutdown access is best done on an antecubital vein or the saphenous vein at either the ankle or in the groin just below the saphenofemoral junction.

At cannulation, blood should be sent for a type and crossmatch and for baseline hematologic and chemical parameters (Table 104.5). Central vein cannulation above the diaphragm is not a preferred primary access route, and in children, such access should be done only by experienced personnel.

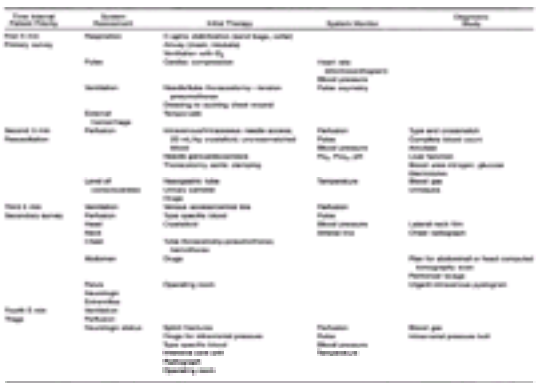

Table 104.5. Rapid Approach to the Pediatric Trauma Patient

The presence of shock must be assessed by appreciating whether or not inadequate organ perfusion exists. Shock after trauma is usually hypovolemic but may be cardiogenic or neurogenic. As a rule, isolated head trauma is not a cause of

shock. Any injured patient who is cool and tachycardic is in shock until proved otherwise.

Hypovolemic shock is most common after major trauma and is usually secondary to a significant acute loss of the 8 to 9% of body weight made up by the child's blood volume. To quantify the extent of the problem and decide on treatment priorities, hemorrhagic shock can be classified according to severity (Table 104.6). Reliance on the hematocrit alone may prove unreliable because a near-normal hematocrit level does not exclude the possibility of significant blood loss. Class I hemorrhage occurs with up to 15% acute blood volume loss (approximately a 250-mL blood loss in a 20-kg child), and physiologic changes will be minimal. Primary fluid replacement will stabilize the circulation. Class II hemorrhage, 15 to 30% blood loss (approximately 250- to 500-mL blood loss in a 20-kg child), is associated with a mild tachycardia and tachypnea along with a fall in pulse pressure as catecholamine release produces elevation of peripheral vascular resistance. Such patients may have impaired capillary refilling, and they may be either frightened or belligerent. These patients initially may be stabilized with crystalloid infusion, although blood transfusion eventually may be necessary. Class III hemorrhage is physiologically more significant, the 30 to 40% blood loss corresponding to 500 to 650 mL of blood in a 20-kg child. These patients have obvious signs of shock with altered mental status, tachycardia, tachypnea, and a measurable diminution in systolic pressure. Crystalloid resuscitation should be begun promptly, and most patients also will require blood products. Class IV hemorrhagic shock is immediately life-threatening. Patients are mentally depressed, cold, and pale; they have profound tachycardia and tachypnea, the pulse pressure is narrow, and there is no urine output. After rapid transfusion, such patients usually require prompt operative intervention.

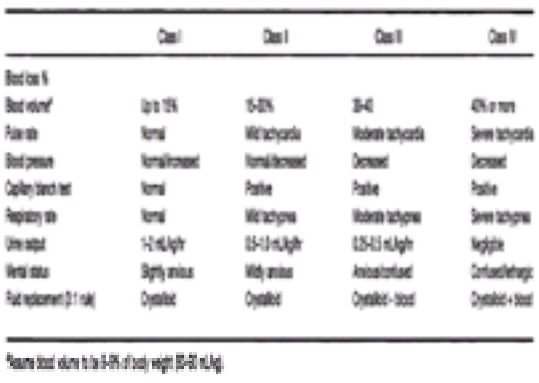

Table 104.6. Therapeutic Classification of Hemorrhagic Shock in the Pediatric Patient

Cardiogenic shock after major childhood injury is rare, but it could be a result of cardiac tamponade or a direct cardiac contusion. Dilated neck veins in a patient with a decelerating injury, sternal contusion, or a penetrating thoracic injury should arouse such suspicion (see Chapter 82 and Chapter 107). Neurogenic shock classically presents with hypotension without tachycardia or vasoconstriction; however, isolated head injuries do not produce shock, and causes of hypovolemia should always be sought in such patients. Septic shock rarely occurs immediately after injury, even in the face of abdominal content contamination.

Crystalloid isotonic solution, preferably Ringer's lactate or normal saline solution, is the initial resuscitative fluid of choice. The initial infusion is given as rapidly as possible in a dose of 20 mL/kg with careful monitoring of patient physiologic response to the fluid. Table 104.6 emphasizes the anticipated fluid needs, depending on the degree of shock, and the formulation is based on the premise that the patient will require 300 mL of crystalloid for each 100 mL of blood loss—the 3:1 rule. The restoration of perfusion may be clinically assessed, and at times invasive monitoring with elective placement of a central venous line or a pulmonary artery catheter facilitates this assessment. A most useful practical guide is the monitoring of urinary output; 1 mL/kg per hour is optimum, although for children less than 1 year of age, preferred output should approach 2 mL/kg per hour.

Blood transfusion preferably is done with fully crossmatched warmed blood passed through a 160-µm macropore filter. In the face of a transient or absent benefit from a rapid crystalloid infusion, fully crossmatched, type-specific, or type O negative blood should be given as a whole-blood transfusion. In summary, fluid and blood are given rapidly enough to maintain stable vital signs and adequate urine output. Vasopressors, steroids, and sodium bicarbonate do not play a role in the initial treatment of hypovolemic shock.

After perfusion has been restored, if not already accomplished, placement of urinary and gastric catheters should be done. Urinary catheterization should not be attempted before a retrograde urethrogram has proved urethral integrity if blood has been noted at the urethral meatus or in the scrotum, or if there is abnormal prostate placement on rectal examination. The urinary specimen should be immediately analyzed. In the presence of blunt head trauma with blood coming from the ears, nose, or mouth, care must be taken in inserting a nasogastric tube to avoid passage into the brain through a cribriform plate fracture. Such patients are better intubated through the mouth or through a soft nasopharyngeal airway.

Secondary Survey

A systematic assessment of organ systems must be done after securing the airway, breathing, and circulation. A pertinent history includes allergies, medications, past illnesses, time of the last meal, and the events preceding the injury.

A head examination includes reevaluation of pupillary size and reactivity, a conjunctival and fundic examination for hemorrhage or penetrating injury, and a quick assessment of visual acuity. A thorough palpation of skull and mandible will detect fracture-dislocations, but if the airway is secure, maxillofacial bony trauma is of low priority in the total

treatment plan.

Injury to the cervical spine is uncommon in children (see Chapter 106), but risk of injury must still be considered. This is especially true for any child with injury above the clavicles. It is also true for young children who fall one or more floors, are hit by a motor vehicle at 30 mph or more, and who are unrestrained or poorly restrained occupants of a motor vehicle involved in a crash. In older children, sports injuries are the second most common cause of cervical spine injury. In a child with a low risk for cervical spine injury (e.g., a fall when running), the neck can be cleared with a normal lateral cervical spine film, showing all seven cervical spine vertebrae. Also, a normal clinical examination in an awake, cooperative child (active but controlled flexion and extension and rotatory motion with no symptoms or signs of spasm, guarding pain, or tenderness) is the most important part of the assessment in ruling out neck injury. Ligamentous disruption and dislocation injuries of the cervical spine without radiographic evidence of bony injury are not uncommon in children because of the weakness of the soft tissue of the neck and the incomplete development of the bony spine. In approximately 40% of children with spinal cord injury, injury occurs without radiologic abnormality (SCIWORA). In children with a high-risk mechanism of trauma, it is best to obtain an anteroposterior, an odontoid, and lateral views. If the patient has an altered sensorium, a cervical collar should be left in place even if the three survey films are negative. When the patient recovers sufficiently to permit a fuller evaluation of the neck, the collar can be removed.

Three situations require a special approach. First, if a seriously injured child has had an endotracheal intubation placed, one can get a computed tomographic (CT) scan of C1–C2 when getting a head CT scan. Second, if the patient is brought to the hospital with a helmet on (e.g., football or motorcycle) and if there is no respiratory distress or other problem requiring immediate intubation, an initial cervical spine series can be done before helmet removal. If it is necessary to remove the helmet before the neck is cleared, a two-person technique ensuring neck immobilization should be used. Third, in the case of penetrating injuries to the neck, wounds deep to the platysma usually warrant operative exploration. In the case of missile injuries, the entry site should be denoted with an opaque marker, and anteroposterior and lateral spine films should be obtained.

Visual inspection of the chest will identify a sucking chest wound, best treated by immediate application of a sterile occlusive dressing; a major flail component, treated by splinting or endotracheal intubation; or a penetrating wound (see Chapter 107). Palpation of all thoracic bony parts must be done quickly, and auscultation may reveal a pneumothorax, hemothorax, or cardiac tamponade. The former two should be treated by tube thoracostomy. The latter may best be detected by muffled heart sounds, distended neck veins, and a narrow pulse pressure, and should be relieved by prompt pericardiocentesis (see Procedures, Section VII). A diagnosis of tension pneumothorax is supported by observing a contralateral tracheal shift and distended neck veins in addition to diminished breath sounds. Needle thoracentesis should provide relief, but tube thoracostomy should follow, with placement of the tube to water seal drainage plus suction. If an impaled object is protruding from the chest or any part of a patient, it is best debrided from surrounding clothing and left in place until definitive operation. If the history suggests a severe deceleration injury and the chest radiograph demonstrates a widened mediastinum with or without a fractured first rib, a thoracic aortic injury is suggested, and aortography is promptly indicated. If the chest radiograph reveals air lucencies suggesting intestine, a ruptured diaphragm is a possibility.

The purpose of the secondary abdominal examination is to establish whether an injury exists (see Chapter 104 and Chapter 108); it is not to give an exact diagnosis. Injury should be suspected in the presence of abdominal wall contusion, distension, abdominal or shoulder pain, signs of parietal peritoneal irritation, and/or shock. Hence, in most patients a baseline imaging study such as an abdominal CT scan should be done as soon as possible. Diagnostic peritoneal lavage (DPL) should be considered in the ED to expedite the decision about whether a patient needs an immediate laparotomy. In children, this is primarily of benefit in a patient who is unstable despite appropriate resuscitation; who has penetrating trauma that does not clearly involve the abdomen (e.g., gunshot wound of the lower chest); or who requires urgent, nonabdominal operative intervention (e.g., decompression of an epidural hematoma). In fact, most children with documented intra-abdominal or retroperitoneal injury who remain stable or rapidly become so do not require surgery. A positive DPL with greater than 100,000 red blood cells (RBCs) per cubic millimeter may correlate with a laceration of the spleen or liver but is not necessarily an indication for surgery in a stable patient. Of such patients, 80% will stop bleeding without operative intervention. However, diagnosis of injury is important in planning for care. Table 104.7 summarizes the indications and contraindications for this procedure. After emptying the urinary bladder, a midline approach above or below the umbilicus is used (see Procedures, Section VII). If the initial aspirate is grossly bloody or if the aspirate after instilling 10 mL/kg of Ringer's lactate reveals greater than 100,000 RBCs/mm ^{3}; greater than 500 white blood cells (WBCs) per cubic millimeter; a spun effluent hematocrit greater than 2%; or the presence of bile, bacteria, or fecal material, the paracentesis is positive. Lavage is most commonly falsely positive in the face of a pelvic fracture, or it may be falsely negative despite injuries to pancreas, duodenum, genitourinary tract, aorta, vena cava, and diaphragm.

Indications
Potential false-negative examination—head injury, medication overlay, spinal cord trauma
Potential false-positive examination—rib, pelvic, or spine fractures
Unexplained hypovolemia
Anesthetic need for unrelated injury
Selected penetrating injury
Absolute Contraindications
Multiple previous operations by history
Already determined need for laparotomy
Relative Contraindications
Pregnancy

Table 104.7. Peritoneal Lavage in the Evaluation of Abdominal Trauma in Childhood

A rectal examination is essential, assessing sphincter tone, rectal integrity, prostatic position, pelvic fracture, and presence of blood in the stool.

A thorough extremity examination should assess deformity, contusions, abrasions, penetration, and perfusion, including pulse palpation. The presence of a distal extremity pulse does not exclude a concomitant proximal arterial injury. Soft-tissue injuries should be thoroughly inspected for both wound foreign bodies and the presence of devitalized tissue. Long bones should be palpated with rotational or three-point pressure for tenderness, crepitation, or abnormal movement, and pressure must be applied to the pubis and anterior iliac spines to assess for the presence of a pelvic fracture. Severe extremity angulations should be straightened, joints should be immobilized, and traction splints should be applied. Compound fracture sites should be covered with sterile dressings. Generous irrigation and debridement of open wounds is beneficial in early wound care to minimize contamination before considering primary or delayed wound closure (see Chapter 123).

Hypothermia is a special risk in injured children who have relatively more surface area than an adult. Hypothermia can develop in the prehospital setting but can further occur in the ED, where proper assessment and treatment may require full exposure of the patient. The dangers of hypothermia are impaired circulatory dynamics, impaired coagulation, increased peripheral vascular resistance, and increased metabolic demand. The use of overhead radiant warmers, warm blankets, and warmed IV solutions are important measures in combating the deleterious effects of hypothermia. These measures should be used as soon after arrival in the ED as possible.

The burned child needs to have an initial appraisal of burn severity including the depth, location, and type of burn (Table 104.8); an appraisal of the extent of the burned area, using the percentage of surface area for children up to or older than 10 years as defined in Table 104.9; and a determination of whether the injury includes pulmonary, soft tissue, or bony damage as well. Burns may be classified in the following categories: 1) critical, in which there is a respiratory tract injury; a partial thickness burn exceeding 20% of body surface area (BSA); a full thickness burn exceeding 10% of the BSA; the hands, face, feet, or genitalia are included; there is a complicating fracture or soft tissue injury; electrical burns are part of the mechanism; or deep acid burns are present; 2) moderate, in which partial thickness is less than 20% and full thickness is less than 2% of BSA and does not include the hands, feet, or genitalia; and 3) minor, in which partial thickness is less than 15% and full thickness is less than 2% of BSA. The burn victim should be undressed, and sterile covers should be placed over the burn wounds. IV fluid resuscitation is necessary immediately if the burn exceeds 20% of BSA (see Chapter 1 and Chapter 114). Referral to a burn center should be considered in critical burns or cases with the possibility of devastating cosmetic and functional deficits.

Anatomic Area	Percentage Adult Surface (Age >10 yr)	Percentage Infant Surface
Head	9	16
Right upper extremity	9	9
Left upper extremity	9	9
Right lower extremity	18	13
Left lower extremity	18	13
Anterior trunk	18	18
Posterior trunk	18	18
Neck	1	4
Total	100	100

Table 104.8. Burn Wound Assessment: Body Surface Estimation (Adult versus Child)

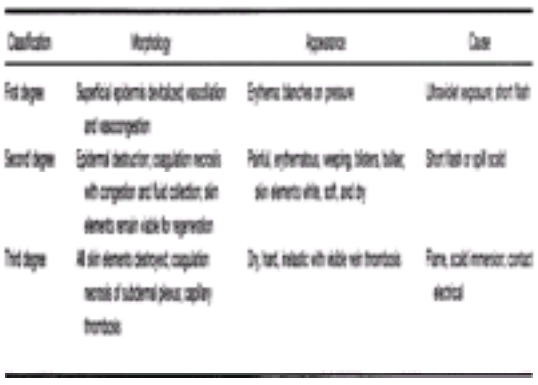

Table 104.9. Burn Injury

Neurologic assessment includes a reevaluation of the level of consciousness, a repeat pupillary examination, and a thorough sensorimotor examination. Not only is serial reassessment critical, but also quantification of the findings using a Glasgow Coma Scale is of benefit to detect early changes (see Chapter 105; Table 104.4). Any evidence of paralysis or paresis suggests a major neurologic injury. Until spinal cord injury is determined or ruled out in any patient with signs of central nervous system injury, maintain the patient in a semirigid cervical collar and immobilize him or her on a long spinal board.

Supplemental studies (including regular and contrast imaging studies; biochemical analyses of liver, pancreatic, and

renal function; and electrocardiographic analysis of cardiac function) may now be done. Tetanus prophylaxis should be considered (see Chapter 103), and antibiotics should be administered if specifically indicated.

Imaging the Pediatric Trauma Patient

In any child with major trauma caused by a blunt mechanism, a basic radiographic survey series should be considered. Traditionally, these included cervical spine, chest, and pelvic radiographs. Recent studies have demonstrated that patients with a Glasgow Coma Scale score of 15, no distracting injury, and no pain in the pelvic region have a low incidence for pelvic fractures. In these patients, the routine use of pelvic radiographs is not necessary but also rarely helpful in the acute initial management of the traumatized child. In a stable, cooperative patient, the clinician should review the lateral cervical spine film first and then proceed with the other films. In a less stable or neurologically compromised patient, it is best to obtain all films at once while continuing to protect the cervical spine. In patients with trauma to the torso, a pelvic film is important as a clinical indicator; 80% of children with multiple fractures of the pelvis have concomitant abdominal or genitourinary injuries. Additional survey films of the thoracolumbar spine and extremities depend on clinical findings and the mechanism of trauma.

The primary and secondary survey may then suggest the need for more definitive imaging studies. For example, any patient who is normotensive but has an abnormal Glasgow Coma Scale score, especially of 13 or less, should undergo a CT scan of the head. Other indications include a history of posttraumatic seizures, prolonged lethargy or loss of consciousness, or an underlying medical risk factor such as hemophilia. A CT scan of the abdomen is indicated in a hemodynamically stable victim of blunt trauma who has clinical signs of intra-abdominal injury, transaminase elevation of greater than 100 U/L, hematuria greater than 20 RBCs per high-powered field, or a worrisome mechanism of trauma in the presence of neurologic compromise. Most CT scans of the abdomen for trauma should be performed with single contrast IV. Double contrast (GI + IV) may delay the process and increase the risk for aspiration. If a Foley catheter is in place, it should be clamped during the abdominal CT scan to provide information about the bladder. Because of the potential for injury to the liver or spleen in children with blunt abdominal trauma, an abdominal CT scan is more comprehensive in evaluating a patient with significant hematuria.

The likelihood of positive findings in abdominal CT scans is significantly increased if three or more of the following indicators are present: 1) gross hematuria, 2) lap belt injury, 3) assault or abuse as a mechanism of trauma, 4) abdominal tenderness, and 5) trauma score less than or equal to 12. However, certain indicators alone, such as positive abdominal findings, worrisome mechanism of trauma (e.g., ejected from a motor vehicle), and neurologic compromise (e.g., Glasgow Coma Scale score of less than 10), warrant obtaining a double-contrast abdominal CT scan to document possible intra-abdominal or retroperitoneal injury. In general, the accuracy of CT scans in diagnosing intraperitoneal or retroperitoneal injuries is 95% or better. The use of newer modalities of scanning, such as ultrafast CT scans, will increase the diagnostic accuracy of CT scans because of less motion artifact and better contrast enhancement. Ultrafast scans will also enhance patient safety: less sedation required, lower radiation dosage, and improved accessibility of the patient. When emergency CT scans of the abdomen are not available, ultrasonography of the abdomen is a useful alternative. In the hands of an experienced examiner, it can be performed in the ED and will document most injuries to the liver, spleen, and/or kidney, as well as demonstrate intraperitoneal fluid.

The limitations of CT scans of the abdomen in trauma patients are in diagnosing injuries to hollow viscus organs, such as perforation of the bowel and bladder. One other striking limitation in the use of abdominal CT scans is in motor vehicle crash occupants who have clinical evidence of lap belt injuries to the abdomen and/or spine; transverse ecchymoses of the abdominal wall, abdominal pain, and/or tenderness; and symptoms or signs of lumbar spine injury with or without spinal cord injury. CT scans in such patients will miss certain injuries: free intraperitoneal air caused by bowel perforation in 75% of cases, and lumbar spine injuries in 77% of cases. In hemodynamically stable patients in this group, the workup should include complete thoracolumbar spine films, especially the lateral view, an abdominal film designed to show the presence of free air (e.g., a left lateral decubitus film), a cystogram, and a DPL. If injury to the bowel or bladder is confirmed, a laparotomy is indicated. If these studies are negative and if there is evidence suggesting possible retroperitoneal injury, a double-contrast CT scan of the abdomen is indicated.

Finally, selective urologic contrast studies are indicated in two situations. First, in a patient with gross blood at the meatus, especially if clinical and radiographic studies suggest a pelvic fracture, one should get a retrograde urethrogram. Gross blood at the meatus often correlates with clinical and/or radiologic evidence of a pelvic fracture. If the urethra is damaged, a surgical or urologic consultation is essential. If the urethra is not damaged, one can then get a cystogram after carefully advancing the catheter into the bladder. Second, if a patient with blunt or penetrating abdominal trauma is too unstable for a CT scan, perform a one-shot intravenous pyelogram in the ED. After IV administration of a bolus of 2 to 4 mL/kg of 50% diatrizoate sodium (Hypaque-Winthrop), the clinician should obtain a survey film of the abdomen 5 minutes after injection. This study will usually confirm the function or malfunction of both kidneys and occasionally the upper ureters. This information can be of great assistance to the surgeon at the time of laparotomy.

Triage

Definitive care may occur in the prehospital setting (e.g., endotracheal intubation), in the ED (e.g., chest tube placement), or in the intensive care unit or operating room. Triage is a process of patient assessment, prioritization of treatment, and selection of appropriate treatment location. In the early stages of patient assessment precise diagnosis of anatomic injury is often impossible. To identify patients with a potential for major morbidity or at risk of dying, a variety of physiologic scoring systems have been developed. In pediatric trauma, the most useful are the Glasgow Coma Scale score, the Trauma Score (TS), which uses the Glasgow Coma Scale (Table 104.4), and the Pediatric Trauma Score (PTS) (Table 104.10). For the purposes of prehospital triage, admission to a designated trauma center is indicated in any patient with a Glasgow Coma Scale score of 12 or less, a TS of 12 or less, or a PTS of 8 or less. Field studies of the TS showed that at night it is difficult to assess capillary refill and respiratory effort. Therefore, the most common tool used in prehospital triage is the Revised Trauma Score (RTS), which deletes these two variables. Admission to a trauma center is then indicated for any one of the following criteria: 1) Glasgow Coma Scale score of 12 or less, 2) systolic blood of 89 mm Hg or less, or 3) respiratory rate above 29 or less than 10. In the ED setting, a complete TS or PTS is usually obtained, but

for trauma outcome studies, the RTS is the most commonly used tool.

Component	Category		
	2+	1+	−1
Size	>20 kg (40 lb)	10–20 kg	<10 kg
Airway	Normal	Maintainable	Unmaintainable
Systolic blood pressure	>90 mm	50–90 mm Hg	<50 mm Hg
Central nervous system	Awake	Obtunded/LOC	Coma/decerebrate
Skeletal	None	Closed fracture	Open/multiple fractures
Cutaneous	None	Minor	Major/penetrating
			Sum _____ (PTS)

LOC, loss of consciousness.

Table 104.10. Pediatric Trauma Score[a]

The PTS is designed to give added emphasis to the importance of patient sizes and airway control in injured children. Indeed, studies confirm the validity of the PTS as a predictor of outcome: 9% mortality for PTS above 8 and 100% mortality for PTS of 0 or less. From 8 to 0, there is a linear relationship between decreased PTS and an increasing potential for mortality. Nevertheless, studies comparing TS, RTS, and PTS do not show any statistical advantage of PTS over the other two for the purposes of triage. Therefore, which ever physiologic scoring system is selected, it should be used consistently and it should be used sequentially. For example, a repeat TS 1 hour after baseline TS shows how the patient is responding to treatment. Alternatively, it may reveal any delayed deterioration of the patient's condition and may suggest the need for more urgent intervention.

SUMMARY

Table 104.5 and Table 104.11 describe a rapid approach to the patient. Over a 20-minute interval, the patient may be sequentially and simultaneously assessed, treated, monitored, and subjected to further diagnostic study while the format of primary survey, resuscitation, secondary survey, and triage is followed. Each physician dealing with the injured child should have such a format within his or her armamentarium. In addition, one should be able to recognize the need for and be able to perform an emergency resuscitative thoracotomy in a patient with chest trauma who is deteriorating despite maximum fluid resuscitation (see Chapter 107). With these treatment formats well in hand, the clinician can optimize the subsequent care of the patient after admission or can provide for successful transfer of the patient to a tertiary care trauma center.

HEAD TRAUMA

Head trauma accounts for approximately 250,000 hospital admissions and nearly 5 million visits to emergency departments (EDs) for pediatric patients each year. Brain injury is the leading cause of death and disability among pediatric trauma patients. Because morbidity and mortality after head trauma can be lessened by prompt stabilization, emergency physicians need to be thoroughly familiar with the manifestations of significant head injury and the necessary diagnostic and therapeutic maneuvers.

The approach to the child with a head injury is outlined in Chapter 38. This chapter focuses on the clinical anatomy, pathophysiology, clinical manifestations, diagnosis, and management of specific traumatic lesions to the head.

Clinical Anatomy

The anatomy of the head can perhaps best be considered initially in layers, traveling from the scalp inwards toward the brain parenchyma.

Injuries to the scalp, including hematomas and lacerations, are common, although not usually serious. The scalp is well vascularized. Therefore, even minor scalp lacerations may result in vigorous bleeding. Rarely, there is enough bleeding to cause some hemodynamic compromise, especially in infants. The rich vascularity of the scalp also makes it prone to the development of impressive hematomas.

Beneath the skin and subcutaneous fat of the scalp is a strong layer of tissue known as the galea aponeurotica. Deep lacerations of the scalp can be associated with a laceration to the galea as well. Hematomas beneath the galea are common after blunt impact to the cranium, especially in cases associated with skull fracture. As the clotted hematomas begin to liquefy several days after the injury, large, boggy subgaleal hematomas will become evident.

The bony “skullcap” or calvarium is composed of the frontal, parietal, occipital, and temporal bones, each of which is joined to one another by cranial sutures. Portions of the temporal and occipital bones, along with the sphenoid, palatine, and maxillary bones, comprise the skull base. Any portion of the cranium may fracture, although fractures are most likely where the bone is thinnest, as in the temporal and parietal regions, and in the skull base. Fractures of the skull base may in some cases involve the mastoid air cells, the sphenoid sinus, or the cribriform plate, and they may also be associated with a tear in the underlying meninges. In such cases, there is a direct communication between the cerebrospinal fluid (CSF) system and the nasopharynx or middle ear, posing a risk for intracranial infection.

Just beneath the skull is the dura mater, which tightly adheres to the skull at the suture lines. Between the dura mater and the skull is a potential space known as the epidural space. The meningeal arteries are embedded between two layers or “leaves” of the dura. As the body matures through childhood, some vessels—most notably the middle meningeal artery—begin to groove into the overlying bone. Therefore, traumatic impacts to the skull are particularly likely to injure these vessels. In addition, layers of the dura mater split away from each other to form the venous channels known as dural sinuses. These sinuses, which drain all of the venous blood from the brain, may be lacerated by trauma to the skull as well. The result of a laceration to the dural sinus or to the meningeal vessels is an epidural hematoma.

The next layer of meningeal tissue is the arachnoid mater. The arachnoid is a thin layer of tissue that is closely associated with the cerebral cortex, but which does not course into the brain sulci. The arachnoid mater separates the CSF-containing cisterns and subarachnoid space below from the subdural space above. The subdural space is traversed by the cerebral veins as they course from the brain to the dural sinuses. These so-called bridging veins may be sheared by acceleration/deceleration forces that violently move the brain relative to the position of the skull. The collection of blood that results is a subdural hematoma.

The subarachnoid space, which separates the arachnoid mater from the pia mater below, contains the CSF that bathes the brain and spinal cord. The pia mater is a layer of tissue that is essentially inseparable from the underlying brain, coursing with it over all gyri and sulci. The pia mater is highly vascularized with small vessels that may be injured when

shear forces or direct blows are applied to the brain. Localized bleeding from these vessels may result in subpial, subarachnoid, or subdural hemorrhage.

Just beneath the pia mater is brain parenchyma. The brain is not adherent to the skull at any point; rather, it is able to move freely within the skull, cushioned to some extent by the CSF in which it bathes. Direct blows to the head, associated with some deformation to the skull, may lead to bruising or hemorrhage in the cortex at the point of impact. In other cases, in which a blunt impact causes the brain to move against a relatively stationary skull, a contrecoup injury to the cortex, on the side opposite the site of impact, may occur.

In other cases, shear forces (as in severe acceleration/deceleration injury) can lead to diffuse injury to the axons comprising the subcortical white matter.

The brain is separated by bony prominences and by projections of the dura into three compartments: the anterior, middle, and posterior fossae. Clinically, the most important separation is that made by the tentorium cerebelli, a projection of dura mater that separates the cerebellum below from the cerebral cortex above. A notch in the tentorium allows passage of the midbrain. Cranial nerve III, the oculomotor nerve, courses along the edge of this tentorial notch. The parahippocampal gyrus and uncus of the temporal lobe lie just above the tentorial notch. When there is an increase in intracranial volume (as from a mass lesion, or from cerebral edema), the temporal lobe is pushed down through the tentorial notch, compressing cranial nerve III and the midbrain and brainstem in the process. The tentorial herniation syndrome results.

Another projection of the dura, the falx cerebri, separates the two cerebral hemispheres. Mass lesions in either hemisphere can rarely cause herniation beneath the falx to the opposite side. Herniation can also rarely occur when mass effect in the frontal lobe pushes the frontal brain posteriorly across the lesser wing of the sphenoid bone, which separates the anterior from the middle cranial fossa.

Deep within the subcortical white matter of the brain lies the ventricular system, comprised of two lateral ventricles, the third ventricle, and the fourth ventricle. The ventricular system is in communication with the subarachnoid space via connections from the fourth ventricle to the subarachnoid space at the levels of the pons and medulla. A mass lesion or cerebral edema may cause compression of the third or fourth ventricles, or of the outflow tracts, thereby blocking CSF egress and causing acute hydrocephalus.

Finally, it is important to consider the foramen magnum, the opening that allows passage of the neural tissue at the level of the junction between the medulla and the spinal cord. Mass lesions in the posterior fossa can lead to herniation of the cerebellar tonsils through the foramen magnum, with resultant compression of the medulla and potentially devastating consequences.

Pathophysiology

Primary versus Secondary Brain Injury

Discussions of traumatic brain injury typically divide the injury into two main components: primary and secondary brain injury. Primary brain injury refers to neural damage that is attributed directly to the traumatic insult itself. Shearing of neuronal axons, contusion or laceration of cerebral tissue, or direct penetration of the brain by a missile, for instance, all constitute primary brain injury.

Secondary brain injury refers to subsequent injury, after a trauma has occurred, to brain cells not injured by the initial traumatic event. Secondary brain injury may result from numerous causes, including hypoxia, hypoperfusion, excitotoxic damage, free radical damage, or metabolic derangements. In some cases, the effect of secondary brain injury is far more devastating than was the primary brain injury itself. Because many of the causes of secondary brain injury are at least theoretically preventable, most of the efforts in neurotrauma care are directed at monitoring for, and attempting to prevent, these complications.

Cerebral Ischemia

Probably the most important cause of secondary brain injury is brain ischemia, resulting from inadequate cerebral blood flow (CBF). Adequate CBF depends first on the presence of patent cerebral vessels to deliver blood to the brain. Rarely, severe head injury can be associated with shear, dissection, compression, or thrombosis of the major cerebral vessels, leading to tissue infarction. Vasospasm of the cerebral vasculature can also contribute to secondary brain injury. Vasospasm is not uncommon in cases of severe head injury, especially in those cases associated with subarachnoid hemorrhage.

Adequate CBF depends not only on patent vessels but also on adequate cerebral perfusion pressure (CPP). The cerebral perfusion pressure reflects a balance between the mean arterial pressure (MAP) of blood flowing to the brain, and the intracranial pressure (ICP), which acts as a counterforce, limiting blood flow to the brain. The relationship between these forces can be described mathematically: CPP = MAP – ICP.

In healthy children, the ICP is less than 20 mm Hg, and MAP is 70 to 80 mm Hg or greater (depending on the patient's age), yielding a CPP of 50 to 60 mm Hg or greater. The CPP fluctuates, but the healthy body maintains constant CBF in the face of minor fluctuations in CPP through autoregulation. Autoregulation is a process of reflex vasoconstriction or vasodilation in response to changes in CPP, thereby modulating resistance to blood flow in the cerebral vasculature to maintain a constant CBF. However, if the CPP drops too low (i.e., less than 40 or 50 mm Hg), the body will not be able to maintain adequate CBF despite maximal vasodilation. At this point, cerebral ischemia ensues.

Increased Intracranial Pressure

Severe drops in CPP can result from systemic hypotension (as in the multiply traumatized patient with exsanguinating injuries) or from significant increases in ICP. Increases in ICP are common in patients with serious head injuries, and they account for much of secondary brain injury.

Increased ICP may result from any process that increases the volume of the intracranial contents. Because the cranium has a fixed size and is relatively noncompliant, it can only accommodate a certain volume of intracranial contents at low pressure. An idealized pressure-volume curve (as seen in Fig. 105.1) represents the relationship between intracranial volume and ICP. In the normal state, small increments in intracranial volume can be made without significant change in the ICP (point 1 on the curve in Fig. 105.1). At this point, the intracranial contents are not particularly “tightly” packed into the cranium, and there is room for additional volume. After a certain critical point is reached, however (as indicated by point 2 on the curve), additional volume begins to lead to increases in ICP. At some point soon thereafter, the compliance of the intracranial space is exhausted (point 3 on Fig. 105.1), and the pressure-volume curve becomes steep, with even tiny increments in intracranial volume leading to massive increases in ICP. For patients on this steep part of the curve, the addition or removal of even 1 mL of intracranial volume may cause significant changes in the clinical status.

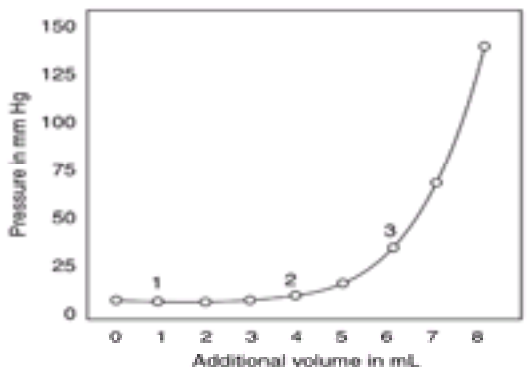

FIGURE 105.1. Effect of additional intracranial volume on intracranial pressure.

Causes of Increased ICP

Increased ICP may result from any abnormal increase in intracranial volume. This increase in volume is often a result of intracranial hemorrhage. When intracranial blood vessels are sheared or lacerated, the blood that is extravasated may accumulate to such an extent that it becomes a sizable intracranial mass. The increase in ICP that results may compromise CPP and lead to global ischemia. In addition to this global effect on ICP, the hematoma may compress the local underlying brain tissue, leading to local ischemia or metabolic derangements. As the mass expands in size, it may lead to significant shift of the brain structures within the cranium, with associated stretching or kinking of the intracranial blood vessels, and resultant ischemia to areas of brain served by these vessels. If the hematoma continues to expand, it may ultimately become so large that it leads to cerebral herniation, with resultant compression of the brainstem, neurologic deterioration, and ultimately death from cessation of brainstem functions.

A similar mass effect may occasionally be seen with large cerebral contusions, even in the absence of frank hemorrhage. Increases in ICP may also be a result of diffuse brain swelling, in the absence of focal mass lesions. Progressive brain swelling, if left unchecked, may ultimately lead to cerebral herniation.

Cerebral Herniation Syndromes

Cerebral herniation refers to the abnormal passage of brain tissue into an anatomic space in which it does not normally reside. Cerebral herniation occurs when the brain tissue is displaced by a large intracranial hematoma and/or massive brain swelling. Several distinct herniation syndromes exist, each correlated with distinct anatomic sites of herniation.

The best known herniation syndrome is tentorial herniation, which refers to the herniation of the parahippocampal gyrus and often the uncus of the temporal lobe through the tentorial notch, from the middle into the posterior fossa. Tentorial herniation most typically results from a focal mass lesion in or overlying the ipsilateral cerebral hemisphere, although it may also result from massive diffuse brain swelling. As the mass lesion or swelling expands, it pushes the brain tissue down, until a portion of the temporal lobe begins to slide through the tentorial notch. As the temporal cortex passes through, it becomes pressed against the brainstem structures and against cranial nerve III, which runs along the edge of the tentorial notch. In addition, the feeding vessels (branches of the basilar artery system) in this region may be stretched and distorted.

Most discussions of tentorial herniation describe a stereotyped sequence of clinical events that follows from the anatomic progression described previously. In many patients, however, the constellation of clinical findings varies considerably from this “classic” presentation. Classically, the patient first complains of headache, which may reflect stretching of the dura or the basal blood vessels. Next, a depression in the level of consciousness occurs, as the reticular activating system is compressed. The ipsilateral third nerve is compressed next, with resulting pupillary dilation (“blown pupil”) and eventually loss of third nerve motor function (ptosis, and loss of medial gaze). As the process continues and the cerebral peduncle is compressed, hemiparesis or decerebrate posturing develops (usually contralateral to the herniating cortex, but sometimes ipsilateral). Brainstem control of vital signs is also affected, with the development of bradycardia, hypertension, and irregular respirations (Cushing's triad). As herniation and brainstem compression continue to progress,

the patient typically loses function of both pupils and develops decerebrate posturing or flaccid paresis bilaterally. Ultimately, respiratory arrest ensues. Even if the cause of the herniation is relieved before cardiorespiratory arrest occurs, prolonged compression of brainstem structures may be associated with hyperemia of the brainstem and fatal brainstem hemorrhages after the compression is relieved.

Some other brain herniation syndromes should also be recognized. One site of herniation is the foramen magnum, through which the cerebellar tonsils may herniate. This form of herniation is usually a result of the progression of a posterior fossa mass lesion. The herniation process produces compression of the cervicomedullary junction. As the brainstem and aqueduct of Silvius are compressed, ventricular outflow obstruction may occur, with the acute onset of hydrocephalus, which will severely worsen the increased ICP, exacerbating the herniation process. Patients with herniation at the foramen magnum may present with symptoms of neck pain, vomiting, depressed mental status, bradycardia, or hypertension. In other cases, the patient may be relatively asymptomatic until sudden cardiorespiratory arrest occurs.

Another herniation syndrome is subfalcine herniation, which occurs when one cerebral hemisphere herniates beneath the falx cerebri to the opposite side. This form of herniation typically results from the progression of a unilateral supratentorial mass lesion. It is associated with symptoms of unilateral or bilateral leg weakness, and disturbances of bladder control, which result from compression and ischemia in the territory of the anterior cerebral artery.

Finally, the clinician should consider the retroalar herniation syndrome, which results from herniation of frontal lobe tissue posteriorly across the lesser wing of the sphenoid bone, usually as a result of frontal lobe mass lesions, or of swelling of the frontal lobes. The herniation may lead to distortion or compression of one or both intracranial carotid arteries, with resultant ischemia and infarction in the territories of the anterior and middle cerebral arteries.

Metabolic Derangements

Other physiologic mechanisms of secondary brain injury are important as well. Hypoxia, resulting from thoracic injuries, airway obstruction, or inadequate respiratory effort can be an important cause of brain injury. Hyperthermia increases cerebral metabolism and magnifies the severity of ischemia to an already compromised brain. There is increasing evidence that hyperglycemia also contributes to cerebral injury in the compromised brain.

The role of other substances in contributing to secondary brain injury has been carefully evaluated by investigators in the past decade. It appears that excess concentrations of the neurotransmitter glutamate, released from injured neurons into the synaptic cleft, can lead to injury through excess excitation of otherwise healthy postsynaptic neurons. Oxidizing agents and oxygen free radicals, released from injured neurons or elaborated as part of the brain's inflammatory response to injury, also appear to play a role in causing secondary brain injury.

Management and General Principles

Initial Resuscitation

Management of the patient with a head injury focuses on the prevention of secondary brain injury. As with all emergency care, management begins with the ABCs (airway, breathing, and circulation) of resuscitation. A patient with a head injury who has altered sensorium may require assistance with positioning of the airway or suctioning of oral and pharyngeal secretions. The clinician must recognize the potential for cervical spine injury in all patients with head injuries, and cervical spine precautions must be taken during airway management. Immobilization of the cervical spine with a semirigid cervical collar or with in-line manual stabilization must be maintained until the clinician can be certain that no cervical spine injury has occurred.

Breathing may be impaired if the patient's neural control of respiratory function is compromised or if traumatic injuries involve the thorax. All seriously traumatized patients require 100% inspired oxygen until it is certain that supplemental oxygen is not needed. Positive-pressure ventilation with a bag-valve-mask apparatus should be provided for any patient with inadequate respiratory effort. Unless there is increased ICP, the clinician should aim to achieve normocarbia (P_{CO_2} 35 to 40), and oxygen saturations of 100%. If there is evidence of increased ICP, therapeutic hyperventilation may be indicated (see the following).

Endotracheal intubation should be performed for any patient making inadequate or labored respiratory effort, or for patients who have a blunted gag reflex, cannot manage their oral secretions, or are comatose. Orotracheal intubation is generally safer than nasotracheal intubation if there is any concern about injuries to the midface. Care must be taken to minimize manipulation of the cervical spine during the process of intubation. Rapid sequence intubation is indicated for most patients with head injuries to ensure that the patients are comfortable and that intubation can be safely achieved. However, adequate oxygenation, ventilation, and protection of the airway are always the first priority. If intravenous (IV) access cannot be rapidly achieved, attempts at intubation may need to proceed without the use of adjunct medications.

Premedication for rapid sequence intubation begins with atropine 0.02 mg/kg (maximum dose 0.5 mg) for children less than 8 years of age, to lessen the vagal response to intubation. Lidocaine may also be useful, at a dosage of 1 to 2 mg/kg, as premedication to blunt the airway reflexes, thereby reducing the risk of coughing or choking, which may increase ICP.

If possible, a sedative drug should be used, both to make the patient comfortable, and to decrease the patient's responsiveness to airway manipulation. Thiopental at a dosage of 4 to 7 mg/kg is an ideal drug for patients with head injuries who have increased ICP because it decreases cerebral metabolism, thereby reducing the risk of ischemia. It must be used cautiously, however, in patients with any hemodynamic instability because it may reduce vasomotor tone and cardiac contractility, thereby leading to a decrease in blood pressure. If thiopental cannot be used, an alternative regimen is fentanyl (2 to 3 µg/kg) and midazolam (0.1 mg/kg), which provide sedation and analgesia with minimal effect on

cardiac contractility or vasomotor tone. In cases in which intubation must proceed but IV access cannot be achieved, midazolam may be given intramuscularly (0.1 mg/kg), with onset of action in about 3 minutes. Ketamine should be avoided in patients with head injuries because it can increase ICP.

For neuromuscular blockade, succinylcholine (1 to 1.5 mg/kg intravenously) offers the advantage of rapid action, with intubating conditions developing within 45 to 60 seconds. In theory, the diffuse fasciculations caused by succinylcholine may serve to increase resistance to venous drainage from the head and increase ICP. This potential risk can be avoided with the use of nondepolarizing agents, such as vecuronium (0.1 mg/kg intravenously) or rocuronium (0.6 to 1.2 mg/kg intravenously), which do not cause fasciculations. Although the onset of action for these agents is slower than for succinylcholine, rocuronium, at the higher end of its dosage range, can be expected to provide intubating conditions in approximately 60 to 90 seconds.

The circulatory status of patients with isolated head trauma is generally not compromised, although the potential for other organ system trauma, with associated hemodynamic compromise, must be immediately recognized. Intravenous access should be obtained immediately in all patients with moderate or severe head injuries.

Isotonic crystalloid solutions—normal saline or lactated Ringer's solution—should be given as needed to restore normal intravascular volume (see Chapter 104). The clinician should remember that the patient will only have an adequate cerebral perfusion pressure if the MAP is maintained in a normal range. On the other hand, for patients with adequate intravascular volume, excess fluid administration should be avoided. These patients can be treated with normal saline or Lactated Ringer's solution, running at one-half to two-thirds the maintenance fluid rate, while evaluation and treatment of the head injuries are being performed.

Brain-Specific Therapies

Once the ABCs of resuscitation have been addressed and the patient has been stabilized, attention can be given to the neurologic status. The neurologic assessment of the patient with a head injury, and the criteria for deciding which patients need neuroimaging are described in detail in Chapter 38.

In any patient with signs of increased ICP on examination (i.e., a progressively deteriorating neurologic status and/or signs of impending herniation), a computed tomography (CT) scan of the head should be performed immediately, with the goal of identifying any mass lesions that require evacuation. If a head CT scan is not available on site, emergent transfer to a facility where CT can be performed is usually the most appropriate course.

There is a long history in emergency neurotrauma care of empiric “blind” trephination (drilling of burr holes) for patients with signs of impending herniation. The goal of such therapy is to provide immediate decompression for patients who are clinically suspected of having an intracranial hematoma. As emergency CT imaging of the head has become more readily available, the role for empiric trephination is more limited. In most cases, the benefits of the information provided by head CT outweigh the costs of waiting a few extra minutes to have the scan performed, even in cases where herniation is impending. Especially for the pediatric age group, in which most cases of increased ICP result from diffuse brain swelling rather than intracranial hematoma, empiric trephination is likely to be of limited benefit. Nonetheless, empiric trephination may still have a role in select patients who are too unstable to be transported to the radiology suite, or in cases where the nearest CT scanner is too far away.

Medical treatment for increased ICP should be undertaken immediately when increased ICP is suspected. This treatment includes elevation of the head of the bed to an angle of 30 degrees, which promotes venous drainage from the head (thereby decreasing the volume of the intracranial vasculature). The head should be maintained in a midline position, which helps maintain venous outflow through the jugular system as well. Furthermore, sedating medications may be needed to prevent the patient from coughing and choking or from becoming agitated, both of which might be associated with increased intrathoracic pressure and, therefore, impaired venous drainage. Sedation should be used as sparingly as possible, however, so that the neurologic status can be monitored. Paralytic agents should be used only when sedating agents cannot be tolerated or when maximal therapy with sedation fails to control the patient's behavior.

Hyperventilation also decreases ICP by decreasing the volume of the intracranial vasculature. The cerebral arteriolar circulation responds to hypocarbia with reflex vasoconstriction. The therapeutic use of hyperventilation requires a delicate balance: too little ventilation leads to vasodilation and increased ICP, but too much ventilation leads to excess vasoconstriction and decreased CBF. The optimal balance for therapeutic hyperventilation appears to be achieved at a P_{CO_2} of 30 to 35 mm Hg. The gold standard for monitoring P_{CO_2} is the arterial blood gas. Therefore, an arterial line is invaluable in monitoring the progress of hyperventilation in the patient with a head injury. In the short run, however, useful information about trends in P_{CO_2} can be obtained readily with the use of end-tidal CO_2 monitoring.

Mannitol can also be given to lower the ICP, at an IV dose of 0.5 to 1 g/kg, which increases the serum osmolarity. The increased serum osmolarity draws free water into the vasculature, thereby leading to a decrease in the viscosity of blood. Because of the lower viscosity of blood, CBF is improved. The improvement in CBF leads to improved cerebral oxygenation, which helps prevent cerebral ischemia. Furthermore, the autoregulatory system responds to the improved cerebral oxygenation with reflex vasoconstriction, thereby lowering intracerebral volume (and ICP) without compromising CBF. The effect of mannitol on ICP is seen within a few minutes of administration. Over the ensuing hour or so, mannitol also leads to some degree of intravascular volume depletion because of its action as an osmotic diuretic. Clinicians should be cautious about the use of mannitol in any patient with possible hemodynamic compromise because the administration of a diuretic may exacerbate hypovolemia and worsen perfusion.

There is disagreement in the literature about the optimal use of hyperventilation and mannitol in the management of the patient with a head injury. The clearest indication for these maneuvers is to “buy time” for several minutes in a patient with clinical signs of impending herniation. Stabilization of the patient with impending herniation by using hyperventilation and/or mannitol may allow enough time for the patient to be safely transferred to the radiology suite, for emergency head

CT imaging. If an evacuable hematoma is discovered on CT, these maneuvers can be used to stabilize the patient en route to the operating suite, where the increased ICP will be more definitively relieved.

It is less clear that sustained hyperventilation or repeated doses of mannitol are useful in patients who have diffuse brain swelling but who do not have surgical mass lesions. In particular, numerous studies in recent years have documented a clear relationship between even mild degrees of hyperventilation (P CO_2 30 to 35) and decreased CBF. Because the overall goal of resuscitation in the patient with a head injury is to optimize CBF, prolonged hyperventilation may be counterprotective in that it may actually worsen cerebral ischemia. Therefore, hyperventilation is most useful as a transient therapy for acute changes in neurologic condition or as a second-line therapy after other methods of managing ICP have failed.

Some concern has also been raised that repeated doses of mannitol may be counterproductive in the ongoing care of patients with brain swelling because mannitol can leak across the injured blood–brain barrier, with its osmotic pull serving to worsen cerebral edema. Although some experimental models have documented this phenomenon, most data from clinical studies indicate lasting improvements in CBF with repeated doses of mannitol. Therefore, many authors consider mannitol to be a useful adjunct in the management of increased ICP in patients with brain swelling.

No evidence exists that hyperventilation or mannitol prevents the development of brain swelling. Therefore, the prophylactic use of these therapies is not recommended.

Many studies over the years have evaluated the utility of corticosteroids in the patient with a head injury. Theoretically, corticosteroids might blunt the inflammatory response to brain injury, thereby decreasing brain swelling. However, clinical researchers have been unable to show any improvement in outcome for patients with head injuries treated with corticosteroids. The use of corticosteroids for the treatment of head injury is therefore not recommended.

Anticonvulsant medications are clearly indicated for patients who are having ongoing seizure activity. Short-acting benzodiazepines (lorazepam or diazepam) may be used acutely in the management of ongoing seizures, and phenytoin or fosphenytoin may be used for maintenance anticonvulsant effect.

Phenytoin is also commonly used as prophylaxis for patients who have intracranial lesions associated with an increased risk of seizure activity, such as cerebral contusion, intraparenchymal hemorrhage, subarachnoid hemorrhage, or subdural hemorrhage. Patients who have epidural hematoma but no associated parenchymal injuries usually are not treated prophylactically.

Disposition

Generally, all patients with intracranial hematomas or brain injuries noted on head CT imaging should be hospitalized, no matter how mild or severe their symptoms. In addition, any patient with an abnormal mental status or neurologic examination should be hospitalized, even if head CT findings are normal. Patients with neurologic compromise and sizable intracranial hematomas require emergency operative intervention, and they are monitored postoperatively in the intensive care unit (ICU) for development of cerebral edema or recurrence of bleeding. Patients with neurologic compromise but no surgical lesions also need intensive care monitoring, often with the placement of a device for the measurement of ICP. In general, ICP monitors are indicated for any patient with a head injury who is comatose and who has an abnormal head CT. Although numerous different types of ICP monitors have been used, the intraventricular catheter has the advantage of being useful both for monitoring and for therapy because CSF can be drained through the catheter if needed to lower the ICP acutely. The goal of ICU management for patients with ICP monitors is to maintain an adequate CPP, which generally entails maintaining ICP at 20 mm Hg or less. More mildly symptomatic patients with a normal neurologic status and small cerebral contusions or intracranial hematomas may be candidates for observation in a ward setting.

Well-appearing patients with head injuries who either required no head CT scan (see Chapter 38) or who have no intracranial lesions on head CT imaging may be suitable for discharge to home with careful instructions. A discussion of the management of these patients follows.

Blunt Trauma: Specific Lesions

Concussion

Concussion is defined by the Centers for Disease Control and Prevention as a head trauma–induced alteration in mental status that may or may not involve loss of consciousness. Most clinicians use the term concussion to refer to mild head injuries, with no or minor depression in the level of consciousness (Glasgow Coma Scale scores of 13 to 15), and with no associated focal neurologic deficits. Concussion most commonly results from falls in infants and toddlers and from motor vehicle collisions or sports-related injuries in older children and adolescents.

Common symptoms of concussion include initial loss of consciousness, amnesia, confusion, headache, nausea, vomiting, and dizziness. For the most part, clinicians diagnose concussion in those patients with minor head trauma who have no brain imaging performed, or as a diagnosis of exclusion for patients with minor head injury who have no evidence of intracranial pathology on a head CT scan.

Increasingly in recent years, it has been recognized that many concussed patients with normal head CT findings do have subtle evidence of brain contusion or diffuse axonal injury noted on magnetic resonance imaging (MRI) of the brain. Researchers have also found abnormalities in cerebrovascular autoregulation in some patients with concussion who have normal CT scans.

In general, patients with concussion can be expected to do well, and no specific therapy is required. A number of large studies have shown that patients with minor head injury who have normal head CT scans are at low risk for clinical deterioration. In general, these patients may be safely discharged to home if no other issues require inpatient care.

There are several case reports in the literature of the second impact syndrome, in which patients have experienced an initial minor head injury during a sporting event, with some associated concussive symptoms, and then have had serious neurologic deterioration or died after a second seemingly minor head impact occurred. It is presumed that in these cases, the athletes had a relatively asymptomatic contusion or diffuse axonal injury, perhaps associated with impaired autoregulation, that was exacerbated by the second impact. Based on these frightening reports, the American Academy of Neurology has published recommendations for the management of athletes who have sustained a concussion. A summary of the recommendations has been published in *Morbidity and Mortality Weekly Report* and is presented in Table 105.1.

Grade 1 Concussion
Definition: transient confusion, no loss of consciousness, mental status abnormalities for ≤ 15 minutes.
Management: return to sports activities same day only if all symptoms resolve within 15 minutes; if a second grade 1 concussion occurs, no sports activity until asymptomatic for 1 week
Grade 2 Concussion
Definition: transient confusion, no loss of consciousness, mental status abnormalities for >15 minutes.
Management: no sports activity until asymptomatic for 1 full week; if a grade 2 concussion occurs on the same day as a previous grade 1 concussion, no sports activity for 2 weeks
Grade 3 Concussion
Definition: concussion involving loss of consciousness
Management: no sports activity until asymptomatic for 1 week if loss of consciousness was brief (seconds), or for 2 weeks if loss of consciousness was prolonged (minutes or longer)
Second grade 3 concussion, no sports activity until asymptomatic for 1 month
Any abnormality on computed tomography or magnetic resonance imaging, no sports activity for remainder of season; patient should be discouraged from any future return to contact sports
Modified from Morbidity and Mortality Weekly Report, Centers for Disease Control and Prevention.

Table 105.1. Recommendations for Return to Sports Activity after Concussion

In addition to these recommendations, the patient should be instructed to rest until symptoms improve. Acetaminophen may be prescribed for headache, but more potent analgesics should probably be avoided so that any progression of symptoms can be detected. The warning signs of progressing intracranial injury should be reviewed with the patient before discharge, with instructions to return immediately if any of these new symptoms or signs appear.

Symptoms after a concussion generally resolve quickly, often within minutes or hours after the injury. However, some patients develop the postconcussion syndrome, in which symptoms of confusion, amnesia, headaches, or dizziness may persist for days or even weeks after the injury.

Skull Fracture

Clinical Findings and Diagnosis

Skull fractures occur at a rate of approximately 2 per 1000 infants per year, and in approximately 0.5 to 1 per 1000 older children and adolescents. Skull fractures result mainly from falls in infants, but they may also result from motor vehicle collisions, child abuse, or other mechanisms. In older children and adolescents, skull fractures usually result from motor vehicle collisions or sports-related injuries.

Infants are clearly at a higher risk for skull fracture than older children, probably because their skulls are thinner. Many skull fractures in infants result from short distance falls; generally, about 50% of infants with skull fracture have fallen less than 4 or 5 feet. As the child matures beyond the first year of life, the propensity to sustain skull fracture disappears quickly.

Fractures may occur in any bone of the skull, although fractures of the parietal bone constitute about 70% of cases. The occipital and temporal bones are next most commonly involved, with the frontal bone least likely to fracture. Basilar skull fractures commonly occur in pediatrics as well, although less commonly in infants, and more often in older children and adolescents.

Most cases of skull fracture are associated with soft-tissue swelling or hematoma overlying the fracture site. Skull fracture may occur in the absence of recognized soft-tissue findings as well, perhaps because subtle swelling is missed beneath the patient's hair, or because it may take several hours after the injury before the swelling becomes clinically evident. Palpable bony abnormalities are rarely detected in cases of linear or minimally depressed skull fracture but may be evident in cases with more severe depression. Other symptoms and signs of head injury, such as loss of consciousness, vomiting, lethargy, seizures, or irritability, may be present, especially if intracranial lesions are associated, but they are often absent in cases of isolated skull fracture.

Signs of basilar skull fracture may include hemotympanum, Battle sign (hematoma or discoloration overlying the mastoid bone), “raccoon eyes” (blue or purple discoloration of the periorbital tissue), or CSF rhinorrhea or otorrhea. There may be no abnormalities on examination of the scalp, and there may be no signs or symptoms of intracranial injury.

Skull fracture may be diagnosed by plain radiographs of the skull or by head CT imaging (Fig. 105.2,Fig. 105.3 and Fig. 105.4). A head CT scan is usually the preferred imaging modality for evaluating children with head injuries because it provides information not only about the skull but also about the intracranial contents. Skull radiographs are somewhat

more sensitive for detecting skull fracture, especially for those horizontal fractures that run parallel to and between adjacent “cuts” on the CT scan. Head CT imaging is better than skull radiography, however, for detecting subtle degrees of depression of the bony fragments. Head CT imaging is also preferred in cases in which a diagnosis of basilar skull fracture is considered because it allows better imaging of the basilar skull and for visualization of pneumocephaly or fluid in the mastoid air cells, which are common associated findings (Fig. 105.5 and Fig. 105.6).

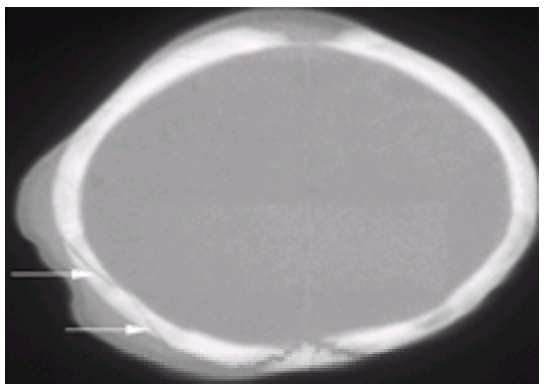

FIGURE 105.2. Linear skull fracture. This is a head computed tomography (CT) scan performed on a 6-month-old girl who fell down 20 steps. The *arrows* indicate a comminuted linear right parietal skull fracture. Note also the extensive soft-tissue swelling of the right parietal scalp. No intracranial abnormalities were identified.

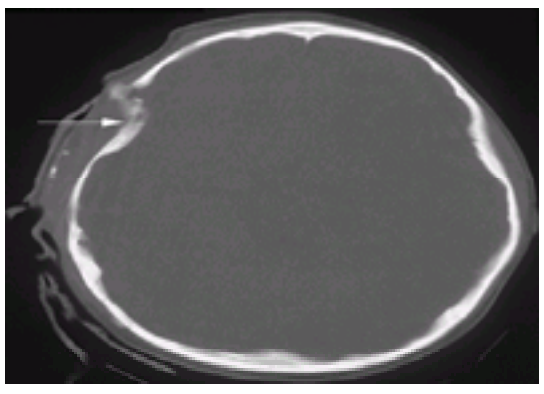

FIGURE 105.3. Depressed skull fracture. This head computed tomography (CT) scan was performed on a 6-year-old boy who was unresponsive and apneic after being a passenger in a high-speed motor vehicle collision. The *arrow* indicates a depressed skull fracture involving the right temporal bone. He also had an associated right temporal contusion (see Fig. 105.7).

FIGURE 105.4. Depressed skull fracture. This 3-month-old boy fell out of bed and was noted to have a palpable depression of the skull. Head computed tomography (CT) imaging shows a “ping-pong ball” type depressed skull fracture. No intracranial abnormalities were identified.

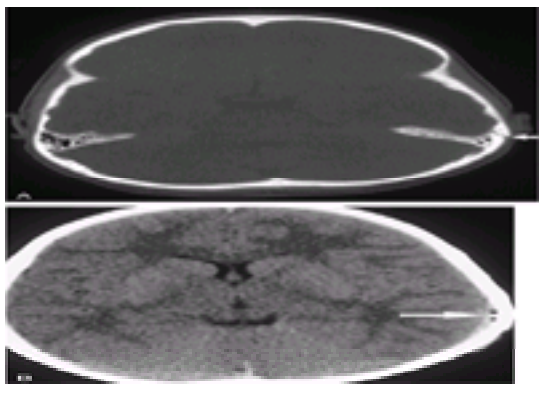

FIGURE 105.5. Basilar skull fracture. This 5-year-old girl was a pedestrian struck by a bicycle. Hemotympanum was noted on examination. **A.** The arrow indicates a fracture of the left temporal bone. The adjacent mastoid air cells are somewhat opacified. **B.** A small extraaxial hematoma with associated pneumocephaly is seen *(arrow)*.

FIGURE 105.6. Basilar skull fracture. This 10-year-old male fell 10 feet to the ground. He had left hemotympanum. A head computed tomography (CT) scan shows a fracture through the petrous portion of the temporal bone (*thin arrow*), extending toward the internal carotid canal *(thick arrow).* The left mastoid air cells are somewhat opacified. Other “cuts” of the CT confirm that the fracture involves the wall of the carotid canal. A cerebral angiogram was performed, which showed normal vascular integrity.

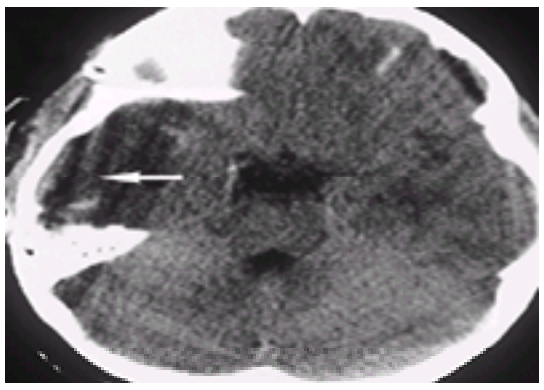

FIGURE 105.7. Cerebral contusion. This head computed tomography (CT) scan was performed on a 6-year-old boy who was found unresponsive and apneic after being a passenger in a high-speed motor vehicle collision. The *arrow* indicates a large area of hypodense nonhemorrhagic contusion in the right temporal lobe.

Management

Linear Skull Fracture. The main significance of linear skull fractures is that they indicate that the risk of intracranial injury is increased by as much as tenfold to twentyfold. In cases in which acute linear skull fracture is diagnosed, therefore, a head CT scan is essential to evaluate for possible intracranial injury. In addition, any diagnosis of skull fracture should lead the clinician to consider the possibility of child abuse. If the history provided is not a plausible explanation for the injuries observed, further evaluation for possible child abuse should be initiated.

Many clinicians routinely admit children with skull fracture to the hospital for a period (e.g., 24 hours) of observation to exclude the small possibility of late complications. For well-appearing children with a linear skull fracture and no associated intracranial injuries, however, the risk of late complications is low. Therefore, if a child with skull fracture but no intracranial lesions remains well over a short period of observation in the ED and child abuse is not suspected, the child may be considered for discharge to home. The warning signs of advancing intracranial injury should be carefully reviewed, with advice to return immediately if any of these signs are noticed. The family should also be counseled to expect the possible development of a subgaleal hematoma, which becomes more evident as the clotted blood overlying the fracture site begins to liquefy, and which presents as a large boggy swelling of the scalp, usually between 5 and 7 days after the injury. Unless the hematoma develops signs of infection, it will resolve gradually on its own and should not be aspirated.

Linear skull fractures generally heal well, with no specific therapy required. Fewer than 1% of patients will develop a growing skull fracture; that is, a fracture that fails to heal and becomes wider over time. All patients should have a follow-up examination 1 month after the initial injury to ensure that there is no evidence of development of a growing fracture.

Depressed Skull Fracture. Skull fractures may be associated with depression of the fracture fragments, which may range from barely detectable depressions to more obvious, palpable deformities in the skull (Fig. 105.3 and Fig. 105.4). If there are no other complicating features, isolated skull fractures with minimal depressions can be managed in a fashion similar to that previously described for linear skull fractures.

More significant depressions of the skull, however, are more serious because they may be associated with contusion or laceration to underlying brain. In cases in which injury to underlying brain is noted on head CT imaging, especially if there are seizures or focal neurologic findings referable to the brain injury, prompt surgical elevation of the fracture fragments may be required. Surgical intervention is also usually necessary for compound, or open, depressed skull fractures, in which early debridement and closure is performed, especially for those patients who have lacerations of the dura mater. Penetrating injuries of the skull are a special case of open, depressed skull fracture and are discussed later in the chapter.

Surgical elevation is generally necessary (although not necessarily emergently) for patients with depressed skull fracture who have associated compression to underlying brain parenchyma or intraparenchymal bone fragments. Patients with significant cosmetic deformity are candidates for surgical repair as well. Most neurosurgeons would recommend operative repair for any skull fracture with a 1-cm or greater depression, or for depressions with a depth greater than the thickness of the skull.

Basilar Skull Fracture. Fractures through the skull base are unique in that they may involve disruption of the mastoid air cells or the paranasal sinuses, raising the possibility of intracranial infection. Most recent studies suggest that the risk of meningitis after basilar skull fracture is low, with rates between 0.4 and 5%. The highest risk is in patients with evident CSF rhinorrhea or otorrhea. Although some controversy exists in the literature, it appears that prophylactic antibiotics reduce the risk of meningitis in high-risk patients. Many would recommend, therefore, that patients with basilar skull fracture and CSF leak be admitted to the hospital for IV antibiotics. Neurosurgical management of CSF leaks may also include several maneuvers, such as external CSF drainage to lower pressure and allow the leak to heal, packing of the sinuses, or operative repair of dural lacerations.

Although it has been traditional management for all patients with basilar skull fracture to be admitted to the hospital for observation, recent authors have suggested that if patients with basilar skull fracture are neurologically normal, have no intracranial pathology on head CT, and have no CSF leak, they may be safely discharged to home. If they are to be discharged, instructions about the management of head injury, as previously described for linear skull fractures, should be discussed in detail. Furthermore, the family should be warned to watch closely for fever, stiff neck, photophobia, or any other signs of developing intracranial infection.

Growing Skull Fracture. Growing skull fractures are seen almost exclusively in patients who sustain the initial injury in the first year of life. Growing skull fractures result from a tear in the dura underlying the fracture, allowing subsequent herniation of meningeal tissue into the fracture line. There is almost always associated injury to the underlying brain parenchyma, sometimes with herniation of parenchyma into the fracture line, and often with a porencephalic enlargement of the adjacent ventricle. Although the pathogenesis of growing skull fracture is not fully understood, it is believed that the constant pressure exerted by the herniated tissue leads to erosion of the fractured edges of bone.

Growing fractures are more likely in patients who had larger, more widely diastatic fractures on presentation, especially if damage to the underlying parenchyma was significant. Growing fractures present weeks or months after the initial injury, usually as persistent swelling overlying the fracture site, sometimes with the development of a boggy or pulsatile soft-tissue mass. Associated neurologic symptoms such as developmental delay, focal neurologic deficits, or seizures may be evident as well, probably reflecting injury and abnormal development of the brain tissue adjacent to the fracture.

Surgical repair is required in cases of growing skull fracture, with repair of the rent in the dura (often involving placement of a synthetic graft) and autologous bone graft over the fracture site.

Parenchymal Injuries

Cerebral Contusion and Intraparenchymal Hematoma

Pathophysiology. Cerebral contusion refers to bruising of the cerebral cortex. On a microscopic level, there is focal injury to neurons, glial cells, and blood vessels, with some extravasation of blood noted, and some swelling of neural cells.

Cerebral contusion occurs after blunt trauma because of the impact of the relatively mobile brain tissue against a relatively fixed skull. Injuries may occur at the point of traumatic impact (coup injuries) or at a site opposite the point of impact (contrecoup injuries). Contusions are most likely to occur in those locations where the brain is less cushioned by CSF and is more able to come into direct contact with the bony skull. Most commonly, contusions are seen in the undersurface of the frontal lobe or in the poles of the temporal lobes.

The presence of cerebral contusion indicates primary brain injury to the tissue involved. Focal neurologic deficits associated with dysfunction of the contused tissue should be expected. In addition, cerebral contusion leads to a risk for secondary brain injury because the contusion may exert some mass effect on surrounding tissue, with resulting cerebral dysfunction and risk for further ischemia. Finally, contusions are associated with a risk of late intraparenchymal hematoma.

Intraparenchymal hematoma may occur as a late complication of an initially nonhemorrhagic contusion, or it may be evident from the initial time of injury. These hemorrhages usually result from severe traumatic forces. The presence of hemorrhage may cause impaired blood flow to the adjacent parenchyma. If the hemorrhage becomes large enough, it may exert mass effect and even lead to cerebral herniation.

Clinical Manifestations. The severity of the clinical manifestations associated with cerebral contusion can vary widely. Often, there is history of loss of consciousness and/or some disturbance in the mental status. Focal neurologic deficits related to the contusion may be noted. Frontal contusions, for instance, may be associated with behavioral alterations, and temporal contusions may be associated with disturbances of memory. Seizures are relatively common as well.

With the increasing use of CT and MRI for patients with mild head trauma, an increasing number of contusions are being discovered in patients with no or mild symptoms (headache, nausea and vomiting, lethargy).

Most patients with intraparenchymal hematomas are comatose, and they may have focal neurologic deficits. Rare patients with intraparenchymal hematoma may initially be alert, but they have a high risk for deterioration over the

ensuing hours.

Diagnosis. Cerebral contusions are generally evident on a head CT scan as hypodense areas of edema, sometimes intermingled with hyperdense areas of hemorrhage (Fig. 105.7 and Fig. 105.8). Intraparenchymal hematomas are more uniformly hyperdense, although areas of active bleeding may be isodense (Fig. 105.9).

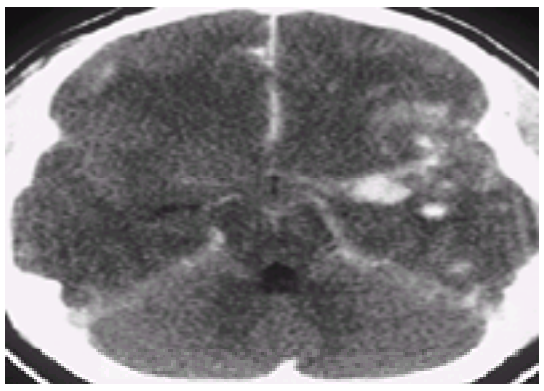

FIGURE 105.8. Cerebral contusion. This 16-year-old girl was comatose after being a passenger in a high-speed motor vehicle collision. A head computed tomography (CT) scan shows hemorrhagic contusion of the left temporal lobe, subdural hematoma along the tentorial margins, and effacement of the sulci throughout. The patient expired despite intensive medical management for increased intracranial pressure.

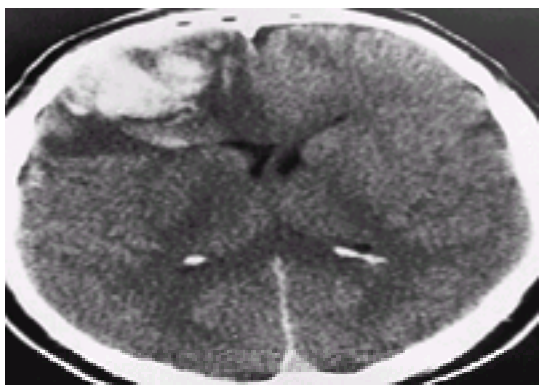

FIGURE 105.9. Intraparenchymal hemorrhage. This adolescent was an unrestrained passenger in a high-speed motor vehicle collision. He was comatose on presentation. A head computed tomography (CT) scan shows a large area of intraparenchymal hemorrhage in the right frontal region. Note also, the surrounding area of low-density cerebral contusion.

Management. All patients with acute cerebral contusion and intraparenchymal hematoma should be admitted to the hospital for observation. Patients with a smaller contusion, a normal neurologic status, and no other lesions noted on head CT imaging may be appropriately managed on the inpatient ward. More seriously ill patients with an abnormal neurologic status generally require ICU monitoring. Patients with intraparenchymal hemorrhage should be admitted to the ICU as well.

Management of cerebral contusions focuses on efforts to prevent secondary brain injury, with the recognition that the contused tissue and surrounding areas are at especially high risk for ischemia. For patients in coma, ICP monitoring is generally indicated, and maneuvers for managing increased ICP may be required. The clinician must be especially alert for the possibility that an initially nonhemorrhagic contusion will undergo late hemorrhage, which would manifest as a sudden increase in ICP and/or deterioration in clinical status.

Patients with large contusions exerting a significant mass effect may require surgical resection. Surgical resection should be avoided when possible, however, because the contused tissue may actually be viable and regain function over the long-term.

The management of intraparenchymal hematomas is problematic in that operative drainage of these lesions risks injury to adjacent brain tissue. Clearly, large hematomas exerting a significant mass effect require operative drainage. Smaller lesions may initially be managed nonoperatively, but with the clinician recognizing the high risk for sudden deterioration. ICP monitoring is necessary for most patients with intraparenchymal hematoma in order to detect early signs of a growing lesion. Prophylactic anticonvulsants are often given for patients with cerebral contusions or intraparenchymal hematoma.

The prognosis for patients with cerebral contusion can vary widely, depending mainly on the patient's neurologic status on presentation, and on the presence or absence of other lesions. Patients with more significant cerebral contusion often have some residual neurologic disability. Follow-up CT scans on such patients show areas of encephalomalacia at the site of injury. Other patients may have essentially full recovery, with no residual neurologic deficits evident. Patients with intraparenchymal hematomas tend to have incurred severe brain injury, and they often have a poor outcome.

Diffuse Axonal Injury

Pathophyisology. Diffuse axonal injury (DAI) is characterized pathologically by injury to the white matter tracts of the brain, often at the junction of gray and white matter or sometimes deeper at the level of the corpus callosum, brainstem, or cerebellum. Pathologically, degeneration of the axons themselves is noted, with the presence of axonal retraction balls, microglial proliferation, and demyelination. In addition, there is usually accompanying endothelial damage to the capillaries, with some punctate areas of hemorrhage. Edema is sometimes, but not always, associated.

DAI results from the application of severe acceleration/deceleration or angular rotational forces to the brain, which lead to shear injuries of the axons and associated vasculature.

DAI reflects diffuse primary injury to the white matter. In addition, DAI is often associated with other focal lesions, or with global brain swelling.

Clinical Manifestations. The clinical manifestations of DAI can vary greatly, ranging from those patients who have symptoms of concussion to those who present in coma. Loss of consciousness is common. In one study of patients with DAI, 82% developed coma. In general, patients with more diffuse areas of DAI noted on radiographic imaging (especially if involving the brainstem) have more severe symptoms.

Diagnosis. DAI is evident on CT scan as small nonexpansive hemorrhagic lesions of the white matter, most typically seen at the gray–white junction of the cerebral hemispheres, or in the corpus callosum, brainstem, or cerebellum. Cerebral swelling sometimes accompanies DAI, but it need not be present for a diagnosis of DAI to be made. Intraventricular hemorrhage is sometimes noted (Fig. 105.10). Intraparenchymal hemorrhages and cerebral contusions are commonly noted in patients with DAI as well.

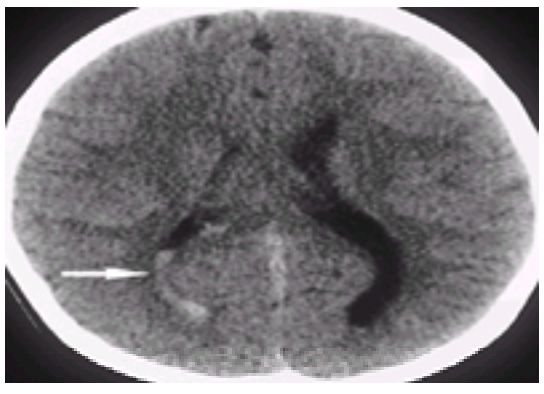

FIGURE 105.10. Intraventricular hemorrhage. This head computed tomography (CT) scan was performed on an 8-year-old girl who was involved in a sledding accident. She presented in coma. The *arrow* indicates hemorrhage in the right lateral ventricle. Note the layering of blood inferiorly in this supine patient. Other “cuts” of the CT showed areas of punctate hemorrhage consistent with diffuse axonal injury. The patient made an excellent recovery, with minimal neurologic deficits.

Management. Patients with a radiographic diagnosis of DAI should be admitted to the hospital for observation. Patients with DAI who have a normal neurologic examination and no other lesions evident on CT scan may be able to be managed on a general inpatient unit. Those with an abnormal neurologic status require ICU level monitoring. Management of patients with DAI is supportive, with efforts directed mainly at preventing secondary brain injury. ICP monitoring is generally indicated for patients who present in coma. Specific therapies may be required for the management of increased ICP, as outlined previously.

In some large series of patients with DAI, mortality rates range from 10 to 15%. Of those who survive, persistent neurologic dysfunction is common, occurring in 30 to 40% of patients. In general, however, children with DAI have a better prognosis than adults. A good functional outcome can be expected for patients with DAI who have mild symptoms of head injury (Glasgow Coma Scale score of 13 to 15).

Diffuse Brain Swelling

Pathophysiology

Diffuse brain swelling (DBS) is a common manifestation of head trauma, especially in pediatrics. In one large series of children with severe brain injury, 41% had DBS. The origin of DBS is probably multifactorial. One component of DBS appears to be an increase in intracerebral vascular volume, probably caused by a loss of normal autoregulatory reflexes and diffuse vasodilation.

Many authors argue that the time course of DBS, occurring within minutes after a traumatic insult, is most consistent with this process of vasodilation, rather than the development of edema, which might be expected to take longer. Nonetheless the development of edema likely plays at least some role in many, if not all, cases of DBS as well. Edema may be vasogenic (extravasated from injured or inflamed blood vessels), cytotoxic (representing intracellular swelling of injured brain cells), or interstitial (from inadequate drainage of CSF).

DBS is probably a final common manifestation of brain injury caused by a number of different mechanisms. It may, in some cases, be a manifestation of primary brain injury, as when it accompanies large areas of brain contusion or DAI. In

other cases, it probably represents secondary brain injury, caused by hypoxia or hypoperfusion. If left unchecked, the development of DBS can lead to a vicious cycle. That is, the presence of DBS causes an increase in ICP, and then the resulting ischemia leads to the development of more DBS.

Clinical Manifestations

Most patients with DBS are comatose on initial evaluation, sometimes with associated focal neurologic deficits. Rarely, patients with DBS have less impressive symptoms, with more minor neurologic deficits. These patients often experience neurologic deterioration over the ensuing several hours.

Diagnosis

DBS is diagnosed by a head CT scan when there is evidence of smaller ventricles, effacement of the sulci, or obliterated basal cisterns, in the absence of other intracranial pathology that may be exerting significant mass effect (Fig. 105.11). Signs of cerebral edema per se, such as loss of gray–white differentiation, may be present. Other accompanying intracranial lesions, such as diffuse axonal injury, subdural hemorrhage, cerebral contusion, or subarachnoid hemorrhage are often diagnosed as well. In one large study of children with DBS, however, 60% had no other intracranial lesions identified.

FIGURE 105.11. Brain swelling. This 1-year-old boy fell from a second-story window. The neurologic examination was normal. A head computed tomography (CT) scan shows a small, right-sided subdural hematoma in the temporal region. Note also the effacement of the sulci on the right *(straight arrow*), which can be compared with the normal sulci on the left *(curved arrow).* There is also a mild shift of the midline toward the left.

Management

Patients with DBS need to be admitted to the hospital. Generally, admission to the ICU is required for careful monitoring of hemodynamics, oxygenation and ventilation, and ICP. ICP monitors are indicated for any patient with DBS in coma.

Management of the patient with DBS focuses on optimizing cerebral perfusion and minimizing any stressors that may lead to worsening of the DBS. If the ICP is elevated, measures to control the ICP are required. DBS is often worse between 1 and 3 days after the primary injury occurred, so patients who initially have well-controlled ICP may have more serious difficulties later.

Numerous studies have shown that the outcome of DBS after head trauma is better for children than it is for adults. In one large study, 78% of children with DBS had a functional outcome. Patients with more severe neurologic symptoms on presentation clearly have worse outcomes, as do those with accompanying intracranial lesions, especially subarachnoid hemorrhage or intraventricular hemorrhage. Patients who experience secondary systemic insults (e.g., hypotension, hypoxia) clearly have a worse prognosis as well.

Epidural Hematoma

Pathophysiology

Most epidural hematomas (EDHs) result from blunt impact to the cranium. In most cases of EDH, the skull is fractured, with an associated laceration to the epidural vessels underlying the fracture site. In other cases, there is no fracture, but the deformation of the skull and associated linear deceleration from impact leads to shearing of the epidural arteries or veins.

Many patients with EDH have experienced relatively low-energy mechanisms of injury. In pediatrics, most cases of EDH result from falls, although a minority result from motor vehicle collisions, child abuse, or other mechanisms. About half of pediatric cases of EDH result from falls from heights of 6 feet or less.

Other mechanisms of injury, such as the shaking often implicated in cases of child abuse, are less likely to be associated with EDH because they do not lead to deformation of the skull. On the other hand, because the low impact falls that lead to EDH rarely involve high energy being applied to the brain itself, about 90% of cases EDH have no associated parenchymal injuries.

A small EDH may be asymptomatic. As the EDH expands, however, it begins to occupy an increasingly large intracranial

volume. This increasing mass effect leads to an increase in ICP and, if left unchecked, may result in diffuse secondary brain injury. If the EDH continues to expand, it may lead ultimately to cerebral herniation.

If an EDH can be recognized and surgically drained before this process occurs, secondary brain injury can be prevented. In many cases, the patient has a completely normal neurologic status after the EDH is drained. If the EDH is not drained in time, however, persistent neurologic deficits may result.

Approximately 18 to 36% of patients with EDH have an arterial source of bleeding identified. In most cases, the middle meningeal artery is involved. Another 10 to 20% have bleeding from meningeal veins, the emissary veins, the diploic veins, or from the dural sinuses. Finally, about 30 to 40% have no recognized source of bleeding identified and are probably oozing from small venous sites in the dura. In general, the more severe symptoms are seen in those patients with arterial bleeding, with an intermediate course in those patients with venous sources, and the most benign course in patients with no discrete source identified. Occasionally, patients with venous or oozing EDH are first diagnosed days or even weeks after the injury.

EDH in the occipital and frontal regions may be fairly well tolerated. In contrast, bleeding in the temporal region is more likely to cause symptoms early, because a temporal EDH will more quickly lead to tentorial herniation. Posterior fossa bleeding may also lead to earlier symptoms because of the potential for early compression of vital brainstem structures, as well as the potential for obstruction to CSF outflow and the development of hydrocephalus.

Clinical Symptoms/Signs

The classic presentation of EDH involves an initial loss of consciousness at the moment of impact, the “lucid interval” of several hours after the trauma when the patient is awake and relatively asymptomatic, and then neurologic deterioration as the enlarging hematoma begins to exert its mass effect.

In fact, however, pediatric patients with EDH rarely present with these classic symptoms. In one large series of pediatric patients with EDH, only 20% had an initial loss of consciousness, and 38% were alert with normal neurologic examinations at the time of diagnosis. The most common symptoms of EDH in pediatrics are headache, vomiting, and lethargy. In addition, ataxia may be noted in cases of posterior fossa EDH. Seizures are relatively rare, occurring in less than 10% of cases.

A small number of patients with EDH may not have any symptoms indicative of brain injury. Skull fracture may be a particularly important indicator of the risk of EDH, especially in patients with few other symptoms because skull fracture is noted in 70 to 80% of cases of EDH. Temporal or parietal skull fractures are particularly associated with a risk of EDH.

Diagnosis

EDH can be readily diagnosed by noncontrast CT of the head. The classic appearance on CT is that of a high-density biconvex lesion just subjacent to the skull (Fig. 105.12). The EDH is usually bounded by suture lines but may rarely cross these lines if diastasis of the suture has occurred. EDH is most commonly noted in the parietal, temporal, or temporoparietal regions (approximately 78%), and rarely in the frontal (16%) or occipital (6%) regions. The classic high density appearance on CT indicates clotted blood. Occasionally, an adjacent or intermixed, swirled isodense lesion is noted, which represents ongoing acute bleeding that has yet to clot (Fig. 105.13).

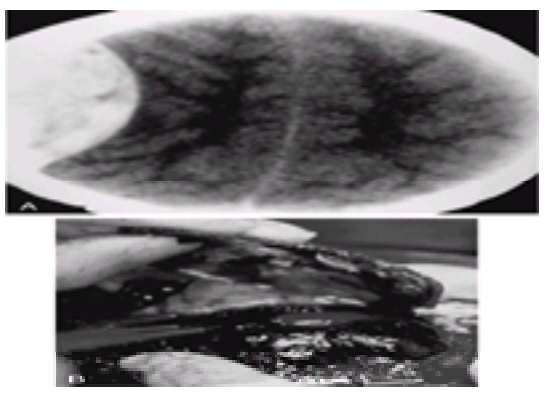

FIGURE 105.12. Epidural hematoma. This 8-year-old boy presented after a sledding accident. He had no loss of consciousness, but he complained of headache and vomiting. A head computed tomography (CT) scan **(A)** shows the classic biconvex hyperdensity of an epidural hematoma. He proceeded to the operating room, where a large mass of clotted blood **(B)** was removed.

