CHAPTER 116

Minor Trauma—Lacerations

STEVEN M. SELBST, MD and *MAGDY ATTIA, MD

*Department of Pediatrics, *Jefferson Medical College, Thomas Jefferson University, and Division of Emergency Medicine, PEM Fellowship Program, A. I. duPont Hospital for Children, Wilmington, Delaware*

LACERATIONS

Each year an estimated 12 million wounds are treated in emergency departments (EDs) in the United States. Lacerations account for 30 to 40% of all injuries for which care is sought in a pediatric ED. Broken glass, wooden furniture, asphalt or concrete, or other sharp objects cause most of these lacerations. Animal bites also account for many. More than 40% of the wounds involve a fall. Boys are the injured victims twice as often as girls. The mechanism of injury varies with patient's age. Household items, fences, and trees most likely injure preschoolers; violent encounters injure older children.

Two-thirds of the injuries occur during warm weather months, although half of the injuries in an urban environment occur indoors. Deaths from minor lacerations are rare; however, complications occur in about 8%. Complications include infection, hypertrophic scarring or keloid formation, and poor cosmetic results.

Pathophysiology

Wound Healing

Normal skin is under constant tension, produced, in part, by underlying joints and muscles. The amount of tension varies by anatomic location and position of a body part. For example, skin overlying a joint will vary in tension, depending on whether the joint is flexed or extended. Lacerations that run parallel to joints and normal skinfolds usually heal more quickly and with better cosmetic results. Wounds under a large amount of tension, crossing joints or perpendicular to wrinkle lines often heal with wide, unattractive scars. When skin is injured, sutures may be placed to provide temporary support until the skin can regenerate and overcome tension to allow wound closure.

A wound such as a laceration regains about 5% of its previous strength 2 weeks after injury and 30% after 1 to 2 months. It reaches full tensile strength 6 to 8 months after the original injury. Many factors, such as infection, tissue edema, and poor nutrition, may delay this progression.

All wounds deeper than the dermis have the potential for scar formation. Scar formation involves the laying down of collagen, which is a complex process essential in restoring tensile strength of the skin. Collagen synthesis begins within 48 hours of the injury and reaches a peak within the first week afterward. Anything that interferes with collagen synthesis, such as infection, may lead to wound dehiscence at this time. Wound contraction is expected with all healing wounds through the action of fibroblasts. Therefore, eversion of suture lines is desired at the time of repair so that the skin will contract to a flat wound during healing. Remodeling may occur for up to 12 months. Thus, the scar may fade and recede over the first 3 months, and the final appearance of the scar may not be apparent until 6 months after injury.

Wound Infection

Wound infection plays a major role in wound healing. Bacteria inhabit normal intact skin. This is the usual source of infection when skin tissue is disrupted. The amount of bacteria on the skin varies by anatomic location. High counts of bacteria are in moist areas such as the axilla and perineum. Low counts of bacteria are in dry areas such as the back, chest, and abdomen. High bacteria counts can also be expected in areas of exposed skin such as the hands, face, and feet. Areas colonized with high bacterial contamination are most prone to infection. Wounds in regions of high vascularity, such as the scalp and face, more easily resist bacterial infection despite the high bacteria count. Certainly, the oral cavity is highly contaminated with bacteria, and this is an important source of infection when a child sustains a

bite wound.

Wounds inflicted by shearing forces with a sharp object such as a knife cause minimal devitalization of adjacent areas and thus are less likely to lead to infection. Wounds caused by a blunt object striking the skin at an angle of less than 90 degrees result in a tension injury such as an avulsion or flap. These injuries involve a larger force applied to the skin than that of a shearing injury, and there is more devitalized tissue. They are more likely to become infected than shearing injuries and are often more difficult to repair. Finally, compression injuries from blunt trauma to the skin at about a 90-degree angle, cause the most tissue disruption and devitalization. They are characterized by ragged edges and lead to the highest infection rates and unacceptable scarring.

Clinical Manifestations

History

In the evaluation of a laceration, it is important to learn the *mechanism* of the injury because this may radically change management plans. For instance, if the wound was caused by an animal bite, the likelihood of devitalized tissue and infection is higher and repair may be omitted (see Chapter 91). Also, a wound caused by a blunt object may be associated with an underlying fracture or crush injury. Certain crush injuries, such as wringer injuries, are inherently more complicated and may require surgical consultation and hospital admission. A wound caused by a sharp object may have injured deeper tissues. The *age* of the wound should be determined, as well as the possibility of a *foreign body* in the wound.

The *location* of the wound must also be considered. If the wound is in the neck area, the physician should consider possible extension through the platysma muscle, with potential for a serious injury to underlying structures. If the wound involves the chest, the physician should look for crepitance in the subcutaneous tissue, suggesting injury to the underlying lung. An injury to the lower extremities is more likely to result in infection because of the relatively poor blood supply. Likewise, a wound overlying a joint space can be complicated if the joint cavity is violated. Injury to distal body parts such as the ear, nose, and fingers may threaten the viability of more distal tissues because of vascular compromise. Conversely, in areas where the vascular supply is good, such as the face, scalp, and tongue, the infection rate is low regardless of the mechanism of injury.

The *environment* in which the injury occurred should also be assessed. If the injury occurred on the street, it is possible that small particulate matter may be embedded in the wound. If this debris is left in place, tattooing of the skin could result, leaving an unfavorable appearance to the healed wound. Injuries that occurred in a field; farm; or a wet, swampy area may have high bacterial loads.

The patient's *health status* should be addressed. If the patient has diabetes, immunosuppression, malnutrition, or other chronic conditions, such as cyanotic heart disease, chronic respiratory problems, or renal insufficiency, higher infection rates may be anticipated. Bleeding disorders and current medications should be determined because some drugs, such as ibuprofen and corticosteroids, may have an impact on the wound. *Allergies* to latex, antibiotics, and local anesthetics, as well as the child's *tetanus status,* should be ascertained.

Physical Examination

A careful physical examination is essential before local anesthesia is given. First, determine whether there is an associated injury distant from the obvious wound. Wound management should not preempt care of more life-threatening injuries. It is important to assess the wound for *vascular damage* and to control bleeding if present. Brisk flow of dark blood may indicate injury to a major superficial vein. These vessels can usually be safely tamponaded and later ligated or sutured. Arterial bleeding is suspected when there is rapid flow of bright red blood. The bleeding site must be identified, although it is often obscured by profuse bleeding. Pressure applied to the site or temporary use of a tourniquet or inflated blood pressure cuff (less than 2 hours) controls hemorrhage and allows identification of the bleeding vessel. Blind clamping of an artery should be avoided except in the scalp. Palpation of pulses and capillary refill distal to the site of injury must be checked.

Next, potential *nerve damage* must be assessed. In an older, cooperative child, the physician should always test the median and ulnar nerve of an injured upper extremity. If a young child does not permit this, sensation may be tested with use of pinprick. Fortunately, when sensation is intact, motor function of the nerve is usually intact as well.

Next, the wound must be evaluated for possible *tendon injury.* The superficial location of extensor tendons of the dorsum of the hand predisposes them to injury. Tendon injuries are sometimes visible if the wound is wide and deep. For example, a torn tendon on the flexor surface of the forearm may be seen when the patient with a laceration to the wrist is asked to flex the hand and wrist. Unless the tendon injury is obvious, wounds over joints and tendons should be put through a full range of motion. A young patient may be too uncooperative to flex and extend the fingers on command. Therefore, it is important to inspect the resting position of the injured hand in a young child to note a flexor tendon injury to the finger. One digit may be found extended at rest, while the other uninjured digits are flexed (Fig. 116.1). Applying a noxious stimulus and noting inability to withdraw the finger that is tested may show injury to the extensor tendons.

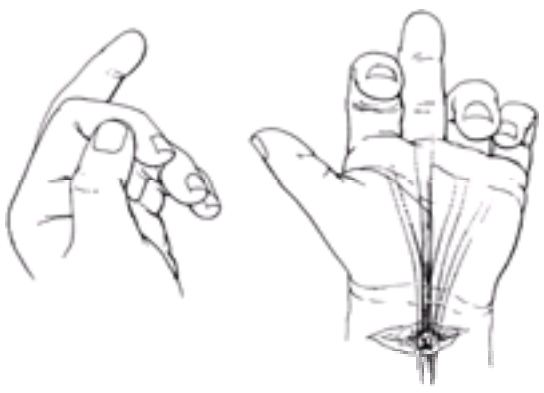

FIGURE 116.1. A seemingly superficial laceration at the wrist might be treated simply by closure of the subcutaneous tissue and skin, unless one appreciates the abnormal posture of the middle finger when the hand is at rest. The loss of normal flexor tone as a result of a divided superficial tendon results in the involved finger lying in a position of relative extension.

It should be determined whether *foreign material* is in the wound. If the history or physical examination suggests a radiopaque foreign body, obtaining a radiograph for confirmation should be considered. This is especially important in assessing a wound caused by glass. A deeply embedded piece of glass may be missed without radiographs. Some recommend obtaining such films in all cases in which glass is involved, except for the most superficial wounds. Ultrasound is also useful in selected cases for detecting and localizing foreign bodies. Further inspection for foreign material should take place after the wound is anesthetized.

Finally, *bones* nearby the wound should be palpated for crepitance, tenderness, or deformity, which may suggest a fracture. Radiographs should be obtained to confirm suspicious findings. Wounds overlying a fracture deserve consultation with a specialist for possible repair in the operating room. Table 116.1 summarizes general principles of wound assessment.

Primary survey—control bleeding	Physical Examination
Secondary survey—other injury?	Location
History	Muscle function
Mechanism	Tendon involvement
Age of wound—time of injury	Vascular injury
Possible foreign body	Nerve injury
Environment	Foreign material
Health status—tetanus	Laboratory
	Consider radiographs or ultrasound if a foreign body or fracture is suspected

Table 116.1. Wound Assessment—General Principles

Patients found to have vascular, nerve, or tendon injury or deep, extensive wounds to the face merit consideration for referral to a surgical specialist for possible repair in the operating room.

Decision to Close the Wound

Children are less likely to get wound infections compared with adults. In children, the infection rate is about 2% for all sutured wounds. Thus, most wounds may be closed primarily, meaning the wound edges are approximated as soon after the injury as possible to speed healing and improve the cosmetic result. If primary closure is long delayed, the risk of subsequent infection increases. However, the length of time before the risk of infection becomes significant is variable. Some authors suggest that the “golden period” for wound closure is 6 hours. However, wounds at low risk for infection (e.g., a clean kitchen-knife injury) can be closed even 12 to 24 hours after the injury. In a study from a developing country where patients presented with wounds after variable delays in care, it was found that wounds of the face and scalp heal well in more than 90% of cases, regardless of the time from injury to repair.

Most wounds of the face are best closed primarily, even up to 24 hours after injury to achieve an optimal cosmetic effect. If the wound is extensive or has a high potential for infection (e.g., a dog bite on the face), thorough irrigation is essential, and in some cases, the operating room may be the best site for this. On the contrary, wounds at high risk for infection such as those in anatomic locations with poor blood supply, contaminated or crush wounds, and those involving immunocompromised hosts should be closed promptly, within 6 hours of injury. Some contaminated wounds (animal or human bites or those occurring in a barnyard) in an immunocompromised host should not be sutured, even if the patient presents immediately for care. Thus, the decision to close a wound must be individualized.

Some wounds should be allowed to heal by *secondary intention* (secondary closure), although scar formation may be more unsatisfactory. Infected wounds, ulcers, and many animal bites are best left to heal by granulation and reepithelialization. Puncture wounds to the foot, with only a small laceration and a low concern for cosmetic results, may also be left open. A small sterile wick of iodoform gauze may be placed inside the wound to keep the edges open. This

gauze can be removed after 2 to 3 days, and the subsequent granulation tissue will aid healing.

If a wound is not closed initially, *delayed primary closure* (tertiary closure) should be considered after the risk of infection decreases, about 3 to 5 days later. This is recommended for selected heavily contaminated wounds and those associated with extensive damage such as high-velocity missile injuries, crush injuries, explosion injuries of the hand, and perhaps bite wounds. The wound should be cleaned and debrided and covered at the time of initial presentation, then reassessed in a few days for infection. It is believed that a contaminated but healing wound gradually gains sufficient resistance to infection to permit uncomplicated closure at a later time. This may still reduce discomfort and lead to a better cosmetic result than no repair at all. Tertiary closure is used rarely in pediatrics because children have few severely contaminated wounds from farm or industrial injuries.

Management of Lacerations

Preparing the Child and Family

It is important to reassure the child and the family that everything will be done to care for the wound appropriately and to relieve the patient's pain and anxiety. In many cases, early removal of blood and foreign material from the surface of the wound is reassuring. Also, carefully chosen words will reduce fear and pain from the procedure. The physician must honestly warn the patient of an impending painful stimulus but may leave open the possibility that it may not hurt as much as the child thinks. Appearing unhurried and confident, giving the child some control of the situation, and explaining the upcoming procedure seems to help reduce anxiety and pain. The parent(s) and child should be informed that steps will be taken to make the procedure as quick and painless as possible, such as with the use of topical anesthetics. The clinician should provide an age-appropriate empathic explanation, rather than give cold, impersonal instructions about a painful procedure to reduce anxiety. Prepare frightening instruments, such as needles and scalpels, away from the child. Allow the child to listen to music or view age-appropriate, entertaining videos during the procedure because this may serve as a distraction (see Chapter 4).

Some debate exists about the value of allowing parents to remain in the room during the procedure. Most parents want to be present during wound repair in the ED, and most can be a stabilizing force if properly oriented. The parent can reassure or distract the child with a story while maintaining physical contact under necessary drapes and restraints. It is usually best if the parent is sitting down and focusing on the child, rather than directly observing the procedure.

Many young children less than 4 years old will need to be placed in a restraining device such as a papoose board for better immobilization. Restraint is needed to ensure the child's safety, protect him or her from self-injury, and allow for more rapid completion of the procedure. Because the child may get excessively warm while in the papoose board, it is important to ensure proper ventilation and assess the child's comfort during the restraint process. A caring, but firm nurse or assistant is often needed to further immobilize the injured body part and complete the procedure successfully. It is better to use such hospital personnel instead of parents to immobilize a child. Sedation may be appropriate in some cases (see Chapter 4). A school-age child can usually cooperate without restraint.

Preparing the Wound

Appropriate use of conscious sedation and *local anesthetics* are essential for successful repair of lacerations in children (see Chapter 4).

Hair near the wound usually creates minimal difficulty during repair and generally does not need to be removed. In any case, nearby hair should not be shaved because this may damage hair follicles and increase infection. Instead, the hair should be clipped with scissors when necessary. Alternatively, petroleum jelly can be used to keep unwanted scalp hair away from the wound while suturing. Hair over the eyebrows should not be removed because this may lead to abnormal or slow regrowth.

It is essential to *clean the wound periphery* at the time of wound evaluation. Povidone–iodine solution (a 10% standard solution) is often used because it is a safe and effective antimicrobial with little tissue toxicity. This solution may be diluted with saline 1:10 to create a 1% solution. Use of chlorhexidine or povidone–iodine surgical scrub preparations, hydrogen peroxide, or alcohol in the wound itself is not recommended. These may be irritating to tissues, and they may increase infection by damaging white cells.

Wound irrigation is extremely important to reduce bacterial contamination and prevent subsequent infection. It is often necessary to anesthetize the wound before thoroughly cleansing. Using universal precautions, the wound should be irrigated with normal saline, about 100 to 200 mL for the average 2-cm laceration. More may be needed if the wound is unusually large or contaminated. Use a large syringe (20 to 50 mL) with a splash-guard attached to the end to reduce splatter during the irrigation. With the splash-guard almost touching the skin surface and the tip of the syringe about 2 cm from the wound, the clinician should apply firm pressure to the plunger. Soaking the injured body part should be avoided because this may lead to maceration of the wound and edema.

Scrubbing the wound should be reserved for particularly “dirty” wounds in which contaminants are not effectively removed with irrigation alone. It may be necessary to extract some foreign material with fine forceps if it remains adherent after copious irrigation. This will avoid tattooing of the skin and reduce the risk of infection.

In rare cases, the wound must be extended with a scalpel to allow proper exploration and cleaning. The physician should trim irregular lacerations and excise necrotic skin but should not make dramatic changes in the wound. Devitalized tissue should be removed only if it looks ischemic or is otherwise clearly indicated. More than a small amount of tissue removal should be attempted only by an experienced physician. Subcutaneous fat can be safely and easily removed if this seems to interfere with wound closure. It is wise to remove this carefully, in small quantities, to avoid disruption of small vessels and cutaneous nerve branches. Debridement is advantageous because it creates well-defined wound edges that can be

more easily opposed. However, excessive removal of tissue can create a defect that is difficult to close or may increase tension at the wound margin such that scarring is more likely. Removal of facial fat should be avoided because this may leave an unsightly depression.

Further examination of the wound should take place after cleansing and debridement. After exploration, it is wise to reevaluate the decision to close the wound primarily. When proceeding further, the clinician should wash hands carefully before donning sterile gloves. Sterile masks are not helpful in reducing wound infections, but a facial splash-shield is useful to protect the clinician. The area surrounding the wound should be appropriately draped before surgical repair. However, if a young child is particularly upset by facial drapes, they can be omitted. Proper cleaning of the wound is more important to uncomplicated healing than meticulous attempts to avoid introduction of small numbers of bacteria by preserving a sterile field.

Wound Closure

Equipment

Suture material must have adequate strength while producing little inflammatory reaction. Nonabsorbable sutures such as monofilament nylon (Ethilon) or polypropylene (Prolene) retain most of their tensile strength for more than 60 days and are relatively nonreactive. Thus, they are appropriate for closing the outermost layer of a laceration. With monofilament nylon, it is important to secure the knot adequately with at least 4 to 5 throws per knot. Polypropylene is useful for lacerations in the scalp or eyebrows because it is more visible and thus easier to remove. It is somewhat more difficult to control while suturing. Silk is rarely used now because of increased tissue reactions and infection.

In many cases, it is appropriate to use fine, absorbable (synthetic) sutures such as Dexon or Vicryl in deeper, subcuticular layers. These materials may elicit an inflammatory response and may extrude from the skin before they are absorbed if they are placed too close to the skin. When subcuticular sutures are used, they should be placed on the deeper surface of the dermis, and epithelial margins may be approximated with tape strips. Synthetic absorbable sutures are less reactive than chromic gut and they retain their tensile strength for long periods, making them useful in areas with high dynamic and static tensions. Absorbable sutures are advantageous for intraoral lacerations. Some recommend using rapidly absorbable sutures (fast-absorbing gut) for skin closure of facial or scalp wounds in children because suture removal is avoided.

A 3-0 suture is recommended for tissues with strong tension, such as fascia, and 4-0 is recommended for deep tissues with light tension, such as subcutaneous tissue. Skin is best closed with 4-0 to 7-0 and oral mucosa with 3-0 to 4-0 sutures. The physician should use the finest sutures (6-0) for wounds of the face; heavier sutures for scalp, trunk, and extremities (4-0 or 5-0); and 3-0 or 4-0 for thick skin such as the sole of the foot or over large joints such as the knee.

Needles are available in a variety of forms, including cuticular, plastics, and “reverse cutting.” The reverse cutting needle is used most for laceration repair. Its outer edge is sharp to allow for atraumatic passage of the needle through the relatively tough dermis and epidermal layers; this minimizes cutting of the skin where suture tension is greatest. A higher grade plastic needle (designated *P* or *PS*) should be used for repairs on the face. A small needle (such as P3) should be used for wounds that require fine cosmesis. Needles come in a variety of sizes such as $^{3}/_{8}$ and ½ circle. Clinicians may develop a preference for a specific needle. In general, a $^{3}/_{8}$ reverse cutting needle satisfies most needs.

General Principles

Perhaps the two most important goals of suturing are to match the layers of the injured tissues and to create eversion of the wound margins so that they will flatten as the wound heals. Layers on one side of a wound should be sutured to the corresponding, matching layers on the other side. First, all layers of skin that have been injured should be identified. Then an attempt to appose each layer (muscles, fascia, subcutaneous tissue, and skin) as nearly as possible back to its original location should be made. This is achieved by carefully matching the depth of the bite taken on each side of the wound when suturing.

Proper *suture placement* should result in slight eversion of the wound so that there is not a depressed scar when remodeling takes place. Eversion may be achieved by slight thumb pressure on the wound edge as the needle is entering the opposite side. Sutures should take equal bites from both wound edges so that one margin does not overlap the opposite margin when the knot is tied. Wound edge eversion is best achieved by taking proper bites while suturing, not by pulling the knot tightly (Fig. 116.2).

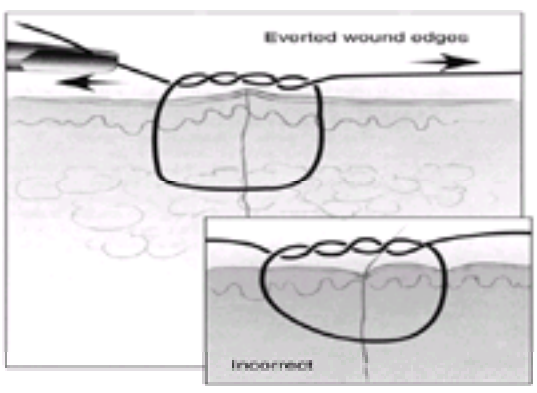

FIGURE 116.2. Suturing technique for wound edge eversion.

Suture placement may be deep or superficial. Deep sutures reapproximate the dermal layers of skin and do not penetrate the epidermis. They help relieve skin tension and improve the cosmetic appearance by reducing the width of the scar. They should be avoided in wounds prone to infection because they will further increase the risk of infection. To place a deep suture, the needle is placed at the depth of the wound and removed at a more superficial level. The needle is then inserted superficially into the opposite side of the wound and exits deeply so that the knot is buried within the wound. The needle end and free end of the suture should be on the same side of the loop before the knot is tied (Fig. 116.3). The simple interrupted technique (described next) with absorbable suture material should be used.

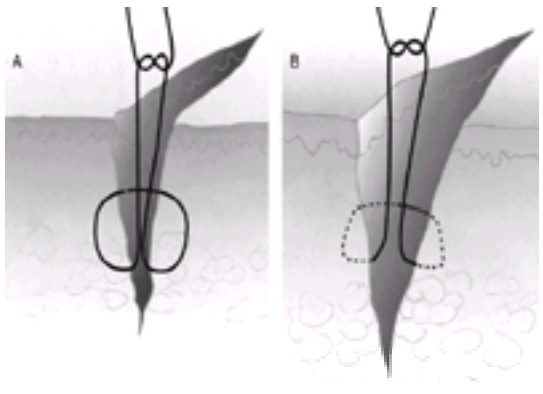

FIGURE 116.3. A. The buried subcutaneous suture. **B.** The horizontal dermal stitch.

Superficial or percutaneous sutures are passed through the dermis and epidermis and leave the knot visible at the skin surface. Skin should be closed with a minimal amount of tension. Sutures should be pulled tightly enough to approximate the wound edges, but not so tightly that they cause tissue necrosis. Sutures that seem well placed initially may begin to cut into the tissue in the next few days because of swelling and inflammation. There is no need to tightly close the skin if other layers have been well sutured. Scalp wounds are an exception. They are under considerable tension, and the knots in this location should be pulled firmly to keep the skin together. The wound will be hidden by hair, so the skin can be pulled more tightly than elsewhere. Firm, but not strangulating, apposition of the wound will help with hemostasis as well.

To ensure proper alignment, the first suture may be placed at the midpoint of the wound, with subsequent sutures then placed in a bisecting fashion lateral to the midpoint. Use of forceps to hold tissue should be encouraged because this allows the operator to precisely pass the needle through the desired points alongside the wound edge. However, forceps use should be kept to a minimum during the repair to avoid tissue damage.

Suture Technique

Skin wounds can generally be repaired using interrupted suturing. To place a *simple interrupted suture,* the needle is held upside down and the wrist is pronated as the needle enters the skin at a 90-degree angle. The needle tip will then move farther away from the wound margin and penetrate deeply. Thus, more tissue is at the depth of the wound and this causes the wound to evert. Sutures should be placed about 2 mm apart and 2 mm from the wound edge on delicate areas such as the face. More sutures placed closer together decrease wound tension and leave a less noticeable scar. Larger bites should be used for body parts where cosmesis is less important.

The physician should use an instrument tie to secure the suture (Fig. 116.4). The knots should ideally be placed on one side of the wound. Knots placed directly over the wound increase inflammation and scar formation. On the first throw, the physician should wrap the needle holder twice to create a surgeon's knot and then wrap subsequent throws a single time. The first and second throws should be snug enough to approximate the wound edges, but not so tight that tissue is strangulated. All subsequent knots are squared to maintain the closure. Four or five throws are usually required to keep the knot from unraveling. A “loop knot” is effective in apposing the wound edge with minimal tension. This involves placing a surgeon's knot, using the instrument tie, followed by a loop. The surgeon's knot will “give” slightly should edema develop subsequently. The loop knot allows easier, painless removal of sutures because it creates a free space between the suture and the skin (Fig. 116.5).

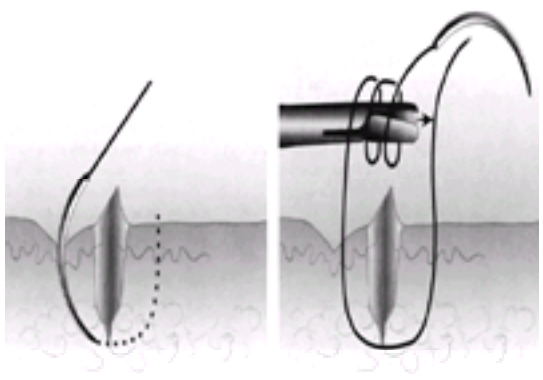

FIGURE 116.4. Simple interrupted skin suture secured with instrument tie.

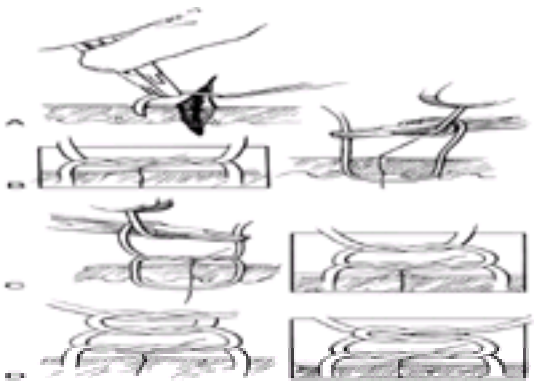

FIGURE 116.5. Placement of a “loop knot” in conjunction with simple sutures of the skin using an eversion technique. **A.** The needle enters the skin at a right angle in a way that allows somewhat less skin and more subcutaneous tissue to be caught in the passage of the needle. The needle should incorporate the same amount of skin and subcutaneous tissue on each side. The ideal suture material for placing a “loop knot” is 4-0 nylon. One can also use 5-0 nylon. **B.** The first knot should be a surgeon's knot drawn down gently so as to barely coapt the skin edges. **C.** The second tie should be placed so as to produce a square knot but should be drawn so as to produce an approximate 2- to 3-mm loop. **D.** The third tie should be placed so as to produce a square knot. This third tie can be secured tightly against the second tie, preserving the loop and allowing for some loosening of the surgeon's knot spontaneously as later edema develops.

Running or continuous sutures can be applied rapidly to close large, straight wounds or multiple wounds. With this technique, the suture is not cut and tied with each stitch. The first suture is placed at one end of the wound and a knot tied, cutting only the end of thread not attached to the needle. The next loop is placed a few millimeters away and continuous loops of equal bites are made to close the wound. On the final loop, the suture is not completely pulled through so that a small loop remains on the opposite side of the wound. Now, the knot can be tied using the preceding loop of suture (Fig. 116.6). This type of stitch is more likely to leave suture marks if not removed in 5 days. Apposition of the edges and eversion are more difficult to achieve with this stitch, and the entire suture line can unravel if the suture breaks anywhere along the repair. However, the technique gives the advantage of having equal tension on the wound edges.

FIGURE 116.6. Continuous skin sutures. **A.** The simple continuous running stitch. **B.** The continuous interlocking skin stitch. **C.** The running lateral mattress stitch or continuous half-buried horizontal mattress stitch.

The *vertical mattress stitch* is useful for deep wounds in which it may be difficult to tie a simple, deep, interrupted suture. It reduces tension on the wound and may close dead space within the wound. It essentially combines a deep and superficial stitch in one suture. The needle is placed deep within the wound (about 3 mm from the wound edge) and brought out to the opposite skin surface. It is then brought across the epidermis to approximate the epidermal edges (Fig. 116.7). This stitch takes more time to accomplish and produces more crossmarks, but it provides excellent wound eversion and apposition of the wound edge. Too tight of a knot will pucker the wound.

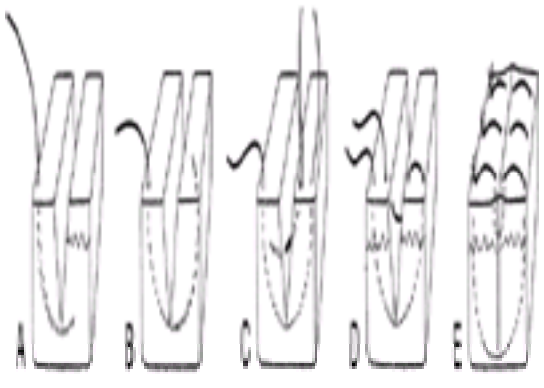

FIGURE 116.7. A–E. The vertical mattress suture. After initially placing a simple interrupted stitch with a somewhat larger bite, make a backhand pass across the wound, taking small, superficial bites. When the knot is tied, the edges of the laceration should evert slightly. (Reprinted with permission from Grisham J. Wound care. In: Dieckmann RA, Fiser DH, Selbst SM, eds. Illustrated Textbook of Pediatric Emergency & Critical Care Procedures. St. Louis: Mosby,

1997:665–679.)

The *horizontal mattress stitch* reinforces the subcutaneous tissue and effectively relieves tension from the wound edges. It does not provide wound-edge approximation as well as the vertical mattress stitch. The needle is passed ½ to 1 cm away from the wound edge deeply into the wound. It is then passed through the opposite side and reenters the wound parallel to the initial suture. To avoid “buckling” and to provide some eversion of the wound edges, the skin must be entered perpendicularly, and the wound must be entered and exited at the same depth (Fig. 116.8).

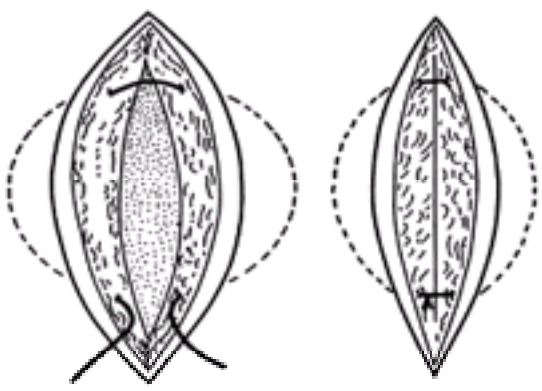

FIGURE 116.8. The horizontal mattress stitch is useful for closing the deep layer in shallow lacerations and in body areas with little subcutaneous tissue. Certain dyed suture materials may cause a tattooing of the skin if placed in such a shallow position. (Reprinted with permission from Grisham J. Wound care. In: Dieckmann RA, Fiser DH, Selbst SM, eds. Illustrated Textbook of Pediatric Emergency & Critical Care Procedures. St. Louis: Mosby, 1997:665–679.)

The *modified horizontal mattress stitch* (half-buried) is often used to close a flap. It is also called the corner stitch. It relieves intrinsic tension and vascular compromise when approximating the tip of the flap. Using 5-0 or 6-0 nylon, the physician should enter intact skin across from the apex of the flap and exit the wound just below the subcuticular plane. The needle should be brought to the tip of the flap, entering and exiting at the subcuticular plane. Then, the needle is brought across the edge of the flap in the subcuticular plane and the skin is exited. A knot should be tied in the usual manner and the tip of the flap brought to the apex of the wound (Fig. 116.9).

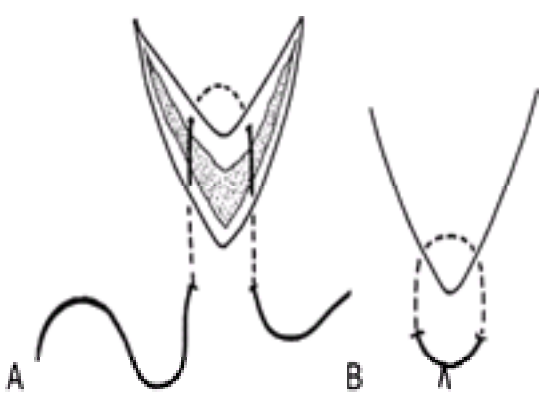

FIGURE 116.9. A and **B.** The corner stitch. Also called the half-buried horizontal mattress stitch, this technique allows repair of flap-type lacerations without further compromising blood flow. Place additional simple interrupted sutures along the sides of the flap if necessary. (Reprinted with permission from Grisham J. Wound care. In: Dieckmann RA, Fiser DH, Selbst SM, eds. Illustrated Textbook of Pediatric Emergency & Critical Care Procedures. St. Louis: Mosby, 1997:665–679.)

Placing the needle in the flap edge first can also repair wounds with flaps. The edge of the flap can then be moved back and forth until proper alignment with the opposite fixed side is obtained. After the tip of the flap is sutured, the sides of the flap are brought together. For wounds with several stellate flaps, subcuticular or subcutaneous sutures should be used to hold the tips of the flap together. Then, a single suture at the tip will provide good apposition without further damaging the tip of the flap. Other interrupted sutures can be placed on the lateral margins of the wound to provide further support. If the wound has many narrow-based stellate flaps or necrotic flap tips, the wound may be better managed with excision and simpler repair (Fig. 116.10).

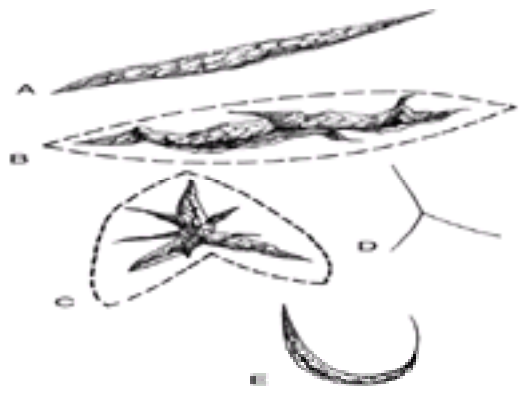

FIGURE 116.10. Variation in laceration injuries and suggestions for management: simple laceration **(A),** elliptical excision of damaged wound margins **(B),** excision and closure of stellate laceration (**C** and **D**), and flap-type laceration **(E).**

Alternative Wound Closure Techniques

Tape causes no suture marks, minimal tissue reaction, and fewer wound infections than sutures. Tape strips, cut to size, can be used to take up tension at the wound margins and can be placed between sutures. These strips are also useful as the only means to close simple lacerations that barely extend through the dermis. Multiple tangential, triangular skin flaps (e.g., those created when an unrestrained passenger hits the windshield of a car) are closed well with tape strips. Likewise, old or contaminated wounds, such as dog bites on the extremities, can be loosely approximated with skin tape.

When tape is used, the wound should be cleansed as any other wound. Care must be taken to properly realign the dermis and epithelium. If the tape is pulled too tightly, the margins of the wound may overlap, causing the wound to heal with a raised ridgelike area where the overlap occurred. The tape is applied perpendicularly across the wound with some space between to allow the wound to drain. In some cases, an adhesive such as benzoin is applied to the adjacent skin (not the wound) to keep the tape strips more securely in place. Some recommend leaving the taped wound uncovered because a bandage may increase moisture and cause the tape to fall off prematurely.

Tape strips should not be used on wounds subject to tension, such as those over flexor surfaces of joints. They should not be applied in areas of the body that are moist, such as the palms or axillae because they will not adhere. They may be impractical for small children, who may inadvertently remove them from the face.

Staples can be applied more rapidly than sutures and have a lower rate of infection, with less of a foreign body reaction. They are best for wounds of the scalp, trunk, and extremities when saving time is important. Therefore, they are particularly helpful when treating mass casualties. Staples are left in place for the same length of time as sutures. They are somewhat more painful to remove and should be removed with a specially designed instrument to avoid tissue damage. Staples do not allow for meticulous cosmetic repair as with sutures. Thus, they should not be used for lacerations of the face, neck, hands, or feet. They should also not be used if the patient requires magnetic resonance imaging (MRI) or computed tomography (CT).

Tissue adhesives, or skin glues, such as cyanoacrylates (Histoacryl Blue) have recently been approved for use in the United States. Skin glues have been used to close wounds for many years in Europe and Canada. They allow rapid and painless closure of wounds. Anesthesia is unnecessary, unless painful irrigation or exploration of the wound is anticipated. No removal is needed because the adhesives slough off after 7 to 10 days. They provide an excellent cosmetic result, comparable with sutures. One study using plastic surgeons blinded to the method of repair graded the wounds repaired with Histoacryl Blue to be cosmetically equal to sutured wounds at 2-month and 1-year follow-up visits.

Tissue adhesives act to decrease wound infections because they have antimicrobial effects against Gram-positive organisms. Dehiscence rates (1 to 3%) are similar to that of sutured wounds. They are less expensive than sutures because little equipment is needed and personnel time is reduced. Studies have noted that patients and families of small children prefer them to sutures. Routine follow-up is not needed for uncomplicated wounds, and no long-term complications have been reported.

Before application of the tissue adhesive, the wound is cleaned and hemostasis achieved with dry gauze and pressure. The wound's edges are held together manually or with forceps while the tissue adhesive is applied drop-wise along the surface of the wound. The tissue adhesive should not be applied to the inside of the wound because it will act as a foreign body and inhibit healing. The wound is then held in place for about 20 to 30 additional seconds to obtain adequate bonding. One study reported that if malalignment is noted, the adhesive can be removed with forceps and reapplied without further complication. The wound is then covered carefully so that bandage removal will not pull off the tissue adhesive.

Tissue adhesives should be used only to close skin of superficial wounds. For many lacerations, deep absorbable sutures will also be needed because the glue has less strength than most sutures. Skin glues should not be used for wounds subject to great tension, such as on the hands or joints.

Table 116.2 summarizes advantages and disadvantages of several techniques available for wound closure.

Technique	Advantages	Disadvantages
Sutures	Greatest tensile strength Meticulous closure Low dehiscence rate	Painful Removal needed Slow application Increased tissue reaction Risk of needle stick (clinician)
Staples	Rapid application Low cost Low tissue reaction	Not for use on face (less meticulous closure)
Tissue adhesive	Rapid application Painless No removal needed Low cost No risk of needle stick (clinician)	Lower tensile strength Not for use on joints
Tape strips	Rapid application Painless Low cost Low infection risk Least tissue reaction	High risk of dehiscence Not for use in moist areas, young children

Table 116.2. Common Techniques of Wound Closure

Dressings

Dressings protect the wound from further injury and contamination. They also help absorb secretions (not likely with small wounds) and immobilize the injured part. Some use a nonadherent sterile dressing (e.g., Telfa, Xeroform) to cover the wound. This prevents the wound edges from sticking to the dressing. Then, a second layer of absorbent gauze is applied, and a third layer of gauze wrap or tape is used to stabilize the other two. This protects and immobilizes the area while absorbing exudate from the wound surface.

For most simple wounds, it is adequate to cover the wound with dry sterile gauze after applying topical antibacterial ointment. Some studies indicate that topical antibiotic ointments may reduce infection and prevent scab formation by lubricating the wound edges. This allows for more rapid epithelialization of the wound.

For the face and trunk, a large bulky dressing is not practical. Thus, for small wounds in those areas, a clear plastic adhesive such as Tegaderm should be used to secure the bandage. Rolls of cotton or stretchable tube gauze can be used for larger wounds to keep the sterile dressing in place. This keeps the young child from touching the wound. Scalp wounds are usually not dressed. Patients can generally wash their hair gently after 24 hours.

For children who are active, it may be best to keep the wound covered until sutures are removed. The dressing should remain in place for 24 to 48 hours after which epithelialization is usually sufficient to keep the wound from gross contamination. Then, the bandage should be changed daily and the wound inspected. Any dressing should be changed if it becomes soiled, wet, or saturated with drainage because the wet dressing may be a source of infection.

It may be advisable to splint the wound if it overlies a joint. This is most important for active children who will likely resume full activity soon after the injury. Some even recommend splinting nearby joints for any large laceration of an extremity to reduce stress across the wound even if it does not involve a joint itself. This should be done for no more than 72 hours to facilitate function. The injured extremity should be elevated to provide comfort and reduce edema.

Systemic Antibiotics

Use of prophylactic systemic antibiotics for wound management is controversial. Studies demonstrating proven benefit to use of antibiotics are lacking. They may lead to allergic reactions, growth of resistant organisms, and unnecessary expense. Thus, they are not recommended for routine use. Decontamination with proper irrigation is more efficacious than use of antibiotics to prevent wound infection. Antibiotics should be considered for heavily contaminated wounds that are at greater risk for infection. They are often used for human and cat bites (see Chapter 91), crush injuries, stellate lacerations, and very long wounds (exceeding 5 cm). Other high-risk wounds include intraoral lacerations and wounds of the hands, feet, and perineum. Similarly, open fractures, exposed joints and tendons, and any tetanus-prone wound may benefit from antibiotics. Likewise, wounds that result in exposed cartilage of the nose or ears or extensive facial wounds that may involve contamination from adjacent nasal passages are often treated with antibiotics. It may also be reasonable to use antibiotics for wounds (other than scalp lesions) when repair takes place more than 12 hours after injury. They may be justified for wounds that occurred in a contaminated environment, such as a farm or roadside. Injured immunocompromised patients may warrant antibiotics.

Usually a first-generation cephalosporin or a penicillinase-resistant penicillin is used to cover staphylococci and streptococci. Amoxicillin–clavulanic acid is recommended for wounds created by mammalian bites (see Chapter 91). Additional coverage for Gram-negative organisms with an aminoglycoside may be worthwhile for heavily contaminated open fractures.

Tetanus

Immunization status of all injured patients should be documented in the medical record. If the wound is clean and minor and the patient has received three previous doses of tetanus toxoid, a booster of tetanus toxoid is given only if 10 or more years have passed since the last dose. If a patient has received three or more previous tetanus immunizations but the wound is not a clean, minor laceration, tetanus toxoid is indicated if the last dose was more than 5 years prior.

In many cases, the tetanus immunization record is unknown. If tetanus status is unknown and the wound is not clean or minor, tetanus toxoid and tetanus immunoglobulin (TIG) are indicated. Wounds involving massive tissue destruction and contamination may also require TIG. Patients with such wounds should be admitted to the hospital (see Table 116.3).

Prior Tetanus Toxoid Immunization (Doses)	Clean Minor Wound	All Other Wounds
Uncertain (or less than 3)	DTP or Td	DTP or Td and TIG or TAT
Three or more (most recent more than 10 years ago)	Td	Td
Three or more (most recent within past 5 years)	None	None
Three or more (most recent between 5 and 10 years)	None	Td

DTP, diphtheria, tetanus, pertussis toxoid; *Td*, adult formulation of diphtheria, tetanus toxoid; *TIG*, tetanus immunoglobulin (dose: 250–500 units IM); *TAT*, tetanus antitoxin; should be used only if TIG is not available and after testing (dose: 3000–5000 units intramuscularly).