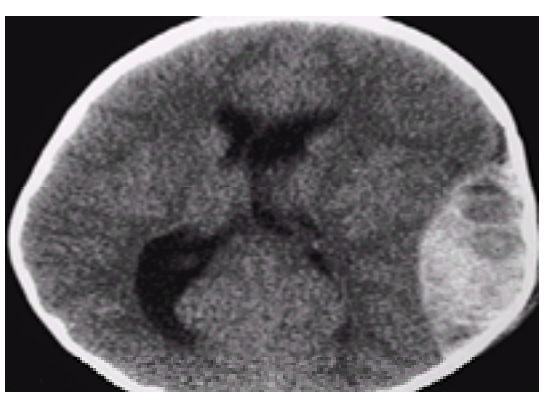

FIGURE 105.13. Epidural hematoma. This 11-month-old boy presented with progressive lethargy and vomiting after falling 2 feet off of a bed. Several hours after the injury, he became unresponsive with dilated, nonreactive pupils. This head computed tomography (CT) scan shows a large epidural hematoma, with intermingled hypodense areas representing active bleeding. Note also the midline shift and the compression of the ipsilateral ventricle. After an emergency craniotomy, the patient made a full recovery.

On CT midline shift, small ventricles, and loss of patency of the basal cisterns indicate a mass effect from the EDH. Signs of herniation may be seen. A careful survey for other associated intradural hematomas or parenchymal injuries should also be undertaken.

Management

The mainstay of treatment for EDH is craniotomy, with drainage of the hematoma and repair of the lacerated epidural vessels. Patients with EDH who have any depression in their level of consciousness, focal neurologic findings, pupillary abnormalities, and/or signs of increased ICP should proceed immediately to surgical intervention.

Increasingly in recent years, however, neurosurgeons have recognized that some patients with EDH may safely be managed with observation. Conservative management is only acceptable for patients with a small EDH (generally less than 30 mL in volume, and with a thickness of less than 2 cm), no focal neurologic deficits, and a normal level of consciousness.

In all cases, however, a neurosurgeon must be consulted immediately because even children who are initially well may experience rapid neurologic deterioration in the first several hours after diagnosis. In one series, 32% of patients who were initially managed conservatively ultimately required surgical drainage of the EDH. Particular caution must be exercised in dealing with those patients who had initial head CT within 6 hours of the trauma because these patients are more likely to have further progression in the size of the EDH. Patients with a temporal EDH, especially if noted to have a fracture overlying the middle meningeal vessels, are at particularly high risk because of the arterial source of their EDH. In addition, patients with posterior fossa EDH are generally not candidates for conservative management because of the high risk of medullary compression and hydrocephalus.

Mortality rates in EDH range from 0 to 10%. Approximately 85% of surviving children with EDH have a good neurologic outcome.

The most important predictor of outcome is the patient's neurologic status on presentation. Patients who present with coma and pupillary abnormalities are much more likely to have sustained secondary brain injury. But even among these patients, a significant percentage will have a good outcome. In one series, 64% of children presenting with an initial Glasgow Coma Scale score of 5 or less had a good neurologic outcome. In another study, 82% of patients with EDH who presented with bilateral nonreactive pupils survived, and 55% had either a good outcome or moderate disability. In general, those patients with EDH who are able to be managed conservatively do well, with a normal neurologic outcome in approximately 95% of cases.

Subdural Hematoma

Pathophysiology

Subdural hematomas (SDHs) result from tearing of the bridging veins that traverse the subdural space. Mechanisms of injury that are associated with shear forces being applied to these veins are especially likely to lead to SDHs. In particular, SDHs result from injuries associated with significant acceleration/deceleration forces.

In older children and adolescents, SDHs most commonly result from motor vehicle collisions. In infants, SDHs are commonly a result of the shaking impact syndrome of child abuse. SDHs may result from falls as well, especially if the fall is from a significant height. Because of the more significant forces applied to the brain in most injuries leading to SDHs, the SDH is often associated with other intracranial lesions. However, infants appear to be prone to the development of small SDHs even after more minor head injury, perhaps because they have wider subarachnoid spaces, which cause the bridging veins to be under more tension and more prone to shear injury.

For some patients with SDH, there is a “lucid interval” of several hours after the initial trauma before the neurologic status begins to deteriorate. For these patients, the mass effect of the accumulating SDH is the cause of significant neurologic morbidity and mortality.

In other patients with SDH, however, serious neurologic symptoms begin at the moment of impact. Many of these patients have cerebral contusions or diffuse brain swelling. For these patients, the SDH may be more of a marker of a high force mechanism of injury than a cause of neurologic injury in itself. Even if the SDH is drained in a timely fashion, therefore, serious brain injury may persist.

Clinical Manifestations

SDHs are often associated with an initial loss of consciousness and with a depressed mental status. Approximately 50% of patients with SDH present in coma. Pupillary abnormalities may be noted as well, indicating impending herniation. In less severely ill patients, headaches, vomiting, lethargy, irritability, visual difficulties, or seizures may be noted. In

patients with SDHs involving the posterior fossa, cerebellar signs such as ataxia or nystagmus may be noted. Because CT scanning is being used more routinely in cases of minor head injuries, many cases of asymptomatic SDH are being discovered as well.

Although most cases of SDH present within hours after the trauma, occasional cases of chronic SDH are diagnosed, days or even weeks after a head trauma. In pediatrics, chronic traumatic SDH is most commonly seen in infants, usually as a consequence of child abuse. Presenting symptoms in these infants may include tense fontanel, macrocephaly, psychomotor retardation, depressed level of consciousness, seizures, vomiting, irritability, or focal neurologic deficits.

Diagnosis

On head CT, acute SDH is seen as a hyperdense crescentic collection of extra-axial fluid (Fig. 105.14). There may be areas of hypodense fluid intermingled, which represent active bleeding, sometimes termed a hyperacute SDH (Fig. 105.14). Because the subdural space is continuous around each hemisphere, subdural blood flows freely through this space, while respecting the midline and tentorial margins (Fig. 105.15 and Fig. 105.16). SDH is usually noted unilaterally, although cases of child abuse are often associated with bilateral SDH. The CT should be evaluated for evidence of mass effect, and for associated intracranial lesions, such as brain swelling, cerebral contusions, or subarachnoid hemorrhage.

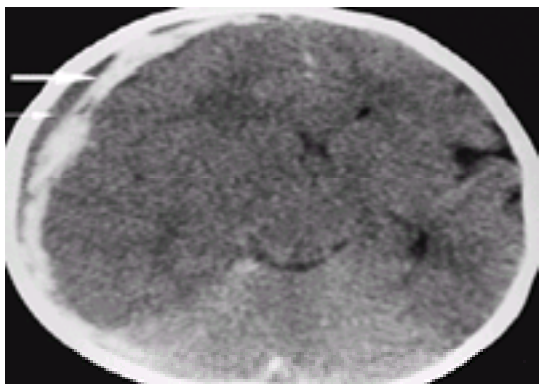

FIGURE 105.14. Subdural hematoma and brain swelling. This 9-month-old boy reportedly became suddenly unresponsive. There was no history of trauma. On examination, he was comatose with fixed dilated pupils and extensor posturing. Massive bilateral retinal hemorrhages were seen. This head computed tomography (CT) scan shows a right-sided subdural hematoma, with acute hyperdense *(thick arrow)* and hyperacute isodense *(thin arrow)* components. Midline shift to the left is noted. There is also evidence of brain swelling, with effacement of the sulci and poor gray–white differentiation. The diffuse hypodensity of the cerebral cortex can be contrasted with the normal density of the cerebellum, which appears whiter in this view. A diagnosis of nonaccidental trauma was made.

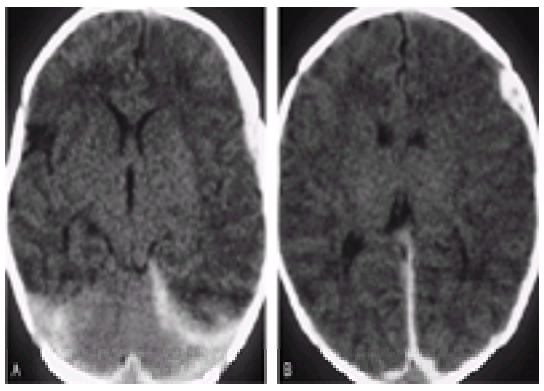

FIGURE 105.15. Subdural hematoma. This 14-day-old patient presented with a complaint of lethargy and vomiting. There was no history of trauma. This head computed tomography (CT) scan shows subdural blood tracking along the tentorium **(A)**, in the interhemispheric fissure **(B)**, and in the left frontoparietal region (**A** and **B**). There is also some effacement of the sulci and loss of gray–white differentiation. Nonaccidental trauma was suspected.

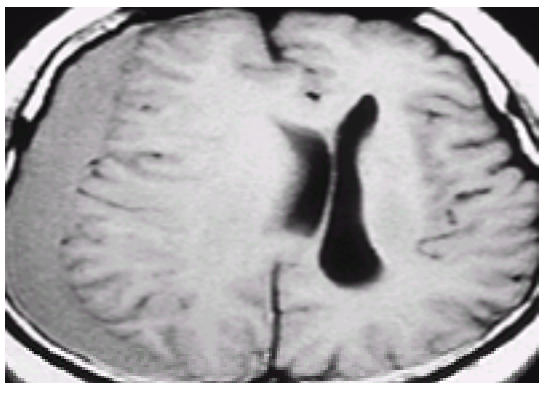

FIGURE 105.16. Subdural hematoma. This T_1-weighted magnetic resonance imaging image shows the classic appearance of a large acute subdural hematoma, with a crescent-shaped extra-axial hematoma that covers the entire right cerebral convexity. There is significant midline shift with compression of the right lateral ventricle and enlargement

of the contralateral ventricle, which probably represents obstruction to cerebrospinal fluid outflow. An emergency operative procedure was performed.

The density of the subdural fluid collection varies over time. With older chronic hematomas, the collection may be almost isodense with CSF.

Management

In the early 1980s a number of researchers were able to show remarkable decreases in mortality from SDH if patients underwent timely surgical drainage. Not surprisingly, this effect was most evident in those patients with large SDHs, associated with midline shift and coma. In this subgroup, the neurologic prognosis is optimized when surgery is performed within 4 hours of the trauma. It appears that early relief of the mass effect in these patients prevents secondary brain injury.

Many patients with SDH who are not so severely ill can be managed nonoperatively. Some authors have proposed nonoperative management for patients with SDH who are not comatose, who have small SDHs with no mass effect, and who have patent basal cisterns. Generally, even well-appearing patients with posterior fossa SDHs are not candidates for nonoperative management because of the high risk of brainstem compression if the lesion expands. Even if a patient appears to be a candidate for nonoperative management, however, immediate consultation with a neurosurgeon is essential because of the potential for rapid clinical deterioration over the first several hours of observation.

Patients presenting with chronic SDH generally do not require craniotomy and decompression. Instead, most centers now manage these patients with a strategy of serial subdural taps or continuous external drainage. In some cases, the SDH is successfully drained in this manner, and no further therapy is necessary. In most cases, eventual placement of a subduroperitoneal shunt for ongoing drainage of the lesion is necessary.

The clinician must recognize the strong association of SDH with child abuse, especially in infants with no clear mechanism of injury reported, and in those patients with associated retinal hemorrhages. If the circumstances of the injury cannot be clearly explained, further evaluation for nonaccidental trauma should be pursued.

In several studies, mortality rates for children with acute SDH range from 10 to 20%. Of those who survive, persistent neurologic sequelae are common. Those patients who are comatose on admission or who have pupillary abnormalities clearly have poorer prognoses. In addition, those patients with CT evidence of more significant brain injury or increased ICP have a worse prognosis. Even the patients who appear to be at high risk, however, may do relatively well. In one study, 14 of 21 patients with a Glasgow Coma Scale score of 8 or less who were less than 40 years of age were functional survivors.

In general, patients who are managed nonoperatively do well, with few if any neurologic sequelae, and with full resolution of the SDH. A small percentage (6% in one series), however, will develop chronic SDH. Chronic SDH is seldom lethal, with a greater than 99% survival rate reported in one large series. Nonetheless, many patients with chronic SDH have ongoing neurologic problems. In one pediatric series, 40% had seizures and 30% had developmental delay.

Subarachnoid Hemorrhage

Pathophysiology

Subarachnoid hemorrhage (SAH) is a common complication of head trauma, especially in more severely injured patients. In one large study SAH occurred in approximately 25% of patients who were comatose on initial evaluation.

SAH results from tearing of the small vessels of the pia mater. SAH generally occurs after relatively severe blunt trauma to the head, or as a result of significant shear forces.

Because the cerebral subarachnoid space is large and freely communicates with the basal cisterns and the spinal subarachnoid space, the blood in an SAH can be distributed widely. As a consequence of this wide distribution and because it is generally smaller pial vessels that bleed, SAH rarely accumulates to the extent that it causes clinically important mass effect.

SAH appears to exert its main pathophysiologic effect by causing cerebral vasospasm. A number of studies have shown that SAH is associated with increased cerebrovascular resistance, and consequently, with an increased risk of cerebral ischemia or infarction. In general, SAH is seen in association with other intracranial injuries, especially SDH, cerebral contusion, and intraparenchymal hemorrhage. Because SAH is often seen in association with other intracranial injuries, its presence may be most important as a marker for severe primary brain injury, rather than as a cause of secondary injury in itself.

Because of the presence of the blood in the subarachnoid space, and probably because of associated release of inflammatory mediators from adjacent cells of the pia and arachnoid mater, SAH causes meningeal irritation and clinically mimics many of the symptoms and signs of meningitis.

Clinical Manifestations

Patients with posttraumatic SAH often have other intracranial hemorrhage or parenchymal injuries as well, so they may

present with a wide range of symptoms, from those who have minimal if any symptoms to those who are comatose with signs of impending cerebral herniation. As an isolated intracranial lesion, SAH most commonly causes headache and other signs of meningeal irritation, such as nausea and vomiting, nuchal rigidity, and photophobia. Patients with isolated SAH often have a history of loss of consciousness, and sometimes present with depressed mental status or even coma. Seizures are reported in 2 to 10% of cases. Subhyaloid or preretinal hemorrhages, located just adjacent to the optic nerve head, may be seen with SAH as well.

Diagnosis

SAH can usually be detected on noncontrast head CT as a collection of hyperdense fluid in the CSF spaces, either in the subarachnoid space overlying the cerebral convexity or in the basal cisterns. Subarachnoid blood overlying the cerebral hemisphere can be distinguished from SDH in that the subarachnoid blood may flow into the depths of the brain sulci, fissures, and cisterns, whereas the subdural space does not penetrate into these depths. Head CT imaging has a sensitivity of only about 90% for detecting SAH, with a lower sensitivity for patients seen later than 24 hours after the SAH began. However, lumbar puncture is not recommended and may be dangerous in the setting of focal intracranial pathology or brain swelling because it may increase the risk of cerebral herniation.

Management

All patients with traumatic SAH should be admitted to the hospital for observation. In most cases, specific therapy directed at the SAH is not required. The general principles of management for patients with head injuries should, of course, be followed. Prophylactic anticonvulsants are often used for patients with SAH.

In one study, 24% of patients with traumatic SAH died, and another 24% had a poor neurologic outcome. Patients with associated intracranial injuries and those with a larger SAH (especially if it involves both the hemispheric convexities and the basal cisterns) have the worst outcome. Patients with minor or no symptoms and small SAH generally do well.

Penetrating Trauma

Penetrating trauma includes injury from sharp objects, such as knives, darts, or animal bites, and from missiles, usually bullets. Penetrating head trauma is far less common than blunt head trauma in pediatrics, but the incidence of penetrating injuries, especially from gun shots, has increased at an alarming rate in the past decade. Several urban hospitals have reported that the rate of hospital admissions for teenagers shot in the head increased by as much as tenfold between the 1980s and 1990s.

Pathophysiology

Penetrating head trauma leads to brain injury by several mechanisms. First, there is direct injury along the path of the penetrating object, with laceration or contusion of neural tissue, and hemorrhage from injured vessels. For low-velocity penetrating injuries (e.g., knife wounds), this may be the primary source of brain injury.

Higher-velocity injuries (from bullets) also cause significant damage because of the shock waves created by the impact of the penetrating object. These shock waves can cause contusions or vascular injury at sites that had no contact with the penetrating object itself.

Vascular injury may result from direct laceration, or from percussion-related damage. Dissection of an intimal flap, thrombosis of the vessel lumen, or aneurysm formation may result. Ischemia or infarction resulting from these vascular injuries may occur immediately after impact, or they may occur days or even weeks later.

Because the skull and dura are violated by the penetrating object, there is direct communication from the CSF spaces or brain to the outside world, and consequently, a risk for intracranial infection. Penetrating objects that pass through the paranasal sinuses or mastoid air cells particularly increase the risk of intracranial infection.

Clinical Manifestations

Patients with penetrating injuries sometimes may present without a clear history, either because the injury was not witnessed or because the patient and/or witnesses fear the repercussions of full disclosure.

The local signs of penetrating injury can sometimes be subtle, especially if the penetrated area is covered by hair or by a dressing. Without careful exploration, the entrance wound might be mistaken for a superficial scalp laceration. In more obvious cases of penetrating injury, meningeal or parenchymal tissue may be visualized in the wound, or CSF may be oozing.

Signs of neurologic injury are often severe for patients with high-velocity injuries, but they may be more subtle in patients with low-velocity injuries. Patients with progressively enlarging intracranial hematomas or worsening brain swelling may deteriorate quickly over the several hours after presentation.

Management

The initial management of the patient who has sustained penetrating head trauma focuses on the ABCs of resuscitation, as outlined previously. Once the ABCs have been addressed, attention can be focused on the possible need for brain-specific therapies, as described.

In addition to the management priorities already outlined, some unique aspects of caring for the patient with penetrating

head trauma should be discussed. The patient should be examined carefully for evidence of entrance or exit wounds. The clinician should recognize the potential for multiple penetrating wounds, or for exit wounds in unpredicted locations because of a complicated migratory path of the penetrating object.

Any bleeding lacerations should be occluded with direct pressure. Occasionally, immediate suturing of the laceration may be necessary to achieve hemostasis. Other penetrating wounds may simply be covered with a sterile gauze dressing, until more definitive debridement and repair can be achieved. Any penetrating objects still in place should not be removed, because of the potential for serious hemorrhage if the object is tamponading a lacerated vessel.

As for all patients with head injuries, cervical spine precautions should be maintained until the clinician is certain that no cervical spine injury has occurred, usually requiring cervical-spine radiographs in addition to a thorough physical examination. In particular, the clinician should recognize the possibility that the bullet or penetrating object may have directly penetrated the neck and injured the vertebral column.

Patients with penetrating head injuries generally require prophylactic antibiotic therapy. A first-generation cephalosporin such as cefazolin (30 mg/kg intravenously; maximum dose 2 g) is usually appropriate.

Most patients with penetrating head injuries are started on prophylactic anticonvulsant therapy (usually with phenytoin), especially if there is any concern about parenchymal injury or subarachnoid hemorrhage.

Patients with penetrating injuries to the head require immediate head CT to delineate the extent of brain injury and to assess for associated intracranial hematomas, brain swelling, and/or mass effect. The head CT is also able to demonstrate the presence of intracranial foreign material.

As with blunt trauma patients, all patients with intracranial hematomas exerting any mass effect will need an immediate operation to evacuate the hematoma. Patients with large areas of contusion exerting a significant mass effect may require surgical resection as well.

In addition, most patients with penetrating injuries to the head require prompt operation to debride the infected or contused brain tissue at the entry site. Controversy exists about the need for extensive debridement of deeper tissues along the path of the penetrating object. Increasingly, published reports have shown equally high success rates with more limited debridement. After debridement, the dura must be repaired to achieve a watertight seal.

In general, it is unnecessary to remove deeply embedded foreign material (e.g., bullets), because the risk of infection does not seem to increase when these objects are left in place. Bullets that are lodged in the ventricular system usually are removed, however, because of the potential for outflow obstruction and hydrocephalus if the bullet migrates.

All patients with penetrating head injury require hospitalization. Except in circumstances of superficial penetration with no underlying brain injury, ICU level monitoring is indicated. Intracranial ICP monitoring is indicated for all patients in coma.

Most patients with penetrating head injuries need to have angiography performed (either conventional or MRI angiography) to exclude the possibility of traumatic injuries to the cerebral vasculature. Although some controversy exists about the optimal timing of angiography, most authors recommend angiography as soon as it can safely be performed.

The prognosis after penetrating head injury depends most on the level of neurologic function at the time of presentation. For patients with severe neurologic dysfunction (Glasgow Coma Scale scores in the range of 3 to 5), the likelihood of a good functional outcome is low, although occasional patients will do well. Most neurosurgeons will not operate on patients who present with an absence of neurologic function (Glasgow Coma Scale score of 3 and nonreactive pupils) because the prognosis is so dismal for this subgroup.

For patients with a better neurologic status, the prognosis is influenced by the degree of tissue damage seen on a head CT scan. Tracks of injury that cross the midline or that involve the ventricles are associated with a worse prognosis, presumably because more brain tissue is injured. Patients with subarachnoid hemorrhage also have a worse prognosis.

SPINAL CORD TRAUMA

Spinal cord injury is rare in pediatrics. Most case series in the literature, from pediatric trauma centers, report only 1 to 2 patients with spinal cord injuries each year. Nonetheless, spinal cord injuries, when they do occur, are associated with significant morbidity and mortality, and the consequences of missing patients with early signs of spinal cord injury can be devastating. Furthermore, recent clinical evidence suggests that prompt diagnosis and therapy for spinal cord injuries may improve the prognosis.

Anatomy

The spinal cord runs from the foramen magnum, where it extends from the base of the medulla, to its distal tip, in the upper lumbar region of the spine. The cord consists of an H-shaped central section of gray matter, and surrounding white matter which is divided by this “H” into a ventral (motor) compartment, and dorsal and lateral (sensory) compartments.

Upper motor neurons originate on one side of the cerebral cortex, but then cross to the other side at the level of the medulla before entering the spinal cord. Axons from motor neurons in the left cerebral cortex, therefore, run in the right-sided white matter of the spinal cord and serve the right side of the body. Sensory neurons, in contrast, originate on one side at the level of the dorsal root ganglion and then cross immediately to the other side (at the level of the spinal nerve roots) before entering the cord. Sensory impulses from the right side of the body, therefore, run in the left-sided

white matter of the spinal cord, before reaching the left cerebral cortex.

The spinal cord is surrounded by three layers of meningeal tissue, which are continuous with the meninges surrounding the brain. As with the cerebral meninges, blood could potentially accumulate in the spaces between these layers of tissue, leading to spinal subdural or epidural hematomas.

The spinal cord runs in the vertebral canal, protected by the bones of the spinal column, with the vertebral bodies anteriorly and the vertebral arches laterally and posteriorly. Injuries to the spinal cord generally involve some injury to the surrounding spinal column. Because the spinal cord is significantly shorter than the spinal column, injuries at a certain level of the spinal column are associated with spinal cord injuries corresponding to a lower level. A low thoracic spinal column injury, for instance, may be associated with neurologic deficits corresponding to the lumbar cord.

Some unique features of the pediatric spine make spinal cord injury more likely in children. Specifically, the ligaments of the pediatric spine are especially lax, allowing more movement, or subluxation, of vertebrae on one another. In addition, the paraspinous musculature, which provides stabilization and support to the adult spine, is less developed in children. Decreased ossification of the spine, which progresses throughout childhood, also makes the cervical spine more pliable. Furthermore, the facet joints between adjacent vertebral bodies are more flattened or horizontal in pediatric patients, which makes subluxation more likely.

Finally, it should be noted that there is excess strain on the cervical spine, especially the upper cervical spine, in young children, because the head is a proportionately larger component of total body weight. The fulcrum of movement of the cervical spine is at the level of C2–C3 in young children, as opposed to C5–C7 in older children and adults. This feature makes the upper cervical spine especially prone to injury in young children. These “immature” features of the pediatric spine persist to around the age of 8 years. For older children, the anatomy of the spine is fairly similar to that seen in adult patients.

Pathophysiology

As with the pathophysiology of brain injury, injuries to the spinal cord can be considered to occur in two phases: primary and secondary cord injury. Primary spinal cord injury refers to the irreversible neural damage initiated at the time of traumatic impact. Secondary spinal cord injury refers to the associated pathophysiologic processes that occur hours to days later, damaging neurons not necessarily injured by the primary impact itself.

Primary injuries to the spinal cord may result from several different mechanisms. Rarely, direct transection of the cord can occur, as a result of penetrating injuries to the spine or, more commonly, from bone fragments displaced after fracture or subluxation. More common are bruises or contusions of the spinal cord, which result from compression of the cord by subluxated bone or herniated intervertebral disks. Spinal cord injuries may also result from the application of shear forces to the cord, as when the spine is hyperflexed, hyperextended, or distracted during blunt trauma. The flexible spinal column of the young child makes these types of shear injuries especially common. Finally the spinal cord can be injured if its vascular supply is disrupted, leading to ischemia and infarction of the cord, sometimes in the absence of any direct traumatic force being applied to the cord itself.

Secondary pathophysiologic changes are thought to cause much of the clinical disease noted after spinal cord injury. One important source of secondary injury is lipid peroxidation, which leads to autodestruction of cell membranes in areas of injured spinal cord. This lipid peroxidation process may be initiated by the mechanical trauma itself, or by free radicals liberated during the inflammatory response. Once this process begins, it leads to the development of more inflammation, with further cell injury resulting. Much of the research on acute spinal cord injury in the past decade has focused on efforts to interrupt this injury cascade.

Secondary pathophysiologic changes may also result from the local mass effect caused by subdural or epidural hematoma, or from the edema associated with a contused area of cord. Secondary spinal cord injury can also be initiated or exacerbated by any systemic process that leads to hypoxia or ischemia. Areas of spinal cord that are already contused, or partially compressed by local bleeding or edema, may be at especially high risk for ischemic injury.

Clinical Manifestations

Spinal cord injuries are generally associated with significant mechanisms of injury, such as motor vehicle collisions, falls from significant heights, or child abuse. Patients with injuries to the spinal cord often have evidence of injuries to other organ systems. In particular, there is a high association between head injuries and injuries to the cervical spine and/or spinal cord. Injuries to the thoracic or lumbar spine may also be associated with head injuries, but they are seen more often in the setting of chest or abdominal trauma.

Patients with high cervical cord injuries may sometimes have abnormal vital signs, reflecting an interruption of autonomic impulses to the heart and the vasculature. These patients demonstrate bradycardia and hypotension, along with peripheral vasodilation, a syndrome known as spinal shock. They may also have abnormal or absent respiratory effort. Because most trauma patients with hypotension are hypovolemic and have a reflex tachycardia, those with bradycardia should be strongly suspected of having spinal shock.

Spinal cord injuries should also be suspected in any traumatized patient who complains of decreased motor strength, or in whom focal deficits in strength or tone are noted on examination. In the acute setting, severe spinal cord injuries are usually associated with decreased or absent reflexes. Partial injuries to the cord, on the other hand, may be associated with initial hypertonia and hyperreflexia. Abnormalities of bladder control and rectal tone may also be noted.

Motor deficits correspond to the spinal roots whose neural impulses are compromised by the spinal cord injury. Most typically, all motor impulses that originate from spinal nerve roots at or below the level of the spinal cord injury are

affected. An understanding of the motor deficits after spinal cord injury requires knowledge of the innervation of the important muscle groups of the body. A list of the important muscle groups and the spinal roots that serve them is presented in Table 105.2.

Muscle	Segmental Innervation	Peripheral Nerve
Diaphragm	C3-C5	Phrenic nerve
Trapezius	C3-C4	Spinal accessory nerve
Deltoid	C5-C6	Axillary nerve
Supraspinatus	C5-C6	Suprascapular nerve
Biceps brachii	C5-C6	Musculocutaneous nerve
Triceps brachii	C6-C8	Radial nerve
Wrist extensors	C6-C7	Radial nerve
Finger extensors	C6-C8	Radial nerve
Wrist flexors	C6, C7-T1	Ulnar, median nerve
Intrinsic hand muscles	C8-T1	Ulnar nerve
Psoas	L1-L2	Psoas nerve
Quadriceps femoris	L2-L4	Femoral nerve
Gastrocnemius	L5-S1	Deep peroneal nerve
Urinary bladder	S2-S4	—

Table 105.2. Major Muscle Groups, Listed with the Spinal Roots and Peripheral Nerves That Supply Them

Sensory deficits may be noted as well, and these may range from paresthesias to complete loss of sensation. Because sensory impulses are carried in both the dorsal columns and the lateral compartments of the spinal cord, injuries to one of these compartments may lead to partial sensory deficits (e.g., loss of pain and temperature sense from the lateral compartment or loss of joint position sense and vibration sense from the dorsal column), but with other forms of sensation intact for the same body part. A diagram of the body's sensory dermatomes is shown in the Appendix (see Appendix D, Sensory Nerve Dermatomes). Often, a well-demarcated sensory “level” of the spinal cord can be identified, below which sensory impulses are absent, and above which sensation is intact.

Many injuries to the spinal cord involve solely or predominantly one of the two lateral sides of the cord. Because of the distribution of sensory and motor neurons in the spinal cord, a lesion to the left spinal cord affects left-sided motor strength but right-sided sensation. This classic crossed pattern of sensory and motor deficits is known as the Brown-Sequard syndrome.

Other patterns of neurologic deficits may also be noted. Partial injuries to the spinal cord may result in partial deficits. In some cases of ventral cord injury, for instance, only motor deficits may be observed. Cases of hyperextension injury may cause more severe injury to the central, or deep regions of the cord (the gray matter) while sparing the more superficial white matter. This leads to a “paradoxical” pattern of symptoms known as the central cord syndrome, in which the more distal function (served by the white matter) is spared, but more proximal function (served by gray matter) is compromised. Finally, occasional patients with more minor injuries to the spinal cord report transient symptoms of paresthesias, numbness, or weakness that may have resolved by the time of evaluation.

Patients with associated head injury may be obtunded and therefore unable to report symptoms of spinal cord injury. However, even in comatose patients, asymmetric motor tone, strength, or reflexes may be noted. Abnormalities of posture or tone may be a clue to the presence of spinal cord injury in these patients. In patients with injuries at the level of C-6, for instance, biceps function (with impulses from nerve root C-5) is intact, but triceps function (impulses from C-6) is not, and the elbow is held in tonic flexion.

Patients with injury to the spinal column are at risk for spinal cord injury even if no such injury has occurred at the time of evaluation. Therefore, children with signs of spinal injury, such as pain, tenderness, decreased range of motion, or deformity of the back or neck must be treated with the utmost caution.

Management

As with all trauma patients, care for the patient with spinal cord injury begins with the ABCs of resuscitation. This initial resuscitation must be accomplished with meticulous attention to the stabilization of the spine. For older children and adolescents, a semirigid cervical collar or manual in-line stabilization should be used. For infants, a semirigid cervical collar might actually be too large and may lead to distraction or hyperextension, which could be deleterious. For some infants, therefore, it may be preferable to immobilize with sandbags on the sides of the head, without using a cervical collar. In addition, the patient should be maintained in a supine position on a backboard so that no undue manipulation of the spine occurs. Because infants have a relatively large occiput, supine positioning on a flat surface may result in flexion of the neck. Proper neutral positioning for these young patients may require that the occiput be allowed to rest at a level slightly lower than the shoulders. Any transfers of the patient from one bed to another or “log-rolling” of the patient to examine the back should be done with careful attention to maintaining neutral positioning at all times.

The patient with spinal cord injury requires adequate oxygenation, ventilation, and perfusion. Careful attention should be given to positioning of the airway (using the jaw-thrust, rather than the chin-lift maneuver), suctioning if needed, and supplemental oxygenation. The head should never be turned in efforts to clear secretions from the oropharynx; if the patient needs to be turned, a log-roll maneuver should be used. Patients with inadequate respiratory effort require positive pressure ventilation. Patients with coma, inadequate respiratory effort, or inadequate airway protective reflexes need intubation with mechanical ventilation. When possible, rapid sequence intubation (as previously described; also see Chapter 5) should be performed. If sedating or paralytic agents are to be used, a brief neurologic assessment (see the following) should precede the administration of the drug if time allows.

The circulatory status of patients with spinal cord injury may be impaired if there are other organ system injuries leading

to hemorrhage and hypovolemia. Fluid and blood product resuscitation should be initiated in the usual fashion (see Chapter 104), and the definitive treatment of the hemorrhagic injuries should be pursued. Rare patients with spinal cord injuries have signs of spinal shock, with bradycardia and hypotension, and signs of peripheral vasodilation. These patients may require the use of pressor agents, such as dopamine, epinephrine, or phenylephrine, to maintain adequate vascular tone.

As soon as possible after an injury, the patient's neurologic status should be assessed and recorded so that any early progression of neurologic symptoms can be noted and so that no undue concerns are raised that the injuries were a result of the emergency care provided. For conscious, cooperative patients, the neurologic examination should include a test of motor strength in all four extremities, tone in all extremities, and deep tendon reflexes. Rectal tone should also be assessed. The sensory examination, assessing for light touch, pain sensation (as from a pinprick), and joint position sense (of fingers and toes) should be assessed as well. For patients with depressed consciousness, an assessment of tone and reflexes may be all that is possible.

Patients with suspected spinal cord injury should have plain radiographs of the spine to evaluate for fractures or subluxations. However, the absence of abnormalities on radiographic imaging does not eliminate the possibility of spinal cord injury. The syndrome of spinal cord injury without radiographic abnormalities (SCIWORA) is well reported in the literature. Several series of children with spinal cord injury report that 15 to 20% of cases may be classified as SCIWORA. Children have an especially high risk for SCIWORA because of the flexibility of the pediatric spinal column, which allows the spinal cord to withstand shear or compressive forces without necessarily causing a fracture. In some cases, the flexible and lax spinal column may sublux transiently, causing a compressive injury to the cord and then reduce back into normal position before radiographs are obtained.

In recent years, MRI has become a mainstay for the diagnostic evaluation of patients with suspected spinal cord injury. MRI offers the advantage of providing good detail of the soft tissue of the spinal cord itself, which cannot be well imaged by plain radiographs or by CT. A number of studies in the literature have reported evidence of spinal cord contusion, transection, or hemorrhage seen on MRI in most patients with spinal cord injury, and especially in those with more severe and lasting deficits. Increasingly, MRI has been used to document spinal cord abnormalities in cases that would be classified as SCIWORA by plain radiographs and CT.

MRI should be performed as soon as possible for patients with progressive neurologic deficits, who may have extra-axial mass lesions compressing the spinal cord, such as subdural or epidural hemorrhage, or a herniated intervertebral disk. In other cases, MRI may provide useful diagnostic and perhaps prognostic information, but it is less likely to alter the acute management.

Specific therapy directed at the spinal cord focuses on the prevention of secondary cord injury. The mainstay of this therapy is careful immobilization, as outlined previously. In all cases of spinal cord injury, a neurosurgeon should be consulted immediately. If compressive spinal cord lesions are noted, especially with incomplete but progressing neurologic injury, emergent laminectomy with surgical evacuation of the lesion may be necessary. Displaced fractures or subluxations of the spinal column require immobilization and generally some form of traction (e.g., a halo brace, skull tongs) to reduce them and maintain stability (see Chapter 106 for more details). Some patients with irreducible subluxations or unstable fractures require urgent surgery to achieve reduction. Patients with SCIWORA usually require long-term immobilization as well because they should be presumed to have some ligamentous instability of the spine, even if the initial radiographic studies show normal alignment.

High-dose corticosteroid therapy is widely used in the setting of spinal cord injury. It is believed that corticosteroid therapy decreases the extent of secondary cord injury by interfering with the lipid peroxidation pathway. The use of corticosteroids is based on the results of a multicenter prospective, randomized trial known as NASCIS (the National Acute Spinal Cord Injury Study). The NASCIS found that high-dose corticosteroid therapy significantly improved the outcome for those patients treated within 8 hours of injury, but not in those patients treated later. On the basis of these findings, the following regimen is recommended for patients with neurologic deficits attributable to spinal cord injury who are seen within 8 hours of injury: methylprednisolone at an initial IV bolus dose of 30 mg/kg followed by an infusion of methylprednisolone at 5.4 mg/kg per hr for the subsequent 23 hours.

All patients with spinal cord injury need to be admitted to the hospital for careful observation, immobilization, and specific therapy as outlined already. For patients with persistent deficits, a long-term plan for rehabilitation and ongoing medical care will need to be developed.

The prognosis after spinal cord injury depends most on the severity of disease at presentation. Patients with complete loss of function below the injured level clearly have the worse prognosis. On the other hand, patients with partial injuries often have significant improvements. MRI findings are of useful prognostic value as well. Those patients with documented transection of the cord clearly have little hope of recovery. In contrast, patients with minor or no abnormalities on MRI generally do well.

Pediatric patients with spinal cord injuries tend to fare better than their adult counterparts. In a few large studies, most pediatric patients with some useful motor function at the time of presentation regained full function of the compromised motor groups. Those patients with no motor function distal to the site of injury usually have some permanent disability, although they still often have some improvement after their initial presentation.

Penetrating Spinal Cord Trauma

Penetrating spinal cord trauma is an especially rare phenomenon in pediatrics. It may occur as a result of violent injuries, from stabbing or from gunshot wounds. Accidental injuries may occur, most commonly from shards of glass that penetrate into the spinal column.

Stab wounds or penetrating sharp foreign bodies usually involve penetration from the posterolateral aspects of the neck. These injuries generally lead to hemisection of the cord, with only one side of the cord affected. This predilection for unilateral injury probably reflects the fact that the posterior spinous processes and lateral transverse processes form an anatomic “gutter” through which the penetrating object is guided, thereby offering some protection to the opposite side of the cord. Bullets, on the other hand, propelled by high energy forces, may penetrate the bones of the spinal column and cause less predictable patterns of injury.

Some cases of penetrating spinal cord injury may not be obvious on presentation. Gunshot wounds to the head, for instance, may involve migration of the bullet to the level of the spinal cord, even if the initial trajectory of the bullet might not have suggested cord involvement. Some cases of stab wounds or penetrating glass present with what appear to be innocent lacerations of the neck or back.

When penetrating spinal cord injury is suspected, the principles of management, as outlined previously, should be followed. Plain radiographs demonstrate the presence of many radiopaque foreign bodies; in some cases, CT may be required to demonstrate less radiodense materials. In cases in which no foreign body is left in the wound, plain radiographs and CT may be normal. MRI is the best imaging modality for delineating injury to the cord itself.

A neurosurgeon should be consulted in all cases of penetrating cord injury. In some cases, surgical removal of intraspinal foreign bodies, bone fragments, or expanding hematomas is indicated. Surgical repair of ongoing CSF leak from the site of injury may also be indicated. In all cases, appropriate immobilization is necessary. Prophylactic antibiotic therapy is recommended for penetrating spinal cord injury as well. Generally, a first-generation cephalosporin such as cefazolin (30 mg/kg intravenously; maximum dose 2 g) is preferred.

PERIPHERAL NERVE INJURIES

Pathophysiology

Peripheral nerve injuries in pediatrics usually involve the extremities, most commonly the hand and upper extremity. Most peripheral nerve injuries in pediatrics result from acute traumatic insults. Transection of the nerve may result from deep soft-tissue lacerations or from severe crush injuries. Rarely, transection of a nerve may also result from a fracture, with laceration of the nerve by a displaced bony fragment.

More commonly, however, displaced fractures or dislocations lead to reversible compression injuries to the nerve. Nerve compression may also occur in the absence of acute trauma, usually because of tight anatomic compartments that exert constant pressure on the nerve (carpal tunnel syndrome is one common example).

Peripheral nerve injuries may be graded in terms of the severity of the clinical course. The mildest form of nerve injury is known as neurapraxia, which refers to nerve conduction impairment without structural injury to the axon itself. Neurapraxia commonly results from a situation of transient compression or ischemia, as when a patient complains that a limb has “fallen asleep.” The numbness and paresthesias reflect a rapidly reversible physiologic conduction block. If biopsy of the nerve were performed in this situation, no histologic abnormalities would be expected.

More severe cases of neurapraxia may be associated with symptoms that persist for as long as several months. In these cases, histologic examination reveals focal demyelination in the injured area of the nerve, but with no injury to the axon itself. In general, as long as the axon itself is not injured, full recovery can be expected.

Axonotmesis is a more severe injury to peripheral nerve, involving injury to the axon itself, but with preservation of the surrounding connective tissue of the nerve sheath. Axonotmesis generally results from crush injuries to the nerve. Good recovery of peripheral nerve function is likely to occur, although it will progress slowly, with lengthening of the nerve axon from its proximal stump progressing at a rate of approximately 1 to 4 mm/day. Distal nerve lesions, in close proximity to the target muscles or sensory regions, are associated with earlier and more complete recovery of function than in more proximal lesions.

The most severe form of nerve injury is known as neurotmesis, which involves injury both to the nerve axon and to the surrounding connective tissue. Neurotmesis usually results from direct laceration to the nerve or, rarely, from severe crush injuries. Because there is no intact nerve sheath to guide the development of the regenerating proximal nerve, spontaneous recovery of function is unlikely, and surgical repair is required.

Clinical Manifestations

Significant peripheral nerve injuries usually are seen in association with other obvious signs of traumatic injury, such as a soft-tissue laceration, crush injuries to the extremity, or fracture. In some cases, however, such as with repetitive microtrauma or with anatomic compressive lesions (as seen in carpal tunnel syndrome), the symptoms of peripheral nerve injury may be the primary complaint.

The cardinal symptoms of peripheral nerve injury are disturbances of sensory or motor function in the distribution of the nerve. Appropriate diagnosis of peripheral nerve injury requires an understanding of the anatomic distribution of sensory and motor function of the major peripheral nerves. A full description of this clinical anatomy is beyond the scope of this discussion, but a summary of the motor functions of the major peripheral nerves is presented in Table 105.2.

Disturbances of sensation may include paresthesias, pain (which may be described as sharp, burning, or stabbing), or numbness. In some cases, the patient may not report a sensory deficit, but sensory abnormalities are noted on examination. A gross assessment of sensory function can be obtained simply by testing the patient's ability to recognize

light touch stimuli in the distribution of the nerve in question.

A more sensitive test for identifying disturbances in sensory function is two-point discrimination. Although instruments for assessing two-point discrimination are commercially available, in common practice, a paper clip is often used. The paper clip should be unfolded so that the two ends are in close proximity, with a distance of approximately 1 cm in between. The patient should then be briefly trained on an uninjured part of the body to differentiate between being touched with one or two points of the paper clip simultaneously. Once it is determined that the patient can reliably perform the task, the injured area should be assessed.

The two points must touch the skin simultaneously, and they must occur in the same axial line. If the patient is able to successfully discriminate one- and two-point stimuli, the distance between the two ends of the paper clip can be decreased successively to find the patient's threshold for discrimination. A hand with normal sensation should be able to distinguish between two points that are 2 to 5 mm apart at the fingertips, 7 to 10 mm at the base of the palm, and 7 to 12 mm on the dorsum of the hand. More proximal parts of the upper extremity may have even less sensitive discriminatory abilities.

A problem occasionally arises in trying to assess sensory function in a patient who is unresponsive or who cannot communicate with the examiner. In these cases, a test of sympathetic innervation, such as the O'Riain wrinkle test, may be useful. To perform this test, the patient's hand is immersed in a warm water bath for approximately 20 minutes. Normal digital pulps will wrinkle; fingers with disrupted sympathetic innervation will not wrinkle.

Appropriate motor testing of the peripheral nerves depends on careful isolation of muscle activity that reflects the peripheral nerve in question. The clinician must be careful to recognize that a patient will compensate for a motor deficit by using other motor groups to accomplish the same task. Motor function can be assessed by examining not only active motor strength but also resting tone and, for more chronic injuries, muscle bulk.

Management

Clean lacerations to a primary nerve are often repaired primarily. There is some evidence to indicate that recovery of function is better if the nerve is repaired within 48 hours of injury. Crush injuries to peripheral nerves are often repaired secondarily, several days or weeks after the injury. For these cases, many surgeons believe that delayed repair allows better debridement of devitalized tissue and easier identification of injured nerve tissue that needs to be resected. In all cases in which transection of a peripheral nerve is suspected, prompt consultation with an appropriate surgical consultant is indicated so that a decision can be made about the appropriate timing of repair.

Injuries to peripheral nerve associated with fracture or dislocation generally improve after the orthopedic injury is reduced. If there is any question about the recovery after reduction, nerve function should be carefully followed.

Nerve compression syndromes not associated with acute traumatic injuries can generally be treated with rest and nonsteroidal antiinflammatory medications. Splinting may be indicated for some syndromes as well. In all cases, appropriate follow-up should be arranged so that the patient can be referred for further interventions if necessary.

The prognosis after peripheral nerve injuries clearly depends on the severity of the injury. Compressive lesions without transection of the nerve have a better prognosis, with full recovery expected in all but the most severe or most chronic cases. With transections of the nerve, however, there is often some degree of permanent disability. In general, those lesions resulting from clean lacerations that can be repaired primarily have a somewhat better prognosis. Children, in general, have a better prognosis after peripheral nerve injury than do adults. In some cases, remarkable recoveries after severe crush injuries to the nerve have been reported.

CHAPTER 106

Neck Trauma

GEORGE A. WOODWARD, MD

Department of Pediatrics, The University of Pennsylvania School of Medicine, and Emergency Transport Services, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Pediatric neck injuries, fortunately, are uncommon. Many children will be evaluated for cervical spine injuries secondary to trauma, but few will have injuries identified. Even fewer children will need to be evaluated for penetrating or direct blunt trauma to the neck. However, neck injuries can be life-threatening and need to be assessed in a timely and orderly manner. It is imperative to appreciate how apparently minor or innocuous neck injuries can progress rapidly to more serious and life-threatening events. Subtle neck injuries can be easily overlooked in a patient with obvious head or chest trauma. This chapter initially discusses evaluation and management of penetrating and direct blunt injuries and then concentrates on evaluation of the cervical spine.

When considering injuries to the neck in a child, initial management must include immediate assessment of airway breathing circulation (ABCs) and treatment of abnormalities with care not to allow an injury to progress to a more significant event. Airway abnormality may be subtle but progressive, with the precipitating injury not obvious on initial examination. Patients should be monitored closely and physically observed during their emergency department (ED) stay. A listing of common mechanisms of neck injury is given in Table 106.1.

Penetrating Trauma	Blunt Trauma
High-velocity missiles	Motor vehicle accidents
Low-velocity missiles	Sports
Knives	Fights
Windshields	Falls
Sharp objects	Clothesline injuries
Explosions	Handlebars
Iatrogenic (intubation, endoscopy, gastric tubes)	Barotrauma (bottlecap under pressure or compressed air source)
	Nonaccidental (abuse)
	Exposures (fires, caustics)

Table 106.1. Common Mechanisms of Blunt and Penetrating Neck Injuries

There are several differences in neck anatomy between children and adults. The child's relatively large head and mandible and short neck make the anterior neck less accessible to direct trauma but may increase the possibility of acceleration/deceleration injuries to the cervical spine. The increased potential for acceleration/deceleration injuries is partially offset by the elasticity of the pediatric cervical spine and the child's light weight. Internal neck anatomy also differs from that of an adult and may influence the types of injuries seen. The cricoid ring is the narrowest portion of the airway and is located at the C-4 level as opposed to the adult location at C-7. The arytenoids are proportionately larger and the child's cartilage is more pliable and easily damaged.

The soft tissues and visceral components of the neck are protected by the spine posteriorly, the mandible anteriorly and superiorly, the shoulders and clavicles anteriorly and inferiorly, and the neck muscles. The head and chest of the child protrude more anteriorly than the neck and will often absorb most blunt traumatic force, lessening the chance of a direct neck injury. Most injuries to the neck involve forces with relatively large masses and slow velocity, which partially accounts for the low incidence of serious direct trauma in this population. If the neck is hyperextended, however, the structures of the anterior neck, including the larynx, trachea, and esophagus, are more susceptible to direct trauma. The large number of vital organs and structures in the relatively small neck area enhances the potential severity of direct penetrating or blunt injuries (Table 106.2).

Musculoskeletal	Vascular	Venous	Gastrointestinal	Glandular
Cervical spine	Arterial	Jugular: internal, external	Esophagus	Thyroid
Cervical muscles	Carotids: common, internal,	Lymphatics	Neurologic	Parathyroid
Ligaments	external	Thoracic duct	Spinal cord	Parotid
Clavicle	Vertebral	Airway	Cranial nerves IX–XII	Submandibular
Pectoralis	Innominate	Larynx	Cervical nerves	
Hyoid	Subclavian	Trachea	Cervical sympathetics	
		Aspiration of lung	Brachial plexus	

Table 106.2. Neck Contents and Closely Approximated Structures

The neck can be divided into three anatomic zones (Fig. 106.1, Fig. 106.2 and Fig. 106.3). Zone I encompasses the area between the thoracic inlet and the cricoid (the lower boundary of zone I is the thoracic inlet, the upper boundary is most often classified as the cricoid; most authors use the clavicle or sternal notch as the upper boundary as well); zone II is the area between the cricoid (clavicle or sternal notch) and the angle of the mandible; and zone III is the area above the angle of the mandible. Knowledge of the divisions and structures they contain is useful in evaluation and management of neck trauma (Fig. 106.1, Fig. 106.2 and Fig. 106.3). Lesions in zones I and III are often occult and difficult to diagnose by physical examination alone. Operative exploration is more difficult in zones I and III than in zone II, where injury presentation and surgical exploration are often more straightforward. The neck can also be divided into anterior and posterior elements, with the dividing line being the palpable transverse processes of the cervical spine. The posterior neck contains muscles with their individual nerve supplies and the posterior elements of the cervical spine, and the anterior neck houses most vital organs and structures. No major vascular components are contained in the posterior area of the neck. Morbidity and mortality with neck injuries result from central nervous system (CNS) trauma, airway compromise, exsanguination, vascular disruption or thrombosis, venous embolism, sepsis, or mediastinitis.

PENETRATING TRAUMA

Penetrating neck trauma is uncommon in children. Penetrating trauma may be associated with extracervical injuries and may involve multiple organ systems within the neck. Most pediatric penetrating trauma is the result of a wound from a gunshot (usually low velocity), knife, broken windshield, other sharp object, or explosion (Table 106.1). The history is important in evaluation of penetrating neck trauma. Inquiries about mechanism of injury, time of incident, events before arrival in the ED, amount of blood loss, history of pulsatile lesions, neurologic dysfunction (including transient ischemic attack, limb paresthesias, hemiplegia, blindness, Horner's syndrome, and aphasia), and airway compromise should all be noted. In particular, knowledge of the mechanism of injury can help direct the management of both the stable and unstable patient. Mortality with penetrating neck trauma is between 3 and 6% with or without surgical exploration. Common causes of death include vascular, neurologic, and airway injury.

Many gunshot wounds seen in pediatric patients involve low-velocity weapons, including handguns (90 m/sec) or shotguns (300 m/sec) at ranges of greater than 5 meters as opposed to shotguns at close range or military-style weapons (760 m/sec) (Fig. 106.4). Unlike higher-velocity missiles, low-velocity missiles tend to be redirected when they encounter vascular or other structures. Visceral injuries may be anticipated but not completely predicted by the path of the missile. Internal injuries may be more predictable with an isolated knife wound. Low-velocity neck wounds are associated with major pathology in approximately 50% of cases compared with more than 90% with high-velocity missiles.

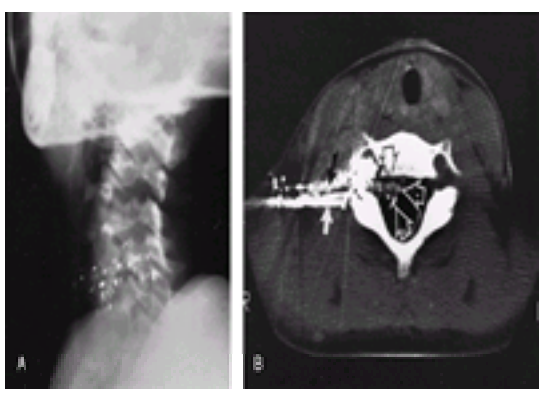

FIGURE 106.4. Gunshot wound (0.22 caliber) to the neck in a 5-year-old girl. **A.** Lateral neck radiograph showing fragmentation of bullet along path. **B.** Computed tomography scan of same patient demonstrating bullet fragments in and around spinal canal, as well as cerebrospinal fluid and contrast leak from disruption of the dura.

Vascular injury is the most common complication of penetrating trauma and is the second most common cause of death. History of large blood loss, pulsatile lesion, rapidly expanding hematoma, hypovolemic shock, or neurologic deficits (paresis, visual loss or aphasia, altered level of consciousness) indicates the possibility of cervical arterial injury. Major vessels that can be injured in the neck include the common, internal, and external carotid arteries; vertebral arteries; internal and external jugular veins; and nearby innominate and subclavian vessels (Table 106.2). Injury to the vessels can be dramatic, with exsanguination, rapidly expanding hematoma causing airway compromise, acute neurologic deficits from ischemia or hypoperfusion, or venous air embolism, or it may be subtle with an initially normal examination. Approximately one-third of arterial injuries present with neurologic deficits, whereas the remaining two-thirds are often more challenging to diagnose. The symptoms and signs suggestive of vascular and other neck injuries are presented in Table 106.3. Completely transected arteries often retract and contract with minimal bleeding. Vessels that are partially severed may continue to bleed significantly with normal pulses because blood flow may not be totally interrupted. Vascular abnormalities can be assessed partially by evaluating the carotid (external), superficial temporal, and brachial pulses, although no pulses are easily accessible to evaluate for the internal carotid or vertebral arteries. Abnormal pulses suggest vascular injury, whereas normal pulses do not guarantee vascular integrity.

Table 106.3. Symptoms and Signs of Neck Injuries

Auscultation of the neck is useful to identify bruits. Although a carotid bruit may be normal in children, a continuous bruit suggests a traumatic arteriovenous fistula, whereas a systolic bruit suggests a partial arterial tear. Bleeding from a posterior neck wound, neurologic deficits in areas supplied by the vertebral arteries (brainstem, cerebellum), bleeding not controlled by carotid compression, a posterior bruit, or bleeding that accompanies a cervical spine transverse process fracture suggests a vertebral artery injury. Carotid artery trauma should be suspected if presentation involves an anterior triangle hematoma, Horner's syndrome (ptosis, miosis, enophthalmos, loss of sweating on the ipsilateral side of the face), transient ischemic attacks, loss of consciousness after a lucid interval, or hemiplegia. Evaluation of the chest for signs of major vessel injury, including hemothorax, widened mediastinum, and cardiac tamponade, should accompany the neck examination.

Neck vessels may be injured indirectly as a result of shock waves from a missile. These patients may have clinically inapparent vascular intimal damage that can progress to vascular thrombus or occlusion. Venous or lymphatic (thoracic duct) injuries also occur with penetrating trauma. These injuries are rarely severe and usually present as an expanding hematoma or less often with a venous air embolism. Pulmonary embolus secondary to a venous thrombus is a rare event.

Injuries to the aerodigestive tract (pharynx, larynx, trachea, esophagus) are also seen in cases of penetrating trauma, although these relatively mobile structures are often spared. The esophagus is usually collapsed as it courses through the neck but may be injured by direct penetrating objects. Penetrating injury of the larynx and trachea occur, although blunt trauma to these areas is more common and can be associated with significant morbidity and mortality (see Chapter 112).

Direct nervous system injury (brachial plexus, spinal cord, cervical nerves, cervical sympathetics) is possible with penetrating neck trauma and evaluation of the patient should assess these structures. Symptoms will correspond to the injured structure, which may or may not require primary surgical repair (Fig. 106.5). Primary injury to the cervical cord often results from bony or foreign body penetration or impingement or cord distraction. Secondary cord injury can occur from vascular compromise, edema, lipid peroxidation, ischemia, and ligamentous damage. When assessing neurologic findings or predicting location of injury, it is important to remember that spinal cord and vertebral levels are not the same. In the cervical area, the cord level lies one segment higher than the corresponding vertebral level (C4 cord level lies opposite the C3 vertebral body) In the lower cervical area, a disparity of up to two levels may be present.

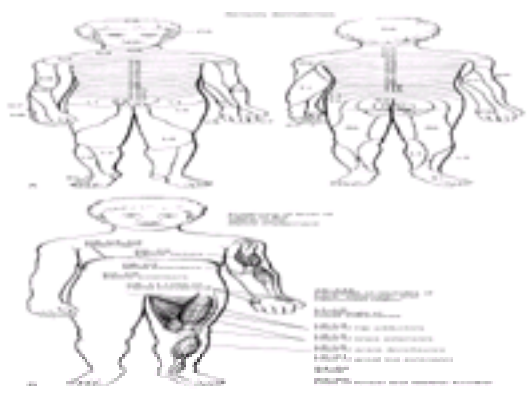

FIGURE 106.5. A. Sensory dermatomes. **B.** Motor dermatomes. Knowledge of sensory and motor dermatomes can be invaluable in description of neurologic findings during initial and subsequent evaluations.

BLUNT TRAUMA

Blunt trauma is often the result of a motor vehicle accident, although it can also be seen from sports; clothesline-type and handlebar injuries from bicycles, motorcycles, all-terrain vehicles, and snowmobiles; strangulation; hanging; blows from fists or feet; and the battered child syndrome (Table 106.1). Blunt trauma is often associated with extracervical injuries, especially maxillofacial, head, and chest, but is less likely than penetrating trauma to involve multiple structures within the neck. Blunt trauma is less likely than penetrating trauma to cause vascular damage, but the incidence of aerodigestive tract injuries is increased. The airway is often injured with direct blunt trauma in part as a result of the anterior and relatively fixed position of the larynx and trachea. As mentioned, the anterior neck is relatively well protected by bony structures unless the neck is extended. With neck extension, the larynx, trachea, and esophagus are exposed to direct trauma, and a blunt force may crush these structures against the posterior spinal column. A tracheal tear or rupture

may occur from a sudden increase in intratracheal pressure against a closed glottis, crush injury, or acceleration/deceleration injury. Shearing forces can cause edema, submucosal hematoma, laceration, perforation, vocal cord injury, and less commonly, partial or complete airway transection. A prime target for airway fracture is the cricoid ring, which is the only complete tracheal ring. The triad of dyspnea, stridor, and hemoptysis suggests laryngeal injury, although any or all of the symptoms and signs listed in Table 106.3 may be present.

Approximately 85% of patients with blunt tracheal injury will reportedly have subcutaneous emphysema, although the onset may be delayed (Fig. 106.6). However, airway injuries may be subtle and not apparent with initial history or physical examination. Unfortunately, these subtle injuries may progress to severe abnormalities. The same percentage of airway narrowing from edema or hematoma may lead to significantly more distress in a child compared with an adult. Airway obstruction from tracheal edema has been reported as late as 48 hours after the injury. If a laryngeal injury is noted, the patient should be evaluated carefully for commonly associated injuries, which include cervical spine, chest, facial, pharyngoesophageal, and recurrent laryngeal nerve. Airway injuries can be seen as a result of endoscopy, thermal trauma, or caustic ingestions. There are numerous reports in the literature of laryngeal and tracheal trauma secondary to intubation attempts.

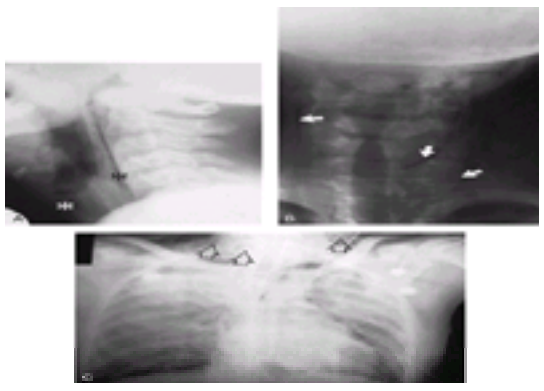

FIGURE 106.6. A–C. Subcutaneous emphysema of neck and chest in 11-year-old patient from barotrauma sustained when opening carbonated beverage container with teeth.

As mentioned, the esophagus is mobile and usually collapsed as it courses through the neck but may be dilated while eating. This mobility helps protect the esophagus, but its delicate mucosal walls can be damaged easily by blunt or penetrating traumatic events. Iatrogenic esophageal injuries can result from endoscopy, passage of a nasogastric or orogastric tube, vigorous suction, and difficult intubations. Esophageal injuries can also be seen with ingested foreign bodies and caustic chemicals. The symptoms and signs associated with esophageal injury are listed in Table 106.3 and include neck tenderness and pain, dysphagia, odynophagia, drooling, crepitus, subcutaneous emphysema, hematemesis, fever, and mediastinitis (see Chapter 29 and Chapter 93). The injuries, which can be subtle, occult, and difficult to diagnose, can lead to increased morbidity and mortality if not suspected and discovered.

Isolated or concurrent hyoid bone injuries are also possible. The hyoid is mobile and fairly well protected, which explains the paucity of isolated injury. In a 1991 review by Szeremeta and Morovati, only four children 16 years of age or younger had been reported with an isolated hyoid fracture, three of whom sustained the injury in motor vehicle accidents. Symptoms and signs of hyoid injury include pain in the throat that worsens with swallowing or coughing, tenderness to palpation, neck crepitus, pain on head rotation, dysphagia, dyspnea, or dysphonia. As with other injuries, these symptoms and signs can be subtle initially, with progressive edema and airway obstruction.

Although vascular injuries are rare with blunt trauma, they do occur. These injuries are often unsuspected and undiagnosed on routine examination. The clinician must consider subclavian or innominate vessel injuries if a fracture of the clavicle or first rib is identified. The most common vascular structure injured with blunt trauma is the common carotid artery. The vertebral arteries are rarely injured by blunt forces unless a concurrent transverse process or other fracture of the cervical spine or atlantooccipital dislocation occurs. Many patients with atlantooccipital dislocation and arterial injury die in the field, but some survive and may recover with appropriate therapy. Vascular contusions with intimal damage may also be seen with blunt neck trauma.

The glandular structures in the neck, including the thyroid, parathyroid, parotid, and submandibular glands, may also be injured. Although these organs may be traumatized, they are rarely completely destroyed.

Burn management is covered in Chapter 114, but the physician should be aware of special considerations involving the neck. The airway must be evaluated and protected as indicated by the severity of the burn, realizing that initial symptoms may be subtle. Circumferential burns may become edematous and require an escharotomy for respiratory or vascular sufficiency. Escharotomy in the neck involves a vertical incision from the chin to the superior aspect of the sternal notch.

EVALUATION AND MANAGEMENT

The goals of management are to ensure airway patency and respiratory sufficiency, control hemorrhage, maintain osseous stability, and identify and prevent progression of all injuries. Methodical and timely acquisition of historical and physical findings is mandatory. The patient must be managed with strict adherence to the ABCS, with consideration of possible rapid or gradual deterioration. Penetrating objects that are in the neck on evaluation should remain until removed under surgical care, preferably in an operating room. All patients, other than those with minor injuries such as contusions, abrasions, or superficial lacerations (not through the platysma muscle), should receive supplemental humidified oxygen, correct airway positioning, suctioning, vigilant observation, and monitoring. The patient should be

maintained in a supine or Trendelenburg position to avoid the possibility of venous air embolism. If venous air embolism is suspected because of an unexplained decrease in cardiac output and blood pressure, increase in central venous pressure, cyanosis, arrhythmias, or air in the heart on chest radiograph, the patient should be placed in the left lateral decubitus and Trendelenburg positions. A decision tree for evaluation of direct blunt and penetrating neck trauma is presented in Figure 106.7.

FIGURE 106.7. Evaluation of blunt and penetrating neck trauma.

Airway assessment is the initial step in the evaluation of all traumatized patients. Any airway manipulation should be accomplished with consideration and prevention of possible cervical spine injury. Potential indications for an artificial airway with neck trauma include stridor, dyspnea, hypoxia, rapidly expanding hematoma, expanding crepitus, pneumothorax, hemothorax, tracheal deviation, altered mental status, quadriplegia, hemiparesis, and other signs of vascular or airway insufficiency. Orotracheal intubation is the preferred method in children. Intubation should be attempted only after preparation for placement of a surgical airway, if time allows. Fiberoptic intubation, if available, may be useful if time and patient condition permit. The physician must be especially careful with the use of blind nasotracheal intubation in the patient with blunt or penetrating neck trauma because the airway anatomy may be distorted. Passage of the nasotracheal or orotracheal tube into a false or blind passage may make subsequent airway control attempts difficult if not impossible. Therefore, along with the difficulty of emergent surgical airway placement in children, elective intubation is not recommended outside of a setting where a surgical airway can be efficiently and skillfully placed.

If there is evidence of crepitus over the larynx, laryngeal or tracheal tenderness, a flattened thyroid prominence, anterior neck deformity, severe respiratory distress, an abnormal neck radiograph, or other evidence suggestive of a laryngotracheal fracture or disruption, a tracheostomy may be preferable. Intubation should be attempted only if the airway is completely obstructed. Attempts at intubation from above may separate a tenuously attached trachea and larynx and result in a total loss of the airway, with the trachea commonly retracting substernally into the chest (Fig. 106.8). Attempts at cricothyrotomy in patients with direct laryngeal trauma may result in retrotracheal placement of the airway. Cricothyrotomy is helpful in patients who have severe facial or other neck injuries that preclude intubation from above. Intubation may be attempted through an open laryngeal wound if present, although if possible a tracheostomy should not be placed through injured tissue. The flexible fiberoptic bronchoscope may be helpful in evaluating the patency of the airway and in establishing the artificial airway. If patient condition allows, rigid bronchoscopy can also be useful in securing an airway in these patients.

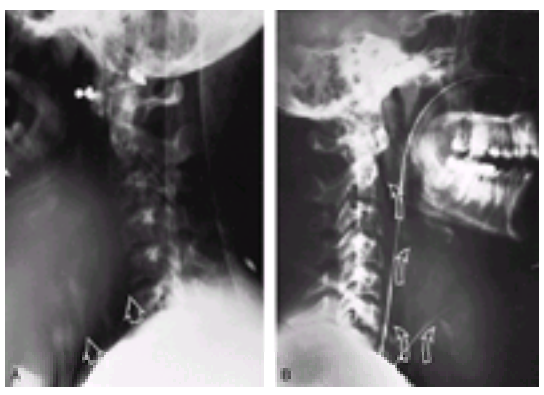

FIGURE 106.8. Tracheal injury. **A.** Initial lateral neck radiograph showing subcutaneous emphysema in 14-year-old girl kicked in the neck by a horse. Patient's airway clinically stable at the time of this radiograph (more than 1 hour after the injury). **B.** Postcricothyrotomy radiograph in same patient demonstrating significant subcutaneous emphysema and an artificial airway in place. Initial attempt at orotracheal intubation separated tenuously attached trachea, completing traumatic disruption of the trachea and requiring immediate placement of surgical airway.

Breathing should be evaluated for associated injuries. Missiles to the neck may also pass through or lodge in the chest. Zone I injuries of the neck can easily involve the lung apices and result in hemothorax, pneumothorax, or pneumomediastinum. Further penetration may lead to cardiac tamponade. A chest radiograph is helpful in the assessment.

In addition to the usual assessment of hypovolemia, the patient should be examined for expanding hematomas or other obvious external bleeding. External bleeding should be treated with gentle compression. Attempts to clamp bleeding

vessels in the neck can injure the vessels and surrounding structures and jeopardize subsequent repair attempts. Two large-bore intravenous (IV) catheters should be inserted. If a subclavian vein injury is suspected, one of the IV lines should be placed in the lower extremity. Type-specific or crossmatched blood should be made available and used with volume expanders as necessary.

The subtle presentation of vascular injuries has led many authors to suggest mandatory exploration of all neck injuries when the outermost muscle layer (platysma) is penetrated. Controversy exists in the literature regarding surgical exploration with low-velocity penetrating neck trauma (Table 106.4). Proponents of mandatory exploration of penetrating neck wounds report that overall morbidity and mortality has decreased with routine neck exploration and surgical repair of vascular and other abnormalities. However, recent literature suggests that careful evaluation with ancillary studies, including arteriography, and the use of selective exploration will identify most significant injuries, and the potential delay in operative evaluation and repair will not increase morbidity and mortality. Surgical exploration is practiced uniformly for high-velocity or multiple low-velocity wounds. With pediatric penetrating injuries, routine neck exploration, even in the relatively straightforward zone II, is not always a benign procedure.

Arguments Favoring Mandatory Surgical Exploration with Penetrating Trauma
Most patients have injuries to important structures.
Morbidity and mortality increase with delay in surgery.
Morbidity of exploration is relatively low.
Negative physical examination does not preclude injury.
Morbidity of missed injuries is high.
Specific radiologic tests and expertise are needed to selectively manage.
More skill is needed to observe appropriately.
Length of hospitalization is similar with or without exploration.
Arguments Favoring Selective Surgical Exploration with Penetrating Trauma
Most injuries are not secondary to high-velocity weapons.
There are high negative rates of injuries with exploration in asymptomatic patients.
It is unclear whether morbidity and mortality increase with delay in surgery.
Zone II is involved most commonly and injuries are rarely occult.
Skill is needed to explore neck.
Morbidity of the more difficult zone I and III explorations is seen.
Ancillary tests are helpful in zone I and III evaluation.
Exploration may miss occult injuries.

Table 106.4. Surgical Exploration with Penetrating Trauma

Repair of vascular injuries depends on the vessel injured, type of injury, and the patient's clinical status. Arterial injuries with neurologic deficits often are not repaired but are ligated to avoid the chance of reperfusion injuries to the brain. Other authors suggest that primary arterial repair may be indicated, despite the possibility of reperfusion injury. Vascular repair in zones I and III is especially difficult and not without operative morbidity. Venous injuries may not need repair unless persistent bleeding or associated morbidity is demonstrated. The need for surgical repair of vascular intimal injuries is controversial.

A neurologic examination for signs of cerebral injury secondary to vascular insufficiency, direct spinal cord, cranial or cervical nerve, or brachial plexus injury should be completed. An abnormal neurologic examination may indicate progressive vascular insufficiency and the need for rapid surgical evaluation. Direct neurologic injuries may not necessitate surgical repair.

Tetanus status should be assessed in all patients with penetrating trauma. The clinician should consider a broad-spectrum antibiotic for a patient with evidence of neck trauma, especially if esophageal or pharyngeal injury seems likely. Placement of a nasogastric or an orogastric tube is controversial for the patient with cervical injury because it may worsen a preexisting esophageal injury or dislodge clots in zone I of the neck. When placed, these tubes should be well lubricated, inserted gently and slowly, and withdrawn if difficulty in passage or evidence of obstruction occurs.

Superficial abrasions, lacerations, and puncture wounds are common in children. Wounds superficial to the platysma can be cleaned and sutured in the normal fashion under local anesthesia in the ED. Clean wounds can be sutured as late as 12 to 18 hours after the injury because of the excellent blood flow in the neck. In wounds older than 12 to 18 hours, closure after 72 hours is recommended. Penetration of the external muscle layer in the neck, the platysma, is an indication for surgical referral and, in some cases, surgical exploration. When neck wounds that penetrate the platysma are evaluated, exploration in the ED is discouraged because of the risk of clot dislodgment and venous air embolism. Rapid surgical exploration and repair is indicated in patients with unstable vital signs, uncontrollable bleeding, rapidly expanding hematomas, progressive airway compromise, worsening neurologic symptoms, those struck by a high-velocity missile, increasing subcutaneous emphysema, or bubbling wounds (Table 106.5).

Unstable vital signs
Expanding or massive hematoma
Pulsatile or active bleeding
Hemorrhagic shock
Vascular deficits in the upper extremities
Abnormal distal pulses (brachial, superficial temporal, ophthalmologic, fundi)
Hematemesis, hemoptysis, epistaxis
Hemothorax
Progressive respiratory distress
Airway obstruction
Expanding subcutaneous emphysema
Bubbling or sucking wound
Pneumothorax
Progressive neurologic deficits
Hemiparesis
Horner's syndrome
Cranial or cervical nerve dysfunction
Diaphragm paralysis
Decreased sensorium
Neurologic deficits in upper extremity
Increasing dysphagia
Odynophagia or dysphonia
Hoarseness
Severe neck pain or tenderness
High-velocity wounds (rifles, explosions)
Multiple low-velocity wounds
Anxiety (allegiance) studies not available
Equivocal observation personnel not available

Table 106.5. Indications for Surgical Evaluation in the Patient with Neck Trauma

Surgical evaluation may be falsely negative with esophageal tears, small vessel lacerations, pharyngeal tears, or tracheal injuries. The patient who has apparently stable vital signs, no symptoms of impaired neurologic or cardiovascular status, an intact airway, and mechanisms of injury with a low-velocity bullet or single knife wound may be managed expectantly with the use of ancillary diagnostic tests and close, experienced observation, preferably for at least 48 hours. These decisions should be made in conjunction with experienced surgical staff.

Adjuncts to the history and physical examination are presented in Table 106.6. Initial evaluation should include cervical spine radiographs to detect bony or structural abnormalities and a soft-tissue lateral neck radiograph to assess for blood, edema, subcutaneous air, foreign bodies, and airway impingement or disruption. A chest radiograph should be evaluated for evidence of hemothorax or pneumothorax, mediastinal emphysema or widening, and heart size. If a serious injury is at all likely, these radiographs should be performed in the ED or the patient should be accompanied to the radiology department by someone skilled in airway management. Fluoroscopy may be helpful in airway evaluation. If the patient is stable and a vascular injury is suspected, an arteriogram should be performed (Fig. 106.9). Arteriography has excellent sensitivity, specificity, and accuracy, as well as low morbidity. Some authors suggest that an arteriogram is not needed in penetrating zone II injuries if an exploration is to be performed because this can be done fairly easily without significant complications. Others suggest that, even with zone II injuries, the stable patient should receive an arteriogram before the operative procedure.

Cervical spine radiographs	Xeroradiography
Soft-tissue neck radiograph	Tomography
Chest radiograph	
Computed tomography scan	Indirect (mirror) laryngoscopy
Arteriography	Direct laryngoscopy
Doppler	Flexible bronchoscopy
Esophagram	Direct broncho/esophagoscopy
Contrast laryngotracheography	Surgical exploration
Oculoplethysmography	

Table 106.6. Adjuncts to History and Physical Examination

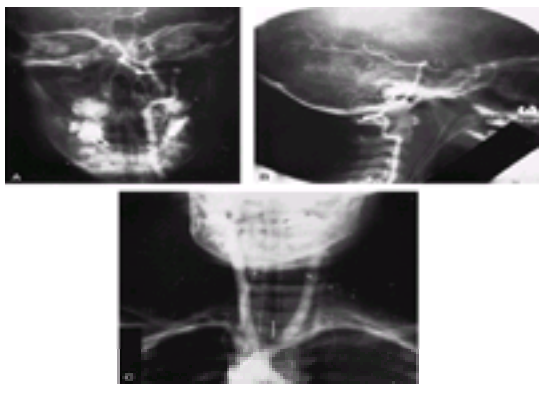

FIGURE 106.9. Angiograms in 5-year-old child shot in neck, demonstrating normal vascular integrity. **A.** Vertebral artery angiogram (anteroposterior view). **B.** Vertebral artery angiogram (lateral view). **C.** Carotid angiogram.

Noninvasive Doppler studies and oculoplethysmography may be useful in evaluating vascular injuries. Contrast laryngography, tomography, and xeroradiography have been used for further evaluation; however, these methods have generally been replaced by the computed tomography (CT) scan. The noninvasive CT scan provides excellent bone and soft-tissue detail and can be obtained easily with a stable, immobilized patient. The addition of IV contrast allows identification and initial evaluation of the cervical vasculature. The advent of spiral CT technology allows rapid scans and illustrative coronal, sagittal, and three-dimensional reconstruction of the neck anatomy. CT may not be accurate for detection of mucosal degloving injuries, mucosal perforation in the presence of subcutaneous emphysema, endolaryngeal edema or hematoma, and partial laryngotracheal separation.

Barium or Gastrografin esophagram is helpful in evaluating the esophagus for tears or perforations, but false-negative rates of up to 50% have been reported. Evaluation can also include indirect mirror laryngoscopy to assess the larynx, vocal cord mobility, presence of mucosal edema, ecchymosis, and mucosal tears and direct endoscopy to examine for tracheal, bronchial, and esophageal damage. Flexible endoscopy may be less invasive and easier to accomplish, but rigid endoscopy offers the most complete examination. Even rigid endoscopy, however, is not 100% sensitive in detecting tracheal and esophageal injuries. As mentioned, operative evaluation is mandatory for some patients and optional for others. Determinants of specific management direction include mechanism of injury, wound size and type, patient signs and symptoms, and relative stability. The clinician must maintain a high index of suspicion for potential injury to the structures contained in the neck. Consequences of missed injuries include airway obstruction, delayed hemorrhage, neurologic compromise, and deep neck infection, with potentially significant morbidity and mortality.

CERVICAL SPINE EVALUATION

Cervical spine injuries are also uncommon in children, occurring in an estimated 1 to 2% of patients with multiple trauma. However, the clinician must assume that all children who sustain multiple trauma, have head or neck injuries, or have symptoms of neurologic impairment, including altered level of consciousness, have a cervical spine injury until proven otherwise. Goals in the care of these children include effectively stabilizing the primary injury that has occurred and preventing progression to a more severe or significant injury. The devastating nature of a cervical cord injury makes it imperative to not inadvertently miss a potentially unstable cervical spine injury. While attending to the basic ABCS of trauma resuscitation, the clinician should stabilize the cervical spine. Caution must be exercised when applying airway maneuvers to a child with a possible cervical spine injury. Airway interventions, however, often cannot wait until the cervical spine is “cleared.” The clinician must prioritize and proceed with lifesaving airway maneuvers, while minimizing motion of the potentially unstable cervical spine.

Hyperextension of the neck to facilitate intubation should be avoided. A vigorous chin lift or jaw thrust may also inadvertently hyperextend the unstable cervical spine. Gentle cricoid pressure should not cause excessive movement to the cervical spine; however, if applied vigorously, it may cause flexion of the spine. When in-line neck immobilization is used to assist with airway maneuvers, the clinician should be careful to avoid applying significant traction to the spine as this pressure can also stress the unstable cervical column. Tracheal intubation in a patient with a potential cervical spine injury ideally requires at least two participants to perform the procedure safely and efficiently. One provider should maintain in-line immobilization of the neck, while another performs the intubation. The immobilization is often best accomplished from below, allowing the intubator as much room as possible to maneuver (Fig. 106.10). The hard cervical collar should be opened anteriorly, or removed, while this process in being performed. It is difficult to intubate a child with the anterior trachea unless the jaw immobilization afforded by the collar is temporarily removed. As usual, oral intubation is often the preferred method because of the child's anterior airway and the usual experience of providers. The collar should be resecured after the airway intervention is complete.

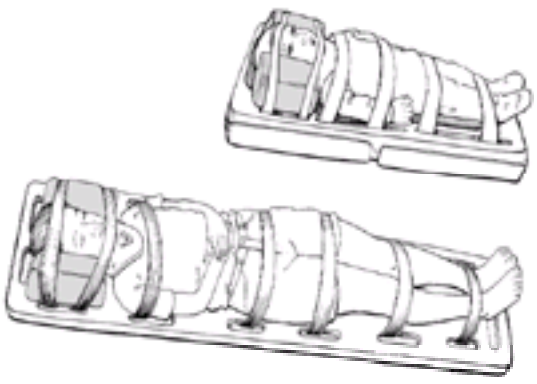

FIGURE 106.10. A. Manual immobilization from below. **B.** Manual immobilization from above. Adequate and expert manual cervical spine immobilization is required during airway maneuvers. The head and neck can be adequately secured from above or below. Immobilization by the second provider from below allows the airway maneuver to be accomplished without requiring a change in preferred positioning of the professional performing the maneuver.

Several concepts should be kept in mind concerning cervical immobilization in children. Soft cervical collars offer no protection to an unstable spine and hard (Philadelphia, Stifneck) collars alone still allow a fair amount of flexion, extension, and lateral movement of the cervical spine. Ideal immobilization involves a hard cervical collar in conjunction with a full spine board, soft spacing devices, and securing straps (Fig. 106.11). An appropriately sized hard cervical collar should be chosen. The tallest collar that does not hyperextend the neck is the correct choice. The choice between a one-piece (Stifneck) or two-piece (Philadelphia) collar is important only in that correct fit must be ensured and the provider must understand how to apply the specific brand of collar. It is helpful to fold over the Velcro connectors on the collar before sliding it under the patient's neck to avoid Velcro attachment to the child's hair or clothing. If a patient is seated and needs to have a collar placed, this maneuver should be accomplished by positioning the collar's chin portion first, followed by placement of the posterior portion. If the patient is wearing a helmet, it should be carefully removed. Helmet removal, if possible, should involve at least two people to avoid potential neck motion. In-line stabilization is ensured by one provider while the helmet is spread and gently removed. Occasionally, mechanical bivalving of the helmet may be required for safe removal.

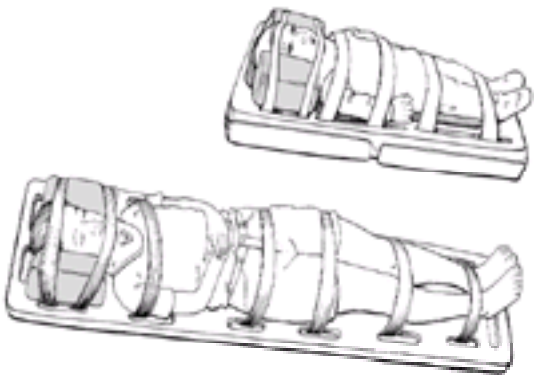

FIGURE 106.11. Cervical spine immobilization should not place the patient at an increased risk for morbidity. Securing straps should be placed around bony prominences, and strap location reassessed after any movement of the patient. A

neutral position of the neck should be ensured, and if necessary (younger child), a spacer can be placed underneath the child's torso and lower extremities to achieve the desired position.

The clinician must be prepared to log-roll the patient if vomiting occurs. This reaction may happen at any stage of the immobilization process and should be anticipated. Adequate personnel to safely log-roll the vomiting patient are required to avoid potential gagging, aspiration, or secondary spinal or cord injury. The patient should be secured to a long spine board by tape or straps that cross the forehead, chin area of the cervical collar, and bony prominences of the shoulders and pelvis. Incorrect immobilization may impede respiration by obstructing chest rise or contributing to secondary spinal injury by hyperextending the neck. The securing straps should be assessed periodically to ensure adequate and safe attachment of the patient to the spine board. When a child is immobilized on a spine board, the clinician must consider that the child's head is disproportionately large compared with the adult's. A child's head reaches 50% of postnatal growth by approximately age 2 years, whereas chest circumference reaches 50% of postnatal growth by about age 8 years. This disparate growth of the head and trunk causes the neck to be forced into relative kyphotic position when a child is placed on a hard spine board (Fig. 106.12). This is distinctly different from the adult patient whose neck is in 30 degrees of lordosis, the neutral position, when immobilized on a hard spine board. Suggestions have been made to allow a recess in the head area of the spine board to accommodate the child's large occiput or to place a spacing device such as a blanket underneath the torso to allow the neck to rest in a neutral position (Fig. 106.12). Figure 106.13 demonstrates that cervical spine alignment can be greatly affected and improved by this technique.

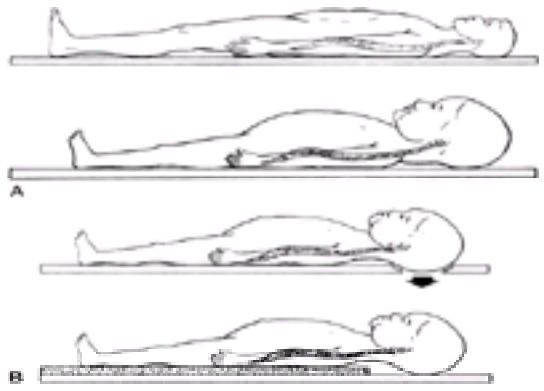

FIGURE 106.12. Effects of backboard on cervical spine position. **A.** Adult and child immobilized on standard backboard. **B.** Backboards modified with occipital recess and mattress pad to allow neutral positioning of the cervical spin in a young child. (Reprinted with permission from Herzenberg J, Hensinger R, Dedrick D, et al. Emergency transport and positioning of young children who have an injury of the cervical spine: the standard backboard may be hazardous. J Bone Joint Surg 1989;71-A:15–21.)

FIGURE 106.13. Anterior subluxation is decreased. (Reprinted with permission from Herzenberg J, Hensiger R, Dedrick D, et al. Emergency transport and positioning of young children who have an injury of the cervical spine: the standard backboard may be hazardous. J Bone Joint Surg 1989;71-A:18.)

Patients often arrive in the ED with full or partial cervical spine immobilization already in place. An immediate assessment of that immobilization is imperative. Several important issues should be examined: 1) Is the patient appropriately and fully immobilized? 2) Is the cervical collar of the correct size and type for that patient? 3) Is the patient's neck in a neutral position? 4) Is the patient securely strapped to a long spine board? 5) Has there been a shift in the patient or the immobilization during the prehospital or interfacility transport that might diminish effective immobilization, cause hyperflexion or hyperextension of the cervical spine, or compromise excursion of the chest with respiration? and 6) Does the immobilization interfere with assessment or management of the ABCs? If these or other immobilization difficulties are identified, they should be immediately addressed.

Occasionally, the use of a semipermanent immobilization device (tongs, halo) may be indicated (Fig. 106.14). This should be accomplished after neurosurgical consultation. Attempts to rapidly reduce a cervical fracture are usually

discouraged to avoid potential further cord injury. Frequent reassessment is necessary for the patient in cervical traction. Transport of the patient in cervical traction has the potential to further damage the injured cervical spine.

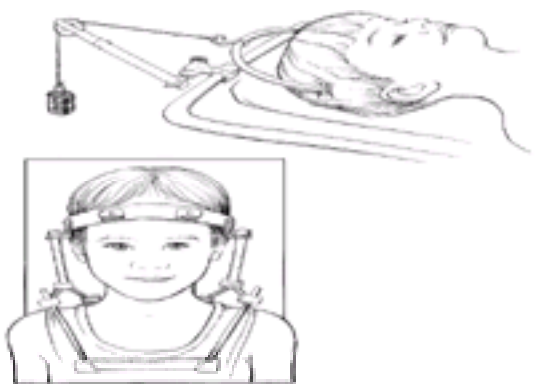

FIGURE 106.14. A. Gardner-Wells tongs. **B.** Halo traction brace. Unstable cervical spine injuries may require immediate placement of semipermanent immobilization devices. These should be administered only by those experienced in appropriate usage and application.

The pediatric cervical spine and its evaluation differ in many ways from the adult spine. The fulcrum of the cervical spine of an infant is at approximately C2–C3 and reaches C3–C4 by the age of 5 to 6 years. At about the age of 8, the fulcrum (C5–C6) and other characteristics of the cervical spine approximate that of an adult. The higher fulcrum of a child's spine in combination with relatively weak neck muscles and poor protective reflexes account for young children often having fractures that involve the upper cervical spine, whereas older children and adults have fractures that more often involve the lower cervical spine. Neurologic disability can occur from cervical lesions at all levels, but high cervical cord injuries are more likely to be fatal than are lower cervical cord injuries.

The large amount of cartilage present in a pediatric cervical spine cushions forces that are transmitted to the spine but can also make radiographic evaluation somewhat challenging. The radiolucent nature of cartilage makes the ability to appreciate soft-tissue changes on the radiograph extremely important. The pediatric cervical spine seems to have more anterior and posterior movement than its adult counterpart as a result not only of radiolucent cartilage, but also of ligamentous laxity and relatively horizontal facet joints. The pediatric cervical spine also has the ability to revert to a relatively normal appearance after a significant distortion, which can hinder the radiographic search for abnormalities. It is important to realize that any persistent distortion demonstrated on the radiographs was probably more exaggerated during the actual precipitating event. There is more room around the spinal cord within the spinal column in a young child than in an adult, which means that compressive problems such as tumors or bleeds may be slower to manifest neurologic symptoms.

Evaluation of the traumatized child begins with a focused history and complete physical exam. The history (if reliable) can be invaluable in helping identify the potential for cervical spine or cord injury. The following questions should be answered: 1) Was the child involved in a high-speed motor vehicle accident? If so, was he or she restrained and at what angle did the car(s) collide? 2) Was there a sports injury? If so, did it involve a spearing motion? 3) Did the child fall? If so, how high was the fall and how did the child land? A neurologic history is imperative to assess whether there was any evidence of abnormal findings such as paresthesias, paralysis, or paresis at any time after the injury. These symptoms may have been transient and may not be present at the time of the examination or volunteered by the patient during gathering of the history, yet they are important because they may suggest a cervical contusion, a concussion, or a spinal cord injury without radiographic abnormality (SCIWORA). The answers to these and other historical questions can often be obtained from the patient, parents, bystanders and Emergency Medical Services personnel and can help rule in or rule out significant possibilities of cervical injury. A plethora of clues can aid in the diagnosis of a cervical cord injury (Table 106.7). The symptoms and signs may be obvious or they may be masked by other abnormalities, such as altered level of consciousness, hypovolemic shock, or concurrent head injury. Head and neck injuries may present with overlapping abnormal neurologic signs and differentiation of causation may be difficult.

Abnormal motor exam (paresis, paralysis, flaccidity, ataxia, spasticity, rectal tone)	Diaphragmatic breathing without retractions
Abnormal sensory examination (pain, sensation, temperature, paresthesias, anal wink)	Spinal (neurogenic) shock (hypotension with bradycardia)
Altered mental status	Priapism
Neck pain	Decreased bladder function
Torticollis	Fecal retention
Limitation of motion	Unexplained ileus
Neck muscle spasm	Autonomic hyperreflexia
Abnormal or absent reflexes	Blood pressure variability with flushing and sweating
Clonus without rigidity	Poikilothermia
	Hypothermia or hyperthermia

Table 106.7. Symptoms and Signs of Cervical Spine Injury

Consideration of cervical spine radiographic evaluation is the next step in assessment. Radiographic options include radiographs, CT, and magnetic resonance imaging (MRI). MRI scans are more appropriate when evaluating the subacute

or chronic stages of injury or when looking for an acute problem with cord impingement by blood or soft tissues such as tumors or intervertebral discs. MRI does not image cortical bone well and should not be used to evaluate the cervical spine for fractures, whereas the CT scan demonstrates fractures clearly. A CT scan is often used as a secondary screen when adequate plain radiographs cannot be obtained or to substantiate suspected fractures. A common scenario is the use of CT to supplement viewing the C1/C2 region in young, traumatized children. The CT scan images soft tissue well; however, it does not demonstrate the intrathecal, ligamentous, disc, or vascular detail that can be obtained with an MRI scan.

The plain radiograph remains the preferred initial test for acutely traumatized patients. Several authors have attempted to devise criteria to limit the use of cervical spine radiographs because the number of positive studies constitutes a small proportion of the total number of radiograph studies completed. The perception of unnecessary tests should be balanced against the severity of consequences that may occur with a missed cervical spine injury. The literature suggests that if the patient does not have a high-risk mechanism of injury (motor vehicle accident, fall, dive, or sports injury), is awake and alert, can have an interactive conversation (not inebriated, no altered level of consciousness, older than 4 to 5 years of age), does not complain of cervical spine pain, has no tenderness on palpation (especially in the midline), has normal neck mobility, has a completely normal neurologic examination without history of abnormal neurologic symptoms or signs at any time after the injury, and has no other painful injuries (which may distract the patient and mask neck pain), the patient probably does not need radiographic evaluation of the cervical spine. The clinician must be sure, however, to never “clear” the cervical spine, regardless of studies performed, in an unconscious patient in the ED.

When radiographs are obtained, a normal lateral radiograph does not “clear” the cervical spine. The sensitivity of a lateral cervical spine radiograph varies between 82 and 98% in the literature. When evaluating a lateral cervical spine radiograph, the clinician must ensure that C-1 through C-7 are included as well as the C7–T1 junction. Additional films, which include an anteroposterior (AP) view of C-3 through C-7, and an AP open-mouth (odontoid) view of C1–C2, increase the sensitivity of initial radiographic evaluation to more than 95%. An adequate open-mouth (odontoid) view is often technically difficult to obtain in young children and those who are intubated. If further information is required, a CT scan of C1/C2 can be useful to augment or replace the open-mouth view. A CT scan is more expensive than a plain film of C1/C2, but it is easier to obtain, offers better and more consistent information, and avoids the risk of missing a subtle injury in that critical area. The advent of the spiral CT scan allows this study to be completed in 1 to 2 minutes and to be reconstructed by the computer to demonstrate vivid detail of the region (Fig. 106.15). An algorithm for considering radiographic evaluation is presented in Figure 106.16. An approach to ordering cervical spine imaging studies is shown in Figure 106.17.

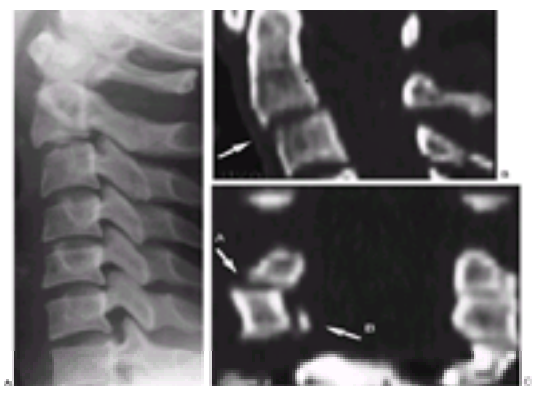

FIGURE 106.15. A. Apparently “normal” lateral cervical spine radiograph (16-year-old patient after motor vehicle accident). **B.** Spiral computed tomography (CT) scan demonstrating dens fracture *(arrow).* **C.** Sagittal view of spiral CT scan demonstrating dens fracture *(arrow A)* and vertebral body avulsion fracture *(arrow B).* The detail demonstrated by the spiral CT scan can help the clinician quickly identify lesions not easily visible or appreciated on conventional radiographs.

FIGURE 106.16. Decision tree for radiographic and clinical evaluation of patient with possible neck injury.

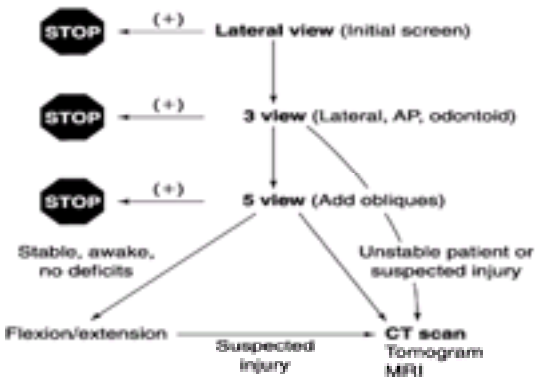

FIGURE 106.17. Approach to ordering cervical spine radiographs. Additional films may not be needed in the acute situation if a fracture or other abnormality is identified. If an abnormality is suspected, but not demonstrated, continue with algorithm as presented.

The cervical spine has anterior (vertebral bodies, intervertebral discs, ligaments) and posterior (lamina, pedicles, neural foramen, spinous processes, ligaments) components (Fig. 106.18). The initial three-view series evaluates the anterior cervical spine well; however, it is not ideal for evaluating the posterior cervical spine. Oblique (pillar) views are helpful in imaging those posterior elements. In practice, however, oblique films rarely add significant information to the initial radiographic assessment. Flexion and extension films are accomplished in an awake patient by having the patient flex and extend the neck as far as possible without discomfort. As the end point involves the sensation of pain, flexion/extension films should not be performed in a patient who has preexisting neck pain. Dynamic fluoroscopy could be substituted in specific instances for flexion/extension films. These studies can help evaluate underlying soft-tissue or ligamentous injury that was not evident on the initial films. These films are often inadequate because the neck muscles have splinted the cervical column into a position of comfort and stability, and alignment does not change with flexion and extension. If a question remains concerning the integrity of the cervical spine after following this radiographic scheme, a CT scan should be considered. Tomograms can also be performed but require patient movement, are time-consuming, and are not performed easily in the acutely ill patient. An MRI should be considered to detect ligamentous, soft-tissue, or subtle cord injuries.

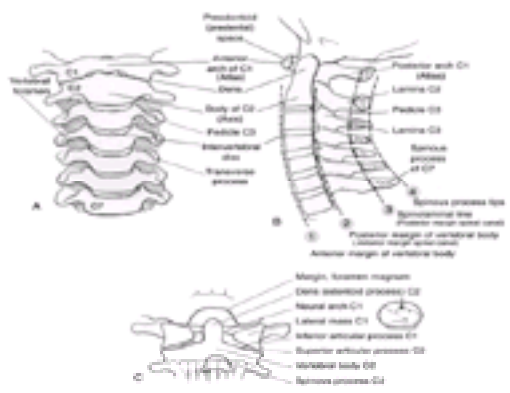

FIGURE 106.18. A–C. Knowledge of normal cervical spine anatomy is useful when evaluating cervical spine radiographs.

A systematic approach should be used when evaluating radiographs of the cervical spine. The ABCS method is a useful approach (Fig. 106.19). Alignment is assessed as demonstrated in Figure 106.20, keeping in mind that the spinal cord lies between the posterior spinal line and the spinolaminal line. These lordotic curves may not be present in children less than 6 years of age, those on hard spine boards or in cervical collars, or those with cervical neck muscle spasm. Gross malalignment should be detectable with this assessment.

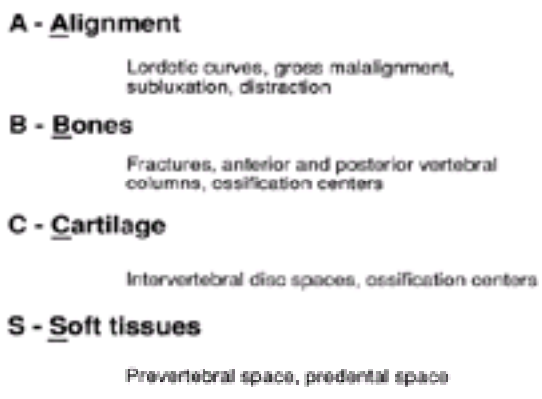

FIGURE 106.19. The ABCS of radiographic cervical spine interpretation.

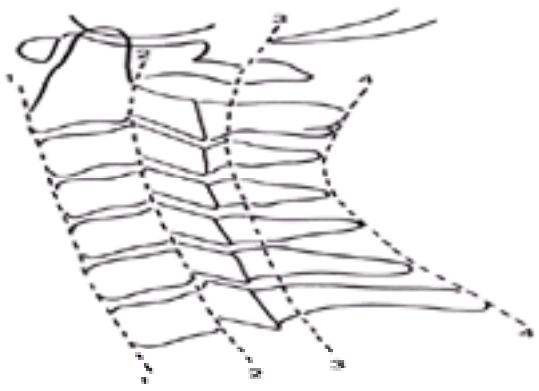

FIGURE 106.20. Four contour lines of alignment with normal cervical spine lordosis: *1,* anterior vertebral bodies; *2,* posterior vertebral bodies (anterior spinal canal); *3,* spinolaminal line (posterior spinal canal); *4,* spinous process tips. (Reprinted with permission from Gerlock A, Kirchner S, Heller R, et al. Advanced Exercises in Diagnostic Radiology: The Cervical Spine in Trauma. Philadelphia: WB Saunders, 1978:6.)

The bones should be evaluated for typical abnormalities, realizing that these may be subtle. The clinician should be aware that structures that overlaythe spine, including the skull and the teeth, may simulate fractures.

The next area of evaluation involves assessing the cartilage. Cartilage is radiolucent on plain radiographs. Children's spinal columns contain significant cartilage that may buffer a traumatic force and help prevent some injuries but that can also make radiographic evaluation challenging. The cartilaginous areas include the synchondroses or growth plates and intervertebral disc spaces (Table 106.8). The growth plates may mimic fractures and may be confusing to those who are unaware of their presence. Growth centers in the anterior-superior vertebral bodies cause a sloped appearance that may appear as a compression fracture to the untrained eye. Vertebral disc abnormalities may indicate specific types of injuries. A vertebral disc space that is narrowed anteriorly may indicate disc extrusion, whereas a widened space suggests a hyperextension injury with posterior ligamentous disruption.

Cartilage artifact
Tapered anterior vertebrae
Apparently absent ring of C-1
Atlas (C-1) body not ossified at birth and may fail to close
Axis (C-2) has four ossification centers
Apex of odontoid ossifies between ages 12 and 15 yr
Spinous process ossification centers
Increased mobility
Pseudosubluxation
C-1 override on dens
Increased predental space (5 mm maximum)
Ligament laxity
Facet joints shallow
Growth plates (synchondrosis)
Dens ossifies between ages 3 and 6 yr (may persist into young adults)
Posterior arch of C-1 ossifies at age 3 yr
Anterior arch of C-1 ossifies at age 6–9 yr
C-1 reaches adult size at 3–4 yr
C-2 through C-7 reach adult size at ages 5–6 yr
Lack of cervical lordosis
Fulcrum varies with age
Soft-tissue variability with respiration
Congenital clefts or other bony abnormalities (ex odontoideum, spondylolisthesis, spina bifida, dysraphism)

Table 106.8. Radiographic Characteristics of the Pediatric Cervical Spine

Soft-tissue evaluation is extremely important. Abnormal soft-tissue spaces may be the only clue to the underlying ligament, cartilage, or subtle bone injury, which may not be obvious on the radiograph. The soft-tissue widening may represent blood or edema, which suggests an underlying injury. The prevertebral space at C-3 should be less than one-half to two-thirds of the AP width of the adjacent vertebral body (Fig. 106.21). This space will double, to approximately the width of the adjacent vertebral body, below C-4 (the level of the glottis) as the usually non–air-filled esophagus is present at this area. Care must be taken when evaluating the prevertebral soft-tissue space because crying, neck flexion, or the expiratory phase of respiration may produce a pseudothickening in the prevertebral space (Fig. 106.22). Soft-tissue abnormality should be reproducible on repeated radiographs if an actual underlying injury exists.

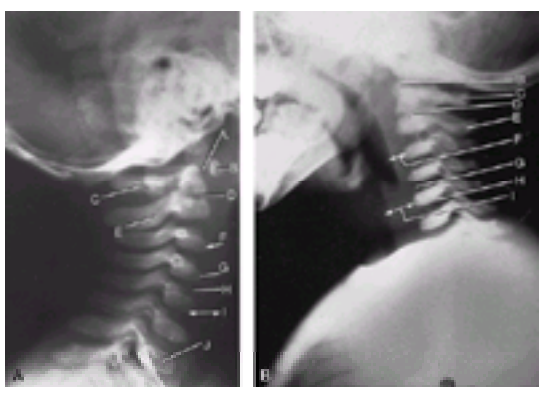

FIGURE 106.21. Normal pediatric lateral cervical spine radiographs. **A.** 3-month-old child. **B.** 20-month-old child. *A,* predental (predontoid) space; *B,* anterior ring of C-1 (note apparent override of C-1 over dens); *C,* posterior ring of C-1; *D,* dens synchondrosis (growth plate); *E,* posterior elements C-2; *F,* normal prevertebral space (C-3 level); *G,* wedged vertebral appearance caused by cartilage artifact; *H,* intervertebral disc space; *I,* Normal prevertebral space below the

glottitis (thickened because of radiopaque collapsed esophagus); *J,* vertebral body C-7.

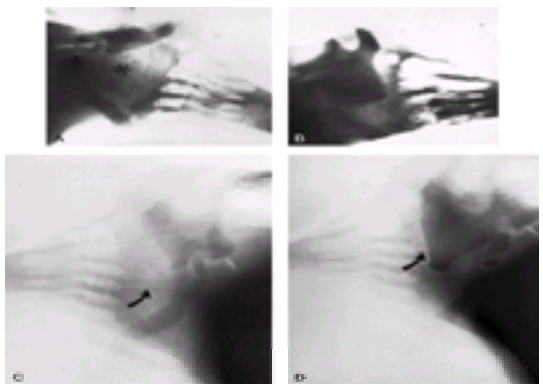

FIGURE 106.22. Effects of inspiration and positioning on prevertebral (retropharyngeal) soft tissues. **A.** Increased prevertebral space with expiration. **B.** Repeat radiograph in same patient during inspiration reveals normal prevertebral space with no suggestion of cervical spine abnormality. **C.** Increased soft-tissue space with expiratory phase of respiration. **D.** Normal soft-tissue space with inspiration in patient **C.** (**A** and **B** reprinted with permission from Harris J, Edeiken-Monroe B. The Radiology of Acute Cervical Spine Trauma. 2nd ed. Baltimore: Williams & Wilkins, 1987:6.)

SPECIFIC INJURIES

The Jefferson fracture is a bursting fracture of the ring of C-1 as a result of an axial load. The axial force compresses the ring of C-1 between the occipital condyles of the skull and the lateral masses of C-2. This reaction can cause an outward burst of C-2, but it rarely causes immediate neurologic impairment because the fracture does not physically impinge on the spinal cord. The radiographic criteria for diagnosis of a Jefferson fracture is lateral offset of the lateral mass of C-1 of greater than 1 mm from the vertebral body of C-2 (Fig. 106.23). Neck rotation may give a false-positive radiograph. These fractures are unstable, however, and require adequate immobilization. Approximately one-third of Jefferson fractures are associated with other cervical spine fractures, most often involving C-2. The clinician must be aware of the pseudo-Jefferson fracture of childhood, which is present in 90% of children at the age of 2 years and usually normalizes by age 4 to 6 years. The pseudo-Jefferson fracture has the radiographic appearance of a Jefferson fracture because of increased growth of the atlas (C-1) compared with the axis (C-2) and radiolucent cartilage artifact. This disorder can present with unilateral or bilateral lateral mass offset. If a Jefferson fracture is suspected by radiographic findings and mechanism of injury in a child less than 4 years of age, a CT scan may be necessary to further elucidate the suspected injury (Fig. 106.15).

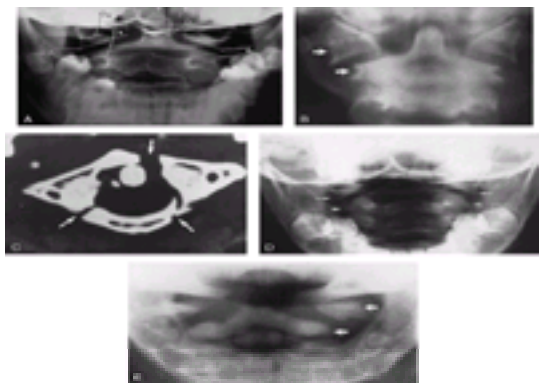

FIGURE 106.23. A. Normal anteroposterior (AP) (open-mouth, odontoid) view of C-1 and C-2. *C_1,* first cervical vertebra (lateral mass); *C_2,* second cervical vertebra; *T,* central incisors overlying dens *(D);A,* normal relationship between lateral mass of C-1 and vertebral body of C-2. **B.** Jefferson fracture in AP view. Note lateral offset of C-1 on C-2. **C.** Jefferson fracture. Computed tomography coronal view. Note three distinct fractures and bursting nature of injury. **D.** Pseudo-Jefferson fracture of childhood in a 3-year-old child because of disparate growth of C-1 and C-2 and cartilage artifact. **E.** Pseudo-Jefferson fracture demonstrating marked offset of the lateral masses of C-1 on C-2. (**B** and **C** reprinted with permission from Swischuk L. Emergency Radiology of the Acutely Ill or Injury Child. 2nd ed. Baltimore: Williams & Wilkins, 1986:591; **D** reprinted with permission from Aslamy W, Danielson K, Hessel S, et al. A 3-year old boy with neck pain after motor-vehicle accident. West Med J 1991;155:301–302.)

The hangman's fracture is a traumatic spondylolisthesis of C-2. This injury occurs as a result of hyperextension, which fractures the posterior elements of C-2. Hyperflexion, with resultant ligamentous damage, may follow the hyperextension or may lead to anterior subluxation of C-2 on C-3 and subsequent damage of the cervical cord (Fig. 106.24). The subluxation associated with a hangman's fracture can sometimes be mistaken for the normal or physiologic subluxation that exists in the C2–C3 or C3–C4 region in approximately 25% of children less than the age of 8 years; it also may be seen up to the age of 16. This pseudosubluxation is caused by ligamentous laxity, relatively horizontal facet joints, weak neck muscles, and cartilage artifact. Distinguishing between a subtle hangman's fracture and pseudosubluxation can be accomplished using Swischuk's “posterior cervical line” as described in Figure 106.25. A value of more than 1.5 to 2 mm suggests an occult hangman's fracture as the source of the anterior subluxation of C-2 on C-3. The increase in

magnitude of the distance between the cortex of the spinous process of C-2 and the posterior cervical line in a hangman's fracture is the result of anterior displacement of the skull, C-1 and the anterior portion of C-2 on the remainder of the lower cervical spine.

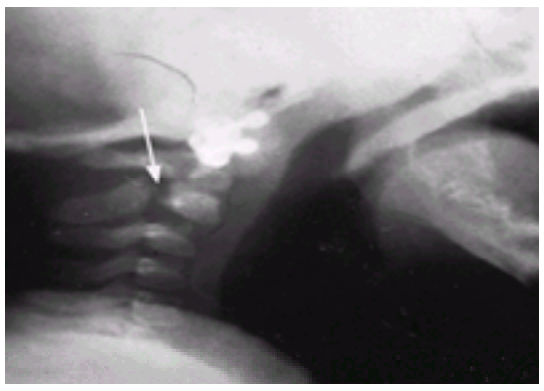

FIGURE 106.24. Hangman's fracture. A 7-week-old infant with fracture through the posterior elements of C-2 as indicated by the *arrow.* (Reprinted with permission from Sumchai A, Sternback G. Hangman's fracture in a 7-week-old infant. Ann Emerg Med 1991;20:87.)

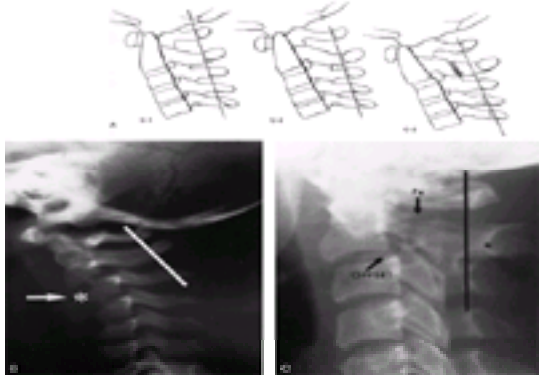

FIGURE 106.25. A. Posterior cervical line of Swischuk. Line is drawn from the cortex of the spinous process of C-1 to the cortex of the spinous process of C-3. Relationship of the line to cortex of the spinous process of C-2 is noted. If the line is situated more than 2.0 mm anterior to the cortex of the spinous process of C-2, underlying cervical pathology should be present. This line should only be used with anterior displacement of C-2 on C-3. **B.** Pseudosubluxation of C-2 on C-3 with normal posterior cervical line in a 2-year-old child. Note apparent widening of prevertebral soft tissue. **C.** Abnormal posterior cervical line with underlying hangman's fracture. Actual offset is 4 mm (**C** reprinted with permission from Swischuk L. Emergency Radiology of the Acutely Ill or Injured Child. 2nd ed. Baltimore: Williams & Wilkins, 1986:562–563.)

Atlantoaxial (AA) subluxation is a result of movement between C-1 and C-2 secondary to transverse ligament rupture or a fractured dens (Fig. 106.26). Ligament instability may be precipitated by tonsillitis, cervical adenitis, pharyngitis, arthritis, or connective tissue disorders. It is also well described in patients with Down syndrome. Approximately 15% of patients with Down syndrome have radiographically demonstrated AA subluxation and therefore should be discouraged from contact sports. The presence or absence of AA subluxation in patients with Down syndrome, once thought to be a static phenomenon, may actually be transient and/or progressive. This ligament instability may progress to ligament rupture with minor trauma. Subluxation caused by a transverse ligament disruption is evidenced by a widened predental (preodontoid, atlantodental interval) space on a lateral radiograph (Fig. 106.26). Normal predental measurement in children is less than 5 mm, compared with less than 3 mm in adults. This space is wider in children than in adults for the same reasons described with pseudosubluxation. Steele's rule of three states that the area within the ring of C-1 consists of one-third odontoid, one-third spinal cord, and one-third connective tissue (Fig. 106.27). Therefore, limited space is available for dens movement or predental space widening without neurologic compromise. Neurologic symptoms often are not seen until the predental space exceeds 7 to 10 mm. A dens fracture is the cause of AA subluxation more often than ligamentous disruption in a young child because the weakest part of the musculoskeletal system in a child is the osseus component (Fig. 106.26). Several case reports describe odontoid fractures in children facing forward in car seats as a result of rapid stops. These fractures may traverse the growth plate in the young child, although the clinician must be careful not to overcall fractures because of the presence of a growth plate. Neurologic damage can occur from direct spinal cord injury or secondarily from vertebral artery damage.

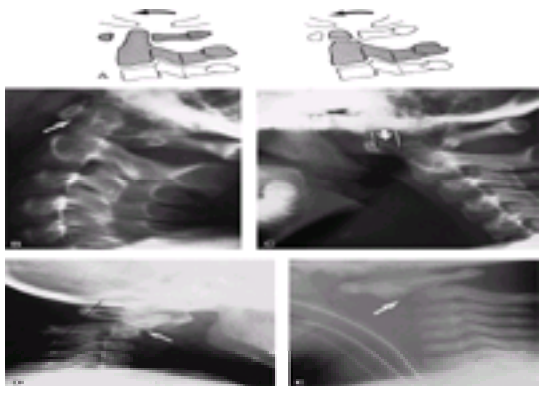

FIGURE 106.26. A. Diagrammatic representation of transverse ligament disruption *(left)* and dens fracture *(right).* **B.** Widened predental space on initial lateral radiograph in 15-year-old girl (actual measurement was 4 mm). **C.** Flexion radiograph in same patient demonstrating increased predental space with evidence of transverse ligament disruption. (**A** used with permission from Swischuk L. Emergency Radiology of the Acutely Ill or Injured Child. 2nd ed. Baltimore: Williams & Wilkins, 1986:572.) **D.** Dens fracture with anterior subluxation of C-1 and the dens on the remainder of the spinal column. *Arrow* indicates fracture. Abnormal posterior cervical line is also shown. **E.** Dens fracture *(arrow)* with anterior subluxation of the dens on the body of C-2.

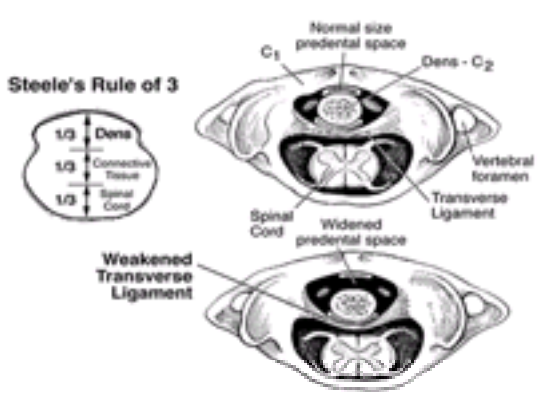

FIGURE 106.27. A cross section through the ring of C1 demonstrates Steele's rule of three. The space between the cervical cord and dens allows limited movement between C1 and C2 without immediate neurologic compromise.

Cervical distraction injuries may result from rapid acceleration- or deceleration-type incidents, such as high-speed motor vehicle or pedestrian accidents (Fig. 106.28). An injury that was incompatible with long-term survival, but for which initial cardiopulmonary resuscitation was successful, is shown in Figure 106.28A. These injuries may be obvious or subtle on the lateral radiograph. Measurements for potential distraction injuries include the atlanto-occipital and C1/C2 interspinous distances. The atlanto-occipital distance should not exceed 5 mm. The C1/C2 interspinous distance should not exceed 10 mm. A ratio of measurements of the basion to the posterior arch of C1 (BC) and the opisthion to the anterior arch of C1(OA) is demonstrated in Figure 106.29. If the BC:OA ratio is greater than 1, it signifies atlanto-occipital dislocation. Atlanto-occipital dislocation is often fatal, but there are reports of survivors. Neurologic deficits may develop from direct spinal damage or associated carotid or vertebral artery injury. Distraction injuries may also be seen with difficult newborn deliveries. These injuries may not be visible on a plain radiograph because the pediatric cervical spine can transiently distract 2 inches before residual radiographic evidence of spinal column separation is present. However, the spinal cord can distract only one-quarter inch before permanent neurologic damage occurs. An MRI scan is useful in assessing an infant with diminished motor activity who is suspected of having a distraction injury.

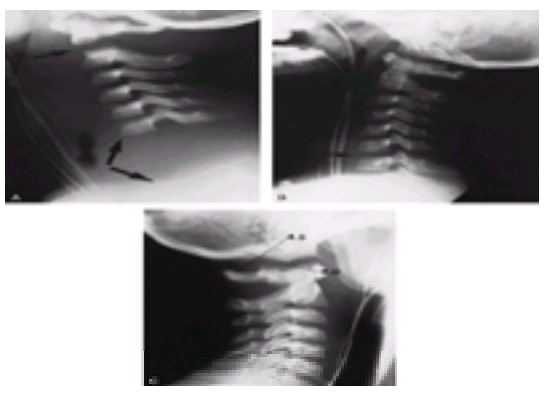

FIGURE 106.28. Distraction injuries. **A.** Dens fractures with distraction and accompanying C6–C7 distraction injury in 3-year-old child. Injury was fatal. **B.** C6–C7 distraction injury in 8-year-old child. **C.** BC:AO ratio is greater than 1.0, suggesting atlanto-occipital dislocation (see also Fig. 106.29).

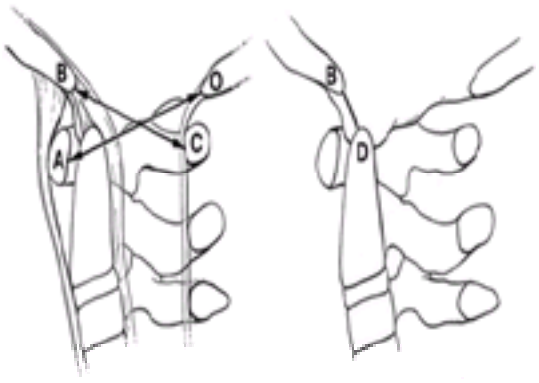

FIGURE 106.29. Examples of methods to assess occipatal/C1 relationships. *A,* C1 anterior arch; *B,* basion (anterior margin of foramen magnum); *C,* anterior portion of the posterior ring of C1; *O,* opisthion (posterior margin of foramen magnum); *D,* tip of the dens (odontoid process). These landmarks may not be easily visible on all radiographs. A BC:AO ratio of greater than 0.9 to 1.0 suggests anterior dislocation or subluxation of the atlanto-occipital joint. A BD distance of greater than 10 to 12.5 mm should be viewed as suspicious for atlanto-occipital dislocation.

Vertebral compression injuries are suggested by isolated anterior wedging, teardrop fractures, or burst vertebral bodies (Fig. 106.30). The vertebral bodies should be regular, cuboid, and consistent between adjacent cervical levels (Fig. 106.30). A flexion/rotation stress can lead to anterior subluxation of one vertebral body on another with facet dislocation ("locked" or "jumped" facet) (Fig. 106.31). If the anterior displacement is less than 50% of the vertebral body width, it is consistent with a unilateral facet dislocation (Fig. 106.31). More than a 50% anterior subluxation suggests a bilateral facet dislocation (Fig. 106.31). These injuries are often accompanied by widened interspinous and interlaminar spaces, anterior soft-tissue swelling, and a narrowed disc space.

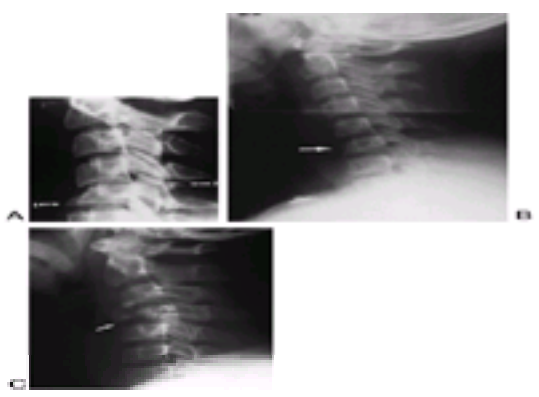

FIGURE 106.30. Examples of cervical compression injuries. **A.** Teardrop fracture. This patient sustained a whiplash injury with resultant flexion injury. A typical flexion teardrop fracture is demonstrated at *(1). (2)* demonstrates an increased interspinous distance and an associated avulsion fracture of the posterior elements of C5. **B.** Anterior C6 vertebral wedge fracture. (**A** reprinted with permission from Swischuk L. Emergency Radiology of the Acutely Ill or Injured Child. 2nd ed. Baltimore: Williams & Wilkins, 1986:674.) **C.** Burst fracture of C4 vertebral body.

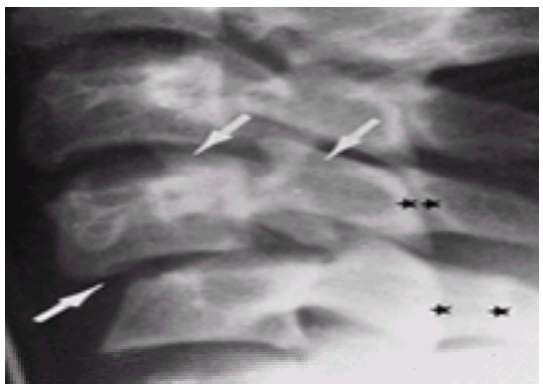

FIGURE 106.31. Unilateral facet dislocation. C4 is offset anteriorly on C5 less than 50% of the width of the vertebral body. *Arrows* denote the offset of vertebral body and apophyseal joints. The disc space between C4 and C5 is narrowed. Note that the distance between the posterior cortex of the apophyseal joint facet and the anterior cortex of the spinous process tip is wider below the level of dislocation than above the level *(stars).* Anterior vertebral offset of more than 50% would denote a bilateral facet dislocation. (Reprinted with permission from Swischuk L. Emergency Radiology of the Acutely Ill or Injured Child. 2nd ed. Baltimore: Williams & Wilkins, 1986:697.)

SCIWORA has been described as occurring in up to 67% of children with cervical cord injuries (Fig. 106.32). SCIWORA probably accounts for about 25% of cervical cord injuries in children less than 8 years of age. These injuries mainly occur in children less than 8 years of age who present with or develop symptoms consistent with cervical cord injuries without any radiographic or tomographic evidence of bony abnormality. SCIWORA is not often seen in the older population (older than age 8) because the forces necessary to injury the spinal cord also cause persistent spinal abnormalities. The young

child's elastic spinal column allows the spine to deform beyond physiologic extremes, injuring the cord, then reducing spontaneously without any persistent (radiographic) evidence of bony injury. The causes of the neurologic compromise can include vascular injury (occlusion, spasm, infarction), ligamentous injury, disc impingement, or incomplete neuronal destruction. A subset of patients have initial transient neurologic symptoms as previously described, apparently recover, and then return an average of 1 day later with significant neurologic abnormalities. Therefore, many authors recommend hospitalization and immobilization for young patients who have a history of transient neurologic symptoms. At the least, neurologic consultation is recommended if the history suggests a SCIWORA-type injury in a child less than 8 years of age.

FIGURE 106.32. Magnetic resonance imaging (MRI) of SCIWORA patient. Accompanying cervical spine radiographs were normal. The MRI demonstrates an area of cord contusion in the midcervical area. This patient had physical evidence of a central cord syndrome. (Reprinted with permission from Swischuk L. Emergency Radiology of the Acutely Ill or Injured Child. 2nd ed. Baltimore: Williams & Wilkins, 1986:710.)

Torticollis (wry neck) is a common complaint in the pediatric ED. The clinician should always inquire about traumatic causes because an underlying bone injury may be present. Often, however, torticollis is caused by spasm of the sternocleidomastoid (SCM) muscle. The patient with muscular torticollis has muscle spasm of the SCM on the opposite side that the chin points because the cause of torticollis is muscular spasm. This condition is opposite from rotary subluxation. Rotary subluxation is a cervical spine injury that is often misdiagnosed or undiagnosed because of difficulty in interpreting these patient's radiographs. Rotary subluxation or displacement may be spontaneous or may follow an upper respiratory infection or minor or major trauma. These patients rarely present with abnormal neurologic findings. They will assume the typical (cockrobin) position with the muscle spasm of the SCM on the same side as the chin points. This reaction is logical considering that the SCM is attempting to reestablish normal neck position. Radiographs may be useful to help distinguish between muscular torticollis and rotary subluxation, although the radiographs may be normal in both cases (Fig. 106.33 and Fig. 106.34). Rotary subluxation should be suspected if, on an open-mouth radiograph, one of the lateral masses of C-1 appears forward and closer to the midline, while the opposite lateral mass appears narrow and away from the midline (lateral offset), although a normal film does not rule out rotary subluxation. Cineradiography can demonstrate that C1-2 moves as a unit; however, the CT scan appears to be the most useful diagnostic tool in rotary subluxation (Fig. 106.34). Patients with mild rotary subluxation should be treated with a cervical collar and analgesia for comfort, whereas those with moderate or resilient rotary displacement may need immobilization and traction. If anterior displacement of C-2 on C-1 is present, longer immobilization may be needed to allow injured ligaments to heal.

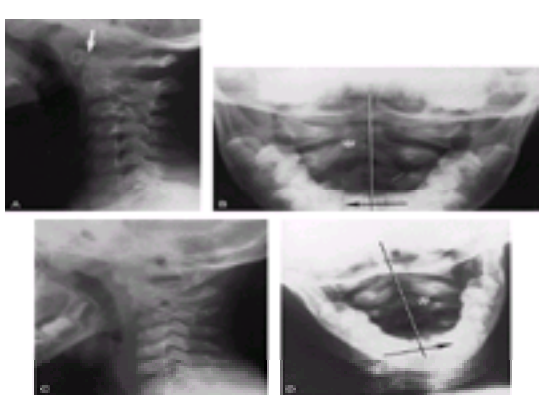

FIGURE 106.33. Torticollis (wryneck). **A.** Lateral cervical radiograph with C-2 cocked forward on C-3 and normal predental space *(arrow).* **B.** Anteroposterior (AP) view demonstrating spinous process of C-2 *(*)* on the same side of the midline as the mandible points. **C.** Difficult to interpret lateral cervical spine because of the rotation effect of torticollis. **D.** AP view demonstrating spinous process of C-2 *(*)* on the same side of the midline as the mandible points. (Reprinted with permission from Swischuk L. Emergency Radiology of the Acutely Ill or Injured Child. 2nd ed. Baltimore: Williams & Wilkins, 1986:588.)

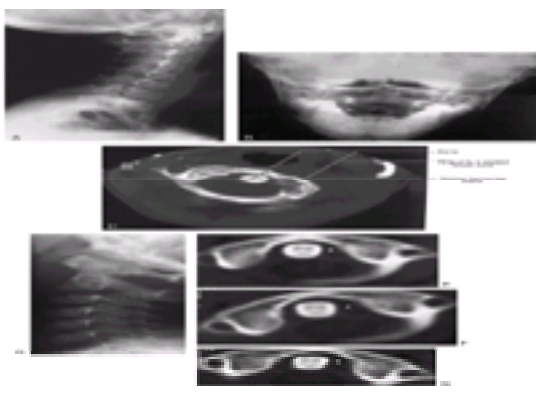

FIGURE 106.34. Rotary subluxation of C-1 and C-2. **A.** Grossly normal lateral neck radiograph in an 8-year-old child with rotary subluxation. **B.** Grossly normal open-mouth (odontoid) radiograph in an 8-year-old child with rotary subluxation. **C.** Compute tomography (CT) scan demonstrating marked rotary subluxation of C-1 clockwise around dens. Actual measurement was 22 degrees of rotation. **D–G.** CT evidence of fixed rotary subluxation in a 6-year-old child. **D.** Lateral radiograph demonstrating mild increased distance of predental space. **E.** Axial CT scan demonstrating increased distance between dens and patient's left side of C1 (asymmetry between right and left sides). **F.** Axial CT scan with patient's head turned to the right, demonstrating asymmetry between the dens and ring of C1. **G.** Axial CT scan with patient's head turned to the left, again demonstrating fixed asymmetry between the dens and the ring of C1.

Several specific spinal cord syndromes may be encountered in the ED (Fig. 106.35). A spinal cord concussion (transient traumatic paralysis) involves neurologic symptoms that completely resolve over a short period. This condition can occur with or without associated fracture or dislocation. A complete cord transection (either mechanical or physiologic) results in immediate and permanent loss of all neurologic function distal to that level (Fig. 106.35). The anterior spinal artery (anterior cord) syndrome results from loss of neurologic function in those areas supplied by the anterior spinal artery (Fig. 106.35). Motor function is lost below the level of the lesion. Touch and proprioceptive functions, carried by the dorsal (posterior) columns, are preserved. The posterior cord syndrome is rare (Fig. 106.35). It involves loss of proprioceptive functions, deep pressure and pain and vibratory sense, with preservation of motor and temperature sensation. This can occur with direct posterior cord trauma or posterior spinal artery involvement. The Brown-Sequard syndrome (hemisection of the cord) involves contralateral loss of pain and temperature sensation with ipsilateral motor findings (weakness or paralysis) below the lesion (Fig. 106.35). The central cord syndrome signifies an injury that is most severe in the center of the cord and less so toward the periphery (Fig. 106.35). The resultant physical examination demonstrates motor strength that is more severely affected in the arms than in the legs. These designations are useful in suggesting prognosis. Approximately two-thirds of those patients with central cord syndrome and one-third of those with Brown-Sequard recover, whereas complete transections and anterior spinal artery syndrome usually signify nonreversible lesions. Patients with posterior cord syndrome usually recover but may demonstrate some degree of ataxia.

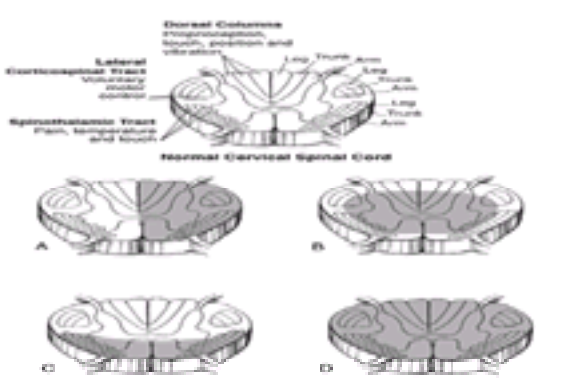

FIGURE 106.35. Graphic illustrations of a normal cervical spinal cord and specific postinjury syndromes. **A.** Brown-Sequard syndrome. **B.** Central cord syndrome. **C.** Anterior artery syndrome. **D.** Complete transection.

The os odontoideum is an abnormality that may be the result of an occult flexion injury with a subsequent incomplete healing and bone resorption (Fig. 106.36). It may also represent an overgrowth of the ossiculum terminale, often associated with a hypoplastic dens. This leads to a risk of increased mobility and cord injury at the C1/C2 level and may require surgical stabilization. This condition can be confused with a fracture at the base of the odontoid. The ossiculum terminale is a small ossicle at the tip of the dens (Fig. 106.37). It is seen in most children, fusing with the rest of the dens by adolescence. This ossicle can be large and associated with a hypoplastic dens, as previously described.

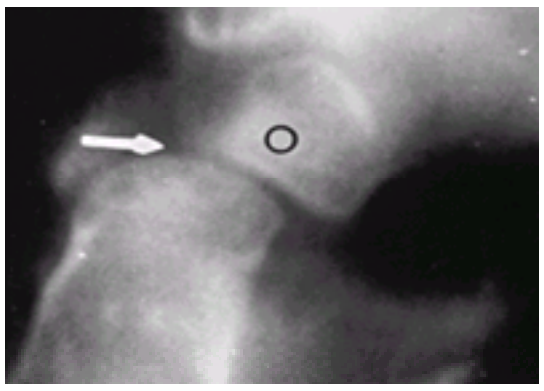

FIGURE 106.36. Example of os odontoideum. Note the hypoplastic dens and overgrown ossiculum terminale or ossiculum odontoideum *(O).* The *arrow* indicates posterior displacement, attesting to instability of the lesions. (Reprinted with permission from Swischuk L. Emergency Radiology of the Acutely Ill or Injured Child. 2nd ed. Baltimore: Williams & Wilkins, 1986:717.)

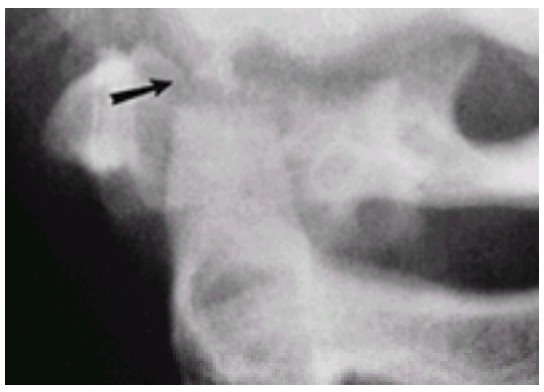

FIGURE 106.37. Normal ossiculum terminale at the tip of the dens *(arrow).* (Reprinted with permission from Swischuk L. Emergency Radiology of the Acutely Ill or Injured Child. 2nd ed. Baltimore: Williams & Wilkins, 1986:717.)

Spinal epidural hematomas are also seen in the pediatric population. These hematomas are venous bleeds that compress the adjacent spinal cord and present hours or days after apparently minor trauma, with ascending neurologic symptoms as the bleed progresses. The MRI scan can be helpful in evaluating these patients (Fig. 106.38). Rapid evaluation and surgical decompression are mandatory.

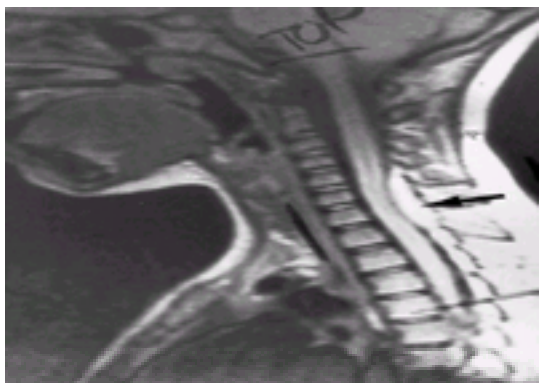

FIGURE 106.38. Magnetic resonance imaging (MRI) of cervical spine demonstrating epidural hematoma *(arrow)* from C-5 to T-1. Note excellent soft tissue, intervertebral disc, and fluid detail afforded by the MRI scan.

Treatment of children with suspected cervical spine injuries involves basic and advanced life support measures, initiation and/or maintenance of immobilization, neurosurgical consultation, and consideration of pharmacologic treatment. Airway support for patients with traumatic quadriplegia should be considered because they will develop respiratory embarrassment as they tire. Children may present in spinal shock (hypotension, bradycardia, peripheral flush) from the loss of sympathetic input to the vascular system. The physical examination may be misleading in that these patients are bradycardic (unable to mount tachycardic response to relative hypovolemia) and demonstrate warm, flushed skin (loss of vasomotor tone). These symptoms may also be superimposed upon traumatic (hypovolemic) shock.

These patients need fluid resuscitation and may require inotropic support such as dopamine to maintain adequate perfusion and to avoid fluid overload. Appropriate fluid management is important in preventing hypoperfusion of the already injured spinal cord. Recent investigations suggests that methylprednisolone (Solu-Medrol) in a dosage of 30 mg/kg over 15 minutes followed by 5.4 mg/kg per hour for 24 to 48 hours may improve functional outcome in patients with spinal cord injury. Although these studies specifically excluded children less than 13 years of age, the medication may be helpful for younger patients. Methylprednisolone appears to be most effective if administered as soon as possible after the injury and maintained for 24 to 48 hours depending on the time of initiation (Table 106.9). If started within 3 hours, it should be maintained for 24 hours. If started between 3 to 8 hours after the injury, continuation for 48 hours is

recommended. Methylprednisolone is not recommended in conjunction with penetrating neck injuries.

Time after Injury	0–3 hrs	3–8 hrs	>8 hrs
Initial IV dosage	30 mg/kg (over 15 mins)	30 mg/kg (over 15 mins)	Efficacy not demonstrated
Maintenance IV dosage	5.4 mg/kg/hr	5.4 mg/kg/hr	
Suggested duration	24 hrs	48 hrs

CHAPTER 107

Thoracic Trauma

HOWARD KADISH, MD

Department of Pediatrics, University of Utah School of Medicine, and Emergency Department, Primary Children's Medical Center, Salt Lake City, Utah

Thoracic trauma in the pediatric population is relatively uncommon and only in the last two decades has it received careful scrutiny. Included in thoracic trauma are injuries to the chest wall, trachea, bronchi, lungs, heart, thoracic aorta and great vessels, esophagus, and diaphragm. The report of the National Pediatric Trauma Registry contains a detailed analysis of major thoracic trauma in children. In the United States, only 4 to 6% of children admitted to pediatric trauma centers have thoracic injuries, but because severe injuries to vital thoracic organs produce profound physiologic disturbances, many patients die at the scene and never reach a hospital. In patients who reach the hospital, most thoracic injuries do not require operative intervention other than tube thoracostomy.

When thoracic trauma occurs in isolation, the mortality rate is relatively low. The mortality rate triples when thoracic trauma occurs concurrently with head or abdominal trauma. In one study, 82% of patients with thoracic trauma had a multisystem injury and 58% of those patients had a concomitant head injury. In the same study, children with thoracic trauma had a lower mean trauma score and a higher mean injury severity score. Mortality rates were 20 times higher for children with thoracic involvement than for those without. Most scene fatalities result from lacerations of the lung, heart, blood vessels, and bronchi. In the hospital, cardiac tamponade, injuries to the aorta and great vessels, and tension hemothorax or pneumothorax have the greatest potential for death.

Similar to other types of pediatric trauma, blunt thoracic injuries are more common than penetrating. Motor vehicle–related accidents account for at least 75% of all blunt thoracic injuries. Other common mechanisms include falls, assaults, and bicycle accidents. Penetrating wounds occur in approximately 15% of children sustaining major thoracic trauma. Gunshot wounds followed by stab wounds are the most common mechanism of penetrating thoracic trauma, although the mechanism varies with geographic location.

The most common injuries in blunt thoracic trauma include lung contusions (53%), pneumothorax or hemothorax (38%), and fractures (38%). Pneumothorax or hemothorax (64%) occur more often in penetrating thoracic trauma, and diaphragmatic (15%), cardiac (13%), and vascular injuries (10%) are also common in penetrating thoracic trauma.

PATHOPHYSIOLOGY

Children with thoracic trauma may present in respiratory or circulatory failure. Children in respiratory failure, which is more common than circulatory failure, may present with tachypnea, chest wall retractions, and agitation secondary to hypoxia.

Respiratory Failure

Because approximately 80% of thoracic trauma occurs as part of a multisystem injury, the most common cause of respiratory failure is neurologic compromise. If left untreated, patients develop anoxic brain injury and respiratory

acidosis caused by hypercarbia. Immediate control of the airway with positive-pressure ventilation followed by treatment of the neurologic emergency is indicated.

Airway obstruction, external compression of the pulmonary structures, direct injury to the pulmonary parenchyma, and chest wall injuries, all caused by thoracic trauma, also affect oxygenation and ventilation if left untreated.

Airway Obstruction

Blood, vomitus, or foreign bodies (teeth) may obstruct the airway. Failure to remove or bypass the foreign body leads to hypoxia and anoxic brain injury. Initial treatment includes repositioning and suctioning of the airway along with cervical spine immobilization. If initial treatment fails, endotracheal intubation is indicated. If the endotracheal tube cannot bypass the obstruction, a cricothyroidotomy or surgical tracheostomy should be performed.

External Compression of the Pulmonary Structures

External compression of the lungs, most commonly caused by air or blood within the pleural cavity, causes respiratory distress. Patients may initially present with tachypnea, retractions, and hypoxia. As more lung segments are involved, ventilation is affected and the carbon dioxide begins to rise. Tube thoracostomy is the preferred treatment for a pneumothorax or hemothorax.

Diaphragmatic hernia and gastric dilation can also cause respiratory distress by external compression of the lungs. Patients with a diaphragmatic hernia need prompt surgical intervention. A nasogastric or oral gastric tube helps decompress the stomach and decreases the likelihood of the patient aspirating vomit or swallowing blood.

Pulmonary Parenchyma Injury

Aspiration of blood or vomitus into the terminal bronchi and alveoli causes chemical pneumonitis. Direct trauma to the lung parenchyma (pulmonary contusion) also causes a leakage of blood and fluid into the alveolar space. Both of these injuries cause shunting of deoxygenated blood into the systemic circulation. Endotracheal intubation with positive-pressure ventilation is indicated if the patient's respiratory status worsens. Patients with severe chemical pneumonitis or pulmonary contusion may require high inflation pressures to maintain adequate oxygenation. These patients are at risk for pneumothorax because of high inflation pressures coupled with an already injured lung.

Although not as common as chemical pneumonitis or pulmonary contusion, penetrating thoracic trauma causes direct pulmonary parenchymal damage but is usually associated with a hemothorax or pneumothorax.

Chest Wall Injuries

Chest wall injuries, such as rib fractures or a flail chest, may cause hypoventilation as well as hypoxia secondary to pain and inadequate air exchange. Endotracheal intubation with positive-pressure ventilation is the preferred treatment in those patients with rising carbon dioxide levels or severe hypoxia.

Circulatory Failure

Thoracic hemorrhage, obstruction of venous return to the heart, or direct cardiac injury can cause circulatory compromise and shock.

Thoracic Hemorrhage

Laceration of the hilum of the lung, a great vessel, or the heart itself causes a significant amount of bleeding. Patients can hemorrhage more than 50% of total blood volume into the pleural cavity. The compensatory mechanisms to the blood loss include an increase in both the heart rate and total peripheral vascular resistance. Relying solely on the systemic blood pressure in children may be deceiving because children may lose up to 25% of their total blood volume before their systemic blood pressure decreases. Children may have a normal blood pressure but be tachycardic and poorly perfused with a prolonged capillary refill time. Therapy should be initiated before the occurrence of hypotension. Treatment includes fluid resuscitation, blood transfusion, and surgical repair if the patient continues to require multiple blood transfusions.

Obstruction of Venous Return to the Heart

A tension pneumothorax or hemothorax occurs when air or blood progressively accumulates within the pleural cavity, which causes a shift of the mediastinal structures to the contralateral side. Venous return to the heart is reduced because the inferior vena cava is relatively fixed and becomes obstructed. As diastolic filling decreases, the stroke volume of the heart drops. Patients with a tension pneumothorax or hemothorax are tachycardic and peripherally vasoconstricted, and if left untreated, develop shock. Initial treatment consists of needle decompression. If a tension pneumothorax is present, an immediate release of air should be noted and the patient's hemodynamic status should improve. Needle decompression is only a temporizing measure and must be followed by tube thoracotomy.

Direct Injury to the Heart

Myocardial contusion, ventricular or atrial rupture, and valvular disruption all may produce cardiogenic shock. Circulatory compromise results from a reduction in cardiac output, usually from a decrease in myocardial contractility. Patients may present in congestive heart failure with an enlarged liver, gallop heard on cardiac examination, and rales. Transesophageal echocardiography is helpful in identifying the type of injury. Positive inotropic agents are the preferred

drugs for improving myocardial contractility.

Pericardial tamponade, resulting from air or blood inside the pericardium, also decreases cardiac output and causes circulatory collapse. If a patient is decompensating and a pericardial tamponade is suspected, a pericardiocentesis should be performed.

DIFFERENCES BETWEEN CHILDREN AND ADULTS

Pediatric thoracic trauma differs from adult thoracic trauma in the mechanism, type of injury, and extent of involvement of other organ systems.

Falls are the most common mechanism in the infant and child. Older children are often injured as pedestrians or as unrestrained passengers in motor vehicle accidents. Adolescents are more likely to be involved as occupants in motor vehicle–related accidents. Penetrating injuries secondary to violence are more common in the adolescent population.

Lung contusion is the most common pediatric thoracic injury, with intrapleural injury second. Lacerations of the heart, great vessels, and lungs are relatively uncommon, occurring in less than 10% of thoracic trauma cases. A multicenter study of adults sustaining thoracic trauma showed that 50% had a chest wall injury and that a flail chest injury occurred in 5% of those with chest wall injuries. Injuries to the lung parenchyma occurred in 26% of patients. Simple rib fractures are the most common type of thoracic injury in adults. Only 30% of pediatric patients, compared with 50 to 75% of adults, sustain rib fractures because of increased compliance in the pediatric thoracic cage secondary to the increased cartilage content and the greater elasticity of the bones. Because of this increased compliance, kinetic energy is transferred more readily to the underlying organs. Thus, a pediatric patient may have an internal injury (lung contusion) without external evidence of trauma (e.g., rib fracture, laceration, bruising). Air or fluid within the pleural space (pneumothorax or hemothorax) more easily displace the mediastinum compromising venous return and cardiac output in children (Fig. 107.1). Adults tolerate greater mediastinal shift and compromised venous return than do pediatric patients. The internal diameter of the pediatric trachea is smaller than the adult trachea (Fig. 107.2). At rest, resistance to air flow is inversely proportional to the fourth power of the airway radius; therefore, any small amount of obstruction secondary to blood, secretions, or edema in children can cause significant respiratory distress and hypoxia. With agitation, air flow becomes turbulent and resistance to air flow increases is inversely proportional to the fifth power of the airway radius. Thus, pediatric patients with respiratory distress must be kept calm and quiet. Younger children are also more sensitive to hypoxia and may develop a reflex bradycardia or asystole.

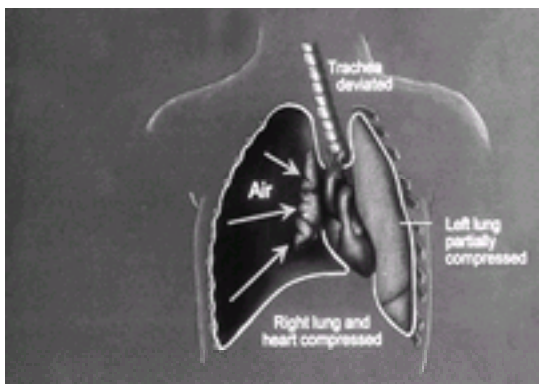

FIGURE 107.1. Tension pneumothorax with a mediastinal shift. *Please see the color-tip insert (Color Plate 107.1).*

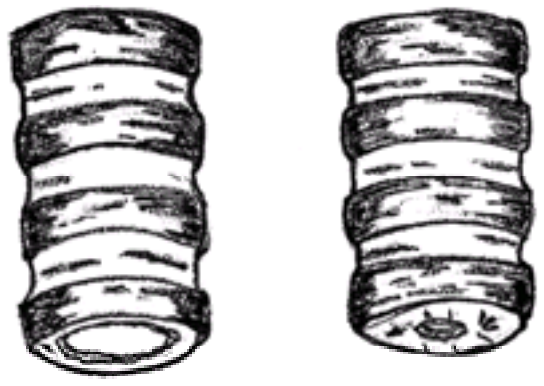

FIGURE 107.2. With swelling or edema, the internal diameter of a pediatric trachea **(A)** is much more compromised than the internal diameter of an adult trachea **(B).**

Because approximately 80% of thoracic trauma occurs as part of a multisystem injury, the physician must also consider head, neck, and intra-abdominal injuries when treating children with chest trauma. Thoracic trauma is routinely associated with abdominal trauma in children because the chest and abdominal cavities lie in close proximity (Fig. 107.3). Gastric distension may also impede pulmonary function, and a nasal or oral gastric tube may relieve this distension (Fig. 107.4).

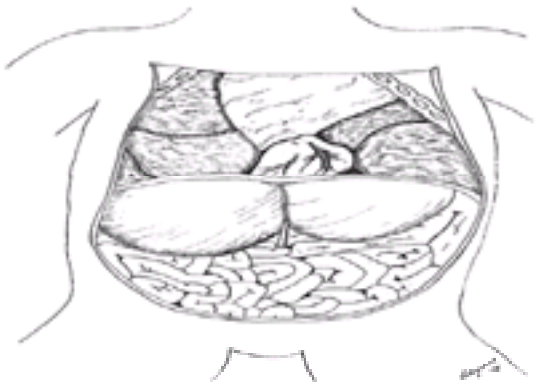

FIGURE 107.3. Drawing demonstrating the close proximity of the chest and abdominal cavities in the pediatric patient.

FIGURE 107.4. Radiograph of a patient with gastric distension. The patient's respiratory distress resolved once a nasogastric tube was inserted.

Mortality in thoracic trauma significantly increases with each organ system involved. Children with an isolated chest injury have a mortality rate of 5%. Children with chest and abdominal injuries have a mortality rate of 20%. The mortality rate increases to 35% in children with head and chest trauma, with more than 50% of those patients dying from their head injuries. In an adult study, 43% of patients with thoracic trauma had a concomitant head injury, but the overall mortality was only 15.5%. Children have a higher incidence of head trauma; therefore, the probability of survival in a pediatric patient with thoracic trauma is lower compared with an adult thoracic trauma patient.

Thermoregulation is a concern in the small child. The pediatric patient can lose significant heat and become hypothermic secondary to large surface area compared to small mass. Because most trauma patients need to be undressed and exposed, heating lights, warm fluids, and warming mattresses can all help stabilize the patient's body temperature.

Finally, the developmental stages of the pediatric patient must be taken into account in the evaluation of thoracic trauma. Younger children are unable to communicate effectively. They may be tachycardic and tachypneic from the injury itself or because they are frightened. Agitation may worsen an already compromised respiratory status. Inclusion of parents during evaluation and treatment is helpful in calming and reassuring children.

CLINICAL MANIFESTATIONS AND EVALUATION

Injuries to the chest can be divided into four main categories: 1) pulmonary, 2) cardiac, 3) vascular (great vessel), and 4) other intrathoracic injuries. Pulmonary injuries are the most common. Cardiac and vascular injuries are less common but have a higher mortality rate.

Pulmonary Injuries

Pulmonary injuries consist of contusion, laceration, pneumothoraces, hemothoraces, or pneumohemothoraces. Contusions are more common in blunt trauma, whereas lacerations occur more often in penetrating trauma.

Patients may complain of chest pain or difficulty breathing or have no symptoms. Physical findings may include tachypnea, asymmetric breath sounds, and/or chest wall tenderness. Patients with a tension pneumothorax may develop tachycardia, muffled heart sounds, hypotension, and/or distended neck veins. In the stable patient, chest radiography and thoracic computed tomography (CT) scan are helpful in the evaluation of pulmonary injuries.

Pulmonary injuries may initially cause hypoxia and respiratory distress, or the patient may present with minimal symptoms but progress to severe respiratory distress. Therefore, all patients with a pulmonary injury need to be observed for worsening of the disease process.

Cardiac Injuries

Cardiac injury in blunt thoracic trauma is rare, occurring in less than 5% of pediatric patients. Most patients with structural damage to the heart secondary to blunt trauma die at the scene and never reach a hospital. Cardiac contusions far outnumber lacerations. Contusions are usually self-limited unless ventricular fibrillation, which is rare, develops. On the

other hand, there are case reports of sudden death following a forceful precordial blow (commotio cordis).

Patients may complain of chest or sternal pain. Physical examination may reveal tachycardia, an irregular heart rhythm, a new heart murmur, acute onset of congestive heart failure, or in the case of cardiac tamponade, muffled heart tones. Evaluation for suspected cardiac contusion should include a 12-lead electrocardiogram (ECG), which may show ST-T wave changes or arrhythmias, and short-term observation. Creatine phosphokinase (CPK-MB) is not a useful screening tool because the test has a high false-positive rate. Symptomatic patients should be further evaluated by either a transesophageal or transthoracic echocardiogram.

Vascular (Great Vessel) Injuries

Life-threatening injuries to the great vessels of the thorax are rare and carry a high incidence of mortality. In blunt and penetrating trauma, the aorta is most commonly involved. Early detection of such injuries is vital for survival. Clinical signs and symptoms may include hypotension, paraplegia, anuria, absent or diminished femoral pulses, or excessive chest tube bleeding. Radiographic findings may include a widened mediastinum, blurred aortic knob, pleural cap, or tracheal or nasogastric tube deviation. The preferred method of diagnosis is angiography, although in the unstable patient a transesophageal echocardiogram often suffices.

Other Intrathoracic Injuries

Diaphragmatic, esophageal, and tracheobronchial disruptions are rare but are often overlooked in the initial evaluation of thoracic trauma. The chest radiograph may initially appear normal in 30 to 50% of diaphragmatic hernias. When abnormal, the chest radiograph may show a bowel gas pattern in the lungs, a displaced nasogastric tube, or an elevated hemidiaphragm. The patient may complain of chest pain or difficulty breathing. The examination may be normal or show decreased breath sounds, respiratory distress, or a scaphoid abdomen. Surgical exploration is indicated in all suspected cases because a diaphragmatic hernia does not improve without surgical correction.

Patients with esophageal and tracheobronchial disruptions may present with a continuous air leak from a chest tube, pneumomediastinum, subcutaneous emphysema, and for those patients with esophageal disruption, gastric contents from the chest tube. Bronchoscopy or esophagoscopy is indicated in suspected cases.

INITIAL MANAGEMENT

The ABCs (airway, breathing, and circulation) of trauma management apply regardless of the organ system injured. A top priority in any patient with respiratory or circulatory failure should be airway stabilization (see Chapter 5) and identification and treatment of shock (see Chapter 3). The injured child should be evaluated according to the primary survey of trauma management. The first priority in trauma patients with or without thoracic injury is establishing a secure, patent airway. Indications for endotracheal intubation in the thoracic trauma patient include depressed neurologic status, inadequate oxygenation or ventilation, compromised circulatory status, or an unstable airway including burns.

After the airway is secured, breathing is assessed. Inspection (symmetry, adequate chest rise, neck veins, displaced trachea) and auscultation (equal breath sounds, heart tones) of the chest provide information about ventilation. The ideal site for auscultation of the lungs is in the midaxillary line. An oxygen saturation by oximetry provides information on oxygenation.

If a patient has an abnormal examination but appears to be oxygenating and ventilating well and is not in shock, chest radiography is indicated. If breathing is inadequate after endotracheal intubation and breath sounds are asymmetric, intervention is required before a chest radiograph. The patient with absent breath sounds on one side and tracheal shift to the opposite side requires immediate needle decompression and subsequent tube thoracostomy. Only after the patient is stabilized should a chest radiograph be obtained.

The patient's circulatory status is evaluated after airway and breathing have been stabilized. Pericardial tamponade and a tension pneumothorax or hemothorax should be considered in the poorly perfused, shocky patient, especially when sources of blood loss have been excluded and volume resuscitation has not improved the patient's status. Physical examination may reveal muffled heart or breath sounds with decreased or absent pulses. Pericardiocentesis or thoracentesis and subsequent tube thoracostomy are lifesaving procedures that usually need to be performed in the unstable trauma patient before going to the operating room for definitive treatment.

Once the patient is stabilized and the immediate life-threatening injuries such as airway obstruction, tension pneumothorax, hemothorax, and pericardial tamponade are treated, a chest radiograph and thoracic CT scan should be obtained to provide valuable information regarding other potentially life-threatening and operative injuries. Thoracic injuries requiring operative intervention are described in Table 107.1 and in Figure 107.5. The use of ultrasound is rapidly becoming a standard diagnostic modality in the evaluation of the adult trauma patient. One adult study demonstrated that thoracic ultrasound was as sensitive and specific in identifying a hemothorax as a chest radiograph. The utility of ultrasound in the pediatric trauma patient has yet to be determined. No study has been conducted to specifically ascertain its usefulness except in the evaluation of cardiac injuries. Numerous studies have shown thoracic CT to be superior to routine chest radiograph in identifying pulmonary contusions, pneumothoraces, and hemothoraces. Thoracic CT should be part of the initial evaluation of pediatric trauma patients if a lung contusion, pneumothorax, or a hemothorax is suspected or if the cause of the patient's respiratory distress is unknown. Thoracic CT is also useful in the asymptomatic patient with chest radiograph findings suggestive of a traumatic rupture of the thoracic aorta.

Injury	Signs and Symptoms
Tracheal/bronchial rupture	Active chest tube air leak
Lung parenchyma, internal mammary artery laceration, intercostal artery laceration	Chest tube bleeding greater than 2–3 mL/kg/hr or hypotension unresponsive to transfusions
Esophageal disruption	Abnormal esophagogram (leak) or esophagoscopy Gastric contents in the chest tube
Diaphragmatic hernia	Abnormal gas pattern in the hemithorax Displaced nasogastric tube in the hemithorax
Pericardial tamponade	Positive pericardiocentesis
Great vessel laceration	Widened mediastinum Tracheal or nasogastric tube deviation Blurred aortic knob Abnormal aortogram (gold standard)

Table 107.1. Thoracic Trauma Injuries Requiring Operative Intervention

FIGURE 107.5. Indications for surgery in thoracic trauma.

Chest Wall Injuries

The elasticity and flexibility of a child's thoracic cage makes chest wall injuries less common than internal organ injuries, such as a pulmonary contusion. When chest wall injuries occur, the patient is at increased risk for intrathoracic injuries. Included in chest wall injuries are rib, sternal, and scapular fractures and flail chest.

Rib Fractures

Rib fractures may occur from either a direct blow to the rib or compression of the chest in an anterior-posterior direction. With a direct blow, the rib will fracture inward and may puncture the pleural cavity, causing a pneumothorax (Fig 107.6A and Fig 107.6B). A hemothorax is caused by a rib lacerating an intercostal artery, an internal mammary artery, or the lung parenchyma. Compression of the chest wall can cause the lateral portions of the ribs to fracture outward. Intrathoracic injury is seen less commonly with this type of fracture.

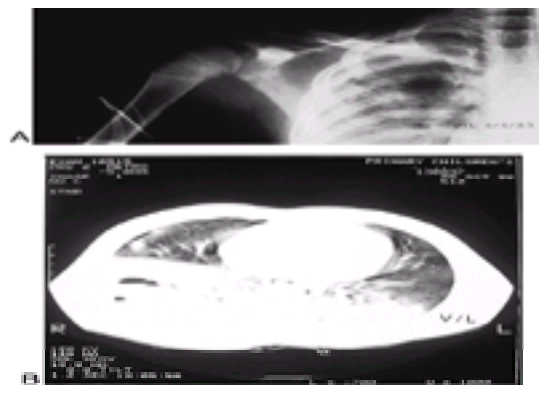

FIGURE 107.6. A 7-year-old involved in an auto–pedestrian accident. Crepitus and decreased breath sounds were noted on the right side. Chest radiograph **(A)** shows rib fractures, clavicle fracture, and a pulmonary contusion. A pulmonary contusion and a pneumothorax are seen on the thoracic computed tomography **(B).**

In one study, rib fractures occurred in 32% of all children admitted with thoracic trauma. Motor vehicle accidents were the most common mechanism of injury, similar to adult studies. Single rib fractures did not correlate with the severity of injury, but as the number of fractures increased, so did the likelihood of multisystem and intrathoracic injuries. Children with rib fractures and both head and thoracic injuries had a doubled mortality rate compared with children with rib fractures and an isolated thoracic injury.

Because of the relatively protected nature of the first rib and the amount of force required to fracture it, first rib fractures should be approached with a high index of suspicion for other serious injuries, such as vascular disruption or tracheal laceration. Patients with these lesions are usually symptomatic (hypotension, anuria, pulse differences or deficits). In one study, all patients with a first rib fracture and injury to the great vessels exhibited physical examination abnormalities such

as loss of the radial pulse on the involved side, discrepancy in blood pressure between the upper extremities, a flail chest, and/or hypotension. No patients with an isolated first rib fracture and a completely normal physical examination had an injury to a great vessel. In this and other studies, no correlation existed between level of rib fracture and associated vascular injury in the otherwise asymptomatic patient.

The pediatric patient with a rib fracture may splint and hypoventilate secondary to pain. Physical examination may reveal point tenderness and, if the pleura has been involved, crepitus. If the patient has any respiratory or circulatory compromise, a tube thoracotomy is indicated for a pneumothorax or hemothorax. The tube should be placed at a separate site from the area of the fracture. If the patient is stable, then relief of pain, monitoring the respiratory status, and further evaluation (chest radiography, thoracic CT) for underlying injury is indicated. Wrapping or binding the chest wall are contraindicated since these measures may impair ventilatory function. Analgesics are helpful but should be used with caution because they can also cause respiratory depression. Epidural analgesia is helpful, especially for lower rib fracture. Intercostal nerve block is also useful but should be performed carefully to avoid puncturing the pleura.

Patients with multiple rib fractures should be admitted to the hospital for pain control, pulmonary physiotherapy, and observation for worsening respiratory status. Prognosis for isolated rib fractures is excellent with most healing within 6 weeks. The chest wall will remodel leaving no permanent disability.

Sternal and Scapular Fractures

Sternal and scapular fractures are uncommon in children, secondary to the marked compliance of the chest wall (Fig. 107.7). Although they require a thorough evaluation for other thoracic injuries because of the significant force required to fracture these bones, sternal and scapular fractures are rarely associated with vascular or brachial plexus injuries. In one adult study, scapular fracture alone was not a significant marker for mortality or neurovascular injury. In another study evaluating patients with blunt cardiac injury, only 2% had an associated sternal fracture.

FIGURE 107.7. A 10-year-old child evaluated after a fall of more than 10 feet. The patient was asymptomatic except for shoulder pain. The only abnormalities noted were a scapular and clavicle fracture.

Flail Chest

Fracturing two or more ribs on the same side may result in that particular chest wall segment losing continuity with the thoracic cage. This condition is called a flail chest. Direct impact to the rib, as in a crush injury, is the most common mechanism for a flail chest. Flail chest is uncommon in children because of the significant compliance of the chest wall. In adult thoracic trauma series, flail chest occurred in approximately 10% of patients compared with less than 1% in the pediatric population. When a flail chest occurs, it is usually associated with an intrathoracic injury, most often pulmonary contusion, because of the force involved.

The pediatric patient may develop respiratory distress and failure as a result of a flail chest caused by numerous mechanisms. In the early 1900s, Bauer described the pendelluft theory, which attributes inefficient ventilation and oxygenation to a pendulumlike movement of air from the injured lung to the uninjured lung. The harder and faster a patient works to breathe, the more shifting of air from one side to the other occurs. The paradoxical movement of the chest also impairs the normal inspiratory/expiratory function of the lung (Fig. 107.8). Another mechanism for respiratory distress is the association of underlying pulmonary injury with a flail chest. Edema within the airways alters alveolar ventilation-perfusion ratios and produces pulmonary arteriovenous shunting with hypoxemia and subsequent respiratory distress. Finally, the pain associated with rib fractures causes voluntary and involuntary splinting. These patients are at increased risk for atelectasis and pneumonia secondary to poor pulmonary function.

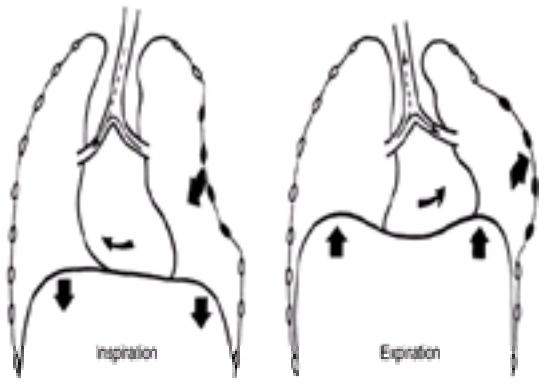

FIGURE 107.8. Pathophysiologic consequence of flail chest with paradoxical motion. (Reprinted with permission from Textbook of Pediatric Emergency Medicine. 3rd ed. Baltimore: Williams & Wilkins, Fig. 101.4.)

The goal of treatment should be to stabilize the involved portion of the thoracic cage. At the scene of an accident, the patient can be placed with the injured side down, thus improving tidal volume and ventilation. Any patient with respiratory distress should be intubated and placed on positive-pressure ventilation. This treatment serves two purposes: 1) the patient's airway is well protected and the effectiveness of breathing is maximized; 2) the positive pressure provides optimal expansion and splinting of the injured segment. Unfortunately, high inflating pressures can cause a pneumothorax and care must be taken when delivering positive pressure to the injured child. If the patient does not need to be intubated, aggressive pulmonary physiotherapy along with pain control is the preferred treatment. For patients with an underlying pulmonary contusion, fluids must be carefully monitored. Fluid may leak out of the injured capillary bed, worsening the pulmonary contusion.

Pulmonary Contusions and Lacerations

Pulmonary contusion is the most common thoracic injury in children. Pulmonary contusion occurs when a blunt force, such as a crush injury, is applied to the lung parenchyma. As in any contusion or bruise, the capillary network becomes damaged, leaking fluid into the surrounding tissues. A ventilation-perfusion mismatch occurs because of the extravasation of fluid, interfering with oxygenation. As the edema and swelling worsens, the patient's respiratory status also deteriorates. A pulmonary contusion may initially be invisible on a chest radiograph. Chest CT is more sensitive in detecting pulmonary contusion (Fig. 107.9A and Fig. 107.9B). Lung parenchymal injuries are often noted when a few cuts of the thoracic cavity are imaged while obtaining an abdominal CT.

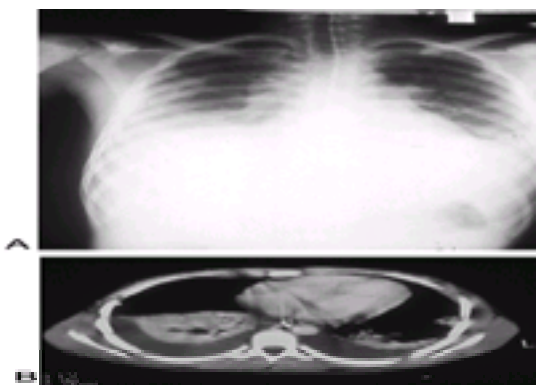

FIGURE 107.9. A 15-year-old child involved in an auto–pedestrian accident. Vital signs were stable at the scene, but the child had decreased breath sounds bilaterally. **(A)** Chest radiograph showed bilateral hemothorax and pulmonary contusions. **(B)** Computed tomography confirmed and better delineated the hemothorax and pulmonary contusions.

In one study, tachypnea, abnormal breath sounds, external thoracic wall contusion, and fracture of the bony thorax were each absent in more than 50% of patients with a pulmonary contusion. Interestingly, the chest radiograph in these patients did not dramatically worsen from time of admission. Nonetheless, mild contusions require close observation in the hospital for worsening respiratory status and supportive care.

Patients with moderate to severe pulmonary contusions may be tachypneic and have an oxygen requirement secondary to shunting within the lung. If the patient can no longer maintain oxygenation, endotracheal intubation and mechanical ventilation with positive pressure is the preferred treatment. Fluid restriction is helpful to avoid exacerbation of pulmonary edema. Many of these patients have associated injuries, making fluid restriction difficult; intensive care management with measurement of central venous and pulmonary arterial pressure may be helpful for those patients with major multisystem trauma. Double-lumen endotracheal–endobronchial tubes can be used in patients with severe lung contusions refractory to normal ventilatory management.

Pulmonary lacerations occur more often in penetrating trauma but can occur in rapid deceleration injuries. Rib fractures secondary to blunt trauma may also puncture the lung. Patients are usually tachypneic and have abnormal breath sounds. Large lacerations may cause hemoptysis. Chest radiograph shows pneumothorax or hemothorax. Treatment includes endotracheal intubation for patients in respiratory distress and tube thoracotomy for pneumothorax or hemothorax. Adequate intravenous access and blood for transfusion should be available before chest tube placement. Insertion of the chest tube can disrupt hemostasis in the chest cavity, and the patient may exsanguinate. Indications for surgery include continuous hemorrhage or air leak through the chest tube, massive hemoptysis, or air embolism.

Air embolism is usually fatal but it should be considered when a patient deteriorates suddenly after endotracheal intubation, when focal neurologic findings develop without evidence of a craniospinal injury, or when frothy blood is withdrawn from an arterial puncture. Treatment includes open thoracotomy with either occlusion of the hilar structure on the affected side or direct aspiration of the air. Neither of these treatment options is usually successful.

Intrapleural Injuries

In one study, intrapleural injury occurred in 40% of children with a thoracic injury. Hemopneumothorax, hemothorax, and

pneumothorax were evenly distributed. Pneumothorax was associated with the lowest mortality rate (15%) and hemothorax had the highest incidence (57%). Auscultation is helpful but not 100% accurate in diagnosing a hemothorax, pneumothorax, or hemopneumothorax. A recent report found that auscultation to detect hemothorax, pneumothorax, or hemopneumothorax had a sensitivity of 58% and a specificity of 98%. Most intrapleural injuries do not need surgical intervention and can be managed either by hospital observation or tube thoracostomy (Fig. 107.10).

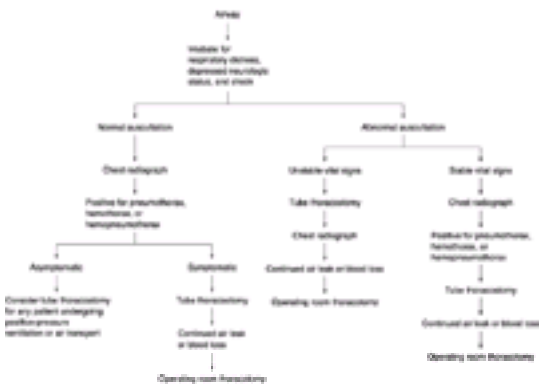

FIGURE 107.10. Algorithm for the management of intrapleural injuries.

Pneumothorax

Pneumothorax is the second most commonly encountered entity in blunt thoracic trauma and the most common in penetrating thoracic trauma. Air within the pleural cavity can arise from chest wall penetration, lung parenchyma disruption, a tear of the tracheobronchial structures, or esophageal rupture.

Patients may be asymptomatic, complain of pleuritic chest pain, have tachypnea, or be in severe respiratory distress. Physical examination may be normal or it may reveal diminished or absent breath sounds, crepitus, or hyperresonance to percussion on the side of the pneumothorax. In the asymptomatic or mildly symptomatic patient, a chest radiograph is helpful in diagnosing and determining the type of treatment necessary (Fig. 107.11). If the pneumothorax is small and the patient asymptomatic, observation in the hospital and administration of 100% oxygen is all that is necessary. A small pneumothorax is classically described as being less than 15%, although it is common to underestimate the size of a pneumothorax on plain films, only to find a much more extensive lesion on CT scan. Tube thoracostomy is indicated in symptomatic patients, patients undergoing positive-pressure ventilation, and those requiring air transport. An asymptomatic patient may rapidly become symptomatic if a small, simple pneumothorax progresses to a tension pneumothorax; therefore, even asymptomatic children with a traumatic pneumothorax should be admitted to the hospital for observation.

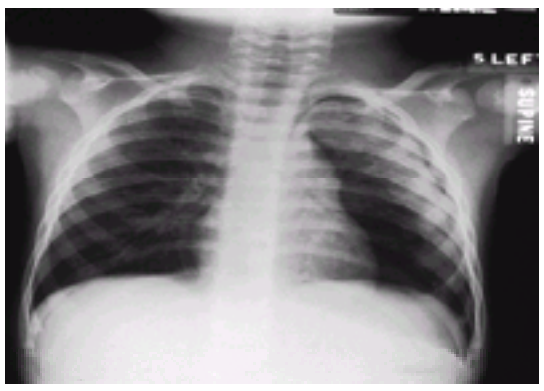

FIGURE 107.11. This 3-year-old child was an unrestrained passenger in a motor vehicle accident. The patient was tachypneic and had decreased breath sounds on the left side, but was otherwise asymptomatic. Chest radiograph revealed a left pneumothorax with a pulmonary contusion.