Table 116.3. Tetanus Prophylaxis

Discharge Instructions and Suture Removal

Careful discharge instructions, regarding wound care, covering the wound, when to get the wound wet, how to dry it, and so on, are extremely important. The family should be warned about signs of infection. Specifically, they should be told to return for medical care if the wound develops increasing pain, redness, edema, and/or wound discharge, or if the child develops a fever. Analgesics may be given for minor pain, but worsening pain should always prompt a wound check. The family should also be informed that the wound was inspected for a foreign body but that there is still a possibility of a retained foreign body or an undetected injury that may require further treatment. Parents should be told that no matter how skillful the operator, every laceration leaves some scar. The appearance of the scar will change during the next several months and the scar's appearance will not be complete for about 6 to 12 months. Patients and parents should be advised to keep the injured part elevated when possible. A sling can be provided to accomplish elevation of the upper extremities. Some recommend that healing skin not be exposed to sunlight for 6 months after injury because this could lead to permanent hyperpigmentation.

Follow-up care should be arranged for 24 to 48 hours in all but very simple wounds. The wound can then be reinspected for signs of infection, and healing can be assessed.

Wounds closed with tape strips do not require removal of the tape because these will fall off spontaneously. Skin glue also sloughs spontaneously. However, nonabsorbable sutures should be removed at the appropriate time, depending on the location of the injury. The importance of timely removal should be stressed to the patient and family. Sutures should be removed when fibroblastic proliferation at the wound interface is strong enough to take the place of sutures. Removing sutures too early may lead to dehiscence and widening of the scar. Sutures left in too long may create an unnecessary tissue reaction and result in visible cross-hatching (“railroad ties”).

Wounds on the scalp or face are nourished by a better blood supply and generally exhibit more rapid healing. Sutures in these areas are removed more quickly than other locations to avoid unsightly tracts. When sutures are subject to considerable tension (over joints and on the hands), they should be left in longer (Table 116.4). After removal of sutures, it is often necessary to reinforce the healing wound with tape strips to prevent dehiscence.

Wound Location	Time of Removal (days)
Neck	3–4
Face, scalp	5
Upper extremities, trunk	7–10
Lower extremities	8–10
Joint surface	10–14

Table 116.4. Timely Suture Removal

In the first 24 to 48 hours, wound dressings should be changed only if wet or soiled. After that, bathing can be permitted as long as the wound is then patted dry and covered again. There is no proven harm to exposing the sutures to soap and water for short periods.

Table 116.5 summarizes an approach to reduce risk in managing wounds in the ED.

1. Take thorough history.
2. Perform a careful examination.
3. Obtain a consult for complex wounds.
4. Obtain radiographs if foreign body or fracture is suspected.
5. Document carefully (inspection, irrigation, and function).
6. Communicate with parents (likely scar).
7. Arrange follow-up, recheck.

Table 116.5. Reducing Risk in Wound Management

CARE FOR COMMON WOUNDS

The principles of wound care discussed earlier should be applied in repairing any of the wounds discussed in this section. These principles include evaluation of the wound by history, physical examination, and when indicated, radiographic examination. After the wound is evaluated, the feasibility of closure and the possible need for consultation with a surgeon should be addressed. The following section discusses some of the commonly encountered wounds in children.

Facial and Oral Wounds

Forehead Lacerations

Forehead lacerations are common in early childhood. Most of these injuries occur secondary to falls on objects or furniture such as coffee tables. Most of these lacerations are simple and not associated with any other significant injuries. However, complete evaluation of the head and neck should be carried out. Superficial transverse lacerations of the forehead are easy to manage, and the outcome is usually favorable. Closure with simple or continuous cuticular sutures using 6-0 nonabsorbable material is recommended. Deeper transverse lacerations involving the deep fascia, the frontalis muscle, or the periosteum should be repaired in layers. Absorbable 5-0 material such as coated vicryl or catgut can be used. If the deeper tissue plains are not closed, the function of the frontalis muscle, eyebrow elevation, may be hampered. Other facial expressions can also be affected because the skin may tether to the scar tissue bridging the unrepaired gaping tissues.

Vertical forehead lacerations tend to have a wider scar because they traverse the tension lines. Complex forehead wounds, such as stellate lacerations from windshield impact and those with tissue loss, particularly secondary to animal bites, may require consultation with a plastic surgeon. Forehead lacerations are rarely associated with skull fractures, but facial or intracranial injuries should be ruled out.

Lacerations of the Eyebrow

Eyebrow lacerations are common. Repairing an eyebrow laceration is complicated by the presence of hair. It is advisable not to shave the eyebrow for wound preparation because it serves as a landmark during repair. Also, eyebrow regrowth is unpredictable; it may be either slow or incomplete, potentially leading to poor cosmetic outcome. Debridement, if required, should be minimal and along the same axis of the hair shafts to avoid damage to hair follicles; otherwise, alopecia of the brow will result. Closure with simple interrupted stitches using nonabsorbable material is usually sufficient. Attention must be paid to avoid inverting the hair-bearing edges into the wound. It is also important to pay attention to proper alignment of both ends along an eyebrow wound.

Lacerations of the Eyelid

Most eyelid lacerations are simple transverse wounds of the upper eyelid just inferior to the eyebrow. Repairing these wounds does not require any special skills. On the other hand, recognizing complicated eyelid lacerations is crucial for proper repair and good outcome. Vertical lacerations involving the lid margin require precision in approximation to avoid deformity and malfunction of the eyelid. Injuries potentially involving the levator palpebrae muscle, the medial canthal ligament, or the lacrimal duct should be considered for ophthalmologic referral. Evaluation for an associated injury of the globe is a must, particularly if periorbital fat is exposed or tarsal plate penetration is present.

Lacerations and Blunt Trauma of the External Ear

Although the ears are subject to trauma because of their exposed position, lacerations involving the ears are rather rare. To obtain the best results in caring for injuries involving the external ear (auricle or ear lobe), attention must be paid to certain anatomic and physiologic facts. The auricle contains a cartilaginous structure that provides the framework for the complex shape of the ear. The pericondrium covering the cartilage provides it with nutrients and oxygen. Separation of the cartilage from the pericondrium because of trauma may lead to necrosis of the cartilage, leaving the auricle deformed. The overlying skin, although thin and with no or little subcutaneous tissue, is well-vascularized. Skin flaps with small pedicles often survive and should not be hastily debrided.

Simple auricular lacerations can be repaired without difficulty. To avoid chondritis, approximation of the skin is important so that no cartilage is exposed. Occasionally, debridement of the cartilage is needed to obtain complete coaptation of the

wound; however, cartilage debridement should be kept to a minimum. It is imperative to avoid catching the auricular cartilage with the needle tip because the skin and the pericondrium are in close proximity to each other.

Complex auricular lacerations with significant skin damage and involvement of the auricular cartilage can be difficult to repair and may require consultation with a plastic surgeon. In general, when repairing auricular cartilage, a few 5-0 absorbable sutures should be used to approximate the edges. Landmarks of the auricle should be used for proper alignment. The pericondrium should be included in the sutures so that the suture material does not tear through the friable cartilage and also to ensure restoration of nutrient and oxygen supply. For the same reason, excessive tension should be avoided. Closure of the skin should follow as described previously. If the laceration involves the anterior and posterior aspects of the ear, closure of the posterior aspect first is recommended.

To avoid a deep scar line (notching) in repairing the ear lobe or the auricular rim, the skin edges should be everted at the time of closure because fibrotic tissue will eventually pull the scar line down, leading to notching.

Partial avulsion or *total amputation of the ear* is possible. Every effort should be made to reattach the amputated part because tissue survival and cosmetic outcome are usually favorable. Furthermore, blunt ear trauma can lead to a simple contusion or a significant *subperichondrial hematoma* that can comprise the auricular cartilage. Classically, a significant perichondrial hematoma is tense and appears as smooth ecchymotic swelling that disrupts the normal contour of the auricle. This injury is particularly common among wrestlers. Auricular hematoma should be promptly drained to avoid necrosis of the cartilage and deformed auricle or cauliflower ear.

Blunt trauma can drive or *bury an earring* or its backing into the ear lobe. This can also result from contact dermatitis reaction to the earring material with swelling. After local intradermal lidocaine, the earring part is usually easily navigated out of its port of entry. Occasionally, a small incision is needed to facilitate the extraction of the earring. If an incision is needed, it should be done on the posterior aspect of the ear lobe and should be left to heal by secondary intention. If the patient desires to maintain the ear lobe pierced, a sterile nonabsorbable suture should be ringed in the existing hole for a few days until the hole is epithelilized.

After repair of ear lacerations or evacuation of an auricular hematoma, a pressure dressing should be applied. Follow-up in 24 hours to evaluate vascular integrity to the area is recommended.

Lacerations of the Nose

Unlike blunt injuries, lacerations to the nose are unusual. When a laceration results from blunt trauma, careful evaluation of underlying nasal bones and examination for a nasal septal hematoma are essential. Other associated injuries, such as facial bone fractures or injuries to the orbit, should also be ruled out.

The skin overlying the nose is taut and stiff. Approximating the edges of simple, nongaping nasal wounds, mostly along the upper half of the nose, is usually straightforward. Wounds with any gaping, commonly in the lower part of the nose, can be difficult to coapt because of the nature of the skin in this location. The suture material can tear through the skin easily. Absorbable subcutaneous stitches are recommended before skin closure to relieve tension and prevent tearing through the wound edges. Skin closure should be with simple interrupted 6-0 nonabsorbable material. Early removal of the sutures is advised for the same reason.

Full-thickness nasal lacerations involving the alae nasi or entering the vestibule require layered closure. The procedure should be begun with the nasal mucosa, using absorbable material and finished with the skin, preferably using continuous subcuticular intradermal suture technique.

The nasal cartilage, when involved, rarely requires sutures. When alignment is difficult, a few fine sutures (vicryl or plain catgut) will help hold it in place. When the free rim of the nares is involved, precise alignment is imperative for good cosmetic outcome. For complex nasal lacerations, lacerations associated with fractures, or when there is tissue loss, consultation with an otolaryngologist or a plastic surgeon is recommended.

Lacerations of Lip

Lip lacerations are a particular concern because of the importance of the lip as a facial landmark. The lip is a vascular structure with multiple layers. The vermilion border, the junction of the dry oral mucosa and the facial skin, serves as an important landmark for proper repair when involved. The relative pallor of the vermilion border to the lip and to the skin easily identifies it. Therefore, the use of epinephrine with local anesthesia should be avoided, so the landmark is not abolished. When parted, the vermilion border should be precisely reapposed using a 6-0 suture. The buccal mucosal surface is then closed with 5-0 absorbable material, followed by the skin, using 6-0 nonabsorbable sutures. The parents should be warned that while the lip is still anesthetized, there is a chance that the child will bite the sutures off and that they should distract the child from doing so. Typically after the local anesthesia has worn off, the site is sore enough that the child will not attempt to manipulate the area.

In general, lip lacerations should be closed in layers, depending on the depth of the wound. In full-thickness lip lacerations, a three-layer repair is required. The physician should begin with the oral mucosa, using 5-0 absorbable material, followed by the orbicularis oris muscle layer to include the inner and outer fibrofatty layers, and finish with the skin, using 6-0 nonabsorbable interrupted sutures. Small wounds, less than 2 cm, on the inner aspect of the lip without communication to the skin surface need not be repaired. External lip wounds not communicating with the mucosal surface can be closed by either single- or double-layer closure, depending on the depth and degree of gaping of the wound. Absorbable sutures (5-0) for the subcutaneous layer and nonabsorbable (6-0) for closure of the skin can be used.

Extensive lip injuries with tissue loss or those caused by electric burns, especially those that involve the angle of the mouth, should be referred to a plastic surgeon. Associated injuries such as dental trauma, mandibular fractures, and

closed head injuries should be ruled out.

Lacerations of the Cheeks

When managing lacerations involving the cheeks, the physician must evaluate the integrity of the underlying structures. The parotid gland and duct, the facial nerve, and the labial artery are in close proximity of the surface of the skin and can be injured often as a result of an animal bite. If parotid gland or duct injury is identified, consultation with a surgeon is advised. Puncture wounds resulting from animal bites should be debrided and irrigated thoroughly. Some of these puncture wounds are better off left without closure to reduce infection rate, especially if the cosmetic outcome is not compromised. Otherwise, simple interrupted 6-0 nonabsorbable sutures can be used to close uncomplicated lacerations of the cheeks.

Lacerations of the Tongue

The tongue is a vascular and muscular organ. Tongue lacerations often hemorrhage excessively in the beginning, but the bleeding usually ceases quickly as the lingual muscle contracts. Lacerations of the tongue can pose a challenge to repair, not only because of their inaccessibility but also because of the controversy surrounding the indications for closure.

Most tongue lacerations can be left alone with good results. However, large lacerations involving the free edge may heal with a notch causing dysfunction of the tongue. Generally, this type of laceration should be repaired. Large flaps and lacerations that continue to bleed should also be repaired. Patients with tongue lacerations requiring repair should be assessed for potential airway problems, as well as for need of conscious sedation or even general anesthesia. Often, local or regional anesthesia is sufficient. The mouth should be retained open using a padded tongue depressor placed on the side between the upper and lower teeth or by using a Denhardt-Dingman side mouth gag. The tongue can be maintained in the protruded position by a gentle pull using a towel clip or by placing a suture through the tip. Interrupted 4-0 absorbable suture, with full-thickness bites to include the two mucosal surfaces and the lingual muscle between, will close the tongue wound and will provide hemostasis. Multiple knots and inverted sutures are recommended to prevent the untying of the sutures. Some authors suggest that only deep muscle closure is required because the mucosal surface heals rapidly. As in lip lacerations, children may chew off the stitches. Parents must be warned of this possibility and should attempt to distract the child at least until the local anesthesia is worn off.

Lacerations of the Buccal Mucosa

Small, isolated lacerations of the buccal mucosa, mostly from impaction of teeth following falls, require no suturing. Lacerations 2 to 3 cm in length or with flaps are best closed with simple interrupted absorbable material. Coated Vicryl (4-0) on a round needle is preferred because it is less irritating to the child and is easier to work with than chromic gut. Closure of the mucosal surface in through-and-through lip lacerations should be carried out before closure of the muscle and skin layers. After repair, a soft diet and avoidance of irritating foods should be advised, as well as vigilant mouth hygiene. Evaluation for associated injuries of the teeth or the alveolar margin is imperative.

Fingertip Injuries

Fingertip Avulsions

Fingertip injuries are rather common in children. In the young child, most of these injuries are blunt and are secondary to entrapment of the finger in closing doors. Most of these injuries are contused lacerations or partial avulsions. Complete amputation of the fingertips is not as common. Sharp injuries are more common in the older child and less likely to be associated with fractures. Fingertip injuries should be evaluated clinically for an associated nailbed injury and radiographically for possible fractures of the phalanges. In general, this type of injury is manageable by the emergency physician, especially in the preadolescent child because tissue regeneration is remarkable and management is mostly conservative.

The management of amputations of fingertips (distal to the distal interphalangeal joint) can be approached based on the absence or the presence of bone exposure. If no or minimal bone is exposed, conservative management is advised. The wound should be cleansed, dressed in nonadherent gauze, and splinted for protection. Frequent dressing changes and appropriate follow-up should be planned. Antibiotic coverage is recommended when a significant amount of bone is exposed. Consultation with a surgeon should be considered. Shortening of the distal phalanx and covering the tip with volar skin flap is usually the treatment of choice. However, some hand surgeons increasingly advocate for a variety of skin-grafting procedures to avoid permanent shortening and deformity. Amputations proximal to the distal interphalangeal joint should be considered for microscopic reimplantation by a surgeon.

Nailbed Injuries

Trauma to the distal fingers is often associated with nail and nailbed (matrix) injuries. Nail avulsion can be partial or complete and may or may not be associated with nailbed laceration. An underlying fracture of the distal phalanx can occur. Injury to the fingertip is often associated with subungual hematoma. In evaluating these injuries, the emergency physician should determine the need to explore the nailbed for a laceration. Unrepaired nailbed lacerations may permanently disfigure the growth of the new nail from the cicatrix nailbed. If the nail is partially avulsed but is firmly attached to its bed, exploring the nailbed is difficult and is probably not warranted. Good outcome is expected because the nail holds the underlying lacerated nailbed tissues in place.

If a subungual hematoma exists, it should be drained (see the following). When the nail is completely avulsed or is attached loosely, the nail should be removed and the nailbed assessed for laceration. If the nailbed is lacerated, it should be repaired using 6-0 absorbable material. After cleansing and trimming its soft proximal portion, the nail should be

replaced between the nailbed and the nail fold (eponychium), then anchored in place with a few stitches. This will splint the nail fold away from the nailbed, which will prevent the obliteration of the space between the nailbed and the nail fold. By preserving this space, the new nail is allowed to grow undisturbed. The preferred method of local anesthesia for nailbed repair is digital block, and the use of a finger tourniquet during the repair allows a bloodless field. Application of a finger splint after repair, especially if there is an associated fracture, is recommended.

Subungual Hematoma

Subungual hematoma is a collection of blood in the interface of the nail and the nailbed. It is commonly seen with blunt fingertip injuries. The usual presentation is throbbing pain and discoloration of the nail. Subungual hematoma may be associated with nailbed injury or fracture of the distal phalanx. The presence of a fracture may complicate the decision to drain a subungual hematoma because the closed fracture then may be transformed into an open fracture.

Usually, drainage of the hematoma provides relief of the symptoms. Generally, no local anesthesia is required for a simple trephination by cauterization of the nail. After drainage, care for simple subungual hematoma includes elevation of the hand and warm soaks for a few days. The family should always be told about the possibility of nail deformity in the future. When the injury is more involved, digital block is advised. If the hematoma is large and extends to the tip of the nail, separation of the nail from the nailbed using either a sharp or blunt method will allow drainage. In the presence of a distal phalangeal fracture, the physician has to be concerned about transforming a closed fracture to an open one by communicating the subungual, and hence the fracture hematoma, to the exterior surface of the nail. If there is a possibility of an underlying fracture, antibiotic coverage and close follow-up should be sought.

CHAPTER 117

Minor Lesions and Injuries

***FRANK A. MAFFEI, MD AND †HOLLY W. DAVIS, MD**

* *Department of Pediatric Emergency Medicine, and Department of Pediatric Critical Care, Strong Memorial Hospital, Rochester, New York;*
†*Department of Pediatrics, University of Pittsburgh School of Medicine, and Division of Pediatric Emergency Medicine, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania*

A variety of minor lesions in children may prompt an emergency department (ED) visit. Most are the result of acute injury or infection (e.g., hair tourniquet, felon). Some formerly quiescent abnormalities (e.g., thyroglossal duct cyst, pyogenic granuloma) become clinically apparent after rapid enlargement secondary to infection or direct trauma. Alternatively, asymptomatic minor lesions (e.g., lipoma, pilomatrixoma) may be noted during the evaluation of an unrelated complaint. Regardless of the presentation, a systematic approach is necessary for proper diagnosis and subsequent management. Although most “lumps and bumps” in children have a benign cause, the examiner should bear in mind the possibilities of associated systemic illness and future complications.

HAND LESIONS

Eponychia and Paronychia

Infections and/or minor trauma are the major sources of hand lesions. By far, the most common infections of the hand involve the eponychium (cuticle). Most of these arise following minor trauma—a traumatized hang nail, finger sucking, or nail biting—that causes a breakdown in the epidermal barrier. In its initial stage, the infection consists of a superficial cellulitis that remains localized to the cuticle and is termed an eponychia. With progression, pus collects in a single thin-walled pocket under the cuticle, forming a paronychia (Fig. 117.1). This may progress, extending under the skin at the base of the nail, and along the nail fold. Less commonly, the pus burrows beneath the proximal nail, forming an *onychia* or subungual abscess. Causative organisms include *Staphylococcus aureus, Streptococcus pyogenes,* and anaerobic species. Treatment of a simple eponychia involves frequent warm soaks and attention to local hygiene. Topical antibacterial ointments may hasten resolution. Incision and drainage is the treatment of choice for a paronychia (see Section VII, Procedures). If an onychia has formed, removal of the proximal portion of nail overlying the abscess is essential to ensure adequate drainage and prevent destruction of the germinal matrix. Occasionally, an onychia may form under the anterolateral aspect of a nail. Here, elevation and excision of the overlying portion of nail suffices. The role of oral antibiotics after incision and drainage has not been clearly established. Most physicians choose a short course of a b-lactamase stable antibiotic (e.g., dicloxacillin, cephalexin). Oral antimicrobial therapy is definitely indicated for patients with associated lymphangitis.

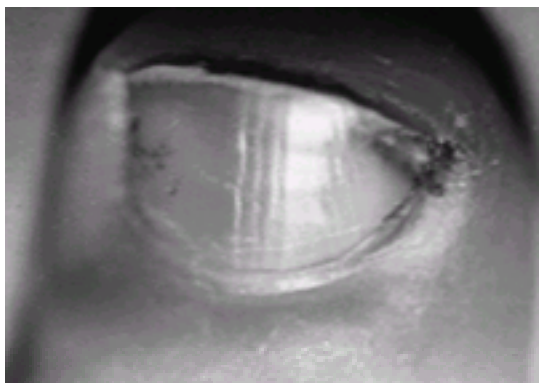

FIGURE 117.1. Small paronychia located along nail fold, noted after minor trauma.

An *herpetic whitlow* involving a finger is sometimes mistaken for a paronychia and is the major differential diagnostic consideration. Clinically, this lesion is characterized by the appearance of multiple, painful, thick-walled vesicles on erythematous bases. Over the ensuing few days, vesicles begin to coalesce and their contents become pustular. A Gram stain of pustular fluid is negative for bacteria. Tczank prep of scrapings from the base of a lesion reveals multinucleated giant cells. Subsequently, ulceration and crusting occur. The process initially results from inoculation of herpes simplex virus into a small break in the skin. The source may be a parent with herpes labialis, or a child with herpetic gingivostomatitis or herpes labialis may inoculate his or her own finger. If the infection is primary, fever and regional adenopathy are seen. With recurrences, these findings are usually absent.

Felon

A *felon* consists of a deep infection of the distal pulp space of a fingertip. Felons are caused by introduction of bacteria into the pulp space usually by punctures (which may be trivial) or splinters. Causative organisms are similar to those found in eponychial infections. A felon typically presents as an exquisitely tender and throbbing fingertip that is swollen, tense, warm, and erythematous. However, its evolution usually is relatively slow, beginning with mild pain and minimal swelling that progresses over a few days. This process is in part caused by the anatomy of the pulp, which consists of multiple closed spaces formed by fibrous septae that connect the volar skin to the periosteum of the distal phalanx. With progression of infection, pressure buildup within these small compartments may cause local ischemia. In some cases, organisms may spread to invade the phalanx, resulting in osteomyelitis. In others, the process may point outward to the center of the touch pad, where the septae are least dense, producing an obvious area of fluctuation. Because the deep septal attachments are distal to the distal interphalangeal (DIP) joint and flexor tendon sheath, there is less risk of spread to these structures.

Treatment consists of incision, blunt dissection, and drainage. A longitudinal incision over the area of maximal tension or fluctulance is the procedure of choice. Care should be taken to extend the incision past the DIP joint to prevent formation of a flexion contracture (see Section VII, Procedures). Older techniques, such as the extended “fishmouth” incision, incision through the touch pad, and the through-and-through incision, should be abandoned to avoid unnecessary complications (e.g., unstable touch pad, persistently painful scar, permanent anesthesia, skin sloughing). After drainage, a course of oral antibiotics is indicated. Close follow-up is essential to assess response to therapy and identify complications, such as septic arthritis and suppurative tenosynovitis. Patients presenting with fever, lymphangitis, or evidence of osteomyelitis should be referred to the hand service for admission, parenteral antibiotics, and definitive care.

Subungual Hematoma

A *subungual hematoma* is a collection of blood located under a nail that arises after trauma to the nailbed. The typical mechanism is a crush injury. Because this mechanism is a common cause of phalangeal fractures, radiographs are advisable. The patient experiences throbbing pain that worsens with increasing pressure as more blood collects. The underlying nailbed injury may be trivial or may involve a laceration that requires repair. If the subungual hematoma involves more than 50% of a nail surface, is associated with a distal phalanx fracture, or the nail or its margins are disrupted, the presence of a significant nailbed injury should be suspected. Nail trephination provides drainage with attendant relief of pressure and pain and suffices for uncomplicated subungual hematomas. This procedure also reduces risk of secondary infection. The trephined opening should be large enough (larger than 3 to 4 mm) to allow for ongoing drainage without risk of closure by new clot (see Section VII, Procedures). When the hematoma is large, the nail or its margins are disrupted, and/or a phalangeal fracture is present, the nail should be removed and the nailbed repaired. Antimicrobial prophylaxis for these injuries remains a source of controversy but is prescribed by most practitioners for patients with underlying fractures and those with severe soft-tissue injuries.

Subungual Foreign Body

Foreign bodies such as a wood splinter or metallic shaving become embedded under the nail and may be the source of pain and/or infection. When the foreign body is only partially embedded, the nail can be trimmed close to the nailbed, and the object's projecting end grasped with splinter forceps and gently extracted. If a portion remains, or the foreign body is deeply embedded from the outset, a digital block should be performed. Then the part of the nail overlying the object can be shaved down with a scalpel until the foreign body is exposed. Alternatively, the nail can be lifted, and the object removed (see Section VII, Procedures). After splinter removal, the finger should be soaked in warm, soapy water and an antibiotic ointment and protective dressing applied. Soaks should be repeated three times daily at home for the ensuing 3 to 5 days. In the unusual case of a child with multiple subungual splinters or fragments, it is best to remove the

nail, clean out the foreign material, irrigate thoroughly, and then replace the nail (after trephining it to allow drainage).

Hair Tourniquet

A *hair tourniquet* injury is an entity unique to pediatrics. It involves strangulation of a digit (or occasionally the penis) by a hair or fine thread. It is seen most commonly in young infants and can be the cause of unexplained irritability or crying. The mechanism involves entwinement of the hair around an infant's digit. This may occur during a bath, during subsequent toweling, or as a result of wiggling of the toes in a sock, bootie, or mitten that inadvertently has a hair or loose thread in it. A hair shed from a parent during diapering is the probable source of penile tourniquets. As the hair or thread becomes more tightly entwined, it produces a tourniquet effect, impairing blood flow with resultant ischemic pain and distal swelling. When noted early, the hair is often visible in a crease just proximal to the swollen area. If seen later, the hair may have cut through the skin, making it difficult to visualize (Fig. 117.2). In rare cases, frank ischemic necrosis of the distal digit may be seen on presentation. Removal requires a fine-tipped forceps and the aid of a thin loupe or probe that is inserted proximally under the constricting hair. Usually the hair can be unwound from the digit intact or cut with scissors. When the hair is deeply embedded or there is any question of a remaining constricting band, a nerve block should be performed and a perpendicular incision made over the hair. To avoid damage to neurovascular structures, such an incision should be made on the lateral aspect of a finger or toe at 3 or 9 o'clock or at 4 or 8 o'clock along the penile shaft. When the entire hair cannot be removed with certainty, plastic surgical consultation is indicated.

FIGURE 117.2. Hair tourniquets of third and fourth toes.

Ganglion

A *ganglion* is a cystic outgrowth or protrusion of the synovial lining of a tendon sheath or joint capsule. Common locations of such lesions include the dorsal or volar surface of the wrist (usually on the radial side), the dorsum of the foot, or near the malleolus of an ankle (Fig. 117.3). Occasionally, a flexor tendon sheath ganglion may present on the palmar surface of the hand at the base of a digit. The cause is thought to involve prior trauma that causes partial disruption of the synovium and subsequent herniation of synovial tissue. The cysts are soft, slightly fluctuant, and transilluminate. Most are painless or only mildly uncomfortable. However, those on the foot or ankle may cause pain when shoes are worn. Elective surgical excision with obliteration of the base is indicated only if function is impaired or the lesion is of cosmetic significance. Even then, up to 20% recur. The old folk remedy of striking the cyst with a large book or against a hard surface should be strongly discouraged because the cystic fluid may be dispersed through the surrounding soft tissue, inciting diffuse scar formation.

FIGURE 117.3. Ganglion cyst of the tendon sheath of flexor carpi radialis.

FACE AND SCALP LESIONS

Epidermal Inclusion Cyst

Among the most common postpubescent skin lesions is the *epidermal inclusion cyst* (EIC). These have also been termed epithelial, sebaceous, and pilar cysts. Most result from occlusion of pilosebaceous follicles, although some stem from inoculation of epidermal cells into the dermis via needle stick or other trauma. A few may arise from epidermal cells that became trapped along embryonic lines of closure. Lesions consist of firm, slow-growing, 1- to 3-cm, round nodules. Most are found about the scalp and face, although they also may be located on the trunk, neck, and scrotum. Most are solitary.

Histologically, these dermal and subcutaneous nodules consist of epidermally lined keratin-filled cysts. Presentation is that of a slow-growing painless lump that may provoke concerns of malignancy. At times, these cysts become acutely infected, and the patient complains of pain, erythema, and sudden increase in size. Infected cysts are incised and drained and treated with oral antibiotics before elective excision. Noninflamed cysts can be referred for elective excision that must include the entire sac to prevent recurrence.

When a patient presents with multiple large EICs, Gardner's syndrome should be suspected. This autosomal-dominant disorder is characterized by multiple EICs, intestinal polyposis, desmoid tumors, and osseous lesions. Early diagnosis is especially important because of a 50% risk of malignant transformation of the intestinal polyps.

Dermoid Cyst

Dermoid cysts are congenital, subcutaneous nodules derived from ectoderm. They, too, are lined with epithelium, but unlike EICs, they may contain multiple adnexal structures such as hair, glands, teeth, bone, and neural tissue, as well as keratin. The cysts usually present as solitary, round, firm nodules. They have a rubbery or doughy consistency on palpation, a smooth surface and normal overlying skin. Lesions tend to grow slowly, and malignant transformation is rare. Whereas some dermoids may be mobile, many are fixed to overlying skin or underlying periosteum. Some have other deeper attachments. Because these cysts form along areas of embryonic fusion, common sites include the nasal bridge, midline neck, or scalp, the lateral brow (Fig. 117.4), anterior margin of the sternocleidomastoid, and midline scrotum or sacrum. Midline dermoids tend to have especially deep attachments that may extend intracranially or intraspinally along with an accompanying sinus tract. An external ostium may or may not be visible. Because the sinus tract can serve as a conduit for spread of secondary infection, all midline lesions should have appropriate imaging (usually magnetic resonance imaging [MRI]) followed by elective excision.

FIGURE 117.4. Dermoid cyst of right lateral brow. (Reprinted with permission from Zitelli BJ, Davis HW, eds. Atlas of Pediatric Physical Diagnosis. 3rd ed. St Louis: Mosby, 1997.)

Nasal Bridge Lesions

Midline nasal masses in infants and children may be acquired (e.g., EIC) or congenital, the latter stemming from improper embryologic development (e.g., dermoid cyst, encephalocele, and glioma).

Dermoids are the most common embryologically derived midline nasal lesions (see previous discussion). Clinically, a firm, round, subcutaneous mass is seen in the midline over the dorsum of the nose. Some have an overlying dimple, which may have an extruding hair (Fig. 117.5). Its attachment may extend only to the nasal septum or may go deeper through the cribriform plate into the calvarium. Because of their proximity to the nasopharynx, these dermoids are particularly prone to secondary infection and fistula formation. Hence, prompt excision is indicated after careful MRI or computed tomography (CT).

FIGURE 117.5. Midline nasal dermoid with overlying dimple. (Reprinted with permission from Zitelli BJ, Davis HW, eds. Atlas of Pediatric Physical Diagnosis. 3rd ed. St Louis: Mosby, 1997.)

Gliomas contain neuroectodermally derived elements. A *glioma* is a benign growth composed of ectopic neural tissue. The lesion usually consists of a firm, gray or red-gray nodule, ranging in size from 1 to 5 cm and can be mistaken for a hemangioma. Most are extranasal (60%), occurring on the bridge of the nose. The remainder are either solely intranasal

masses (30%) or have both intranasal and extranasal elements (10%). By definition, they do not have intracranial communication. They are composed of neural and fibrous tissue, covered by nasal mucosa. To prevent possible distortion of surrounding bone and cartilage, surgical excision is the treatment of choice.

Encephaloceles consist of neural tissue that has herniated through a congenital defect in the midline of the calvarium and thus, always have an intracranial communication. Lesions appear as soft, at times pulsatile, compressible masses that enlarge with crying or straining. Compression of the jugular veins (Furstenberg test) may also cause the mass to expand in size. Some infants with nasal encephaloceles are born with overt craniofacial deformities and a rounded swelling at the base of the nose, whereas in others the mass is confined to the nasopharynx, and external facial features are normal. The latter may present with signs of persistent nasal obstruction. In these patients, a grapelike mass is found on nasopharyngoscopy. MRI is the modality of choice for differentiating encephaloceles from other midline nasal masses and for determining their size and extent. Neurosurgical evaluation and management is indicated for all encephaloceles.

Preauricular Lesions

Preauricular lesions, located just anterior to the tragus, may be the result of imperfect fusion of the first two branchial arches *(sinus tract*, *pit)* or may consist of first arch remnants *(cutaneous tag).* They may be unilateral or bilateral, single or multiple. Usually, they are seen as isolated minor anomalies, but on occasion, they can be found in association with other developmental anomalies involving the first branchial arch or in infants with chromosomal disorders. Most lesions are evident shortly after birth. Some individuals simply have a surface pit or dimple, whereas in others, the overlying dimple represents the entrance to a sinus tract or blind pouch with a small cyst at its base (Fig. 117.6A). The latter may contain hair and other epidermal elements. Sinuses are prone to infection and abscess formation, whereupon the child presents with sudden enlargement of a painful preauricular mass and overlying erythema (Fig. 117.6B). When this occurs, the patient should be treated with appropriate antimicrobial therapy before elective excision of the cyst and fistula tract. Cutaneous tags, also called accessory auricles, are flesh-colored pedunculated lesions that may or may not have a cartilaginous component (Fig. 117.7). Some with narrow bases may simply be tied off with silk sutures. Those with wider bases and those containing cartilage can be referred for elective excision for cosmetic reasons.

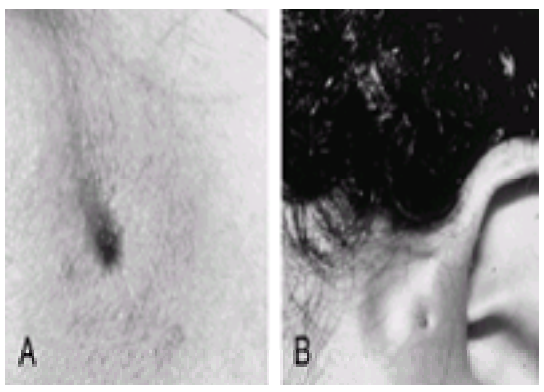

FIGURE 117.6. A. Close-up of preauricular surface pit. **B.** Infected preauricular sinus with overlying pit. (Reprinted with permission from Zitelli BJ, Davis HW, eds. Atlas of Pediatric Physical Diagnosis. 3rd ed. St Louis: Mosby, 1997.)

FIGURE 117.7. Preauricular skin tags. (Reprinted with permission from Zitelli BJ, Davis HW, eds. Atlas of Pediatric Physical Diagnosis. 3rd ed. St Louis: Mosby, 1997.)

Neck Lesions

Neck lesions in children may be of congenital origin or may be acquired as the result of an inflammatory process (Fig. 117.8). Although malignancy is a much rarer cause of neck masses in children, it must always be considered in the differential diagnosis. Neck masses or lesions are most conveniently divided into those occurring in the midline and those located in the lateral aspects of the neck.

FIGURE 117.8. Head and neck congenital lesions seen in children in frontal and lateral views. The shaded areas denote the distribution in which a given lesion may be found. *A,* Dermoid cyst; *B,* thyroglossal duct cyst; *C,* second branchial cleft appendage; *D,* second branchial cleft sinus; *E,* second branchial cleft cyst; *F,* first branchial pouch defect; *G,* preauricular sinus or appendage.

Midline Neck Lesions

Submental lymphadenitis or *lymphadenopathy* occurs in the midline just beneath the chin. Nodal enlargement stems from drainage of primary infection of the lower lip, buccal floor, or anterior tongue.

Dermoid cysts (see Face and Scalp Lesions) can occur throughout the midline of the neck but usually are found above the area of the hyoid. They also may be found more laterally along the anterior border of the sternocleidomastoid.

Thyroglossal duct cysts are among the more common midline neck masses in children. Approximately 40% present before 10 years of age. They are comprised of an ectodermal ductal remnant that fails to regress after fetal descent of the thyroid gland. They may occur anywhere along the path of descent of the thyroid, from the foramen cecum at the base of the tongue to the sternal notch, although most are found near the level of the hyoid bone. Presentation is usually that of a painless, smooth, mobile, cystic mass that is located in the midline or just slightly off-center (Fig. 117.9). Because of its intimate association with the hyoid, the mass moves with protrusion of the tongue or swallowing. On occasion, an overlying pore is present. Some cysts go unnoticed until infection occurs, causing acute swelling, pain, and erythema of the overlying skin. Patients with asymptomatic thyroglossal duct cysts should be referred for elective surgical excision. If the thyroglossal duct cyst is infected on presentation, excision is deferred until appropriate antimicrobial therapy is completed and inflammation has subsided. If incision and drainage are required during treatment, the patient should be referred to a surgeon comfortable with thyroid anatomy. Elective excision involves removal of the cyst, the entire duct to the level of the foramen cecum, and the midportion of the hyoid bone. On rare occasions, ectopic thyroid tissue in a thyroglossal duct cyst is the patient's only functioning thyroid. Therefore, most authorities recommend ultrasound or radioisotope scanning to confirm the presence of a normal thyroid gland before surgery.

FIGURE 117.9. Thyroglossal duct cyst, which elevated with tongue protrusion. (Reprinted with permission from Zitelli BJ, Davis HW, eds. Atlas of Pediatric Physical Diagnosis. 3rd ed. St Louis: Mosby, 1997.)

Diffuse enlargement of the thyroid gland, or *goiter,* may be the result of infiltration, inflammation, or overstimulation of the gland. By far, the most common cause of pediatric thyroid enlargement is chronic *lymphocytic thyroiditis* (also called *Hashimoto's thyroiditis* or *autoimmune thyroiditis*). This disorder is characterized by a defect in cell-mediated immunity that results in lymphocytic infiltration of the thyroid gland. Females are affected predominantly, and peak occurrence is during adolescence. Usual presentation is one of a slow growing, painless midline neck mass. Occasionally, a patient may complain of sore throat. Examination reveals a firm, nontender, diffusely enlarged gland in most affected children, but approximately one-third will have some lobular or nodular enlargement. Evaluation includes assessment of thyroid function and the detection of thyroid autoantibodies in the serum. Most patients with lymphocytic thyroiditis are euthyroid. When thyroid dysfunction is present, it usually takes the form of hypothyroidism. Any degree of nodularity of the gland warrants further investigation to rule out malignancy.

Inflammation of the thyroid gland secondary to infection, *acute suppurative thyroiditis*, is a rare cause of diffuse thyroid enlargement. Presentation usually follows an upper respiratory infection and is characterized by abrupt appearance of a painful, tender, swollen mass in the region of the thyroid. Systemic toxicity in the form of fever and chills and severe dysphagia are often present. Flexion of the neck may alleviate pain, whereas extension worsens it. Etiologic agents

include *S. aureus, Streptococcus hemolyticus, Streptococcus pneumoniae,* and occasionally, anaerobic species. Appropriate parenteral antimicrobial therapy is usually sufficient to eradicate the infection. Abscess formation necessitates incision and drainage by a surgeon comfortable with thyroid anatomy.

Acute immune stimulation of the thyroid gland may also produce diffuse thyroid enlargement. In *Graves' disease,* autoantibody attachment to the thyroid-stimulating hormone (TSH) receptor stimulates an increase in thyroid hormone synthesis and release. This produces glandular enlargement with a soft consistency and symptoms of juvenile thyrotoxicosis, including tachycardia, nervousness, tremor, weight loss, increased appetite, and heat intolerance. An elevated T_4 in the context of a low TSH level and presence of TSH receptor antibodies confirms the diagnosis. A pediatric endocrinologist guides therapy in the form of antithyroid drugs.

Solitary nodular thyroid masses deserve careful attention. Although most are secondary to chronic lymphocytic thyroiditis or consist of a benign adenoma, the incidence of malignant neoplasms is actually higher in children with thyroid nodules than in adults. Hence, every thyroid nodule found in a child merits a complete evaluation that may include ultrasound imaging, radioisotope scanning, and biopsy.

Lateral Neck Lesions

Enlarged cervical lymph nodes constitute the most common lateral neck masses in children. Knowledge of the anatomy of the cervical lymphatics is of fundamental importance to understanding processes that cause enlargement of cervical lymph nodes. This section focuses mainly on local processes that cause nodal enlargement, but it is important to note that many systemic infections and inflammatory disorders can cause diffuse adenopathy that includes the cervical chain. Therefore, any child with a neck mass deserves a complete examination to look for the presence of generalized adenopathy and other signs of systemic disease.

Reactive cervical adenopathy refers to mild enlargement of cervical lymph nodes that accompanies a viral or bacterial upper respiratory infection. Involved nodes are typically located in the upper portion of the cervical chain. They are usually discrete, firm, mobile, and less than 2 cm in diameter. They may be mildly tender but have no overlying erythema, edema, or warmth. Regression within 1 to 2 weeks of resolution of the primary infection is the rule, although occasionally mild enlargement of the node may persist, if fibrosis has occurred.

Local infection of a lymph node itself is termed *acute suppurative lymphadenitis.* The involved node is solitary, typically 2 to 3 cm or larger in diameter, and extremely tender. As the infection proceeds, overlying swelling, erythema, and warmth develop and become more pronounced (Fig. 117.10). Initially the node is firm, but later it may become fluctuant. Acute suppurative lymphadenitis is most often caused by streptococcal or staphylococcal organisms. Because of the high incidence of b-lactamase production by *S. aureus*, b-lactamase stable antibiotics (dicloxacillin, cephalexin) are the treatment of choice. Most patients respond to oral antimicrobial therapy and application of warm compresses. However, if fluctuance develops, incision and drainage are recommended. Other potential causative organisms of acute, subacute, or chronic lymphadenitis include anaerobic bacteria, *Pasteurella multocida* (following animal bites), *Haemophilus influenzae, Streptococcus agalactiae, Francisella tularensis, Brucella* species, *Bartonella henselae* (cat-scratch disease), mycobacteria, and actinomycoses. Kawasaki disease also may present with an acutely enlarged cervical node and should be considered when other clinical criteria are present (fever longer than 5 days, rash, conjunctivitis, extremity and oral changes, and hyperirritability).

FIGURE 117.10. Suppurative lymphadenitis of an anterior cervical lymph node.

Salivary gland infections, *sialadenitis,* and *parotitis*, may cause lateral neck or submental swelling. When the parotid gland is involved, firm indurated swelling is found extending in an arc from the preauricular area down under the ear and behind it. The degree of swelling is often sufficient to blunt the angle of the jaw, and the mass is usually mildly tender. Patients complain of mild pain in the region of the pinna, which increases with eating. Most salivary gland infections affect the parotid gland, with involvement of the sublingual and submandibular glands being much less common. Viral agents (e.g., mumps virus, parainfluenza types 1 and 3, influenza A, Coxsackie A, and rarely, human immunodeficiency virus) cause most of these infections. Less commonly, parotitis is of bacterial origin. In these cases, patients present with rapid gland enlargement and severe pain, and they often have high fever and signs of systemic toxicity. On examination, overlying erythema and exquisite tenderness are present, and purulent material can often be expressed from Stensen's duct by massaging the gland. Symptomatic treatment of sialadenitis includes close attention to hydration and avoidance of foods that require excessive chewing or induce rapid salivary flow (e.g., citrus fruits, sour foods). If bacterial sialadenitis or parotitis is suspected, b-lactamase stable parenteral antibiotics should be administered. Otolaryngologic consultation should be obtained if surgical drainage is needed because of the proximity of the facial nerve. Much less commonly, parotid gland swelling is of noninfectious origin. Causes include occlusion of Stensen's duct by a calculus and

traumatic insufflation of the gland with forceful blowing.