Tension Pneumothorax

A tension pneumothorax is the most common complicated intrapleural injury. Tension pneumothorax develops in up to 20% of children after simple pneumothorax. A tension pneumothorax occurs when air progressively accumulates within the pleural cavity. A laceration to the chest wall, pulmonary parenchyma, or bronchial wall may function as a one-way valve, allowing air to enter but not leave the pleural space. The progressive accumulation of air within the pleural cavity not only collapses the ipsilateral lung but compresses the contralateral lung as well. These patients may present in severe respiratory distress with decreased breath sounds on the side of the pneumothorax. The mediastinal structures also shift to the contralateral side (Fig 107.12). Two-thirds of the blood supply to the body is returned to the heart via the inferior vena cava. Because the inferior vena cava is relatively fixed and cannot shift as much as the superior vena cava, venous return to the heart is reduced and the patient may appear tachycardic, peripherally vasoconstricted, and in hypotensive shock. This underscores the importance that whenever a trauma patient suddenly deteriorates, the treating physician must return to airway and breathing, before jumping to circulation.

FIGURE 107.12. A 5-year-old girl fell off of and was then kicked in the chest by a horse. Upon arrival of the life-flight team, the patient was found to be in both respiratory and cardiovascular distress. Chest radiograph demonstrated a left-sided tension pneumothorax. The patient was intubated, and a chest tube was placed before the patient was transported. After the intubation and chest tube insertion, both the patient's respiratory and cardiovascular status improved.

Initial treatment consists of needle decompression performed in the midclavicular second intercostal space of the ipsilateral side. If a tension pneumothorax is present, an immediate release of air should be noted. If positive, the needle decompression is only a temporizing measure and must be followed by tube thoracotomy. Tube thoracotomy is usually done in the midaxillary line at the level of the fifth intercostal space (nipple level). Chest radiograph is performed only after the insertion of the chest tube and should not be used to diagnose a tension pneumothorax in the symptomatic patient. If a significant air leak continues after chest tube placement, a tracheobronchial rupture must be considered.

Open Pneumothorax

An open pneumothorax is the result of penetrating trauma. A direct connection exists between the pleural space and the outside atmosphere. As in a bronchial tear or lung parenchymal injury, air may enter but not leave the pleural space.

Initial treatment includes placement of an occlusive dressing at the wound site. This is best done when the patient is in full expiration. A chest tube should be placed immediately to prevent development of a tension pneumothorax. The chest tube should be inserted at a site different than the open wound. Larger open wounds may need surgical closure. Any patient in respiratory distress should be intubated and receive positive-pressure ventilation.

Hemothorax

Hemothorax is much more common in penetrating than in blunt thoracic trauma. In blunt thoracic trauma, a hemothorax can occur from rib fractures lacerating the lung, pulmonary parenchymal injuries without rib fractures, lacerations of the internal mammary arteries or intercostal arteries, or disruption of the major vascular structures in the mediastinum or hilum. A hemothorax secondary to a major injury of the great vessels usually results in death. Liver and spleen injuries can also cause a hemothorax with disruption of the diaphragm. The most common cause of a hemothorax is injury to the intercostal or internal mammary arteries, whereas injuries to the lung or great vessels causing a hemothorax are much less common but more serious.

Patients may present in respiratory distress or in profound shock secondary to obstruction of venous return or massive blood loss. Decreased breath sounds are noted on the affected side and tracheal or mediastinal deviation may occur. Thirty to forty percent of the patient's blood volume may be rapidly lost into the pleural cavity. This reaction usually occurs with major vessel lacerations. Bleeding from the intercostal or internal mammary arteries stops secondary to low systemic pressures. Also, when the lung is reexpanded, effective tamponade of the bleeding occurs. A chest radiograph should be obtained to confirm the diagnosis. If a hemothorax is suspected clinically and the patient is in severe respiratory or circulatory distress, immediate tube thoracostomy should be performed before a chest radiograph is taken.

Treatment of a major hemothorax should include aggressive airway and circulatory management and evacuation of the pleural blood. Endotracheal intubation and positive-pressure ventilation should be initiated in any unstable airway. Patients should be typed and crossmatched for packed red blood cells and adequately volume resuscitated, preferably with two large intravenous lines in place. O-negative blood, if type-specific blood is not available, should be available at the patient's bedside as soon as possible.

Tube thoracotomy is performed to evacuate blood within the pleural cavity, reexpand the lung, and prevent or treat any mediastinal shift. The chest tube is placed in the midaxillary line at the level of the fifth intercostal space (nipple level). This location is the same as in a pneumothorax. Many hemothoraxes may actually represent hemopneumothoraxes. After placement of a chest tube, blood should be slowly evacuated from the pleural space. Blood within the pleural cavity may tamponade a significant bleeding source within the chest and evacuating that blood may cause new bleeding to occur. Patients can exsanguinate rapidly; therefore, intravenous access, adequate volume resuscitation, and blood available for transfusion should be a priority. Blood removed by thoracostomy can be administered to the patient as an autotransfusion. Thoracostomy drainage needs to be closely monitored. Large ongoing blood loss from a chest tube should be collected in a system that allows autotransfusion. Thoracotomy is indicated for continued bleeding (greater than 1 to 2 mL/kg per hour), inability to expand the lung, or retained blood within the pleural cavity. Failing to adequately drain a hemothorax may result in restrictive lung disease from a fibrothorax or an empyema from the clotted material becoming infected.

Chylothorax

Chylothorax is rare in thoracic trauma and most commonly occurs secondary to iatrogenic complications. Chylothorax can result from penetrating injuries or from a hyperextension injury to the spine. Disruption of the thoracic duct will lead to chyle draining into the mediastinum and pleural space. Diagnosis is confirmed when chyle is aspirated from the pleural cavity. Infection is rare because chyle is bacteriostatic, and treatment consists of tube thoracostomy, dietary manipulation, and if all else fails, thoracic duct ligation.

Tracheobronchial Injuries

Injury to the tracheobronchial tree in children occurs rarely, with an incidence of less than 1%. This injury is most commonly caused by acceleration or deceleration forces. Major vessels or pulmonary parenchyma are more likely to be injured in penetrating trauma than the tracheobronchial tree or esophagus. Cervical tracheal rupture may be caused by a direct blow to the trachea or from the patient's head violently traveling forward and backward. This whiplash effect can cause a tear between two cartilaginous rings. Lower tracheobronchial injury usually occurs from a sudden increase in intrabronchial pressure. Because the child's chest wall is elastic, the trachea and main bronchi can be compressed between the chest wall and the vertebral spine. Compression of the chest with a closed glottis can cause a sudden increase in intrabronchial pressure, resulting in a tracheobronchial tear. Shear forces, traction, and crushing the airway between the chest and vertebral column may also cause a tracheobronchial injury. Approximately 80% of tracheobronchial injuries occur near the origin of the main stem bronchus.

The diagnosis of tracheobronchial injury may be difficult to make in the pediatric population. Mechanism of injury (e.g., fall, crush, direct blow) provides an important clue. Symptoms such as chest pain and dyspnea are common but nonspecific. Unlike the adult population, rib fractures are rare because of the elastic nature of the child's chest. Clinical signs include cyanosis, hemoptysis, tachypnea, and subcutaneous emphysema (cervical, mediastinal, or both). Pneumomediastinum and cervical emphysema are seen commonly in airway rupture (Fig. 107.13). If a pneumothorax is present with these findings, a bronchial rupture should be suspected. A continued air leak after insertion of a thoracostomy tube should also alert the physician to the possibility of a bronchial tear. Because of anatomic differences, ruptures of the bronchi occur on the right side more often than on the left. In the absence of a pneumothorax, tracheal rupture should be suspected if a pneumomediastinum or cervical emphysema is present.

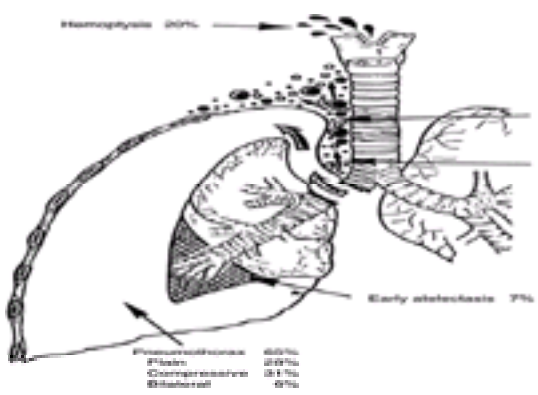

FIGURE 107.13. Initial signs of bronchial rupture. (Reprinted with permission from Textbook of Pediatric Emergency Medicine. 3rd ed. Baltimore: Williams & Wilkins, Fig. 101.9.)

Treatment includes initial airway stabilization and then bronchoscopic evaluation of the airway. Numerous reports in the literature record a partial tracheal tear becoming complete after endotracheal intubation. Therefore, if the airway is stable, oral tracheal intubation should be performed in the operating room under bronchoscopic guidance. This procedure prevents further trauma to the airway, and if a complication arises, emergency surgical access to the airway is readily available. If the airway is unstable and emergent endotracheal intubation needs to be performed, efforts should be made to prepare for backup measures such as cricothyroidotomy, tracheostomy, or fiberoptic bronchoscopy. An advantage of early bronchoscopy is exact identification and location of the lesion. The best surgical results are achieved when operative exploration is performed early. In the stable patient, CT of the chest can also help confirm the diagnosis and identify other injuries.

Esophageal Injuries

Esophageal injury is rare in children but presents a diagnostic challenge when it does occur. Timely and accurate diagnosis of an esophageal injury is paramount. The complications include mediastinal sepsis and death. The most common cause for esophageal perforation in the pediatric population is iatrogenic, followed by penetrating trauma (e.g., gunshot wound, stab wound). Esophageal perforation can occur in blunt trauma if a significant amount of chest compression occurs. The cervical and thoracic regions are more commonly affected, with the thoracic region having the highest mortality rate (35%).

The patient's signs and symptoms depend on the region injured. Patients with an esophageal rupture in the cervical region may complain of neck stiffness or neck pain. They may regurgitate bloody material and have cervical subcutaneous emphysema or odynophagia. A lateral neck radiograph may show retroesophageal emphysema. In the thoracic region, patients may present with abdominal pain and guarding, chest pain, subcutaneous emphysema, tachycardia, or dyspnea. A chest radiograph may show a pneumothorax, pneumomediastinum, or an air–fluid level in the

mediastinum. Perforation of the intra-abdominal esophagus may cause retrosternal, epigastric, or shoulder pain.

Patients with suspected esophageal perforation should be adequately volume resuscitated, have a nasogastric tube placed, and receive antibiotics covering Gram-positive, Gram-negative, and anaerobic organisms. The diagnosis of an esophageal perforation can be made by either esophagography, esophagoscopy, or both. In one study, flexible esophagoscopy had a sensitivity of 100% and specificity of 96%. Depending on the expertise at each institution and the patient's stability, these studies may be paired to lessen the chance of a misdiagnosis. Once the diagnosis is made, prompt surgical correction is mandatory. If the diagnosis is made within 24 hours, mortality is approximately 5%. Delayed diagnosis for more than 24 hours after injury is associated with a mortality of 70%.

Diaphragmatic Injuries

In the 16th century, diaphragmatic rupture was described by Ambrose Paré. He noted that “the stomach and intestines are sometimes drawn into the thoracic cavity” after diaphragmatic injury. Diaphragmatic injuries are more common in blunt trauma. A crushing force will produce a sudden increase in the intrathoracic and intra-abdominal pressure against the fixed diaphragm. Because of the flexible nature of the child's chest wall, rib fractures are rare. Even though penetrating thoracoabdominal trauma is uncommon in children, a diaphragmatic injury should be suspected in any thoracic or abdominal penetrating injury. The level of the diaphragm fluctuates greatly with respirations, and injuries of the diaphragm have been reported with penetrating wounds as high as the third and as low as the twelfth rib. Early reports of blunt traumatic diaphragmatic rupture were mostly left-sided. Because of a greater awareness of diaphragmatic injuries, right and bilateral diaphragmatic injuries have been reported more recently. Approximately 80% of diaphragmatic injuries still occur on the left, and 20% occur on the right. The left diaphragm is relatively unprotected, whereas the liver protects the right side. Right-sided diaphragmatic injuries are associated with increased mortality; patients usually have a greater physiologic insult and more numerous associated injuries.

Motor vehicle accidents are the most common mechanism of injury, and some authors believe the direction of impact may play a role in the side and type of diaphragmatic rupture. A lateral torso impact has been shown to be three times more likely than a frontal impact to result in a ruptured diaphragm. The rupture tends to be on the same side as the impact. Right-sided diaphragmatic ruptures may be associated with right-sided impact to the passenger side of the vehicle. Associated injuries, such as pulmonary contusions, hepatic or splenic lacerations, and fractures of the extremities, are present in more than 75% of patients. Thoracic aortic injuries have been reported in up to 10% of adults with diaphragmatic injury and should be considered in children with diaphragmatic trauma.

Patients may present in respiratory distress and have a scaphoid abdomen, although they are more likely to be symptomatic from associated injuries than from the diaphragmatic rupture. The verbal child may complain of chest pain or ipsilateral shoulder pain. The presence of bowel sounds within the thoracic cavity is nonspecific because in children bowel sounds can be transmitted from the abdominal cavity. More commonly, bowel sounds are absent because of an associated ileus. A nasogastric tube may be difficult to pass in patients with a diaphragmatic injury and gastric herniation. Even though the diagnosis is usually made upon initial review of the chest radiograph (Fig. 107.14), some series reported that up to 30 to 50% of initial chest radiographs were normal with a diaphragmatic injury. This finding emphasizes the importance of serial evaluations and chest radiographs in patients suspected of having a diaphragmatic injury. Other diagnostic studies, such as chest and abdominal CT with contrast or upper and lower gastrointestinal tract series, can help confirm the diagnosis.

FIGURE 107.14. This 5-year-old boy was on a snowmobile when it crashed into a tree. Initially there was no respiratory distress, but upon arrival at the emergency department, the patient became tachypneic and required oxygen. Breath sounds were reportedly normal. Chest radiograph showed a left-sided diaphragmatic hernia. This injury was surgically repaired in the operating room and the patient did well postoperatively.

Before performing a tube thoracostomy for a pneumothorax or hemothorax, the physician should consider diaphragmatic injury to avoid injury to herniated intra-abdominal organs. In patients who clinically appear to have a diaphragmatic injury (scaphoid abdomen, bowel sounds auscultated in the thoracic cavity), a finger should be inserted in the chest tube incision site and the diaphragm should be palpated before placing a chest tube.

Herniation and strangulation of bowel may result from a delayed diagnosis. Diaphragmatic defects do not spontaneously heal because of motion associated with respirations and cyclical tension. Exploratory laparotomy or laparoscopy should be performed in cases in which a diaphragmatic hernia is strongly suspected.

Traumatic Asphyxia

Traumatic asphyxia results from direct compression of the chest or abdomen. The most common mechanism is a child being run over by a motor vehicle or pinned underneath a heavy object. In anticipation of impending injury, the child may inspire, tensing the thoracoabdominal muscles and closing the glottis. Traumatic asphyxia also occurs in patients with asthma, seizures, persistent vomiting, and pertussis.

Positive pressure is transmitted to the mediastinum and blood is forced out of the right atrium into the valveless venous and capillary system. The clinical manifestations occur because the increase in pressure dilates the capillary and venous system. Areas drained by the superior vena cava are particularly affected, explaining the significant difference between the patient's head and neck as opposed to the lower body. Patients with traumatic asphyxia usually present with the clinical picture of subconjunctival and upper body petechial hemorrhages, cyanosis, periorbital edema, respiratory distress, altered mental status, and associated injuries.

The primary goal of treatment is to stabilize the patient and identify associated injuries. The external appearance of a patient with traumatic asphyxia is impressive, but initial attention should be paid to the airway, breathing, and circulatory status. Pulmonary contusions and hepatic injuries are commonly seen with traumatic asphyxia and CT is helpful in identifying head, chest, and abdominal injuries. Because the most severe injuries cause immediate death, the prognosis is good for any patient surviving the first few hours after the incident. Cutaneous manifestations resolve with time, and neurologic sequela are rare. Neurologic injury usually results from hypoxia, not intracranial hemorrhage.

Aortic and Other Vascular Injuries

Traumatic rupture of the thoracic aorta (TRA) is uncommon in children but carries a high mortality rate (75 to 95%). TRA is associated with sudden deceleration forces, commonly from automobile accidents, causing a sheering stress. The aortic arch remains fixed, but the descending aorta is mobile. With deceleration, bending or sheering take place at the level of the ligamentum arteriosum, which is the most common site of aortic tears in adults and children.

TRA occurs in approximately 10 to 30% of adults sustaining blunt trauma but is much less common in the pediatric population. In one study, TRA occurred in only 2.1% of pediatric patients with thoracic trauma. The overall mortality rate was 93%. Why pediatric patients have a lower incidence of TRA than adults is unclear. One reason may be the mechanism of injury. In adults, most TRAs occur when the driver of an automobile forcibly strikes the steering wheel. The sudden deceleration force is isolated to the chest. Children who are passengers in a motor vehicle are less likely to strike an object that can deliver deceleration forces centrally to the chest. In children, one of the most common causes of blunt trauma is auto–pedestrian accidents, which produce forces distributed over a much wider area.

Children are usually symptomatic from associated injuries, and TRA can easily be missed. Clinical signs may include difference in pulses between the arms or arms and legs, thoracic ecchymosis, thoracic and back tenderness, paraplegia, and anuria. Patients with paraplegia and back pain may be initially diagnosed with a spinal cord injury. Unfortunately, 50% of patients may have no signs pertaining directly to TRA. More than 90% of patients have an abnormal chest radiograph (Fig. 107.15). Widened mediastinum, loss of the aortic knob, left-sided pleural cap, tracheal deviation, and nasogastric tube deviation may all be seen on a chest radiograph. Much has been written in the adult literature about the association of TRA with first rib fractures. More recent studies have shown that isolated first rib fractures without any other signs or symptoms do not correlate with TRA.

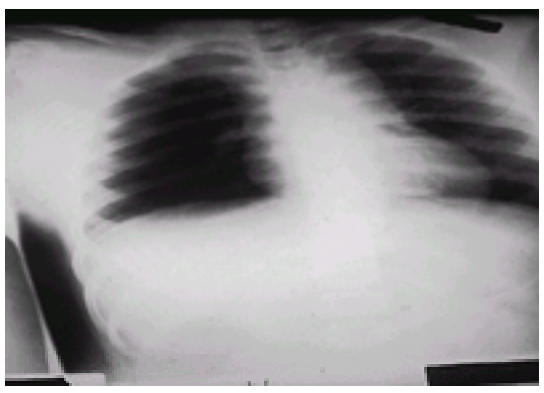

FIGURE 107.15. This 12-year-old girl was an unrestrained passenger involved in a motor vehicle accident. The patient was hypotensive at the scene and could not move her legs. In the emergency department, she had no motor or sensory function to her lower extremities and was anuric. Chest radiograph showed a widened mediastinum from traumatic rupture of the aorta.

Early diagnosis is imperative in patients with TRA (Fig. 107.16). Morbidity and mortality increase threefold if operative intervention is delayed more than 12 hours. The preferred method for diagnosing TRA is aortography (Fig. 107.17). Thoracic CT is only 55 to 65% accurate but helpful in diagnosing associated injuries. In one study, transesophageal echocardiography was shown to be a highly sensitive and specific method of detecting injury to the thoracic aorta. In contrast, another study showed transesophageal echocardiography to be only 63% sensitive and 84% specific in identifying patients with TRA. Pediatric patients were not included in either of these studies. If the patient is stable and TRA is suspected, aortography should be performed. Life-threatening intracranial, thoracic, or intra-abdominal injuries must first be evaluated and stabilized before aortography. If the patient is unstable, a transesophageal echocardiography can be performed while the patient's other life-threatening injuries are being treated.

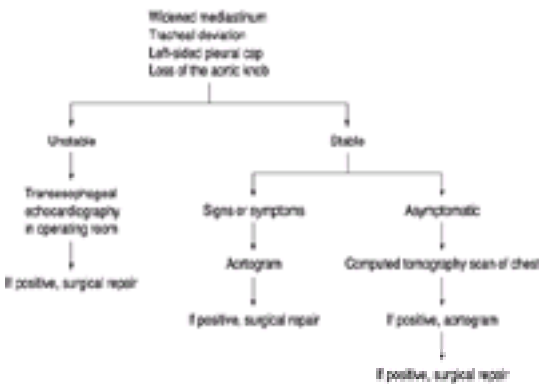

FIGURE 107.16. Algorithm for the evaluation and diagnosis of traumatic rupture of the thoracic aorta.

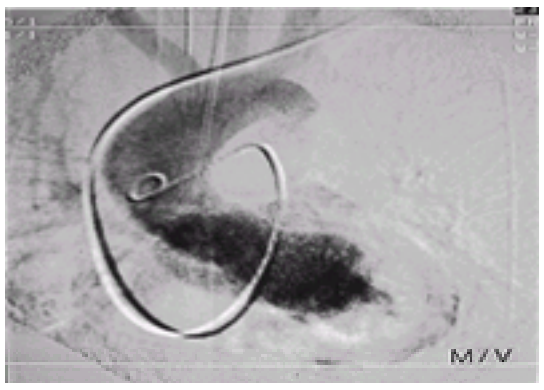

FIGURE 107.17. Emergency pulmonary angiography confirmed an aortic transection distal to the left subclavian artery with a pseudoaneurysm and narrowing of the proximal descending thoracic aorta in a 12-year-old girl.

Pericardial Tamponade

Pericardial tamponade occurs when the myocardium is injured and blood accumulates in the pericardial sac. Because of the nondistendible pericardium, pressure is exerted on the heart. Cardiac output decreases secondary to a decrease in venous return and stroke volume. The body initially tries to compensate with an increase in the pulse rate and peripheral vascular resistance. As the pressure within the pericardial sac increases, the systolic blood pressure decreases, causing a narrowing of the pulse pressure and subsequent hypotension and cardiogenic shock.

Pericardial tamponade may initially be difficult to diagnose because of associated injuries obscuring the clinical signs and symptoms. Patients may present with distant heart sounds, low blood pressure, poor perfusion, a narrow pulse pressure, or electromechanical dissociation (Fig. 107.18). Pulsus paradoxus, blood pressure falling more than 10 mm Hg during inspiration, occurs in less than one-half of patients with pericardial tamponade and should not be relied on to make the diagnosis of pericardial tamponade. Chest radiograph may show an enlarged heart (Fig. 107.19) and an ECG may show low-voltage QRS waves. Neither of these tests is diagnostic for pericardial tamponade, and performing these tests should not delay treatment in the unstable patient. In the stable patient, an echocardiogram can demonstrate fluid within the pericardial sac.

FIGURE 107.18. Algorithm for the evaluation and diagnosis of pericardial tamponade.

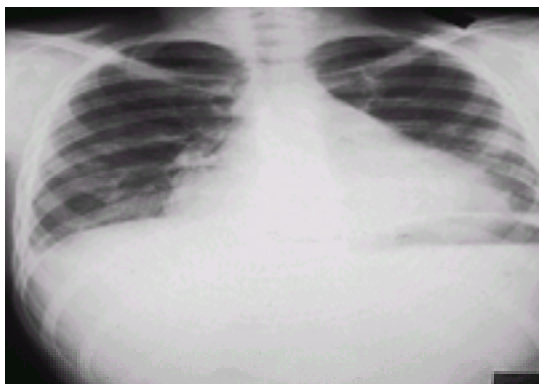

FIGURE 107.19. A 16-year-old boy had a steel bar strike him in the chest. Initially, he was hemodynamically stable but had muffled heart sounds. The patient quickly decompensated and required emergent pericardiocentesis after the chest radiograph. In the operating room, the patient was noted to have a small epicardial laceration on the surface of the heart.

In the unstable patient in whom pericardial tamponade is suspected, treatment includes control of the airway, intravascular volume resuscitation, and pericardiocentesis (Fig. 107.20). Pericardiocentesis is performed by inserting a 20-gauge spinal needle below the xiphoid process at a 45-degree angle toward the left shoulder. If time permits, an ECG monitor can be attached to the spinal needle. If the needle touches the heart, a current will be noted on the ECG monitor. Blood aspirated from the pericardial sac can be differentiated from intracardiac blood because pericardial blood is defibrinated and does not clot. Even though patients may show transient improvement after removal of blood from the pericardial sac, the patient should be taken to the operating room immediately for a pericardial window or other surgical intervention. A catheter should be placed in the pericardial sac over a wire guide for continual drainage of blood until surgical correction can be performed.

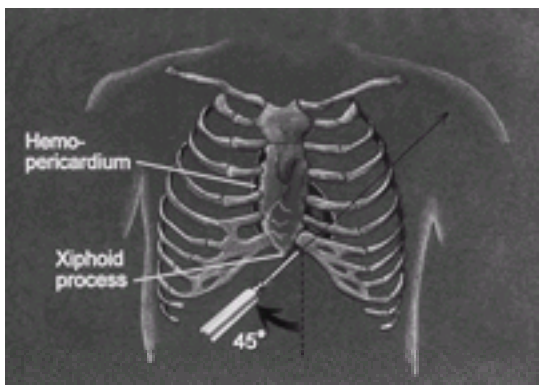

FIGURE 107.20. Pericardiocentesis is performed by inserting a 20-gauge spinal needle below the xiphoid process at a 45-degree angle toward the left shoulder. *Please see the color-tip insert (Color Plate 107.20).*

Blunt Cardiac Injuries

Blunt cardiac injury (BCI) occurs more commonly with associated injuries than in isolation and represents a spectrum of injuries. Myocardial contusion, ventricular or atrial rupture, and valvular disruption are all considered BCIs. Myocardial contusion is the most common and ventricular rupture the most lethal of injuries. In one study of 1288 patients with blunt thoracic trauma, 60 (4.6%) had a diagnosis of BCI. Other series have reported the incidence of BCI to range from 0 to 43%. Complications of BCI include arrhythmias, pump failure, congestive heart failure, and shock.

Cardiac rupture is the most common cause of death in blunt cardiac trauma. The right ventricle is the chamber most commonly ruptured because of its location directly beneath the sternum. Septal rupture can also occur, with the condition of the patient correlating with the size of the rupture. Patients with valvar injury may present in congestive heart failure with a new regurgitation murmur. Coronary artery injury is rare but should be considered in patients with persistent ECG changes consistent with ischemia following blunt thoracic trauma.

Unlike adults, pediatric patients with BCI often have few presenting signs or symptoms. Approximately 70% of adults with BCI complain of chest pain, whereas in one pediatric study less than half of the awake patients with BCI complained of chest pain, and external evidence of thoracic injury was present in only 60% of these patients. In the same study, cardiac examination was abnormal in less than one-quarter of the patients. BCI should be considered in any patient with thoracic trauma who develops a cardiac arrhythmia or a new murmur, or who is in congestive heart failure.

Evaluation of suspected BCI remains controversial. In one study, all children who developed heart failure or serious cardiac arrhythmias during their hospital course initially presented to the emergency department (ED) either in shock or with a serious arrhythmia. Patients with suspected BCI can be monitored in the ED or hospital and, if no arrhythmias develop on ECG, can be safely sent home. CPK-MB ratios have a high false-positive rate and are not a helpful screening tool. Transesophageal echocardiography should be performed in thoracic trauma patients with an abnormal ECG or arrhythmia, or a new heart murmur. Transesophageal echocardiography is more sensitive than transthoracic echocardiography in detecting myocardial injury.

Some general guidelines regarding patients with suspected BCI include the following: 1) If a pediatric patient with

suspected BCI is hemodynamically stable and has not experienced any arrhythmias, a serious life-threatening arrhythmia or pump failure is unlikely. 2) Any patient with suspected BCI who is hemodynamically unstable or has arrhythmias should undergo a thorough evaluation, such as with transesophageal echocardiography, and be admitted to the intensive care unit. 3) All patients with suspected BCI need close follow-up.

Penetrating Thoracic Trauma

Although not as common as blunt thoracic trauma, penetrating thoracic trauma is becoming more common in the pediatric population. In one study, penetrating thoracic trauma occurred in 20% of pediatric patients evaluated for a thoracic injury. The most common mechanism of injury was gunshot wounds followed by stab wounds (Fig. 107.21). Pediatric patients with blunt thoracic trauma are more likely to die from associated intracranial and intra-abdominal injuries. In contrast, penetrating thoracic trauma is usually a single-system disease and more than 95% of deaths are caused by the thoracic wound.

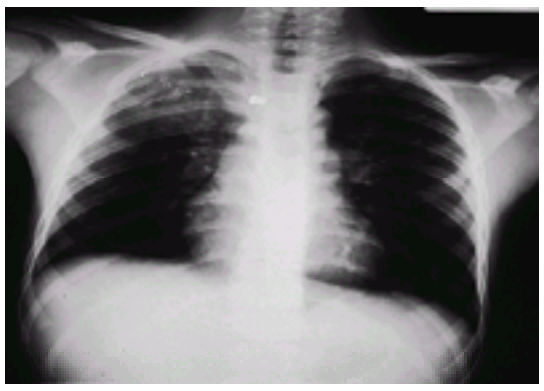

FIGURE 107.21. A 12-year-old boy playing with his father's loaded gun when it accidentally discharged. There was no cardiac or great vessel involvement and the patient did well postoperatively.

The most common penetrating thoracic injuries are hemothorax and pneumothorax, which almost always require tube thoracostomy. Intra-abdominal injuries should always be suspected because of the close proximity of abdominal contents to the thoracic cavity. In one study, intra-abdominal injuries occurred in 20% of patients with penetrating thoracic injury. More than half of children with penetrating thoracic injury require operative intervention. This percentage is higher than the 15% reported in the adult literature. Why children have this higher rate of operative intervention is unclear, but it may be a result of the close proximity of the vital organs in the thoracic cavity compared with adults.

Evaluation and treatment includes airway stabilization, fluid resuscitation, and management of the chest wound. Radiopaque markers (paper clips) may be placed by the entry and exit sites to help determine the course of the missile. Penetrating injuries near the mediastinum may be critical, especially if the patient is hemodynamically unstable. Pericardial tamponade should be considered and treated in the unstable patient. In the stable patient, transesophageal or transthoracic echocardiogram is helpful in evaluating the heart and determining whether fluid has entered the pericardial sac. Diaphragmatic lacerations are difficult to diagnose and sometimes require exploratory laparotomy or laparoscopy for diagnosis and treatment.

Emergency Department Thoracotomy

Emergency department thoracotomy (EDT) is one of the most aggressive resuscitative measures for patients with thoracic trauma. With the advancement of transport systems and the regionalization of trauma centers, patients who would have died at the scene are arriving at trauma centers for evaluation and treatment. EDT allows the physician to evaluate and evacuate the pericardial sac, perform open cardiac massage, and temporarily control bleeding from the heart, hilum, or lung. Catheters can also be placed directly into the right atrium, helping with fluid resuscitation, and the thoracic aorta can be compressed, improving central circulation to the brain and heart.

Anecdotal reports that suggest that EDT may be useful in the pediatric trauma patient who has vital signs but loses them during transport or resuscitation have been published. Other studies have shown the outcome of EDT in pediatric blunt trauma victims has been poor. The more recent literature has reevaluated the need for EDT and tried to select a more specific population. In one study, none of the 17 pediatric patients undergoing EDT after thoracic trauma survived, although 15 of 17 patients had blunt trauma and only two had isolated penetrating thoracic trauma. The authors concluded that EDT was not indicated in the blunt thoracic trauma patient arriving in the ED without any vital signs or ECG tracing. Another study of thoracic gunshot wounds in the pediatric population found no survivors in patients undergoing EDT and advocated a reappraisal of the indications for EDT among pulseless pediatric victims of thoracic gunshot wounds.

The one accepted indication for EDT is the patient with penetrating thoracic trauma who had and then lost vital signs before arrival or during ED resuscitation. In addition, EDT may be useful for the patient with blunt thoracic trauma who acutely deteriorates in the ED during resuscitation, but the chance of survival is dismal. Lifesaving interventions, such as airway management, fluid resuscitation, and pericardiocentesis, should not be delayed while waiting for EDT to be performed. The pediatric patient with vital signs but not responding to initial treatment, such as tube thoracotomy and pericardiocentesis, is a candidate for thoracotomy in the operating room, rather than the ED.

The outcome is directly dependent on the patient's status before arrival in the ED and mechanism of injury. In blunt thoracic trauma, 100% of patients who present to the ED without vital signs have a fatal injury, regardless whether EDT is

performed. Pediatric patients who present with cardiac arrest or tamponade caused by penetrating trauma, and in whom vital signs were present either in the field or in the ED, have the best chance of survival, although small, if EDT is performed.

CHAPTER 108

Abdominal Trauma

***RICHARD A. SALADINO, MD and †DENNIS P. LUND, MD**

**Department of Pediatrics, Harvard Medical School, and Emergency Department, Children's Hospital, Boston, Massachusetts; †Department of Surgery, University of Wisconsin, and Pediatric Surgery, Children's Hospital of the University of Wisconsin, Madison, Wisconsin*

Childhood injuries are the leading cause of death after the age of 1 year. In particular, trauma causes nearly 70% of deaths from age 5 to 19 years of age, with head and thoracic injuries accounting for most. Abdominal injuries occur in approximately 20% of children with fatal polytrauma. Importantly though, abdominal trauma is the most common unrecognized cause of fatal injuries.

Recognition of intra-abdominal injuries may be difficult, especially in the context of multisystem trauma. The physician should approach any child with a high index of suspicion for intra-abdominal injury. As well, intra-abdominal injury may be occult in cases of child battering, and the examining physician must exclude abdominal trauma in these instances.

APPROACH

The assessment of any trauma patient must begin with the ABCs: airway, breathing, and circulation. Priorities in evaluation and treatment include recognition and relief of airway obstruction, appropriate protection of the cervical spine, and management of life-threatening chest injuries and shock. Once resuscitation and cervical spine stabilization have begun, evaluation of the abdomen is included in both the primary and secondary surveys.

The evaluation for intra-abdominal injuries in children begins with an elicitation of the mechanism of trauma. Blunt injuries account for most morbidity and mortality of childhood trauma, although the frequency with which penetrating injuries occur is increasing. Penetrating trauma is usually evident on careful inspection of both the anterior and posterior torso. In contrast, blunt abdominal trauma must be suspected from historical information and careful physical examination. Children with severe multiple trauma are obviously at risk for intra-abdominal injuries, but sufficient energy to injure also may be present in apparently minor falls and direct blows to the abdomen from balls, bats, bicycle handlebars, and countless toys.

Life-threatening abdominal injuries may be occult or manifest in several ways: abdominal distension, shock, and/or external hemorrhage (e.g., from a penetrating injury). Historical information or physical examination findings are often lacking or subtle. Children have the capacity to maintain a normal blood pressure in the face of significant blood loss, and hence mask major intra-abdominal bleeding. The examining physician must always keep in mind that the abdomen is a large potential reservoir.

Physical Examination

A traumatized child is often difficult to examine; extra-abdominal injuries may obscure abdominal findings. In addition, the results of physical examination may be subtle or unreliable in the unconscious, intoxicated, agitated, or fearful child. Vital signs, including blood pressure and pulse, are often normal for age, especially in children with isolated injuries of the liver and spleen. Furthermore, external signs of injury, abdominal tenderness, and absent bowel sounds seldom differentiate pediatric patients who require laparotomy from those who do not.

However, careful serial examinations are critically important in maintaining the index of suspicion necessary to proceed with more sophisticated testing when appropriate. Inspection should note abrasions, lacerations, ecchymoses, penetrating wounds (including missile entry and exit sites), and telltale markings (e.g., tire tracks, seat belt marks). Attention should be paid to the anterior and posterior abdomen and to both flanks, as well as to the lower thorax when considering abdominal injuries. Abdominal distension may be caused by hemoperitoneum or peritonitis but most often results from gastric distension from air swallowed by the crying child. Early gastric decompression may assist the

abdominal examination and prevent vomiting with aspiration of gastric contents. The presence or absence of bowel sounds is generally not of much significance in the initial evaluation, but prolonged ileus may be a sign of intra-abdominal pathology. Tenderness upon palpation, percussion, or shaking may all be caused by abdominal wall contusion but may also indicate intra-abdominal injuries. Pelvic stability is evaluated by gently compressing the ileac wings. Digital rectal examination should be performed; the presence of blood may indicate perforation of the bowel. A boggy or high-riding prostate, blood at the urethral meatus, or a distended bladder may be present with urethral disruption, and preclude bladder catheterization until a retrograde urethrogram has been performed (see Chapter 109). Diminished rectal sphincter tone may indicate a spinal cord injury.

Laboratory Data

Blood should be obtained and sent for immediate typing and crossmatching not only in all instances of multiple trauma but also if isolated intra-abdominal injury is suspected. The hospital's blood bank must have O-negative blood ready for resuscitation if needed. Additional laboratory studies should include serum amylase, liver transaminases, and urinalysis. Hyperamylasemia may be present with pancreatic injury, but its absence does not preclude injury. Elevated serum liver transaminases may also be associated with intra-abdominal injuries, especially hepatic injuries. Screening for intra-abdominal injuries by evaluating transaminase levels is not universally accepted because sensitivity and specificity varies widely in the literature. In general, though, significantly elevated transaminase levels (AST greater than 450 IU/L and ALT greater than 250 IU/L) correlate well with hepatic injuries, and the evaluation of patients with such elevations should always include abdominal computed tomography (CT) scan. Urine should be tested for the presence of blood. Grossly bloody urine or a microscopic examination of urine that reveals more than 20 red blood cells per high-powered field (RBC/hpf) suggests injury to the kidneys and potentially the adjacent organs (see Chapter 109).

Arterial blood gas determinations may be helpful in the evaluation of pulmonary injuries and may indicate persistent metabolic acidosis when volume resuscitation is inadequate. A decreasing hematocrit on serial determinations suggests ongoing blood loss.

INITIAL MANAGEMENT PRINCIPLES

Basic Principles of Management

Treatment of the seriously injured patient requires a team approach, which includes a designated leader who directs team members who have specific responsibilities during the initial evaluation and management. Airway management and cervical spine stabilization are first priorities (Fig. 108.1). Any child with significant injuries should receive supplemental oxygen, especially if signs of shock are present. Intravenous or intraosseous access should be obtained while the primary survey is completed; immediate life-threatening injuries should be managed and hemorrhagic shock should be treated with infusion of isotonic crystalloid solution, when necessary, starting at 20 mL/kg. Large-bore catheters should be used whether in the upper or lower extremities to allow rapid infusion of large volumes of fluid during resuscitation. Accessing the femoral vein is acceptable and in fact is a preferred site in the child.

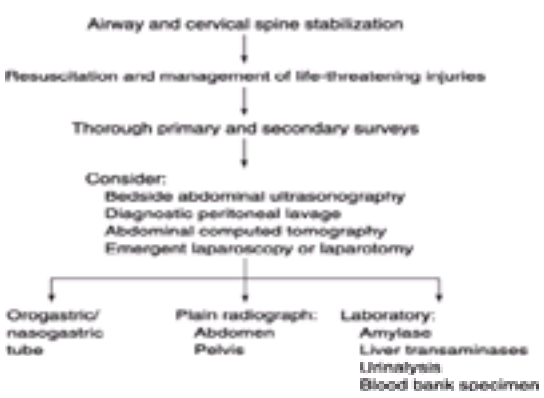

FIGURE 108.1. Initial evaluation and treatment of the child with abdominal trauma.

The current recommendation by the American College of Surgeons remains that aggressive fluid resuscitation be pursued. Although animal data suggest that limited (hypotensive) fluid resuscitation may improve survival by limiting hemorrhage into the peritoneal space, application to the management of children is still controversial.

As the initial evaluation proceeds, the priorities of management depend on the extent of multisystem injuries and the stability of the patient (Fig. 108.2). Patients who are unstable as a result of ongoing blood loss or an expanding intracranial hemorrhage require intervention early in the evaluation phase.

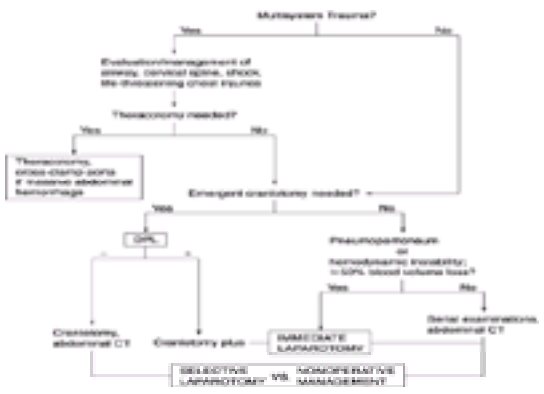

FIGURE 108.2. Management of blunt abdominal trauma. *DPL,* diagnostic peritoneal lavage; *CT,* computed tomography (see Table 108.2).

1. Mechanism of injury suggesting abdominal trauma
2. Slowly declining hematocrit
3. Unaccountable fluid or blood requirements
4. Neurologic injury precluding accurate abdominal examination
5. Hematuria
6. Acute "need to know" (e.g., before general anesthesia)

Table 108.1. Indications for Abdominal Computed Tomography Scan in the Pediatric Trauma Patient

The Unstable Patient

Immediate life-threatening injuries, such as airway obstruction, tension pneumothorax, pericardial tamponade, and obvious sources of external blood loss, must be treated promptly. The role of emergency department (ED) thoracotomy is controversial in children; its use should be confined to situations in which control of intrathoracic bleeding is needed (e.g., with lung or heart lacerations) or in situations in which previously detected vital signs are lost. If emergent thoracotomy is performed in the latter instance for presumptive intra-abdominal hemorrhage, the aorta is cross-clamped at a level just above the diaphragm.

If significant head trauma has occurred, a determination must be made with regard to the need for immediate neurosurgical intervention. A rapidly performed CT scan of the head is usually sufficient to determine the presence of a hematoma, which can be drained by the neurosurgeon. If hemodynamic instability or the need for immediate craniotomy exists and does not allow for CT evaluation of the abdomen (Table 108.1), a diagnostic peritoneal lavage (DPL) should be performed either in the ED or in the operating suite. If the peritoneal lavage is positive (Table 108.2), laparotomy and craniotomy proceed simultaneously. Finally, if neither thoracotomy nor craniotomy is indicated, emergent laparotomy is performed when pneumoperitoneum is noted on a plain radiograph or when the patient remains hemodynamically unstable in the face of historical or physical evidence of abdominal trauma (Fig. 108.2).

1. >5 mL of gross blood
2. Obvious enteric contents (e.g., bile)
3. Peritoneal lavage fluid exiting from chest tube, urinary bladder catheter
4. Positive laboratory analysis of peritoneal lavage fluid
   a. >100,000 RBC/mm^3
   b. >500 WBC/mm^3
5. Elevated amylase in effluent

RBC, red blood cells; WBC, white blood cells.

Table 108.2. Positive Diagnostic Peritoneal Lavage Criteria

The Stable Patient

Commonly, the injured child can be stabilized in the ED with proper airway and cervical spine management, and with intravenous fluid therapy and blood transfusion. A careful secondary survey should then be performed. Based on history and careful and serial abdominal examinations, CT is indicated when intra-abdominal injuries are suspected (Table 108.1). Children who have had even minor injuries should be examined serially and monitored in the ED. At times, an abdominal CT scan is merited based solely on severe force inherent in a particular mechanism of injury despite an

unremarkable physical examination. The utility of abdominal ultrasonography in trauma is now well documented in the adult literature, and the stable patient may benefit from an early ultrasound, especially when an abdominal CT is not immediately available or if evaluation of the abdomen will be delayed during head or chest CT. In addition, the emergence of the utility of emergent laparoscopy for adults with trauma may preclude the need for DPL or laparotomy in many instances. Importantly, ultrasonography and laparoscopy may eventually allow diagnosis and management of intra-abdominal injuries in the stable pediatric patient.

Additional Management

Children with abdominal trauma often need decompression of the stomach; this procedure facilitates examination, may provide information concerning gastric or diaphragmatic injury (bloody aspirate; radiographic evidence of the nasogastric tube in the thoracic cavity), and relieves the discomfort of an ileus. Maxillofacial trauma precludes nasogastric tube placement, but an orogastric tube suffices in these instances. Urinary bladder catheterization may provide evidence of genitourinary system injury and is helpful in monitoring urinary output. Bladder catheterization is contraindicated when urethral disruption is suspected.

Diagnostic Imaging

Radiographic evaluation of children with abdominal trauma includes plain radiographs, contrast studies, radionuclide scans, ultrasound, and CT. The stable child with abdominal trauma is best evaluated with abdominal CT using intravenous contrast. If a nasogastric or orogastric tube is in place, it should be withdrawn temporarily into the esophagus to avoid an artifact from its radiopaque marker. Abdominal CT has its lowest sensitivity for small gastrointestinal perforations and pancreatic injury. Although CT is the most common technique used in childhood trauma, the surgeon's decision to proceed to laparotomy may be based more on the clinical status of the child than on the radiologic findings. Although abdominal CT is considered the most sensitive diagnostic tool, abdominal ultrasonography may provide important data early in the course of the management of a child with suspected intra-abdominal injuries. Data from the adult literature show that the sensitivity for the detection of intraperitoneal fluid ranges from 85 to 98%. Although currently not a universal component of the evaluation of the child with blunt abdominal trauma, the value of ultrasound as a rapid diagnostic tool is evident, and will likely become a part of trauma evaluation protocols.

Diagnostic Peritoneal Lavage

DPL is occasionally a helpful adjunct to the management of children with abdominal trauma. The disadvantages of DPL include the introduction of air and fluid into the abdomen (subsequent radiologic evaluations are less helpful) and peritoneal irritation caused by the procedure (subsequent physical examinations are less reliable).

It is rarely necessary to perform laparotomy on children with free intraperitoneal blood; thus, DPL, which effectively detects small volumes of blood, is often too sensitive in children. The primary indication for DPL in children is an urgent “need to know” with regard to the status of the peritoneal cavity, such as in the child who is hemodynamically unstable or requires immediate craniotomy and cannot delay for abdominal CT.

The technique for DPL in children is similar to that in adults, although in young children a small supraumbilical incision is preferred over the usual infraumbilical approach to avoid the bladder. If a nasogastric tube and urinary bladder catheter have not been placed, they should be inserted before peritoneal lavage is performed. Ringer's lactate solution (10 mL/kg, maximum 1000 mL) is instilled into the peritoneal cavity over 10 minutes and then removed for analysis. Criteria for a positive lavage are shown in Table 108.2.

Emergent versus Selective Laparotomy

The indications for immediate laparotomy are limited in blunt abdominal trauma (Table 108.3). In most cases of childhood trauma (Fig. 108.2), emergency laparotomy is not necessary and further diagnostic studies direct either elective (selective) laparotomy or observation and monitoring. Most children with blunt abdominal trauma require only in-hospital observation and monitoring after delineation of the site and extent of their injury by abdominal CT.

1. Multisystem injuries with indications for craniotomy in the presence of a positive diagnostic peritoneal lavage, free peritoneal fluid on ultrasonography, or strong historical, physical, or radiographic evidence of abdominal injury
2. Persistent and significant hemodynamic instability with evidence of abdominal injury in the absence of extra-abdominal injury
3. Penetrating wounds to the abdomen
4. Pneumoperitoneum
5. Significant abdominal distension associated with hypotension

Table 108.3. Indications for Immediate Laparotomy for Children with Abdominal Trauma

The indications for emergent laparotomy in children with penetrating trauma are illustrated in Figure 108.3. Any gunshot wound to the abdomen mandates immediate exploration. Other types of penetrating wounds in the presence of unexplained hemodynamic compromise, evisceration, pneumoperitoneum, or any evidence of violation of the peritoneum

require prompt laparotomy.

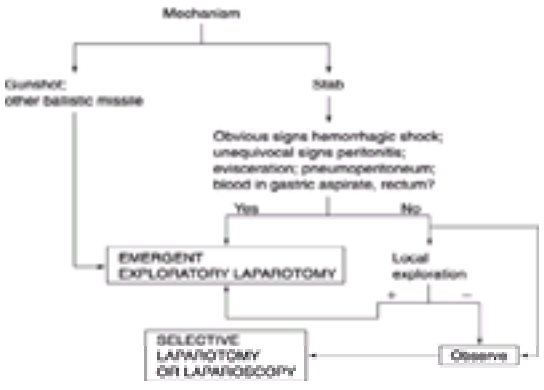

FIGURE 108.3. Management of penetrating abdominal trauma.

BLUNT ABDOMINAL TRAUMA

Abdominal Wall Contusions

Many children have minor trauma to their abdomen in the course of play and as a result of minor accidental events. Balls, bats, swings, toys, and rough play may cause contusions of the abdominal wall.

Children without signs of intra-abdominal pathology can be sent home. Those with a troubling history or any worrisome signs should receive a diagnostic laboratory evaluation and be observed in consultation with a surgeon. Suspicion for more serious intra-abdominal injuries is based on mechanism of injury and careful abdominal examination. Bilious or bloody vomiting, persistent vomiting, abdominal distension, any signs of peritoneal irritation, rectal blood or hematuria, hyperamylasemia, and elevated liver transaminase levels all suggest possible visceral injury. A low threshold for the use of abdominal CT should be maintained. Children with even minor contusions of the liver, spleen, pancreas, or hollow viscera should be hospitalized by the surgery service.

Solid Organ Injuries

The spleen is the most commonly injured intra-abdominal organ, followed by the liver. Most of these injuries are the result of automobile–pedestrian trauma, although falls and bicycle accidents are also common mechanisms. The potential morbidity and mortality result from the highly vascular anatomy of this organ, and hemorrhage into the large potential space of the peritoneal cavity.

Patients who have splenic injuries may present with either diffuse abdominal pain or localized tenderness. Subphrenic blood may cause referred left shoulder pain. Percussion and palpation tenderness is usually of greatest magnitude in the left upper quadrant of the abdomen. Abdominal radiographs occasionally reveal a medially displaced gastric bubble. CT or a radionuclide splenic scan will identify the extent of injury (Fig. 108.4 and Fig. 108.5).

FIGURE 108.4. Abdominal computed tomography from a 13-year-old girl who fell from a horse onto her left side, showing a splenic laceration.

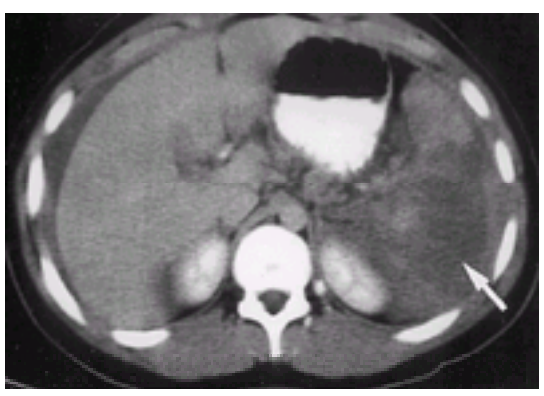

FIGURE 108.5. Abdominal computed tomography from a 10-year-old boy struck by a motor vehicle while crossing a street, showing massive splenic rupture and hemoperitoneum.

Management of splenic injuries has evolved over the last three decades since the recognition of the postsplenectomy sepsis syndrome, resulting from the influence of both clinical and diagnostic advances. Nonoperative management of splenic injuries has largely replaced the traditional treatment, which included splenectomy or splenorrhaphy. The safety of nonoperative management for most childhood spleen injuries has been well documented, and postsplenectomy sepsis has declined. The availability of noninvasive diagnostic CT also has allowed for greater confidence in the nonoperative approach to splenic trauma.

Blunt liver trauma is the most common fatal abdominal injury (Fig. 108.6). Mechanisms of injury are those common to splenic trauma. Diffuse abdominal tenderness may be a result of hemoperitoneum, but maximal tenderness is elicited in the right upper quadrant of the abdomen.

FIGURE 108.6. Abdominal computed tomography from a 9-year-old boy struck by a motor vehicle while riding his bicycle, showing a large liver laceration.

As with trauma to the spleen, nonoperative management of blunt hepatic injuries has become more common and is now the rule rather than the exception.

Blood transfusion therapy was necessary in 5.5% of patients in the National Pediatric Trauma Registry in 1997, and fewer than 1% of patients with blunt trauma admitted to Children's Hospital in Boston over the last year required transfusion therapy. The need for blood transfusion is based on careful monitoring of vital signs, clinical status, serial abdominal examinations, and analysis of hematocrit and fluid balance.

Pancreatic Injuries

Blunt abdominal injuries, particularly from bicycle handlebars, are the most common cause of pancreatic pseudocyst formation in children, although this injury is uncommon. Diagnosis is often delayed because of the nonspecific nature of subjective complaints and physical examination findings. The classic triad of epigastric pain, a palpable abdominal mass, and hyperamylasemia are detected only rarely in children and may develop slowly. The pancreas is relatively well protected, and associated trauma such as hepatic and intestinal injuries commonly are present when injury to the pancreas has occurred. Abdominal ultrasound and contrast CT (often serial examinations) are used to make the diagnosis (Fig. 108.7); however, acute pancreatic injuries may not be apparent on the initial CT scan.

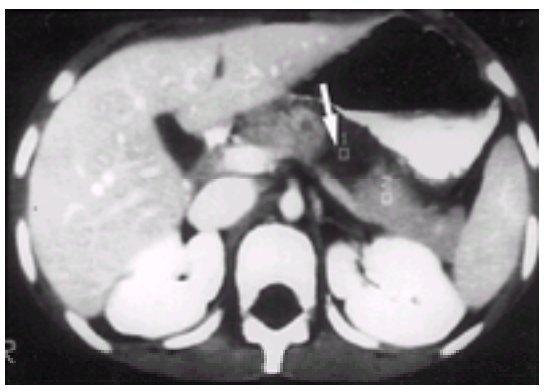

FIGURE 108.7. Abdominal computed tomography from a 6-year-old boy who fell onto the handlebar of his bicycle, showing a pancreatic hematoma and pseudocyst formation.

Severe injury of the pancreas is rare, but blood loss and leakage of enzyme-laden secretions may result in hypovolemia and peritonitis. Blunt abdominal trauma may also injure the ductal elements of the pancreas, and diagnosis depends on a

high index of suspicion, consideration of the mechanism of injury, physical examination, serum amylase determination, and diagnostic imaging. Of note, however, is that the absence of hyperamylasemia does not preclude pancreatic trauma because elevated serum amylase is detected in 16 to 80% of cases of blunt injury. Elevated serum amylase should suggest the possibility of pancreatic injury, but the absolute value does not correlate with the degree of injury. Elevation of the amylase in fluid returned from DPL suggests injury to bowel or pancreatic ductile elements.

Nasogastric decompression and bowel rest are indicated when pancreatic injury is suspected. Nonoperative therapy is normally used initially for children with isolated pancreatic pseudocyst caused by blunt trauma. Maturation of the pseudocyst may necessitate surgical drainage, although spontaneous resolution may occur in 25% of children. Experience with percutaneous drainage of pancreatic pseudocysts in children is increasing, but the traditional approach has been to use surgical internal drainage once a pseudocyst has persisted beyond 6 weeks. When severe pancreatic crush or transection is suspected, the surgeon may elect to perform immediate exploration and resection or drainage.

Hollow Abdominal Viscera Injuries

Intestinal perforation caused by blunt abdominal trauma is rare in the pediatric age group, but the most common causes of these injuries are automobile–pedestrian trauma, automobile lap belt injuries, and child abuse. The mechanisms of injury usually involve rapid acceleration or deceleration of a structure near a point of anatomic fixation (e.g., ligament of Treitz), or trapping of a piece of bowel between two unyielding structures such as a lap belt and the spine. Hollow viscera injury may be difficult to diagnose because physical findings may be minimal and/or nonspecific for the first few hours and abdominal CT is not particularly sensitive for this injury. However, succus entericus, bile, and activated pancreatic enzymes are extremely irritating to the peritoneum over time; the development of fever or worsening peritonitis on serial physical examinations should alert the examining physician to the possibility of bowel perforation.

Plain radiographs of the abdomen demonstrate free intra-abdominal air in only 30 to 50% of cases. Similarly, pneumoperitoneum or leakage of gastrointestinal contrast is only rarely seen on the CT scan. DPL may demonstrate bile or amylase in the effluent and is sensitive for bowel perforations. Most perforations or transections of bowel are found through laparotomy, which the surgeon has chosen to perform because of advancing peritonitis or unexplained persistent fever. Management depends on the site and extent of structural injury.

Late Presentations of Intra-Abdominal Trauma

Some children with abdominal trauma do not have evidence of intra-abdominal pathology on the initial evaluation but may return days or weeks later with abdominal distension and/or pain, persistent emesis, or hematochezia. In particular, three injuries are characterized by late presentations: 1) pancreatic pseudocyst (previously discussed), 2) duodenal hematoma, and 3) hematobilia.

Intramural duodenal hematoma is an uncommon injury that results from a direct blow to the epigastrium (blunt force delivered by a small-diameter instrument such as a broom handle or the toe of a boot) or from rapid deceleration and may cause partial or complete gastric outlet obstruction. Bleeding into the wall of the duodenum causes compression and therefore symptoms of intestinal obstruction, including pain, bilious vomiting, and gastric distension. Diagnosis is made by ultrasonography or a contrast upper gastrointestinal study, revealing the “coiled spring sign.” Injury of the pancreas must be suspected when duodenal hematoma is considered. Nonoperative management includes nasogastric decompression and parenteral nutrition for up to 3 weeks.

Rupture of the gallbladder is rare and is almost always associated with severe blunt trauma to the liver. Likewise, hematobilia is associated with hepatic trauma and is a result of pressure necrosis from an intrahepatic hematoma or direct injury to the biliary tree. Children with hematobilia present several days after a blunt abdominal trauma with abdominal pain and upper gastrointestinal bleeding. Cholangiography confirms the diagnosis. Embolization is used to achieve hemostasis, but hepatic resection is necessary when this treatment fails.

PENETRATING ABDOMINAL TRAUMA

Penetrating abdominal trauma is much less common than blunt trauma in the pediatric age group. However, the evolution of a more heavily armed society has resulted in a worrisome increase in the frequency with which children sustain penetrating injuries.

The high morbidity and mortality associated with penetrating trauma to the abdomen is a result of the destructive force of ballistic missiles and fragments, rapid hemorrhage of vascular structures and solid organs after missile and stab injuries, difficulty of surgical repair of grossly injured intra-abdominal organs, and postoperative complications. Intra-abdominal organs are at risk for penetrating trauma, depending on their size and location. The colon and small bowel are large in volume and are the most commonly injured structures, followed by the liver, spleen, and major vessels. Hypovolemia and/or signs of peritonitis are then the result of brisk hemorrhage and spillage of enteric contents into the peritoneal space.

The approach to these patients includes resuscitation of all life-threatening injuries and treatment of hemorrhagic shock. The need for laparotomy must be determined quickly, and broad-spectrum antibiotics, such as ampicillin (50 to 100 mg/kg), clindamycin (10 mg/kg), and gentamicin (2.5 mg/kg), should be given.

Gunshot Wounds

The destructive energy of ballistic missiles and fragments is related to mass and velocity (kinetic energy = $\frac{1}{2}MV^2$, where M is the mass, and V is the velocity), and more than 90% of gunshot wounds to the abdomen are associated with significant injuries. Hollow viscera and large vessels are often involved, and solid organs such as the liver and spleen

may demonstrate burst injuries. Therefore, laparotomy is mandated in all gunshot wounds to the abdomen.

Stab Wounds

Stab wounds to the abdomen carry potential for devastating injury depending on which intra-abdominal structures are involved. The extent of the injury also depends on the type, size, and length of the weapon and on the trajectory. Major vascular injuries pose the greatest threat; commonly injured vessels include the intra-abdominal aorta, the inferior vena cava, the portal vein, and the hepatic veins.

Anterior stab wounds are explored via laparotomy if hemodynamic instability or signs of peritonitis are present, if blood is noted in the gastric aspirate or on rectal examination, or if pneumoperitoneum or evisceration is noted (Fig. 108.3). Local exploration is needed to rule out penetration of the peritoneum even in minor stab wounds.

Stab wounds to the flank or back are less readily and less quickly diagnosed than anterior wounds; the retroperitoneal structures are more protected by paraspinal musculature, and bleeding is often tamponaded in this area. Dorsal stab wounds are sometimes managed nonoperatively unless hemodynamic instability or signs of peritonitis are present, although selective laparotomy is a common surgical strategy.

LAP AND SHOULDER BELT AND AIR BAG INJURIES

Children who are too large for child safety seats but too small for adult seat belts are at increased risk for injuries. In particular, children restrained only by lap belts in motor vehicles involved in rapid deceleration crashes are at risk to sustain Chance fractures (compression or flexion-distraction fractures of the lumbar spine) in association with intra-abdominal injuries (the lap belt complex). As many as half of the children with Chance fractures have intra-abdominal injuries; therefore, a high index of suspicion must be maintained to detect such injuries. The hallmark indicator of the lap belt complex is abdominal or flank ecchymosis in the pattern of a strap or belt. A normal abdominal CT does not rule out ruptured viscous, and laparoscopy or laparotomy should be considered for children in whom the lap belt complex is suspected. Carotid injuries caused by high-riding shoulder restraints in motor vehicle collisions are much less common.

Although it is well advertised that children younger than 12 years or less than 5 feet in height should not ride in the front seat of a vehicle that has functioning air bag restraints, significant injuries and deaths have occurred. Life-threatening injuries caused by air bag deployment are typically related to cervical spine injuries and closed head trauma. Less severe airbag injuries include abrasions to the face, neck, and chest; minor burns to the upper extremities; blunt ocular trauma; and chemical keratitis.

CHILD ABUSE

At least 1.6 million children are abused or neglected every year in the United States. Major blunt abdominal trauma resulting from physical child abuse is uncommon but highly fatal; mortality rates are as high as 50%. This high fatality rate is the result of the unfortunate but typical delay with which parents or caretakers who abuse children seek treatment.

Children who are seriously injured because of physical abuse commonly have more than one site of trauma; some of the injuries can be occult, and others may have been inflicted at different times. Abdominal injuries are usually inflicted by fists, feet, or small handheld objects and are rarely penetrating. The diagnosis of blunt abdominal injury caused by battering is difficult to make unless a high index of suspicion for child abuse is maintained. An important clue is often an implausible historical account for the seriousness of the injury. As with abdominal trauma caused by other mechanisms, physical examination findings may not be obvious. Laboratory analyses and abdominal CT may be necessary to confirm the diagnosis. However, severe injuries may present with obtundation and shock, abdominal distension, and tenderness. Intra-abdominal injuries most commonly involve the liver and spleen, as well as the pancreas–duodenum–jejunum region. In all such cases in which child battering is suspected, a child protection consultant should be involved early.

CHAPTER 109

Genitourinary Trauma

CARMEN TERESA GARCIA, MD

Pediatric Emergency Department, Jackson Memorial Hospital, Miami, Florida

In children who sustain multiple injuries, genitourinary trauma is second in frequency only to central nervous system trauma. Approximately 10% of trauma patients have urogenital injuries. Most injuries (90%) are the result of blunt trauma that involves crush injuries and acceleration/deceleration forces. Vehicular and pedestrian accidents account for a large percentage of blunt trauma. Other mechanisms of injury include falls and sports-related incidents. Penetrating injuries are less common in children than in adults. High-velocity bullet wounds produce direct tissue injury as well as damage to adjacent tissue because of the energy liberated by the missile. Low-velocity bullet wounds and stab wounds cause injury by penetrating the tissue directly. Iatrogenic trauma has been reported after operative procedures.

Injuries to other systems are often encountered in patients sustaining genitourinary trauma. Common associated problems include head injuries, fractures (extremities, pelvis, ribs, spine, skull), spinal cord injuries, and lacerations of the liver and spleen. Simultaneous upper and lower tract injuries are rare and are usually incompatible with survival. Isolated urologic injuries are rarely the cause of death.

The clinical approach to the injured child should strictly follow Advanced Trauma Life Support guidelines. Figure 109.1 provides an algorithm for diagnostic evaluation of the pediatric patient with genitourinary trauma. Urologic management may be temporized to permit urinary drainage in the initial phases; the patient may subsequently require operative procedures.

FIGURE 109.1. Algorithm for evaluation of the pediatric patient with genitourinary trauma. *IVP,* intravenous pyelogram; *CT,* computed tomography; *RBC,* red blood cells; *hpf,* high-powered field; *US,* ultrasound.

KIDNEY

The most common urinary tract injury encountered in children is injury to the kidney. More than 47% of genitourinary injuries involve the kidney. Blunt trauma accounts for up to 90% of renal injuries. Most pediatric renal trauma is sustained in motor vehicle accidents. Falls, sports incidents, and direct blows are also common mechanisms of injury.

Penetrating trauma accounts for a small percentage (4%) of cases. However, an increasing prevalence nationwide of gunshot and stab wounds may significantly alter these figures in the future. Approximately 10% of penetrating abdominal injuries involve the kidney. Penetrating renal trauma may occur as a complication of amniocentesis or percutaneous manipulation.

Associated injuries often occur, with head injuries being the most common. Associated intraperitoneal injuries occur in 80% of patients with penetrating renal trauma and 20% of patients with blunt renal trauma.

Children are more likely than adults to sustain renal injuries. In the child, the kidney is larger in proportion to the size of the abdomen than in the adult. The child's kidney may retain fetal lobations, which allow for easier parenchymal

disruption. Weaker abdominal musculature, a less well-ossified thoracic cage, and less developed perirenal fat and fascia fail to provide adequate protection for the kidney.

Coincidental congenital renal anomalies and intrarenal tumors have been documented in up to 10% of injuries. Symptoms and signs of a significant renal injury sustained with only minimal trauma should alert the clinician to the presence of preexisting anomalies, such as ureteropelvic junction obstruction, horseshoe kidney, pelvic kidney, or Wilms' tumor.

Classification

Renal injuries have been described using different classification systems based on the clinical and radiologic assessment of the patient. The Organ Injury Scaling Committee of the American Association for the Surgery of Trauma has devised an injury severity score, which represents an amalgamation of previous scales and was developed to facilitate clinical research. This classification system is illustrated in Figure 109.2. Grade I injuries include contusions or subcapsular, nonexpanding hematomas. Grade II injuries include nonexpanding hematomas confined to the retroperitoneum or lacerations less than 1 cm in depth without urinary extravasation. Grade III injuries include lacerations extending more than 1 cm into the renal cortex without collecting system rupture or urinary extravasation. Grade IV injuries include lacerations extending into the collecting system or renal vascular injuries with contained hemorrhage. Grade V injuries include completely shattered kidneys or avulsions of renal hilum with devascularized kidneys.

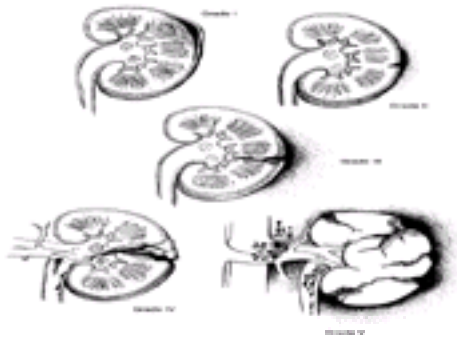

FIGURE 109.2. Classification of renal injuries as proposed by Organ Injury Scaling Committee.

Parenchymal contusions and hematomas are the most common renal injuries, accounting for 60 to 90% of all lesions from blunt trauma. Lacerations account for up to 10% of renal injuries and may involve disruption of the capsule, collecting system, or both. Severe injuries, such as shattered kidney or pedicle injuries, constitute approximately 3% of renal injuries. Pedicle injuries result from lateral displacement of the kidney with stretching of the tethered renal vessels.

Clinical Presentation

Children who sustain significant renal injuries usually present with localized signs such as flank tenderness, flank hematoma, or a palpable flank mass. Findings also include nonspecific symptoms and signs often associated with injury to other intra-abdominal organs. Generalized abdominal tenderness, rigidity of the abdominal wall, paralytic ileus, and hypovolemic shock may all be part of the clinical picture. Penetrating injuries to the chest, abdomen, flank, and lumbar regions should alert the clinician to the possibility of renal injury.

Hematuria has long been considered the cardinal marker of renal injury. Although controversy exists about the correlation between the degree of hematuria and the severity of the injury, the presence of any degree of hematuria should be regarded as potential indication of underlying renal injury or anomaly. It should be emphasized that hematuria may be absent in up to 50% of patients with vascular pedicle injuries and in 29% of patients with penetrating injuries. Hematuria out of proportion to the mechanism of injury should suggest a congenital anomaly or neoplasm.

Hematuria with abdominal symptoms has been associated with an increased risk of nonurologic intra-abdominal injuries. Injuries to other organs can be seen regardless of renal injury. Some series suggest that clinically significant liver and spleen injuries are more common in children with hematuria than are renal injuries.

Diagnostic Evaluation

Evaluation of the genitourinary system can be undertaken once life-threatening conditions have been identified and the child has been resuscitated. A urinalysis should be obtained in all patients with multisystem trauma or suspected isolated renal injury.

Radiographic evaluation of the genitourinary tract is necessary in patients with gross hematuria or microscopic hematuria associated with major mechanism, clinical findings indicative of renal injury, or other significant injuries (Fig. 109.1). Hematuria of more than 20 red blood cells per high-powered field (RBC/hpf) in patients without associated clinical findings has been recommended as a threshold for radiographic workup. Microscopic hematuria with shock is one of the clinical criteria used to guide radiographic evaluation in the adult population. Hypotension is an uncommon event in children with renal injuries and therefore is not a reliable indication of renal injury in the pediatric population.

Initial evaluation of suspected pediatric renal trauma should include radiographs of the chest, abdomen, and pelvis. Plain

films may show obliterated renal and psoas shadows, scoliosis with the concavity toward the injured site, intra-abdominal mass effect, or a coincident rib, spinous process, or pelvic fracture.

Traditionally, the intravenous pyelogram (IVP) has been the cornerstone of evaluation in renal trauma (Fig. 109.3). IVP is available in most institutions and provides information about both kidneys. It can be obtained on an unstable patient urgently in the emergency department (ED) or in the operating room before surgery. A scout radiograph should be made before the contrast study. IVP is performed by administering 1 to 4 mL/kg (maximum 100 mL) of nonionic contrast agent intravenously, followed by abdominal films in 1, 5, and 15 minutes. A one-shot IVP may be indicated for the unstable patient and is completed by obtaining a single film 3 to 5 minutes after injection of contrast material. Indications of renal injury include delayed excretion of contrast by the injured kidney, nonvisualization of the caliceal system, or extravasation of contrast into the perinephric tissues. The presence of a normally functioning kidney contralateral to the injured kidney should be specifically noted.

FIGURE 109.3. Renal contusion. Intravenous pyelogram (IVP) *(left panel)* shows decreased concentration of contrast material in the left kidney. Follow-up IVP *(right panel)* 1 month after the injury reveals normal renal function.

Even under optimal conditions, the IVP cannot always reliably identify and stage renal trauma. In one review, Cass reported the urogram to be definite in 5% of contusions, 50% of lacerations, and 29% of pedicle injuries. However, the importance of the IVP lies in rapidly assessing the overall functional and anatomic integrity of the kidney, as well as the presence of urinary extravasation and the presence of a congenital anomaly. More recently, contrast-enhanced computed tomography (CT) has become the preferred study for evaluation of major abdominal injury, including renal injury (Fig. 109.4). CT scan has certain advantages over the IVP, the most important of which is the detection of associated injuries. In addition, CT provides three-dimensional views and imaging independent of the vascularity of the kidney.

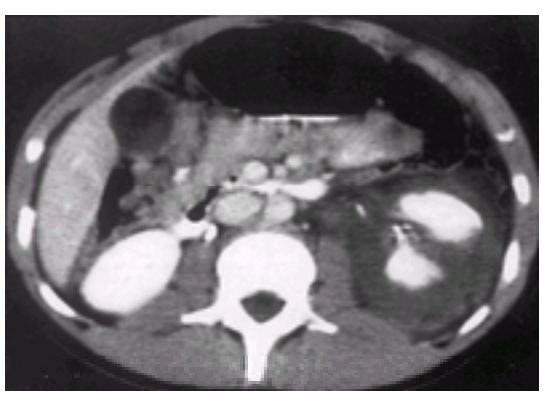

FIGURE 109.4. Renal fracture. Computed tomography section of the abdomen shows fracture of the left kidney with moderate subcapsular hematoma.

CT imaging can be used to determine the degree of renal parenchymal injury, to evaluate the presence of nonviable tissue, to demonstrate extravasation and perirenal collections, and to diagnose most pedicle injuries. The diagnostic accuracy of the CT scan has been reported as high as 98%, and CT scanning is becoming the standard imaging modality for renal trauma. CT scanning has also proven to be a useful tool for following patients after trauma.

Ultrasonography has been advocated for the staging of renal trauma. Its sensitivity in demonstrating renal injury is only 70% compared with CT scanning. However, ultrasound has certain advantages over CT scanning. It is readily available, can be performed at the bedside, and does not require the use of contrast material or sedation. Ultrasound can evaluate the size of the kidney and the integrity of the urinary drainage system. Pulsed flow duplex Doppler ultrasound can assess renal arterial and venous flow and may represent the most immediate means of screening for renal pedicle injury.

Ultrasound can be particularly helpful in patients with perirenal collections who require early follow-up imaging during the hospital stay. It may be an alternative modality for the evaluation of the pregnant trauma patient. It is also often used for long-term outpatient follow-up.

Angiography (Fig. 109.5) has been largely replaced by noninvasive modalities, especially in the pediatric patient in whom technical problems with vascular access result in a higher complication rate than in adults. Arteriography does not add

useful information to contrast CT scanning and may increase diagnostic delay during the preoperative workup. It is useful in patients who require therapeutic embolization of an active bleeding site.

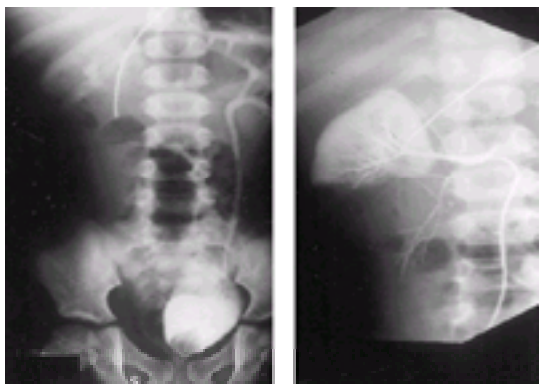

FIGURE 109.5. Renal fracture. Intravenous pyelogram *(left panel)* demonstrates nonvisualization of the lower pole of the right kidney. The arteriogram *(right panel)* confirms the diagnosis.

Radionuclide imaging can assess pedicle competence, parenchymal integrity, and renal function. A nuclear scan can be obtained instead of sonography to assess change in size of perinephric collections. Its most important role is in follow-up evaluation of renal injury (Fig. 109.6), particularly in the setting of new-onset hypertension.

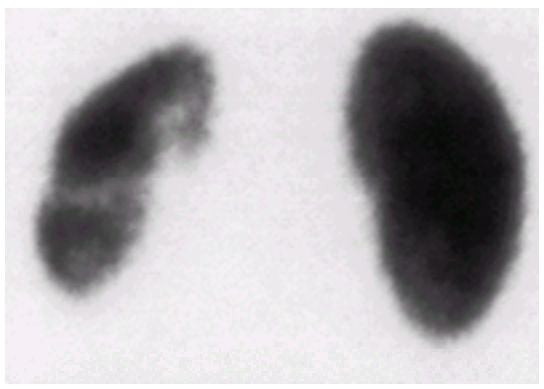

FIGURE 109.6. Follow-up renal scan of patient in Figure 109.5 obtained 4 months after the injury. The study reveals several areas of decreased radiotracer uptake in the left kidney.

In conclusion, hemodynamically stable patients who have experienced major mechanisms of injury, and who have associated injuries, clinical findings, or gross hematuria should undergo radiographic evaluation. These patients should be evaluated by CT scan. Children with suspected isolated renal injuries or microscopic hematuria of more than 20 RBC/hpf without associated findings can be evaluated by IVP or CT scan. Children who remain unstable despite resuscitative measures should undergo a one-shot IVP before emergency laparotomy. This procedure is particularly important to confirm the presence of a normal contralateral kidney. Patients with microscopic hematuria of less than 20 RBC/hpf, stable vital signs, no focal findings, and no signs of injury to other organ systems do not require emergent imaging. These patients may be discharged and can be evaluated on an outpatient basis with CT, IVP, or ultrasound if hematuria persists. However, in some centers, management of these patients involves hospitalization for observation followed by nonemergent radiographic evaluation.

Management

The principle underlying the management of pediatric renal trauma is preservation of renal tissue and function with minimal morbidity and mortality. Once the patient's general condition has been assessed and the presence of associated injuries established, treatment of renal trauma should proceed based on staging of the traumatic lesion.

In cases of blunt trauma, minor injuries, such as contusions and lacerations without urinary extravasation (grades I, II, and III), are treated conservatively. Current therapy involves strict bed rest, analgesia, and prophylactic antibiotics. Once gross hematuria has cleared, limited activity is instituted until microscopic hematuria resolves.

Management of the remaining patients (grades IV and V) evokes significant controversy. Treatment of deep lacerations and fragmentation depends on the child's hemodynamic status, degree of urinary extravasation and renal bleeding, and associated injuries. More patients are now being managed conservatively with close monitoring of vital signs, serial hematocrits, and broad-spectrum antibiotics. Patients treated with conservative nonoperative management have a complication rate of up to 50%. These complications include persistent or recurrent hemorrhage, extravasation and urinoma formation, infection, infarction, and segmental hydronephrosis. The nephrectomy rate with delayed surgery is usually less than 10%. Immediate surgical intervention results in a nephrectomy rate of 10 to 20% in most series. However, there is a significant decrease in the number of surgical procedures performed for subsequent complications.

Renal pedicle injuries are uncommon in the pediatric population and few revascularization attempts are successful. Reconstruction of unilateral pedicle injuries should be attempted only in children who are stable, who do not have major

associated injuries, who are less than 12 hours from initial injury, where the kidney is shown to be intact, and where contralateral function is good. If reconstruction fails, nephrectomy should then be performed. Whether the infarcted kidney should be removed electively in children treated nonoperatively is debatable. Bilateral renal vascular injury is associated with high morbidity and mortality. Surgery in these patients should be performed within 24 hours after the injury.

Penetrating renal injuries have traditionally been managed with operative intervention. Hemodynamically stable patients with isolated lower-grade injuries can be treated expectantly. Delayed bleeding may occur in up to 24% of patients with grades III and IV injuries who are managed nonoperatively. Therefore, these patients should undergo renal exploration when laparotomy is indicated for other injuries. Children with vascular injuries, urinary extravasation, or hemodynamic instability require surgery.

Complications

Short-term complications of renal trauma include delayed hemorrhage, urinary extravasation, abscess formation, and ureteral obstruction secondary to clot formation. Long-term complications include hypertension (probably less than 5%), hydronephrosis, arteriovenous fistula, renal intestinal fistula, and stone formation. The child with a history of renal trauma requires regular follow-up for at least 1 year, and longer in severe trauma, to ensure that complications are diagnosed and treated promptly.

URETER

Ureteral injuries are uncommon in the child, accounting for less than 1% of all urologic trauma. These injuries can be caused by blunt, penetrating, or iatrogenic trauma.

Blunt trauma usually involves the ureteropelvic junction. Disruption of the ureter from the pelvis results from stretching of the ureter by sudden hyperextension of the trunk. Traditionally, this injury has been described more often in children. The degree of hyperextension necessary to cause avulsion of the ureter was thought to be fatal in adults. However, an increased number of ureteropelvic junction injuries has recently been reported in adults. In the past, many of the injuries in adults may have been misdiagnosed as parenchymal lacerations involving the collecting system.

Trauma to the ureter should be suspected in patients presenting with fracture of the transverse process of a lumbar vertebra. Pelvic fracture, hip fracture, lower rib fracture, splenic laceration, liver laceration, and diaphragmatic rupture have also been reported in association with ureteral injuries.

Early diagnosis of blunt ureteral injuries is critical. The injury is often overlooked. Fewer than 50% of patients are diagnosed within 24 hours of presentation. The physical examination may be unremarkable. However, an enlarging flank mass in the absence of signs of retroperitoneal bleeding suggests urinary extravasation. Hematuria is an unreliable sign. The urinalysis may be normal in 30% of confirmed cases. When the diagnosis has been delayed, ureteral injury may manifest with fever, chills, lethargy, leukocytosis, pyuria, bacteriuria, flank mass or pain, fistulas, and ureteral strictures.

Avulsion of the ureter should be suspected when the IVP demonstrates extravasation of contrast material and nonfilling of the affected ureter. Contrast-enhanced CT is an appropriate alternative to the IVP. CT findings suggestive of ureteral injury include medial perirenal extravasation of contrast material, a circumrenal urinoma, and lack of opacification of the ureter distal to the injury. Delayed images must be obtained regardless of which diagnostic modality is used. Both CT scan and IVP have been shown to have a low sensitivity for ureteral injuries, identifying only 33% of cases. Retrograde pyelogram may be a more reliable examination, but it is rarely performed in the initial evaluation of the trauma patient.

The management of complete transection of the ureter depends on the level of the injury. Important elements include debridement of devitalized tissue and a watertight, tension-free anastomosis. Ureteroureterostomy, transureteroureterostomy, or pyeloureterostomy is recommended for upper and midureteral injuries. Mid- to lower ureteral injuries are best treated with ureteroneocystostomy. Placement of a ureteral stent is indicated in most cases. Conservative treatment with stent placement alone may be adequate for patients with lacerations.

If the ureteral lesion is identified within 5 to 10 days of the injury, prompt repair of the ureter is indicated. If diagnosis is delayed for more than 10 days, urinary diversion above the lesion should be performed with subsequent definitive repair 4 to 6 months later. The incidence of nephrectomy is approximately 5% when the injury is detected early, but it is as high as 32% when recognition is delayed.

Penetrating injuries may occur at any point along the length of the ureter and are associated with injuries to other intra-abdominal organs in up to 90% of cases. Stab wounds rarely cause ureteral injuries. However, up to 50% of patients with gunshot wounds to the abdomen have injury to the ureter. Occasionally, the ureter may be accidentally injured during pelvic operations or ureteroscopy. Repair of penetrating injuries to the ureter in the child follows the same guidelines as those observed in adults. Injuries caused by high-velocity missiles require wide debridement to ensure an adequate anastomosis and to preserve blood supply.

BLADDER

Bladder injuries may occur after blunt or penetrating trauma. Blunt trauma secondary to motor vehicle accidents is the leading cause of bladder injuries. Approximately 80% of bladder injuries are associated with pelvic fractures and penetration of the bladder by a bony fragment. However, only 10% of patients with pelvic fractures sustain lower urinary tract injury. The probability of having an associated bladder injury increases proportionally with the number of fractured pubic rami. Mortality rate associated with bladder rupture may be as high as 40%. Death is usually caused by associated

head injuries rather than by bladder injuries themselves.

During childhood, the bladder has a higher abdominal location, which renders the organ more susceptible to injury than in adults. The bladder can also be more easily damaged when full.

Bladder injuries are classified as extraperitoneal, intraperitoneal, or combined. Extraperitoneal injuries are more frequently associated with pelvic fractures. Intraperitoneal injuries are usually caused by blunt trauma to a distended bladder. Combined injuries are usually seen with gunshot wounds. Bladder injuries may range from contusions to rupture. Contusions are incomplete, nonperforating tears of the mucosa.

Hematuria and dysuria are symptoms commonly seen at presentation. More than 90% of patients with rupture of the bladder have hematuria. Microscopic hematuria is associated with less severe injuries such as contusions. Inability to void may be associated with large tears. Patients with intraperitoneal ruptures may develop a palpable fluid wave from extravasation of urine into the peritoneal cavity and peritoneal irritation. Elevated levels of blood urea nitrogen out of proportion to creatinine result from more rapid peritoneal reabsorption of urea.

Diagnostic evaluation is indicated in patients who sustain pelvic or lower abdominal trauma with hematuria and inability to void. Evaluation begins with a radiograph to exclude a pelvic fracture. If no pelvic fracture, no blood at the meatus, and no dislocation of the prostate on rectal examination are present, the urethra can be catheterized gently and a retrograde cystogram can be performed. A stress cystogram with the bladder full and anteroposterior and oblique views and a postdrainage film should be obtained. Observation of strict sterile technique is mandatory when performing the cystogram. Foley balloon catheters may result in false-negative cystograms because the inflated balloon may occlude a small tear. False-negative results may also occur if the bladder is not adequately distended with contrast material. If urethral catheterization is not successful or a urethral injury is suspected, a retrograde urethrogram should be completed. Once bladder or urethral injury is ruled out, imaging of the upper tract can be initiated.

Cystogram of a contused bladder may show a teardrop shape or elevation of the bladder out of the pelvis. No evidence of extravasation of contrast material will be apparent. Extraperitoneal perforation is demonstrated by the presence of extravasated medium in the area of the pubic symphysis and pelvic outlet. In cases of intraperitoneal rupture, contrast may outline intra-abdominal organs or paracolic gutters. Contrast-enhanced CT scan and CT cystography can also be used in the evaluation of bladder injuries.

Conservative management with or without urethral catheter drainage is the standard of care in patients with contusion. Extraperitoneal vesical rupture can be managed by urethral catheter or suprapubic drainage for 7 to 10 days. Treatment of large extraperitoneal tears or intraperitoneal tears involves transperitoneal exploration and repair with placement of a suprapubic cystostomy tube.

Iatrogenic bladder injuries may occur during herniorrhaphy, cystoscopy, and umbilical artery cutdown. Patients with myelodysplasia who have undergone bladder augmentation may experience spontaneous bladder rupture in the presence of infection, bacteremia, or overdistension. Symptoms and signs of sepsis, as well as shoulder pain, may be encountered at presentation. Emergent exploration is indicated after a cystogram is completed.

URETHRA

Motor vehicle accidents, straddle injuries, and instrumentation account for most urethral injuries sustained during childhood. Urethral injuries occur primarily in males. In boys, the urethra is divided by the urogenital diaphragm into an anterior (pendulous and bulbous) and posterior (membranous and prostatic) urethra (Fig. 109.7). Anterior and posterior urethral injuries differ from each other by mechanism of injury, clinical presentation, and treatment.