Cystic hygromas (lymphangiomas) represent malformations of the lymphatic system. They consist of dilated lymphatic channels and may be multiocular or unilocular. They occur most often in the posterior triangle of the neck (Fig. 117.11) but may be found in the axillae, groin, popliteal fossae, or on the chest or abdominal wall (Fig. 117.12). When found in the neck, extension of the mass into the anterior triangle, sublingual space, retropharyngeal space, or mediastinum is possible. Such infiltration can result in airway compromise and/or compression of vascular and neural structures. Most cystic hygromas are present at birth or become apparent shortly thereafter. Patients usually present with a slow-growing, painless neck mass that is soft and compressible, although some are brought for care because of sudden enlargement caused by secondary infection or hemorrhage within the lesion. Anatomic delineation of the mass is best done using MRI or ultrasonography. When lesions are located in the neck, the potential risk to the airway and neurovascular structures, coupled with the possibilities of hemorrhage or lymphangitis, dictates the need for early intervention. Therapy has traditionally consisted of meticulous surgical excision; however, recurrences have been common. Recently, use of a new sclerotherapeutic agent has produced excellent results. OK-432 is a mixture of penicillin G and a low virulent Su strain of type II, group A streptococcus that has lost its ability to produce streptolysin-S. When injected into the lesion, it destroys the endothelial lining of the cyst, and thus accelerates drainage and shrinkage of the mass.

FIGURE 117.12. Lateral abdominal wall cystic hygroma (lymphangioma).

Branchial cleft anomalies consist of a group of congenital malformations, including subcutaneous cysts, sinus tracts, and cartilaginous remnants. They are caused by persistence of structures derived from the embryonic branchial arches. Of these anomalies, 90% arise from the second branchial arch and are found along the anterior border of the sternocleidomastoid muscle. Sinus tracts of second branchial arch remnants may end in an internal ostium located near the tonsillar fossa. Less commonly, first branchial arch anomalies may be noted as masses or sinus tracts near the mandibular ramus. Some first branchial arch remnants end in an internal ostium located in the external auditory canal. Branchial cleft anomalies may be noted shortly after birth either as a firm, mobile mass with or without an overlying pore or simply as an external ostium or pore without an underlying mass (Fig. 117.13). More commonly, branchial cleft cysts are detected later in childhood when they may present as an asymptomatic mass or with acute painful enlargement as a result of secondary infection. All branchial cleft anomalies should be referred for surgical excision for cosmetic purposes and to avoid potential morbidity, which includes infection and the development of carcinoma in situ. When patients present with infection, excision must be deferred until antimicrobial therapy and incision and drainage (if needed) have quelled all signs of inflammation.

FIGURE 117.13. Second branchial cleft pit that had an underlying sinus tract.

The combination of torticollis and a lateral neck mass in early infancy is highly suggestive of a *sternocleidomastoid tumor.* Clinically, a nontender, firm, ovoid mass is found along the middle third of the sternocleidomastoid muscle. The mass represents local muscle hemorrhage that subsequently undergoes fibrosis. It is thought to be the result of traumatic extraction of the head during delivery, or of fibrous dysplasia secondary to intrauterine positioning. Some are noted at birth, whereas others become apparent within the ensuing few weeks. The head is bent toward the affected side, and limitation of bending to the opposite side and rotation toward the involved side are noted. Initial treatment consists of passive stretching exercises and positioning of the infant so he or she has to turn from the affected side to see others. If this fails, surgical release of the contracture is indicated to prevent secondary facial deformity with growth. Infants with this disorder should be carefully assessed for associated hip dysplasia, which coexists in up to 20% of cases.

The possibility of *malignancy* must be considered in the differential diagnosis of any child with a cervical mass. History regarding the presence of persistent fevers, malaise, night sweats, weight loss, and other constitutional symptoms should be sought, and the child assessed for presence of pallor, petechiae, generalized adenopathy, and hepatosplenomegaly. Primary lymphoid malignancies, such as leukemia and lymphoma, may present initially with a rapidly enlarging neck mass. In contrast to infectious adenopathy, involved nodes tend to be firm, matted, nontender, and poorly mobile. Posterior triangle and supraclavicular masses carry a much higher risk for neoplasm than do anterior triangle masses. Metastatic tumors, such as rhabdomyosarcoma and neuroblastoma, also may initially be manifest as a neck mass. If malignancy is suspected, the ED workup should include complete blood count, electrolytes, uric acid, liver function studies, heterophile antibody titer, and a chest radiograph. Further evaluation, including imaging and biopsy, should be performed in consultation with a pediatric oncologist.

SURFACE LESIONS

Vascular Malformations

Vascular malformations result from errors in vascular morphogenesis. Unlike hemangiomas, they are present at birth, grow only in proportion to the child, and do not undergo regression. They may be of capillary, venous, or arterial origin, or combinations of vessel types may exist within the same lesion. *Port-wine stains* are among the more common capillary vascular malformations. They have a characteristic deep red to purple hue (Fig. 117.14). Children with facial port-wine stains that lie in the distribution of the ophthalmic branch of the trigeminal nerve (which includes the forehead, upper eyelids, and nose) merit careful evaluation for associated anomalies. Specifically, the *Sturge-Weber syndrome* is characterized by ipsilateral vascular angiomatosis of the leptomeninges and ocular vessels. Clinical manifestations may include seizures, mental retardation, hemiplegia, and glaucoma. Serial head CT scans performed on these children often demonstrate evolution of serpiginous calcifications and progressive atrophy of the cerebral cortex underlying the pial vascular malformations. Children with port-wine stains involving an extremity may develop hemihypertrophy of the affected limb because of an unusually rich underlying blood supply, the *Klippel-Tréenaunay-Weber syndrome*.

FIGURE 117.14. Facial port-wine stain that does not involve the distribution of the ophthalmic branch of the trigeminal nerve. (Reprinted with permission from Zitelli BJ, Davis HW, eds. Atlas of Pediatric Physical Diagnosis. 3rd ed. St Louis: Mosby, 1997.)

All cosmetically significant port-wine lesions should be referred to a dermatologist. Some can be masked by using camouflage cosmetics (Covermark). Others may warrant definitive treatment using pulsed dye laser therapy.

Salmon patches, the most common form of vascular malformation seen in infancy, occur in 30 to 40% of all newborns. These flat pink lesions, which become more prominent with crying or exertion, are most commonly located on the nape of the neck (stork bites), on the glabella, or over the eyelids (angel kisses). They consist of distended dermal capillaries and almost always fade or disappear by the end of the first year of life, although nuchal salmon patches may persist into adulthood.

Hemangiomas

Hemangiomas, the most common benign neoplasm of infancy, occur in 10% or more of children less than 1 year of age.

Histologically, they are composed of hyperplastic vascular endothelium that develops from angioblastic tissue that has failed to connect normally with the vascular system during gestation. Although only a small portion of hemangiomas are evident at birth (2.5%), most become apparent within the first month of life. Lesions tend to undergo a period of rapid growth over the ensuing 6 to 12 months, then plateau. Subsequently, a slow process of involution begins, usually by 18 months. Approximately 50% of lesions involute completely by 5 years of age, and 95% by 9 years of age. A simple way to categorize hemangiomas is to subdivide them into three types: 1) *Superficial hemangiomas* are confined to the upper dermis. Formerly called capillary or strawberry hemangiomas, these lesions are well demarcated and compressible (Fig. 117.15). 2) *Deep hemangiomas*, previously called cavernous hemangiomas, lie in the lower dermis. They tend to have indistinct margins, and the overlying skin often has a bluish hue (Fig. 117.16). 3) On close inspection, many hemangiomas have a combination of both superficial and deep elements, and thus should be called *mixed hemangiomas* (Fig. 117.17).

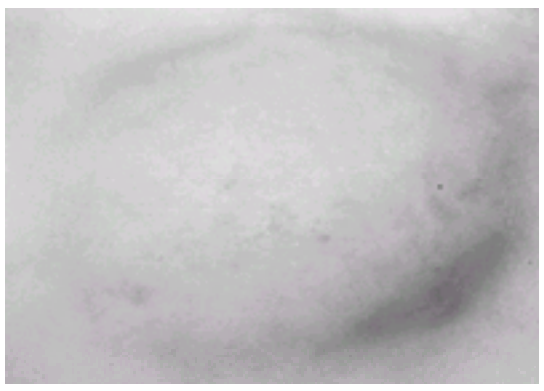

FIGURE 117.16. Deep hemangioma of upper lateral chest.

FIGURE 117.17. Mixed hemangioma containing both superficial and deep components. (Reprinted with permission from Zitelli BJ, Davis HW, eds. Atlas of Pediatric Physical Diagnosis. 3rd ed. St Louis: Mosby, 1997.)

Because of their natural history of ultimate regression, a combination of watchful waiting and parental reassurance remain the standard of care for most hemangiomas. However, active intervention is indicated for lesions that compromise vital structures (airway, eyes, nose); lesions that are susceptible to trauma, hemorrhage, or infection; and those that grow at an alarming rate. Extremely large cavernous hemangiomas pose a risk for development of *Kasabach-Merritt syndrome,* which is characterized by sequestration of platelets with secondary thrombocytopenia and high-output cardiac failure. For lesions requiring active intervention, new treatment modalities that show promise include pulsed dye laser therapy and parenteral a-interferon. Intralesional steroid injections have also proved successful in some cases. Other options include cryotherapy and grenz ray therapy (which has replaced radiation). Decisions regarding which lesions to treat and how are best made in consultation with either a pediatric dermatologist or a plastic surgeon.

Lipoma

Lipomas are benign subcutaneous tumors composed of mature adipose cells. They often present in adolescence as

painless and usually solitary nodules. Although they may be located anywhere on the body, preferential sites include the neck, shoulders, back, upper chest, abdomen, and arms. Clinically, lipomas are nontender and have a soft, rubbery consistency, often with lobulations. Overlying skin is normal and easily slides across the mass, which helps distinguish lipomas from other skin nodules such as pilomatricomas. *Angiolipomas* are a variant of lipoma that have a component of capillary proliferation. Unlike lipomas, they tend to be painful. Lesions that are cosmetically significant, large, or painful warrant elective surgical excision.

Pilomatricoma

Pilomatricomas (calcifying epitheliomas) are relatively common lesions, accounting for 10% of superficial nodules seen in children. These benign tumors arise from cells of the hair matrix, hair cortex, or inner root sheath. Most are found on the head and neck but some arise on the trunk and extremities. They appear as firm (resulting from calcification), solitary nodules ranging in size from 0.5 to 5 cm. An overlying bluish hue may help distinguish the lesion from other benign nodules such as epidermal or dermoid cysts. When pinched, the overlying skin "tents," providing another distinguishing feature. Multiple pilomatricomas have been associated with myotonic dystrophy. Familial occurrences have been reported but are rare. If the lesion is located in a cosmetically sensitive area, elective surgical excision is the treatment of choice.

Pyogenic Granuloma

A *pyogenic granuloma* (also called lobular capillary hemangioma) is a benign vascular lesion most commonly found on exposed skin surfaces such as the face, hands, and forearms. Occasionally, lesions form on oral or nasal mucosal surfaces. They are comprised of granulation tissue with significant vascular overgrowth and are considered the result of an exaggerated vascular growth factor response after local trauma. Lesions are usually solitary and pedunculated, measuring from 0.5 to 2 cm. At times, multiple satellite lesions are found around a central granuloma. The color and character of a pyogenic granuloma varies according to its stage of growth. Early on, the lesion appears as a glistening, red, polypoid nodule with a friable surface that bleeds easily (Fig. 117.18). Later (weeks to months), the lesion becomes fibrotic and shrinks, taking on a reddish brown hue. The most common reasons for presenting to the ED are bleeding or chronic oozing of an early lesion. Treatment consists of excision followed by silver nitrate cauterization of vessels at the base. Recurrence merits referral to a dermatologist.

FIGURE 117.18. A. Pyogenic granuloma of the face. **B.** Interdigital pyogenic granuloma. (Reprinted with permission from Zitelli BJ, Davis HW, eds. Atlas of Pediatric Physical Diagnosis. 3rd ed. St Louis: Mosby, 1997.)

Umbilical Granuloma

An umbilical granuloma presents as a soft, friable, polypoid mass that is pink or dull red. It arises from the base of the umbilical stump and at times may be pedunculated with a short stalk (Fig. 117.19). It is the product of an exuberant granulation tissue reaction, probably secondary to excessive moisture and/or low-grade infection. Treatment of most lesions consists of cauterization with a silver nitrate stick. During this procedure, care should be taken to cover the skin of the umbilical rim with gauze to protect it from burns. Following cauterization, the lesion should be blotted dry to avoid seepage of excess silver nitrate to surrounding tissue. Home care consists of keeping the umbilicus clean and dry. Large granulomas may require repeated cautery at intervals of several days. Pedunculated granulomas are candidates for suture ligation (3-0 nylon). The parent is then instructed to return for follow-up for cauterization of the base (once the granuloma has necrosed and dropped off) to prevent recurrence. Umbilical granulomas must be differentiated from persistent embryonic remnants such as an *omphalomesenteric duct* or *patent urachus.* The presence of a central lumen or chronic discharge should prompt the clinician to consider these rare umbilical anomalies. The distinction is of great clinical significance because these problems may be associated with other congenital malformations, and surgical excision of the entire remnant is necessary to prevent sequelae, such as infection.

FIGURE 117.19. Large pedunculated umbilical granuloma that responded to suture ligation and repeated silver nitrate applications.

Granuloma Annulare

The lesions of *granuloma annulare* are comprised of infiltrates of lymphocytes and altered collagen within the dermis. They first appear as raised nodules that gradually expand centrifugally to form annular rings ranging from 1 to 5 cm in diameter. They have a firm, fibrous, sometimes lumpy consistency on palpation. Overlying skin is usually normal or slightly hyperpigmented (Fig. 117.20). Although most are asymptomatic, a patient occasionally may report mild pruritus and present with superficial excoriation caused by scratching. The lack of an active microvesicular border, firm consistency on palpation, and the deeper dermal location of these lesions help distinguish them from *tinea corporis.* Lesions are commonly found on the extensor surfaces of the lower legs and the dorsum of the hands and feet and, less often, on the trunk or abdominal wall. Although granuloma annulare may present at any age, more than 40% of cases appear before age 15. Because most lesions undergo resolution within 1 to 2 years, reassurance is usually all that is necessary. In the rare case of a patient with severe or widespread lesions, dermatologic consultation should be sought. Although adult studies have shown an association of granuloma annulare with diabetes mellitus, this is not the case for children.

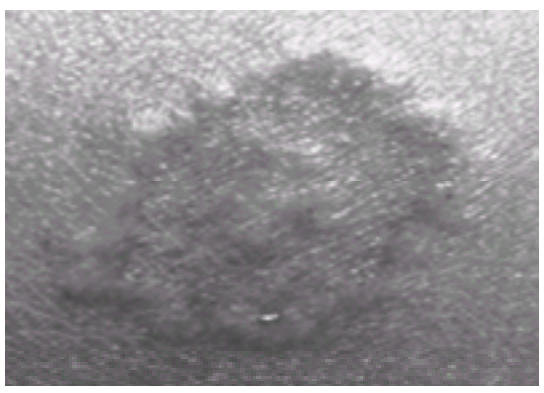

FIGURE 117.20. Granuloma annulare.

Juvenile Xanthogranuloma

Juvenile xanthogranulomas (JXG) present as nodular or plaquelike lesions with a firm or rubbery consistency. Initially reddish in color, they evolve to have a distinct yellow or orange hue (Fig. 117.21). Many are noted at birth, whereas others appear within the first several months. They range in diameter from 0.5 to 4 cm. Like hemangiomas, they tend to grow rapidly in infancy, then spontaneously regress in early childhood. Common sites include the scalp and face, proximal extremities, and occasionally, the subungual area of a digit or a mucocutaneous junction. Lesions may be solitary but are often present in groups. Histologically, xanthogranulomas are comprised of lipid-laden macrophages or histiocytes within a granulomatous matrix whose inciting source is unknown. In rare cases, giant or disseminated lesions may occur. Patients who have multiple or diffuse lesions may have ocular lesions as well. Specifically, lesions of the iris that have been associated with spontaneous anterior chamber hemorrhage and glaucoma. On occasion, ocular lesions have been misdiagnosed as retinoblastoma. A systemic form of JXG exists, and affected patients may or may not have concomitant cutaneous findings. In this variant, noncutaneous lesions may involve the brain, heart, liver, spleen, and lungs. Children who have both JXG and neurofibromatosis are at a much higher risk for unusual forms of leukemia and thus should be appropriately monitored. Last, unlike children with disseminated xanthomas, there is no relationship between JXG and lipid abnormalities. All children with suspected xanthogranuloma should undergo biopsy. An ophthalmologic evaluation is necessary if JXG is confirmed, and careful observation for evidence of systemic involvement is warranted.

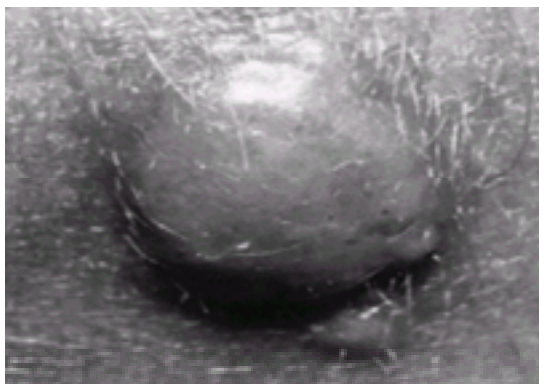

FIGURE 117.21. Yellow nodular lesion typical of juvenile xanthogranuloma.

Neurofibroma

A neurofibroma may present as a solitary lesion in an otherwise normal patient or as a feature of neurofibromatosis type I. Cutaneous neurofibromas arise from nerve sheath cells located in the dermis. They appear as pink or flesh-colored nodules that are soft and range in size from 0.5 to 3 cm. Most do not appear until adolescence. Lesions may be confused with angiolipomas and hemangiomas; however, a distinguishing feature is the tendency of neurofibromas to be especially soft centrally and invaginate with digital pressure, described as “button-holing.” Elective excision is indicated only if the lesion is compressing a nerve, causing nerve root pain, because excision is often followed by recurrence of an even larger lesion.

Keloid/Hypertrophic Scar

Exaggerated proliferation of fibrous connective tissue in the process of cutaneous wound healing results in formation of *hypertrophic scars* and *keloids.* Wounds involving areas of skin that are thick or under high tension (shoulders, back, chest, or chin) are at greatest risk. The ear lobe is another commonly affected site. Individuals with dark skin are much more susceptible to abnormal scarring, which has its highest incidence in adolescence and early adulthood. Hypertrophic scars remain confined to the area of original injury. They are rarely painful and tend to undergo slow regression over 6 to 12 months. In contrast, keloids extend beyond the original wound margins and rarely regress spontaneously. Initially, keloids may be painful and tender or pruritic. They have a rubbery consistency on palpation and a smooth pink surface (Fig. 117.22). Ear piercing, tattooing, and elective cosmetic procedures should be avoided in persons who have a tendency to form keloids. Severe keloids should be referred to a dermatologist or plastic surgeon for optimal treatment, which may include injection of intralesional steroids, cryosurgery, or meticulous excision with steroid infiltration along wound margins.

FIGURE 117.22. Large keloid that formed after ear piercing in a susceptible child.

Lumbosacral Lesions

Pilonidal dimples, typically located in the midline in the sacrococcygeal area, are benign lesions of no clinical significance. On close inspection, there is no evidence of a central pore or opening. In contrast, pilonidal sinuses, which are found in the same area, do have a small surface opening to a tract lined by stratified squamous epithelium that extends toward, but not into, the spinal canal. In some instances, sinuses appear to be of embryonic origin, stemming either from an abnormality of midline fusion or invagination of ectodermal elements. The base of such a lesion may consist of a small cyst containing products of skin cells and epithelial appendages, including hair. In other cases, the source may be a distorted hair follicle. Pilonidal sinuses and cysts are asymptomatic until the sinus becomes obstructed and/or infected. This phenomenon is most likely to occur during adolescence or early adulthood. Males are much more commonly affected than females. Excess weight and hirsutism and a sedentary lifestyle or occupation that requires prolonged sitting also appear to be predisposing factors.

Infecting organisms usually gain access through the external sinus tract. Once infection occurs, an abscess forms and tends to enlarge rapidly. Because the overlying skin is thick, expansion tends to occur deep to the skin surface, and acquired sinus tracts may form external to the postsacral facia. Patients typically complain of low back pain, increased on sitting, and local tenderness. On examination, a tender, indurated swelling is noted overlying the sacrococcygeal area with the original sinus at its cephalad end (Fig. 117.23). Treatment consists of incision and drainage with careful probing

to break up loculations and extract any hairs present because these act as foreign bodies. Cultures grow mixed organisms, including staphylococci, anaerobes, and fecal flora. Home care includes sitz baths and oral antimicrobial therapy. Elective excision of the entire cyst and all associated sinus tracts is indicated once inflammation has resolved.

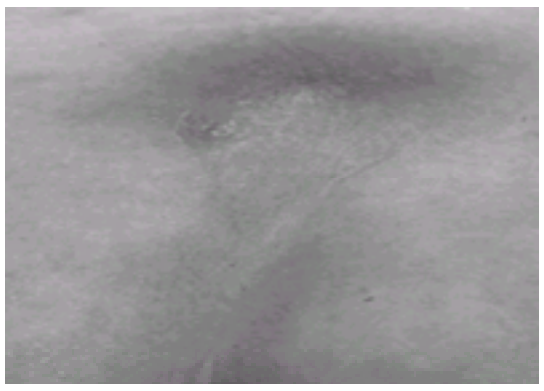

FIGURE 117.23. Infected pilonidal cyst.