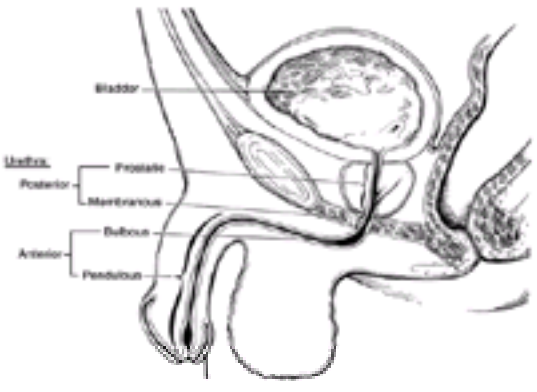

FIGURE 109.7. Sagittal section of male lower urinary tract illustrating levels of urethra.

Anterior urethral injuries result from direct trauma, are often isolated, and are associated with a low mortality rate. The pendulous urethra may be damaged by blunt or penetrating forces. Bulbar injuries are commonly caused by straddle injuries as the urethra is compressed between the symphysis pubis and a solid object. The major sign of acute anterior injury is bleeding from the urethra. Blood at the meatus has been reported in up to 90% of patients sustaining anterior urethral injuries. Other findings include hematuria, inability or difficulty voiding, and periurethral or perineal edema and ecchymosis. Perineal ecchymosis in the shape of a butterfly is typical for these injuries. Blind placement of a urethral catheter may convert a partial tear into a complete transection and therefore should be discouraged.

Diagnosis can be made by performing a retrograde urethrogram under sterile conditions. A Foley catheter appropriate for the size of the patient is inserted into the urethra to the fossa navicularis without inflating the balloon. Contrast material is injected via the catheter into the urethra and images are obtained in an oblique position. If a Foley catheter is already in place, the urethrogram can still be performed via a small feeding tube passed alongside the catheter. An optional technique involves simple retrograde syringe injection through the urethral meatus. Retrograde urethrography should be performed under fluoroscopy with minimal pressure. Gross extravasation of contrast agent at the site of the injury without visualization of the proximal urethra and bladder is diagnostic for complete rupture of the urethra. Partial rupture is represented by localized extravasation at the site of the injury with contrast passing into the proximal urethra and bladder. If no extravasation is noted, the urinary catheter can be gently advanced into the bladder.

Anterior urethral injuries can be managed by 7 to 10 days of urethral catheterization and antibacterial therapy. More severe injuries require urinary diversion by suprapubic cystostomy. Penetrating wounds demand surgical repair with exploration, debridement of devitalized tissue, and copious irrigation.

Posterior urethral injuries occur with severe trauma to the body and are usually associated with other injuries, particularly pelvic fractures. The mortality rate with fractured pelvis has been reported to be as high as 30%. The high death rate in these patients is attributed primarily to associated injuries.

The urogenital diaphragm located between the pubic rami fixes the membranous urethra and makes it vulnerable to rupture when the pubic arch is fractured. Tears may also result from shearing of the prostatic urethra at the superior border of the urogenital diaphragm. Injuries to the prostatic urethra may extend to the bladder neck. Posterior urethral injuries in men almost uniformly occur distal to the prostate. In adults, the mature prostate, puboprostatic ligament, and bladder stabilize the prostatic urethra making it less susceptible to trauma.

Signs of proximal urethral injury include blood at the meatus, hematuria, inability to void, displacement of the prostate on rectal examination, and perineal ecchymosis. Catheterization of the urethra is contraindicated. The diagnosis is best made by retrograde urethrography as described for anterior urethral injuries. CT scan is not adequate for diagnosing urethral injuries and is only presumptive if extravasation is detected at the bladder neck or urethra (Fig. 109.8). The IVP may demonstrate elevation of the bladder out of the pelvis.

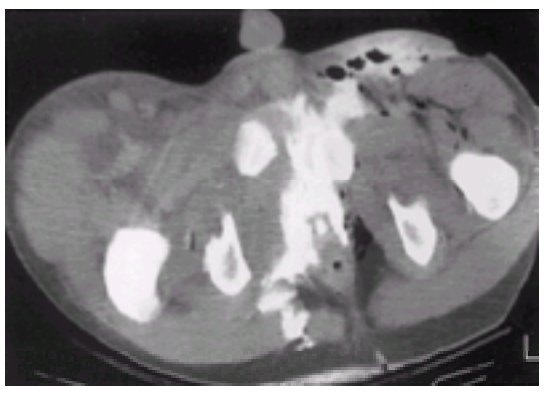

FIGURE 109.8. Posterior urethral disruption and pelvic fracture. Computed tomography of pelvis shows extravasation of contrast from posterior urethra into the surrounding tissues.

Initial management of posterior urethral injuries remains controversial. Therapeutic options vary from immediate exploration with primary repair to placement of a suprapubic tube with delayed urethroplasty. Urethral rupture may also be treated by realigning the urethra over an indwelling urethral catheter. Primary repair or operative realignment should be reserved for urethral injuries associated with rectal laceration, a high-riding bladder, or injury to the bladder neck.

Although the incidence of urethral strictures is higher in patients undergoing cystostomy with delayed repair, impotence and urinary incontinence are more prevalent when immediate urethral repair or realignment is performed and secondary repair of stricture is often needed. Some studies suggest that long-term outcome may be determined by the location of the injury, regardless of treatment method. Membranous urethral tears may have a more favorable outcome. Bladder neck injuries have the lowest rate of continence.

Trauma to the urethra in girls is rare because the female urethra is relatively mobile and short. Injuries may occur after surgical procedures or instrumentation. Most serious injuries involve the vesicourethral junction and result from blunt abdominal trauma in motor vehicle accidents. The lesion generally occurs in association with pelvic fractures. The injury often extends to the vagina. Urethral injuries in the female are treated with suprapubic drainage and elective repair. Some authors recommend primary operative repair of the urethral rupture with closure of associated vaginal tears. Long-term complications of this injury include urethrovaginal fistula, vaginal stenosis, incontinence, and urethral stricture.

SCROTUM

Scrotal trauma may occur as a result of straddle injuries or bicycle accidents or during sporting events. The patient may present with scrotal tenderness, edema, and ecchymosis. Potential injuries include skin or dartos ecchymoses and lacerations, intrascrotal hematomas, testicular hematomas, testicular dislocation, and testicular rupture. In addition, a testicle may torse after trauma.

When inspection of the scrotum and its contents is obscured by local swelling and pain, ultrasonography is helpful to define the extent of the injury. An intratesticular hematoma may show as an echogenic or hypoechoic testicular mass. A hematocele produces a complex extratesticular fluid collection. Sonographic findings of rupture include presence of hematocele, mixed parenchymal echogenicity, intraparenchymal hemorrhage, and disruption of the tunica albuginea or parenchyma. If the ultrasound exam is inconclusive, radionuclide scanning may provide additional information. Both ultrasonography and nuclear scintigraphy help in the diagnosis of testicular torsion (see Chapter 122).

Patients without evidence of injury to the testes who sustain intrascrotal hematomas, skin ecchymosis, or skin and dartos injury only can be managed conservatively. Treatment consists of ice packs and scrotal support. Minor testicular injuries such as contusions or hematomas can also be treated conservatively. Large testicular hematomas may require surgical management. Delay in surgery may lead to ischemic necrosis, secondary infections, and disruption of testicular function.

Testicular dislocation occurs as a result of an upward blow to the scrotum. In most cases, the dislocated testis lies under the abdominal wall. Associated injuries, such as pelvic fracture, are common. Operative repair is required if closed reduction fails.

Testicular rupture with tear of the tunica albuginea and extravasation of testicular contents into the scrotal sac requires surgical exploration and repair. Testicular salvage is more likely when exploration is performed within 24 hours of the injury. Other injuries requiring surgical management include tense hematoceles and torsion after trauma.

Superficial lacerations of the scrotum can be repaired using absorbable sutures. Local infiltration with lidocaine with epinephrine provides adequate anesthesia. Urologic consultation should be obtained if the laceration extends through the dartos. Physical examination of the scrotal contents determines the need for debridement and primary closure. All penetrating testicular injuries require surgical exploration.

Degloving injuries of the scrotum can be seen after motor vehicle (particularly motorcycle), industrial, or farm machinery accidents. Scrotal injuries are associated with varying degrees of penile skin loss. The underlying penile and scrotal structures are usually spared. Management involves debridement and coverage of the defect by skin flaps or grafting.

PENIS

The most common cause of penile trauma in infants is iatrogenic, especially at the time of circumcision. Complications include transection of the glans, urethrocutaneous fistula, deskinning of the penile shaft, and coagulation necrosis of the entire penis from electrocautery. These injuries usually require extensive surgical repair.

Blunt penile trauma from toilet seats falling on the glans or distal shaft has been described in toddlers. Significant injury to the corporal bodies or the urethra is rare and patients can be managed expectantly with warm soaks. Although the child does not commonly experience urinary retention, he may be more comfortable voiding in a tub of warm water.

Tourniquet injuries may result from bands, rings, or human hair. In the infant, strangulation with a fine hair may be difficult to recognize because of local edema. The initial diagnosis may be balanitis or paraphimosis. Local or general anesthesia may be required to expose and remove the hair. Complications include urethrocutaneous fistula or loss of the penis.

Zipper entrapment of the penis or foreskin can be managed in the ED by cutting the median bar of the zipper with wire cutters and disassembling the zipper mechanism (Fig. 109.9). Conscious sedation may facilitate the procedure. Edema can subsequently be treated with warm soaks.

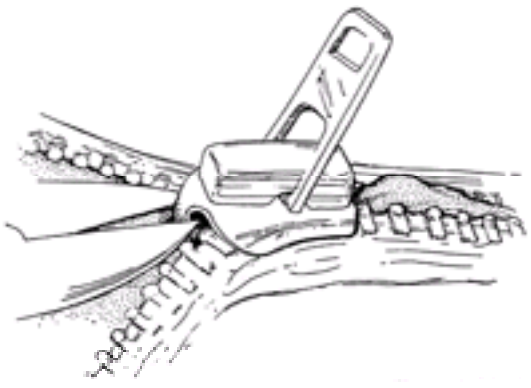

FIGURE 109.9. Penile zipper injury. A wire cutter may be used to cut the median bar of the zipper, releasing the two sides of the zipper and freeing the penis.

Fracture of the penis is produced by traumatic rupture of the corpus cavernosum. This injury usually occurs when the erect penis is forced against a hard surface. The patient may hear a cracking sound and develop pain, edema, and deformity of the shaft of the penis. The urethra is rarely involved. Fracture of the penis can be managed conservatively with bed rest, ice packs, and a pressure dressing. Most injuries require surgical treatment with evacuation of the penile hematoma, repair of the torn tunica albuginea, and a pressure dressing.

Superficial lacerations of the penile shaft can be repaired with absorbable sutures under local anesthesia or penile block. Lacerations extending to the corporal bodies or the urethra, as well as lacerations of the ventral surface of the penis,

require urologic consultation. Diagnostic evaluation includes a retrograde urethrogram to define the extent of the injury. Injuries to the corporal bodies should be repaired primarily to prevent fibrosis and impotence. Injuries to the urethra may require urinary diversion.

PERINEUM

The mechanism most commonly associated with trauma to the female perineum is a straddle-type injury. These injuries may cause vulvar hematomas, which usually respond to treatment with ice packs and bed rest. Patients experiencing mild urinary retention may be more comfortable voiding in a tub of warm water. Massive or expanding hematomas may require evacuation.

Superficial lacerations of the perineum can be treated conservatively at home with sitz baths. Deep lacerations may extend into the rectum or urethra. Rectal penetration requires a diverting colostomy. Suprapubic cystostomy or primary repair should be performed if the urethra is disrupted.

Vaginal lacerations must always be suspected in patients with severe trauma to the external genitalia or penetration by foreign object. If a significant vaginal laceration is noted, endoscopy with sedation or general anesthesia is necessary for a full evaluation. The possibility of extension into the urethra, bladder, or rectum must be investigated. The vaginal laceration is debrided and repaired with fine absorbable sutures.

SEXUAL ABUSE

When common accidental situations fail to explain certain genitourinary injuries, the possibility of sexual abuse should be considered. Injuries resulting from sexual abuse include abrasions and hematomas in the penile shaft, vaginal lacerations, and perineal hematomas (see also Chapter 76 and Chapter 128).

CHAPTER 110

Facial Trauma and Plastic Surgical Emergencies

[*]KEITH T. PAIGE, MD, [†]SCOTT P. BARTLETT, MD, and [†]LINTON A. WHITAKER, MD

[*]*Section of Plastic and Reconstructive Surgery, Virginia Mason Medical Center, Seattle, Washington;* [†]*Department of Surgery (Plastic), The University of Pennsylvania School of Medicine, and The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania*

The moment a child sustains a facial injury, a process, which may range from a trip to the local emergency department (ED) to an altered quality or length of life, begins. An appreciation on the part of the emergency physician for the probable overall events that will occur with each particular patient will provide better patient care and more efficient triage. This appreciation comes from an understanding of what happens to the patient not only during the emergency encounter but also days and months later.

Difficulties in decision making in the ED revolve around what constitutes a plastic surgery emergency and which problems can be reasonably treated without specialist consultation. Few plastic surgery problems require an emergent trip to the operating room in the pediatric setting. Traumatic amputations of digits or extremities, severe burns that require emergent escharotomies, or electrical injuries to extremities requiring urgent amputation are some examples of pediatric plastic surgery emergencies. Most injuries in this chapter either require the plastic surgeon, as specialist, to render input regarding the best way to begin treatment, or require no particular specialist input. This chapter covers the evaluation and management of common injuries to the face, with an appreciation for long-term treatment goals.

Patients who have sustained enough force to sustain significant facial injury may have occult injuries elsewhere, and a complete trauma evaluation is often indicated. Patients with obvious facial trauma are sometimes rapidly assigned to plastic surgery services without adequate multisystem evaluation. Diagnostic failures occur in 12% of motor vehicle accident victims and 23% of motorcycle victims. The most common errors include 1) clinical judgment, 2) failure to follow routine systems evaluation, 3) false interpretation of tests, and 4) inadequate radiographs.

In particular, the head and neck should be treated delicately until an injury to the cervical spine is ruled out. In patients with obvious maxillofacial trauma, 10% have a spine fracture. This incidence can be even higher in series of patients with mandibular fractures. If any doubt exists, the patient should be placed in a semirigid collar or the head should be immobilized with sandbags in preparation for radiologic examination. An undiagnosed injury to the cervical spine in this case could lead to serious consequences, especially for patients who receive operative treatment of their facial injuries and undergo neck manipulation under general anesthesia.

Although no trauma book could be written without reference to the ABCs (airway, breathing, and circulation), the airway is obviously of particular relevance in the management of facial injuries. Patients can have airway obstruction resulting from a variety of factors, including blood, loose teeth, the tongue, and pharyngeal edema; therefore, the airway should be cleared and examined for patency as a priority. Loss of support of subglottic musculature can result secondary to severe mandibular fractures, and the tongue can fall posteriorly and occlude the airway in a comatose patient. If necessary, the tongue can be grasped with an instrument or even stitched with a heavy silk suture as a means to pull it outward and relieve the obturator effect.

Children who are hypoxemic are usually agitated and may attempt to sit up from a supine position. If clinically acceptable, they should be allowed to do so because this position may help clear the airway and reduce venous pressure and resultant edema. An oxygen saturation monitor should be used in all cases in which the stability of airway patency is in question, and oral or nasal airways can be used.

Because of the abundant vascular supply to the face, the clinician should never underestimate the amount of hemorrhage that has occurred in cases of lacerations to the face and scalp. In acute hemorrhage without fluid resuscitation, the hematocrit does not reflect the amount of blood lost. Children have an excellent ability to compensate in hemorrhagic shock by vasoconstriction and increased heart rate to a point of rapid decompensation and circulatory arrest. Obtaining serial hematocrits, providing rapid fluid resuscitation, and obtaining a careful history for amount of blood lost at the scene help avoid this potential problem.

Tracheostomy is rarely indicated in the emergency setting in the treatment of pediatric facial injuries. Cricothyrotomy rarely may be necessary but is not to be undertaken except as a last resort because of 1) the small size of the cricothyroid membrane, 2) technical difficulties encountered, and 3) potential damage of important laryngeal structures in the process of airway insertion, all of which may lead to a difficult or unsuccessful laryngeal reconstruction. In some instances, a “needle” cricothyrotomy can be used as a temporizing measure to stabilize a patient before operative intervention. Formal tracheostomy is performed optimally in an operating room; however, in extreme circumstances, a

“slash” tracheostomy is the preferred procedure and can be performed in the ED.

A final point relates to tetanus immune status. Proper documentation in the medical record that a tetanus immunization history was obtained is essential and is a standard of care. If indicated by such history, the administration of any and all antitetanus treatment should also be documented carefully. This procedure not only ensures proper antitetanus treatment but also avoids confusion later and obviates redundancy in treatment. Guidelines for reimmunization are given in Chapter 84 and Appendix D.

FACIAL INJURIES

Background

The cause of facial injuries is varied and includes motor vehicle accidents, accidents at home, and assaults. A distinction should be made and an understanding should be developed regarding facial trauma, analogous to the trauma of gunshot wounds; that is, trauma is either “low velocity” (e.g., fall from a chair, hit with a fist) or “high velocity” (e.g., motor vehicle accident, fall from a height). Distinction between the two types of trauma can aid in diagnosis of injuries and predict efficacy of treatment in many cases. The incidence of fractures in children is low, with those in the range of 0 to 5 years of age accounting for 1% of the facial fractures observed and those in the range of 5 to 12 years of age accounting for 3 to 5% of the fractures observed. The face of a child is small compared with the head, and the face undergoes a twelvefold size increase compared with only a fourfold increase in cranial size over the period of growth. In addition, the face is much stronger because the sinus cavities are not developed and the proportion of cancellous to cortical bone is greater, providing more elasticity. Falls against various objects account for a large number of injuries in children. As children grow, they engage in more adult activities (e.g., tricycles, bicycles, cars) and increase their potential for applying greater and greater forces to their faces. Therefore, as children grow, the severity of facial injuries tends to increase.

Clinical Manifestations

Bony Injuries

Fractures of the mandible are the most common facial fracture, with nasal fractures being more common in some cases. In contrast to adults, the most common site for mandibular fractures in children less than 10 years of age is the condyle or condylar neck (Fig. 110.1). When a fall onto a child's chin results in a parasymphyseal fracture, an associated fracture in the opposite subcondylar region often occurs and should be looked for and documented if present. Pain and difficulty with mouth opening are important signs. The inferior alveolar nerve exits at the mental foramen, an anterior opening in the mandible on a common vertical line with the second premolars. The mental nerve, exiting this foramen, supplies sensation to the lower lips and lower incisor teeth. The sensation in these regions should be evaluated and documented. During the acute period after injury, patients may not recall decreased sensation, and subsequent surgical manipulation may be incorrectly indicted as the cause for such sequelae. Anesthesia in these areas should raise suspicion of injury to the mandible.

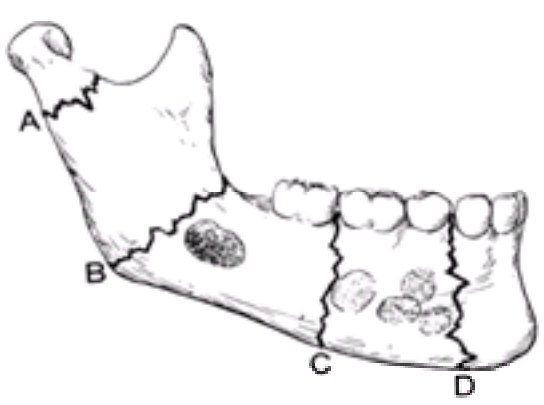

FIGURE 110.1. Examples of various types of possible mandibular fractures. A child's mandible with unerupted dentition is shown. *A,* subcondylar fracture; *B,* fracture at the angle; *C,* body fracture; and *D,* symphyseal fracture.

Powerful muscles of mastication are normally set at resting tensions and rely heavily on proper bony length for strength. When bony anatomy is disrupted, distracting forces are applied to the fractured mandibular segments, often causing acute occlusal disharmony. In a simple subcondylar fracture, the lateral pterygoid on the nonfractured side is unopposed and pulls the mandible medially, or toward the fractured side. In bilateral subcondylar fractures, muscle imbalance causes premature closure of the molar teeth, resulting in an anterior open bite. The growth center for the mandible is located in the area of the condyle, and damage to this area, similar to that from a fracture, can cause significant growth disturbances, especially if sustained before 3 years of age. Therefore, the clinical evaluation of any chin laceration should include examination of the mandible, particularly the condyles.

Fractures of the floor of the orbit, otherwise known as “orbital blowout fractures,” probably result from an acute increase in pressure within the orbital contents, thus pushing down on the thinner bone of the medial orbital floor (Fig. 110.2). Alternate theories suggest direct force applied to the inferior orbital rim, with subsequent buckling of the rim and floor, as a mechanism. The globe often reveals subconjunctival hemorrhage, and occasionally a traumatic meiosis is present in the affected eye. Rarely, retrobulbar hemorrhage with an afferent pupillary defect occurs, and emergency optic nerve decompression would be indicated.

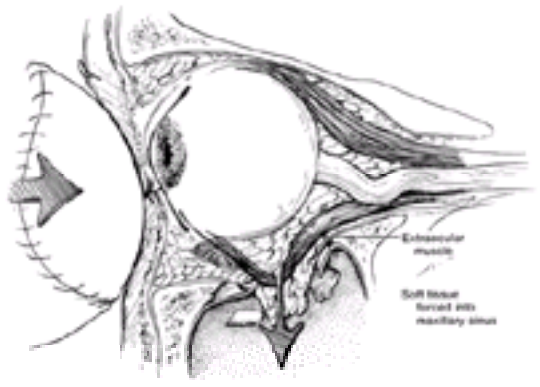

FIGURE 110.2. Mechanism of blowout fracture. In a sagittal view, a ball is shown striking the eye, deforming it, and causing increased pressure of the intraorbital contents. The periorbital fat is forced through the floor of the orbit. Retropositioning of the eye (enophthalmos), lowering of the eye, and extraocular muscle entrapment can result.

Because the volume of the globe and surrounding structures (fat, extraocular muscles) is fixed and because an acute increase in orbital space (an opening in the floor of the orbit) occurs, the globe may sink down in the orbit, producing enophthalmos, a sunken appearance to the eye. Blood and orbital fat may sink into the maxillary sinus, clouding the sinus on the radiograph (Fig. 110.3). Asymmetry in the horizontal level of the eyes (orbital dystopia) may also be present. Both enophthalmos and orbital dystopia may not be present initially, however, because of periorbital edema, which tends to compensate for the deformity. These findings usually become apparent after 5 to 7 days when swelling subsides. The infraorbital nerve, the terminal branch of the maxillary division of the trigeminal nerve, exits the maxilla just below the infraorbital rim and is often injured. Manifestations of injury to this nerve include decreased sensation to the cheek, upper lip, and upper gums on the affected side. If extraocular muscles are entrapped in the fracture gap in the floor of the orbit, voluntary extraocular movements may be limited. The inferior rectus is the muscle most commonly entrapped, which results in an inability to fully gaze upward on the affected side and often in diplopia. The presence of entrapment is one indication to operate on a blowout fracture on an emergent basis. Studies suggest that early repair of orbital fracture and release of the entrapped muscles (within 24 to 48 hours) avoids muscle ischemia and fibrosis and results in better functional recovery.

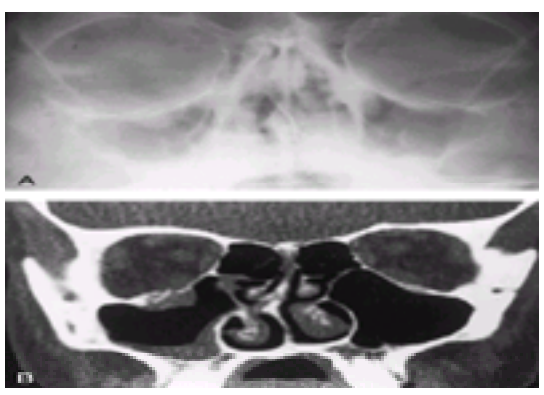

FIGURE 110.3. A. Blowout fracture. The sinus view shows teardrop configuration of the blowout fractures in the right orbit. Note associated fracture through the orbital floor and air–fluid level in the maxillary sinus. **B.** In the same patient as **A,** computed tomography section more clearly demonstrates the multiple fragment fracture through the orbital floor. Teardrop and air–fluid level are evident in the right maxillary sinus. (Courtesy of Soroosh Mahboubi, MD.)

Because of their prominent position on the face, the nasal bones are among the most commonly fractured bones of the facial skeleton. Nasal fractures may be difficult to detect clinically because of the significant swelling. The role of radiographs in nasal fractures is one of documentation only because they contribute little, if at all, to management. Most nasal injuries can be followed by a specialist on an outpatient basis, and evaluation after the swelling subsides dictates the need for further intervention. Two particular nasal injuries that deserve specific comment are the intractable nosebleed and septal hematomas. Because of the rich vascular network in the nose, supplied by branches of both the internal (anterior ethmoidal) and external (superior labial, palatine) carotid arteries, nasal hemorrhage can be difficult to stop, despite usual conservative measures (e.g., elevation, gauze compression). Septal hematomas (see Chapter 112 and Procedures, Section VII) arise because of hemorrhage from an artery beneath the mucoperichondrium, separating it from the septal cartilage. Because the septal cartilage is avascular and relies on the overlying mucoperichondrium for its blood supply, a hematoma results in cartilage necrosis and eventual septal perforation.

The zygoma is the second most commonly fractured bone in the face when all age groups are considered. The zygoma attaches to the craniofacial skeleton at three distinct areas: the 1) zygomaticofrontal, 2) zygomaticotemporal, and 3) zygomaticomaxillary regions (Fig. 110.4). A complete fracture of the zygoma results in fractures at each of these sites, and extends through the floor of the orbit. The masseter muscle is the most powerful muscle that contributes to jaw closure, averaging 200 pounds of bite force in the average male adult. The masseter muscle origin is the malar eminence of the zygoma, and this muscle accounts for the inferior displacement characteristic with these fractures. The resultant increase in apparent orbital volume leads to enophthalmos and orbital dystopia, as seen in blowout fractures. A “bird's eye” view often reveals a loss of anterior projection of the affected malar eminence. Decreased sensation along the distribution of the infraorbital nerve is also common as zygomaticomaxillary fractures usually include the infraorbital foramen. In isolated zygomatic arch fractures, a decrease in temporal width can be appreciated when viewing the face

from the front as a result of buckling of the zygomatic arch. If this buckling is severe, the mandibular condyle may be impinged, with resultant difficulty in mouth opening.

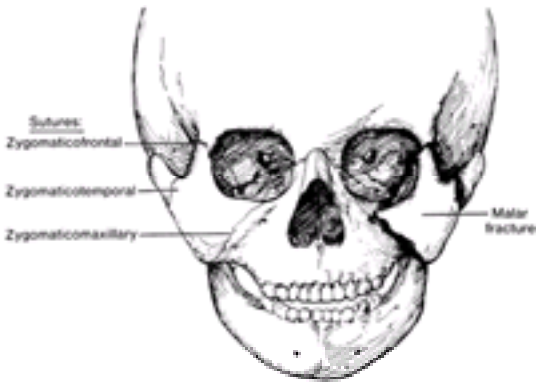

FIGURE 110.4. Zygomatic sutures and a malar fracture are shown. Fractures do not necessarily occur at these points. The zygomaticofrontal suture separation occurs most commonly.

Higher-energy injuries to the craniofacial skeleton can result in a series of fracture patterns, as originally described by Le Fort (Fig. 110.5). The Le Fort I fracture pattern extends through the zygomaticomaxillary region to the base of the pyriform aperture. The Le Fort II pattern, also called a pyramidal fracture, is similar but extends more superiorly to the infraorbital rims and across the nasofrontal sutures. The Le Fort III pattern, also called craniofacial dissociation, extends across the zygomatic arch, zygomaticofrontal region, floor of the orbit, and nasofrontal sutures, effectively separating the face from the skull base. In prepubescent children, facial fractures tend not to follow the classic Le Fort patterns. The fractures in this age group have a more oblique pattern because of the lack of full paranasal sinus development and the presence of undescended secondary dentition reinforcing the midface. In either age group, the fracture patterns are rarely symmetric because impact is sustained on one side more than the other. Because of massive swelling and atypical as well as asymmetric fracture patterns, computed tomography (CT) scans are often essential in the diagnosis of facial fractures in children. Even with good quality CT scans of the face, the definitive diagnosis is sometimes made only in the operating room under direct visualization.

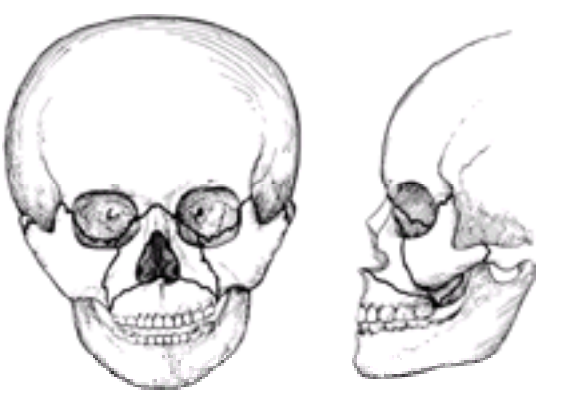

FIGURE 110.5. Le Fort classification of fractures. With type I, the maxilla is separated from its attachments. Type II (pyramidal) produces a mobile maxilla and nose. With type III (craniofacial dysjunction), all attachments of the midface to the skull have been separated. Traction on the anterior maxilla produces motion up to the inferior orbital rims and zygoma. These fractures are not mutually exclusive. For example, a Le Fort I can be present with a type II or type III. Le Fort II may exist on one side with type III on the other side.

Naso-orbito-ethmoid (NOE) fractures involve complete separation of the nasal bones and medial walls of the orbits from the stable frontal bone above and infraorbital rim laterally. These injuries are usually the result of high-velocity trauma to the central midface. The bones are often fragmented and telescoped posteriorly into the ethmoid region. These patients display a characteristic pugnacious nose, with loss of anterior projection on lateral view. Because the medial canthal tendons attach firmly to the medial walls of the orbits, lateral drift of the fracture segments results in traumatic telecanthus (Fig. 110.6). Normal mean intercanthal distance is 16 mm at birth, which increases to 25 mm in a female and 27 mm in a male at full facial growth. A significant increase in intercanthal distance or gross asymmetry in the medial canthal to facial midline distance should raise suspicion for this fracture.

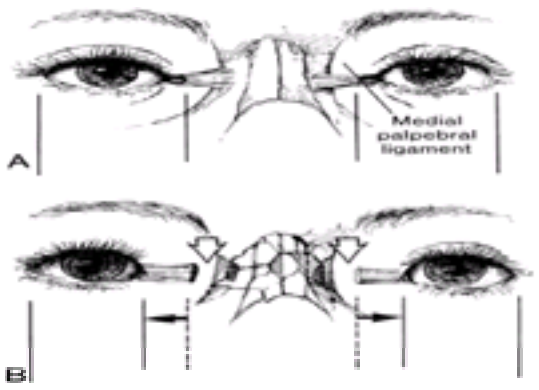

FIGURE 110.6. Mechanism of telecanthus. **A.** Normal attachment of medial palpebral ligament to medial aspect of orbital wall. **B.** Trauma producing comminution of nasal and orbital bones allows the ligaments to drift laterally, resulting in rounding of the medial canthus.

In the forehead, injury to the frontal sinus may reveal a palpable or visible depression if the anterior wall of the sinus has been compressed. Frontal sinus injuries are seen only in children older than 8 years of age because the sinus cells begin to aerate the frontal bone at this age. A forehead depression in a younger child is a depressed skull fracture until proven otherwise. In more severe frontal sinus fractures associated with forehead lacerations, a fracture of the posterior wall of the sinus and dural tear may allow cerebrospinal fluid (CSF) to leak from the wound. Wound fluid can be sent for glucose and chloride levels to help determine this diagnosis, or a “halo test” can be performed at the bedside. A drop of wound fluid is placed on filter paper, and the fluid is allowed to diffuse. CSF travels further from the center of the drop than does serum, and a “halo” will be present. Recently, the ability to test for b_2-transferrin provides an easy means of identifying CSF. b_2-Transferrin is a protein produced by neuraminidase activity in the brain and is uniquely found in CSF and perilymph. The presence of b_2-transferrin in wound fluid, detected by immunofixation electrophoresis, confirms a CSF leak.

Soft-Tissue Injuries

Facial lacerations are usually more obvious in their clinical presentation. However, an appreciation for deeper anatomic structures in the soft tissues aids in the diagnosis of injuries to these areas. Lateral periorbital lacerations should raise suspicion to injury to the frontal branch of the facial nerve, which travels superficially along a line from just above the tragus to a point 1.5 cm above the lateral eyebrow. Lacerations in the medial periorbital region near the medial canthus should raise suspicion for lacrimal duct injury. Because 85% of tears are drained via the lower canaliculus, failure to repair a laceration to it results in excessive tearing (epiphora). If deep lacerations are present in the cheek region, the clinician must determine whether injury to the buccal branch of the facial nerve and to the parotid duct has occurred (Fig. 110.7).

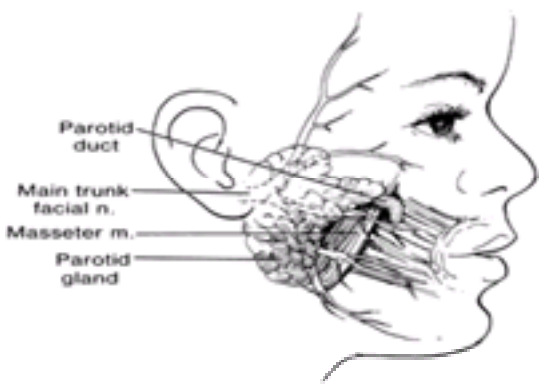

FIGURE 110.7. Deep lacerations to the cheek can injure the facial nerve, parotid gland, or parotid duct. The facial nerve becomes more superficial as it branches and proceeds distally. Distal nerve injuries can thus occur with more superficial wounds.

Once flaps of skin have been raised traumatically, their ultimate fate is directly proportional to their existing blood supply. A random skin flap can survive if the ratio of length to base width is 3:1; in the face, which is privileged with an excellent blood supply, this ratio can be even higher. If the injury included a significant crushing component, flaps of tissue can necrose on the basis of capillary thrombosis. In general, most facial lacerations initially look much worse than they are, and a conservative approach to removal of tissue is advocated. When in doubt, leaving tissue of questionable viability is always preferable. The tissue can always be removed or the resultant scar revised at a later time, if necessary.

Assessment and Management

The keys to successful management are predicated on making a correct diagnosis. Although seemingly mundane, this factor is most pertinent in the ED. The trauma patient makes a “first pass” through the health care system during the initial encounter. Errors in diagnosis and errors of omission at this point can set the stage for a multitude of complications. A methodical, standardized assessment is therefore mandated. Once a diagnosis is made, the decision must be made regarding the necessity for a specialist, based on an appreciation for the complexity of the problem and its long-term course.

History

The importance of a detailed history cannot be overemphasized. If the patient is unable to give a history, witnesses, emergency medical technicians (EMTs), and family should be questioned. If the validity of the facts is in doubt, “allegedly” or “reportedly” can precede the history and may save time in the long run. This situation is mentioned because, in certain criminal cases, attorneys have subpoenaed emergency physicians on the basis of their medical record history (a legal document) and have attempted to discredit the history if everything stated (e.g., “patient shot in face by girlfriend”) cannot be proven. Pictures of the injury should be taken when possible and included in the medical

record. If recent preinjury photographs are available (school pictures), they are of special benefit in the management of major facial injuries and should be sought.

As in all trauma histories, the mechanism and instrument of injury should be determined, as well as the timing and location of the injury and the likelihood of contamination. Specific attention should be given to the possibility of foreign bodies. If lacerations are present, an attempt should be made to determine whether these are caused by a crush mechanism (stellate lacerations from a blunt impact on a windshield) or a sharp object (facial lacerations from the steel trim of a car door).

Physical Examination

Soft-Tissue Injuries. Abrasions of the face should be evaluated for size, likely depth of the wound, presence of foreign bodies, and exposure of underlying structures. Especially in the pediatric population, local anesthesia will be necessary before adequate wound inspection can be performed. Classic “road tattoos” are created from falls out of motor vehicles or off bicycles and demonstrate particulate matter embedded in the dermal elements of the wound.

Probably the most common laceration seen on the face is a simple linear laceration. These injuries usually occur secondary to blunt trauma over bony prominences (e.g., supraorbital ridge, malar eminence, chin), causing the skin to burst. When superficial, this problem is relatively simple. When deep, punctate, or crushing in nature, tissue viability, presence of possible foreign bodies, and possible deeper structure injury must be considered. These wounds tend to be more complex, and flaps of various forms result (Fig. 110.8). For the purposes of efficient communication, lacerations should be described as simple or complex, linear or stellate, superficial or deep, and with an estimation of total length. This method aids in decision making regarding the need for specialist intervention. Wound margins should be inspected carefully for presence of bleeding and for capillary refill. A very pale color implies arterial ischemia. A dark blue color, which refills briskly when compression is released, implies venous engorgement. These flaps must be handled carefully during cleansing and evaluation because any further separation from their blood supply could be the determinant from tissue survival to necrosis.

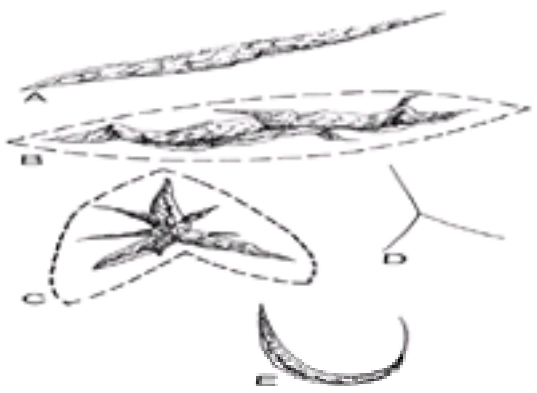

FIGURE 110.8. Variation in laceration injuries and suggestions for management: simple laceration **(A);** elliptical excision of damaged wound margins **(B);** excision **(C)** and closure **(D)** of stellate laceration; and flap-type laceration **(E).**

Local anesthesia is advised before wound exploration. Topical agents are available but do not substitute for local field blocks. Topical agents are most effective in the infant and toddler. With increasing dermal thickness, they become less efficacious. The most commonly used agent for local injection is 1% lidocaine with epinephrine 1:100,000 solution. Epinephrine should be used with caution if tissue viability is questionable or in end-arterial systems such as the earlobe or nasal tip. Lidocaine with epinephrine is supplied at a slightly acidic pH; premixing with bicarbonate has been described and is purported to decrease pain on injection. Practically speaking, the pressure that results from the rapidity of injection is the variable most easily controlled, and slow injections with a small, 30-gauge needle seem to work well. Maximum safe lidocaine doses are 4 mg/kg when no epinephrine is used (maximum dose 300 mg), and 7 mg/kg when epinephrine is used (maximum dose 500 mg). Percutaneous injection along a wound edge, as opposed to within the wound itself, theoretically reduces the potential for bacterial inoculation, although this is probably of significance only in heavily contaminated wounds. Intravenous or intramuscular sedation can be used if necessary.

Regional peripheral nerve blocks of the face can assist in the examination and management of facial lacerations in the pediatric patient. Nerve blocks have several advantages: 1) the total amount of anesthetic injected can be reduced, 2) they can augment local infiltration, 3) distortion of local anatomy can be avoided, and 4) injection sites can often be moved to less painful locations. The peripheral nerves most optimal for blockade by the pediatric emergency physician are the supraorbital and supratrochlear nerves, the infraorbital nerve, the preauricular and postauricular nerves, and the mental nerve. The supraorbital and supratrochlear nerves exit at the supraorbital rim in the medial third of the brow approximately 2 to 3 cm from the facial midline. Local infiltration in this region can effectively block these nerves and provide anesthesia to the ipsilateral hemiforehead.

The infraorbital nerve exits through the infraorbital foramen in the midface approximately 5 mm inferior to the infraorbital rim and in line with the first premolar tooth. Effective anesthetic block of this nerve can deaden sensation to the ipsilateral medial cheek and upper lip. The preauricular and postauricular nerves can be blocked by infiltrating local anesthetic approximately 1 cm inferior to the lobule and posterior to the ramus of the mandible. From this point, the infiltration is continued superiorly, anteriorly, and posteriorly to encircle the ear. With the addition of anesthetic injection in the choncal bowl, the entire ear can be anesthetized. The mental nerve can be blocked as it exits the mandible by injecting local anesthetic through the buccal sulcus to a point approximately 2 to 3 cm superior to the border of the mandible and

between the first and second premolar teeth. This technique achieves anesthesia of the ipsilateral lower lip.

Examination for foreign bodies can be aided by the history and helps determine how extensive a search should be. Radiographs can be a helpful adjunct to exploration, particularly because most glass is radiopaque. Careful probing of the wound digitally for foreign bodies can also be performed. If the wound is too small to accept a gloved finger or if digital probing is contraindicated, probing with a closed small hemostat often transmits the feeling of foreign bodies.

The potential for deep lacerations to involve important underlying structures has been mentioned, and specific maneuvers to rule this condition out are discussed. In general, if only subcutaneous fat is visible in the bed of the wound, it is considered superficial to facial nerves. If cut muscle is seen in the bed of the wound, nerve and glandular duct injury is possible. When facial nerve injury is suspected, patients can be tested by having them move specific muscles of facial expression. This testing should take place before infiltration with local anesthetic. The frontal branch can be tested by asking the patient to frown, looking for symmetry of frontalis action. The buccal branch can be tested by asking the patient to smile because most elevators of the corner of the mouth are innervated by this branch.

The marginal mandibular branch, or ramus mandibularis, may course as much as 1 to 2 cm below the border of the mandible and is responsible for depression of the corners of the mouth. Injury of this branch results in a characteristic upward pull of the corner of the mouth on the affected side, as a result of unopposed levator tone on that side. Examination for potential injury to Stenson's (parotid) duct is accomplished by grasping the commissure between thumb and index finger and gently everting the buccal mucosa to identify Stenson's duct, which lies on a vertical line with the maxillary second premolar. With the opposite hand, gentle massage of the parotid gland is accomplished by pressing in the preauricular region. The appearance of clear fluid from Stenson's duct suggests an uninjured duct. The absence of fluid after several minutes of inspection, or bloody fluid, suggests injury to the gland or duct. In this case, inspection of the depth of the wound may reveal salivary fluid, and cut ends of the duct may be identified. A sialogram can be a useful adjunct in the diagnosis of parotid duct injuries. In wounds with substantial bleeding, clamping all but the most obvious cut ends of blood vessels is to be avoided, for possible injury to a facial nerve branch.

The mouth should be evaluated for lacerations of the mucosa or tongue, injury to the palate, and loose or missing teeth. Chapter 113 details specific oral injuries.

Subperichondrial hematomas should be ruled out when injury to the nose or the external ear is present. These two appendages are based on a specific cartilage framework, and distortion of this framework can lead to functional and aesthetic deformities. Subperichondrial hematomas of the ear commonly occur in boxers and wrestlers and are characterized by a swelling of the conchal portion of the ear. Simple inspection of both sides of the nasal septum with a speculum reveals a septal hematoma, which presents as a boggy swelling, partially or completely obstructing the nasal airway on the affected side.

Bony Injuries. Many patients being examined for facial bone injury have potential head injury, and the Glasgow Coma Scale should be used. This tool aids in communication between specialists and, if operation is necessary, helps weigh the risks and benefits of such a procedure. Patients with a Glasgow Coma Scale score of less than 10 are considered poor risk for general anesthesia, and if possible, surgery for facial injuries should be delayed.

Examination for specific bony injuries begins with observation. Full-face anterior view and a bird's-eye view from the top of the head, with attention to possible asymmetry, aid the trained eye toward potential injury. The malar eminences and zygomatic arches are well visualized for differences in projection from this view. Asymmetry can take the form of swelling or loss of projection or flattening.

Any differences can be further assessed in the second or palpation phase of the examination (Fig. 110.9). Systematic palpation should be performed to avoid errors of omission. It is simple to begin from the top and work down. The forehead should be palpated for depressions or “stepoffs,” seen in frontal sinus fractures. The position of the malar eminences should be palpated simultaneously to aid in detection of asymmetry. Palpation of the zygomatic arches often can detect an outward buckling or depression. The thin skin of the lower eyelid affords easy palpation of the infraorbital rim for possible stepoffs. Intraoral palpation of the lateral maxillary buttress, by placing a gloved finger above the second maxillary premolar, can help diagnose a fracture in this area. Maxillary fractures are further checked for by grasping the anterior maxilla in the area of the incisors and attempting to move it. Alveolar fractures can be looked for in the same fashion. External palpation of the mandicular symphysis, body, angle, and ramus can help diagnose fractures in these areas, and intraoral palpation of the mandible along the lingual surface likewise is useful. The body of the mandible can be grasped on either side, with the right hand of the examiner on the left body and the left hand on the right body of the mandible. The index and long fingers can be placed in the mouth and the thumb in the submental area. An attempt is then made to produce unnatural motion in the mandible by torquing the bodies in opposite directions. In less cooperative or younger patients, gentle compression of the mandibular angles can elicit pain, suggesting the presence of a fracture. Placement of index fingers in the external auditory canals during active jaw opening can elicit differences in condylar position.

FIGURE 110.9. Sequential steps in examination for facial fractures. **A.** The supraorbital ridges are palpated while steadying the patient's head. **B.** The infraorbital ridges are lightly palpated using the index, middle, and ring fingers to determine symmetry or fractures. **C.** The zygomatic arch is palpated on each side to determine continuity and the possible presence of displaced fractures. **D.** The infraorbital rims, zygomatic bodies, and maxilla are palpated and examined from the top of the head to determine depressions and fracture displacement. **E.** The nasal bone and maxilla are examined for stability and possible fracture displacement. **F.** The nose is examined intranasally to determine placement of the nasal septum and possible displacement of nasal bones or disruption of nasal mucosa. **G.** The occlusion is observed to determine any disturbances of normal teeth relations. **H.** The mandible is palpated and then retracted to determine sites of discomfort and possible mandibular fractures.

Examination of the eyes should include observation for pupillary reactivity and size, noting possible asymmetry. Direct trauma to the globe should be excluded. Assessment for orbital dystopia and enophthalmos should be performed. Examination of extraocular motility is obtained if the patient is awake and cooperative. Alternately, passive extraocular motility can be checked by applying topical anesthesia to the conjunctiva and performing forced duction tests, which involve gentle grasping of the inferior fornix of the conjunctiva and passive ranging of the globe in all four directions. Gross visual acuity should be checked and charted. If any concerns are noted, an ophthalmologist should be consulted.

Inspection of the mouth for specific bony injuries is of vital importance because occlusal disharmonies are a tip-off to mandibular or maxillary displacement. Occlusion should be observed and an assessment made about its normalcy. The patient can simply be asked if the bite feels “normal,” if he or she is awake and cooperative. Opposing teeth that do not come together but that exhibit wear facets (smoothing of mamillations along the incisal surfaces of the teeth) suggest a traumatic malocclusion. Preauricular pain and pain or limitation with mouth opening are suggestive of mandibular fracture.

The patient should be checked for anesthesia of the cheek (infraorbital nerve distribution) and lower teeth and lower lip (inferior alveolar nerve distribution). After thorough observation, palpation, and sensory evaluation, the examiner usually can predict a specific area of injury, which is confirmed by radiologic evaluation.

Radiographic Studies

Because of the occult nature of pediatric facial fractures, the emergency physician should have a low threshold for radiographic evaluation. CT scans have virtually replaced radiographs in the assessment of serious acute bony facial injuries. Most medical centers are equipped with CT scanners, and these studies have greater ability to show exact locations of craniofacial fractures. Furthermore, patients with potential facial fractures are also patients with closed head injuries, and a CT scan often is already indicated. CT scans also can help rule out cervical spine fractures, and it is routine in many centers to scan a patient's head, face, neck, and abdomen in one sitting. Axial views provide excellent visualization of the zygomaticofrontal regions, the zygomatic arches (Fig. 110.10), the frontal sinus (Fig. 110.11) and patency of the nasofrontal ducts, the maxillary sinuses and their anterior walls, and the mandible. Coronal cuts with 1.5-mm cuts through the orbits (Fig. 110.12) are useful in viewing the status of the orbital floors and infraorbital rims, nasoethmoid region, malar eminences, and midfacial buttresses, as well as the status of the mandibular condyles and symphyses. Coronal views require considerable neck extension to orient the anterior facial plane as vertical as possible, and neck clearance should precede coronal scanning. Three-dimensional computerized reconstructions are dramatic to view, demonstrate fractures easily, and are useful for teaching, but they are not considered necessary for evaluation of routine fractures.

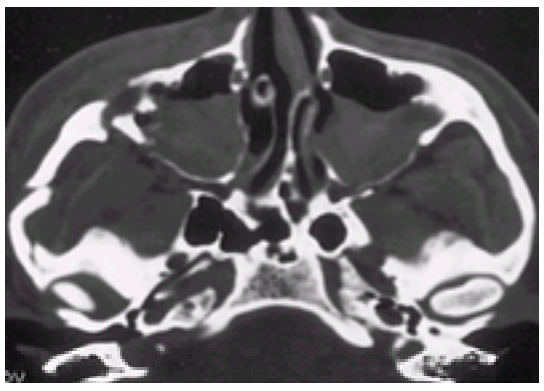

FIGURE 110.10. Axial computed tomography scan of the midface on a patient with a right zygoma fracture. Note the buckling of the zygomatic arch, the fractures of the zygomaticomaxillary and zygomaticotemporal areas, and the opacification of both maxillary sinuses.

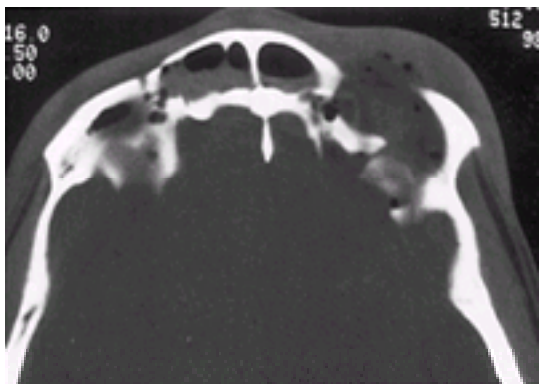

FIGURE 110.11. Axial computed tomography (CT) scan on the upper face in a patient with forehead lacerations. A bony defect in the anterior wall of the frontal sinus and fracture of the posterior wall on the patient's left side (*right side* of photography) suggest a fracture through both walls of the frontal sinus. Note the air–fluid levels in both sides of the sinus. Before CT, such detailed information regarding the status of the posterior wall was unavailable without operative examination.

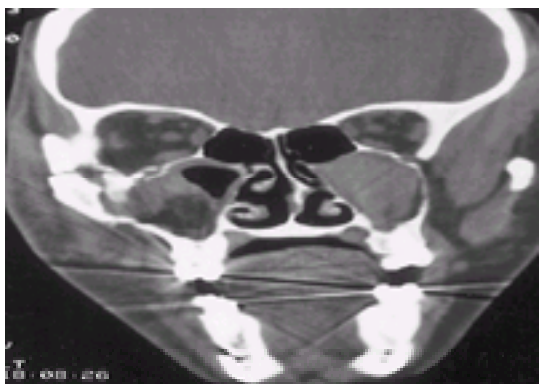

FIGURE 110.12. Coronal computed tomography scan of the same patient as shown in Figure 110.10. Note the excellent visualization of the fractured orbital floor associated with the zygoma fracture and increase in orbital volume. The lower portion of the scan demonstrates artifact created by dental filings (plates can cause similar scatter).

Panorex views show the mandible in its entirety and also clearly demonstrate tooth root anatomy and condylar position. However, Panorex views are limited in acute trauma evaluation because imaging suites are usually located some distance from the ED and require the patient to sit upright and remain still.

The Water's view (occipitomental) is useful for viewing the orbital rims, particularly the infraorbital rims and the maxillary sinuses. Lateral facial views provide reasonable imaging of the mandible on that side as well as a view of the sinuses and nasal bones. The submentovertex, or “jughandle,” view demonstrates the zygomatic arches well. Although, in general, the use of these standard radiographs has been superseded by CT scans.

GUIDELINES FOR CONSULTATION

In many cases, management of a specific injury is best handled in the ED. A telephone call to a consultant can be made to clarify the issue, but the judgment of the primary physician ultimately dictates the eventual outcome of patient care.

Abilities vary greatly, and rather than describe examples of injuries that might be expected to be handled by primary physicians in the ED, general principles are stressed. The decision must be made whether to treat the patient or to consult a specialist to assist in treatment. Vacillation between these two options should be avoided. This decision should be based on a balance of confidence in the diagnosis and the ability to treat it properly, and a realistic appraisal of present conditions in the ED regarding affordability of time. Specialists achieve good results not only because of specialty training but also because they can optimize their working conditions through the use of an operating room.

For the pediatric population, the parent(s) or guardian often requests a specialist consultation for problems that normally would not require specialist intervention. In these cases, instilling confidence is important. The physician should explain to the patient or family that the specialist has no additional techniques to render and that delays in treatment may increase the possibility of complications (e.g., infection, stress of being in the ED). Once patients and families are confident in the primary physician's ability, they usually opt for the fastest way to complete the treatment.

Injuries that should be left to the specialist for repair include 1) lacerations with evidence of injury to deep structures (a major motor nerve or a glandular duct), 2) cases in which a substantial amount of devitalized tissue exists or actual tissue loss has occurred, 3) wounds in which the amount of bleeding cannot be easily controlled, 4) full-thickness defects of the ear and nose, and 5) cases in which it is unclear exactly what tissue to approximate to restore preinjury anatomy and aesthetics (e.g., lips, eyelids, nostrils, ears).

SPECIFIC MANAGEMENT PROBLEMS

Soft-Tissue Injuries

Minor abrasions can usually be handled in the ED. The key principles are adequate anesthesia to perform acceptable cleansing of the wound, removal of devitalized tissue and debris, and proper dressing. Regional peripheral nerve blocks can be essential adjuncts to appropriately anesthetizing large facial abrasions. Normal saline and a mild soap or Betadine are commonly used for irrigation, cleansing, and scrubbing, if necessary, although special isotonic cleansers are available. Injuries on road or gravel can implant particulate matter into dermal layers and create “road tattoo.” These areas require aggressive scrubbing and possible picking out of individual particles with the tip of a No. 11 blade. The best chance of removing road tattoos is at the time of the initial treatment, and attention to detail is key. Minor abrasions represent a loss of epidermal and partial dermal layers. The remaining dermal structures in the bed of the wound should be kept moist and free of infection by using a thin layer of antibiotic ointment, such as Silvadene or Bacitracin. Keeping gauze dressings on the face of a child is difficult unless a head wrap is used, and for small area abrasions, ointment alone is practical. These ointments should be washed off gently with soap and water several times daily and reapplied until reepithelialization occurs. The risk of infection is probably related more to inadequate cleansing and debridement than to the use or choice of antibiotic dressing, underscoring the importance of anesthesia.

Deeper abrasions involve near total or complete loss of all dermal elements. Often, they are seen as part of a large abrasion with more superficial surrounding components. If the resultant full-thickness defect is 1 to 2 cm^2 or less, it is reasonable to allow the defect to contract in for possible scar revision at a later time. Acute primary closure is a less attractive option because increased skin tension on the wound leads to a widened scar, and ischemia could result. An acute skin graft for a defect this small is not indicated because a small graft gives a patchy appearance and it is unnecessary to cover so small a defect.

With larger surface area, full-thickness losses of skin, coverage with autogenous tissue to gain “control of the wound” is a short-term goal. This approach protects deeper structures below, reduces transwound fluid losses, and reduces the likelihood of soft-tissue contamination and infection. Control of the wound does not always guarantee a good aesthetic result, and an understanding of reconstructive planning helps illustrate this problem. For example, a 4 × 4-cm full-thickness abrasion on the cheek of a 10-year-old child might be treated by cleansing, several days of moist dressings, and a split-thickness skin graft to cover the wound. However, this treatment represents only the first phase of the reconstruction. After 4 to 6 months, the skin graft will have contracted slightly, thereby pulling the normal facial skin closer together. Serial excisions of the skin graft could be performed, each time stretching the surrounding normal skin and bringing it closer together. Finally, the remaining graft could be excised completely and the defect covered with facial skin. The complete process may take more than 12 months to complete and may require several operations, but the aesthetic result of replacing “like tissue with like” is superior to the patch of a skin graft. Why not close the original defect primarily? The tension created by such a would closure would be excessive, and tissue necrosis and scar widening would surely result. “Control of the wound” would not be accomplished.

In general, lacerations should be repaired within 8 to 12 hours after the injury was sustained. However, on the face, clean, sharp lacerations can be reapproximated up to 24 hours after the injury, and even late-presenting lacerations (48 to 72 hours after the injury) can be closed after thorough sharp debridement, usually by a specialist. The risks of infection in closing such a wound must be weighed against the benefits of reducing the facial scarring that will result if the wound is allowed to heal secondarily. Factors such as mechanism of injury, immunocompetence, and hygiene must be considered. Similar to abrasions, anesthesia, copious irrigation and cleansing, and exact, tension-free approximation are vital to a successful closure. The purpose of sutures is to reapproximate tissues so wound repair can be facilitated, not to hold the tissues together forever. Excessive tension on sutures simply causes tissue ischemia by exceeding capillary filling pressure. This condition leads to tissue necrosis and a dehisced wound. The capacity of the human body to heal greatly precedes the advent of suturing, and scar revision can always be performed at a later time once the wound has contracted. If in doubt regarding closure of a late-presenting or heavily contaminated wound, the clinician should call a specialist or consider leaving the wound open to heal by secondary intention or delayed primary closure. In this case, cleansing is still important, and moist, saline-soaked sponges can be placed in the wound (to be changed several times a day).

If injury to deeper structures is ruled out, deep lacerations can be closed in layers, using absorbable suture material in the deeper layers. Each layer of closure attempts to reorient the preinjury anatomy and sets up the orientation of the next layer. A poorly approximated subcutaneous layer results in an uneven wound, no matter how well the skin stitches are placed. In fact, a well-closed wound should demonstrate the skin edges to be 1 to 2 mm apart or closer at the layer preceding final skin closure. Suture is a foreign body; more is not necessarily better. Inexperienced stitchers tend to use too many sutures, which leads to tissue ischemia, excessive foreign body in the wound, and unnecessary expense. Deep layers eliminate dead space in the depth of the wound, which, if not eliminated, could lead to formation of a fluid collection and eventual depression in this area. Deep-layer sutures commonly used for facial lacerations are 4-0 or 5-0 chromic, Dexon or Vicryl. Skin suture material is commonly nonabsorbable monofilament suture, such as nylon or prolene, except in the infant or toddler who benefits from the use of absorbable sutures such as 6-0 fast-absorbing gut to avoid the trauma of suture removal.

A vertical simple suture that catches the lower dermis should approximate the wound edges (Fig. 110.13). Forceps should be used delicately to avoid crushing skin edges; therefore, fine-toothed forceps are preferred. An alternative is to use no forceps and to provide traction on the skin by pressing down on the wound with the index finger of the nondominant hand. Skin margins should be everted by placing the needle into the skin at an angle of 90 degrees or greater and by coming out at the same angle. If a portion of the wound is excised because of devitalized tissue, severe contamination, or to join two adjacent wounds into a single wound, care should be taken to orient the incisions parallel to the relaxed skin tension lines (Fig. 110.14). If a laceration extends into the hair-bearing scalp, care must be taken to align the hairline. Shaving of hair before suturing should be avoided in these cases and is not necessary in any case. Lacerations extending across the mucocutaneous junction of the lip should be closed with careful approximation of muscle layers, if evident in the wound. Skin edges should be closed with monofilament suture; mucosa should be closed with absorbable material, which is left in place. Great care should be taken to identify the “white roll,” the segment

between the skin and the pink vermilion (mucosa) because a discrepancy in this area is obvious.

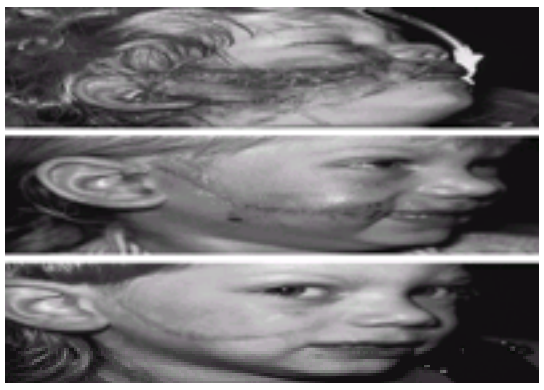

FIGURE 110.13. Photographs of a 3-year-old boy after an attack by a dog. Child was evaluated in the pediatric emergency room, intravenous antibiotics were given, his facial wounds were irrigated, and a plastic surgery consultation was made. The **top** photograph shows the child in the operating room before sharp debridement, facial nerve exploration, and an exacting layered closure of his complex wound. The **middle** panel pictures the child 1 week after his repair and demonstrates the precise reapproximation of the facial soft tissues. The **bottom** photograph was taken 8 months after the attack and demonstrates a nicely healing facial scar that will continue to fade and soften. (Courtesy of David W. Low, MD.) *Please see the color-tip insert (Color Plate 110.13).*

FIGURE 110.14. This illustration shows the natural pattern of skin creases that occurs with aging. If a circular type of wound needs to be converted to an elliptical shape for closure, an attempt should be made to have the wound parallel these lines.

Repair of complex injuries to laminated structures (e.g., ear, eyelid, nose, lip) requires careful attention to reapproximation of each layer of the structure. For example, a full-thickness laceration to the nose at the nostril rim requires closure of three separate layers. The nasal lining is usually closed first with an absorbable suture material. Next, the cartilage must be exactingly repaired. Finally, the overlying skin of the nose can be reapproximated. Similarly, complex injuries of the ear, the eyelid, or the lip require layered closure to achieve the best final results. A specialist's input is often helpful in managing complex injuries to these structures (Fig. 110.14).

Skin sutures can be continuous or interrupted and should be removed in 3 to 5 days. Leaving skin sutures in too long produces stitch marks in the skin and creates suture sinus tracts. If a wound complication such as a hematoma or wound abscess requires drainage, interrupted sutures allow for partial opening of the wound without disruption of the entire suture line. In cases in which these complications cause particular concern, interrupted sutures are advised. In cases in which the difficulties of suture removal outweigh potential aesthetic drawbacks (e.g., scalp sutures in a 4-year-old), absorbable sutures can be used on the skin and simply left in place to dissolve.

Bony Injuries

Facial fractures are more of a diagnostic problem than a treatment problem for the emergency physician. The diagnosis can usually be made by careful history and physical examination, as outlined previously, liberally augmented by CT evaluation. Once the diagnosis is made, a specialist consultation is appropriate for further patient management. Specialists' recommendations can be better understood by a brief overview of standard facial fracture treatment.

In general, fractures of the upper face are managed such that anatomic alignment is restored. For displaced facial fractures, reaching this goal often requires open reduction of the fractures in the operating room. The coronal, lower eyelid, and upper buccal sulcus incisions are the standard incisions used to gain access to the upper facial bones. Because bony healing is especially rapid in children, anatomic reduction becomes increasingly difficult when healing in the displaced position has occurred, and early treatment (within 2 to 4 days) is preferred. After anatomic reduction is achieved, the fractures are rigidly fixed if unstable. In children, facial fractures are often of a “greenstick” type, and reduction alone is adequate. If reduction alone is inadequate, rigid fixation can be accomplished by using small metallic plates and screws or, more recently, plates and screws fabricated from a biodegradable copolymer.

Because of concern regarding mandibular growth retardation and injury to permanent tooth buds, mandibular fractures in children are treated by more conservative measures compared with adults. A substantial proportion of fractures may be

managed by closed reduction and intermaxillary fixation (50%) and a soft diet (25%), and the remaining fractures are treated by either open reduction, internal fixation, or the use of splints.

CHAPTER 111

Eye Trauma

ALEX V. LEVIN, MD

Departments of Pediatrics, Genetics, and Ophthalmology, University of Toronto, and The Hospital for Sick Children, Toronto, Ontario, Canada

When faced with a child who has sustained eye trauma, the pediatric emergency physician must keep in mind four important basic principles:

1. The management of life-threatening systemic illness or central nervous system trauma must always take precedence over the eye injury.
2. The structural integrity of the eyeball must be ensured.
3. Check the vision in both the injured and uninjured eye.
4. When in doubt, seek ophthalmology consultation.

The most serious eye injury may be acutely “neglected” if urgent lifesaving procedures are under way. It is reassuring to know that even if a child lost an eye because of the inability of medical personnel to tend to an eye injury while managing other urgent medical problems, that child will function entirely normally, both at school and in athletic activities, with one remaining eye. If possible, a shield (see Fig. 111.9) can be placed over an obviously injured eye while resuscitative efforts are ongoing to prevent further accidental injury or contamination by the medical staff. This precaution prevents unwanted pressure on the eyelid or eyeball in case of an unrecognized ruptured globe. Such pressure could otherwise lead to extrusion of intraocular contents through an eyeball laceration. This situation would significantly worsen the prognosis for that eye.

FIGURE 111.9. Patient shielded for right ruptured globe, which was caused by a thrown pen.

This chapter is designed to assist the pediatric emergency physician in the diagnosis and management of basic and uncomplicated ocular injuries. However, it is important to recognize when ophthalmology consultation is necessary. Even with the increasing number of emergency departments (EDs) that have slitlamp biomicroscopy available to the nonophthalmologist, the ophthalmologist is more expert at using the slitlamp and has experience with a wide array of diagnostic tools that allow viewing and recognition of intraocular injuries that cannot be seen with a direct ophthalmoscope. In fact, most children who sustain high-risk blunt trauma to the eye, even in the absence of injury that can be seen on external examination, warrant a dilated retinal examination by an ophthalmologist using the indirect ophthalmoscope. This examination allows viewing of the edges of the retina just behind the iris where much of the damage (e.g., retinal tears) is sustained after blunt trauma. Even when ophthalmology consultation is not readily available, it is important to identify an ophthalmologist in the community who is comfortable examining children for outpatient follow-up.

History

Certain questions help identify possible intraocular injury: 1) What was the child's prior visual status? If the child was previously known to have poor vision in the eye, then less concern will be elicited if the same poor vision is noted after the trauma. 2) Has the child ever had a prior eye examination, and if so, what were the results? 3) Has the child ever had a patch over one eye for an extended period? This history would indicate that the child previously had poor vision secondary to amblyopia in the unpatched eye. 4) Has the child ever had eye muscle surgery? Children who have had strabismus are at a greater risk of developing amblyopia and therefore poor vision in one eye is more common. 5) Does the patient wear glasses? If so, they should be worn when visual acuity is tested. 6) Does the patient wear contact lenses? If so, location and removal of the lenses may be necessary.

Additional questions include the following: What was the nature of the injury? How hard was the eye struck? Certain types of trauma have a particularly high risk for causing intraocular damage: significant blunt impact directly to the eyeball (e.g., fist, ball), projectiles, and sharp implements (e.g., pencil, stick). Different antibiotic coverage may be necessary for suspected contamination (e.g., *Bacillus spp.*) by soil or other “outdoor” implements. Hammering is a particularly high-risk behavior for causing intraocular foreign bodies. If an intraocular foreign body is suspected, the clinician must establish whether it is metallic. Magnets are sometimes used by the ophthalmologist during surgical removal of an intraocular foreign body.

Examination

An attempt should always be made to assess the visual acuity in the injured eye before proceeding with the rest of the eye examination. Some patients may be unable to perform this task because of eye pain, noncompliance, an inability to open swollen lids, or obtundation from accompanying head trauma. At the very least, even if the eyelids remain closed, the physician can test for light perception. By shining a bright penlight or direct ophthalmoscope in the direction of the eyeball through the closed eyelid, the physician can ask the patient to indicate whether he or she perceives the additional light on that side. Even without a patient response, a reflex contraction of the lids may be seen, indicating light perception.

If the patient is able to exhibit a greater degree of compliance, the examiner may ask the patient to count fingers that are held before the affected eye at varying distances. The maximum distance at which these fingers can be counted should be noted on the chart (e.g., “counting fingers at 4 feet”). If the patient cannot stand but can identify letters or numbers, a commercially available near card or any other reading material can be used to assess the quality of near vision. Virtually no injury causes very abnormal distance vision but normal near vision. Normal near vision usually indicates that the patient has not sustained a significant ocular injury that is impairing vision at that time.

Should the patient be able to comply, the examiner can try to obtain a standard visual acuity using a distance chart. Letter charts should be used only if the child is known to be able to identify accurately all letters either by parental report or by walking up to the distance chart and identifying them at close proximity. If the child has any trouble with letters, a “tumbling E” chart or a picture chart can be used (see Chapter 120).

The patient's visual acuity in each eye should be tested. Certainly, the presence of bilaterally poor vision in a patient with unilateral eye trauma suggests that the cause of the poor vision is unrelated to the trauma. The eye that is not being tested should be covered well to prevent any conscious or unconscious attempt on the part of the patient to peek around the obstruction. Children will naturally try to do this if their better eye is being covered. To ensure that the child is actually viewing the chart with the eye that is being tested, the examiner should stand by the chart, facing the patient, indicating which letters are to be read while observing the patient's compliance.

If a patient demonstrates poor vision in the traumatized eye, the clinician can readily establish whether this deficit is related to the trauma. When a person looks through a pinhole and experiences improvement in performance on visual acuity testing, he or she can have only a refractive error as the cause of the initially tested poor vision. In other words, if a patient comes in with a traumatized eye that is able to read only 20/400 (needs to stand at 20 feet to see what a normal person can see at 400 feet) but then improves to 20/25 using a pinhole device, the patient has not sustained visual impairment from the ocular injury. Rather, the patient simply needs glasses. The maximum vision obtainable through a pinhole may be only 20/25 to 20/30. A pinhole can be created by poking holes through opaque paper or cardboard with an 18-gauge needle. A cluster of five or six holes may be easier for the patient to use.

After visual acuity has been established, an attempt may then be made to examine the eyeball. Using a stepwise anatomic approach, the examiner should first inspect the periorbital tissues and eyelids for the presence of ecchymosis, lacerations, and ptosis. Eye muscle movements (see Chapter 25) and the anterior surface of the eye should be evaluated next. All attempts should be made to examine these structures without touching or upsetting the child, particularly if by history or examination a ruptured globe is suspected. An upset child creates a Valsalva maneuver while crying, which may lead to extrusion of intraocular contents through a ruptured globe. If a ruptured globe or hyphema has been ruled out, the examiner may proceed with full eye examination, including pharmacologic dilation of the pupil. Regimens are suggested in Table 111.1.

Phenylephrine 2.5%	For brown irides add
Tropicamide 1%	cyclopentolate 1%

[a]May repeat regimen in 30 minutes if needed

Table 111.1. Emergency Department Ocular Dilating Regimen[a]

If pupillary dilation is not to be performed in the ED, a red reflex should be documented. By standing 2 to 3 feet away from the patient, the examiner should shine the largest available circle of illumination from the direct ophthalmoscope onto the patient's face such that both eyes are illuminated simultaneously (Fig. 25.6). The focusing dial is then spun until the patient's face and eyes come into focus. The patient should be instructed to look at the observer. The light should be turned out in the room to encourage maximum physiologic pupillary dilation. The red reflex is usually orange–red or yellow–orange; only rarely is it actually red (Fig. 25.6). The absence of a red reflex may indicate an obstruction within the eyeball to the passage of light, such as a corneal scar, cataract, or hemorrhage within the eyeball. A darkened reflex may also be caused by small pupils or a misaligned eye (Fig. 25.6). Rechecking the reflex after pharmacologic dilation may be helpful in these situations. A white reflex may also indicate the presence of a corneal scar, cataract, or other white intraocular pathology, such as a coloboma or retinoblastoma.

When trauma damages the retina, it often does so at the edges of the retina. This area is out of the field of view of the direct ophthalmoscope and requires indirect ophthalmoscopy to be viewed adequately. Therefore, any patient with severe blunt trauma to the eyeball should be considered for ophthalmology consultation so that the inside of the eye may be examined completely.

The emergency physician often finds the direct ophthalmoscope to be useful for the identification of possible papilledema or retinal hemorrhages in the setting of acute central nervous system injury. Pupillary size should be maximized by the use of dim ambiant illumination and a small circle direct ophthalmoscope beam. Pharmacologic agents (Table 111.1) can also be used. The patient should be told to fixate on a distant target. The examiner must avoid inadvertently lowering his or her head in a way that obstructs the eye that is not being examined, therefore obstructing the fixation of that eye. The child could then begin looking around, making adequate examination of the optic nerve difficult. To avoid this reaction, the examiner should sit or stand such that his or her head is level with and parallel to the patient's head rather than leaning over (Fig. 111.1B). If the examiner is standing above the patient, the patient's head can be tilted away from the examiner such that it becomes parallel to the examiner's head when he or she leans over to look into the eyes (Fig. 111.1C).

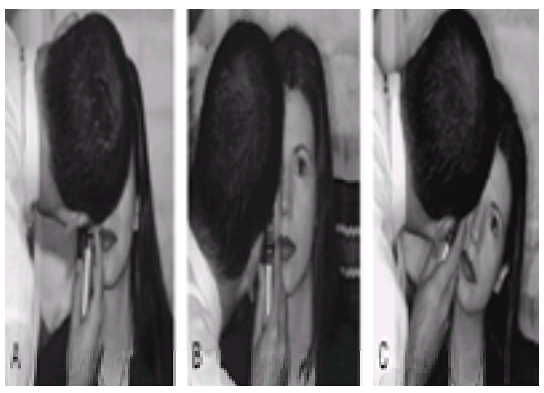

FIGURE 111.1. Use of the direct ophthalmoscope. **A.** Examiner is in incorrect position. His head is blocking patient's ability to fixate with the left eye during examination of right eye. By placing his head at level of patient's **(B)** or by tilting patient's head away **(C),** the left eye can continue to fixate.

The ophthalmoscope may be used with or without the examiner's glasses (or contact lenses) in place. The examiner simply holds the direct ophthalmoscope approximately 1 foot from the patient while standing at his or her side holding the instrument in the same hand that corresponds to the eye to be examined (i.e., right hand for right eye). The focusing dial should be set at zero, and a red reflex should be obtained. Then the examiner approaches the patient slowly until a blood vessel is seen within the red reflex. As the examiner moves closer, he or she should follow the blood vessels while spinning the focusing wheel with the forefinger to keep the blood vessels in focus. The apex of any branching blood vessel points in the direction of the disc (Fig. 111.2). The optic nerve head (disc) is best found in this manner. When the disc is located and in focus, the examiner's forehead should be no more than 1 to 3 inches away from the patient's forehead.

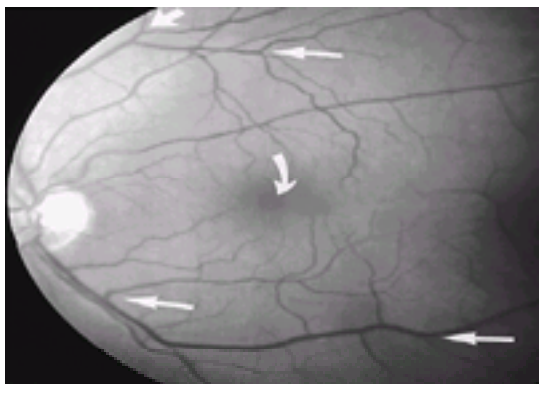

FIGURE 111.2. Normal retina as viewed by indirect ophthalmoscope. Central dark area *(curved arrow)* represents fovea. Note that the apex of the branch point of the blood vessels *(straight arrows)* always points back toward the direction of the optic nerve head.

The optic nerve should be yellow–orange to pink (Fig. 111.2). Centrally, a white depression called the optic cup is apparent. Normally, this depression may be barely visible or may occupy up to 50 to 60% of the optic nerve surface area. Both optic nerves usually have symmetric cup sizes. The retinal blood vessels usually emerge from the center of the cup. In papilledema (Fig. 111.3), the edges of the optic nerve become indistinct and difficult to differentiate from the surrounding retina. The blood vessels may become engorged and tortuous. There may be associated hemorrhages on the optic nerve surface or immediately surrounding the disc. Exudate may also be seen within the retina. The optic nerve cup may not be identifiable because of swelling of the neurons. It may be difficult to focus on the optic nerve surface and the retina at the same time because of the elevation of the optic nerve. However, papilledema may at times be subtle. If any question exists in the mind of the examiner that papilledema may be present, ophthalmology consultation is appropriate. Papilledema is almost always bilateral. Presence of unilateral papilledema suggests an ipsilateral orbital trauma, such as an orbital hemorrhage or direct injury to the optic nerve. The optic nerve can be injured from blunt trauma without a penetrating orbital injury.

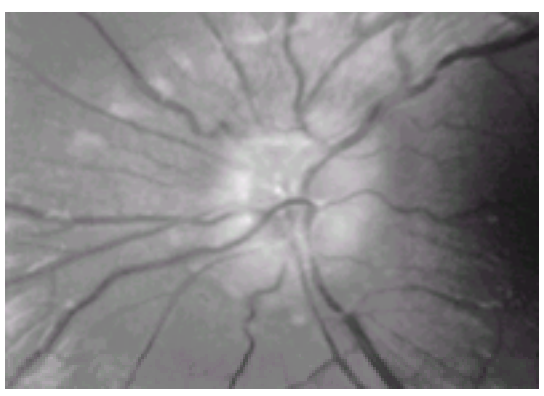

FIGURE 111.3. Papilledema. Note blurred disc margins and loss of view of blood vessels on disc. *Please see the color-tip insert (Color Plate 111.3).*

If the eye has been traumatized such that the patient is unable to voluntarily open the eyelids, attempts should be made to assist the patient in doing so. A warm compress may be gently applied to the eyelashes to loosen any crust or discharge that may be holding the eyelashes together. When opening the eyelids, it is essential to avoid pressure on the eyeball, which might lead to extrusion of intraocular contents via an underlying ruptured globe. By placing his or her thumbs on the supraorbital and infraorbital ridges while exerting pressure against the underlying bone, the examiner's thumbs can then be pulled away from each other such that the eyelids are separated (Fig. 111.4). Various commercially available speculums can also be used to open swollen eyelids (Fig. 111.5). However, in the trauma setting, which is severe enough to cause lid swelling that precludes a readily available view of the eyeball using the techniques previously described, it is probably safer to refer the patient for an ophthalmology consultation. Risking the use of a speculum may upset the patient and cause a struggle that could also contribute to disruption of the intraocular contents in the presence of a ruptured globe.

FIGURE 111.4. Opening swollen eyelids from superior and inferior orbital rims.

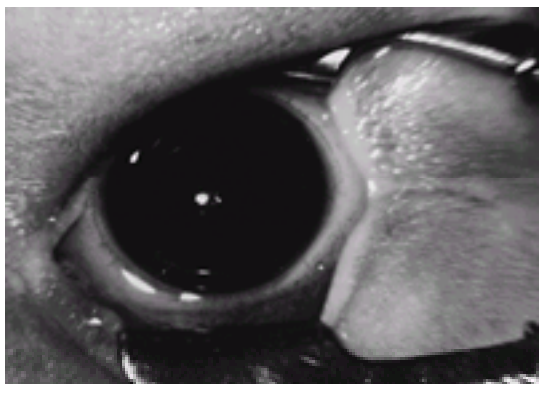

FIGURE 111.5. Commercially available eye speculum in place.

The Desmarres retractor is perhaps one of the least uncomfortable yet effective means for opening swollen lids. After instillation of a topical ophthalmic anesthetic (proparacaine, tetracaine), the cupped end of the retractor (Fig. 111.6A) is slipped under the upper lid and gently retracted with the handle parallel to the forehead (Fig. 111.6B). A second retractor can be simultaneously applied to the lower lid to further improve exposure. Paper clips can also be used (Fig. 120.3).

FIGURE 111.6. A. Desmarres retractor. **B.** Desmarres retractor in use to elevate upper lid.

RUPTURED GLOBE

Clinical Manifestations

Laceration or puncture of the cornea and/or sclera creates a ruptured globe. This condition can occur following trauma by projectile, sharp implement, or blunt trauma. Although severe intraocular disruption may occur, the eyeball has a remarkable ability to maintain its integrity. Immediately upon laceration, the iris or choroid (which is the extension of the iris posteriorly underneath the sclera) plugs the wound. This plug may appear as a blue, brown, or black material on the surface of the sclera (Fig. 111.7) or at the corneal–scleral junction. The iris will come forward and plug a corneal wound (Fig. 111.8). Because of this iris or choroid movement, the pupil may take on a teardrop shape, with the narrowest segment pointing toward the rupture (Fig. 111.7). Hemorrhage within the anterior chamber (hyphema) often accompanies a corneal or anterior scleral laceration (Fig. 111.8). With small lacerations that are plugged by iris or choroid, the eyeball does not deflate but rather takes on a remarkably normal external appearance. Subconjunctival hemorrhage for 360 degrees may obscure an underlying scleral rupture but leave the eye fairly intact. Patients who present following trauma with this finding or with severe 360 degree conjunctival swelling without hemorrhage should be treated as if they had a ruptured globe and referred immediately to an ophthalmologist.

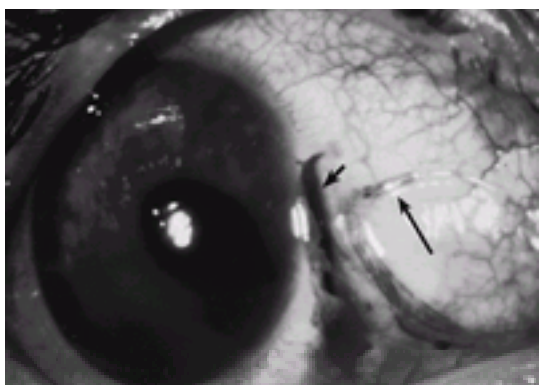

FIGURE 111.7. Ruptured globe. The scleral laceration *(short arrow)* appears as a linear brown line on the white of the eye. The pupil has a teardrop shape, the apex of which points in the direction of the rupture. The *long arrow* points to the upper border of a large conjunctival laceration. Note that the underlying sclera is intact. There is a diffuse hyphema in the anterior chamber, which partially obscures the pupil. *Please see the color-tip insert (Color Plate 111.7).*

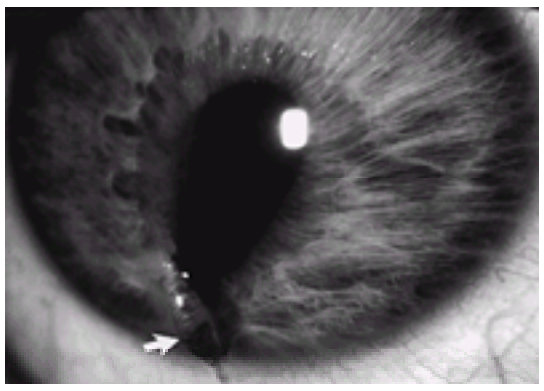

FIGURE 111.8. Corneal laceration (ruptured globe). Note iris protruding through wound *(arrow)* and teardrop-shaped pupil pointing in direction of laceration.

Management

Although the outcome in some ruptured globes, particularly small peripheral corneal lacerations, may be good, eyeball rupture is certainly an ominous sign that warrants emergent referral for ophthalmology consultation. Further ocular examination should be stopped immediately. No eyedrops should be instilled. A patch should never be used in this circumstance. A plastic shield should be placed over the eye such that the edges of the shield make contact with the bony prominences above and below the eyeball (Fig. 111.9). If a commercially marketed shield is not available, the clinician should cut off the bottom of a styrofoam or plastic cup and use it as a shield, resting it against the bony prominences (Fig. 111.10).

FIGURE 111.10. The bottom of a styrofoam cup is used as an eye shield.

Severe eye trauma may cause sedation or vomiting without head trauma or brain injury. If not, every attempt should be made to keep the child calm, even if sedation must be used. Keep in mind that crying, screaming, and Valsalva maneuvers such as vomiting can result in extrusion of intraocular contents through the rupture. Although broad-spectrum intravenous antibiotic coverage is desirable, particularly if a delay may occur before the patient sees an ophthalmologist, this treatment must be weighed against the potential aggravation of the child, which might accompany the needle puncture for catheter placement.

Even if a ruptured globe is not seen clearly on examination, any patient who has a high-risk history, severe lid swelling, and extreme resistance to examination should be given an eye shield and referred to an ophthalmologist as if a ruptured globe was confirmed.

BLOWOUT FRACTURE

Clinical Manifestations

The pathophysiology and diagnosis of blowout fractures are discussed in Chapter 25. Following blunt compressive eye trauma, the eyeball may be retroplaced in a manner that increases the pressure within the orbit and “blows out” one or more bones of the orbital wall. Direct blunt trauma to the orbital rims may also cause bony fractures that extend back into the orbit. Therefore, orbital fractures may occur after facial trauma with or without eyeball trauma.

The most common orbital fracture is an inferior and/or medial wall fracture. The lateral wall is the least commonly fractured. The intraocular contents often sink back into the fracture, giving an enophthalmic appearance (“sunken eye”). However, proptosis can also occur from orbital hemorrhage. Superior wall fracture (roof fractures) may be associated with pulsating proptosis as a result of communication between the orbit and intracranial cavity. Fractures of the inferior wall may be associated with numbness of the ipsilateral malar region caused by injury to the infraorbital nerve, which travels along the floor of the orbit. Palpation of the bony rim of the orbit is often remarkably normal contrary to the

common teaching about point tenderness and “step off” signs.

The hallmark sign of orbital fracture is a restriction of extraocular movement. Usually, the eye is unable to look away from the fracture site because of a tethering of intraocular muscle or other orbital tissues in the fracture (Fig. 25.4). However, orbital hemorrhage at the fracture site can displace the eyeball away from the fracture and make it difficult for the eye to look in the direction of the fracture.

Management

Some controversy exists among ophthalmologists, otorhinolaryngologists, and craniofacial surgeons regarding the urgency for radiologic evaluation and surgical intervention in the management of orbital wall fractures. Approximately 20% of orbital fractures are associated with eyeball injury. Therefore, ophthalmology consultation for complete dilated retinal examination and slitlamp biomicroscopy is indicated in virtually every case. Axial (proptosis) or coronal displacement of the eyeball is an ominous finding because it may be a sign of orbital hemorrhage, which can cause compression of the optic nerve, requiring emergency surgical intervention. If a decision is made to proceed with radiologic imaging, the optimal test is a computed tomography (CT) scan of the orbit with both axial and coronal views. The brain should be included, particularly when a roof fracture is suspected. Plain skull radiographs have little role in the management of orbital wall fractures and need not be ordered.

EYELID LACERATIONS

Clinical Manifestations

Although eyelid lacerations are usually easy to detect, the clinician must remember that the underlying eyeball also might have been lacerated or injured. Seemingly superficial lacerations of the eyelid may be associated with penetration into the orbit or intracranial cavity, particularly when the injury was caused by a pointed implement such as a tree branch or pencil. If possible, the eyelid should be everted to look for a conjunctival wound indicating that the laceration is actually a complete perforation of the eyelid.

Oblique lacerations that extend into the medial canthal area (juncture of the upper and lower lids medially) may involve the proximal portion of the nasolacrimal duct (Fig. 111.11). Sometimes, the lid margin puncta, which drain tears into the system, is displaced laterally as a result of the laceration (Fig. 111.11). Lacerations in this area should usually be referred for ophthalmology consultation if any question persists regarding whether the tear drainage system is intact.

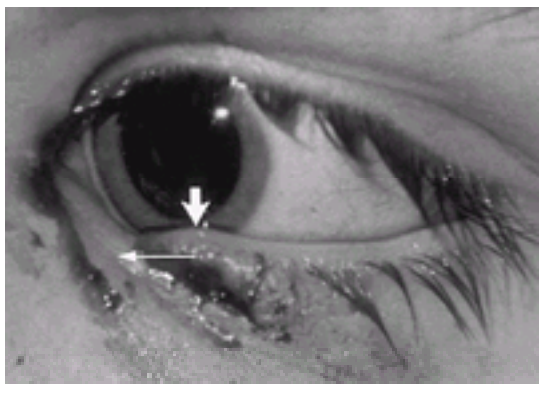

FIGURE 111.11. Lower lid laceration involving tear drainage system. *Large arrow* indicates lower lid punctum, which has been displaced laterally. *Thin arrow* indicates normal course of canaliculus, which drains tears from the puncta to the lacrimal sac located medially.

Management

Lacerations of the periorbital skin and superficial eyelid skin may be managed by standard skin closure techniques discussed elsewhere in this book. However, it is important that sutures not grasp deep tissue within the eyelid because this may result in cicatrical eversion of the eyelid margins. Table 111.2 summarizes those findings that, when associated with eyelid lacerations, should prompt ophthalmology consultation for wound closure.

Consult ophthalmology if laceration associated with:
Full-thickness perforation of lid
Ptosis
Involvement of lid margin
Possible damage to tear drainage system
Tissue avulsion
Eyeball injury

Table 111.2. Eyelid Lacerations

PERIORBITAL ECCHYMOSIS

Clinical Manifestations

Periorbital ecchymosis is usually a benign finding, although it may be associated with bony fracture or eyeball injury. Because of the loose connection of the eyelid skin and underlying tissues, dramatic ecchymosis can occur with mild blunt trauma. It is of forensic importance that bilateral ecchymosis may occur from midline forehead injuries. The dating of injuries should not be made on the basis of the color of periorbital ecchymosis. Because accumulation of blood tends to be more dramatic in the eye than in other body sites, periorbital ecchymosis often looks much darker than what might be expected elsewhere for a bruise of similar age.

Management

No treatment is routinely needed for periorbital ecchymosis. Ice packs applied to the area, with the eyelids closed, can be helpful in reducing swelling. Anticipatory guidance may be given to inform the family that the ecchymosis may persist for more than 2 weeks. An ongoing color change from purple to green and yellow may occur as the blood is resorbed and broken down. A hyperpigmented area may be left for several weeks or months thereafter.

CORNEAL AND CONJUNCTIVAL INJURY

Clinical Manifestations

The conjunctiva can be abraded or lacerated (see Fig. 111.7), although the management of this problem is usually identical to that of corneal abrasion because the tissues heal so rapidly. Corneal or conjunctival abrasions may occur even from mild surface trauma. Self-inflicted abrasions may occur accidentally.

Corneal abrasion can be painful and accompanied by dramatic photophobia and resistance to opening of the eyes. Yet, some children have remarkably few symptoms. They may complain of a foreign body sensation even though no foreign body is present. A drop of topical proparacaine 0.5% or tetracaine 0.5% may have both diagnostic and temporary therapeutic usefulness. Any patient who is made more comfortable by the instillation of these drops must have an ocular surface problem (conjunctiva or cornea) as the cause of pain. The child who is crying and refusing to open the eyes may be compliant and easy to examine just a few minutes after the instillation of a topical anesthetic. Onset of action is approximately 20 seconds, and duration is approximately 20 minutes.

Topical fluorescein is used as a diagnostic agent to stain the affected area. Fluorescein is available as impregnated paper strips and as a solution combined with a topical anesthetic (Fluress, Barnes-Hind, Inc.). Considering the limited use in an ED setting, strips may be a more practical method because bacterial contamination over time may be less likely. When impregnated strips are used, they must be wet before instillation. Otherwise, the strip itself may cause a corneal abrasion, thus preventing the examiner from correctly identifying the patient's problem. Topical anesthetic or saline may be used to wet the strip. The lower eyelid should be pulled down, exposing the pink inner surface (palpebral conjunctiva) against which the strip may be placed. The solution then diffuses off the strip into the area between the lower eyelid and the eyeball (inferior fornix) where it is then displaced across the ocular surface with the next blink. The clinician must avoid placing too much fluorescein because the tear film can be so oversaturated that it may be difficult to find a small abrasion.

Fluorescein, which is orange, fluoresces yellow–green when exposed to blue light. Many modern ophthalmoscopes have a blue light. The examiner can view through the peephole of the direct ophthalmoscope, spinning the focusing dial to allow the ocular surface to be in focus with the examiner 2 to 3 inches away from the patient, inspecting the cornea and conjunctiva for an area that is stained. A Wood or Burton lamp can also be used. Some of these devices have handheld magnifying glasses attached. Although the staining may not be as dramatic, white light from a direct ophthalmoscope or penlight can also be used because some blue wavelengths are incorporated in white light. Green light (red free), available on most direct ophthalmoscopes, may make identifying stained areas more difficult than white light.

If the staining pattern reveals one or more vertical linear abrasions, the examiner should suspect the presence of a retained foreign body under the upper lid. This foreign body may be viewed by upper lid eversion (Fig. 111.12). The patient should be asked to look down repeatedly throughout this procedure. With the eye in downgaze, a cotton swab should be placed against the midbody of the upper eyelid and gently rotated downward toward the eyelashes so that the skin is rolled with the swab by friction. This procedure causes the eyelashes to turn out toward the examiner so that they may be grasped between the examiner's thumb and forefinger. It may be necessary to grab the entire lid margin in some children. If a topical anesthetic is instilled before lid eversion, this procedure is painless. After the lashes (or margin) are grabbed, they should be lifted vertically while the cotton swab is used to apply gentle downward pressure in the opposite direction. The eyelid then flips around the cotton swab. If a foreign body is identified, it can be gently lifted away using a cotton swab or forceps. To revert the eyelid, simply have the patient look upward or massage the lid down.

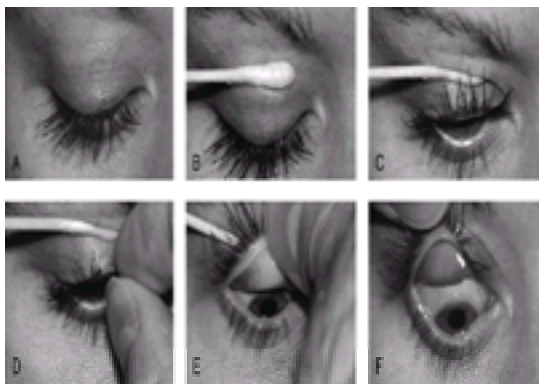

FIGURE 111.12. Upper lid eversion. Note that patient is looking down throughout procedure. In frame **C,** the swab is being rolled clockwise to engage skin and indirectly lift lash line. In frame **E,** the swab is being pushed downward as the examiner lifts the lashes upward in the opposite direction. In **F,** note that patient is wearing a contact lens.

Subconjunctival hemorrhage may result from blunt trauma, conjunctivitis, chemical irritation, and increased intrathoracic pressure (e.g., chest trauma, suffocation). Although usually focal, the lesions may be multiple or diffuse. Hypertension, coagulopathy, or anticoagulant medications may result in subconjunctival hemorrhage out of proportion to the injury. After blunt eyeball trauma, a 360 degree subconjunctival hemorrhage may mask an underlying ruptured globe (Fig. 111.13). No treatment is needed for isolated subconjunctival hemorrhages. They may take up to 2 weeks to resolve, turning yellowish in the process.

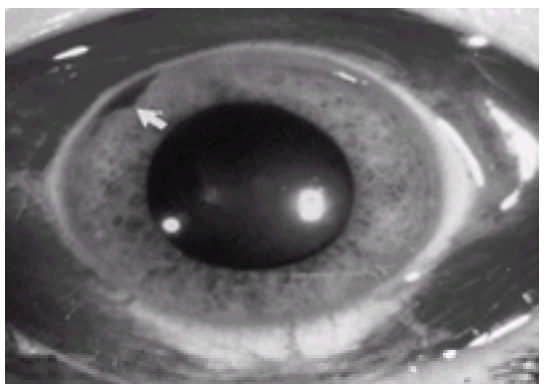

FIGURE 111.13. Subconjunctival hemorrhage extending for 360 degrees. Note the small hyphema *(arrow)*.

Chemical injuries of the cornea and conjunctiva may also occur. These injuries are discussed in Chapter 120.

Management

Several studies have suggested that patching, especially in children with small corneal abrasions, may not accelerate healing or decrease symptoms. Although some controversy exists in this regard, many physicians prefer to apply a lubricating antibiotic ointment (e.g., bacitracin, erythromycin, Polysporin [Burroughs Wellcome]) to the ocular surface, followed by a pressure patch over the closed eyelid. For patients who are in significant pain, a drop of cyclopentolate 1% can be instilled to relieve spasm of the eye's ciliary muscle. Ointments containing steroids or neomycin should not be used. For patients who are relatively asymptomatic, with corneal or conjunctival abrasions that are small and that do not involve the visual axis (i.e., not involving central cornea over the pupil), management with antibiotic or artificial tears alone may be sufficient. If desired, a pressure patch can be created by stacking two or three patches on top of each other over the closed eyelid before applying tape. The patch should be worn overnight. For conjunctival abrasions and small corneal abrasions not involving the central cornea, the patch may be removed by the patient or parents on the following day (approximately 18 to 24 hours later). If the patient is asymptomatic, no follow-up is required. However, if pain or foreign body sensation continues, the patient should be instructed to seek ophthalmologic care. A topical antibiotic ointment may be prescribed for use after patch removal two to three times daily for approximately 3 days. Larger corneal abrasions and those involving the visual axis should be seen the next day by an ophthalmologist.

If concern exists that a superficial abrasion may actually represent penetration into the deeper corneal tissues, a teardrop or irregular pupil may be seen. Urgent ophthalmic consultation is indicated. Any patient with a staining corneal defect who has a history of ocular herpes or who wears contact lenses should be referred urgently for ophthalmology consultation. Patients who wear contact lenses should never be patched under these circumstances. The contact lenses should be removed immediately.

HYPHEMA

Clinical Manifestations

The presence of blood between the cornea and iris is a sign of severe ocular trauma. Although the entire anterior chamber may be filled with blood (“8-ball hyphema”), clots may also be small, requiring careful inspection for detection (Fig. 111.13). Sometimes the blood is more diffuse throughout the anterior chamber (Fig. 111.7) or may even be microscopic, requiring slitlamp examination for detection (microhyphema). The size of the hyphema is directly

proportional to the incidence of secondary glaucoma and is inversely proportional to visual prognosis. Patients with hyphema enter a vulnerable period 3 to 5 days after injury when spontaneous rebleeding may occur. Patients with hemoglobinopathies are also at particular risk for ocular complications of hyphema. Therefore, all patients who are in a high-risk ethnic group should receive a screening test (“shake test”) or formal hemoglobin electrophoresis at presentation unless their status is already known.

Management

All patients who have hyphema must be seen by an ophthalmologist. Although microhyphemas and perhaps some small hyphemas may be managed in select clinical situations as outpatients with careful daily follow-up, hospital admission is often recommended. The eye should be shielded, not patched (see Fig. 111.9), and the patient should be placed at bedrest with the head elevated 45 degrees. This position helps allow blood within the anterior chamber to settle inferiorly, thus allowing a clearance of the visual axis, improvement of vision, and a better view for the ophthalmologist looking into the eyeball. If an ophthalmologist is not readily available, the examining physician may recommend admission and the use of a dilating agent to paralyze the ciliary muscle within the eye. Some ophthalmologists may even recommend sedation of an active or distressed child. Oral antifibrinolytics may be used to prevent spontaneous rebleeding. However, these agents should be used only under the supervision and recommendation of an ophthalmology consultant.

TRAUMATIC IRITIS

Clinical Manifestations

Inflammation within the anterior chamber of the eye often does not present for 24 to 72 hours after blunt trauma to the eyeball. The patient may complain of eye pain, redness, photophobia, and sometimes visual loss. The pupil on the affected side may be constricted (see Chapter 26). The ocular injection may be confined to a ring of redness surrounding the cornea (ciliary flush). Definitive recognition of traumatic iritis requires slitlamp biomicroscopy.

A beam of light projected from a light source can be seen only as it reflects from surfaces. For example, the light from a movie projector in a movie theater would not be visible unless smoke and dust were present in the air to reflect the light as it passes between the projector and the screen. Likewise, the slit beam of light projected from the slitlamp is normally visible only as it reflects off (and through) the cornea and then passes unseen through the optically clear fluid of the anterior chamber, landing on the iris and lens (within the pupil), where it is again visible as it reflects from their surfaces. When white blood cells are floating within the anterior chamber fluid (aqueous humour), along with protein that has leaked from inflamed blood vessels, this beam of light then becomes visible as it passes through the aqueous humour. The white blood cells appear as small specks floating within the beam of light. Red blood cells from microhyphema can also be detected in this manner.

Management

Traumatic iritis may be an indicator that other ocular injuries have occurred. Ophthalmology consultation should be obtained in the diagnosis and management of this condition. The ophthalmologist often recommends dilating drops and topical steroids for treatment. Because of the risks associated with the use of topical steroids, they should not be prescribed except in consultation with an ophthalmologist.

TRAUMATIC VISUAL LOSS

Clinical Manifestations

Some techniques for the recognition of true traumatic visual loss are discussed in pages 1397–1398. Occasionally, the emergency physician is faced with a child who is feigning visual loss. These situations seem to be more common after motor vehicle accidents or other injuries in which legal action may be involved. Functional visual loss can also be idiopathic or associated with other overt or covert stress in the child's life. In the absence of other signs of ocular or head trauma, this diagnosis should be suspected. It then becomes necessary to “trick” the child into demonstrating that he or she can actually see. Patients who are truly acutely blind should demonstrate some degree of anxiety and virtually complete inability to navigate in the new surroundings of the ED. When asked to write their names on a piece of paper, truly blind patients can do so accurately, unlike children who are functionally blind who assume that they are unable to write. When a mirror is held before a truly blind eye and then tilted in the vertical and horizontal planes, the eye will not follow. However, any eye that truly has enough sight to recognize its own image moves involuntarily with the motion of the mirror.

Children who are feigning visual loss but not complete blindness can be more difficult to “trick.” Sometimes, by placing a drop of saline or topical anesthetic in the eye while giving the child the suggestion that these “magic drops” will cause a return of vision, the child then begins to see better. The pinhole test (previously discussed) can also be used in this manner. Ophthalmology consultation is sometimes critical in discovering whether a child has truly sustained visual loss.

A rare cause of visual loss after head trauma is transient cortical visual impairment/blindness. As a result of a direct or centre coup occipital contusion, a child may experience acute blindness despite an otherwise normal eye examination. This centrally mediated phenomena may resolve spontaneously. Ophthalmology consultation can be useful to rule out other causes of the visual loss.

A multitude of intraocular injuries, including traumatic cataract, vitreous hemorrhage, retinal bruising (commotio retinae), retinal detachment, and optic nerve injury, can result in true visual loss or blindness. The pediatric emergency physician is the “gatekeeper” in recognizing that true intraocular injury has occurred, although in most of these circumstances, ophthalmology consultation is then required. Perhaps the best screening test for intraocular injury is the examination of

the red reflex and direct ophthalmoscope exam.

CHILD ABUSE

Clinical Manifestations

Virtually any eye injury can be the result of child abuse. Unusual types of ocular trauma, such as the covert instillation of noxious substances onto the conjunctiva, should also be considered in the differential diagnosis of recurrent red eyes in the absence of an apparent cause. Perhaps the most common ocular manifestation of child abuse is the finding of retinal hemorrhages associated with the shaken baby syndrome (Fig. 111.14). Although these hemorrhages can be seen with the direct ophthalmoscope, ophthalmology consultation is indicated. Children who present to the ED before the age of 4 years with a history of head trauma or sudden unexplained cardiorespiratory arrest should have a full dilated examination to look for retinal hemorrhages that may indicate that a nonaccidental shaking injury has occurred.

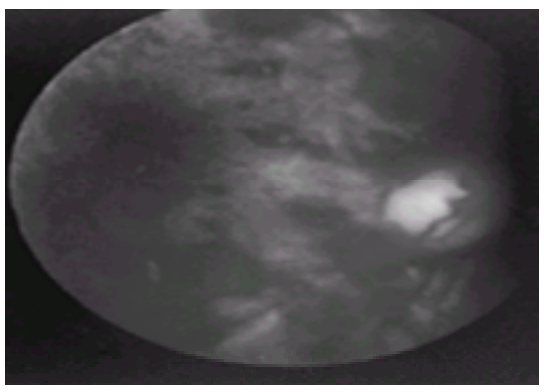

FIGURE 111.14. Retinal hemorrhages in shaken baby syndrome. *Please see the color-tip insert (Color Plate 111.14).*

CHAPTER 112

Otolaryngologic Trauma

STEVEN D. HANDLER, MD and WILLIAM P. POTSIC, MD

Department of Otorhinolaryngology: Head and Neck Surgery, The University of Pennsylvania School of Medicine, and Division of Pediatric Otolaryngology & Human Communication, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

The ear, nose, and throat are common sites for trauma; therefore, emergency medicine specialists must be familiar with the head and neck region because they will often be called on to evaluate this area. Although the presenting complaints may seem extremely distressing to the patient and cause considerable anxiety for the parents, the conditions prompting the visit are rarely life-threatening. Many instances of trauma may be isolated to the ear, nose, or throat, but associated injuries (e.g., eye, dental, central nervous system, thorax) are common and must be detected when evaluating and treating otolaryngologic trauma.

Evaluation of the patient with otolaryngologic trauma requires a careful examination of the head and neck. The specific methods of examination of each anatomic area are detailed in Chapter 121.

EAR

Foreign Bodies

Foreign bodies in the ear canal are common in children. Solid objects, such as stones, beads, or paper, are the most commonly encountered foreign bodies, but live insects may also enter the ear canal. Foreign bodies should be removed as soon and as safely as possible. Most objects can be gently rolled out of the external meatus with an ear curette or grasped and removed with an otologic forceps (see Procedure 5.3 in Section VII). Round or occluding objects may be removed by irrigation of the canal with body-temperature water. (Irrigation, however, should not be performed if a tympanic membrane [TM] perforation is suspected or if a ventilating tube is in place.) The stream is directed along the side of the foreign body, forcing it to the external meatus. Insects should be killed by filling the ear canal with alcohol or mineral oil before they are removed from the ear canal by the techniques already described. Objects resting against the TM are best removed by irrigation to avoid injury by manipulation.

Care must be taken to remove the foreign material without causing pain; if the removal is unsuccessful, a general anesthetic is usually necessary for removal of the object by the otolaryngologist.

Trauma

External Ear Trauma

External ear trauma is common in children because the pinna is in an exposed position on the side of the head. Reflex turning of the face to the side to avoid a blow or a fall places the ear directly in the line of injury. External blunt trauma often occurs secondary to an athletic injury, a fall, or a direct blow to the ear; the injury may result in simple ecchymosis or it may disrupt perichondrial blood vessels with subsequent hematoma or seroma formation. These collections form a smooth bluish colored mass on the lateral surface of the auricle that obscures its normal contour. Hematomas and seromas must be evacuated immediately to prevent cartilage necrosis (see Procedure 5.4 in Section VII). Lacerations of the pinna should be closed using the same surgical principles applied to repairing lacerations in other end-organ areas of the body. Earrings in pierced ears may be torn from the lobule. These lacerations should be closed like all skin lacerations, reestablishing the normal anatomy.

Thermal injury of the external ear commonly occurs because the ear protrudes from the head and is exposed to burns

and cold. Burns of the ear should be treated in the same manner as burns of other parts of the body (see Chapter 114). Frostbite is suspected when the ear is pale and painful on warming. The frostbitten ear should be rewarmed rapidly by applying warm soaked cotton pledgets at 38° to 40°C (100.4° to 104°F); the ear should be completely thawed and never recooled.

Middle Ear Trauma

A slap to the side of the head (by a hand or a breaking wave) may result in perforation of the TM by sudden compression of the air in the external auditory canal, but traumatic perforation of the drum is usually caused by poking an object into the ear canal. The structures of the middle ear may also be damaged by the penetrating object. The ossicles may be fractured and a perilymph fistula may be created in the footplate of the stapes. This reaction causes immediate vertigo and a sensorineural hearing loss. The facial nerve may be injured and cause facial paralysis. Traumatic perforations of the TM must be examined carefully to be certain that the edges of the perforation do not fold into the middle ear. If they do, skin may grow into the middle ear and a cholesteatoma will develop. Clean perforations with margins that do not fold into the middle ear usually heal spontaneously in 2 to 3 weeks. The perforation should be kept clean and dry. If the ear is draining, topical otic drops (neomycin, polymyxin, and hydrocortisone) should be used for 10 days. Systemic antibiotics are usually unnecessary. Any perforation that does not heal within 3 weeks should be referred to an otolaryngologist for evaluation and repair. Traumatic perforations associated with vertigo, sensorineural hearing loss, or facial nerve paralysis require urgent consultation and possible exploration of the middle ear by an otolaryngologist.

Barotrauma to the ear may occur during an airplane trip or while scuba diving, especially if the child has an acute upper respiratory infection. A direct open communication between the middle ear and the nasopharynx normally permits prompt equalization of changes in ambient pressure. If the eustachian tube is obstructed, however, changes in ambient pressure may not be transmitted to the middle ear, and barotrauma can result. As the child descends in an airplane (or during an underwater dive), the increased ambient pressure is transmitted to the cardiovascular system and, thus, to the vessels of the mucosal lining of the middle ear. The mucosa becomes edematous and the vessels become engorged. If the eustachian tube is obstructed and has not equalized the air pressure, a large differential pressure occurs between the middle ear mucosa and its air-filled cavity. This condition results in a rupture of the blood vessels within the mucosa and bleeding into the middle ear. Serous fluid may also accumulate in the middle ear secondary to eustachian tube obstruction. Rarely, perforation of the TM occurs. These injuries usually resolve spontaneously over several weeks. Antimicrobials may be prescribed to prevent infection of the middle ear fluid/blood. The rare case that does not respond to this regimen should be referred to an otolaryngologist for further evaluation and treatment. Persistent symptomatic fluid may require myringotomy and ventilation tube placement. Barotrauma with acute sensorineural hearing loss and/or vertigo may indicate the presence of a perilymph fistula (previously described). Persistence of symptoms and signs of a fistula require urgent middle ear exploration to close the fistula.

Inner Ear Trauma

Concussive injuries to the head may cause inner ear trauma by disrupting the delicate intracochlear membranes. Sensorineural hearing loss and/or vertigo may occur as a result of such an injury. Occasionally, the losses from these injuries can improve spontaneously, but most are permanent. Temporal bone fractures (especially transverse) have a high incidence of cochlear disruption.

Constant exposure to loud noise or amplified sound may cause a progressive high-frequency sensorineural hearing loss. Loud blasts from explosions may cause sudden permanent sensorineural hearing loss.

Cerebrospinal Fluid Otorrhea

Cerebrospinal fluid (CSF) otorrhea may occur secondary to a temporal bone (usually longitudinal) fracture that results in a fracture through the inner ear and a ruptured TM. Manipulation or instrumentation of the external auditory canal in the presence of CSF otorrhea is discouraged because it could introduce bacteria and contribute to the development of meningitis. If CSF otorrhea is suspected, the child should be placed at bed rest with the head elevated and neurosurgical consultation should be obtained. The use of prophylactic antimicrobials in CSF otorrhea is controversial.

Facial Nerve Paralysis

Facial nerve paralysis may occur as a result of temporal bone trauma (see Chapter 105). Transverse fractures of the temporal bone can cause disruption of the facial nerve in its intratemporal segment. Longitudinal fractures are less likely to cause facial nerve paralysis. Patients with traumatic facial nerve paralysis should be referred to the otolaryngologist for possible exploration and nerve repair.

NOSE AND PARANASAL SINUSES

Nasal Trauma

General Principles/Nasal Fracture

Facial trauma often occurs in children as a result of play activities, contact sports, and automobile accidents. Most of these injuries are minor. Nevertheless, any child with facial trauma should be assessed for associated, possibly more serious, injuries to the cervical spine, central nervous system, and chest (see Chapter 104).

Because of its prominent position on the face, the nose is subject to frequent trauma and accounts for most facial injuries in children. It is important, however, to realize that nasal trauma may also be associated with ocular injury, such as hyphema or retinal detachment. If the initial survey suggests a serious ocular injury, an ophthalmologic consultation must

be obtained.

Trauma to the nose most often causes ecchymosis and edema of the overlying skin. However, a direct blow to the nose can fracture the nasal skeleton with resultant deviation and/or depression of the nasal bones and septum. The deformity should be readily apparent by clinical examination, but the postinjury edema may prevent its recognition for several days until the swelling has subsided (Fig. 112.1). A stepoff or bony irregularity may often be detected in these patients. Radiographs of the nose are notoriously unreliable in the evaluation of nasal injuries and are not recommended in the routine management of simple nasal fractures. Epistaxis commonly accompanies nasal trauma but usually has stopped by the time the child reaches the emergency department (ED). Persistent or severe bleeding may require local pressure, topical vasoconstrictors, or nasal packing (see the section on epistaxis in Chapter 121). The presence of any associated ocular injury, such as hyphema or retinal detachment, must be detected, and ophthalmologic consultation must be obtained.

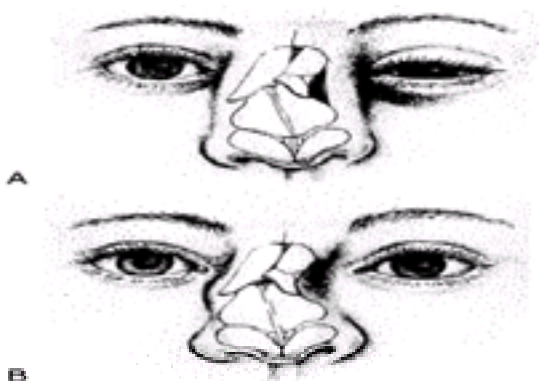

FIGURE 112.1. A. Postinjury edema may mask underlying nasal bone deformity. **B.** Nasal deformity manifests as edema subsides.

In assessing the nasal injury, the emergency physician must determine the nature and extent of trauma to the overlying skin, the nasal skeleton, and the nasal septum. A septal hematoma, if present, requires incision drainage. The amount of nasal deviation and/or depression should be noted. Because this condition can be masked by postinjury edema, it may be best to examine the child again in 3 to 4 days when the swelling has subsided to allow an accurate determination of nasal deviation and/or depression.

If no septal hematoma or associated ocular or intracranial injuries are present, then the deviated nose and septum can be reduced by the otolaryngologist when the swelling has subsided enough to permit an accurate evaluation of the nasal deformity. If more than 7 days elapse between the time of injury and the attempt at reduction, the fracture fragments begin to form a strong fibrous union in their deviated positions, making reduction difficult. Antimicrobials (usually amoxicillin 25 to 50 mg/kg per day for 7 days) are generally administered to these patients to prevent complications from occurring in what is almost always a compound fracture (i.e., open into the nasal cavity).

Septal Hematoma

The presence of a septal hematoma must be recognized as soon as possible after the injury. A septal hematoma appears as a bulging of the nasal septum into one or both sides of the nasal cavity. Accumulation of blood between the septal cartilage and its overlying mucoperichondrium deprives the cartilage of its blood supply. Otolaryngologic consultation should be obtained as quickly as possible if a septal hematoma is suspected. The hematoma is drained as soon as possible and the mucoperichondrium packed back against the septal cartilage to restore its blood supply (see Procedure 7.4 in Section VII). If the hematoma is left for any length of time, septal abscess or cartilage destruction may occur. A saddle nose deformity is the result of an improperly treated septal hematoma.

Cerebrospinal Fluid Rhinorrhea

A clear, watery rhinorrhea occurring after nasal trauma may be CSF rhinorrhea, which would indicate a skull fracture, usually through the cribriform plate. Less commonly, the CSF originates from a temporal bone fracture and enters the nasopharynx through the eustachian tube. If the patient leans forward, allowing the nasal drainage to drip onto a piece of paper, a characteristic target pattern will often appear, with a blood stain in the center of the drop and a clear halo of CSF around it. CSF is high in glucose, which can be detected with the use of a glucose oxidase test paper (used in urinalysis). Care must be taken in interpreting these tests, however, because normal nasal mucus can look like CSF, and the oxidizing substances present in nasal and lacrimal secretions may give a false-positive reaction. If CSF rhinorrhea is suspected by history or clinical examination, the child should be admitted and restricted to bed rest with his or her head elevated in an attempt to decrease the leak, and neurosurgical consultation should be obtained. The use of prophylactic antimicrobials in CSF rhinorrhea is controversial. Further diagnostic studies, such as computed tomography (CT) scans and isotope scans, can be performed to confirm the diagnosis of CSF leak.

Sinus Trauma

Fractures of the paranasal sinuses may occur as isolated injuries or in association with trauma to the nose and orbital structures. Fractures of the ethmoid sinus or anterior wall of the maxillary sinus usually occur as a result of blunt trauma to the nose or cheek, respectively. The otolaryngologist should assist the emergency physician in evaluating these injuries. Subcutaneous crepitance may be felt in the cheek or around the eye. Radiographs may demonstrate air in the cheek or orbit, or air-fluid levels. After determining the absence of associated ocular injury, the patient is usually placed

on oral antimicrobials (usually amoxicillin 25 to 50 mg/kg per day for 7 days) and observed as an outpatient until the crepitance resolves.

Facial Trauma

Blunt facial trauma can result in focal injuries and fractures or more generalized fractures involving much of the midface. Blunt trauma to the orbit may result in the force being transmitted through the globe to break the orbital floor (roof of maxillary sinus) or the medial orbital wall (lamina papyracea of the ethmoid sinus). These blowout fractures are discussed in detail in Chapter 110 and Chapter 111.

Midface fractures include fractures of the malar bone, which affect both the orbital floor and the maxillary sinus. A complete malar (incorrectly called trimalar or tripod) fracture is present when the malar bone fractures at the infraorbital rim, zygomatic arch, and zygomaticofrontal suture line. Isolated malar fractures can also occur at the zygomatic arch or the lateral wall of the maxillary sinus. (For more detail regarding sequential steps and examination for facial fractures, see Chapter 110.) Severe midface injuries often require multidisciplinary cooperation between otolaryngology, ophthalmology, plastic surgery, oral surgery, and neurosurgery.

Sinus Barotrauma

A direct open communication between the paranasal sinuses and the nasal cavities normally permits prompt equalization of changes in ambient pressure. If a sinus ostia is obstructed, however, changes in ambient pressure may not be transmitted to the affected sinus cavity (most commonly the maxillary sinus, although the frontal sinus may be affected in older children and adolescents), and barotrauma can result. As the child descends in an airplane (or during an underwater dive), the increased ambient pressure is transmitted to the cardiovascular system and, thus, to the vessels of the mucosal lining of the sinus. The mucosa becomes edematous and the vessels become engorged. If the sinus is obstructed and has not equalized the air pressure, a large differential pressure occurs between the sinus mucosa and its air-filled cavity. This condition results in a rupture of the blood vessels within the mucosa and bleeding into the sinus. The child usually complains of cheek pain and may have epistaxis. Treatment for this condition involves amoxicillin 25 to 50 mg/kg per day for 7 days (to prevent infection of the blood-filled sinus), antihistamine–decongestant therapy and topical nasal sprays to restore the normal physiologic communication between the sinus and the nasal cavities, and the avoidance of further barotrauma. The rare case that does not respond to this regimen should be referred to an otolaryngologist for further evaluation and treatment.

Foreign Bodies

Nasal foreign bodies are common in children. These children are usually brought to the ED with the history of putting an object into the nose, but the presence of a foreign body may often be unsuspected and may be discovered only during evaluation of a child with persistent, unilateral, foul-smelling, purulent rhinorrhea. This mode of presentation for these problems is so common that any child with a foul-smelling unilateral nasal discharge (even without a history of placing an object in the nose) should be considered to have a nasal foreign body until proven otherwise. The foreign body is usually visible on anterior rhinoscopy. However, purulent secretions may have to be suctioned from the nose before the object is seen. Radiographs are of limited value because most of the foreign bodies are radiolucent (e.g., paper, cloth, sponge, food).

If the object is located in the nasal vestibule, the emergency physician may attempt to remove it (see Procedure 7.3 in Section VII). The child should be adequately restrained, and the necessary equipment, including a nasal speculum, directed light, suction, small hooks, and forceps, should be available. Otologic instruments are often very useful in the removal of nasal foreign bodies. A few drops of 4% lidocaine can be placed in the nostril to provide topical anesthesia before removing the foreign body. An otolaryngologist should be consulted if the foreign body cannot be removed easily. Hygroscopic foreign bodies, such as beans, may swell with nasal secretions and become difficult to remove. The foreign body should never be pushed or irrigated into the nasopharynx, where it could be aspirated by the struggling child. Antimicrobials (usually amoxicillin 25 to 50 mg/kg per day for 7 days) are administered to prevent (or treat) an infection (rhinitis, sinusitis) in this already traumatized area, especially after removal of a long-standing foreign body.

ORAL CAVITY, PHARYNX, AND ESOPHAGUS

Trauma

Oral cavity trauma is usually caused by biting the inside of the cheek or tongue. This condition is painful and can cause a laceration or hematoma formation. Treatment of self-inflicted bites is rarely needed, but a laceration may require suturing if it bleeds excessively or is severe enough to alter intraoral anatomy or physiology (i.e., breathing, deglutition, or speech).

Children may have oropharyngeal lacerations or puncture wounds when they fall with an object, such as a stick, in their mouths. If the injury is restricted to the central portion of the palate, damage to vascular or neural structures of the neck is unlikely. These children are usually safe to send home after confirmation of absence of any retained foreign body (see the following section). However, trauma to the lateral aspects of the palate or the posterior pharyngeal wall may be associated with vascular injuries of the carotid artery or the jugular vein. Expanding hematoma of the neck or pharynx, continued intraoral bleeding, and diminished pulses in the neck are all signs of serious vascular injury. These children need to be admitted and have an urgent angiogram and possible neck exploration. If a lateral pharyngeal or palatal puncture injury is present without signs of vascular injury, the child should be observed closely in the hospital or at home for signs of neurologic deterioration.

In treating puncture wounds of the pharynx, it is imperative to determine whether the foreign body has been recovered intact or if a portion of the foreign body may have been left in the palatal tissues. For example, a portion of pencil lead left

in the palatal tissue causes a chronic foreign body reaction if it is not removed at the time of initial treatment and repair. Plain radiographs may not be useful in determining whether a foreign body has been left in the wound because most of the objects are radiolucent and/or too small to be seen. Inspecting the actual object that caused the wound to make sure that it is intact is more important. If a retained portion of the foreign body is suspected, CT scan may be required, followed by exploration of the wound, usually under general anesthesia.

Clean puncture injuries or simple lacerations do not require surgical repair and usually heal by secondary intention. Large gaping injuries may require formal layered closure to restore normal function to the palate.

Caustic Injuries

Caustic substances (lye or acid) may be ingested, causing burns anywhere from the lips to the stomach. Burns of the oral mucosa appear as patches of erythema, blebs, or ulcerated areas. Although caustic burns are usually visible in the oral cavity and pharynx, large skip areas may exist. Therefore, the absence of oral or pharyngeal burns does not rule out esophageal injury. If a history of significant caustic ingestion exists (see Chapter 88), an esophagoscopy should be performed 6 to 12 hours later to establish the presence of esophageal burns, regardless of the condition of the oral cavity and pharynx. Because burns occur rapidly after ingestion, the child need not be given any oral antidote in the ED. In fact, emesis should not be induced because it only exposes the esophagus to the caustic substance again.

Caustic substances may burn the larynx when ingested and can cause rapidly progressive edema and respiratory distress. Orotracheal intubation for acute airway management should be performed in the ED if necessary. A tracheotomy should be performed as soon as possible after the intubation to minimize the possibility of laryngotracheal stenosis.

Foreign Bodies

Foreign bodies in the oral cavity and pharynx are uncommon because of the child's protective reflexes. The tongue is sensitive and can detect sharp foreign objects that are then spat out. The gag reflex often expels foreign material from the pharynx, but sharp objects, such as fish bones, pins, and pieces of plastic, may get stuck in the oral mucosa, tonsils, or pharynx (Fig. 112.2). If a foreign body is visible and the patient is cooperative, the object may be removed in the ED with a clamp or forceps.

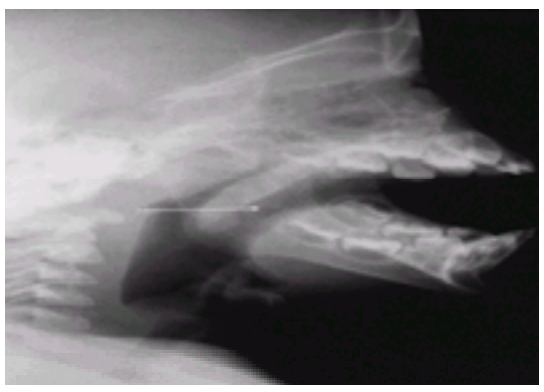

FIGURE 112.2. Lateral neck radiograph of a straight pin lodged in posterior pharyngeal wall.

Objects of all types may lodge in the hypopharynx or esophagus. Esophageal foreign bodies generally lodge at the areas of natural narrowing of the esophagus. The most common sites are the cricopharyngeal area, thoracic inlet, arch of the aorta, and gastroesophageal junction. If the child can breathe and talk, no attempt should be made to remove the object in the ED. The safest method of removal is endoscopically, using a general anesthetic. If the child is gagging and unable to breathe, the Heimlich maneuver should be used (see Chapter 1). If this method is not effective, emergency intubation or tracheotomy may be required to bypass the obstructing object.

Lateral neck and chest radiographs reveal radiopaque hypopharyngeal and esophageal foreign bodies. Plastic and other nonradiopaque objects cause the same foreign body sensation (something stuck in the throat) but are not visible on radiograph). Young children often have dysphagia and drooling because of painful swallowing.

Although ingestion of a foreign body usually causes gagging and choking that last for several seconds and subsequently subside, the initial episode may take place unobserved by an adult. Thus, unexplained dysphagia or drooling should initiate a search for a possible foreign body.

If a child presents to the ED with a history of swallowing an object, such as a toy or a fish bone, and complains of a foreign body sensation, a careful examination of the oral cavity and hypopharynx must be performed. If no foreign body is seen, plain radiographs of the neck should be obtained. Barium esophagrams are rarely helpful in pinpointing sharp foreign bodies in the esophagus but may be useful to confirm esophageal obstruction from an impacted foreign body such as a bolus of food. Foreign bodies easily seen in the oral cavity may be removed by the emergency physician. Consultation with an otolaryngologist (or similarly skilled specialist) should be obtained if a foreign body is detected in the pharynx or esophagus because removal usually requires endoscopic examination under anesthesia.

If the physical examination and radiographs fail to detect a foreign body, management is determined by the child's symptoms. If the child is having significant pain, the otolaryngologist should be consulted to perform esophagoscopy in the operating room. If the pain is mild, the child can swallow his or own saliva, and no evidence of respiratory distress is present, the foreign body sensation may be secondary to a mucosal scratch from a foreign body that has passed into the

stomach. In that instance, it may be appropriate to send the child home to return the next day if the sensation persists, which would indicate the presence of a persistent foreign body and require endoscopic removal.

LARYNX AND TRACHEA

Trauma

Laryngeal trauma can occur in a variety of ways. Blunt or penetrating injuries of the larynx can result in mucosal lacerations, laryngeal hematomas, vocal cord paralysis, or fractures of the thyroid and cricoid cartilages. Proper treatment requires prompt recognition of the presence and nature of a laryngeal injury and protection of the airway. Patients with laryngeal trauma present with varying degrees of neck pain, hoarseness, hemoptysis, and airway obstruction. Physical examination of a child with blunt trauma can reveal anterior neck tenderness, crepitance, and absence of the normal prominence of the thyroid cartilage or “Adam's apple” (Fig. 112.3). The otolaryngologist (or similarly skilled specialist) may be needed to perform an indirect examination of the larynx on the child with a suspected laryngeal injury. A direct laryngoscopy may be required when the child is in respiratory distress. The otolaryngologist should be prepared to intervene with intubation, tracheostomy, and/or surgical exploration of these laryngeal injuries.

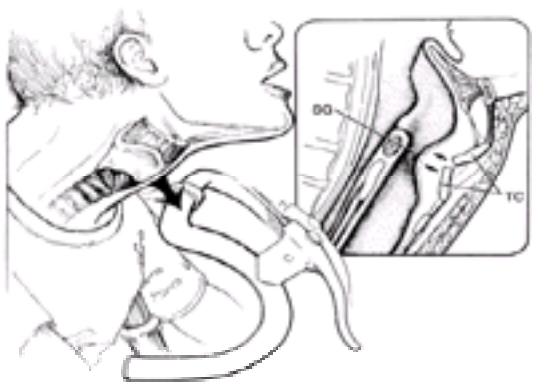

FIGURE 112.3. Loss of thyroid cartilage prominence and associated acute airway obstruction secondary to laryngeal fracture. *SG,* narrowed subglottic space; *TC,* fracture of thyroid cartilage.

Ingestion of caustic substances can cause severe burns of the larynx and pharynx; airway obstruction may occur secondary to the edema related to this injury. Laryngeal burns should be suspected in the child who has hoarseness or stridor after caustic ingestion. The child should be hospitalized, and otolaryngologic consultation should be obtained. If signs of respiratory distress (e.g., tachypnea, stridor) occur, the child should be taken to the operating room, where endoscopy can be performed, and an artificial airway, usually a tracheostomy, can be placed.

Foreign Bodies

Foreign bodies may become trapped in the laryngeal inlet, causing acute upper airway obstruction. The child usually presents with severe coughing, hoarseness, and significant respiratory distress. If the child is able to phonate, air is moving through his or her larynx, indicating only partial obstruction. “Back blows” or the Heimlich maneuver should not be performed in these children because this action may cause the foreign body to lodge more firmly in the larynx and convert a partial obstruction into a complete one. The child should be taken immediately to the operating room, where the otolaryngologist (or similarly skilled specialist) can perform the direct laryngoscopy necessary to remove the foreign body. In contrast, if the child is unable to speak, the foreign body may be causing total obstruction. In this case, back blows or the Heimlich maneuver may be lifesaving. Care must be taken in performing the Heimlich maneuver in young children because of the potential hazard of liver laceration. Emergency laryngoscopy, intubation, or tracheostomy is rarely required, and only if the previously described maneuvers are unsuccessful.

Foreign bodies that pass the larynx to lodge in the trachea or proximal bronchi can present problems in diagnosis and management. A history of coughing or choking on food (e.g., a peanut, raw carrot) or a toy is usually obtained. The child is often in no acute distress but may demonstrate a mild cough and/or wheezing. Inspiratory and expiratory stridor are characteristic of tracheal foreign bodies. Unilateral wheezes and decreased, or even absent, breath sounds are often seen with unilateral bronchial obstruction. Because most of the foreign bodies are radiolucent, they are not identifiable on radiographs. However, a radiographic difference in aeration of the lungs often helps detect the presence and identify the site of bronchial obstruction. Volume decrease, atelectasis, and infiltrate on the involved side may be seen on plain chest films if the bronchus is completely occluded by the foreign body. Hyperaeration (air trapping) secondary to a ball-valve effect of a foreign body that is partially blocking the bronchus is best seen by comparing inspiration and expiration films (Fig. 112.4). If the child will not cooperate to obtain these views, right and left lateral decubitus films can often demonstrate the same phenomena. Although differentiating hyperaeration and contralateral volume loss from atelectasis and compensatory contralateral lung expansion may help predict the location of a possible foreign body, this distinction is not as important as recognizing that any radiographic asymmetry signals a possible foreign body and requires endoscopy. However, a normal chest radiograph does not rule out the possibility of a foreign body. If a foreign body is suspected (by history or clinical examination), the child should be admitted and otolaryngologic consultation should be obtained to perform the endoscopy necessary for the prompt and safe removal of the object, if present.

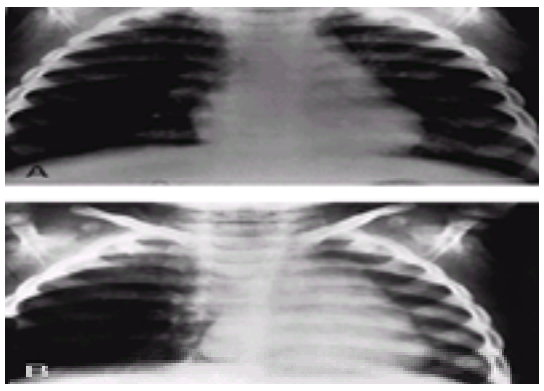

FIGURE 112.4. Chest radiograph of child with bronchial foreign body. **A.** Inspiratory film demonstrates only subtle hyperaeration of right lung. **B.** Expiratory film shows accentuated hyperaeration on the right side secondary to air trapping (“ball-valve” phenomenon) by the foreign body in the right mainstem bronchus. In addition, the mediastinum is displaced to the left.

CHAPTER 113

Dental Trauma

***LINDA P. NELSON, DMD, MScD, *HOWARD L. NEEDLEMAN, DMD, and †BONNIE L. PADWA, DMD, MD**

**Department of Pediatric Dentistry, †Oral and Maxillofacial Surgery, Harvard School of Dental Medicine, and †Division of Plastic and Oral Surgery, Children's Hospital, Boston, Massachusetts*

ASSESSMENT OF TRAUMATIC DENTAL EMERGENCIES

The care of pediatric patients with oral and maxillofacial and dental trauma should follow the basic tenets of emergency medicine. An initial general assessment includes evaluation of airway patency, breathing adequacy, and cardiovascular status (ABCs). Control of bleeding, assessment of the degree of shock, evaluation of neurologic status, and notation of other injuries must all be done sequentially.

Life Support

The most common cause of airway obstruction in a child with facial injuries is the accumulation of blood in the oral cavity and pharynx. Unconscious children may be unable to clear their airway by coughing or swallowing. A tooth aspirated by a child can block the airway. A fractured mandible may cause the tongue to fall posteriorly and create obstruction. The mouth should be gently suctioned clean. If the tongue of an unconscious child is causing obstruction, the mandible can be pulled forward by pressure at the angles or an oropharyngeal or nasopharyngeal airway can be placed. Chapter 1 details the procedures for establishing a patent airway. If endotracheal intubation fails, a surgical airway must be obtained with either a cricothyrotomy or tracheostomy.

The soft tissues and bones of the lower and midface are well vascularized and bleed profusely when injured. Hemorrhage is best controlled by ligating any vessels that are easily seen. However, vessels of the face often retract when severed, and if a vessel cannot be seen, direct pressure should be applied to control bleeding. With extensive blood loss, the patient should be assessed for signs of shock (see Chapter 3).

History

A thorough history and physical examination are paramount to any treatment considerations. Traumatic orofacial injuries can be dramatic, making a history difficult to obtain. Informants other than the patient may have to be questioned. The practitioner should always be alert to the possibility of “nonaccidental” trauma (i.e., child abuse) if the history is not consistent with the observed injury. One key question of significance is the immunization history. Many traumatic facial injuries occur with concomitant soft-tissue injuries, and the need for tetanus prophylaxis is based on the history of immunization. Antibiotic prophylaxis may be indicated before treatment in the child with congenital heart defects to prevent subacute bacterial endocarditis (see Table 82.25) and in children who have certain hematologic, oncologic, or endocrine disorders (e.g., sickle cell disease, leukemia, diabetes). The history should also give the physician an indication of the preinjury and postinjury neurologic status. A thorough neurologic assessment must be made as early as clinically possible because the risk of neurologic injury is high in all head and neck trauma.

Physical Examination

Children with facial injuries are usually frightened and apprehensive. Hence, the initial contact with the child should be authoritative and reassuring. The examination should be organized to include inspection, palpation, percussion, and auscultation of both extraoral and intraoral aspects.

Extraoral Examination

Inspection

The extraoral examination should start with inspection. The clinician should note the symmetry of the face in the anterior

view as well as in profile. A loss of symmetry is often associated with dental infection or swelling from trauma. The child should be inspected for any nasal or orbital malalignments. The clinician should carefully note the location and nature of any swollen or depressed structures and the color and quality of the skin and should look for lacerations, hematomas, ecchymoses, foreign bodies, or ulcerations. The child should be asked to open and close his or her mouth while facing the clinician to see whether the mandible deviates during function. If the child is unable to open or close his or her mouth because of pain, the action should not be forced because it may increase the extent of injury. The clinician should inspect for lip competency (the ability of the lips to cover the teeth) because loss of competency may indicate displacement of the teeth from trauma.

Palpation

Gentle digital palpation bilaterally, to feel the temporomandibular joints (TMJs), should be the next point of the examination. The clinician should feel the TMJs as the child opens and closes his or her mouth. There should be equal movement on both sides without major deviations. The clinician should palpate to the orbital rim, checking to be sure it is continuous and intact all the way to the inner canthus of the eye. The clinician should then move across the zygoma to the nose and palpate for any crepitus or mobility and move back to the preauricular region and along the posterior border of the mandible, palpating the ramus. The clinician should then move anteriorly from the angles to the symphysis, palpating for any discontinuity, mobility, swellings, or point tenderness. Finally, the clinician should palpate the major lymph nodes of the neck and note any paresthesia or hypoesthesia (numbness) of the lips, nose, and cheek, which may indicate a fracture. Figure 113.1 shows the main nerve supply to facial structures.

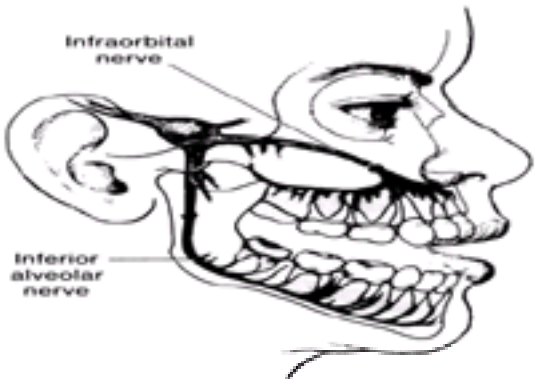

FIGURE 113.1. Infraorbital and inferior alveolar main nerve supplies the teeth.

Auscultation

The clinician should listen for crepitus as the child opens and closes his/her mouth, at the same time palpating the TMJ. Crepitus may indicate TMJ pathology.

Intraoral Examination

Inspection

A good light is essential for the intraoral examination. The clinician should inspect the color and quality of the lips, gingiva (gums), mucosa, floor of the mouth, tongue, and palate. The gingiva should be pink, firm, and stippled (like a grapefruit skin). The mucosa should be pink, moist, and glassy in appearance. The floor of the mouth should be flat and well vascularized. The clinician should inspect the mouth for any swellings of soft tissue that may be bluish as a result of vascularization and/or hematoma. Hematomas or mucosal ecchymoses in the floor of the mouth or vestibular area are highly suggestive of mandibular fractures. The clinician should note any inflamed, ulcerated, or hemorrhagic areas, as well as any foreign bodies or denuded areas of bone. Traumatically displaced teeth often produce the complaint that the child's teeth do not fit together when he or she bites on the back teeth. However, a similar complaint may be expressed by a child when a primary tooth is mobile and about to exfoliate. Figure 113.2 shows key eruption times for primary and secondary teeth. Exfoliation of primary teeth is often confused with traumatic injuries. The child should be inspected for any chipped or missing teeth. If a tooth is chipped or missing, the clinician should check for any fragments of teeth or foreign bodies in adjacent soft tissues. If the child's teeth are missing yet no bloody socket is present, the eruption/exfoliation timetables (Table 113.1A and Table 113.1b) can be helpful in determining whether the loss is normal.

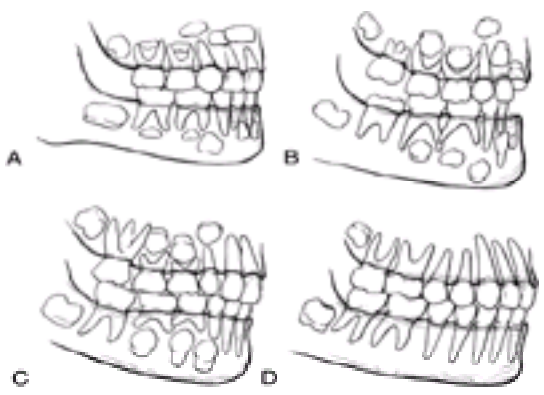

FIGURE 113.2. A. At age 3, 20 primary teeth should be erupted. The permanent teeth are in various stages of calcification underneath and behind the primary teeth. **B.** At age 6, 16 primary teeth should be present. The permanent

6-year molars should be erupting distal to the last primary molars. The permanent anterior central incisors should be erupting. **C.** At age 9, 8 to 12 primary teeth should still be present. The permanent 6-year molars should be totally erupted and in occlusion. The permanent anterior central and lateral incisors are totally erupted and are most prone to fracture at this time. **D.** At age 12, 28 permanent teeth should be present. Only teeth not present should be third molars (wisdom teeth).

	Maxillary	Mandible
Primary*	Mean Age (mo)	Mean Age (mo)
Central incisor	10 (8–12)	8 (6–10)
Lateral incisor	11 (9–13)	13 (10–16)
Canine	19 (16–22)	20 (17–23)
First molar	16 (13–19 boys) (14–19 girls)	16 (14–18)
Second molar	29 (25–33)	27 (23–31)
Permanent†	**Mean Age (yr)**	**Mean Age (yr)**
Central incisor	7–7.5	6–6.5
Lateral incisor	8–8.5	7.2–7.7
Canine	11–11.6	9.7–10.2
First premolar	10–10.3	10–10.7
Second premolar	10.2–11.2	10.7–11.4
First molar	6–6.3	6–6.2
Second molar	12.2–12.7	11.7–12.0
Third molar	20.1	20–20.5

*Ages are for right side of mouth; however, exfoliation is generally bilaterally symmetric.

Table 113.1B. Sequence of Primary Tooth Exfoliation

Palpation

Using the thumb and index finger, the clinician should palpate the alveolar ridges, evaluating for any swellings, discontinuity, or mobility of the soft tissues. This procedure should be done circumferentially in all four quadrants. The palate should be palpated for any swellings or point tenderness. The masseter muscle should be palpated with fingers placed intraorally and extraorally and rolling the muscle between the two. Using a gauze pad, the clinician should hold the tongue and lift it gently to better view and examine its dorsal, ventral, and lateral surfaces. The lips should be palpated for any swellings or nodules. The quality of the swellings should be noted (i.e., fluctuance versus induration). The teeth should be palpated for mobility, tenderness, and fracture. The gums should be palpated for any erupting teeth. Finally, the clinician should look for any purulent exudate during palpation.

Percussion

The teeth should be percussed individually with the end of a mouth mirror handle or tongue depressor. Mobile, abscessed, vertically fractured, or traumatized teeth may be hypersensitive and often sound dull on percussion.

Radiographs are a valuable supplement to the clinical examination. However, obtaining diagnostically perfect radiographic surveys in a child with acute orofacial/dental injuries may be difficult. Table 113.2 indicates the radiographic view that would be the preferred diagnostic aid for these injuries.

Radiographic View	Diagnostic Aid for
Right and left lateral oblique	Fractured body and ramus of mandible
Anteroposterior view of mandible	Fracture of mandibular condyles and symphysis
Towne's	Fractured condyles
Waters'	Maxillary fractures
Intraoral radiographs	
Panoramic	Maxillary and mandibular fractures and related pathology
Occlusal	
Periapical/bite wing	Tooth fractures and pathology; alveolar fractures and pathology

Table 113.2. Radiographic Diagnostic Aids

OROFACIAL/DENTAL TRAUMA

Dental trauma occurs in a variety of forms that can be confusing to the primary care provider. The emergency physician needs to know which injuries can be managed without dental consultation, which need follow-up care, and which need emergency dental care. Table 113.3 shows the types of chief complaints associated with pediatric dental emergencies at Children's Hospital of Boston from 1989 to 1990. Trauma represented 21.7% of the chief complaints and 29.2% of the diagnoses. Several factors, including age, occlusion, and agility in sports, predispose pediatric patients to orofacial trauma. Traumatic dental injuries occur at the following peak ages: 1) as the toddler becomes ambulatory (ages 1 to 3), 2) as the child enters school (ages 7 to 10), and 3) in the older adolescent (ages 16 to 18) engaged in athletic activities. In addition, proclined or prominent maxillary anterior teeth are usually more susceptible to being displaced or fractured in orofacial injuries. Use of a preformed or custom-made mouthguard in children with prominent maxillary incisors is helpful in reducing the chance of these accident-prone teeth sustaining traumatic injuries. This section details the management of dental injuries that are most commonly seen in the pediatric emergency patient.

Type of Emergency	Chief Complaint (% of Total)	Diagnosis (% of Total)	Referral Status
Oral pain/infection	46.1	39.0	Stat
Trauma	21.7	29.2	Stat
Caries	3.4	9.4	Next day
Soft-tissue trauma	0.9	2.8	Stat
Erupting/exfoliating teeth	8.2	5.5	Next day
Other	19.7	14.1	N/A[b]

Table 113.3. Dental Emergencies at Children's Hospital Boston, 1989–1990 [a]

Soft-Tissue Lacerations

Management of injuries to the soft tissues of the oral cavity follow the same emergency care principles used for other soft tissue injuries. Lip injuries swell alarmingly even after minor trauma. Lacerations of the tongue and frenum bleed profusely because of the richness of their vascularity. However, as with lip injuries, ligating specific vessels is usually unnecessary because the bleeding normally stops with direct pressure and careful suturing. Because they heal well spontaneously, frenum lacerations usually do not require suturing, especially in young children. The injured area should be thoroughly examined for foreign bodies. To confirm the presence of a foreign body in a deep laceration of the tongue or lip, a radiograph should be obtained before suturing. If chipped teeth are present, radiograph examination becomes even more important. The decision to primarily repair a laceration of the oral cavity that is more than a few hours old depends on the relative risk of secondary infection (see Chapter 124).

Suturing of the lip must be done carefully to achieve a precise approximation of the edges of the vermilion border to avoid a disfiguring scar even with superficial lip lacerations. If necessary, the lip must be sparingly debrided and the skin closed with 5-0 or 6-0 nylon sutures. Deep lip lacerations are sutured with 4-0 chromic and then with 5-0 or 6-0 nylon for the skin and vermilion. If the lip laceration is through and through, debridement may be necessary. In children less than 5 years of age, 4-0 chromic on the deeper mucosal aspects of the lip and 6-0 chromic on the superficial aspects are preferred. In children older than 5 years of age, 4-0 chromic is used on the deeper mucosal aspects of the lip and 5-0 or 6-0 nylon on the superficial edges. Most superficial tongue lacerations heal without suturing; however, deep lacerations or those that create a flap need to be sutured. When necessary, tongue lacerations are usually sutured with 4-0 chromic if superficial and 3-0 chromic in deeper wounds. With tongue lacerations, it is important to consider the excessive muscular movements that pull at the sutures; therefore, tongue sutures should be made deep into the musculature. Most superficial mucosal injuries are sutured with 4-0 chromic. If the mucosal laceration is deep, 3-0 chromic can be used.

Injuries to the Teeth

Traumatic dental injuries can be categorized into two groups: 1) injuries to the teeth—hard dental tissues and pulp; and 2) injuries to the periodontal structures—periodontal ligaments and alveolar bones. Figure 113.3A indicates the relative positions of these structures. Andreason further categorized traumatic fractures of the teeth into complicated and uncomplicated fractures.

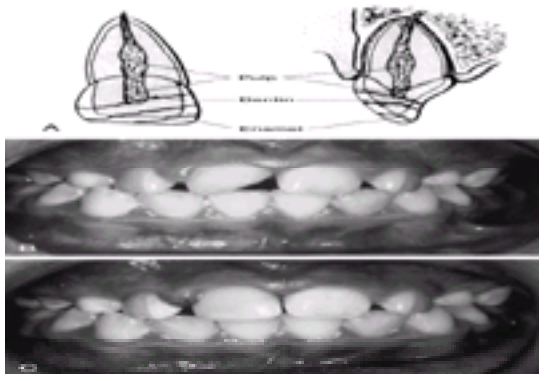

FIGURE 113.3. A. The anatomy of a tooth should be considered during a traumatic injury: enamel fracture, no emergency treatment; dentin fracture, emergency treatment as soon as convenient; and pulpal fracture, emergency treatment as soon as possible. **B.** Enamel and dentin fracture of a permanent incisor. **C.** The same child after bonded restoration.

Injuries to Hard Dental Tissues and Pulp

Uncomplicated tooth fractures are confined to the hard dental tissue (enamel, dentin, cementum). Clinically, there may be a jagged edge of tooth. The fracture line may appear deep, but no sign of bleeding from the central core (pulp) of the tooth is apparent. The child may complain of sensitivity, especially to cold air and fluids. Emergency treatment is aimed at protecting the pulp, even if no frank pulp exposure is noted. The dentist should be called as soon as possible to place a dressing of calcium hydroxide or glass ionomer over the exposed dentin for thermal and chemical insulation and for prevention of (pulpal) necrosis. A temporary restoration is then placed to prevent the insulation material from dissolving. At some later date, an aesthetic resin acid-etched restoration can be placed. The prognosis for uncomplicated tooth fractures is usually good.

A complicated tooth fracture involves the pulp of the tooth. Often, bleeding is noted from the central core of the tooth. To best preserve the viability of that tooth, dental pulpal treatment must be initiated immediately. Prognosis depends on the size of the exposure (less than 1 mm carry the best prognosis) and the time interval between the trauma and therapy (less than 24 hours carries the best prognosis). Thus, calling the dental consultant as soon as possible to institute pulpal therapy is important. Root fractures generally are seen after the tooth has reached full root formation, which is approximately 2 to 3 years after eruption begins (Table 113.1). These fractures usually involve maxillary anterior teeth. The child may clinically have a displaced crown in which the tooth seems to be mobile and extruding from the socket. Definitive diagnosis depends on intraoral dental radiographs; therefore, immediate dental consultation is necessary. Treatment often involves reduction with splinting and pulpal therapy of the involved teeth.

In any injury resulting in fragmentation of teeth, the emergency physician should attempt to account for all of the fragments. Soft-tissue lacerations, especially of the lower lip and tongue, should be evaluated clinically and, if necessary, radiographically to rule out embedded tooth fragments. Infection and poor wound healing are the sequelae of such an oversight.

Displaced Teeth

The tooth is held in the socket by slender elastic and collagen fibers collectively known as the periodontal ligament. These fine, slender fibers are easily injured or broken with trauma to the teeth. Clinically, the physician may note either an increase or decrease in mobility depending on the extent of the cortical plate fracture and/or displacement of the affected teeth. If asked, the child will be able to point to an injured tooth because of the tooth's heightened sensitivity. Periodontal injuries may be further subdivided into five clinical types: 1) concussion, 2) subluxation, 3) intrusion, 4) extrusion/lateral luxation, and 5) avulsion, as noted in Figure 113.4.

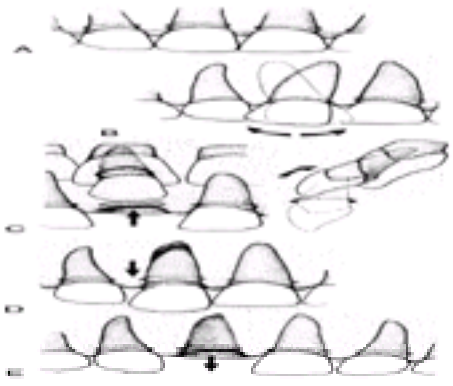

FIGURE 113.4. The various types of trauma to the periodontal structures. Concussion **(A);** subluxation **(B);** intrusion (if primary tooth is intruded note location of developing permanent tooth bud) **(C);** extrusion **(D);** and avulsion **(E).** Refer emergencies **B** through **E** to the dental staff as soon as possible.

Concussion is usually caused by minor damage to the periodontal ligaments, resulting in slight edema. Teeth sustaining lateral displacement injuries exhibit no displacement or excessive mobility. They are often percussion-sensitive when tapped with the blunt end of a metal instrument such as an intraoral mirror. No emergency treatment is indicated for such

injuries, although baseline radiographs are taken to rule out more serious dental injuries. Therefore, a dental consultation should be arranged. The prognosis for concussion injuries is good, although pulpal necrosis is possible over time.

Subluxation is usually more damaging to the periodontal ligaments because of increased edema. There is excessive mobility in the horizontal and/or vertical direction but no displacement within the dental arch. The tooth is often sensitive to percussion. The child will complain that his or her teeth feel like they do not meet when biting down. Because subluxated teeth, especially in the permanent dentition, may require immobilization with a bonded resin splint, this type of injury should be referred to the dental service as soon as possible.

Intrusion, although more commonly seen in the primary dentition, can be seen in the permanent dentition with high velocity or high force injuries. Intruded teeth are teeth displaced directly into the socket. Intruded teeth may not be visible and, thus, give the false appearance of being avulsed. To confirm intrusion and to rule out avulsion, an intraoral dental radiograph is indicated. An intruded primary tooth must be evaluated for its proximity to the developing permanent tooth. Again, immediate dental consultation and treatment are necessary. In addition, compression fractures of the alveolar socket and anterior nasal spine may be seen radiographically. The prognosis for intruded teeth is poor because of pulpal compression and severance, which occurs on impact. Treatment of intruded primary teeth can include extraction, orthodontic repositioning, or allowing for spontaneous reeruption. Intrusive injuries in the permanent dentition usually require repositioning and splinting. Pulpal treatment (endodontics) is almost always needed because the pulp is rendered nonvital as a result of trauma, which can cause root resorption and periapical infection.

Extrusion/lateral luxation is manifested clinically as displacement of the tooth from the alveolar socket in various directions. Usually, the anterior maxillary tooth is extruded and displaced lingually, causing a fracture of the labial cortical plate of the alveolar socket. Luxated permanent teeth must be realigned and immobilized with a splint as soon as possible. Endodontic treatment is often needed in the long term. Extrusive/lateral luxations of the primary dentition usually necessitate extraction to avoid potential injury to the permanent tooth bud during realignment or as a result of eventual pulpal necrosis.

Avulsion is the term used to describe a tooth that has been completely displaced from its socket. Radiographs may show the tooth to be actually intruded, ingested, or aspirated. The best prognosis exists if therapy is instituted within 30 to 60 minutes of the avulsion. The emergency physician or the parent should (as seen in Fig. 113.5): 1) find the tooth; 2) determine whether it is a primary tooth by checking the child's age and the table of tooth eruption (if it is a primary tooth, do not reimplant); 3) if it is a permanent tooth, gently rinse the tooth under running water or saline, taking care to hold the crown of the tooth and not the root (do not scrub the crown or root); 4) insert the tooth into the socket in its normal position (do not be concerned if it extrudes slightly).

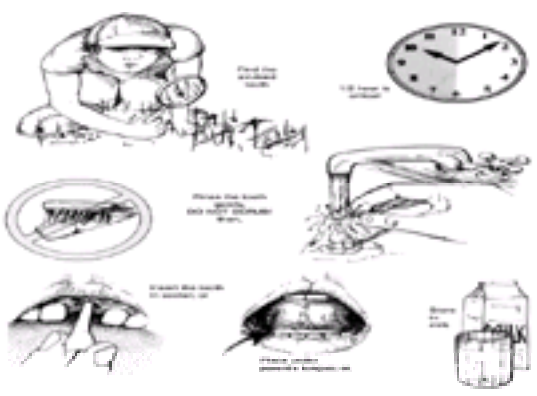

FIGURE 113.5. If a child loses or avulses a tooth. 1. Find the tooth. 2. Determine whether it is a primary or permanent tooth by checking Table 113.1. If it is a primary tooth, DO NOT REIMPLANT. 3. Gently wash but do not scrub the tooth. 4. Insert the tooth back into the socket or place in milk and take immediately to the dentist. Remember, you have only 30 minutes to preserve the vitality of the tooth.

If on-site reimplantation is impossible, the optimal storage to preserve the vitality of the periodontal ligament of the root surface is a cell culture medium such as Viaspan or Hank's balanced salt solution. A commercial product such as the 3M Save-a-Tooth Emergency Tooth Preserving System (Smart Practice, Phoenix, AZ) containing Hank's is available to place the tooth into during transportation to the dental office. If none of these products are available, milk is an excellent alternative transport medium. Although saliva or saline are not ideal, they are alternative mediums that are preferred over allowing the root surface to air dry. The patient should go directly to the dentist for immobilization (splint). Dental follow-up is mandatory to prevent resorption of the root. Prophylactic pulpal therapy (endodontics) helps improve the prognosis by limiting pulpal necrosis and thus root resorption. Avulsed primary teeth are generally not reimplanted because of the close proximity of the permanent tooth and possible negative effects on development of this tooth.

Orthodontic Trauma

Orthodontic trauma often results from loose wires or ligatures that are attached to orthodontic brackets or bands. These emergencies should be seen by the dental service as soon as possible to alleviate any discomfort and soft-tissue trauma. If dental service is unavailable, the physician can bend or cut the wire away from the soft tissues with a hemostat. Softened wax can be molded over the loose wire as a temporary method or to allow the traumatized soft tissues to heal. If no discomfort is noted and no loose foreign bodies are present, the definitive treatment often can be delayed until a more convenient time.

Mandibular Fractures/Dislocations

The incidence of facial fractures in children is low. However, the most common facial bones fractured in children are the nasal bones, followed by the mandible. The emergency physician must therefore be knowledgeable in the diagnosis of mandibular fractures. Physical examination of the head and neck and obtaining radiographs should confirm the diagnosis of mandibular fracture.

The mandible can be compared to an archery bow, which is strongest at its center and weakest at its ends. Thus, most fractures occur at the neck of the condyles. Other areas of the jaw that are predisposed to fracture include the angle of the mandible where deep impacted teeth or unerupted 6-year molars make the mandible more vulnerable. The clinician should examine the teeth for any changes in occlusion and any raised or depressed fragments. Areas of bleeding, gingival/mucosal tears, or sublingual ecchymosis are also clues. Pain when opening the mouth, especially if the child is unable to open it fully, often indicates mandibular fracture. A unilateral condylar fracture should be suspected if the mandible deviates toward the affected side on opening.

Radiographic views detailed in Table 113.2 should be obtained. In the pediatric patient, a mandibular fracture generally necessitates hospital admission. The appropriate consulting service should be called to stabilize the fracture, using either open or closed reduction.

Mandibular dislocation occurs when the capsule and TMJ ligaments are sufficiently stretched to allow the condyle to move to a point anterior to the articular eminence during opening. Dislocation can be unilateral or bilateral and often accompanies a history of extreme opening of the mouth (e.g., deep yawn) or after a long dental treatment session. The muscles of mastication then enter a tonic contraction state, and the patient is unable to move the condyle back into the glenoid fossa and is unable to close the mouth. Treatment consists of reassuring the patient and gently massaging the muscles of mastication. If this approach fails, intravenous diazepam (0.2 mg/kg, maximum 10 mg) can be administered as an adjunct. When relaxation is achieved in the muscles of mastication, gentle downward and backward pressure should be applied by the physician's thumb (wrapped in gauze) on the occlusal surfaces of the posterior teeth (Fig. 113.6). The downward pressure moves the dislocated condyle below the articular eminence; subsequent backward pressure on the molars shifts the condyle posteriorly into the mandibular fossa. Figure 113.7 shows the anatomic landmarks and repositioning of the TMJ.

FIGURE 113.6. Position for reduction of a dislocated mandible.

FIGURE 113.7. Dislocation of the temporomandibular joint occurs when the mandibular condyle moves to a point anterior to the articular eminence during opening. Reduction is accomplished by pushing downward and backward on the occlusal surfaces of the posterior teeth.

Maxillary Fractures

Premaxillary or anterior maxillary alveolar bone fractures are a common finding associated with displacement or avulsion of maxillary anterior teeth. By gentle digital manipulation, the labial plate of bone can often be guided back into position under local anesthesia. (Infiltration with 2% lidocaine with epinephrine is commonly used.) Splinting the loose teeth and suturing the gingival tissue holds the bone fragments in place. After infiltration of local anesthesia and digital manipulation, the bone fragment can be held in place temporarily by aluminum foil (three thicknesses) molded over the teeth and alveolar ridge. This emergency splint should be held in place by having the child bite down. A dental consultant

should be contacted as soon as possible for fabrication of a more permanent dental splint. Figure 113.8 shows an acid-etch composite splint in place. Mandibular and other facial fractures are covered in greater detail in Chapter 110.

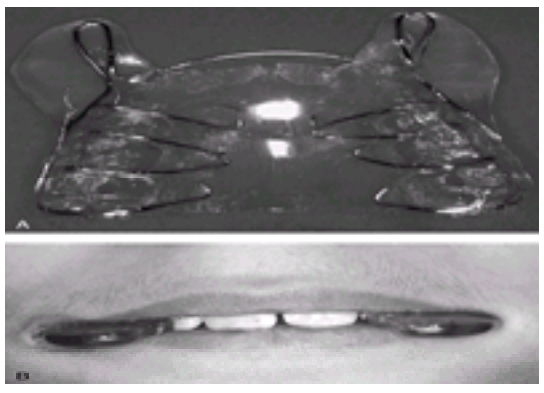

FIGURE 113.8. A. Removable maxillary intraoral acrylic appliance with extraoral commissure extensions. **B.** Appliance in place, separating the upper and lower lip with electrical burns at the commissure.

Electrical Burns

Electrical burns of the mouth occur when children bite on electrical cords. The saliva in the child's mouth acts as a conductor to complete the circuit. In the emergency department, the first consideration is the patient's respiratory status. Next, the patient should be assessed for the presence of shock or other injuries. Although the commissure of the mouth is most likely affected, the tongue, alveolar ridge, and floor of the mouth are occasionally involved. Most children with these injuries can be managed as outpatients. A bland, soft, cold diet is initially recommended. If refusal of food and dehydration are problems, the child requires admission to the hospital for intravenous fluids. Meticulous oral hygiene using a toothbrush with or without toothpaste must be performed three to four times a day, as well as hydrogen peroxide and water (1:1) rinses. With severe burns of the lips and mouth, severe arterial bleeding may continue 5 to 8 days after the burn occurs. The clinician should instruct the parent on the method for digitally compressing the labial artery or consider elective admission to the hospital for wound management. To prevent scarring down of the commissure, electrical burns of this area require the fabrication of an intraoral or extraoral device to separate the upper and lower segments during healing (see Fig. 113.8A and Fig. 113.8B).

CHAPTER 114

Burns

MARK D. JOFFE, MD

Department of Pediatrics, The University of Pennsylvania School of Medicine, and Community Pediatric Medicine, Pediatric Emergency Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

BACKGROUND

Modern technology has increased the exposure of children to potentially injurious thermal energy in their environment. Physicians who care for children must be prepared to treat the many different types of thermal injury. Burns and related injuries are the third leading cause of death in childhood, killing approximately 2,500 children per year. Serious morbidity is three times more common than mortality, generating medical costs exceeding $1 billion per year. Competent management of minor burns can optimize cosmetic results and minimize functional morbidity for children, a benefit that is difficult to estimate in dollars.

Major advances in burn treatment have occurred during the past 40 years despite underfunding of burn-related medical research relative to diseases with far less impact on public health. The LB_{50} (percentage of body surface area [BSA] burn resulting in 50% mortality) has increased from 30% in the 1930s to approximately 70% today. State-of-the-art care of burned children, which has improved survival and reduced morbidity, starts with competent management in the emergency department (ED).

Only 3 to 5% of all burns in children are life-threatening. Most are minor scalds, accounting for about 80% of all thermal injuries. Flames produce 13% of burns and, with associated smoke inhalation, result in the majority of deaths. Electrical or chemical burns account for 2 to 3% of injuries and pose special challenges in management.

Males and children less than 5 years old are at highest risk of thermal injury. Bathing-related scalds are a particular risk during infancy. Hot liquid spills are common in toddlers. School-age children are often injured as a result of playing with matches, with high morbidity and mortality to the child and his or her family. Burns related to volatile agents and high-voltage electrical lines are seen primarily in teenagers.

Several preventive strategies can reduce the risk of thermal injury to children. Lowering the temperature of water heaters from over 130° (54.4°C) to 120°F (48.9°C) increases the time for full-thickness scalding from under 30 seconds to 10 minutes. Burn centers have noted a decrease in full-thickness flame burns since the introduction of flame-resistant children's sleepwear. Cigarette misuse is responsible for more than 30% of house fires. “Fire safe” cigarettes, which are less likely to ignite household materials, are technically feasible but are not yet being manufactured. Smoke detectors and sprinkler systems can greatly reduce deaths, but only if installed and maintained properly. Advances in burn prevention can have a far greater impact on public health than refinements in burn management.

PATHOLOGY AND PATHOPHYSIOLOGY

The vital functions of skin, which accounts for 15% of total body weight, are often unappreciated until it is severely injured. Skin preserves body fluids, efficiently regulates heat loss to the environment, and acts as a barrier to infectious pathogens. Skin is composed of an outer, mostly nonviable epidermis and dermis. The stratum corneum, a layer within the epidermis, prevents passive water loss and is lethal to most viruses and Gram-negative bacteria. It has a fatty acid film that is fungistatic and bacteriostatic. The dermal–epidermal junction prevents loss of macromolecules through the skin. Dermis contains eccrine sweat glands that actively secrete fluid to increase evaporative heat loss. The vasculature in the dermis can regulate radiant heat loss through vasodilation and vasoconstriction, with a 100-fold variation in skin perfusion. Therefore, children with extensive burns have difficulty retaining body fluids and regulating temperature (Fig. 114.1).

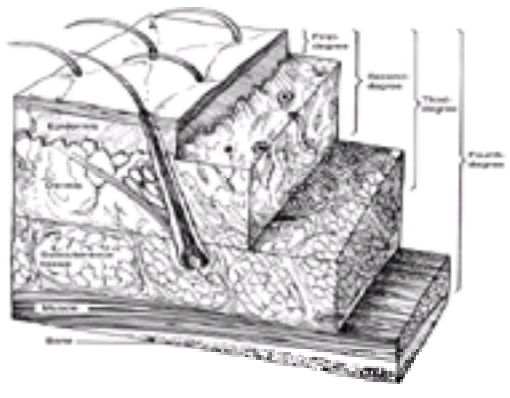

FIGURE 114.1. Degree of burn wound depth. First-degree involves only epidermis, second-degree extends into the dermis, third-degree into subcutaneous tissue, and fourth-degree to muscle, tendons, or bone.

Larger burns can have systemic effects. Capillary permeability in burned tissues is greatly increased. Burning releases osmotically active molecules to the interstitial space, further driving the extravasation of fluid. In patients with large burns, vasoactive mediators released from burned tissue result in systemic capillary leakage. Edema develops in both noninjured and burned tissue. Cardiac output is decreased by circulating factors that depress myocardial function. Acute hemolysis of up to 15% of red blood cells occurs from direct heat damage and a microangiopathic hemolytic process. The profound circulatory effects of severe burns can result in life-threatening shock early after injury.

Hair follicles, sweat glands, and sebaceous glands in the dermis play a crucial role in the healing of partial-thickness burns. After an inflammatory phase characterized by leukocyte infiltration, cytokine release, and complement activation, epithelial cells in these structures undergo metaplasia to produce the stratified squamous epithelial cells required for healing of skin. Neovascularization and fibroblast migration occur 1 to 3 weeks after partial-thickness burns. Overproduction of collagen can result in hypertrophic scarring. In full-thickness burns, the absence of intact dermal appendages precludes reepithelialization by this mechanism and necessitates skin grafting.

Thermal energy damages the skin structures in proportion to the intensity and duration of exposure. Hot grease or thick soup cause deeper injuries because they usually cling to the skin longer than scalding water. Ignition of synthetic fabrics often causes melting and adherence to the skin, resulting in more serious burns than ignition of cotton garments. Skin thickness is also a variable in the severity of injury with a given thermal exposure. Submersion of the hand may result in deep burns of the dorsum, with relative sparing of the thick skin of the palm. The thinner skin of young children accounts for deeper burns when compared with adults with similar heat exposures.

A first-degree burn is characterized by redness and a mild inflammatory response confined to the epidermis, without significant edema or vesiculation. First-degree burns are not included in the calculation of burn surface area used for therapeutic decisions. These minor burns are somewhat painful, healing in 3 to 5 days without scarring.

Most burns treated in EDs are partial-thickness or second-degree burns. Superficial second-degree burns involve destruction of the epidermis and less than half of the dermis. Blistering is often present. Increased capillary permeability, resulting from direct thermal injury and local mediator release, results in edema. These injuries are usually painful because intact sensory nerve receptors are exposed. The capillary network in the superficial dermis gives these burns a pink–red color and moist appearance. Healing occurs in about 2 weeks and scarring is usually minimal.

Deep partial-thickness burns involve destruction of epidermis and greater than 50% of the dermis. Edema can lessen the exposure of sensory nerve receptors, making some partial-thickness burns less painful and tender. Deep partial-thickness burns have a paler, drier appearance than superficial injuries. They are sometimes difficult to distinguish from areas of full-thickness injury. Thrombosed vessels often give the deep partial-thickness burn a speckled appearance. Burns evaluated immediately may appear to be partial-thickness and subsequently become full-thickness injuries, especially if secondary damage from infection, trauma, or hypoperfusion ensues. Deep partial-thickness burns can take many weeks to heal completely. Unacceptable scarring is not uncommon. Skin grafting is often necessary to optimize cosmetic results.

Full-thickness or third-degree burns involve destruction of the epidermis and all of the dermis. They usually have a pale or charred color and a leathery appearance. Destruction of the cutaneous nerves in the dermis make them nontender, although surrounding areas of partial-thickness burns may cause pain. Full-thickness burns cannot reepithelialize and can only heal from the periphery. Most require skin grafting. Fourth-degree burns are those full-thickness injuries that involve underlying fascia, muscle, or bone.

All burns become colonized by potentially pathogenic organisms. Most organisms are acquired from the skin and intestinal flora of the burned patient and not from exogenous sources. Heat causes coagulation necrosis of tissue, producing a protein-rich medium that nourishes bacterial growth. Removal of this material by cleansing and debridement reduces substrate for bacterial proliferation. Aggressive topical antimicrobial therapy, with or without systemic antibiotics, can reduce the number of microorganisms but cannot sterilize a burn.

FIRST AID AND PREHOSPITAL CARE

Emergency physicians may be consulted about the immediate care of minor burns. The first step is to stop the burning and help dissipate the heat. Running cool water over the injured area accomplishes both of these goals. Applying ice directly to the wound is painful, and the extreme cold can worsen the injury. Parents should be reminded not to put grease, butter, or any ointment on the burn because they do not dissipate heat well and may contribute to the

contamination. Blisters should not be broken. The burn should be covered with a clean cloth or bandage.

Small burns from mechanisms unlikely to cause full-thickness injury can be managed at home with a topical antibiotic and a bandage. Burns of larger size and burns involving the face, hands, feet, or perineum should be evaluated promptly by a physician. Telephone advice, without the benefit of physical examination, should always err on the side of caution with recommendation for a medical evaluation.

The concerns for children with major burns are different. Prehospital care providers should initially forget about the burn and focus on airway, breathing, and circulation as they would for any other trauma victim. Rapid transport to a hospital setting is still crucial and should be emphasized. Oxygen should be administered. The trachea should be intubated if there are signs of upper airway obstruction apnea or severe hypoventilation. If transport time is likely to be prolonged, intravenous fluids should be given.

MAJOR BURNS

Evaluation and Management

During the first few seconds after arrival, the physician must determine if a burned patient requires aggressive therapy for major burns (greater than 15% BSA) (Fig. 114.2). In children with severe injuries, the evaluation and initial management take place simultaneously. Smoldering clothing or other sources of continued burning must be removed. Information about the circumstances of the burn and the potential for associated injuries should be sought from prehospital care providers, police, or family members but should not delay the initial treatment.