Cutaneous Manifestations of Spinal Dysraphism

A number of midline cutaneous abnormalities found in the lumbosacral area are associated with underlying vertebral or spinal cord defects that are the result of defective closure of the caudal neural tube, *occult spinal dysraphism.* Skin findings include *hairy patches* (Fig. 117.24), *skin tags*, *port-wine stains*, *hemangiomas,* and *congenital dermal sinuses.* The latter tend to be more cephalad than pilonidal sinuses, and their sinus tracts often extend to the spinal column. Underlying intraspinal lesions include dermoid tumors, lipomas, and diastematomyelia. In the latter condition, the lower cord is divided sagittally by an osseous or fibrocartilaginous septum, which tethers the cord at that level, impeding its normal ascent within the spinal canal as the child grows. Patients with tethering may present with lower extremity neurologic deficits at birth or may insidiously develop symptoms later in infancy or childhood, especially during a period of rapid growth. Complaints may include back or leg pain or stiffness, buttock pain, weakness or numbness, and bowel and bladder complaints.

FIGURE 117.24. Lumbosacral hairy patch in a patient with diastematomyelia.

Any child found to have one of the midline cutaneous findings just described should undergo neuroimaging to detect and delineate underlying vertebrospinal defects because early neurosurgical intervention enables substantial reduction in morbidity.

Perineal Lesions

Urethral prolapse is a phenomenon seen primarily in obese prepubescent girls. Two-thirds or more are African-American. In this condition, the urethra prolapses through the urethral meatus and is seen as a red or purplish red, friable, edematous mass overlying the anterior portion of the introitus (Fig. 117.25). It often has a donut shape, and close inspection reveals a central orifice. The prolapsed mucosa is usually mildly painful and tender and tends to bleed easily. Presenting complaints may include perineal pain, dysuria, and blood spotting on underwear. Urination is not impaired. The precipitating event is characterized by increased intra-abdominal pressure, usually severe straining with constipation, a severe coughing spell, or prolonged crying. Because the red friable mass often overlies the hymenal orifice, it can be mistaken for traumatized hymenal folds, raising suspicion of sexual abuse. Correct diagnosis is made by examination under magnification after applying a topical anesthetic. This enables visualization of the central orifice and elevation of the mass to visualize the hymen. Management consists of treating the predisposing condition, oral analgesics and topical antibiotic/anesthetic creams for symptomatic relief, and twice daily application of estrogen cream.

FIGURE 117.25. Typical doughnut appearance of urethral prolapse.

Perianal skin tags are common sequelae of anal fissures and thus tend to be seen in children with a history of large, hard stools. They consist of pedunculated masses on short stalks that form during the process of healing of an anal fissure, probably in part caused by frictional forces common to this area. They are usually asymptomatic. They also can be seen in association with hypertrophic scars, another common sequela of the healing of an anal fissure. Although most patients with these lesions are otherwise normal, a small percentage have them as manifestations of perianal disease, internal fissures and/or fistula, which may be the primary problem or one manifestation of inflammatory bowel disease. Management is directed at treating the predisposing or underlying condition. Bothersome pedunculated lesions can be tied off with silk suture.

Rectal prolapse, herniation of the rectum through the levator and then the anal orifice, is a phenomenon typically seen in children between 1 and 2 years of age. The most common predisposing conditions, severe constipation and severe diarrhea, are characterized by repeated straining on defecation, which stretches pelvic suspensory structures, facilitating herniation. Patients with spina bifida may have prolapse as a consequence of deficits in perineal innervation with attendant atrophy of the supporting perineal muscles. In children with undiagnosed cystic fibrosis, passage of large to voluminous stools and poor muscle tone secondary to malnutrition appear to predispose. Occasionally, an apparent rectal prolapse represents the lead end of a sigmoid intussceptens. In these cases, patients have a history of antecedent, intermittent, abdominal pain or irritability and may have vomiting, lethargy, and/or rectal bleeding as do other infants and children with intussusception. Clinically, a cylindrical mass with a central orifice and a glistening red surface is seen protruding through the anus. Acutely, the mass can be reduced with gentle pressure. Attention is then directed at identifying and treating the underlying condition to prevent recurrences. The need for operative intervention for persistent recurrences is rare and is largely limited to neurodevastated patients with intractable constipation.

CHAPTER 118

Abdominal Emergencies

***LOUISE SCHNAUFER, MD and † SOROOSH MAHBOUBI, MD**

**Department of Pediatric Surgery, †Departments of Radiology and Pediatrics, The University of Pennsylvania School of Medicine, and †Body CT, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania*

Although some acute intra-abdominal diseases may affect both adults and children, other conditions occur specifically in children and are extremely uncommon in adults. Appendicitis is similar in both age groups. Disorders such as malrotation and volvulus, Hirschsprung's disease, and congenital bowel stenoses affect the younger age group. The emergency physician must be aware of the unique problems that occur in infancy and childhood and gear his or her thinking to an understanding of the clinical manifestations of these entities. There must also be an awareness and sensitivity to the special techniques for evaluating a child with a potential “surgical abdomen.”

The abdominal surgical problems most commonly found in infants and children are discussed under the following categories: 1) diseases that produce peritoneal irritation; 2) acute intestinal obstruction; 3) chronic, partial intestinal obstruction; 4) problems that produce rectal bleeding; 5) intra-abdominal masses; 6) abdominal wall defects; and 7) foreign bodies of the gastrointestinal (GI) tract. Nonsurgical GI emergencies are covered in Chapter 93. Chapter 108 deals with major trauma to the abdominal contents. Chapter 50 reviews the diagnostic approach to the child with abdominal pain.

EVALUATION

History

Neither an infant nor a young child can give a complete history, but it is useful to obtain whatever history possible from the child. Younger children, for example, are likely to recall recent events. Events somewhat more remote in time may be

better remembered by an adult, although the adult's accuracy may be clouded by his or her emotional state. If a child has been toilet-trained for a few years, neither the child nor the parent may be sufficiently attentive to give an accurate history of bowel habits. In general, however, once a child reaches school age, taking a history becomes considerably easier.

In obtaining the history, the emergency physician should seek an accurate chronology of events, with direct questions: When did the pain start? Where was it felt at first? What happened next? The physician should also obtain a careful history of other symptoms. By asking when the child was last perfectly well, one may get a more accurate assessment of the child's pathophysiology. In this way, one may better evaluate a child with multiple symptoms, such as fever, vomiting, abdominal distension, and any changes in bowel habits, appetite, feeding pattern, or general activity level. The physician then develops a feeling for the patterns of different diseases in children.

For example, if there is high fever at the onset of the problem, it is more likely infectious in origin (i.e., viral gastroenteritis or a urinary tract infection rather than appendicitis). The child with acute appendicitis usually has a low-grade fever, which develops after the onset of the first vague midepigastric pain. If the appendix has perforated and the child is dehydrated and septic, the temperature may reach as high as 39° to 40°C (102.2° to 105.8°F).

Vomiting is often associated with acute or chronic abdominal pain, especially in the younger child. Infants with a history of colicky pain and vomiting should cause suspicion of intussusception or malrotation with volvulus. The younger child with acute appendicitis often has vomiting, whereas a teenager does not. Voluminous bilious vomiting is often the first symptom in a child who has had previous abdominal surgery and has intestinal obstruction.

There must be concern about a possible underlying surgical condition in any child whose first presenting symptom is abdominal pain. It is important to determine the type of pain, its location, and whether it is constant or intermittent and colicky. Visceral pain has a colicky character and is usually generalized in the upper, middle, or lower abdomen, depending on which level of the GI tract is involved. A child who complains of a sharp pain, often in the right lower quadrant, that comes and goes, does not have appendicitis. Peritoneal pain reflects secondary features of the abdominal disease process such as inflammation, bowel perforation, or infarction. Often, a child can perceive the actual change from visceral-type pain to peritoneal pain. A catastrophic event such as infarction of the entire small intestine from a volvulus or a closed loop obstruction can cause lethargy and a shocklike picture rather than extreme abdominal pain in a short period.

If the child's illness begins with nonbloody diarrhea, it is less likely to be surgical in nature, in contrast to a child with a 3-day history of abdominal pain and fever in whom the onset of diarrhea may be secondary to a perforated appendix with pelvic abscess formation. Bloody diarrhea may or may not be surgical in nature, but it warrants a very thorough assessment (see Chapter 19 and Chapter 30).

In addition to detailing the chronology of events and the characteristics of the symptoms, the physician should inquire about any treatments which have been attempted at home, such as cathartics, enemas, or drugs. Often, these home remedies will have modified the symptoms and their chronology in some way.

It is important not to overlook the history. For example, a child known to have sickle cell disease may have an acute abdominal crisis as the cause of abdominal pain. The presence of this underlying hematologic abnormality forces the examiner to be more precise in the interpretation of the physical examination. A child with known cystic fibrosis or inflammatory bowel disease may also commonly have abdominal pains that do not require surgery.

Examination

Children vary a great deal in their ability to cooperate during the abdominal examination, and often the physician must make patient, repeated efforts to perform an adequate evaluation. A few minutes spent gaining the child's confidence is important to the child and helpful to the examiner. The best abdominal evaluation is done before the child becomes disturbed by the drawing of blood samples or the performance of a rectal examination. On some occasions, it is helpful to let the distraught, crying child actually go to sleep; a second examination while the child is sleeping may determine whether real tenderness is present. It may also be helpful to relax the child by having a parent hold him or her for the examination. The use of narcotics should be avoided because they might mask findings of peritonitis. All infants and children should have an examination that is not hindered by the child's clothes. Small incarcerated indirect inguinal hernias can easily escape detection if the entire abdomen is not observed and palpated. Some children need reassurance that being undressed for the examination is important. The child's sense of modesty must be respected when possible.

Once the child relaxes, the physical examination should follow an orderly progression: inspection and observation, nontouching maneuvers, abdominal palpation, auscultation, examination of nonabdominal areas, and rectal examination (Table 118.1).

Physical Findings	Meaning
Abdominal distension	Peritonitis, intestinal obstruction, ileus with gastroenteritis
Visible bowel loops	Intestinal obstruction, intussusception
Asymmetry	Appendiceal abscess
	Tumor
Point tenderness	Appendicitis, cholecystitis
Guarding	Peritonitis, appendicitis, abscess
Rigidity	Cholecystitis
Rebound	Infarcted bowel
Palpable mass	Tumor or cyst, intussusception
	Chronic constipation
Gas palpable in cecum	Not appendicitis
High-pitched bowel sounds	Intestinal obstruction
No bowel sounds	Peritonitis, infarcted bowel, perforated appendix or bowel
Rectal examination: tenderness or bogginess on right	Appendicitis

Table 118.1. ***Abdominal Physical Findings and What They Mean***

The initial step of inspection should focus on the presence of distension, visible bowel loops, and asymmetry. Inspection is easily done because of the relative prominence of the child's abdomen and thinness of the overlying muscles and subcutaneous tissue. Sometimes, observation during a feeding gives important information. The child should be observed in motion—for example, behavior when getting on and off the examination table and walking. Nontouching maneuvers include having the child cough or jump up and down while noting any change in symptoms.

Palpation is the most difficult, yet most informative, aspect of physical examination. When possible, the child can initiate his or her own examination by self-palpation. Ask the child to point to the place where the pain is most severe. Avoid the tender area initially but return to palpate it last. A number of “tricks” can be used to facilitate the palpation, such as diverting the child with conversation, palpating with the head of the stethoscope in hand, and palpating while asking the child to take a deep breath. For example, quick withdrawal of a palpating stethoscope may confirm rebound tenderness and the presence of an underlying peritoneal irritation.

Auscultation of the abdomen indicates the state of bowel motility. The presence of normal bowel sounds may not rule out surgical pathology, but a silent abdomen or one with high-pitched tinkles and rushes suggests the possibility of sepsis or obstruction. Auscultation and palpation of nonabdominal areas is important. In addition, evaluation of the acute abdomen requires careful examination of the lung fields, testes and scrotum, inguinal regions, femoral triangles, and costovertebral areas. Failure to examine these areas carefully will result in missing important diagnostic clues to nonabdominal problems that may present with abdominal symptoms.

The final step in the evaluation should be a rectal examination. The important technical aspects include use of generous amounts of lubricant, slow insertion of the examiner's finger as the patient takes slow deep breaths, and the palpation of the presumed painful area last. If done carefully and gently, the rectal examination is usually well tolerated by the child. Any stool on the examiner's glove should be tested for the presence of blood.

Laboratory

Laboratory and radiographic studies vary, depending on the diagnoses that are being considered. Most children accept radiographic studies as “having your picture taken.” A urinalysis is an important part of the evaluation of any abdominal symptoms in children. A complete blood count (CBC) and differential is essential when considering surgical conditions. The need for other tests—blood urea nitrogen (BUN), electrolytes, serum amylase, sickle cell preparation, and so on—depends on the child's condition and the diagnostic considerations.

Assessment

Once the history, physical examination, and laboratory data are all available, the emergency physician must synthesize them into an overall assessment. If the physical findings are reproducible and consistent in location and character, an accurate diagnosis can often be made and appropriate treatments started. If the findings are both worrisome and equivocal, and do not fit into a comprehensive picture, the patient should be admitted for observation and reassessment. The following sections detail the cardinal symptoms and signs of the common acute surgical problems in children. Initial emergency department (ED) management is discussed, but in all cases of presumed surgical disease, the definitive treatment requires consultation with a surgeon.

DISEASES THAT PRODUCE PERITONEAL IRRITATION

The physician must perform a careful examination to elicit accurate signs of peritonitis. Tenderness is not necessarily an indication of an intra-abdominal surgical problem in a child. A child with localized peritonitis may have only minimal findings, while a patient with a nonsurgical condition may have severe pain and generalized tenderness. For example, on examination, a child with severe colic caused by gastroenteritis may appear to have genuine peritoneal signs. In fact, such a child may have only exaggerated voluntary guarding of the abdominal wall, mimicking the true rigidity of peritonitis.

The well-known features of peritonitis—rigidity, spasm, involuntary guarding, and rebound—are as valid for a child as they are for an adult. In a child with abdominal pain, however, one has to be patient and gentle enough in the initial phases of the examination so that signs of peritonitis can be checked repeatedly without breaking rapport with the child. Reproducible anterior peritoneal tenderness in the same location is much more suggestive of peritonitis than deep abdominal tenderness that shifts in location with each reexamination of the child.

Acute Nonperforated Appendicitis

Background

Acute appendicitis is one of the most common abdominal surgical conditions seen by the emergency physician or surgeon who cares for children. It occurs in all age groups and is particularly difficult to diagnose in its early states and in infants and toddlers. The emergency physician must accurately evaluate the child and promptly consult a surgeon when the diagnosis is clear or when appendicitis cannot be safely ruled out. Such consultation is especially urgent in younger children, in whom perforation can occur within 8 to 24 hours of the onset of symptoms.

Clinical Manifestations

Usually the child with appendicitis complains initially of poorly defined and poorly localized midabdominal or periumbilical pain. Unfortunately, this symptom is common to many other intra-abdominal, nonsurgical problems. In the young and, to a lesser extent, the older child, vomiting and a low-grade fever often occur soon thereafter. Characteristically, the pain then migrates to the right lower quadrant (Table 118.2).

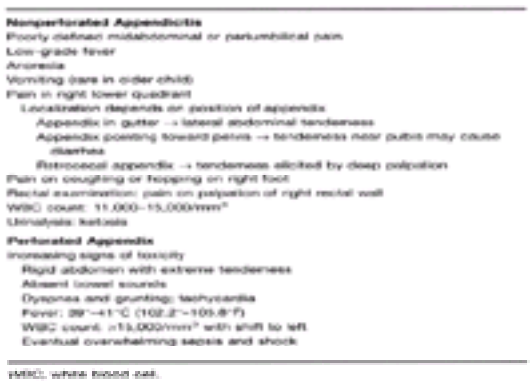

Table 118.2. ***Progression of Symptoms and Signs of Appendicitis***

Because the position of the appendix may vary in children, the localization of the pain and the tenderness on examination may also vary. An appendix that is located in the lateral gutter may produce flank pain and lateral abdominal tenderness; an inflamed appendix pointing toward the left lower quadrant may produce hypogastric tenderness. An inflamed low-lying, pelvic appendix may not cause pain at McBurney's point but instead may cause diarrhea from direct irritation of the sigmoid colon. Often, the child with appendicitis is anorexic, suggesting the presence of nausea even if he or she is unable to verbalize this complaint. Because motion aggravates peritoneal irritation, a child with appendicitis typically prefers to lie still or, when moving, splints toward the painful area.

When obtaining the history, the physician needs to consider other causes of abdominal pain which may appear as appendicitis but, in fact, are nonsurgical. Concurrent GI illness in other family members or friends suggests the possibility of an infectious gastroenteritis. Chronic constipation, urinary tract disease, or an emotional disturbance may also point to an explanation other than appendicitis for the abdominal pain. Cough, fever, and rapid breathing suggest the possibility of a lower lobe pneumonia.

On examination, palpation is usually reliable in demonstrating focal peritoneal signs at the site of the inflamed appendix. If the appendix is in the pelvis or retrocecal area, however, typical anterior peritoneal signs may be absent. The physician can confirm his or her impression of point tenderness by pressing gently in each quadrant and asking the child to indicate which area is most tender. When the inflamed appendix is not close to the anterior abdominal wall, as in the case of retrocecal appendix, tenderness may be more impressive on deep palpation of the abdomen or by palpating in the flank. This impression of focal tenderness can sometimes be confirmed by shaking the child's abdomen or getting him or her to cough, which often produces a wince of pain at the involved area. Finally, a well-done rectal examination may make the difference between deciding to operate or observe the child. The examining finger should be inserted as fully as possible without touching the area of presumed tenderness. Then, when the child is relaxed and taking deep breaths, the examiner can gently stroke or indent an area high on the right rectal wall. A sudden involuntary reaction of pain confirms the presence of inflammation. In a child with a history of probable appendicitis for more than 2 or 3 days, a boggy, full mass may also be in this location, suggesting an abscess.

A CBC in a child with appendicitis usually shows an elevated white blood cell (WBC) count in the range of 11,000 to 15,000/mm^3 in the first 12 to 24 hours of the illness. As the appendix becomes more gangrenous, the WBC count rises further, and the differential demonstrates more and more neutrophils and an increasing number of bands. Urinalysis often shows ketosis. If the inflamed appendix lies over the ureter or adjacent to the bladder, a few WBCs may be found in the urinary sediment. The presence of numerous WBCs and bacteria on a freshly spun specimen may indicate an acute urinary tract infection. However, a child with a chronic urinary tract infection may also develop appendicitis.

If the clinical and laboratory diagnosis of acute appendicitis is convincing, no further studies are indicated.

As far as the abdominal roentgenogram is concerned, many consider it a peripheral study valid only for the demonstration of a fecalith or free air. Abdominal roentgenograms are normal in many cases of acute appendicitis. In 8 to 10% of cases, however, a calcified appendiceal fecalith can be identified on abdominal roentgenograms. Because the incidence of subsequent appendicitis with perforation is significant, it has been suggested that prophylactic appendectomy be performed on the asymptomatic child in whom a calcified fecalith is detected.

Most children with an acute nonperforated appendix show diminished air in the GI tract. This is a result of anorexia, nausea, vomiting, and diarrhea. Other roentgenographic signs of appendicitis are thickening of the cecal wall and mucosal folds with air–fluid level, indistinct psoas margins with scoliosis concave toward the right, focal obliteration of the adjacent properitoneal fat pad, or presence of air in the appendix. However, a retrocecal appendix may be filled with gas in the normal person. Ileus secondary to peritoneal irritation or an inflamed appendix crossing the terminal ileum may be seen. Rarely, a perforated appendix may produce pneumoperitoneum.

Barium enema in the diagnosis of appendicitis is no longer used because in 8 to 10% of normal children, barium does not

fill the appendix. However, partial or nonfilling of the appendix with local impression on the cecum or terminal ileum, or associated with other evidence of a pelvic or right lower quadrant mass, is indicative of appendicitis. In a child with leukemia, a tender right lower quadrant mass may indicate typhlitis, an inflammatory reaction of the cecum. Differentiation of typhlitis and an appendiceal abscess in a child with leukemia, therefore, may be difficult. Today, for evaluation of appendicitis Doppler ultrasound or computed tomography (CT) is preferred.

Routine chest radiographs are not indicated unless the patient has a history of pulmonary problems, such as asthma, or unless the symptoms and signs indicate atypical right abdominal pain with splinting respirations. A chest radiograph in such a case may reveal subtle evidence of a right lower lobe pneumonia. With good hydration, these subtle findings on radiograph may develop into an early visible infiltrate in a few hours.

Unfortunately, laboratory findings do not differentiate mesenteric adenitis, which closely mimics acute appendicitis. A complete approach to the child with abdominal pain is covered in Chapter 50.

Management

The preoperative preparation of a patient with acute appendicitis should include BUN and electrolytes if the patient has been vomiting or has had poor fluid intake for more than a few hours. If an unexpected anemia is discovered on the CBC, a crossmatch should also be done. Intravenous (IV) fluids should be started, with emphasis on replacing the child's deficits as quickly as possible. Protracted GI losses, as with vomiting, may lead to potassium depletion. Therefore, the initial IV fluids should contain at least 0.5 n saline with 10 mEq of potassium chloride per 500 mL. These fluids can then be altered, if necessary, once the serum chemistries are known. During this period, the patient and the family should be psychologically prepared for surgery.

The emergency physician must keep in mind the many variations in the way appendicitis can present. As a good rule of thumb, a patient should at least be admitted for observation if there are positive findings in two of the three classical modes of assessment: history, physical examination, or laboratory. For example, a child with an excellent history of appendicitis and a high WBC count should be admitted even if the abdominal examination is normal. The appendix may have perforated just before the examination, causing temporary cessation of physical findings. In equivocal situations, the key element is follow-up assessment. A child who is admitted can, if necessary, be reexamined every 1 to 2 hours. As for a child in whom the possibility of appendicitis seems more remote, the physician may elect to have the child return for reexamination in the office or in the ED. Such follow-up arrangements work best when the parents are reliable and do not live too far from the hospital. Arrangements for follow-up should be specific, including time of appointment, the specific doctor to be seen, and a contact telephone number in case the child does not return as scheduled.