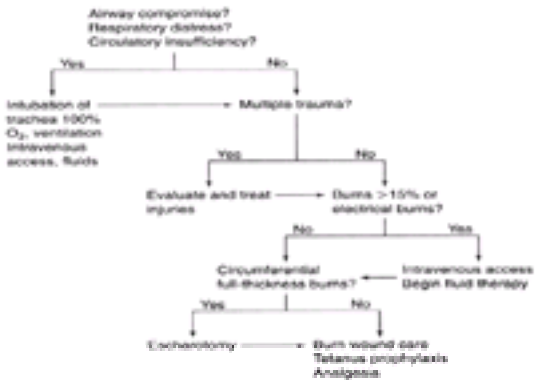

FIGURE 114.2. Diagnostic approach to the burn patient.

Airway

There are several causes of airway obstruction in the severely burned patient. Most life-threatening burns are the result of house fires. The inhalation of hot gases can burn the upper airway, leading to progressive edema and airway obstruction. Any child with burns of the face, singed facial hairs, or hoarseness is at high risk, but airway burns can occur in the absence of these signs. Edema of the burned airway will worsen over the first 24 to 48 hours. Knowledge of the time course of airway swelling warrants intubation of the trachea for subtle signs of airway compromise that occur shortly after the injury. Early intubation may prevent the later difficult intubation of a child with severe pharyngeal and airway swelling. Endotracheal tubes of smaller diameter than expected for age should be available in anticipation of a narrowed airway.

Children who have jumped or fallen in house fires, been burned in motor vehicle accidents, or been burned by explosions are at risk for associated cervical spine injuries. A history of trauma may not be available at the time of airway management. Physicians should manage the airway with the neck in a neutral position, avoiding any flexion or extension. Radiographs can be obtained later to help exclude cervical spine injury (see Chapter 106). Children with severe burns may have depressed levels of consciousness for many reasons. Airway obstruction by the mandibular block from loss of pharyngeal tone is not uncommon. A chin-lift is preferable to a jaw-thrust maneuver in patients with possible cervical spine injury.

Breathing

A rapid assessment of ventilation includes respiratory effort, chest expansion, breath sounds, and color. Pulse oximetry is useful, but patients with significant levels of carboxyhemoglobin will look pink and have normal oxygen saturation as measured by a pulse oximeter. Every severely burned child should receive 100% oxygen. Arterial blood gases with cooximetry should be obtained promptly. Patients whose ventilatory status is questionable should receive careful assisted ventilation. Avoidance of high inflating pressures and application of cricoid pressure can minimize gaseous distension of the stomach and reduce the risk of regurgitation with pulmonary aspiration.

Children burned in house fires or in any closed space are at high risk of inhalation injury. Facial burns, singed facial hairs, and carbonaceous sputum are not always present in children with significant inhalation injury. Chest radiographs may be normal initially, even if pulmonary injury has occurred. Smoke is responsible for most of the lower airway abnormalities in burned patients and management of smoke inhalation is covered in Chapter 89. The efficient heat-exchanging function of the upper airway can dramatically reduce the temperature of inspired dry gases, protecting the lower airway from thermal injury. Inhalation of steam, with its higher heat capacity, is more likely to result in burns of

the lower airway.

Circulation—Burn Shock

The physiology of circulatory impairment in severely burned patients is complex. Burn shock occurs in adults with burns over 30% of BSA but occurs in children with burns over 20% of BSA.

The rapid assessment of circulation includes skin color, capillary refill time, temperature of the peripheral extremities, heart rate, and mental status. Blood pressure is often maintained until decompensation occurs, making it an unreliable measure of early circulatory impairment. Hypertension from increased systemic vascular resistance has been reported immediately after severe burns, particularly in pediatric patients.

Vascular access should be obtained soon after arrival of the severely burned child. Intravenous lines in the upper extremity through intact skin are preferred because they are easier to secure, but access through burned areas may be necessary. Attention to aseptic technique when starting intravenous lines in the ED can prevent infectious complications during subsequent care. Circumferential taping is dangerous because the swelling that occurs during the first 24 hours can cause circulatory insufficiency distal to the constriction. Sites for central line placement should be saved, if possible, for future use for hyperalimentation. In severe burns with associated inhalation injury, however, central venous pressure monitoring is useful.

An initial bolus of 20 mL/kg Ringer's lactate solution is recommended while assessment of the extent of the burns takes place. A urinary catheter should be placed, and urine output monitored to assess the adequacy of fluid therapy. Major burns cause decreased splanchnic blood flow and ileus. After ensuring that the airway is protected with an endotracheal tube or an adequate gag reflex, the clinician should place a nasogastric tube. Hypothermia can occur rapidly in small children, especially in those whose skin injury impairs normal thermoregulation. Core temperature should be monitored and the child kept covered, except as necessary for examination and burn assessment. Tetanus toxoid is indicated if the child has not been immunized in the preceding 5 years; unimmunized patients require tetanus immune globulin as well.

Assessment

Major burns are three-dimensional injuries. To estimate the size of a burn one must assess the surface area and depth of burned skin. Decisions about fluid therapy, referral, disposition, and prognosis are based on the size of the burn. After stabilization of vital functions in the primary survey, a systematic evaluation of the surface area and depth of burns follows. The rule of nines used to estimate burn surface area in adults cannot be applied to children with their different body proportions. Young children have relatively larger heads and smaller extremities. Areas of partial- and full-thickness injury should be recorded on an anatomic chart (Fig. 114.3) and then total percentage burn surface area computed using age-appropriate proportions. First-degree burns are not included. A child's palm (not including the fingers) is approximately 1% of BSA and can be used to estimate the extent of smaller burns (Fig. 114.3).

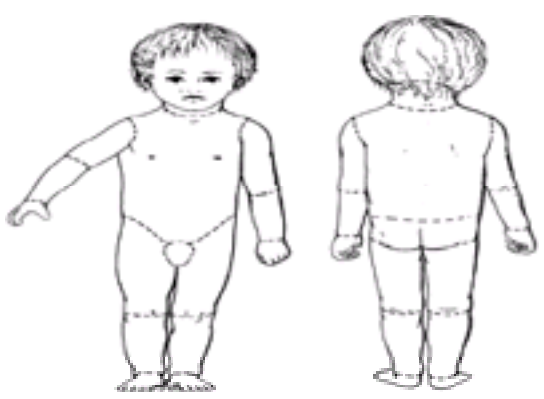

FIGURE 114.3. Estimation of surface area burned based on age. This modification by O'Neill of the Brooke Army Burn Center diagram shows the change in surface of the head from 19% in an infant to 7% in an adult. Proper use of this chart *(above)* provides an accurate basis for subsequent management of the burned child.

Fluid Therapy

Prompt treatment of the hypovolemia that occurs early in children with severe thermal injuries is of prime importance. The fluid status of burned children is a dynamic process that requires careful reevaluation and therapeutic adjustments. Extravasation of water and sodium through abnormally permeable capillaries continues for about 24 hours after injury. Capillary integrity then improves and intravascular volume stabilizes. Most burn centers recommend crystalloid during the first 24 hours because colloid may extravasate through the leaky capillaries and worsen interstitial edema. Once capillary integrity is restored, colloid is used for volume expansion and for preservation of serum oncotic pressure. The sodium ion is critical for maintaining adequate intravascular volume, so isotonic crystalloid solutions are recommended in the resuscitation phase. Hyperosmolar therapy with 3% saline appears to have little benefit and increased risk. Potassium is released from damaged cells and may elevate measured serum levels shortly after injury. Potassium replacement is not recommended during the early phase of fluid therapy.

Several formulas for calculation of fluid therapy exist (Table 114.1). The Parkland formula recommends 4 mL/kg per %BSA of crystalloid over the first 24 hours, half during the first 8 hours and half over the next 16 hours. This formula underestimates the needs of young children. Adding maintenance requirements to this volume more accurately estimates the requirements of burn victims younger than 5 years of age. The Carvajal formula uses BSA rather than weight to

calculate fluid therapy. Carvajal recommends 5000 mL/m^2 per %BSA, half in the first 8 hours and half over the next 16 hours, plus 2000 mL/m^2 per day as maintenance. Formulas for fluid therapy in burn patients must be used carefully in small children. The calculated volume requirements are useful to the clinician in providing an initial rate of fluid infusion. Adjustments of infusion rates are the rule, not the exception. Many pediatric burn centers prefer to follow urine output rather than central venous pressure to assess the adequacy of fluid therapy. Children should produce at least 1 mL/kg per hour of urine. Oliguria, as determined by this measure, is almost always the result of inadequate fluid administration. Intrinsic renal disease is sometimes noted after electrical injuries because of myoglobinuria. Hyperglycemia may cause an osmotic diuresis and complicate care of the burned patient. Before infusions are decreased in response to excessive urine output, a measurement of blood sugar should be made.

Parkland: 4 mL/kg/%BSA second- and third-degree burns, half in the first 8 hr, half in the next 16 hr. Add maintenance in children <5 yr old.
Carvajal: 5000 mL/m^2/%BSA second- and third-degree burns, half in the first 8 hr, half in the next 16 hr. Add 2000 mL/m^2/day maintenance.

Table 114.1. Fluid Resuscitation Formulas

Trauma associated with burns may increase fluid requirements. Additional fluids are often necessary when burns are associated with an inhalation injury. Fractures or other traumatic lesions causing blood loss and edema also increase the need for fluids. Neurogenic shock from unrecognized cervical spine or head injury may cause hypotension, usually with a relative bradycardia. Toxins that were ingested before the burn or inhaled during the fire can depress myocardial function or vascular tone. Any patient with shock that appears out of proportion to the extent of the burn injury or who is poorly responsive to fluid therapy should have an aggressive diagnostic workup for concurrent problems.

Antibiotics

Burn sepsis continues to be the major cause of mortality after a burned patient survives the period of resuscitation. Meticulous antiseptic techniques can lessen colonization of burns with potential pathogens. Topical antibiotics further reduce bacterial number. Streptococcal cellulitis does not occur as frequently in the first days of burn therapy as in previous years, before the development of topical antibiotics for burns. Most burn centers do not routinely treat patients with prophylactic penicillin and have not seen a rise in early streptococcal infections. Pediatric patients may have greater risk than adults, however, and some pediatric burn centers continue to use intravenous penicillin for the first 3 to 5 days after injury. Broad-spectrum antibiotics should not be used prophylactically because they do not significantly reduce the incidence of infections and they increase the likelihood of acquiring resistant organisms. Frequent examination of healing burns for signs of infection and cultures to monitor colonization can direct specific antibiotic therapy for documented infections.

Care of the Burn Wound

Early surgical management of some partial-thickness and most full-thickness burns with excision and grafting has been an important advance in burn treatment. In the ED a few basic measures initiate the wound care. Burns should be covered loosely with clean sheets during the early phase of resuscitation in severe injuries. Once the cardiorespiratory status is stabilized, the wounds are uncovered and assessed for size and depth. The goals of burn wound care are to promote rapid healing and prevent infection. Cleansing with large volumes of lukewarm sterile saline reduces contamination. Loose tissue can often be wiped away with sterile gauze, simplifying and expediting burn debridement. In general, bullae should be left intact to preserve the barrier to bacterial invasion. Certain large bullae in locations that are likely to rupture may benefit from debridement.

Full-thickness burns cause a loss of skin elasticity. The burned skin cannot expand as tissue edema develops during the first 24 to 48 hours of fluid therapy. Circumferential injury can cause vascular insufficiency of the distal extremities. Assessment of blood flow with a Doppler device is useful for monitoring peripheral circulation because the usual methods of assessment, including capillary refill and temperature, may be difficult in the severely burned child. Absent flow is an indication for escharotomy. Extensive full-thickness burns of the trunk may restrict expansion of the chest and impair ventilation. Respiratory embarrassment in this setting is also an indication for escharotomy. Escharotomy involves incision through the depth of the eschar on the medial and lateral aspects of the extremities, including the hands and fingers. It is especially important to extend across the joints because at these locations the skin is tightly adherent to the underlying fascia where vascular obstruction is likely to occur. The procedure does not require anesthesia because the wounds are full thickness and insensate. If reperfusion of the extremities is not immediate, hypovolemia should be suspected. Reperfusion of the extremities after escharotomy may reduce intravascular volume and require adjustment of fluid therapy. With extensive, full-thickness thoracic burns, incision along the anterior axillary lines allows adequate chest expansion.

Pain Management

Reducing pain is an important consideration in the management of children with burns. Pain is a subjective experience

influenced by the preceding events. Children rescued from house fires, separated from their parents, transported in ambulances, and brought to EDs are usually extremely anxious. Calm, developmentally appropriate verbal reassurance, even to preverbal children, can reduce anxiety and dramatically reduce the perception of pain.

The exposure of sensory nerve receptors in partial-thickness burns makes them sensitive to environmental stimuli. Movement of cool air across burned tissue increases pain significantly. The simple measure of covering burns with a clean sheet, only exposing them when necessary for burn assessment, is extremely effective and safe analgesia.

Many children will still have significant pain after reassurance and covering of the burns. Narcotic analgesics are useful when administered appropriately. Morphine may reduce the blood pressure, especially in patients who are hypovolemic. Narcotics should not be given until adequate circulation is established.

Analgesic medications given intravenously are preferred because they are more effective and predictable. Intramuscular injections or oral doses should not be given to patients with significant burns. Circulation to muscle and gut is reduced and absorption of medication given via these routes is delayed and unpredictable. Morphine (0.1 to 0.15 mg/kg) is the drug of choice for most burn patients who require analgesia. In children who do not respond well to the initial dose of morphine, a careful assessment for other causes of pain or agitation should be sought. Hypoxemia, early shock, and occult injuries should be excluded before repeating doses of analgesics. Analgesic administration just before debridement of the burn wound is recommended.

Disposition

Guidelines for admission must be individualized when treating burned children. Hospitals, physicians, and parents have varying capabilities for managing pediatric burn patients. In general, children with burns of smaller percentages of BSA than adults require admission, especially patients less than 2 years old.

Children with partial-thickness burns greater than 10% of BSA should be admitted to a hospital. Partial-thickness injury over 20% of BSA warrants admission to a children's hospital or burn center. Full-thickness burns over 2% of BSA require inpatient treatment. Burns in certain locations are higher risk for disability or poor cosmetic outcome and should be considered for treatment in the hospital. These include over 1% burns of the face, perineum, hands, feet, circumferential burns, or burns overlying joints. Children with inhalation injury or associated trauma require admission with burns involving lesser percentages of BSA. Any time the physician suspects that the burns cannot be adequately cared for in the home, admission to the hospital is warranted.

OUTPATIENT MANAGEMENT OF BURNS

A small minority of all burns in children require therapy in the hospital. Once a careful assessment has led to a decision to manage a burn as an outpatient, preparations for treatment at home should begin. Parents become the physician's partner in this context and need to be instructed carefully. If no one in the household seems able to adequately manage the burn wound, inpatient care must be considered.

A first-degree burn usually requires no therapy. Moisturizers and acetaminophen or ibuprofen can be given as needed. Partial-thickness burns are first cleansed with mild soap and water, one-quarter strength povidone–iodine solution, or saline alone. Devitalized tissue can usually be removed by wiping with gauze. Large bullae that are likely to rupture because of their location can be debrided. Clean partial-thickness burns less than 2% BSA can be dressed with petrolatum gauze. Topical antibiotics are recommended for larger or more contaminated burns. Silver sulfadiazine cream (Silvadene) or bacitracin are the topical antibacterial agents of choice at most burn centers. A $^{1}/_{16}$ to $^{1}/_{8}$ inch layer of silver sulfadiazine is applied to the burn with a sterile tongue blade or gloved hand. Silver sulfadiazine is soothing to the burn and has few side effects. Mild bleaching of the skin may occur. Bacitracin is often chosen for burns of the face. About 5% of children are allergic to sulfa and can be treated with bacitracin or povidone–iodine ointment. Leukopenia has also been reported in patients treated with silver sulfadiazine. Mafenide acetate (Sulfamylon) is a topical antimicrobial agent that is more penetrating than silver sulfadiazine. It causes pain when applied, cannot be used in sulfa-sensitive patients, and inhibits carbonic anhydrase, which can cause a metabolic acidosis. Some experts recommend mafenide acetate for burns overlying cartilaginous structures such as ear and nose. Small, superficial partial-thickness burns may be treated with sterile dressings and no antibiotics.

A loose gauze dressing should be placed over the burn and secured with tape. Burns of the face can be treated with an open technique. Dressings should be changed twice each day. The parent should rinse off residual antibacterial cream with warm water and inspect the wound. Signs of infection, such as redness and tenderness around the margin of the burn, warrant immediate evaluation by a physician. A greenish material formed by serous drainage from the burn mixing with the silver sulfadiazine cream is often mistaken for purulence. If the burn is healing well, the parent should reapply the antibiotic cream and dress the wound as demonstrated by the physician or nurse in the ED. Burns should be examined by a physician every 2 or 3 days until healing is well under way. Large burns or burns of the hands, feet, perineum, or overlying joints that are managed as an outpatient should be referred for follow-up to a burn specialist and evaluated more frequently. Prophylactic antibiotics are not recommended.

INFLICTED BURNS—CHILD ABUSE

Physicians who treat children with burns must consider child abuse in patients with specific patterns of injury. Between 10 and 20% of burns in children are inflicted, accounting for 10% of child abuse cases. Most inflicted burns are scalds. Forced submersion of the hands or feet often causes burns that are deep, have a clear line of immersion, and are symmetric. Scald burns of the buttocks and thighs in toddlers are usually the result of child abuse. Forcible submersion in a tub of hot water is often punishment for toilet-training mishaps. Inflicted contact burns also have characteristic patterns. Small, round, deep burns result from cigarettes intentionally applied to the skin. Deep injuries with distinctive patterns

may be noted in children held against portable heaters or burned with irons.

In many children with inflicted burns the pattern of injury is nonspecific. A clear history of abuse is usually not offered. A deep wound with a geometric pattern and sharply demarcated borders suggests a contact burn. Scald burns usually have scattered splash lesions. In burns from spilled hot beverages there is often a pattern of injury spreading downward from the falling liquid. Physicians need to consider if the characteristics of the burn correspond with the reported mechanism in a plausible way. Identifying suspicious injuries and notifying the appropriate authorities can prevent subsequent injuries to abused children.

ELECTRICAL BURNS

Burns that result when electrical current passes through the body have unique characteristics. Each year there are more than 4000 ED visits caused by electrical injuries, most in children (see Chapter 89). Electrical burns account for 3% of burn center admissions and are increasing in number. Most injuries occur in young children from contact with low voltage (less than 120 V) alternating household current, often from mouthing plugs or extension cords. Severe high voltage (greater than 500 V) injuries are seen most often in adolescent males as a consequence of risk-taking behaviors.

Thermal energy is released in proportion to the amount of electrical current that passes through tissue. Current flows preferentially through tissues of low electrical resistance, such as blood vessels, nerves, and muscles. Moisture on the skin decreases resistance, accounting for the greater severity of injury in the antecubital and axillary areas in victims of electrical burns. Current arcing through the skin can ignite clothing and cause severe thermal burns in addition to the electrical injury. In some electrical burns, a depressed entrance wound and a blown out exit wound can be identified. The concentration of current at these points results in higher temperatures and more severe tissue damage. If the flow of current traverses the heart at certain points of the cardiac cycle, ventricular fibrillation or asystole can occur. Electrical injury, especially direct current, can cause prolonged tetany of the musculature, including the respiratory muscles, leading to suffocation.

The initial approach to victims of electrical burns is similar to that in other severely burned children. The potential for arrhythmias requires close cardiac monitoring. Electrical burns are usually more severe than they appear. Significant deep and internal injuries may occur in patients with relatively small entrance and exit wounds. Fluid requirements are higher than predicted by formulas based on estimates of percentage of BSA because a larger portion of the injury is internal. Destruction of muscle often causes myoglobinuria. Renal failure usually can be prevented with forced diuresis and alkalinization. Electrical injury and edema within fascial compartments can cause a compartment syndrome with vascular insufficiency. Severe electrical injuries require extensive evaluation for internal injuries, which should be done at a children's hospital or regional burn center.

A common electrical injury occurs to the lips and mouth of toddlers who suck on plugs or extension cords. Deep burns at the corner of the mouth require specialized attention to prevent severe scarring and contracture. Bleeding from the labial artery 1 to 2 weeks after injury, when the eschar separates, can result in significant blood loss. In previous years these children were hospitalized for 2 weeks, but some burn specialists now manage these children as outpatients. See also Chapter 89 for additional discussion of electrical burns, including lightning strikes.

CHEMICAL BURNS

More than 25,000 different caustic products can cause burns. Most are either acidic or alkaline. Acids cause coagulation of tissue proteins, which limit the depth of penetration. Alkali results in liquefaction and deeper injury. Caustic chemicals on the skin cause a prolonged period of burning compared to most thermal burns. Edema of the underlying tissue can make full-thickness injuries appear deceptively superficial. Treatment of caustic burns, whether acid or base, involves copious irrigation to dilute the chemical and stop the burning. Attempts at neutralization are usually ineffective and should be avoided. The pH of the effluent can be monitored to help determine whether irrigation has been adequate. A thorough examination is necessary to identify other areas of skin exposed from splashes or contact that also require irrigation. Consultation with a burn specialist and admission are recommended at smaller percentages of BSA with chemical burns than with thermal injuries. Chemical burns to the eye can threaten vision and, after starting irrigation, require prompt consultation with an ophthalmologist.

CHAPTER 115

Orthopedic Trauma

[*]DAVID BACHMAN, MD and [†]STEPHEN SANTORA, MD

[*]Department of Pediatrics, University of Vermont School of Medicine, Burlington, Vermont, and Pediatric and Adult Emergency Services, Portland, Maine; [†]Department of Orthopedics, University of Utah School of Medicine, Primary Children's Medical Center, Salt Lake City, Utah

Orthopedic trauma currently accounts for 10 to 15% of emergency department (ED) visits in urban pediatric hospitals. The number and spectrum of musculoskeletal injuries sustained by children and adolescents appear to be on the rise in recent years, in part because of the rapid growth of organized sports. As the result of a number of anatomic and physiologic differences, the array of orthopedic injuries seen in pediatrics differs greatly from that seen in adult practice. An understanding of these differences allows the emergency physician to make accurate diagnoses and to avoid complications. The purpose of this chapter is to provide a set of principles and guidelines to be used in the initial evaluation, diagnosis, and treatment of common orthopedic injuries in children.

GENERAL PRINCIPLES OF PEDIATRIC ORTHOPEDICS

Structural and Physiologic Differences between the Musculoskeletal Systems of Children and Adults

The bony architecture in children includes a thick and active periosteum, a growth plate (physis), an epiphysis (secondary ossification center), and perichondrial rings (Fig. 115.1). The bones of a child are much more porous and thus more pliable than those of an adult. On the other hand, because of this increased porosity, stiffness and overall bony strength are less and the incidence of fractures is greater in children. During growth, the skeleton undergoes changes that cause different anatomic regions to be more susceptible to fracture at certain stages of development. In general, the ligaments attaching one bone to another have greater strength than the epiphyseal plates and perichondrial rings. As a result, although the number of fractures is greater, the incidence of sprains, ligamentous injuries, and dislocations is much reduced in children.

FIGURE 115.1. Diagrammatic representation of the femur in late childhood.

The periosteum plays an important role in the reparative process of fracture healing. In children, the periosteum is thick and physiologically active and is easily stripped from the bony cortex during injury. When injuries occur, the periosteum is often torn on the convex side of the fracture while remaining intact on the concave side. The intact periosteum on the concave aspect often aids the orthopedist in the reduction of the fracture fragments. Callus formation is exuberant in the young and declines with age as the physiologic activity of the periosteum decreases. Nonunions almost never occur in children.

Remodeling, although rare in adults, is expected to a degree in children. Significant remodeling can be anticipated in younger children and when the fracture occurs in the metaphysis of growing bones. Deformities occurring in the plane of motion of the adjacent joint remodel to the greatest degree. Fractures that occur in the diaphysis of long bones in adolescents, away from the plane of motion of the joint, cannot be expected to correct spontaneously with growth. In general, it is important to obtain as near an anatomic reduction of fracture fragments as possible in all age groups and not to rely on remodeling to align angulated fractures.

Fractures Unique to Children

The anatomic and physiologic differences between adults and children are reflected in a number of fractures and injuries unique to the pediatric age group, including physeal fractures, torus fractures, greenstick fractures, bowing deformities, and avulsion fractures.

Physeal Fractures

Fractures often occur at the physis (growth plate) in children. Most such fractures occur through the zone of provisional calcification, a relatively weak area of the germinal growth plate. Overall, up to 18 to 30% of pediatric fractures involve the physis. Physeal injuries are more common in adolescents than in younger children, with a peak incidence at 11 to 12 years of age. Most growth plate injuries occur in the upper limb, particularly in the radius and ulna.

Several classification systems have been described for physeal fractures. The most widely used is that of Salter and Harris, who described five types of growth plate fractures, each having specific prognostic and treatment implications (Fig. 115.2).

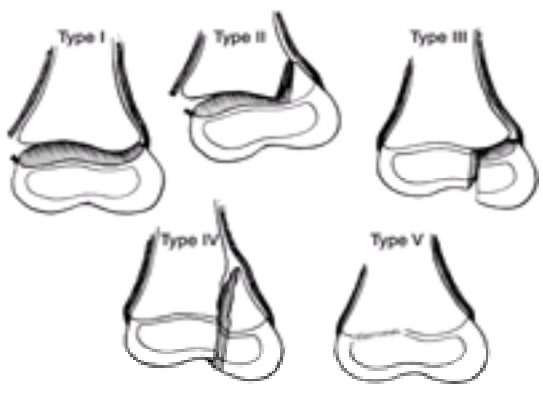

FIGURE 115.2. The Salter-Harris classification for physeal fractures. The prognosis for growth disturbance worsens from type I through type V.

Salter-Harris Type I Fracture

Salter-Harris type I fracture involves separation of the metaphysis from the epiphysis through the zone of provisional calcification. Diagnosis is often difficult if displacement is minimal. Type I fractures are generally benign, with little chance of growth disturbance if near anatomic reduction is achieved. Exceptions include type I injuries of the proximal radius, the proximal and distal femur, and the proximal tibia, all of which are subject to premature physeal closure and posttraumatic growth arrest. In general, when radiographic studies are negative but physical findings are suggestive of a Salter-Harris type I injury (e.g., point tenderness over a growth plate), immobilization and a follow-up examination are essential.

Salter-Harris Type II Fracture

Salter-Harris type II fracture is the most common type of pediatric physeal fracture. It is similar to a type I fracture except that a portion of metaphyseal bone is displaced with the epiphyseal fragment. The fracture line crosses the germinal growth plate as it courses toward the metaphysis. Like the type I injuries, these fractures generally carry a good prognosis.

Salter-Harris Type III and IV Fractures

Salter-Harris type III and IV fractures are intra-articular injuries that also involve the growth plate. Anatomic position must be reestablished to restore normal joint mechanics and prevent growth arrest. Because of the increased incidence of growth disturbance, altered joint mechanics, and functional disability following Salter-Harris type III and IV fractures, an orthopedic consultation is usually obtained for all but the most minor type III and IV injuries while the patient is in the ED.

Salter-Harris Type V Fracture

Salter-Harris type V fracture results from axial compression of the germinal growth plate. It is often difficult to diagnose; the radiograph may be normal or may demonstrate any of the above Salter-Harris growth plate fractures. The diagnosis is often made on hindsight after a growth arrest becomes evident.

Torus Fractures

Torus (buckle) fractures are common fractures in young patients. They occur in the metaphyseal region of bone from a compressive load. The cortex of the bone buckles in a small area, resulting in a stable fracture pattern (Fig. 115.3). As the child matures, the stiffness of the metaphyseal region increases, and the incidence of this fracture pattern decreases.

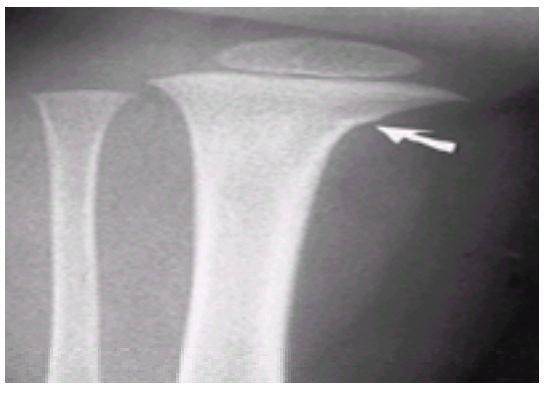

FIGURE 115.3. Torus fracture of the proximal right tibia in a 1-year-old child *(arrow).*

Greenstick Fractures

Greenstick injuries are the most common fracture pattern in children, accounting for up to 50% of fractures before 12 years of age. They are incomplete fractures that occur at the diaphyseal–metaphyseal junction and in which the cortex remains intact on one side. Angulation and rotation are common. To obtain an anatomic reduction, the fracture must often first be completed (Fig. 115.4).

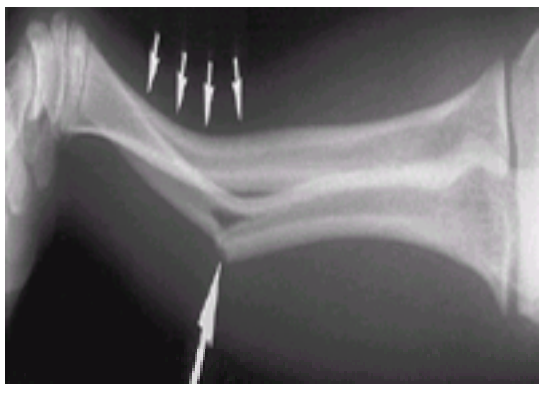

FIGURE 115.4. Greenstick fracture of the ulna *(large arrow)* and a bowing fracture *(small arrows)* of the radius. The extent of bowing can often be fully appreciated only with comparison views of the opposite extremity.

Bowing Fractures

Bowing fractures occur uniquely in children. Recent evidence suggests that the force causing the deformation is longitudinal. The force stops short of creating a fracture but does cause persistent plastic deformation (bowing) of the bony structure (Fig. 115.4). Little remodeling can be expected from the injury, and both cosmetic and functional deficits

are common. Anatomic reduction produces the most satisfactory result. All bowing deformities should be referred to an orthopedic surgeon.

Avulsion Fractures

Avulsion fractures are common in children. Strong muscular attachments adhere to secondary centers of ossification known as apophyses in the developing skeleton. During intense muscular contraction, fractures occur through the apophyseal plate. Most avulsion fractures occur in the pelvis and heal uneventfully. Other common sites include the tibial tubercle and the phalanges. Rarely do avulsion fractures require open or closed reduction. Conservative care is the mainstay of treatment.

Physical and Radiographic Examination

Approach to the Physical Examination

A systematic approach to the child with a suspected fracture is necessary to avoid overlooked injuries and undue complications. The basic principles of a history and physical examination should be followed. In all cases, it is necessary to consider the possibility of associated head and truncal injuries. Often the history is obtained from a parent or bystander who witnessed the accident. At times, no history is available. Attention to the mechanism of injury and the force causing the injury gives clues to the severity of the fracture and soft-tissue injury. The activity of the patient following the injury also helps define the likelihood and nature of orthopedic injuries. Whether the child is able to provide any details of the accident obviously depends on both age and the extent of associated head and internal injuries.

The physical examination should begin with careful observation of the patient's behavior. Is he or she guarding or not moving an extremity? Is there pain? How is the patient's color? Is the child interacting normally with his or her parents and the environment? After observing the child and determining the area or areas of injury, the physician can look for swelling and deformity. It is best to always begin with the extremities that do not appear to be injured. An effort should be made to gain the patient's trust by gently moving all joints and extremities that appear uninjured while trying to distract the child from the examination itself. This also allows detection of unsuspected areas of injury. Attention should then be turned to the injured extremity. Swelling, ecchymosis, deformity, and the presence of lacerations and puncture wounds should be noted. When open wounds are present, the exact location, degree of contamination, presence of fat globules, and rate of active bleeding should be documented. It is not always obvious whether there is an open fracture or simply a laceration that does not communicate with the fracture; operative exploration may ultimately be required.

While continuing to distract the child, the physician should then carefully palpate the soft tissues and bones above and below the area of injury. The point of maximal bony tenderness should next be gently defined. Evidence of increased compartment pressures should be sought both by palpation and by careful assessment of the pulses and capillary blood flow distal to the injury. However, the compartment syndrome can occur in the presence of palpable pulses (see Compartment Syndrome, following). If no significant deformity is discovered, joint motion both proximal and distal to the fracture should be assessed. As detailed a sensory and motor examination as the age and overall condition of the child will permit should be performed.

Radiographic Examination

All unstable and significantly deformed fractures *must* be immobilized before the initiation of radiographic studies. By so doing, further deformity and soft-tissue injury is avoided, and patient discomfort during positioning for the radiographs is decreased. A plaster or fiberglass splint can be applied quickly and does not prevent adequate radiographic assessment of the fracture (Fig. 115.5). Unless a specific contraindication exists, pain medication, often parenteral, should be administered as well. Recent studies continue to demonstrate that many children with skeletal injuries receive no or inadequate pain medication, both in the ED and upon discharge. No patient should be allowed to take any food or drink by mouth until all examinations and referrals are completed.

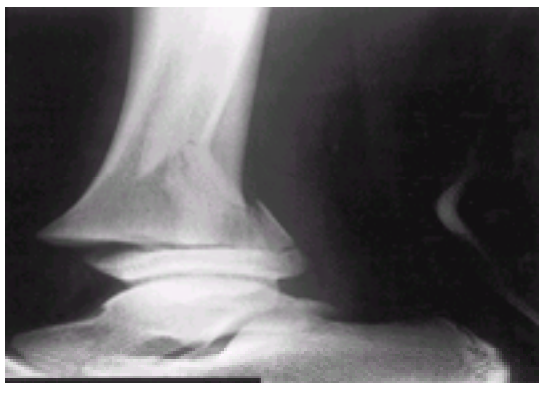

FIGURE 115.5. Lateral radiograph through a fiberglass splint showing angulated distal tibial and fibular fractures in a 13-year-old boy. Splinting before radiologic studies provides fracture stability and comfort but does not prevent adequate visualization of bony injury.

After a complete history and physical examination, the physician should be able to order specific radiologic views to identify the injury. In some instances (e.g., a toddler who is refusing to bear weight but who has no localizing signs), the history and a knowledge of the most common injuries for a given age have to guide the choice of radiographic studies. A complete examination should include the joints above and below the fracture and at least two views taken at 90 degrees

to one another (generally anteroposterior and lateral views). Oblique and other additional views are necessary at times for certain body parts (e.g., the hand, ankle, foot, phalanges) and when routine views are normal but suspicions of a fracture are high. Given the degree of normal variability in bony anatomy, particularly in growing bones, comparison views are indicated on occasion (Fig. 115.6).

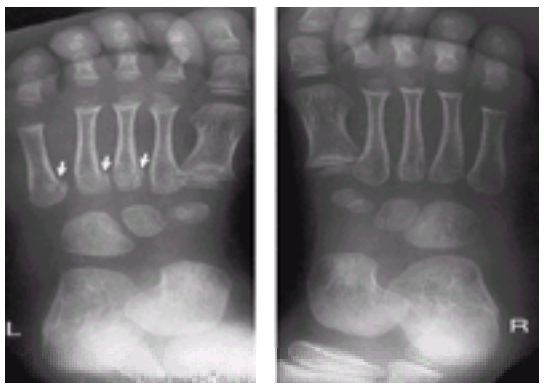

FIGURE 115.6. Radiographs of the feet of a 3-year-old child who sustained a crush injury of the left foot. The soft-tissue swelling of the left foot *(L)* is readily apparent. That the irregularities of the proximal third, fourth, and fifth left metatarsals *(arrows)* are indisputably fractures is immediately apparent when the injured foot is compared with the uninjured right foot *(R).* A proximal second metatarsal fracture was suspected as well and was better visualized on other views.

Although plain film radiography will no doubt remain the primary imaging technique used in fracture evaluation, other modalities, notably bone scintigraphy, computed tomography (CT), and magnetic resonance imaging (MRI) have come to play an important adjunctive role. Scintigraphy is more sensitive than plain films in certain settings, for example, when a stress fracture is suspected (Fig. 115.7). CT plays an important role in the definition of complex fractures, particularly intra-articular ones, as well as in the evaluation of spine injuries. The roles of MRI in the same settings continue to be defined and expanded.

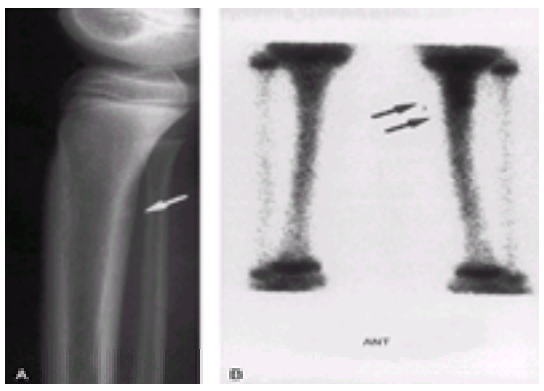

FIGURE 115.7. A. Routine radiographs of this 10-year-old girl revealed only a minor cortical irregularity of the posterior aspect of the proximal left tibia *(arrow).* **B.** Bone scintigraphy was performed. The increased isotope uptake seen along the proximal left tibia *(arrows)* confirmed the clinical suspicion of a stress fracture.

Fracture Description

When obtaining an orthopedic consultation, the emergency physician must relay accurate and descriptive information to allow the orthopedist to make appropriate treatment recommendations. A clinical description should include the patient's age and sex, the mechanism of injury, the anatomic location, the status of the neurovascular structures, and the extent of associated soft-tissue injury. A careful and precise radiographic description should include the anatomic location of the fracture; the type of fracture (e.g., transverse, spiral, oblique); the amount of displacement; the degree of angulation, shortening, or malrotation; the degree of comminution; and the extent of involvement of the joint and growth plate. Accurate descriptions using appropriate terminology are helpful in assisting the orthopedist in his or her recommendations (Fig. 115.8).

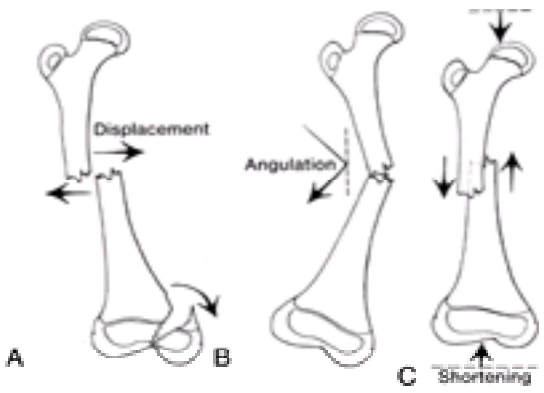

FIGURE 115.8. Diagrammatic representation of fracture deformities: displacement **(A);** angulation **(B);** overriding with

shortening **(C).**

Orthopedic Referral and General Principles of Acute Fracture Care

Indications for Orthopedic Referral

The indications for an orthopedic consultation vary somewhat with the ability and experience of the emergency physician and the availability and preferences of the orthopedist. Certainly, if any question exists regarding the diagnosis, treatment, complications, or follow-up of an orthopedic injury, a consultation should be obtained. An orthopedic surgeon should be called to evaluate all fractures that are open, unacceptably displaced, or causing neurovascular compromise. Other indications for immediate orthopedic referral include significant growth plate or joint involvement, many fractures of the long bones of the lower extremity, pelvic fractures (other than avulsions), spinal injuries, and dislocations of major joints other than the shoulder. On the other hand, the emergency physician should be expected to provide the initial, if not the definitive, care for many pediatric fractures. Most nondisplaced Salter I fractures; clavicular injuries; nondisplaced upper extremity, foot, and phalangeal fractures; incomplete, nondisplaced fractures of the long bones of the lower extremity; and routine dislocations of minor joints and the shoulder can all be managed initially by physicians other than orthopedists (Table 115.1).

Injuries That Require Immediate Orthopedic Referral
Open fractures
Unacceptably displaced fractures
Fractures with associated neurovascular compromise
Significant growth plate or joint injuries
Complete or displaced fractures of the long bones of the lower extremities
Pelvic fractures (other than minor avulsions)
Spinal fractures
Dislocations of major joints than the shoulder
Injuries That Can Be Managed Initially by the Emergency Physician
Nondisplaced Salter-Harris type I fractures (exceptions are femur, proximal tibia)
Clavicular fractures
Nondisplaced upper extremity fractures
Incomplete, nondisplaced fractures of the long bones of the lower extremities
Nondisplaced fractures of the hand and foot
Routine dislocations of the shoulder and minor joints (no fractures)

Table 115.1. Indications for Orthopedic Referral

Acute Fracture Care

Immobilization is the mainstay of the initial treatment of any fracture. Plaster and fiberglass materials are both satisfactory, although the greater strength of fiberglass has advantages in splinting of lower extremities. Immobilization of the joints above and below the fracture provides both the greatest degree of comfort and the best guarantee against additional injury or deformity. (An exception is a minor torus fracture of the distal forearm, for which a short arm splint or cast is often adequate.) Several layers of padding material should always be applied before the actual splint or cast because the padding provides greater comfort, and the risk of neurovascular compromise, if swelling occurs, is diminished. (See the Procedures section for detailed descriptions of splinting techniques.) The degree of actual or anticipated swelling, the propensity of the fracture to lead to a compartment syndrome, and the training of the emergency physician dictate whether a splint or a cast is applied at the time of initial evaluation.

Most fractures that are initially casted should be reevaluated within 24 hours for signs of neurovascular compromise, either in the ED or by the orthopedist. Otherwise, when orthopedic follow-up is necessary, an appointment within the week following injury is generally reasonable (assuming the immobilization is adequate). Certain injuries (e.g., any fracture that could possibly displace) should be seen more promptly. Other fractures need no orthopedic referral at all. Discharge instructions should include a review of the need for elevation and ice application and a discussion of the signs of neurovascular compromise. The need for pain medication in children should not be ignored. All radiographs should be reviewed by a radiologist, and parents should be routinely informed that further evaluation and radiographs will be necessary despite initially negative studies should symptoms persist. The importance of immobilization of all but the most minor injuries and of careful documentation of follow-up instructions cannot be overemphasized.

Postfracture Care

Two factors influence the function regained following fractures in children: the establishment of a bony union and the restoration of normal alignment and growth. Unlike postfracture care for the adult, physical therapy usually is not necessary to regain normal range of motion. Stiffness rarely becomes a long-standing problem for children. The child acts as his or her own physical therapist through normal activities. On occasion, it may become necessary for the parents or physical therapist to “supervise” active range of motion exercises until normal range of motion is obtained. If the orthopedic injury is associated with tissue loss, head injury, nerve damage, or vascular compromise, physical and occupational therapy may play a major role in reestablishing normal or near-normal function in the child.

SPECIAL CONSIDERATIONS

Open Fractures

Several considerations dictate that the emergency physician approach open fractures with special concern. Such fractures generally result from high-energy accidents, namely falls, motor vehicle collisions, and auto–pedestrian accidents. Multiple injuries are common in such settings. The physician should not allow an open fracture to distract from the detection and orderly management of other less apparent but potentially life-threatening injuries. A complete examination is imperative.

The incidence of complications is higher with open fractures, and a complete evaluation for neurovascular compromise and for signs of compartment syndrome should be performed. In addition, the incidence of infection is increased with open fractures. Management should include cleansing the wound, applying a sterile Betadine dressing, administering prophylactic intravenous antibiotics (e.g., broad-spectrum cephalosporins), and immobilizing the fracture. Tetanus prophylaxis should be administered according to the usual guidelines. Clearly, open fractures must be regarded as true orthopedic emergencies. Surgical debridement, irrigation, and definitive care of the wound and fracture are uniformly necessary. The patient should be given nothing by mouth and an urgent orthopedic consultation obtained. The laceration over a fracture should never be closed, even if the fracture is in good alignment.

Compartment Syndrome

The compartment syndrome is a devastating fracture complication that, if left untreated, may progress to muscle necrosis and nerve palsies. It occurs when a buildup of intracompartmental pressure results in ischemia of the muscle and neurovascular tissue. The pressure initially blocks venous outflow, resulting in increased pressure in the nonelastic compartment. Eventually, the small arterioles and capillaries are occluded and irreversible muscle and nerve damage results.

The compartment syndrome can occur in the forearm, hand, thigh, leg, or foot; the most common site is the anterior compartment of the leg. The fracture need not be a severe one; indeed, the compartments are often torn with significantly displaced fractures and thus are less subject to pressure buildup. Pain, particularly pain with passive extension, is the earliest sign of the compartment syndrome. With any fracture or blunt tissue injury presenting with pain out of proportion to the injury, the compartment syndrome must be suspected. On palpation, the muscular compartment may feel hard, swollen, and tense. Other physical signs, including pulselessness, paresthesia, pallor, and paralysis, may or may not be present. Direct measurement of compartmental pressures confirm the diagnosis. When clinical and objective signs of compartment syndrome are present, a fasciotomy should be performed as soon as possible.

In the patient with multiple injuries, it is imperative to palpate every muscular compartment to rule out impending compartment syndrome. An orthopedic consultation should be obtained in every case of suspected compartment syndrome.

Multiple Trauma

Although fractures are common in the child with multiple injuries, only rarely are they life-threatening. There is no question that orthopedic injuries are often the most obvious. And there is no question that more children require operative orthopedic surgical procedures than general surgical procedures after major trauma. On the other hand, it is definitely a mistake to disregard the usual tenets of trauma management and forsake an orderly and thorough evaluation of a child's respiratory, cardiovascular, and neurologic status in a rush to provide fracture care. The B of the ABCs is not for bone.

Only in a few instances is the blood loss associated with a fracture significant enough to cause signs of shock. Exceptions include pelvic fractures and multiple long bone fractures (even an isolated femur fracture rarely causes hemodynamic compromise). Clearly, then, signs of significant volume loss in a child thought only to have sustained fractures should prompt an immediate search for other injuries.

In most instances, initial fracture management in the ED should consist simply of immobilization. Traction splints are extremely useful for lower extremity fractures. The role of pneumatic antishock garments continues to be debated; their use should be considered for unstable pelvic injuries. On occasion, application of an external fixator device may help tamponade bleeding from such fractures.

Many fractures, primarily nondisplaced ones, go undetected during initial ED management. Little harm occurs as a result. On the other hand, the consequences of missing a thoracic or lumbar spine fracture can obviously be much greater. Physical signs of such fractures are generally lacking, and the status of the child often precludes an assessment of pain and neurologic function. When the mechanism of injury is unknown or suggests the possibility of a spinal injury, radiographs should be ordered and careful immobilization maintained.

Child Abuse

Although the diagnostic significance of skeletal injuries in child abuse has long been recognized, only 5 to 18% of abused children sustain fractures. On the other hand, a large percentage of fractures in infants less than 1 year of age are not results of accidents. Careful consideration of the details of the injury, particularly from the viewpoint of the child's developmental stage, provides the first clue regarding the likelihood of abuse. Only a limited number of fracture types and patterns can be considered almost uniformly specific for child abuse (Table 115.2). In most cases of abuse, the radiographic findings will not by themselves confirm suspicions of an intentional injury. Although spiral fractures in nonambulating children and metaphyseal–epiphyseal injuries are essentially diagnostic, transverse fractures are common and diaphyseal fractures predominate in abused as in nonabused children (Fig. 115.9, Fig. 115.10 and Fig. 115.11).

1. Fractures inconsistent with history
2. Fractures inconsistent with developmental stage of child
3. Fractures with associated injuries suggestive of abuse
4. Multiple fractures, particularly in various stages of healing
5. Multiple, complex, or depressed skull fractures
6. Epiphyseal-metaphyseal rib fractures
7. Spiral fractures of the femur or tibia in preambulating children
8. Spiral fractures of the humerus
9. Metaphyseal chip (corner) fractures
10. Avulsion fractures of clavicle and acromion process

Table 115.2. Fractures Strongly Suggestive of Child Abuse

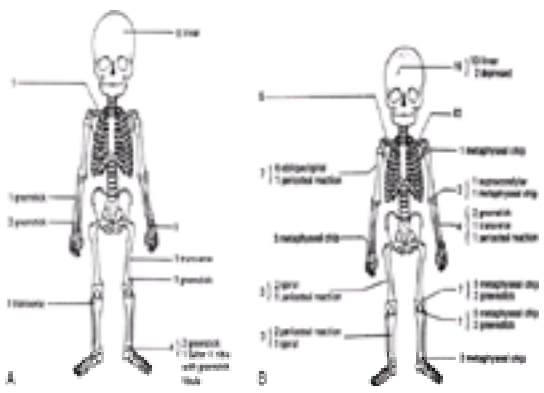

FIGURE 115.9. Comparison of the locations and types of accidental **(A)** and nonaccidental **(B)** fractures in infants less than 18 months of age. (Reprinted with permission from Worlock P, Stower M, Barbor P. Patterns of fractures in accidental and nonaccidental injury in children. Br Med J 1986;293:100–102.)

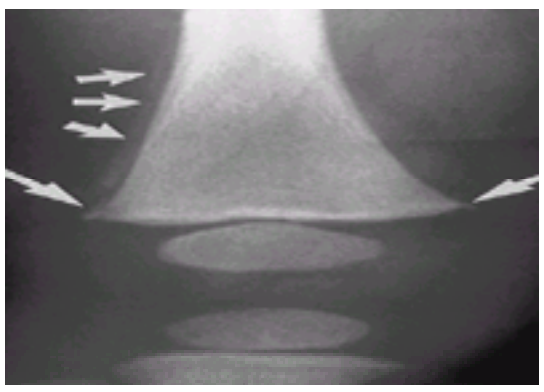

FIGURE 115.10. Radiograph of the right knee of a 3½-month-old victim of child abuse. The metaphyseal corner fractures *(large arrows)* are considered diagnostic of abuse. Also evident is periosteal new bone formation *(small arrows),* proof of a significant delay between injury and medical evaluation.

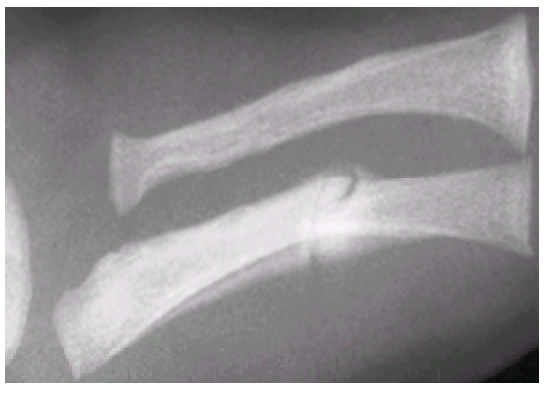

FIGURE 115.11. Radiograph of the left forearm of a 3-month-old victim of child abuse. Although the ulnar fracture is transverse and thus by itself is not diagnostic of intentional injury, both the child's age and the extent of periosteal bone formation (again establishing a significant delay between diagnosis and medical evaluation) should strongly suggest the possibility of child abuse to the examining physician.

As for diagnostic studies, any clinically suspected fracture should be evaluated using the radiographic views customary for the site in question. In addition, a skeletal survey must be performed routinely as part of the evaluation of all cases of strongly suspected abuse in children less than 2 years of age. For children 2 to 5 years of age, individual considerations determine whether a skeletal survey is needed. Skeletal surveys have little role in the evaluation of children older than 5

years of age. Routine radionuclide bone scans are not indicated, although this technique may be an adjunct to the detection of subtle rib and long bone shaft fractures, as well as of some spine injuries.

Pathologic Fractures

A pathologic fracture is one that occurs through abnormal bone. Many conditions, including tumors, hereditary diseases, metabolic disorders, neuromuscular diseases, and infections, can cause either generalized or localized bone weakness (Table 115.3, Fig. 115.12 and Fig. 115.13). On occasion, the predisposing condition does not become obvious until a fracture occurs. All pathologic fractures require orthopedic consultation. The nature of the underlying disease that is identified or suspected determines the need for consultation of other specialists. In most instances, the initial treatment parallels that of a nonpathologic fracture in the same site.

Tumors and Cysts—Benign	**Metabolic Disorders**
Aneurysmal bone cyst	Copper deficiency
Endochondroma	Cushing's syndrome
Eosinophilic granuloma	Hyperparathyroidism
Fibrous dysplasia	Renal osteodystrophy
Giant cell tumor	Rickets
Nonossifying fibroma	Scurvy
Osteochondroma	**Neuromuscular Diseases (osteoporosis from disuse)**
Unicameral bone cyst	Cerebral palsy
Tumors—Malignant	Muscular dystrophy
Chondrosarcoma	Poliomyelitis
Ewing's sarcoma	Severe head injury
Neuroblastoma	Spina bifida with paraplegia
Osteogenic sarcoma	Traumatic paraplegia or quadriplegia
Hereditary Diseases	**Infections**
Gaucher's disease	Osteomyelitis
Neurofibromatosis	
Osteogenesis imperfecta	
Osteopetrosis	
Sickle cell disease	

Table 115.3. Differential Diagnosis of Pathologic Fractures

INJURIES OF THE UPPER EXTREMITIES

Injuries of the Shoulder Region

For the purposes of this discussion, injuries of the shoulder region are grouped as follows: 1) clavicular fractures, 2) scapular fractures, and 3) shoulder dislocations.

Clavicular Fractures

The clavicle ranks as the most commonly fractured bone in children. More than half of all clavicular fractures occur in children less than 10 years of age. In children younger than 2 years (excluding the newborn period), such fractures are

uncommon and should provoke consideration of intentional trauma. For the sake of discussion, clavicular injuries can be divided into fractures of the shaft, the medial end, and the lateral end.

Fractures of the clavicular shaft result from direct trauma and from indirect forces transmitted by falls onto an outstretched hand. Most are greenstick injuries of the midshaft; the thick periosteum enveloping the clavicle prevents significant displacement or angulation. The diagnosis is usually self-evident. Typically, a child complains of shoulder pain and is cradling the arm on the injured side with the opposite one. Occasionally, the initial injury is unnoticed and comes to attention only when a lump appears as callus forms. Radiographs are confirmatory, although visualization of nondisplaced fractures may require several views. (It can be debated whether radiographs are strictly necessary when the diagnosis is self-evident on physical examination.) Despite the proximity of the brachial plexus and subclavian vessels, neurovascular injury is rare other than when a violent direct blow results in significant displacement of the fracture fragments.

Medially, strong ligaments anchor the clavicle to the sternum. Eighty percent of the growth of the clavicle occurs at the medial physis. The last epiphysis in the body to close, the medial clavicular epiphysis, is rarely visible radiographically before 18 years of age. Apparent dislocations of the sternoclavicular joint are invariably epiphyseal separations in children and young adults. With such fractures, either anterior or posterior displacement can occur. The direction of displacement can often be determined by direct palpation. Radiographic visualization may be difficult; special views and/or CT scans are often required to define the degree and direction of displacement. Posterior displacement is of particular concern as compression of the mediastinal vessels and the trachea can result. Should there be evidence of neurovascular or respiratory compromise, prompt orthopedic consultation and closed reduction are indicated.

Laterally, the clavicle is anchored by the coracoclavicular and acromioclavicular ligaments. Once again, fracture through the physis rather than dislocation is the rule. The usual mechanism of injury is a direct blow to the point of the shoulder. Typically, the proximal fracture fragment is displaced superiorly; the radiographic appearance suggests acromioclavicular separation. However, the periosteum remains whole inferiorly, its ligamentous connections intact. As a result, most distal clavicular fractures heal uneventfully with no loss of joint stability (Fig. 115.14).

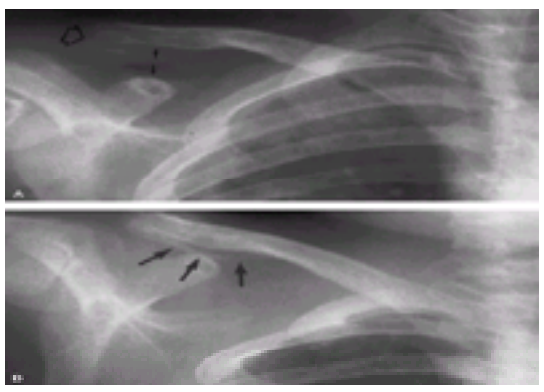

FIGURE 115.14. Radiograph of the right clavicle of a 5-year-old child. **A.** A lateral clavicular fracture *(open arrow)* and widening of the space between the clavicle and the coracoid process *(small arrows)* are evident on the initial film. **B.** The pattern of new bone formation *(arrows)* seen on the follow-up radiograph demonstrates that the periosteum and the ligaments have remained intact inferiorly.

Only rarely is orthopedic consultation or, for that matter, any follow-up necessary for a clavicular injury. Exceptions include significantly displaced midshaft fractures, for which closed reduction is occasionally desirable; posteriorly and significantly anteriorly displaced medial fractures; grossly unstable distal injuries; and all open fractures. Immobilization in a figure-of-eight dressing or a sling and swathe for 3 weeks followed by 3 weeks of restriction from sporting activities is adequate treatment for most shaft fractures. (See Section VII, Procedures, Application of Figure-of-Eight Harness .) Repeat radiographs are usually unnecessary given that nonunion is extremely unusual. It is best to inform parents that a lump will appear as callus forms and may persist for as long as a year. With medial and distal fractures, a sling is recommended along with progressive motion as the pain subsides.

Scapular Fractures

Fractures of the scapula are unusual in adolescents and rare in children. In the isolated instances in which they do occur, the usual mechanism is a severe direct blow, such as can be sustained in a fall from a height or a motor vehicle accident (Fig. 115.15). The same force that produces the scapular fracture may result in more concerning and potentially life-threatening injuries to the chest, neck, or head. Fractures of the body and neck of the scapula are usually well visualized on plain radiographs; adequate definition of glenoid injuries may require a CT scan. Although a sling and swathe is usually the only treatment necessary, orthopedic consultation is suggested given the rarity of these injuries.

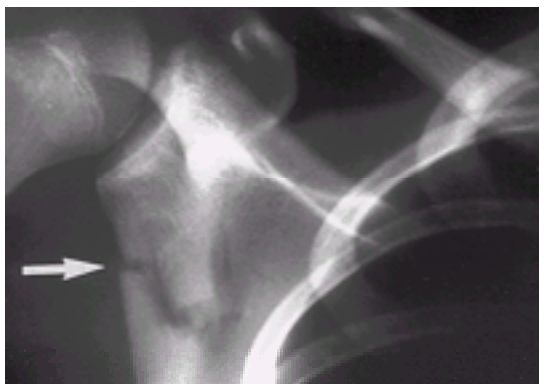

FIGURE 115.15. Radiograph of a 13-year-old boy who sustained an isolated right scapular fracture as the result of a skateboarding accident *(arrow).*

Shoulder Dislocations

Dislocations of the shoulder are unusual before physeal closure. Other than medially, the proximal humeral physis runs external to the shoulder capsule, and injuries that in an adult would cause dislocation result in fractures in children and skeletally immature adolescents. Most dislocations that do occur are anterior, as is the case with adults. Findings on physical examination include swelling and deformity with loss of the usual rounded contour of the shoulder. Palpation generally reveals the displacement of the humeral head anterior to the glenoid fossa. Signs of axillary nerve injury may be present. Radiographic studies should include an axillary (Y) view in addition to the customary views of the shoulder to best define the direction of displacement. As for treatment, closed reduction of anterior dislocations can be accomplished by any of a number of techniques, one of which is reviewed in detail in Section VII, Procedures. Postreduction radiographs should be performed routinely in part to ensure that no fracture has occurred in conjunction with the dislocation. Given their rarity, posterior dislocations merit orthopedic consultation before reduction. The rate of chronic shoulder instability and recurrent dislocation is high; even seemingly routine anterior dislocations should be immobilized in a sling and swathe for several weeks and referred to an orthopedist for subsequent care.

Fractures of the Humerus

In this section, humeral fractures are grouped as follows: 1) proximal humeral fractures and 2) humeral shaft fractures. Supracondylar fractures are discussed under Injuries of the Elbow.

Proximal Humeral Fractures

About 80% of the growth of the humerus occurs at the proximal humeral physis. As a result, the potential for fracture healing and remodeling with fractures that involve the proximal humeral shaft and physis is remarkable. Nonunion is unheard of; malunion is rare, other than with significantly displaced or angulated injuries in older adolescents. Before adolescence, most proximal humeral fractures are metaphyseal (Fig. 115.16), although Salter-Harris type I injuries are seen occasionally. With the onset of adolescence, rapid growth makes the physeal region relatively weak and thus vulnerable to injury. The incidence of proximal humeral fractures is highest in this age group; most are Salter-Harris type II injuries. Type III, IV, and V injuries are most unusual. Common mechanisms of injury include falls on an extended, adducted arm and direct blows to the shoulder.

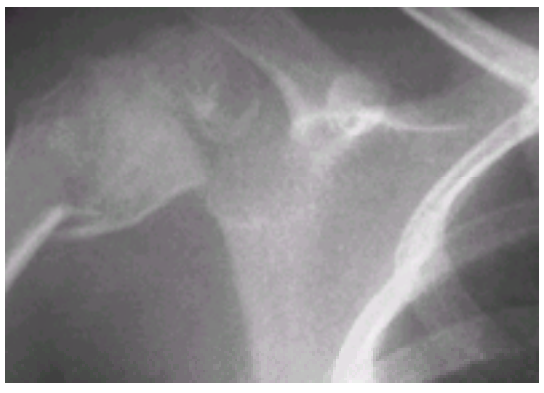

FIGURE 115.16. Impacted proximal right humeral fracture with approximately 25 degrees of angulation in a 3-year-old child. Full remodeling can be anticipated.

Physical findings with proximal humeral fractures range from mild swelling to obvious deformity and shortening of the arm. Routine radiographs are generally sufficient. Care must be taken not to confuse the normal variations in the epiphyseal line with a fracture; comparison views can be useful. Conservative management is the rule. Before adolescence, as much as 50 degrees or even 70 degrees of angulation is satisfactory. In younger children, even totally displaced fractures can remodel completely. Recommendations regarding the degree of deformity acceptable in adolescents vary somewhat; 20 to 50 degrees of angulation and 50% apposition are generally tolerable. The indications for open reduction are limited. A sling and swathe for several weeks is usually the only treatment necessary. Orthopedic follow-up is recommended.

Humeral Shaft Fractures

Fractures of the humeral shaft are much less common than those involving either the proximal or distal segments. The pattern of fracture reflects the mechanism of injury; transverse fractures result from direct blows, whereas spiral fractures are caused by indirect twisting, as with a fall. When a child less than 3 years of age sustains a spiral fracture of the humerus, the strong possibility of child abuse must be considered seriously (Fig. 115.17).

FIGURE 115.17. Spiral fracture of the right humerus in an 18-month-old girl. Although in this case the injury was accidental, spiral humeral fractures in children less than 3 years old must always evoke concerns about child abuse.

Many humeral fractures are obvious on physical examination, although only minimal swelling and tenderness may be present with buckle and greenstick injuries. Vascular injury is relatively uncommon. On the other hand, evidence of radial nerve injury must always be sought, particularly with a fracture that involves the distal two-thirds of the humeral shaft. Physical findings suggestive of damage to the radial nerve include loss of motor strength in the extensors of the wrist and fingers and loss of sensation on the dorsum of the hand in the web space between the thumb and index finger. Of note is that, with proper fracture management, nearly all cases of radial nerve palsy resolve. As for radiographs, anteroposterior and lateral views usually suffice. A prominent vascular groove in the distal humerus is a normal finding that should not be confused with a fracture.

The thick periosteal sleeve of the humeral shaft limits fracture displacement and promotes rapid healing. A sling and swathe is all that is needed for incomplete fractures. For complete or minimally displaced fractures, application of a sugar-tong splint of the upper arm, followed by a sling to support the forearm is recommended. In older children and adolescents, a hanging long arm cast is an alternative. Given the potential for overgrowth with healing, overriding of the fracture fragments by up to 2 cm is acceptable. Remodeling of as much as 40 degrees of angulation can be expected in younger children. Immediate orthopedic consultation is suggested for any completely displaced fracture, any fracture angulated more than 20 degrees in children and 10 degrees in adolescents, and any fracture with evidence of radial nerve injury. All humeral fractures should be referred for orthopedic follow-up within 5 days.

Injuries of the Elbow

Normal Anatomy and Radiographic Diagnosis

Of all the fractures encountered in the pediatric age group, those of the elbow rank as the most problematic in terms of diagnosis, treatment, and complications. For the emergency physician, an understanding of normal anatomy and normal radiographic findings ensures that misdiagnoses and untoward outcomes are uncommon. The elbow is a complex hinge joint composed of three separate articulations, namely those between the trochlea of the humerus and the ulnar notch, the capitellum and the radial head, and the proximal radius and ulna (Fig. 115.18). To further complicate matters, there are four growth centers within the distal humerus alone, and ossification of these growth centers begins at different but predictable times (Table 115.4). The ages shown in Table 115.4 are averages; ossification begins at an earlier age in girls than in boys, and much variation exists overall. When there is confusion about what is a normal growth center and what is a fracture fragment, comparison views of the uninjured elbow can be extremely helpful.

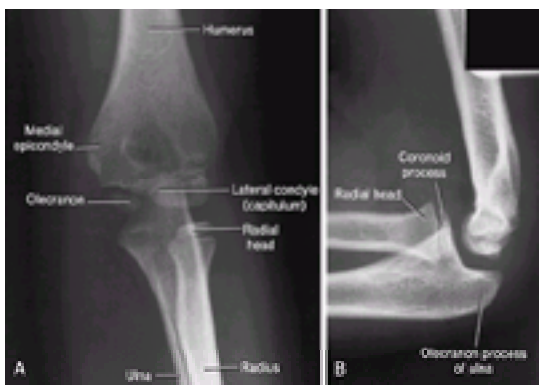

FIGURE 115.18. A. Anteroposterior radiograph of a normal elbow of a child. **B.** Normal lateral radiograph.

Capitellum	11 mo
Medial epicondyle	4-6 yr
Trochlea	9-10 yr
Lateral epicondyle	10-12 yr
Radial head	5-6 yr
Olecranon	6-8 yr

Table 115.4. Growth Centers of the Elbow: Average Age for Onset of Ossification

When a fracture is grossly displaced, the radiographic diagnosis is straightforward. Radiographic detection of subtle torus and nondisplaced fractures of the elbow joint is difficult. Close inspection of the radiographs for the presence of abnormalities of the fat pads and the anterior humeral line will prevent missed diagnoses in most cases. These radiographic signs are reliable only if the elbow has been properly positioned for the radiographs; the importance of a true lateral view in particular cannot be overemphasized. Of the two fat pads overlying the joint capsule along the distal humerus, only the anterior fat pad is normally visible on a lateral radiograph (Fig. 115.19). When fluid is in the joint space, as with a hemarthrosis from a fracture, these fat pads are displaced upward and outward (Fig. 115.20). If soft-tissue edema is extensive, one or both of the fat pads, although elevated, may be obscured. In the setting of known or suspected trauma, the presence of an abnormal fat pad sign should be considered a marker of an occult fracture and an indication for careful immobilization and close follow-up. Of note is that fractures of the distal humerus and of the proximal radius and ulna can all produce a hemarthrosis and thus positive fat pad signs. On occasion, oblique views will reveal the fracture line.

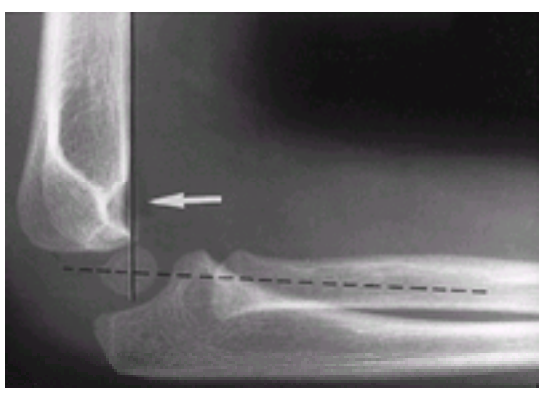

FIGURE 115.19. Normal lateral radiograph of the elbow of a 2-year-old child. The anterior fat pad is readily seen *(arrow);* the posterior fat pad is not visible. A line drawn along the anterior cortex of the humerus intersects the capitellum in its middle third *(solid line).* A line drawn along the axis of the radius also passes through the center of the capitellum *(dashed line).*

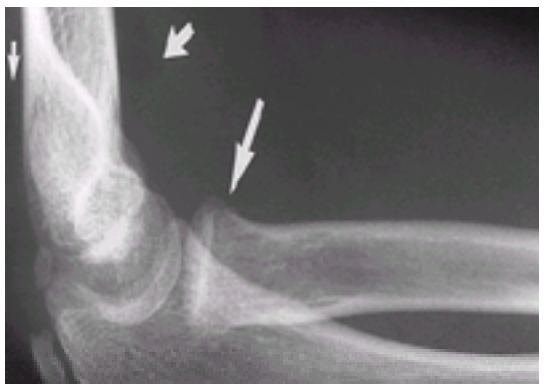

FIGURE 115.20. Lateral radiograph of the elbow of a 12-year-old girl, demonstrating marked elevations of both the anterior and posterior fat pads *(small arrows).* A subtle radial neck fracture is also visible *(large arrow).*

Close inspection of a true lateral view of the elbow for abnormalities of the anterior humeral line is also essential. In the normal elbow, a line drawn through the anterior cortex of the humerus intersects the capitellum in its middle third (Fig. 115.19). Because the most common mechanism of injury to the elbow is hyperextension, posterior displacement of the distal humerus is to be expected when a fracture occurs. As a result, the anterior humeral line, rather than intersecting the middle third of the capitellum, passes through its anterior third or even fails to intersect it all together (Fig. 115.21). Detection of abnormalities of the anterior humeral line in children less than 2½ years of age is complicated by the variable rates of ossification of the capitellum; once again, comparison views can be helpful in uncertain cases.

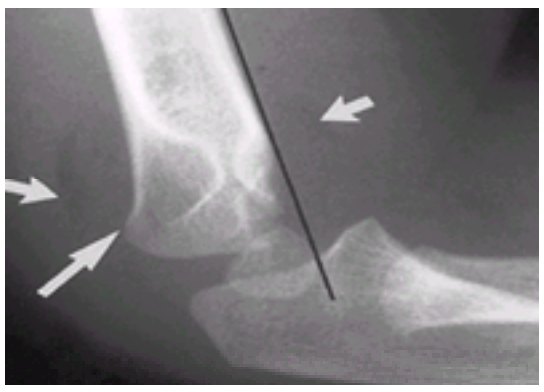

FIGURE 115.21. Lateral radiograph of the elbow of a 2-year-old girl. Once again, both the anterior and posterior fat pads are elevated *(small arrows).* In addition, the anterior humeral line passes along the anterior edge of the capitellum rather than through its center. Mild buckling of the posterior cortex of the distal humerus can be seen *(large arrow).*

In summary, errors in the management of pediatric elbow injuries can be minimized by an understanding of normal anatomy and development, careful interpretation of properly obtained radiographs, and immobilization with careful follow-up when there is even the mildest suspicion of a fracture. For the sake of discussion, elbow injuries are divided as follows: 1) supracondylar fractures, 2) lateral condylar fractures, 3) medial epicondylar fractures, 4) distal humeral physeal fractures, 5) olecranon fractures, 6) radial head and neck fractures, 7) elbow dislocations, and 8) radial head subluxation.

Some of these injuries are presented diagrammatically in Figure 115.22. Fractures of the medial humeral condyle and the lateral humeral epicondyle are rare and are not discussed.

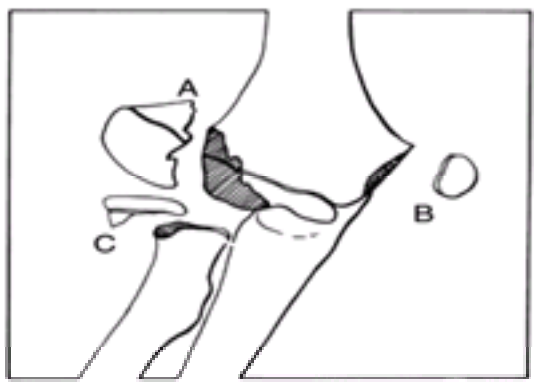

FIGURE 115.22. Common elbow fractures in children: lateral condylar fracture *(A);* medial epicondylar fracture *(B);* radial neck fracture *(C).*

Supracondylar Fractures

Supracondylar fractures account for more than 50% of the fractures of the elbow in the pediatric age group. Most are sustained by children 3 to 10 years of age. A fall on the outstretched arm with hyperextension of the elbow is the most common mechanism. Accordingly, posterior angulation or displacement of the distal fracture fragment nearly always occurs (Fig. 115.23). A direct blow to the posterior aspect of the elbow can lead to anterior angulation or displacement of the distal fragment, but such injuries are rare by comparison. With minimally displaced or nondisplaced fractures, recognition can be difficult. There may be only mild soft-tissue swelling. A suggestive history coupled with localized tenderness should prompt a radiologic examination. The radiographic findings also may be subtle. Close attention to the fat pads and the anterior humeral line, as detailed previously, facilitate diagnosis. At times, the actual fracture may be visualized only with an oblique view.

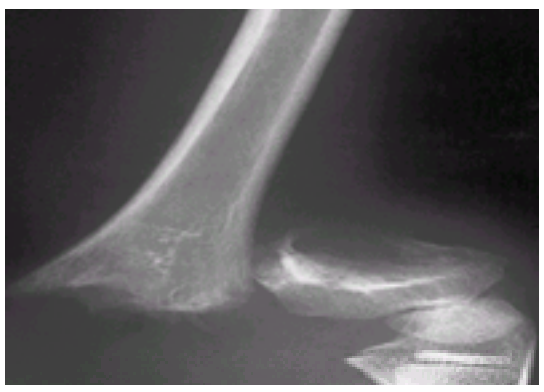

FIGURE 115.23. Displaced and rotated supracondylar fracture in an 8-year-old girl. The distal pulses were absent in this case but returned with reduction of the injury.

With more severe supracondylar injuries, the problem is not that of diagnosis (although a dislocated elbow may have a similar clinical presentation) but that of the recognition and prevention of complications. The complications associated with supracondylar fractures are multiple, ranging from immediate neurovascular compromise to long-term deformities and range-of-motion abnormalities. For the emergency physician, the first priorities are those of neurovascular assessment and fracture stabilization. The vascular examination should begin with palpation of the distal pulses and assessment of capillary refill. Use of a Doppler may allow detection of distal arterial flow when no pulse can be palpated. Absence of a pulse by itself is not extremely worrisome. Direct vascular injury is uncommon. In most instances, vasospasm or arterial compression has occurred instead, and arterial flow will resume with fracture reduction. On the other hand, significant muscle ischemia can be present even when pulses and capillary refill are judged to be normal. Forearm pain, pain with passive extension of the fingers, paralysis of finger extension, and paresthesias are each worrisome and should be considered evidence of an impending compartment syndrome.

Neurologic deficits, usually transient, are also common with supracondylar fractures. Radial, medial, and ulnar nerve palsies all occur, as do isolated injuries of the anterior interosseous nerve (a motor branch of the median nerve). Table 115.5 outlines the innervation of these nerves and should be used as a guide to the neurologic examination. Once the neurovascular examination is completed and *before* radiographic studies, all displaced supracondylar fractures must be immobilized. It is usually best to simply splint the limb in the deformed position in which it lies. More than 20 to 30 degrees of elbow flexion will place undue tension on the neurovascular structures and should be avoided. All patients must have nothing by mouth because reduction, whether open or closed, requires general anesthesia. Frequent repeat neurovascular examinations should be performed and documented.

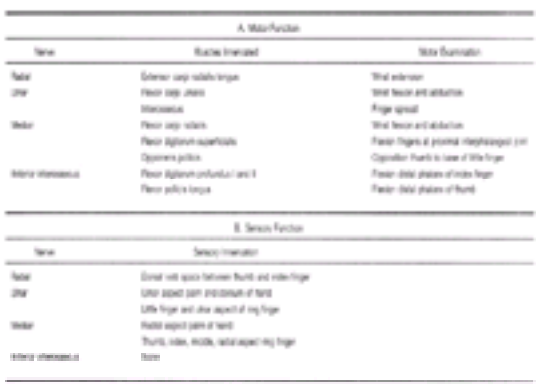

Table 115.5. Guide to the Neurologic Examination of the Distal Upper Extremity

Minimally displaced or nondisplaced supracondylar fractures may be immobilized in a well-padded long-arm posterior splint with the elbow at 90 degrees and the forearm in pronation or neutral rotation. Orthopedic referral for casting is suggested when the swelling subsides. Immobilization for a total of 3 weeks is adequate in most cases. All nonminimally displaced supracondylar fractures require immediate orthopedic referral.

Lateral Condylar Fractures

Fractures of the lateral condyle, like those of the supracondylar region, are prone to poor functional outcome if misdiagnosed or mismanaged. Unlike supracondylar fractures, lateral condyle injuries involve the articular surface; they are true Salter-Harris type IV injuries. The most commonly proposed mechanism of injury is a varus stress on the elbow, as can occur with a fall on an extended and abducted arm. The lateral ligament and the common extensor tendon remain attached to the fracture fragment, which can be partially or totally avulsed from the distal humerus (Fig. 115.24). Clinically, swelling, ecchymosis, and tenderness localized over the lateral aspect of the elbow should suggest a lateral condylar fracture. With severely displaced fractures, routine anteroposterior and lateral views usually provide adequate fracture definition. With less severe injuries, the fracture line and the degree of displacement may be evident only on oblique views. On occasion, stress views, an arthrogram, or CT scan may be needed to adequately visualize the extent of injury.

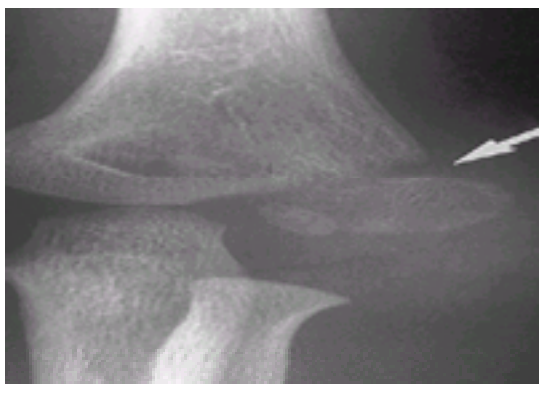

FIGURE 115.24. Lateral condylar fracture in a 2-year-old girl *(arrow).*

For minimally displaced and nondisplaced injuries, immobilization in a posterior splint with the elbowflexed to 90 degrees

and the forearm in pronation (some authorities suggest supination instead) is satisfactory emergency management. Lateral condylar fractures as a group are inherently unstable and prone to displace despite immobilization; orthopedic follow-up within 3 to 4 days is essential. All fractures displaced more than 2 mm require reduction and often pinning.

Medial Epicondylar Fractures

Fractures of the medial epicondyle occur both as the result of falls directly onto the elbow and falls onto the outstretched arm in which the elbow is subjected to a valgus stress. With the latter mechanism, the flexor muscles of the forearm avulse the medial epicondyle from the humerus (Fig. 115.25). Medial epicondyle injuries are particularly common with elbow dislocations. The physical findings are those that would be expected, namely swelling and tenderness localized to the medial aspect of the elbow. Valgus instability may be evident. Given its proximity, paresis of the ulnar nerve can occur. Oblique views and comparison views may be needed on occasion. The diagnosis is particularly problematic before the onset of ossification of the medial epicondyle at 4 to 6 years of age; fortunately, it is an uncommon injury in younger children. Open reduction is almost invariably necessary for displaced fractures. Nondisplaced fractures can be placed in a posterior splint with the forearm in pronation. Orthopedic follow-up is encouraged strongly, as it is with most elbow injuries.

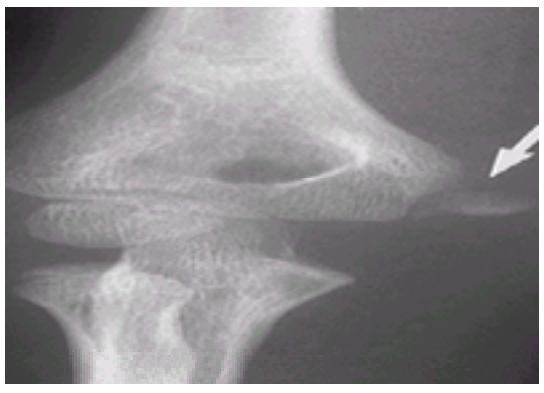

FIGURE 115.25. Displaced fracture of the medial epicondyle in an 8-year-old girl *(arrow).* Note the extensive soft-tissue swelling.

Distal Humerus Physeal Fractures

Fractures of the entire distal humerus physis are relatively uncommon. Most such injuries take place in children less than 2½ years of age; nearly all the remainder are sustained by children less than 7 years of age. Recognition is both difficult and important, especially in infants, in whom this particular injury is often the result of child abuse. The proposed mechanism in abused children is forceful twisting of the arm that shears off the distal epiphysis. In children 5 to 7 years of age, a fall on an extended arm with hyperextension of the elbow usually results in a supracondylar injury but occasionally can lead to a fracture of the distal humerus physis instead.

Elbow swelling without significant deformity is the usual clinical finding. When displacement is significant, the appearance may mimic that of an elbow dislocation. The latter, however, is an injury of early adolescence. Radiographic diagnosis can be difficult, particularly in infants in whom the capitellum has not yet begun to ossify. Posteromedial displacement of the ulna and radius in relation to the humerus is the most important finding. Recognition of this displacement may necessitate comparison views. Given the difficulty in recognition and the frequent need for reduction and pinning, all suspected epiphyseal separations of the distal humerus merit immediate orthopedic referral. In addition, the strong possibility of abuse needs to be considered seriously with this injury in children under 3 years of age.

Olecranon Fractures

Isolated fractures of the olecranon are seen only rarely. More often than not, they occur in conjunction with another injury of the elbow, in particular a fracture or dislocation of the radial head. Various mechanisms have been described, including sudden flexion of the elbow when the triceps is strongly contracted (essentially an avulsion injury) and direct trauma. Physical findings range from swelling localized to the olecranon to a marked hemarthrosis. Elbow extension may be weak or lacking altogether. Nondisplaced fractures may be somewhat difficult to discern radiographically; fat pad abnormalities are commonplace, however, and should be viewed as presumptive evidence of a bony injury (Fig. 115.26). A nondisplaced olecranon fracture can be splinted in partial extension and referred for orthopedic follow-up. Displaced fractures often require open reduction and internal fixation. Isolated olecranon fractures almost invariably heal quickly and without significant complications.

FIGURE 115.26. Nondisplaced fracture of the olecranon in an 8-year-old boy *(bottom arrow).* Note the elevated fat pads *(top arrows).*

Radial Head and Neck Fractures

Falls on an outstretched, supinated arm account for most fractures of the radial head and neck. Salter-Harris types I and II and pure metaphyseal (i.e., radial neck alone) injuries are the most common. Involvement of the epiphysis (i.e., radial head), which is largely cartilage in childhood, is rare. The physical examination typically reveals localized swelling and ecchymosis. Tenderness overlying the proximal radius strongly suggests the diagnosis. Of note is that pain may be referred to the wrist and thus distract from the true injury (Fig. 115.27). As for radiographic diagnosis, oblique and comparison views can clarify the diagnosis in uncertain cases. When the metaphysis alone is injured, a hemarthrosis may be absent and the fat pads normal. Associated fractures are common. The incidence of complications, especially loss of motion and overgrowth of the radial head, is significant. For this reason, orthopedic referral is recommended for all radial head and neck fractures. Immobilization with the elbow in 90 degrees of flexion and the forearm in neutral rotation is acceptable emergency management for minimally displaced or nondisplaced fractures. Angulation of greater than 15 degrees is an indication for immediate orthopedic consultation.

FIGURE 115.27. Buckle fracture of the radial neck in a 9-year-old girl. Wrist pain was the chief complaint. The treating physician failed to identify the proximal radial fracture, which was, however, noticed by the radiologist.

Elbow Dislocations

The elbow is dislocated more often than any other major joint in children and adolescents. Nonetheless, it is an unusual injury. As discussed previously, the ligaments and tendons are relatively stronger than the neighboring bones (particularly the physeal plates) in children; injuries that would lead to dislocations in adults almost invariably result in fractures in the younger age group. It is not surprising, then, that dislocations of the elbow are accompanied by significant soft-tissue and bony damage. A fall on an extended or partially flexed arm with the forearm in supination is the usual mechanism of injury. Accordingly, the radius and ulna are displaced posteriorly and, in most cases, laterally (Fig. 115.28). The anterior capsule is torn and the medial collateral ligament typically ruptured. Fractures of the medial epicondyle, coronoid process, olecranon, and proximal radius are the most commonly associated bony injuries.

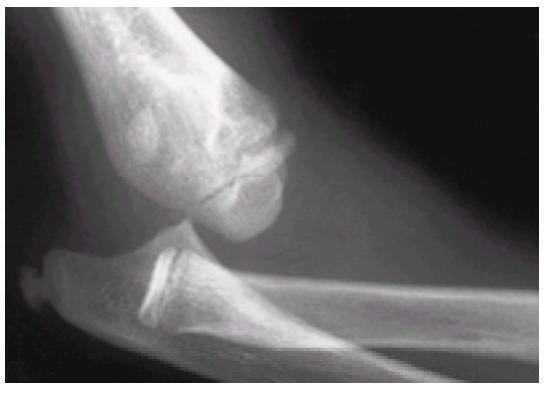

FIGURE 115.28. Elbow dislocation in an 8-year-old girl. A displaced fracture of the medial epicondyle was evident on the postreduction radiographs.

Major neurovascular compromise often accompanies elbow dislocations. True arterial rupture is seen almost exclusively with open dislocations but has been described on occasion with closed injuries. When reduction of the dislocation fails to relieve arterial compromise, further investigation regarding the extent of vascular injury is warranted. Overall, the risk of compartment syndrome with dislocations of the elbow is such that some authors recommend hospitalization for close observation even after successful closed reduction. Nerve injury, particularly of the ulnar nerve, is even more common than vascular injury. Ulnar nerve lesions typically occur when the medial epicondyle is avulsed and then entrapped in the joint. Early recognition and appropriate treatment of such entrapment nearly always lead to complete recovery of ulnar

nerve function. Median nerve entrapment is much rarer, but when it occurs, the degree of nerve damage is such that full recovery cannot be guaranteed. Moreover, recognition of median nerve injury is made difficult by the relative lack of pain and the subtlety of the initial motor and sensory deficits.

Clinical findings with dislocation of the elbow include obvious deformity and significant swelling. The forearm appears shortened. Often, the ulnar notch can be palpated posteriorly, and the humeral head can be detected as a fullness in the antecubital fossa. The importance of a thorough and well-documented neurovascular examination should be obvious from the preceding discussion. Immobilization before radiographic studies is recommended to minimize the risk of further neurovascular injury. Standard radiographic views are satisfactory. They should be closely inspected for the direction of the dislocation and for the presence of associated fractures. Although most elbow dislocations can be reduced uneventfully, the risks of entrapping a fracture fragment or a nerve in the joint space during the procedure are such that immediate orthopedic consultation is recommended. A number of techniques for reduction have been described. Either conscious sedation or general anesthesia should be considered. If orthopedic consultation is unavailable, the child should be placed prone and the forearm allowed to hang over the side of the stretcher. The physician should then encircle the upper arm with his or her hands and use the thumbs to push the olecranon forward and downward. Whatever technique is used, hyperextension should be avoided at all times. Postreduction films are mandatory because only then will many of the associated fractures be evident. Finally, the arm should be immobilized in a posterior splint with the elbow at 90 degrees and the forearm in midpronation.

Radial Head Subluxation

Of all the injuries discussed in this section, by far the most common is radial head subluxation, otherwise known as “nursemaid's elbow” or “pulled elbow” (see Procedures). Pathologically, radial head subluxation occurs when the annular ligament becomes partially detached from the head of the radius and slips into the radiohumeral joint where it is entrapped. The usual mechanism is that of axial traction on an extended and pronated arm. Radial head subluxation is an injury of children a few months to 5 years of age. After 5 years of age, the strength of the annular ligament is such that the injury is uncommon.

The classic history is that of a child who cries with pain and refuses to use an arm after being pulled or lifted by that same arm. With some regularity, however, the history is one of a fall. In infants, radial head subluxation can occur when an extended arm is trapped beneath the trunk as the child is rolled over. The chief complaint is typically that the child is not using the arm; concerns about a wrist or a shoulder injury are common. Children with radial head subluxation uniformly hold the arm in pronation with the elbow slightly flexed. Much more often, the degree of distress is minimal, although supination, pronation, and elbow flexion usually elicit pain. Mild tenderness may be noted with palpation of the radial head. Significant point tenderness or swelling should suggest an alternative diagnosis (e.g., a supracondylar fracture). The radiographic findings with radial head subluxation are minimal at best. Radiographs are not routinely recommended when the history and clinical presentation are classic. Indeed, the subluxation is often reduced when the radiology technician places the forearm in supination for the anteroposterior view.

As for treatment, various reduction techniques have been described. The most widely used is that described in Section VII, Procedures, namely, supination and flexion. Should that approach prove unsuccessful, either supination or pronation with elbow extension should be attempted. When reduction succeeds, the child typically uses the arm normally within 5 to 10 minutes. The delay until normal use is longer in younger children and when there has been greater than a 4- to 6-hour period between injury and treatment. When there is no evidence of recovery, the diagnosis must be reconsidered; fractures of the elbow and clavicle in particular should be excluded because the clinical presentations can be similar. With recurrent subluxations, immobilization for a few weeks in a posterior splint with the elbow at 90 degrees and the forearm supinated is suggested. Note that even when efforts at closed reduction fail, spontaneous reduction almost invariably occurs. The need for open reduction is exceedingly rare.

Fractures of the Forearm and Wrist

Children fracture the radius and ulna more often than all bones other than the clavicle. Fortunately, the incidence of neurovascular complications is low and the potential for healing with proper management high. In many instances, the emergency physician can provide the satisfactory initial, if not definitive, management for forearm injuries. However, certain types of fractures require immediate orthopedic referral, and as such they receive particular emphasis. In this section, forearm fractures are divided as follows: 1) fractures of the radial and ulnar shafts, 2) Monteggia and Galeazzi fracture dislocations, 3) fractures of the distal radius and ulna, and 4) fractures of the bones of the wrist.

Fractures of the Radial and Ulnar Shafts

The usual mechanism of injury with forearm fractures, including those of the radial and ulnar shafts, is a fall on an outstretched hand. Direct blows account for some injuries, displaced and open shaft fractures in particular. Approximately three-quarters of all shaft fractures involve the distal third of the shaft; most of the remainder involve the midshaft. The clinical findings generally make the diagnosis self-evident. A number of fracture patterns are seen; greenstick injuries are especially common. Standard radiographic views are sufficient other than with suspected bowing fractures when comparison views may be necessary. The emergency physician should insist that radiographs of the forearm always include both a true lateral and a true anteroposterior view and both the elbow and the wrist. In general, isolated ulnar fractures do not occur, as is discussed further in the next section.

The periosteum and remaining intact cortex limit the degree of angulation with greenstick injuries. Keep in mind that many greenstick fractures have a significant rotational deformity and that the degree of angulation alone should not determine the need for closed reduction. It must also be remembered that the potential for remodeling decreases with the distance from the epiphysis and with the age of the child. Less angulation is therefore accepted in midshaft fractures than in more distal injuries and in adolescents than in younger children. Although it is hard to make any absolute rules, any shaft fracture angulated more than 10 degrees merits immediate orthopedic consultation, at least by telephone. This is

not to say that all such fractures will require reduction. (Another simple rule is that any forearm that looks crooked should be straightened.) Dorsal angulation is usual; immobilization with the arm in supination minimizes the tendency of the forearm muscles to cause further deformity.

Complete fractures can be particularly problematic, again because significant angulation can occur. Should the ends of the bones be well opposed and angulation and rotation be minimal, a well-applied sugar-tong splint is adequate initial treatment. Otherwise, immediate orthopedic referral is necessary. Closed reduction, although not always as simple as it may appear, is preferable (Fig. 115.29). In children older than 10 to 12 years, adequate alignment is often obtained only with open reduction and internal fixation.

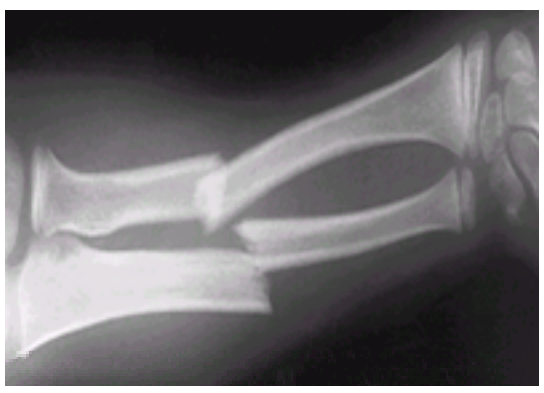

FIGURE 115.29. Complete fractures of the midshafts of the radius and ulna in a 9-year old boy. Efforts at closed reduction failed; internal fixation was necessary.

Recognition of when a bowing fracture has occurred is crucial simply because the potential for remodeling with such injuries is minimal (see Fig. 115.4). Failure to correct bowing can result in permanent loss of supination and pronation. As already mentioned, in the absence of obvious deformity, comparison views may be necessary before the true extent of bowing can be appreciated. Again, no hard and fast rules regarding indications for closed reduction are offered; however, any bowing fracture that causes obvious forearm deformity or restrictions of pronation or supination certainly merits immediate orthopedic referral.

Monteggia and Galeazzi Fracture Dislocations

In general, isolated fractures of the ulna do not occur. Instead, the same force that causes the ulnar fracture leads to a radial injury, in some instances a dislocation of the radial head. It is this combination of an ulnar fracture and a radial head dislocation that is known as a Monteggia fracture. Recognition is most important because failure to reduce the radial head dislocation results in permanent disability. Clues to the diagnosis on physical examination include elbow pain and swelling, which accompany signs of any ulnar fracture. Palpation may confirm the dislocation of the radial head, which may be displaced anteriorly, posteriorly, or laterally, depending on the mechanism of injury. A palsy of the posterior interosseous nerve, a motor branch of the radial nerve, may also be present.

If the radial head dislocation is to be recognized radiographically, the rule that a line drawn through the axis of the radius should pass through the center of the capitellum on all projections must be remembered (Fig. 115.30). Once again, the need for a true lateral view that includes the elbow with all forearm studies must be emphasized. Even bowing fractures of the ulna, which may require comparison views for recognition, are associated with radial head dislocation. Any suspected Monteggia injury requires immediate orthopedic referral.

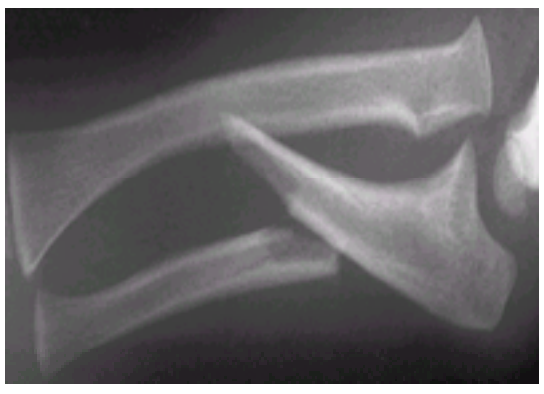

FIGURE 115.30. A Monteggia fracture in a 3-year-old boy. Note that a line drawn along the axis of the radius would fail to intersect the capitellum (compare with Fig. 115.29.)

The Galeazzi fracture is a radial shaft fracture, generally at the junction of the middle and distal thirds, that is accompanied by disruption of the distal radioulnar joint. It is relatively rare. Physical examination reveals prominence of the distal ulna and joint instability. Radiographs are confirmatory. Once again, orthopedic consultation is necessary. The complications are few with proper management.

Fractures of the Distal Radius and Ulna

Distal radial and ulnar fractures bear special mention, not because of any undue rate of complications, but rather because of their overall frequency. Of all the fractures that occur in childhood and adolescence, those of distal forearm are by far the most common. Except for the occasional instance of nerve entrapment at the time of reduction of a complete fracture, significant neurovascular complications are rare. Overall, the capacity for remodeling is significant. The difficulties facing the emergency physician are those of diagnosis with subtle fractures and of recognition regarding when reduction is necessary with displaced fractures.

More often than not, localized swelling and tenderness accompany distal radial fractures and can guide interpretation of the radiographic studies. However, wrist pain can be the chief complaint with more proximal injuries, for example, radial head fractures. Once again, the need for studies that include the whole forearm must be reinforced. Torus fractures are most often overlooked. Often, the location of the soft-tissue swelling on the radiographs helps highlight the position of the fracture, which may be evident on only one projection and then only as a minor irregularity in the contour of the cortex. A fracture of the ulnar styloid should also prompt a diligent search for a radial injury. Ulnar styloid fractures only rarely occur in isolation; as a rule, they are accompanied by either a torus or physeal fracture of the radius. When a torus fracture is identified, a volar splint or, if the swelling is minimal, a short arm cast for 3 to 4 weeks is recommended. Orthopedic referral is optional.

Greenstick and complete fractures are readily recognized. What must be remembered is that such fractures have a tendency to displace if not properly immobilized. The distal fragment is angulated posteriorly in most greenstick and complete fractures of the distal forearm. Angulation of greater than 10 to 15 degrees is an indication for immediate orthopedic referral (Fig. 115.31). Otherwise, immobilization with orthopedic follow-up within 3 to 5 days is adequate emergency management. Although there is some disagreement, immobilization with the forearm in supination is thought to decrease the likelihood of further displacement. Accordingly, either a long arm posterior splint or a well-applied sugar-tong splint are recommended with all greenstick and complete radial and ulnar fractures. Short arm volar splints should be reserved for torus injuries.

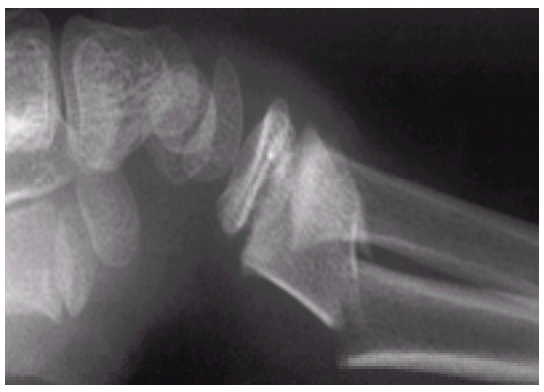

FIGURE 115.31. Complete fracture of the distal radius of a 9-year-old child demonstrating 35 degrees of posterior displacement of the distal fragment. Closed reduction was uneventful.

Salter-Harris type I and II injuries of the distal radial physis rarely lead to growth disturbance, which is fortunate because they are common injuries, particularly from 6 to 12 years of age. The issue again is one of recognition with these fractures. When point tenderness on the physical examination is accompanied by swelling localized to the distal radius on the radiograph, the presumptive diagnosis should be a Salter-Harris type I injury even when there is no obvious displacement of the epiphysis. Immobilization and orthopedic referral are recommended. Closed reduction is needed for all displaced physeal fractures. Of note is that the risk of growth disturbance increases with repeated and delayed manipulations.

Fractures of the Bones of the Wrist

The carpal bones are rarely fractured during childhood and adolescence. Adolescents in the later stages of skeletal maturity sustain scaphoid (navicular) fractures. Most injuries of the scaphoid in adolescence are nondisplaced fractures through the distal third of the bone (Fig. 115.32). The rate of nonunion is much lower than in adults, in whom scaphoid fractures generally involve the middle third of the bone and are more often displaced. The usual mechanism is a fall on an outstretched arm with extreme hyperextension of the wrist. Physical findings that should suggest the possibility of a scaphoid fracture include snuffbox tenderness, pain with supination against resistance, and pain with longitudinal compression of the thumb. As with adults, radiographic visualization of a nondisplaced scaphoid fracture may be difficult even with special views. Should the physical signs suggest a scaphoid fracture, immobilization in a thumb spica splint or cast for 2 weeks is recommended, regardless of the radiographic findings. At that time, radiographs should be repeated; fractures not detectable on the initial films should now be evident. Should radiographs remain normal but clinical suspicions high, a bone scan or an MRI study should be considered. Although the likelihood of complication is low, orthopedic referral is recommended once a scaphoid fracture is identified.

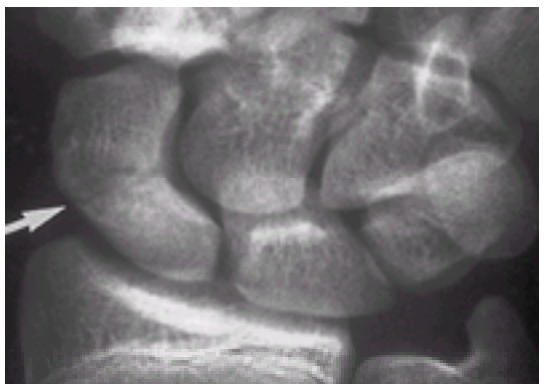

FIGURE 115.32. A scaphoid fracture in a 16-year-old boy *(arrow).* In this case, the fracture is through the middle third of the scaphoid; fractures through the distal third are actually more common during adolescence.

Injuries of the Hand and Fingers

By comparison with adults, children sustain relatively few bony injuries of the hand. The most commonly encountered hand injuries in the pediatric ED are crush injuries of the distal phalanx, in which lacerations and fractures often coexist. It has been stated that such injuries are often undertreated; definitive management often entails removal of the nail, repair of any nailbed injury identified, careful immobilization, and close follow-up. (See Chapter 116 for additional discussion of the management of such crush injuries.)

A wide variety of other injuries, including a whole array of avulsion and physeal fractures, also occur. The types of injuries seen at a given joint reflect the underlying complex anatomy of the tendons and ligaments of the hand, a full discussion of which is beyond the scope of this chapter. However, by adhering to a few basic principles of physical and radiographic diagnosis, the emergency physician should have little difficulty in recognizing which injuries merit referral to a hand specialist.

Given the risks of permanent deformity and stiffness, all displaced fractures, particularly those extending intra-articularly, should be referred. Such fractures are generally self-evident. Before concluding that a fracture is a simple nondisplaced one and thus amenable to routine splinting, the practitioner must first assure himself that there is no accompanying malrotation or joint instability. Malrotation is not always that apparent when the fingers are extended; it becomes much more obvious with finger flexion (Fig. 115.33). Joint stability must also be assessed in flexion and extension, as well as in both the lateral and anteroposterior planes. Adequate examination may be possible only after performance of a digital block. Should either malrotation or joint instability be detected, consultation is again in order.

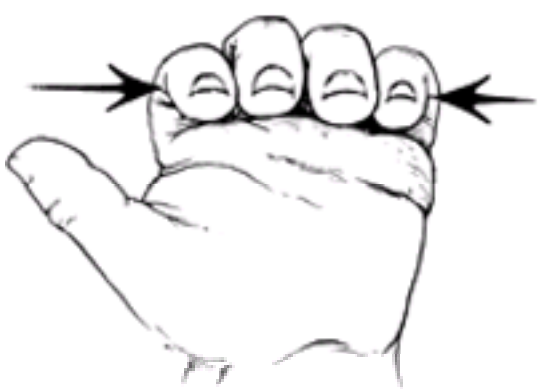

FIGURE 115.33. It is important to check for malrotation with all fractures of the metacarpals and phalanges. When flexed as shown, the fingers should all point in the same direction. If malrotation is present, overlapping will occur.

When the hand is radiographed, oblique views should be included in addition to the usual anteroposterior and lateral projections. Interpretation of the radiographs is complicated by the presence of multiple epiphyses and secondary ossification centers. It is essential to remember that the epiphyses of the phalanges and of the thumb metacarpal are located at the proximal ends of the bones. The growth centers of the remaining metacarpals are distal. Once again, the number of fractures missed will be minimized if close attention is paid to the physical findings and the presence of soft-tissue swelling on the radiographs. For the purposes of further discussion, hand injuries are divided as follows: 1) metacarpal fractures and 2) phalangeal fractures and dislocations.

Metacarpal Fractures

Perhaps the most commonly encountered metacarpal fracture in pediatrics is one of the distal fifth metacarpal in an adolescent who has struck someone or something with a closed fist. The equivalent of a boxer's fracture in an adult, these fractures are metaphyseal rather than physeal injuries and are typically angulated. Closed reduction is usually performed if the angulation is more than 30 to 40 degrees. Salter-Harris type I and II injuries occur on occasion, primarily in the second, third, and fourth metacarpals. Nondisplaced injuries may be immobilized in a gutter splint with the wrist neutral and the metacarpal phalangeal joints at 70 degrees and then referred (Fig. 115.34 and Fig. 115.35). If they are not displaced or rotated, metacarpal shaft fractures can be managed similarly. Proximal metacarpal fractures of the second through fifth metacarpals are rarely displaced; recognition is more of an issue than management (Fig. 115.36).

However, angulation is common with proximal fractures of the thumb metacarpal. Metaphyseal and Salter-Harris type II and III injuries occur and when displaced require closed reduction.

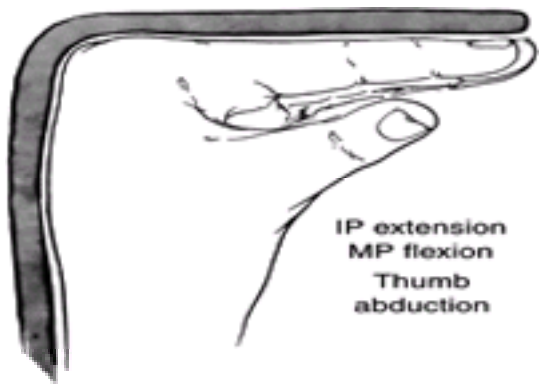

FIGURE 115.34. The hand should be splinted in this position to prevent extension contractures of the metacarpophalangeal *(MP)* joints and flexion contractures of the interphalangeal *(IP)* joints.

FIGURE 115.35. Splinting the hand in any of the positions shown here tends to promote joint contractures and recurrence of deformity.

FIGURE 115.36. Radiograph of the left hand of an 8-year-old girl showing fractures of the proximal second and third metacarpals *(arrows).* Significant displacement is unusual with proximal metacarpal fractures.

Phalangeal Fractures and Dislocations

As already mentioned, distal phalanx fractures typically accompany crush injuries of the fingertip. If only the distal tuft is fractured, anatomic closure of the laceration usually results in adequate realignment of the fracture. Displaced physeal fractures merit immediate referral (Fig. 115.37). Hyperflexion injuries of the distal phalanx, leading to so-called mallet finger deformities, are also common. In the child, Salter-Harris type I or II injuries result, whereas type III injuries are the rule in adolescents. The latter often require open reduction and internal fixation. In either case, examination reveals an extension lag at the distal interphalangeal joint. Recognition of the tendonous disruption is important, given that proper treatment entails 6 to 8 weeks of continuous splinting in hyperextension.

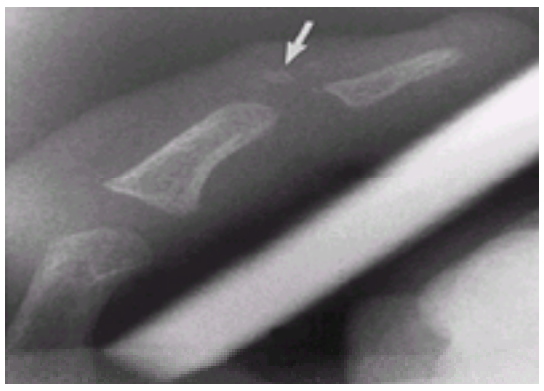

FIGURE 115.37. Displaced Salter-Harris type I fracture of the distal phalanx in an 11-month-old girl that resulted from a crush injury. The *arrow* points to the epiphysis, which is only beginning to calcify. Careful reduction is necessary if the risk of growth disturbance is to be minimized.

A whole range of proximal and middle phalangeal fractures occur, many of which the emergency physician can manage successfully (Fig. 115.38). Gutter splints that incorporate both the injured and an adjacent uninjured finger are used commonly with the positioning discussed previously. Complete fractures almost invariably angulate as the result of the actions of the intrinsic muscles, the direction of angulation determined by the position of the fracture relative to the flexor and extensor tendons. Phalangeal neck fractures are of particular concern in that complete fractures can rotate by as much as 90 degrees and unicondylar fractures are prone to displacement. The radiographic findings may be subtle; the consequences of improperly evaluating such injuries are certainly substantial. In the proximal phalanx, particularly that of the fifth finger, laterally angulated Salter-Harris type II fractures are common. If the displacement is minimal, splinting with follow-up in 3 to 5 days is acceptable.

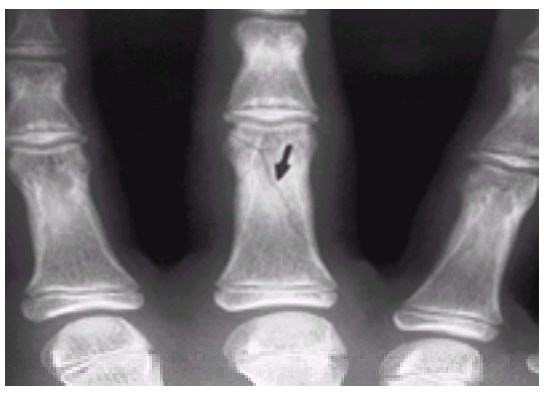

FIGURE 115.38. Oblique fracture of the proximal phalanx of the right third finger in a 12-year-old boy *(arrow).* Before splinting such an injury, the emergency physician must first make certain that no malrotation is present.

Special mention should be made of the so-called gamekeeper's or skier's thumb, an avulsion of the ulnar collateral ligament of the proximal phalanx of the thumb. Localized tenderness should raise concerns about this injury and prompt an assessment of the joint for adduction stability with the metacarpal joint extended and in 30 degrees of flexion. In the pediatric age range, this is a Salter-Harris type III injury. When there is evidence of only minor instability (firm endpoint, increased laxity of less than 30 degrees), thumb spica splinting for 3 to 6 weeks is generally sufficient. More severe injuries require operative intervention. Consultation is suggested when such injuries are suspected.

Despite the strength of the ligaments and tendons, hyperextension can lead to dislocations of the metacarpophalangeal and proximal interphalangeal joints in children. Dislocations of the proximal interphalangeal joints can usually be readily reduced (Fig. 115.39). After a digital block, the joint should be gently hyperextended and the distal bone then pushed back into place. Radiographs both prereduction and postreduction should be scrutinized for fractures and the stability of the collateral ligaments carefully assessed. Buddy taping for 3 weeks is adequate for routine dislocations (Fig. 115.40).

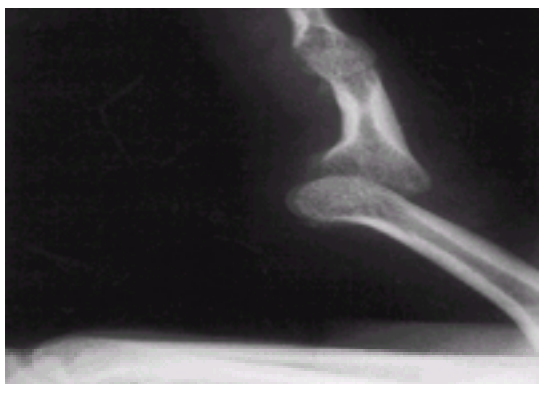

FIGURE 115.39. Dislocation of the right fourth proximal interphalangeal joint in a 15-year-old boy. Most such injuries can be readily reduced, which is not the case with metacarpophalangeal joint dislocations.

FIGURE 115.40. Buddy taping is a convenient way of splinting uncomplicated dislocations postreduction, as well as minor finger fractures.

Metacarpophalangeal dislocations are particularly problematic. Although closed reduction may be successful, often the volar plate is entrapped in the joint and open reduction is therefore necessary. Such volar entrapment can be suspected when physical examination reveals puckering of the palmar skin adjacent to the affected joint. Visualization of a sesamoid bone within the joint space is pathognomonic of volar plate entrapment. (See Section VII, Procedures, for a more in-depth review of techniques for reduction of finger dislocations.) Should an initial attempt at reduction of a metacarpophalangeal dislocation fail, the finger should be immobilized and a hand specialist consulted.

FRACTURES OF THE PELVIS

When evaluating a child with a suspected pelvic fracture, attention to surrounding viscera and to signs of blood loss are the most important immediate considerations. Pelvic fractures are caused by high-energy accidents and are often associated with head, abdominal, and vascular injuries. Overall, pelvic fractures in children have a favorable outcome and rarely require any more treatment than bed rest for 4 to 6 weeks. Exceptions to this rule include severely displaced sacral or sacroiliac joint dislocations and displaced acetabular fractures. An immediate orthopedic consultation is required for all pelvic fractures other than minor avulsions.

Pelvic fractures in children can be divided into three groups: 1) avulsion fractures, 2) pelvic ring fractures, and 3) acetabular fractures.

Avulsion Fractures

Avulsion fractures occur most commonly from sporting activities. The muscular attachments to the secondary centers of ossification (i.e., the anterior superior iliac spine, the anterior inferior iliac spine, and the ischial tuberosity) can be pulled off during strong, active contractions against resistance (Fig. 115.41). Localized tenderness is usually present. The diagnosis is usually readily apparent on plain film radiographs, although bone scintigraphy may be necessary to confirm the diagnosis on occasion (Fig. 115.42). Treatment is based on symptoms. Often, crutches with partial or no weight bearing for 4 to 6 weeks with slow resumption of activities are all that is required even with significantly displaced fractures. With widely separated (more than 2 cm) avulsion fractures of the ischial tuberosity, some authors recommend open reduction and fixation; others continue to advocate conservative treatment.

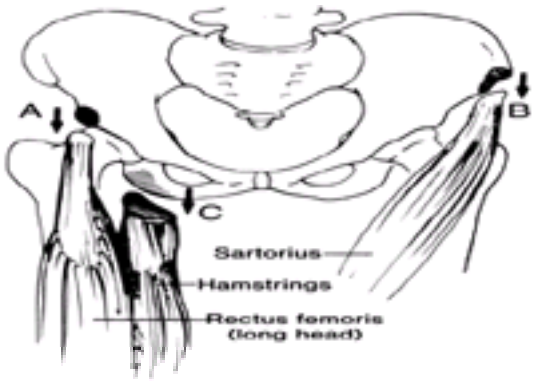

FIGURE 115.41. Common avulsion injuries of the pelvis: anterior inferior iliac spine *(A);* anterior superior iliac spine *(B);* ischial tuberosity *(C).*

FIGURE 115.42. Avulsion fracture of the right ischial tuberosity in a 13-year-old girl *(arrow).*

Pelvic Ring Fractures

Single Breaks in the Pelvic Ring

Symphysis pubis diastasis, superior and inferior pubic rami fractures, and straddle fractures are classified as single breaks in the pelvic ring. These common childhood fractures often seem worse than they are. Although they are caused by high-energy accidents, they are generally stable fractures. A careful search for accompanying genitourinary and neurovascular injuries must be made. Fractures of the superior and inferior pubic rami rarely require any treatment in the child or adolescent as long as the sacroiliac joints and sacrum remain intact. One exception to this rule is a diastasis of the pubic symphysis, which often is associated with anterior disruption of the sacroiliac joint. This fracture configuration with pubic diastasis and anterior sacroiliac joint disruption is called the open book deformity. If significant displacement occurs through the symphysis pubis, closed reduction with an external fixator or a pubic plate must be considered.

Double Breaks in the Pelvic Ring

Fractures of the pubic rami or symphysis pubis associated with displaced sacroiliac joint dislocations or sacral fractures are classified as Malgaigne's fractures (Fig. 115.43). The hemipelvis is unstable and displaced cephalad. This group of fractures is associated with a high incidence of complications, including genitourinary, abdominal, and vascular injuries. Life-threatening hemorrhage can occur from pelvic vein disruption. In severe cases of bleeding, emergent application of an external fixator or a pneumatic antishock garment in the ED with compression of the pelvis may slow bleeding by a tamponade effect. Angiographic embolization should also be considered in the face of persistent bleeding.

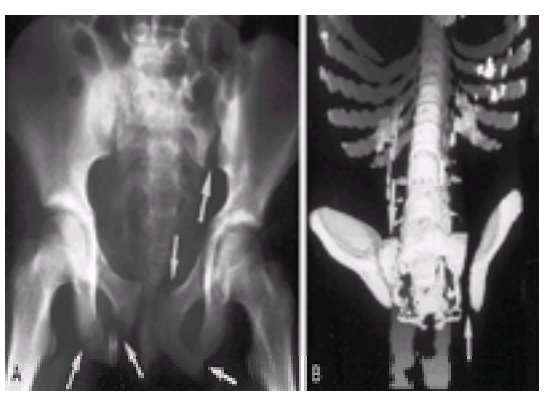

FIGURE 115.43. An unstable pelvic injury. **A.** On the plain film, multiple fractures of the pubic rami *(small arrows)* and widening of the right sacroiliac joint *(large arrow)* are apparent. **B.** On the three-dimensional reconstruction of the CT scan, the left sacroiliac fracture is even more obvious *(small arrow),* and a right-sided sacral fracture is seen as well *(large arrow).*

Initial treatment of the unstable pelvic fracture is bed rest. Special radiographic views consisting of an inlet and outlet view or CT scan assist the orthopedist in deciding whether to place the child or adolescent in traction or to undertake an open reduction and internal fixation of the posterior fracture–dislocation.

Acetabular Fractures

Fractures involving the acetabulum are rare in children. They often are associated with a dislocation of the hip joint. Attention should be directed toward obtaining an early congruent reduction and evaluating the stability of the hip. Acetabular fractures associated with major pelvic disruption should be treated like those involving double breaks in the pelvic ring. An orthopedic consultation should be obtained early and treatment of life-threatening complications initiated.

INJURIES OF THE LOWER EXTREMITIES

Injuries of the Hip and Proximal Femur

Hip dislocations and femoral neck fractures in children and adolescents are the result of high-energy accidents. The care

and resuscitation of the child is paramount before addressing the orthopedic injury. In many instances, the child can be managed in a traction splint until definitive care is given.

Injuries of the hip and proximal femur in children can be divided into five groups: 1) hip dislocation, 2) proximal femoral physeal fractures, 3) slipped capital femoral epiphysis, 4) femoral neck fractures, and 5) intertrochanteric fractures.

Hip Dislocation

Dislocation of the hip in children and adolescents is uncommon. It probably occurs more often than it is diagnosed, however, because of spontaneous reduction at the time of injury. A dislocation or fracture–dislocation is rather obvious if the injured limb is shortened, externally rotated, and painful. Radiographic examinations make the diagnosis (Fig. 115.44). In evaluating suspected dislocations of the hips with spontaneous reduction, attention must be directed to the radiographic medial clear space of the hip. If a suspected dislocation with spontaneous reduction has occurred, the medial clear space is often wider than the normal contralateral side. The posterior labrum and capsule of the joint may be detached when a dislocation occurs. At the time of reduction (either spontaneous or after closed reduction), tissue may get trapped in the joint space, resulting in asymmetry of the joint space and an incongruent reduction. Further evaluation should consist of a CT scan or MRI (Fig. 115.45).

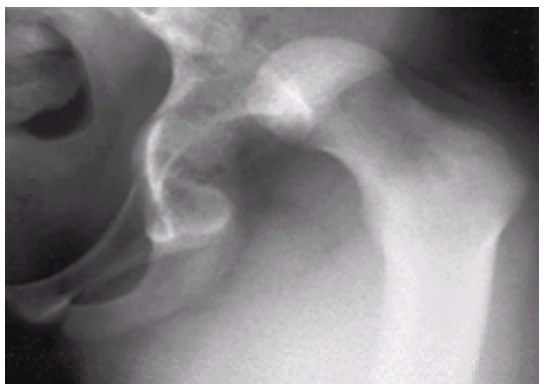

FIGURE 115.44. Dislocation of the left hip in a 9-year old boy. If dislocation is delayed beyond 6 hours, the risk of osseous necrosis rises.

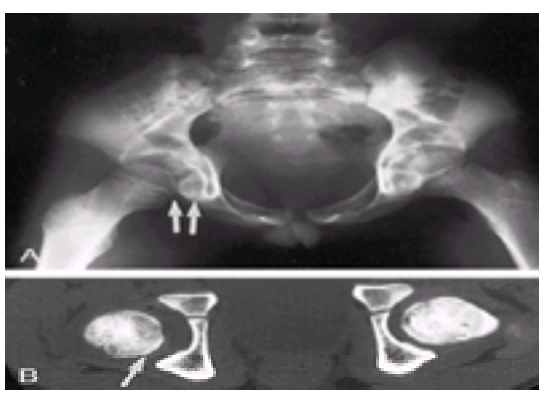

FIGURE 115.45. Radiographs taken following closed reduction of a right hip dislocation. **A.** The plain film demonstrates residual widening of the joint space *(arrows).* **B.** Widening is also apparent with magnetic resonance imaging, as is entrapment of a portion of the posterior joint capsule. Under general anesthesia, further efforts at closed reduction were successful.

A patient presenting with a dislocated hip should undergo a closed reduction in the ED or under general anesthesia. Reduction within 6 hours of the accident is essential to decrease the incidence of osseous necrosis. The technique of closed reduction consists of hip and knee flexion to 90 degrees and axial distraction of the thigh. When closed reduction is unsuccessful or when it is suspected that tissue is trapped in the joint space, open reduction is necessary. Congruency of both hips is imperative to a good result. Complications of traumatic hip dislocation in children include osseous necrosis of the femoral head, posttraumatic arthritis, and persistent instability of the hip joint.

Proximal Femoral Physeal Fractures

Proximal femoral physeal fractures occur through the zone of provisional calcification of the proximal femoral growth plate. The degree of displacement can be mild to complete (Fig. 115.46). Anatomic reduction, either by open or closed means, is essential. Unfortunately, the incidence of osseous necrosis approaches 100% in totally displaced fractures and can lead to long-term disability. In minimally displaced fractures, it may be far better to accept mild displacement than to further compromise the vascularity of the femoral head by performing a reduction.

FIGURE 115.46. Displaced Salter-Harris type I fracture of the left proximal femur in a 2-year-old boy *(large arrow).* Also seen are fractures of the right pubic rami *(small arrows).* The pelvis is disrupted posteriorly as well.

Slipped Capital Femoral Epiphysis

Although most cases of slipped capital femoral epiphysis (SCFE) present with chronic pain, a significant percentage present acutely. Several studies have suggested that structural weakness is present in the capital femoral physis during the onset of puberty. Others have identified a genetic or hormonal influence predisposing to SCFE. This malady occurs predominantly in children 8 to 15 years of age, with a male:female predominance of 2:1 to 4:1. Obese children and African-Americans are particularly susceptible.

The diagnosis of SCFE should be considered in any preadolescent or adolescent complaining of hip or knee pain. The history is often one of minimal trauma, causing pain in the hip, thigh, or knee region. Vague hip or knee pain and a limp in the preceding weeks is common. The diagnosis is made by the physical and radiographic examination. Range of motion abnormalities of the hip, in particular limitation of internal rotation, abduction, and flexion, are almost universal. When flexing the hip from the extended position, the examiner will often note external rotation. Range of motion in all directions may be painful. The radiographic examination should include anteroposterior and frog-leg views of the pelvis. Changes on the anteroposterior film may be obscure. The slip is often seen more easily on the frog-leg view. Comparison with the normal side may assist in the diagnosis. However, 10 to 25% of slips may be bilateral (Fig. 115.47).

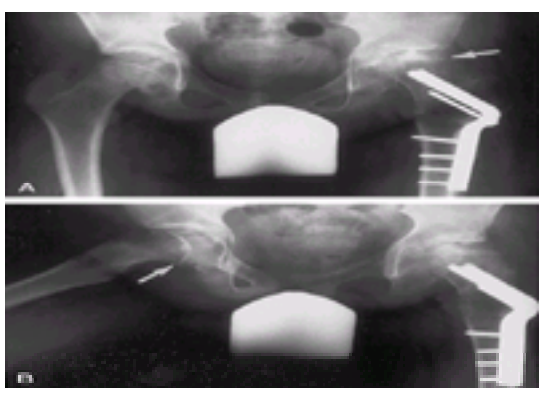

FIGURE 115.47. Radiographs of the hips of a teenager with bilateral slipped capital femoral epiphysis. **A.** Despite surgical intervention, significant avascular necrosis of the femoral head has occurred *(arrow).* The right hip appears normal. **B.** On a simultaneous frog-leg view, however, it can be seen that the right capital femoral epiphysis has slipped as well *(arrow).*

Once diagnosis has been made, treatment should consist of strict non–weight bearing and an urgent orthopedic consultation. Prompt pinning is required to prevent further slippage. This may be performed the night of assessment or shortly thereafter, depending on the availability of anesthesia.

Femoral Neck Fractures

Fractures of the femoral neck are relatively common. Initial treatment is traction and splinting followed by either closed or open reduction, depending on the position of the fracture. If the blood supply to the femoral head is damaged at the time of injury, osseous necrosis can occur. As would be expected, this complication is more likely with displaced than nondisplaced fractures. Overall, the incidence of osseous necrosis in this setting is 40% (Fig. 115.48). Stress fractures of the femoral neck are also being increasingly reported, generally in adolescents involved in repetitive activities such as long distance running. Exercise-induced hip pain should prompt consideration of the diagnosis, which may require bone scanning or MRI study for confirmation. Early recognition is important because restriction of activity may allow healing and thus prevent progression to more complete fractures with displacement.

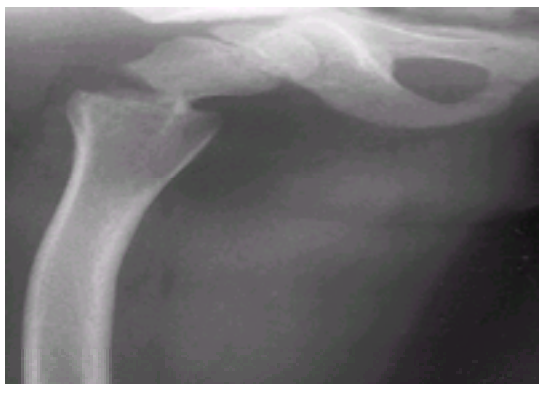

FIGURE 115.48. Fracture of the right femoral neck in a 3-year-old girl.

Intertrochanteric Fractures

Although common in adults, intertrochanteric fractures are uncommon in children and adolescents. Nondisplaced or minimally displaced fractures can be treated easily in a spica cast for 6 to 8 weeks. If significant displacement occurs, internal fixation to restore the normal anatomy may be the best approach to treatment. The incidence of complications is low in this group of patients. The rate of osseous necrosis is approximately 5%.

Fractures of the Shaft of the Femur

Femoral shaft fractures occur in all age groups, from newborn to adolescents. Each group has its specific mechanisms of injury, complications, and treatments. The following age groups are considered: 1) birth to 2 years of age, 2) 2 to 10 years of age, and 3) adolescents.

Birth to 2 Years of Age

Most femoral fractures in the first 2 years of life result from either a slow twisting motion or a direct blow (Fig. 115.49). A large percentage of femoral fractures in this age group are the result of intentional trauma. Overhead skin traction, once the cornerstone of the treatment, has fallen out of favor because of reports of neurovascular compromise and skin problems. Treatment options include immediate spica casting or a short period of Buck's traction followed by spica casting. Shortening and angulation are rarely problems in this age group, although rotational deformity can occur if careful alignment is not maintained during casting.

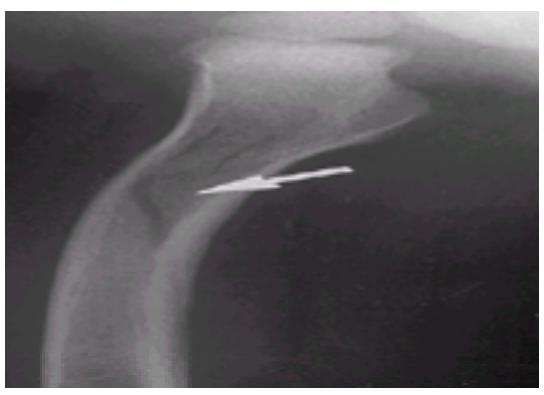

FIGURE 115.49. Spiral fracture of the right femur in a 20-month-old boy *(arrow).* In this instance, the injury occurred as the result of a motor vehicle accident. In general, spiral femur fractures in young children should prompt consideration of child abuse.

2 to 10 Years of Age

Femoral fractures in children 2 to 10 years of age are most often the result of high-energy motor vehicle or vehicle–pedestrian accidents. Concomitant injuries are common. Only rarely does an isolated femur fracture cause hemodynamically significant blood loss. Neurovascular evaluation should be performed and documented at regular intervals. Initial treatment consists of traction or splinting and care of other injuries (Fig. 115.50).

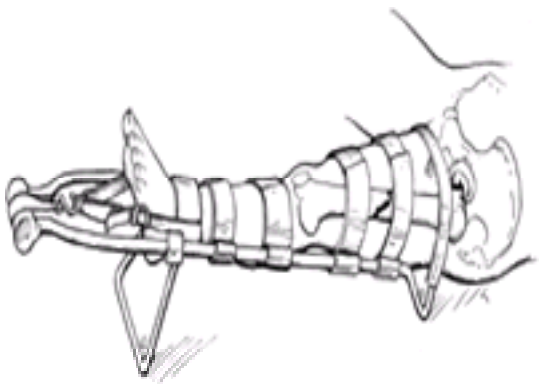

FIGURE 115.50. Use of a traction splint to stabilize femoral fractures is strongly recommended. Both adult and pediatric sizes are available.

Distal femoral skeletal traction for several weeks followed by spica cast application has been the cornerstone of treatment in the past. Recently, early or immediate spica casting under general anesthesia has replaced traditional methods. This has reduced the hospital stay and alleviated the need for the invasive intervention of the traction pin placement. Contraindications to immediate or early spica casting are shortening greater than 2.5 cm, open fractures, and major concomitant injuries. The long-term complications of femur fractures in this age group include excessive shortening or overgrowth, malrotation, and malunions of the healing femur. It is usually desirable to leave the bone fragments overlapping by 1 cm to allow for some “overgrowth” of the healing femur. Stiffness of the knee and hip has been reported following prolonged spica casting treatment but is usually not a long-term complication.

Adolescents

Femur fractures in adolescents are also caused by high-energy accidents. Once again, attention to other injuries should precede treatment of the femoral fracture. Stabilization with traction splints is adequate until an orthopedic consultation can be obtained. The management of these fractures has changed over the last several years. Closed reduction and intramedullary rodding are currently recommended to improve alignment and promote an early return to activity.

Injuries of the Knee

Although relatively uncommon, fractures about the knee arguably rank as the most serious long bone injuries in children and adolescents (Fig. 115.51). The growth centers of the distal femur and proximal tibia together account for two-thirds of the length of the lower extremity. Growth arrest and deformity can occur after physeal injuries about the knee; the resultant limb length discrepancies are hardly trivial problems. On the other hand, ligamentous injuries are uncommon. For the purposes of discussion, pediatric knee injuries can be divided into the following groups: 1) ligamentous injuries and avulsion fractures, 2) distal femoral physeal fractures, 3) proximal tibial physeal fractures, 4) knee dislocations, and 5) patellar fractures and dislocations.

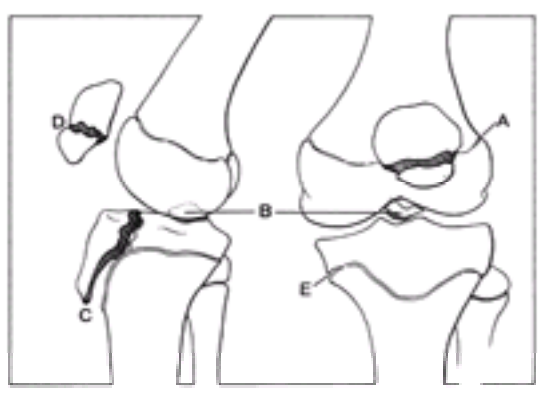

FIGURE 115.51. Common fractures of the knee in children: distal femoral physis *(A);* tibial spine *(B);* tibial tubercle *(C);* patella *(D);* proximal tibial physis *(E).*

Ligamentous Injuries and Avulsion Fractures

Compared with fractures of the epiphyses and physes about the knee, ligamentous injuries are relatively uncommon before growth plate closure. Such injuries do occur, however, both in isolation and in conjunction with fractures. Most ligamentous injuries result from direct trauma to the knee, typically when a child is struck by a motor vehicle while walking or riding a bicycle. Others occur during vigorous sporting activities when the knee is subjected to significant valgus or varus stress. The medial collateral and anterior cruciate ligaments are the ones injured most often, and injury to the latter almost invariably occurs in conjunction with an avulsion of the tibial spine.

Given the propensity for knee injuries in children younger than 14 years to result in fractures rather than ligamentous injuries, radiographs should be ordered routinely for all but the most minor injuries. Stress views after adequate sedation are necessary when routine views are normal, but the history is that of a significant valgus or varus stress. Evidence of distal femoral or proximal tibial epiphyseal separation or of collateral ligament instability may thus be uncovered. Of the growth plates about the knee, the distal femoral physis is particularly vulnerable to injury. Both the medial and lateral

collateral ligaments attach proximally to the distal femoral epiphysis. Their attachment to the tibia and fibula is distal to the epiphysis (Fig. 115.52). Given the relative strengths of the ligaments and the physeal plate, forceful valgus or varus stress results in distal femoral epiphysis separation rather than proximal tibial epiphysis injury or ligament rupture. Such injuries are discussed later in this chapter.

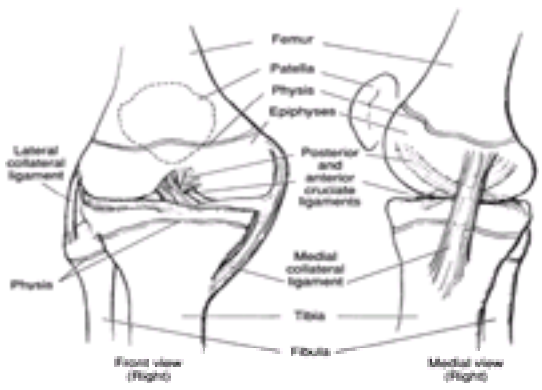

FIGURE 115.52. The ligaments of the knee. Proximally, both collateral ligaments attach to the epiphysis, whereas distally they attach to the tibia and fibula below the tibial epiphysis.

Avulsion of the tibial spine is the pediatric equivalent of an anterior cruciate ligament injury in an adult. The most commonly described mode of injury is hyperflexion of the knee during a fall from a bicycle. Significant pain and a refusal to bear weight are typical; a hemarthrosis is invariably present. Radiographic findings vary from minimal elevation of the anterior portion of the tibial spine (best seen on lateral views) to complete separation (Fig. 115.53). Incomplete separations generally can be managed by closed reduction with the knee held in extension. Open repair is necessary for complete avulsions and when closed manipulation does not lead to a satisfactory reduction. Arthroscopic evaluation of all tibial spine avulsions with instability on Lachman testing (see Chapter 39) has been advocated. Such an approach allows anatomic reduction of the injury with internal fixation and is thought to lead to a better long-term outcome. Immediate management in the ED should include splinting in extensions and arthrocentesis under sterile conditions when the hemarthrosis is causing severe pain.

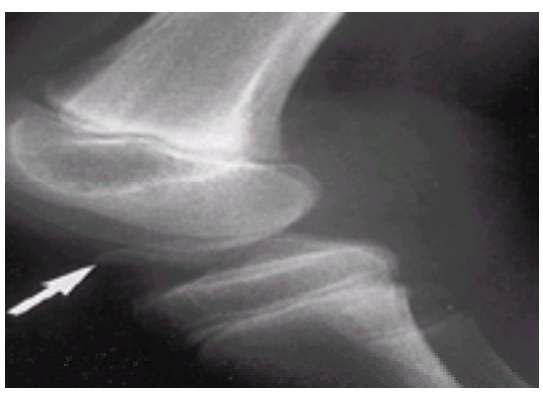

FIGURE 115.53. Avulsion fracture of the tibial spine in a 9-year-old girl. A significant hemarthrosis was present and was aspirated. In an adult, the same mechanism of injury would have resulted in a tear of the anterior cruciate ligament.

Another uncommon but severe knee injury observed in adolescents is an avulsion fracture of the tibial tuberosity. This fracture occurs essentially exclusively in boys 12 to 17 years of age who are involved in vigorous sporting activities. Most such injuries occur during jumping when the quadriceps is strongly contracted. If extension is impeded, as when a basketball player jumps to shoot but is blocked, or if the contraction of the quadriceps is particularly violent, as in high-jumping, the tibial tubercle can be torn either in part or in its entirety from the proximal tibial epiphysis. The result is a Salter-Harris type III fracture. Of note is that the patient often has an antecedent history of Osgood-Schlatter's disease. Once again, the severity of the injury dictates whether closed or open management is chosen.

Distal Femoral Physeal Fractures

Historically, fractures of the distal femoral epiphysis occurred when the leg of a child was caught between the wagon and the spokes of the wheel and thus were known as “wagon wheel injuries” during the 19th century. Today these injuries are caused by high-energy sports injuries, motor vehicle accidents, and falls from a height. Overall, this injury is rare because of the undulating course of the physis and the strong perichondrial ring that surrounds it. Of all the fractures involving the growth plate, however, injuries of the distal femoral physis have the highest incidence of posttraumatic growth arrest.

These injuries are described according to the direction of displacement of the epiphysis and the corresponding Salter-Harris classification. Most common is medial or lateral displacement with a fracture of the adjacent metaphysis (a Salter-Harris type II injury) (Fig. 115.54). As already mentioned, such injuries reflect a marked valgus or varus stress. The risk of neurovascular compromise is low, but peroneal nerve damage can accompany severe medial displacement. Even with adequate reduction, the incidence of premature growth arrest is significant. Somewhat less common is an anterior displacement of the distal epiphysis caused by hyperextension (Fig. 115.55). The risk of neurovascular compromise is high with this injury, which is the counterpart of a knee dislocation in an adult. Both compartment

syndrome and direct compression of the neurovascular structures are well-recognized complications. Posterior displacement of the femoral epiphysis is uncommon but can occur as the result of a direct blow to the flexed knee. The preferred treatment of these injuries in the ED includes a thorough evaluation with splinting in place followed by prompt orthopedic consultation. Gentle closed reduction, often using general anesthesia, is usually successful. Postreduction remodeling cannot be assured because of the high rate of posttraumatic growth arrest associated with these injuries.

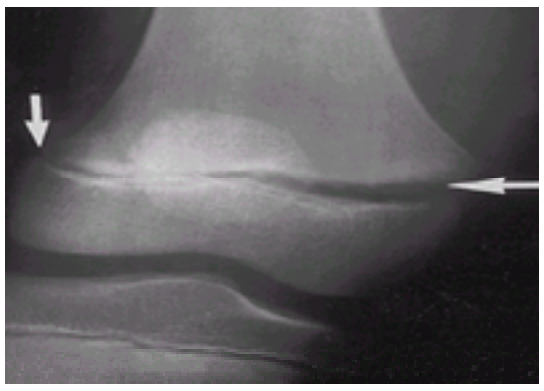

FIGURE 115.54. A Salter-Harris type II fracture of the right distal femoral physis in a 9-year-old boy. Widening of the growth plate is seen medially *(large arrow),* and a small metaphyseal fragment has been displaced laterally *(small arrow).* Closed reduction was successful. In an adult, the same mechanism of injury would have resulted in a medial collateral ligament sprain or tear.

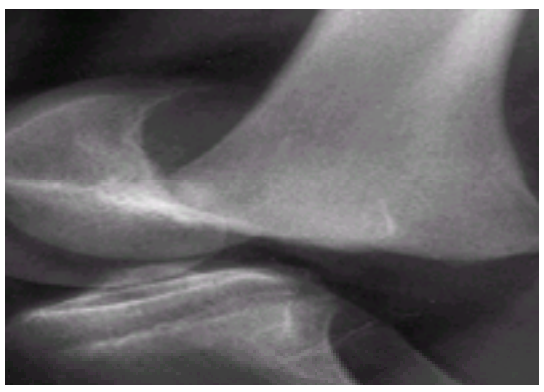

FIGURE 115.55. A Salter-Harris type I fracture of the right distal femoral physis with anterior displacement of the epiphysis in a 14-year-old boy. The injury resulted from a snowboarding accident.

Proximal Tibial Physeal Fractures

Fractures of the proximal tibial physis are also rare. Hyperextension is the usual mechanism of injury. The sheer force tears the posterior periosteum and capsule of the knee, allowing a Salter-Harris fracture to occur through the growth plate. The emergency physician must recognize that the popliteal structures are tethered at this point and are therefore vulnerable to stretch or direct contusion at the time of injury. Careful, sequential neurovascular examinations are mandatory. Compartment syndrome should be considered (p. 1441). Closed or open reduction will be necessary after stabilization. Complications after the injury include recurrent deformity, growth arrest, and limb length inequality (Fig. 115.56).

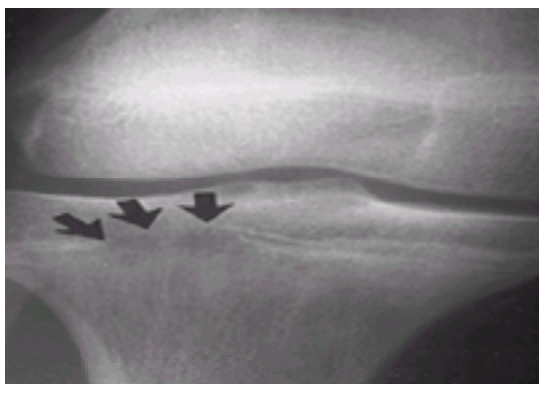

FIGURE 115.56. Although the original injury was only a Salter-Harris type I fracture of the proximal tibial physis, premature closure of the physis occurred *(arrows).* All fractures involving the proximal tibial growth plate require orthopedic referral.

Knee Dislocations

Complete dislocation of the femorotibial joint, another hyperextension injury, is extremely uncommon in children. As a

rule, hyperextension is much more likely to cause a distal femoral epiphyseal separation than a dislocation. Given the high likelihood of neurovascular compromise or compartment syndrome in this setting, femorotibial dislocation is considered a true emergency. A reduction maneuver may be attempted in the ED under intravenous sedation. Axial traction of the tibia with slow flexion of the knee from an extended position may lead to a reduction. Following a closed reduction, an arteriogram must be obtained to rule out an intimal tear of the popliteal artery. Definitive care of the torn ligaments resulting from this injury will ultimately be necessary.

Patellar Fractures and Dislocations

Unlike in the adult, the patella in the child is rarely fractured because of the thick covering of cartilage overlying the patella during growth and development. Fractures of the patella in adolescents are more common and present as avulsion fractures from dislocations, osteochondritis desiccans caused by overuse, symptomatic bipartite conditions, avulsion or “sleeve” fractures, and the occasional transverse displaced fracture (Fig. 115.57).

FIGURE 115.57. Transverse fracture of the patella in an 11-year-old victim of a motor vehicle accident *(arrow).*

Diagnosis of a patellar fracture may be difficult. A congenitally bipartite patella can be easily confused with a fracture. In this case, an accessory ossification center is located along the superior lateral margin of the patella. The margins are smooth and rounded. A comparison view of the opposite knee may assist in the diagnosis. Sleeve fractures of the patella, in particular, can easily be misdiagnosed on radiograph. The sleeve fracture occurs when the lower half of the cartilage cap is pulled free by the patellar ligament. The visible bony portion of the patella is displaced cephalad by the quadriceps mechanism. Often, a small fleck of bone is identified at the superior margin of the patellar ligament (Fig. 115.58). Pain usually prevents active extension of the knee.

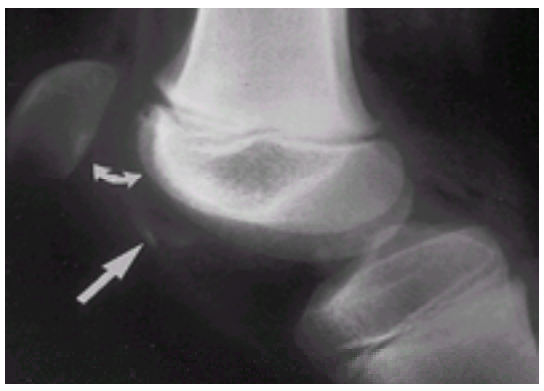

FIGURE 115.58. Radiograph demonstrating a sleeve fracture of the patella in a 10-year-old male. The inferior pole of the patella is displaced anteriorly *(curved arrow).* The bone fragment seen *(large arrow)* was avulsed by and remains attached to the patellar tendon.

The preferred treatment of patellar fractures parallels that of adults. Conservative care is the cornerstone of treatment in nondisplaced fractures. Cylindrical cast treatment from 4 to 6 weeks will result in union. Fractures that are displaced more than 3 to 4 mm are best treated with open reduction and internal fixation. Complications after patellar fractures include knee stiffness, quadriceps atrophy, extensor lag, and persistent pain.

Dislocation of the patella can be classified as an acute or chronic recurrent subluxation or as a dislocation. An acute traumatic dislocation of the patella results from a force displacing the patella laterally while the foot is planted. The patella may reduce spontaneously or may remain dislocated. Examination of the patient reveals an acutely swollen knee with pain to palpation noted along the medial patellar retinaculum. When reduction has already occurred, displacement of the patella laterally will usually elicit an apprehension sign. The patient may state that he or she feels like the knee cap is going to “pop out.” When the patella remains dislocated, the diagnosis is readily apparent by clinical and radiographic examination. Reduction of a dislocated patella usually is accomplished easily with extension of the knee and a medial upward force on the lateral patella (see Section VII, Procedures). Following reduction of an acutely dislocated patella, the physician must exclude the presence of an osteochondral fracture of the lateral femoral condyle or the medial patellar facet. Such fractures may be difficult to identify from a radiographic examination. Physical findings consistent with intra-articular loose bodies should suggest the diagnosis.

Chronic recurrent patella subluxation or dislocation is much less likely to result in osteochondral fractures. Predisposing factors include lateral femoral condyle hypoplasia, a loose medial patellar retinaculum, genu valgum, external tibial torsion, and quadriceps weakness.

The initial treatment of a dislocated patella should consist of a thorough examination, followed by closed reduction. Immobilization in an above-the-knee posterior splint or a commercially available knee immobilizer for 4 weeks is the appropriate ED management. Orthopedic referral is recommended.

Fractures of the Tibia and Fibula

Fractures of the tibia and fibula in children can be divided into the following groups: 1) proximal tibial metaphyseal fractures, 2) tibial and fibular shaft fractures, and 3) toddler's fractures.

Fractures involving the distal growth plates of the tibia and fibula are discussed with ankle injuries.

Proximal Tibial Metaphyseal Fractures

Although usually easy to manage, proximal tibial fractures can lead to two major complications, namely compartment syndrome and progressive posttraumatic valgus deformity (Fig. 115.59). As in other settings, a careful clinical evaluation followed by direct measurement of compartment pressure are the keys to the diagnosis of compartment syndrome. Progressive valgus deformity can develop after any proximal tibial injury, including greenstick and nondisplaced fractures. Deformity has been known to develop even after anatomic reduction of fracture fragments. It is speculated that stimulation of the physis from hyperemia causes asymmetric growth of the proximal tibial physis. Given the propensity for growth deformity, all fractures of the proximal tibial metaphysis should be managed by an orthopedic surgeon.

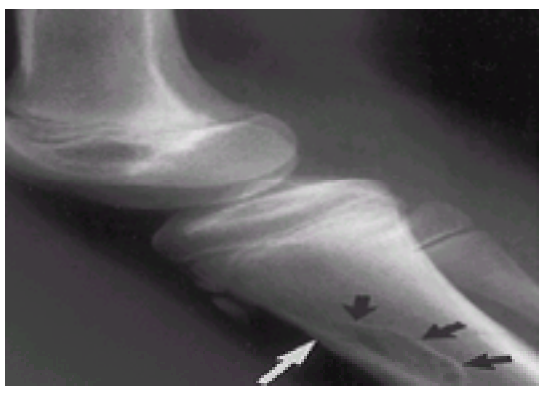

FIGURE 115.59. Nondisplaced proximal tibial metaphyseal fracture in an 11-year-old girl *(large arrow)* through a nonossifying fibroma *(small arrows).* Orthopedic consultation is mandatory both because the fracture is a pathologic one and because it is located in the proximal tibia.

Tibial and Fibular Shaft Fractures

Fractures of the tibial and fibular shafts are the most common fractures of the lower extremity in children. The diagnosis usually is apparent by physical and radiographic examination. Most tibial and fibular fractures are stable and in acceptable alignment (Fig. 115.60). Discussion with an orthopedic consultant helps decide whether any reduction is necessary. In children, these fractures rarely persist to delayed or nonunion. Healing time is quick, averaging 6 to 8 weeks. If the neurovascular status is normal, no signs of compartment syndrome are present (p. 1441), and the fracture configuration is deemed acceptable, a long leg posterior splint may be applied and orthopedic referral within the next few days arranged. Otherwise, more immediate consultation should be sought. (Most cases of compartment syndrome result from minor closed tibial fractures; with more severe injuries, the interosseous membrane typically is torn, allowing decompression of the anterior compartment.)

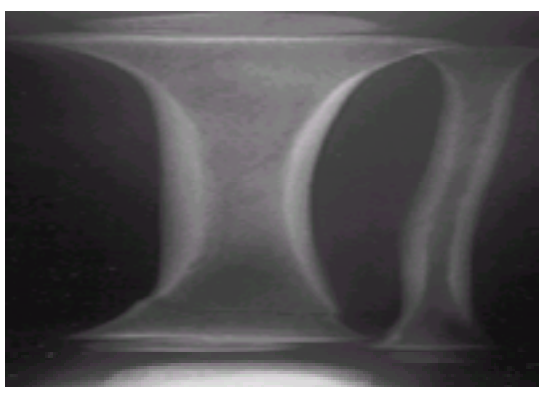

FIGURE 115.60. Nondisplaced transverse fracture of the distal tibia in a 3-year-old girl. Immobilization in a long leg posterior splint with orthopedic follow-up within 3 to 5 days would be adequate emergency treatment. The potential for growth deformity is low.

The indications for open treatment of tibial and fibular shaft fractures in children include open fractures, compartment syndrome, ipsilateral femur fractures, and concomitant severe head injuries. Complications of treatment after tibial and fibular fractures include malunion, limb length inequality, malrotation, and neurovascular deficiency.

Special consideration must be given when evaluating tibial injuries in children with paraplegia. They present with warmth and swelling over the leg or joint, which may suggest infection or inflammatory conditions rather than fractures. When identified, the fracture may be treated in a conservative manner with splints or a short 3- to 4-week period of casting.

Particular note should be made as well of the fact that the tibia and fibula are the most common sites of stress fractures in children. Overall, the proximal third of the tibia is most often affected. The history is usually that of pain and a limp of gradual onset in a child 8 to 15 years of age. Localized swelling and tenderness are present to varying degrees. Radiographs may appear normal, show limited cortical changes, or demonstrate subperiosteal new bone formation. Bone scintigraphy confirms the diagnosis in uncertain cases (Fig. 115.7). Rest is the only treatment needed.

Toddler's Fractures

Occasionally, the ED physician is asked to evaluate a young child with an acute gait disturbance, namely a limp or a refusal to walk. The differential diagnosis is a broad one (see Chapter 43). One possibility that should always be considered is that of a toddler's fracture. Originally, the term *toddler's fracture* referred to an oblique nondisplaced fracture of the distal tibia in children 9 to 36 months of age. The term is now used more loosely.

In most cases, the history is that of a minor accident, such as a fall from a seemingly insignificant height or while walking or running. No history of injury may be recalled in some instances. The physical findings are often subtle and at best difficult to elicit unless a gentle, unhurried examination is performed while the child is calm. The degree of swelling is minimal; warmth and tenderness are more commonly detected but are not uniformly present. Gentle twisting of the lower leg will elicit pain on occasion.

Like the physical findings, the radiographic abnormalities often are subtle. The anteroposterior or lateral views may reveal a spiral or oblique fracture extending downward and medially through the distal third of the tibia. If a toddler's fracture is suspected clinically but the routine radiographic views are normal, an internal oblique projection should be ordered. Consideration should also be given to the possibility of a fracture elsewhere in the limb; fractures of the femur, the foot, and rarely, the pelvis can also present with an acute limp. If no fracture is visualized on routine radiographs, a bone scan may be considered. Alternatively, if symptoms persist, it is certainly reasonable to repeat the plain films after 10 days, at which point subperiosteal new bone formation may be evident or enough sclerosis may have occurred at the fracture edges to render it visible (Fig. 115.61). Immobilization provides symptomatic relief and promotes healing, although no treatment at all may be needed if the history suggests that the fracture occurred several weeks before actual diagnosis.

FIGURE 115.61. Toddler's fracture of the distal tibia *(arrows).* Not until 2 weeks after the onset of symptoms could the fracture line be demonstrated radiographically.

If a toddler's fracture is a spiral one and the caretakers can recall no specific time of injury, suspicions of child abuse may understandably arise. Notably, midshaft fractures are more common in abused children, and most toddler's fractures are distal injuries. When other circumstances or injuries suggestive of abuse are found or when spiral fractures occur in children who are not yet ambulating, the strong possibility of nonaccidental injury should obviously be considered seriously.

Injuries of the Ankle and Foot

Injuries of the ankle and foot in the pediatric age range can be divided into the following groups: 1) ankle sprains, 2) distal tibial and fibular fractures, 3) hindfoot and midfoot fractures, and 4) metatarsal and phalangeal fractures.

Ankle Sprains

Adolescents often present to the ED complaining of ankle injuries (see Chapter 37). The differential diagnosis includes ligamentous injuries; nondisplaced Salter-Harris type I fractures; osteochondral fractures of the tibia, fibula, or talus; and avulsion injuries. Once again, before growth plate fusion, physeal injuries are much more likely than ligamentous injuries. Ligamentous injuries certainly are observed in older adolescents. The most common mechanism is adduction and inversion of the foot while it is held in plantar flexion. Of the three lateral ankle ligaments, the anterior talofibular ligament is the one most commonly injured. Injury to this ligament should be suspected when palpation just anterior to the distal fibula elicits an area of maximal tenderness. Ankle sprains are graded from I to III. In grade I injuries, ligaments are stretched but not torn. Grade II injuries include partial ligament tears without loss of stability. Complete tears of the ligamentous complex with loss of stability are present in grade III injuries. Other than with minor injuries, a three-view radiographic examination should be performed. Should the stability of a ligament be in question, stress views are

recommended.

Controversy exists regarding the appropriate care of ligamentous injuries. One schema is based on the severity of the ligamentous damage. Grade I mild sprains can be treated with an elastic wrap or air splint followed by ice, elevation, and compression for 72 hours. Crutches may be used until the patient is able to walk without a limp. Grade II and grade III injuries should be immobilized either in a cast or a posterior splint. (Because posterior splints break relatively easily, use of fiberglass and/or reinforcement with a stirrup is recommended.) Crutches are used initially. Ambulation in a cast for 3 weeks aids in initial scar formation and healing. This conservative approach with more severe sprains may help prevent recurrent ankle sprains in active athletic adolescents, as may physical therapy once the injury has healed.

Distal Tibial and Fibular Fractures

Although any Salter-Harris type I through V fracture may occur in distal physes of the tibia and fibula, several specific injury patterns are described and discussed here. Fractures involving both the growth plate and the ankle joint often need open reduction and internal fixation to ensure adequate reduction of both the physis and the joint. Only minimal amounts of displacement can be accepted at the articular surface, or altered joint mechanics will develop with possible posttraumatic pain, stiffness, and arthritis (see also Chapter 106).

Of the fractures of the distal fibula, a Salter-Harris type I injury is the most common. Tenderness and swelling are present over the growth plate on physical examination. Often the only radiographic finding is soft-tissue swelling overlying the distal fibula (Fig. 115.62). When suspicions of a Salter I injury are high, a short leg cast may be applied at the time of initial evaluation. When the diagnosis is less certain, immobilization with a repeat examination in a week to 10 days is recommended. If tenderness persists, a presumptive diagnosis of a type I fracture should be made and a walking cast applied. After 10 days, repeat radiographs may reveal periosteal changes confirming the presence of a fracture. In most cases, a total of 3 weeks of immobilization is adequate.

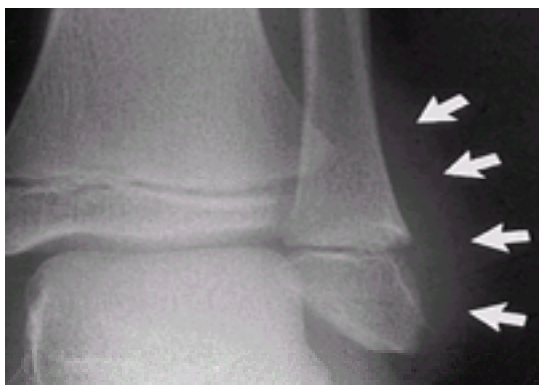

FIGURE 115.62. Radiograph of the left ankle of a 10-year-old boy notable only for soft-tissue swelling localized to the distal fibula *(arrows).* The presumptive diagnosis must be a Salter-Harris type I injury of the fibula.

Although type I injuries of the tibia are uncommon, type II injuries are often observed, usually in combination with a greenstick fracture of the fibula. The mechanism of injury is plantar flexion with eversion. Closed reduction and a long leg cast application usually lead to a satisfactory recovery. Growth disturbance is unusual.

The Tillaux fracture is a Salter-Harris type III injury of the ankle joint that occurs as the medial distal tibial physis begins to close in adolescents who are nearing skeletal maturity (Fig. 115.63). During external rotation of the foot, the anterior tibiofibular ligament avulses the lateral epiphysis from the medial malleolus. When displacement occurs, open reduction with internal fixation is required to ensure restoration of joint anatomy.

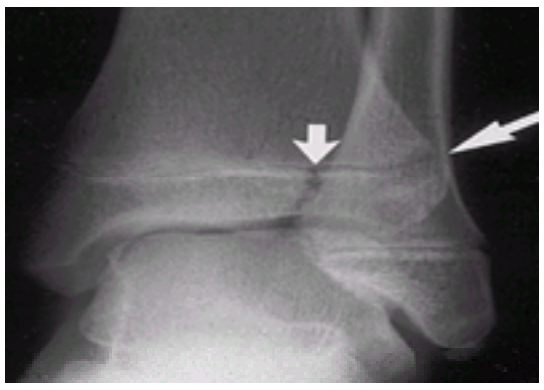

FIGURE 115.63. Classic Tillaux fracture of the distal tibia in a 14-year-old boy. The fracture line runs vertically through the epiphysis *(small arrow)* then laterally along the physis *(large arrow).* The lateral portion of the physis is widened.

The triplane fracture is a complex but uncommon ankle injury that is a combination of a Salter-Harris type II fracture and a Tillaux fracture. The resultant type IV injury may appear innocuous on the anteroposterior and lateral radiographs, but the degree of growth plate damage is generally significant. Suspected triplane fractures should be evaluated by CT scan to delineate the amount of displacement at the physis and the articular surface and to determine the number of fracture

fragments (Fig. 115.64).

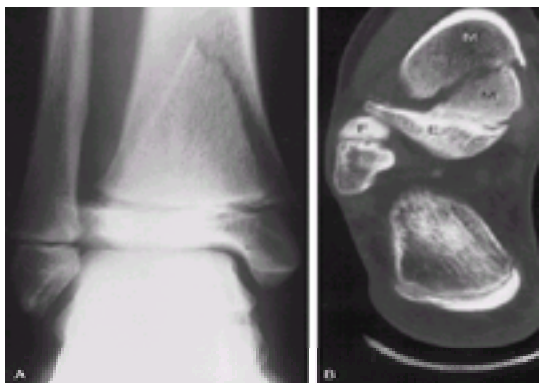

FIGURE 115.64. A. A triplane fracture was suspected from the plain film of the right ankle of this 11-year-old girl, although no clear epiphyseal fracture line could be seen. **B.** The coronal computed tomography scan made it possible to establish that the injury was indeed a Salter-Harris type II injury rather than the triplane fracture suspected. The fracture line runs laterally along the growth plate. *E,* epiphysis; *F,* fibula; *M,* tibial metaphysis.

The treatment of physeal and ankle fractures depends on the type of fracture, the amount of displacement, and patient's the age. Nondisplaced fractures may be treated with a bulky posterior splint, crutches, and a referral to the orthopedist. Immediate orthopedic referral is otherwise necessary.

Hindfoot and Midfoot Fractures

Fractures of the foot in children are uncommon and lead to few complications. Fractures of the hindfoot, which consists of the talus and the calcaneus, are particularly uncommon. When they do occur, they are usually obvious because of swelling, pain, and occasionally, deformity. “Occult” fractures of the calcaneus have been increasingly recognized in children less than 3 years of age. Pain with dorsiflexion may indicate a talar neck fracture. Should suspicions of a fracture be high but routine radiographs normal, additional views and/or bone scintigraphy may be necessary. Because calcaneal fractures generally occur as the result of a fall from a height, associated compression fractures of the spine can occur and must be considered. Treatment of hindfoot fractures are dictated by the amount of displacement. Often, a bulky posterior splint, crutches, and no weight bearing will suffice until an orthopedic consult can be obtained. Complications include osseous necrosis of the talus and chronic pain from calcaneal fractures.

Fractures of the midfoot include the navicular; the cuboid; and the first, second, and third cuneiforms. Fractures of these bones are extremely unusual and usually form part of a more severe injury to the foot (Fig. 115.65). They can be produced by blunt trauma, in which case soft-tissue damage is usually significant and a potential for neurovascular compromise results. Occasionally, an accessory ossification center on the medial side of the navicular may be confused with a fracture.

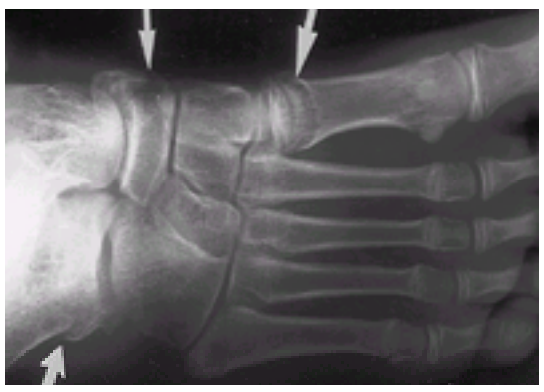

FIGURE 115.65. Radiograph of the right foot of a 13-year-old boy demonstrating fractures of the calcaneus *(small arrow),* scaphoid *(medium arrow),* and the first metatarsal *(large arrow).*

Although well documented in the adult literature, tarsal/metatarsal fracture–dislocations have received little attention in children. These injuries present with swelling and tenderness over the dorsum of the foot. Radiographs, including anteroposterior, lateral, and oblique views, may be necessary to identify subtle abnormalities. Once again, treatment is based on the severity of the injury with reduction and stabilization necessary if more than 2 mm of displacement is identified.

Metatarsal and Phalangeal Fractures

Metatarsal and phalangeal fractures are common in children. The diagnosis is not difficult because pain, swelling, and occasionally, a deformity accompany the fracture. Radiographic evaluations should include anteroposterior, lateral, and oblique views. The possibility of compartment syndrome must be kept in mind with crush injuries or multiple fractures in the midfoot or forefoot.

Two fractures that occur commonly at the base of the fifth metatarsal bear mentioning. The Jones fracture is a fracture at the diaphyseal–metaphyseal junction at the base of the fifth metatarsal. Although more common in adults, reports in adolescents can be found. This fracture has a high incidence of delayed or nonunion and should be splinted and referred to an orthopedist. An avulsion fracture of the base of the fifth metatarsal at the site of attachment of the peroneus brevis is relatively common in children. This fracture occurs more proximally than the Jones fracture and has a better prognosis. The usual treatment is 3 to 6 weeks of immobilization in a weight-bearing cast. When considering the possibility of a proximal fifth metatarsal fracture, care should be taken to distinguish a fracture fragment from the accessory ossification center found in the same location.

The care of most metatarsal and phalangeal injuries is relatively straightforward. If the fracture is nondisplaced or minimally displaced with little angulation, as is the usual case, a bulky splint can be applied and crutches prescribed. Intra-articular fractures of the big toe and significantly displaced fractures of the other toes often require pinning (Fig. 115.66). Buddy taping and hard-soled shoes provide adequate stabilization for most other phalangeal fractures.

FIGURE 115.66. Displaced fractures of the right second, third, and fifth, proximal phalanges in a 7-year-old girl *(arrows).* Stability and proper healing of the fractures of the second and third toes could be guaranteed only with pinning.

INJURIES OF THE THORACOLUMBAR SPINE

Fortunately, injuries to the spine are rare in children and adolescents. When a child does have a spine injury, distinguishing what is normal from what is abnormal on plain radiographs can be extremely challenging. The advent of CT scans and MRI has made evaluation of spinal injuries much less problematic.

The child's spine differs from the adult's in that growth plates are present, the proportion of cartilage is higher, and the overall flexibility is greater. Because of the overall high elasticity of the pediatric spine, significant spinal cord injury can occur in the absence of radiographic signs of bony injury. By adolescence, the spine has mechanical qualities more like those of the adult, and the fracture patterns are similar. Unlike in adults, the risk of posttraumatic scoliosis after a complete spinal cord injury in children is extremely high.

In general, any child with significant head or multisystem injury should be assumed to have a spinal injury until proven otherwise. Diagnosis of a spinal injury in the child with a severe brain injury can be particularly problematic. However, certain physical findings can suggest the possibility of a coexisting spinal cord injury and should be sought routinely whenever a child with a severe head injury is examined. These findings include asymmetry of movement and reflexes between the arms and legs, absence of sacral reflexes, lax anal tone, priapism, spinal shock, autonomic hyperreflexia, diaphragmatic breathing, and urinary retention, as well as any evidence of a motor or sensory deficit level. When a child is sedated and/or paralyzed, as often is the case when a child has a severe brain injury, many of these findings will be particularly difficult to elicit. Therefore, spinal immobilization must always be maintained until a more detailed neurologic examination becomes possible. Another setting in which spinal cord injuries are overlooked on occasion is that of the lap belt complex, which is discussed in the following.

It is important to classify spine injuries according to the neurologic deficits to make possible a determination of prognosis. A complete lesion involves the entire cord at a given level with no motor or sensory function below that level. An incomplete lesion is associated with sparing of function or sensation below the level of injury; the degree of motor deficit is generally greater than the degree of sensory loss. After a thorough neurologic examination, a complete radiographic evaluation is necessary to determine the stability of the fracture. When faced with equivocal radiographs, flexion–extension views, CT scans, and MRI should be considered. Patients with a neurologic injury should be considered to have an unstable fracture until proven otherwise.

Initial treatment in the ED must focus on maintaining the stability of the spine with a backboard and a cervical collar. Patients should not be moved unless absolutely necessary. Patients can be log-rolled to inspect the spine as long as flexion, extension, or twisting movements do not occur. After stabilization of the patient and the spinal column, orthopedic and neurosurgical consultations should be obtained. Early intervention can decrease the risk of further injury to the spine in unstable, incomplete spinal injuries. Current data suggest that administration of high-dose corticosteroids within 8 hours to teenagers and adults with acute spinal cord injury improves neurologic recovery. Although data for younger children are lacking, it seems reasonable at this time to recommend that steroid therapy be strongly considered for any pediatric patient with evidence of an acute spinal cord injury. According to the protocol, methylprednisolone 30 mg/kg should be administered intravenously over 15 minutes. An infusion of 5.4 mg/kg per hour should then be begun 45 minutes after the completion of the bolus.

Fractures of the spine in children and adolescents can be divided into the following groups based on the mechanism of injury and the radiographic appearance: 1) compression fractures, 2) flexion and distraction fractures, 3) shear fractures, and 4) neurologic injuries without fractures.

Compression Fractures

Compression fractures result from hyperflexion producing an axial load and causing failure of the anterior vertebral body. Multiple fractures are the rule rather than the exception; the first lumbar vertebra is the most commonly injured segment (Fig. 115.67). Compression fractures heal quickly in children and have little tendency to progress. Many children do not require hospitalization for compression fractures and can be treated with bed rest and symptomatic mobilization. Occasionally, a well-molded thoracolumbar sacral orthosis may be necessary for persistent pain or multiple areas of compression.

FIGURE 115.67. Compression fractures of the lumbar vertebrae in a 3-year-old boy *(asterisks).* Multiple fractures are the rule in children.

Flexion and Distraction Fractures

Flexion–distraction injuries are rare in the immature spine. When they do occur, the most common mechanism of injury is hyperflexion over a seat belt during sudden deceleration in a motor vehicle accident. Associated intra-abdominal injuries, particularly tears and transections of the duodenum, jejunum, and mesentery, are common. This combination of spinal and abdominal injuries is often referred to as either the seat belt syndrome or the lap belt complex. The tendency for lap belts to ride higher on children than the recommended position across the iliac crest combined with their relatively higher center of gravity predisposes them to both the abdominal and spinal injuries. A so-called seat belt sign, an abdominal contusion in a band corresponding to the seat belt, is often observed. Instances in which diagnosis of the spinal injury has been delayed because of the presence of the abdominal injury, as well as the reverse, have been described; the discovery of one component of the lap belt complex should obviously prompt a search for the other.

The lumbar spine is most commonly injured as the result of hyperflexion over a seat belt. Among the spinal injuries that can occur are distractions, subluxations, facet dislocations, and ligamentous ruptures, as well as fractures, including compression fractures as previously discussed. One particular fracture, the Chance fracture, merits special mention. A horizontal splitting through both the body and posterior elements of a vertebra, the Chance fracture was formerly thought to occur exclusively in adults. It is now recognized that the same fracture pattern occurs in children, almost always as a seat belt injury (and, once again, often in combination with an abdominal injury). Most Chance fractures are stable; associated neurologic injury is uncommon. Immobilization with a well-molded orthosis for several months is generally adequate treatment.

Shear Fractures

Although the cervical spine is most vulnerable to shear injuries, violent trauma can cause such injuries in the thoracic and the lumbar spine as well (Fig. 115.68). Unfortunately, neurologic deficits are common in this setting. All shear fractures should be considered unstable injuries that will need stabilization procedures to avoid progressive deformity and enhance any possibility of neurologic recovery.

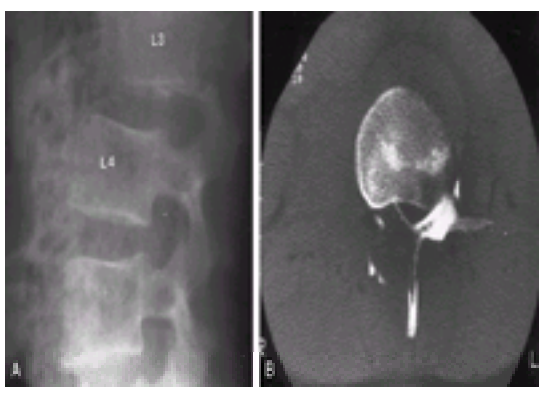

FIGURE 115.68. A. Fracture dislocation of the third *(L3)* and fourth *(L4)* vertebrae in a 12-year-old girl, the result of a shear injury in a motor vehicle accident. **B.** Permanent paralysis of the lower extremities resulted, as suggested by the

degree of collapse of the spinal canal seen on the computed tomography scan.

Neurologic Injuries without Fractures

It is well known that the immature spine is more flexible than the spinal cord. Injuries causing hyperflexion or extension may produce damage to the cord and neurologic injury while leaving the bony, cartilaginous, and ligamentous structures intact. Termed SCIWORAs (Spinal Cord Injury WithOut Radiographic Abnormality), two-thirds of such injuries occur in children less than 8 years of age. Cervical and thoracic spine injuries are the most common. Both incomplete and complete neurologic deficits can occur. Any history of neurologic deficit following spinal trauma should prompt consideration of a SCIWORA. As for radiographic evaluation, MRI can best identify cord damage in the absence of a fracture. To reemphasize, in all cases of severe trauma, spinal immobilization must be maintained until the patient's condition permits a satisfactory neurologic examination.