Perforated Appendicitis

Ideally, once the diagnosis of appendicitis is considered seriously, the patient will have surgery before the appendix has perforated. Unfortunately, some patients, particularly younger children and infants, may arrive for emergency care with an already perforated appendix because of a delay in seeking treatment or in making the diagnosis. Once the appendix has perforated, there are usually signs of generalized, rather than localized, peritonitis. In a young child, the omentum is flimsy and often incapable of walling off the inflamed appendix. As a result, perforation occurs more quickly, and secondary dissemination of the infection occurs more widely. Although the mortality from appendicitis has decreased, the incidence of perforation in children has remained the same over the last several decades.

Clinical Manifestations

Within a few hours after perforation has occurred, the child begins to develop increasing signs of toxicity. First, the lower abdomen and then the entire abdomen becomes rigid with extreme tenderness. Bowel sounds are sparse to absent. In addition, there are signs of prostration such as pale color, dyspnea, grunting, significant tachycardia, and higher fever (39° to 41°C [102.2° to 105.8°F]). Rarely, the patient may develop septic shock (see Chapter 3) from the overwhelming infection caused by bowel flora.

Initially, the findings may be confused with those of pneumonia because the extreme abdominal pain may cause rapid shallow respirations and decreased air entry to the lower lung fields. There is impaired excursion of the diaphragm and respiratory failure in some cases. In infants and toddlers, the findings may also be confused with meningitis because any movement of the child (even flexion of the neck) produces pain and irritability. The high fever and other signs of prostration may be indications for a lumbar puncture. After the spinal fluid analysis is found to be normal, the suspicion of perforated appendicitis may be heightened.

The laboratory findings in the child with perforated appendicitis often suggest this diagnosis. The WBC count is significantly elevated, usually above 15,000/mm^3, with a marked shift to left; leukopenia may be seen when perforation has resulted in overwhelming sepsis and septic shock.

The radiologic evaluation of suspected perforated appendicitis should include both plain abdominal radiographs and pelvic ultrasound. The plain film of the abdomen may show free air or evidence of peritonitis (Fig. 118.1). The ultrasound of the pelvis may show a complex mass with or without a calcified fecalith or free fluid within the abdominal cavity (Fig. 118.2).

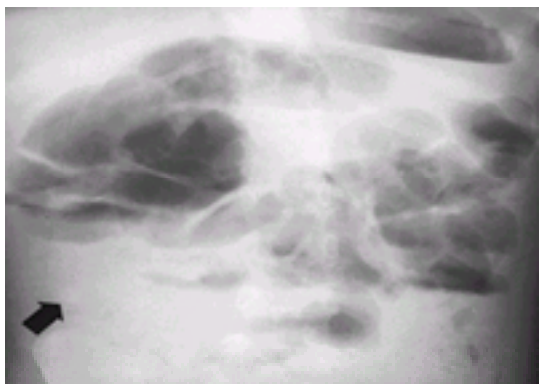

FIGURE 118.1. Perforated appendicitis with abscess and fecalith. The upright abdominal roentgenogram shows numerous dilated loops of bowel and a calcified fecalith *(arrow).* Note that the space between the individual loops indicates the presence of intraperitoneal fluid.

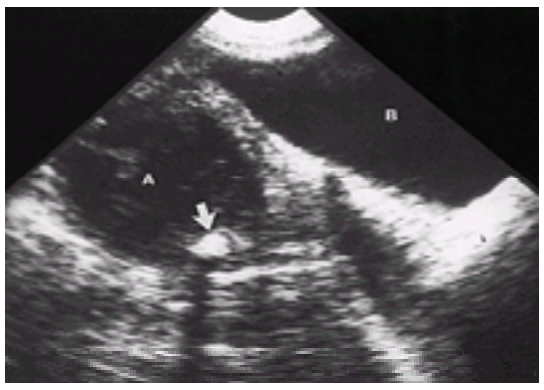

FIGURE 118.2. Perforated appendicitis with abscess and fecalith. Ultrasonography of the pelvis shows a complex mass *(A)* with a fecalith *(arrow)* producing characteristic acoustic shadowing to the right of the bladder *(B).*

Management

Initially, the focus of therapy should be on resuscitation. There must be careful attention to airway, breathing, and circulation (see Chapter 1). The severely septic child may need positive-pressure ventilation with high concentrations of oxygen to overcome ventilatory insufficiency. Hypovolemia should be corrected with 5% dextrose in either normal saline or Ringer's lactate solution. An alternative volume expander is 5% albumin solution in normal saline. An initial bolus starting at 20 mL/kg is given over 30 minutes or less until vital signs are restored and the patient produces urine. Metabolic acidosis should be treated with sodium bicarbonate, the dose being determined by the results of the serum electrolytes or, more precisely, the base deficit from an arterial blood gas.

Hypovolemia and acidosis must be treated vigorously until adequate circulation has been reestablished, as measured by the strength of the pulse, blood pressure, skin perfusion, capillary refill in the extremities, and urine output. If it is difficult to reestablish an adequate circulation, a central venous pressure catheter may be helpful in determining the amount of volume needed. Once adequate circulation has been attained, much of the acidosis may correct spontaneously as homeostatic mechanisms are restored.

Additional steps in the management include treatment of infection and further preparation of the patient for surgery. The child should receive broad-spectrum antibiotics (e.g., ampicillin 200 mg/kg per day, gentamicin 6 to 7.5 mg/kg per day, and clindamycin 25 mg/kg per day) for additional anaerobic coverage. Once the emergency physician is certain that the airway can be controlled and the circulation is adequate, relief of pain can be accomplished by using narcotic agents (e.g., morphine 0.1 mg/kg). The patient's fever can usually be controlled by the use of a hypothermia mattress and/or acetaminophen (10 mg/kg per dose rectally). A nasogastric tube should be placed to evacuate the contents of the stomach and to drain ongoing gastric secretions. Several units of blood or packed red cells, must be prepared for the operative procedure.

Children with perforated appendicitis can deteriorate quickly. Moreover, the fever, often 40°C (104°F) or higher, may not be controlled until the intra-abdominal infection is drained. Therefore, emergency resuscitation should be quickly followed by operative intervention. At surgery the appendix is removed, the area is drained, and other appropriate treatments are given. The child will recover more rapidly if this approach is taken than if prolonged medical management is instituted and surgery delayed. Rarely, the abscess may be drained with the expectation that an appendectomy will be performed later.

Meckel's Diverticulitis with and without Perforation

Most patients with a Meckel's diverticulum are asymptomatic or, if symptomatic, have rectal bleeding from ulceration at the junction of the ectopic gastric mucosa and the normal ileal mucosa, where the diverticulum is attached. A preoperative diagnosis of an inflamed or a perforated Meckel's diverticulum is rarely made but, nevertheless, should be considered in the differential diagnosis of a perforated viscus leading to generalized peritonitis. The diagnosis is usually made in the operating room by the surgeon who finds a normal appendix, and then an exploration of the bowel finds a

diseased diverticulum 20 to 25 cm of the ileocecal valve.

Primary Peritonitis

Primary peritonitis is a bacterial infection of the peritoneal cavity, usually secondary to a bloodborne or lymphborne infection. Although rare, it can occur in children with nephrosis or cirrhosis, ascites, or other etiology, and may mimic appendicitis. Primary peritonitis is usually caused by pneumococcus, group A Streptococcus, or Gram-negative organisms. When peritonitis is a Gram-negative infection, the portal of entry is often the vagina. This occurs in girls from 5 to 10 years old in whom the cervix is usually open and the vaginal fluid is not yet acidic enough to retard the ascent of infection.

The clinical manifestations include fever, vomiting, and abdominal pain. The physical examination includes findings of peritoneal irritation. An elevated WBC count (greater than 15,000/mm ^{3}) and left shift are also seen. Often, the symptoms, signs, and laboratory findings are indistinguishable from those for perforated appendicitis; thus, the diagnosis may be made at laparotomy. If the diagnosis is suspected before surgery, the patient should undergo paracentesis. The diagnosis may be confirmed by a Gram stain showing Gram-positive cocci, followed by a positive culture. It is important to remember that children with nephrosis or cirrhosis may have appendicitis unrelated to their underlying disease.

Pancreatitis

Although acute pancreatitis is common in adults, it occurs rarely in children. The most common cause is abdominal trauma. Pancreatitis produces upper abdominal or periumbilical pain, often radiating to the back. Occasionally, the presentation is that of a patient in shock. Findings that support the diagnosis include paralytic ileus, distension, and ascites. Serum or urine amylase is usually elevated. When severe, the serum calcium is also decreased. When pancreatitis occurs in a child without a history of trauma, the physician should evaluate the patient for possible congenital abnormalities of the biliary tree or pancreatic ducts, such as abnormal insertion of the main pancreatic duct or the presence of a choledochal cyst. Surgical intervention is rarely indicated in the acute phase. However, active surgical consultation from the beginning is essential, in case the patient deteriorates in spite of maximal medical therapy (see Chapter 93). Signs of deterioration or nonresponse to therapy include persistently low serum calcium, a falling hematocrit, increasing toxicity, and deterioration of the patient's coagulation profile.

ACUTE INTESTINAL OBSTRUCTION

In any child who vomits persistently, particularly if the vomitus becomes stained with bile, the diagnosis of acute intestinal obstruction must be considered. If the obstruction is high in the intestinal tract, the abdomen does not become distended; however, with lower intestinal obstruction there is generalized distension and diffuse tenderness, usually without signs of peritoneal irritation. Only if the bowel perforates or vascular insufficiency occurs will signs of peritoneal irritation be found. If complete obstruction persists, bowel habits may change, leading to complete obstipation of both flatus and stool. All patients with suspected bowel obstruction should have radiographs of the abdomen in supine, upright, and prone cross-table lateral views. In patients with acute mechanical bowel obstruction, multiple dilated loops are usually seen. Fluid levels produced by the layering of air and intestinal contents are seen in the upright or lateral decubitus radiographs (Fig. 118.3).

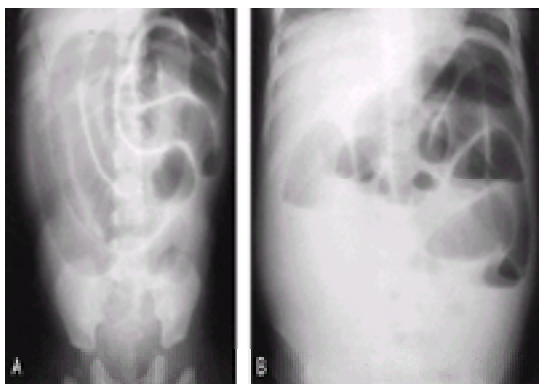

FIGURE 118.3. A. Small bowel obstruction. Numerous dilated small bowel loops occupy the midabdomen and have a stepladder configuration. Minimal air is seen in the rectum. **B.** Same patient as in **A.** The upright abdominal roentgenogram shows numerous dilated loops in the small bowel with differential fluid levels in one loop indicating mechanical bowel obstruction.

Intussusception

Background

Intussusception occurs when one segment of bowel telescopes into a more distal segment. This is the leading cause of acute intestinal obstruction in infants and occurs most commonly between 3 and 12 months of age. The most common intussusception is ileocolic but the small bowel may intussuscept into itself. Often, it will be ileoileal at a location close to the cecum. Typically, this small bowel intussusception then prolapses through the ileocecal valve (Fig. 118.4). The intussusception continues through the colon a variable distance, occasionally as far as the rectum, where it can be palpated on rectal examination. Colocolic intussusceptions are very rare. In infants the lead point for the intussusception may be hypertrophied Peyer's patches. In children older than 2 years of age, a specific lead point, such as a polyp, a Meckel's diverticulum, a duplication, or a tumor, is much more likely. A diarrheal illness, viral syndrome, or

Henoch-Schönlein purpura may be a preceding illness several days to a week before the onset of abdominal pain and obstruction.

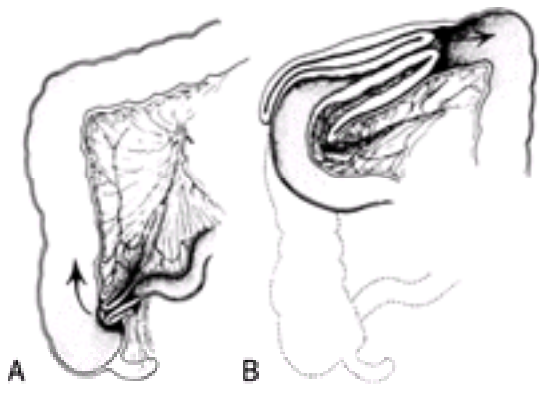

FIGURE 118.4. Ileocolic intussusception. **A.** Beginning of an intussusception in which terminal ileum prolapses through ileocecal valve. **B.** Ileocolic intussusceptum continuing through the colon. This can often be palpated as a mass in the right upper quadrant.

Clinical Manifestations

The main manifestation of intussusception is crampy abdominal pain. This symptom may have been preceded by the symptoms and signs of a viral gastroenteritis or even an upper respiratory infection. Gradually, the child becomes more irritable and anorectic and may vomit. The pattern of pain in a child with an intussusception is often consistent and characteristic, and the diagnosis is suggested strongly if a history of episodic pain is obtained. The pain may cause the infant to cry out with intermittent spasms, but the child then appears to be perfectly comfortable or only slightly irritable between these episodes. More often, lethargy is a typical sign that occurs between the episodes of pain. The infant may become still and pale and exhibit an almost shocklike state because of the intense visceral pain. At times, patients with intussusception have been misdiagnosed as being in the postictal state.

The localized portion of the intussusception leads to either partial or complete obstruction and generalized abdominal distension. In some cases, the intussuscepted mass can be palpated as an ill-defined sausage-shaped structure if the abdomen is not too distended. This mass is most often palpable in the right upper quadrant.

When children arrive in the ED early in the course of intussusception, there is often no history of having passed a currant jelly stool, although blood may be seen on the examining finger. However, the absence of bloody stools should not preclude making the diagnosis of a possible intussusception, and a barium enema should be obtained.

As the bowel becomes more tightly intussuscepted, the mesenteric veins become compressed, while the mesenteric arterial supply remains intact. This leads to the production of the characteristic currant jelly stool, which may be passed spontaneously or found on the rectal examination. However, development of melena may occur fairly quickly, and this fact reinforces the need for a rectal examination in a child with unexplained abdominal symptoms. Once the intussusception has become tight, even the arteries are occluded by the pressure of entrapment. At this point, the bleeding lessens, but the bowel can become gangrenous and even perforate, leading to peritonitis.

Management

The patient should be prepared by inserting an IV line and a nasogastric tube. IV fluids should be given to correct dehydration. Nasogastric suction minimizes the risk of vomiting and aspiration. Once blood has been sent to the laboratory for CBC, BUN, serum electrolytes, and a crossmatch, the patient should be taken to the radiology department.

Plain film roentgenographic findings of intussusception are variable and depend primarily on the duration of the symptoms and the presence or absence of complications. In early cases, a normal gas pattern is seen. In the patient with symptoms longer than 6 to 12 hours, flat and upright films often show signs of intestinal obstruction, including distended bowel with air–fluid levels (Fig. 118.3). Occasionally, the actual head of the intussusception can be seen on a plain film as a soft-tissue mass. If the plain film shows the presence of feces in the right colon, it is likely that the child has intussusception.

In recent years, hydrostatically controlled barium enema reduction has been a successful therapy in more than 50% of cases (Fig. 118.5). Strict guidelines must be adhered to so that perforation is avoided when this method is attempted. The barium column should be no higher than 3 feet above the abdomen, and manual palpation of the abdomen during the study is contraindicated. Often an IV dose of morphine 0.1 mg/kg or the use of another sedative is helpful to relax the child during the study or if there is difficulty in accomplishing the reduction. The full reduction of the intussusception is confirmed only when there has been adequate reflux of barium into the ileum. Otherwise, only the ileocolic component of an ileocolic intussusception may be reduced, leaving the ileoileal intussusception unreduced. A 24-hour follow-up film should be taken to determine whether the intussusception has recurred.

FIGURE 118.5. Ileocolic intussusception. Barium enema shows the intussusception as the filing defect within the hepatic flexure surrounded by spiral mucosal folds. Significant distended small bowel represents distal small bowel obstruction.

Recent series have described reduction of intussusception by air insufflation rather than barium. This may be a safer method because if a perforation is present the peritoneal cavity is not contaminated with barium. Many pediatric radiology departments in this country are now evaluating this method of air reduction.

A barium enema reduction is contraindicated if free peritoneal air is present. In the seriously ill infant with signs of peritonitis or a frank small bowel obstruction, the diagnosis of intussusception should be made with isotonic water-soluble contrast media with no attempt at reduction. The reduction in such infants should be performed surgically to prevent the complication of barium peritonitis after perforation of the colon.

Many youngsters with intussusception require emergency surgery, especially if the intussusception has been of long duration or the child shows evidence of gangrenous bowel, including high fever, leukocytosis, significant distension, and general toxicity. If a barium enema seems safe and appropriate, the operating room should be placed on standby and the operating team should be ready to commence immediate surgery if complications develop or if the hydrostatic reduction by barium enema is unsuccessful. Preoperative preparation and resuscitation begins in the ED and continues during the course of the barium enema. Undue delay may well result in gangrene of the entrapped bowel. The moment surgery is decided on, the patient should receive broad-spectrum IV antibiotics.

The recurrence rate after barium enema reduction ranges from 1 to 3%. When there is a recurrence, a second attempt at reduction may be done by barium enema. This is usually successful in most cases, but with a third episode of intussusception, an exploratory laparotomy must be done. Recurrences are more common in older children and may be caused by a lead point such as a Meckel's diverticulum, an intestinal polyp, or an intraluminal tumor such as lymphoma. Therefore, it may be wise in an older child to operate with the first recurrence.

Incarcerated Inguinal Hernia

Incarcerated inguinal hernia is a common cause of intestinal obstruction in the infant and young child. Approximately 60% of incarcerated hernias occur during the first year of life. Incarceration occurs more often in girls than in boys but usually involves the ovary rather than the intestine. Often, the patient or family has no previous knowledge of the presence of a congenital hernia. Incarceration does not necessarily mean that the nonreducible portion of intestine is compromised or gangrenous. However, strangulation can occur within 24 hours of a nonreduced incarcerated hernia because of progressive edema of the bowel caused by venous and lymphatic obstruction. This obstruction then leads to occlusion of the arterial supply with resulting necrosis of the bowel and perhaps perforation.

The clinical presentation of a child with an incarcerated hernia is usually irritability, crying because of pain, vomiting, and occasionally abdominal distension. A firm, discrete mass can be palpated at the internal ring and may or may not extend into the scrotum. Occasionally, the testicle may appear dark blue because of pressure on the spermatic cord causing venous congestion, and in a prolonged incarceration, the testicle may be infarcted. Intestinal obstruction may develop quickly and an abdominal radiograph shows gas-filled loops of intestine in the scrotum.

It is often difficult to differentiate a tense hydrocele in the scrotum from an incarcerated hernia. If the child has had a hydrocele, a sudden increase in fluid in the tunica vaginalis may produce discomfort and the concern is that the child has developed an incarcerated hernia. However, it is uncommon for a hernia to appear in the presence of a communicating hydrocele because of the narrowness of the patent processus vaginalis that is associated with the hydrocele. The acute hydrocele presents only in the scrotum but may extend somewhat up into the inguinal canal. However, no mass can be felt in the area of the internal ring, indicating that no intestine is exiting from the ring.

Unless the child is extremely ill with signs of intestinal obstruction or toxic from gangrenous bowel, a manual reduction of the incarcerated hernia should be attempted. The child should be sedated with morphine 0.1 mg/kg intravenously. The mother should then cuddle the baby until it relaxes and falls asleep. An older child may be placed in the Trendelenburg position to allow gravity to facilitate the reduction. Once the child is asleep, gentle manipulation of the incarcerated mass should be attempted. Mild pressure should be exerted at the internal ring with one hand, while the other attempts to squeeze gas or fluid out of the incarcerated bowel back into the abdominal cavity. If the reduction is unsuccessful, the child should be taken immediately to the operating room.

After the hernia has been reduced manually, the child may be admitted for observation but not immediate repair. The hernia sac and spermatic cord are edematous after a reduction, making the repair difficult. Usually, it is done 24 hours after admission. In a youngster who vomits persistently after a manual reduction of an incarcerated hernia, the possibility that the bowel has not been entirely reduced, causing continued obstruction, must be considered. Rarely should a child

be sent home after a manual reduction unless the parents are properly informed concerning signs of recurrence or intestinal obstruction and they are thoroughly reliable (see Inguinal Hernias, p. 1535).

Incarcerated Umbilical Hernia

Incarceration of an umbilical hernia is rare. If present, there is a persistent and tender bulge in the umbilical hernia sac. If the incarceration is of short duration, a gentle effort might be made to reduce it manually, but it often is necessary to prepare the child for urgent surgery. At the time of surgery, the loop of incarcerated bowel should be inspected, rather than letting it drop back into the abdominal cavity, to be certain there has been no vascular impairment (see Umbilical Hernias, p. 1536).

Malrotation of the Bowel with Volvulus

Background

Malrotation of the bowel is a congenital condition associated with abnormal fixation of the mesentery of the bowel (Fig. 118.6). Therefore, the bowel has a proclivity to volvulize and obstruct at these points of abnormal fixation. Although malrotation with volvulus usually occurs either in utero or during early neonatal life, malrotation can be unrecognized until childhood. This is an extraordinarily dangerous situation because a complete volvulus of the bowel for more than an hour or two can totally obstruct blood supply to the bowel, leading to complete necrosis of the involved segment. When a volvulus involves the midgut, the entire small bowel and ascending colon may be lost, making the patient dependent on IV hyperalimentation for survival. The only way to prevent such a catastrophe is to have a high index of suspicion for malrotation in any child with signs of obstruction and to be prepared to get a child with a presumed volvulus to the operating room immediately.

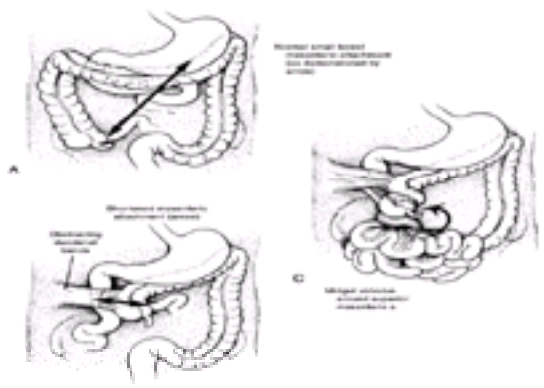

FIGURE 118.6. Malrotation with volvulus. **A.** Normal small bowel mesenteric attachment (as demonstrated by the *arrow*). This prevents twisting of small bowel because of the broad fixation of the mesentery. **B.** Malrotation of colon with obstructing duodenal bands. **C.** Midgut volvulus around the superior mesenteric artery caused by the narrow base of the mesentery.

Clinical Manifestations

Any child with bile-stained vomiting and abdominal pain may have malrotation with volvulus. The pain is usually constant and not crampy. Blood may appear in the stool within a few hours and suggests the development of ischemia and possible necrosis of the bowel. Clinically, malrotation can present in several different ways: first, and most dangerous, is the sudden onset of abdominal pain with bilious vomiting with no prior history of GI problems; a second is a similar abrupt onset of obstruction in a child who previously seemed to have “feeding problems” with transient episodes of bilious vomiting; third is a child with failure to thrive because of alleged intolerance of feedings. This last example may involve a child who has been fed a dozen different formulas and in whom the vomiting is chronic and generally not associated with pain.

On physical examination, there may be only mild distension of the abdomen inasmuch as the obstruction usually occurs high in the GI tract. On palpation, the physician may discern one or two prominently dilated loops of bowel. The abdomen may be diffusely tender and yet not have clear signs of peritonitis. On rectal examination, the presence of blood on the examining finger is an alarming sign of impending ischemia and gangrene of the bowel.

Management

The key to management is to be suspicious of malrotation and to obtain flat and upright roentgenograms of the abdomen immediately. The presence of loops of small bowel overriding the liver shadow is suggestive of an underlying malrotation. When complete volvulus has occurred, there may be only a few dilated loops of bowel with air–fluid levels. Distal to the volvulus there may be little or no gas in the GI tract. A “double-bubble sign” is often present on an upright film because of partial obstruction of the duodenum causing distension of the stomach and first part of the duodenum (Fig. 118.7A).

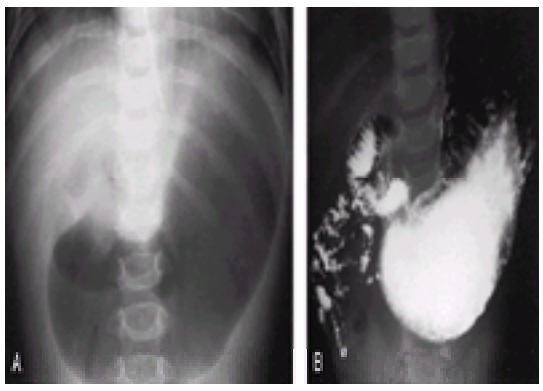

FIGURE 118.7. A. Malrotation of the bowel. Supine plain roentgenogram of the abdomen shows distended stomach and proximal duodenal loop. **B.** Same patient as in **A.** Upper gastrointestinal series shows dilated proximal duodenum with abrupt transition to normal caliber of small bowel. Abnormally placed ligament of Treitz. Proximal jejunum in the right abdomen.

When a child is being assessed for possible malrotation, an upper GI series is the study of choice. The ligament of Treitz is absent in the malrotation anomaly, so the C-loop of the duodenum is not present, the duodenum lies to the right of the spine, and the jejunum presents a coiled spring appearance in the right upper quadrant (Fig. 118.7B and Fig. 118.8). The cecum is not fixed and usually assumes a position in the right upper quadrant. However, because of its mobility, the cecum on barium enema may be seen in its normal position in the right lower quadrant. Therefore, a barium enema is not the most reliable study to rule out malrotation. In the neonate, the cecum sometimes takes a high position and this could give a false impression of malrotation.

FIGURE 118.8. Malrotation. Upper gastrointestinal study showing absence of the ligament of Treitz and coiled spring appearance of jejunum.

As in the case of a child with an unreduced intussusception, a child with a possible volvulus should be prepared for immediate surgery. The operating room and operating team should be on standby. IV fluid and electrolyte replacement should begin immediately. A nasogastric tube should be inserted and blood crossmatched. Because this entity can present even in adulthood, every physician should understand the pathogenesis and the need for surgical therapy of malrotation. If immediate transfer to a children's hospital cannot be accomplished within an hour, a laparotomy should be performed without delay.

Pyloric Stenosis

Narrowing of the pyloric canal as a result of hypertrophy of the musculature often occurs in the first-born male of a family. A familial incidence has been shown, particularly if the mother had hypertrophic pyloric stenosis as an infant. There is a male:female ratio of 5:1. The age of onset is usually 2 to 5 weeks. Rarely, the onset may be late in the second month of life. The cause of the muscle hypertrophy is unknown, but the symptoms, diagnosis, and therapy are well defined.

Clinical Manifestations

Characteristically, the infant does well, without vomiting, for the first few weeks of life and then starts regurgitating, either at the end of feedings or a few minutes later. The infant is hungry and will eat heartily immediately after such a regurgitation. The vomiting becomes more prominent and eventually becomes more forceful, called projectile vomiting. The vomitus ordinarily contains just the feeding that has been given and does not contain bile or blood. Occasionally, some mucus is in the vomitus. Infants with pyloric stenosis may also become jaundiced with the onset of the other symptoms. The hyperbilirubinemia usually improves or abates postoperatively for reasons that are unknown.

The examination of an infant is best accomplished after the infant's stomach has been emptied. With the child lying on his or her back, the examiner holds the infant's ankles and flexes the thighs at a right angle to the trunk as the mother feeds some warm sugar water with the infant's head turned to the right but not elevated. Once the infant starts to suck, the upper abdominal musculature will relax and the examiner's opposite hand can then gently palpate the upper right abdomen. Palpating under the edge of the liver in an up-and-down direction, the physician may discern a firm, fusiform, ballotable mass in the shape of an olive. If this “olive” is not felt, the stomach can be emptied with a nasogastric tube to allow easier palpation and the examination is repeated. Another diagnostic clue is the presence of prominent gastric

peristaltic waves that course from left to right across the abdomen.

If the child has vomited for an extended period, he or she will show signs of growth failure. There may be loose, hanging skin and an absence of subcutaneous tissue. The infant may take on an “old man” appearance, with wrinkled skin on the face and body. Weight gain is inadequate, which may be calculated by knowing that the average child regains birth weight by 10 days of age and thereafter 15 to 30 g (0.5 to 1 ounce) per day.

Serum electrolytes may be abnormal because of gastric losses. The potassium and chloride are low, and serum bicarbonate is high. This hypochloremic alkalosis may be profound with serum chlorides in the 65 to 75 mEq/L range. When dehydration becomes severe, the patient may then develop acidosis, indicating an advanced and even more dangerous metabolic imbalance (see Chapter 86).

Management

Infants should be hospitalized and rehydrated with appropriate fluid and electrolyte replacement. Initially, IV fluids should be 5% dextrose in normal saline. Potassium chloride (3 to 5 mEq/kg) should be added once urine output has been established. If hypotonic solutions are used, there is significant risk of causing hyponatremia (see Chapter 86). A volume of fluid should be used appropriate to the patient's level of dehydration.

If a pyloric “olive” or mass is palpable and clear gastric waves are visible, roentgenogram confirmation of the diagnosis is not needed. If the history of vomiting is not typical and a mass cannot be felt, real-time ultrasound is the first study to confirm the diagnosis. The real-time ultrasound scanning not only increases the accuracy of the diagnosis of pyloric stenosis but can also localize the “olive.” The hypertrophic pyloric muscle is seen as a thick hypoechoic ring surrounding a central echogenic mucosal and submucosal region (Fig. 118.9). The quantitative criteria for the sonographic diagnosis of hypertrophic pyloric stenosis are 1.4 cm or longer length of the pyloric canal with 0.3 cm or greater thickness of the circular muscle.

FIGURE 118.9. Hypertrophic pyloric stenosis. Ultrasonography of the abdomen shows thick pyloric muscle surrounding a centered echogenic mucosal and submucosal region *(arrows).*

If the ultrasound study does not show a hypertrophic pylorus, an upper GI series should then be done to eliminate gastroesophageal reflux, malrotation, and antral web as diagnostic possibilities. In general, pyloric stenosis can be identified by the presence of a “string sign” in the pyloric channel, seen best on oblique projections on the upper GI series (Fig. 118.10).

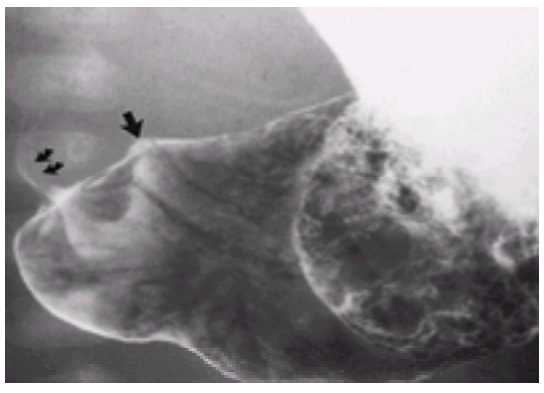

FIGURE 118.10. Pyloric stenosis. Long, narrowed, and tilting upward antropyloric canal. Parallel streaks of barium producing typical string sign with complete obstruction *(arrows)* and eccentric lesser curvature indentation pyloric tilt *(arrow).* The tilt is performed when the peristaltic wave meets the muscle mass

To lessen the risk of vomiting and aspiration, the barium should be evacuated from the stomach after the upper GI series has been completed. Surgical pyloromyotomy is a most successful form of therapy, and such infants can usually be discharged from the hospital 2 days after surgery. Some infants will have some regurgitation postoperatively as a result of a temporary relaxation of the gastroesophageal sphincter.

Postoperative Adhesions

Prior abdominal surgery or peritonitis places a child at risk for intestinal obstruction from adhesions (Fig. 118.11). Such obstruction can occur relatively early in the postoperative course or months or even years later. Suddenly and without warning, the child develops abdominal cramps, nausea, vomiting, and abdominal distension. Although most intestinal obstructions from adhesions do not jeopardize the vascularity of the bowel, occasionally a loop of intestine, caught under a fibrous band, can become gangrenous. Therefore, the diagnosis should be made quickly. All such patients need to be admitted to the hospital and evaluated by a surgeon who should direct the complete management.

FIGURE 118.11. Dilated loops of small intestine and absence of air in lower abdomen indicating a high intestinal obstruction caused by postoperative adhesions.

CHRONIC PARTIAL INTESTINAL OBSTRUCTION

Any child with intermittent abdominal distension, nausea, anorexia, occasional vomiting, or chronic constipation or obstipation may have partial intestinal obstruction. A number of diagnostic considerations exist.

Chronic Constipation

Chronic constipation is probably one of the most common causes for abdominal pain, distension, and vomiting in children. The history, if available from a reliable parent, may attest to chronic constipation; however, occasionally, such a child is diagnosed only by palpating a large fecaloma through the intact abdominal wall or a hard fecal mass blocking the anal outlet on rectal examination. Such youngsters may have a history of encopresis and appear malnourished. Chapter 14 covers the diagnostic approach to the child with constipation.

These children should be disimpacted by instilling a generous amount of warm mineral oil into the rectum, followed by copious saline lavages using a large-caliber rectal tube with extra holes. Often, a gloved finger is necessary to break up a hard fecal mass and allow its evacuation. If the process has reached this stage, it is unlikely that the mother or father can manage it at home, and either ED or in-hospital management is necessary to clean out the bowel adequately. Once the bowel has been cleaned, it is important to institute an appropriate regimen to retrain the child and produce better bowel habits.

Aganglionic Megacolon (Hirschsprung's Disease)

In patients with Hirschsprung's disease, the parasympathetic ganglion cells of Auerbach's plexus between the circular and longitudinal muscle layers of the colon are absent. The involved segment varies in length, from less than 1 cm to involvement of the entire colon and small bowel. The effect of this absence of ganglion cells produces spasm and abnormal motility of that segment, which results in either complete intestinal obstruction or chronic constipation.

These children have a lifelong history of constipation, so it is important to obtain an accurate account of the child's stool pattern from birth. A child with Hirschsprung's disease typically has never been able to stool properly without assistance (e.g., enemas, suppositories, stimulation with the finger or thermometer). Normal stooling is not possible because of the failure of the aganglionic bowel and interval anal sphincter to relax. The child usually has no history of encopresis, as one would find in chronic functional constipation. These youngsters have chronic abdominal distension and are often malnourished. Vomiting is uncommon, as are other symptoms. Complete intestinal obstruction in Hirschsprung's disease is more likely to occur in early infancy and only rarely in the older age groups.

Table 118.3 summarizes the pertinent diagnostic features differentiating functional constipation from Hirschsprung's disease.

	Functional Constipation	Hirschsprung's Disease
Onset	≥2 years	Birth
History	Coercive training	Enemas necessary
	Colicky abdominal pain	No abdominal pain
	Periodic volume stools	Episodes of intestinal obstruction
Encopresis	Present	Absent
Abdominal distension	Absent or minimal	Present
Rectal examination	Feces-packed rectum	Empty rectum
Barium examination	Dilated rectum	Narrow segment
Motility	Normal	Abnormal
Biopsy	Ganglion cells	No ganglion cells

Table 118.3. ***Differential Diagnosis of Functional Constipation and Hirschsprung's Disease***

After flat and upright abdominal roentgenogram radiographic studies have been obtained, a properly performed barium enema with a Hirschsprung's catheter is the best initial diagnostic procedure. There should be no preparation of the bowel. Ideally, the rectum should not be stimulated by enemas or digital examination for 1 to 2 days before the procedure. The key to diagnosis is seeing a “transition zone” (Fig. 118.12) between the contracted aganglionic bowel and the proximal dilated ganglionated bowel. Stimulation of the rectum shortly before the study may result in decompression of the proximal bowel, with loss of definition of the transition zone. When a clear-cut transition zone is seen, it is not necessary to fill the colon with barium more than 12 to 18 inches above the transition point. It is important, however, not to empty the colon of barium at the end of the study. The presence of retained barium above the transition point 24 hours later strongly suggests the diagnosis of Hirschsprung's disease.

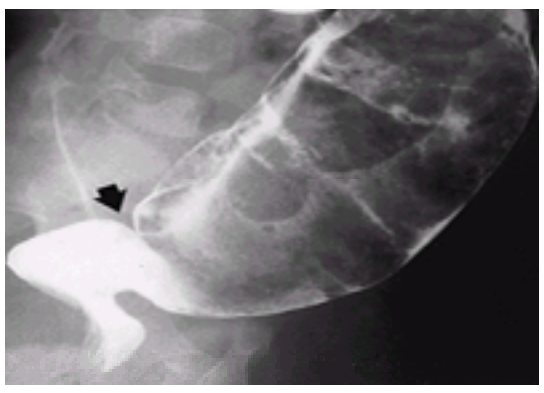

FIGURE 118.12. Hirschsprung's disease. Barium enema studies in lateral view show transition zone *(arrow)* with narrow rectum but dilated sigmoid colon.

Anorectal manometry to determine the presence or absence of relaxation of the internal anal sphincter is helpful in establishing the neurogenic dysfunction of the bowel. Barium enema studies and manometry are clearly complementary in the diagnosis of Hirschsprung's disease. However, rectal manometric studies are more reliable than radiologic methods for short aganglionic segments that are usually not apparent on barium enema studies (Fig. 118.13). Manometric studies are not dependable in infants less than 3 weeks of age. If the barium enema and anal manometry studies indicate Hirschsprung's disease, rectal biopsy is not necessary to confirm the diagnosis.

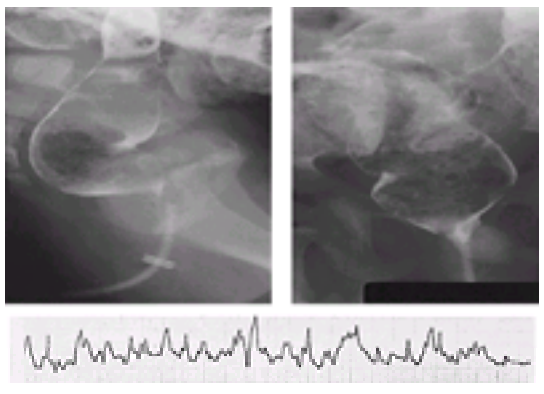

FIGURE 118.13. Ultrashort Hirschsprung's disease. Barium enema and rectal manometry studies in a 2-year-old child. Barium enema study in anteroposterior and lateral view. There is no transition zone but the sigmoid is somewhat dilated, suggesting idiopathic megacolon **(A).** Rectal manometry 2 days later shows no relaxation of the internal sphincter pressure after rectal stimulation **(B).** The tracing **(C)** shows no decrease in anal sphincter pressure, indicating Hirschsprung's disease. At surgery, low-segment Hirschsprung's disease was found.

In children of all ages, an adequately performed suction mucosal biopsy of the rectum 2 cm or more above the dentate line can be reliable in diagnosing Hirschsprung's disease. Because of the complicated evaluation and management of

this disease, referral to a pediatric surgeon is recommended.

Duplications

Duplications occur anywhere from the mouth to the anus and produce a variety of symptoms. In the abdomen, there may be a noncommunicating cyst that gradually fills up with secretions and compresses the adjacent normal bowel, producing a palpable abdominal mass or chronic intestinal obstruction. An occasional duplication has a communication, particularly at its distal end, that produces a large mass that may be confused with the fecal mass felt with aganglionic Hirschsprung's disease. Rarely, a marginal ulcer resulting from ectopic gastric mucosa may occur, and this produces painless bleeding. After appropriate radiographic diagnosis, surgery is indicated; the surgical procedures vary, depending on the locations, size, and communications of the anomaly.

Inflammatory Bowel Disease

The older child or adolescent may develop either Crohn's disease or ulcerative colitis (see Chapter 93), and this must be included in the differential diagnosis of chronic intestinal obstruction. Usually, the child has a history of changing bowel habits, with mucus or blood in the stools, chronic abdominal pain, and weight loss. Chapter 93 covers inflammatory bowel disease in detail.

DISEASES THAT PRODUCE RECTAL BLEEDING

Rectal bleeding is an alarming symptom. It is important to determine the quantity of bleeding and whether the blood is on the outside of the stool or mingled with it. A “tarry” stool suggests a source of bleeding in the proximal portion of the GI tract and bright red blood a more distal origin (Fig. 118.14). Occasionally, the child will have an episode or two of blood with his bowel movements. All patients with rectal bleeding should have a rectal examination. Those with significant hemorrhage require flexible colonoscopy and a contrast enema. In some patients, no definite diagnosis may be reached despite extensive studies. In any patient with significant bleeding, however, surgical consultation is indicated. Chapter 30 and Chapter 93 further discuss the diagnosis and management of patients with GI bleeding.

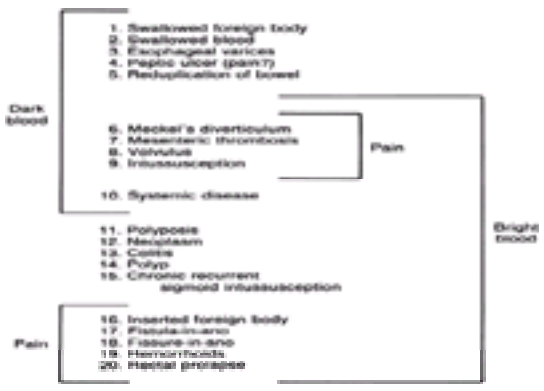

FIGURE 118.14. Causes of rectal bleeding in children.

Fissures

An anal fissure is probably the most common cause of bleeding, especially in infants. However, fissures may occur at any age. The child usually has a history of passing a large, hard stool with anal discomfort. Often, the child has a history of chronic constipation with progressive reluctance to pass stool because of the associated discomfort. If bleeding occurs, it usually involves streaking of bright red blood on the outside of the stool, or red blood on the toilet tissues. The diagnosis can easily be made by inspection or anoscopic examination and appropriate measures taken to relieve the chronic constipation (see Chapter 14). Children may be helped by sitz baths and the application of local anesthetic ointments such as Nupercainal. Rarely does a child require hospitalization or surgery.

Juvenile Polyps

Older infants and children can develop either single or multiple retention polyps. Usually, the polyps occur in the lower portion of the colon and can often be palpated on rectal examination. Polyps bleed, but they rarely cause massive hemorrhage. They may intermittently prolapse at the anus or on occasion come free and be passed as a fecal mass associated with bleeding. Colonic polyps may be lead points for intussusception. Usually, however, polyps are asymptomatic except for the associated bleeding. These are not premalignant lesions, and they tend to be self-limiting (Fig. 118.15).

FIGURE 118.15. Juvenile polyp. Double air-contrast barium enema shows a single polyp with long stalk in transverse colon *(arrow).*

If a polyp can be felt on rectal examination or viewed through the sigmoidoscope, it may be safely removed from below. Polyps beyond the reach of the sigmoidoscope should be removed by colonoscopy.

Familial Polyposis

Families with multiple adenomatous colonic polyps are rarely encountered. Bleeding is rare. More often, a colitis type of mucous discharge is present. Rectal examination and endoscopy reveal multiple “cobblestone” sessile polyps. These individuals are at risk for neoplasia because these are premalignant adenomatous polyps. The child should be referred to a pediatric surgeon and gastroenterologist for evaluation and long-term management.

Meckel's Diverticulum

Two percent of the population is born with a Meckel's diverticulum. This is the most common omphalomesenteric duct remnant. The diverticulum is usually located 50 to 75 cm proximal to the terminal ileum. Only 2% of persons with a Meckel's diverticulum manifest any clinical problems. The most common complication of a Meckel's diverticulum is a bleeding ulcer. Ectopic gastric mucosa in such patients is usually present in the diverticulum. The acid secretion produces an erosion at the junction of the normal ileal mucosa with the ectopic mucosa. Currant jelly stools are supposed to be classic for this type of bleeding, but it can be severe at times. Other modes of presentation include diverticulitis, perforation with peritonitis, or intussusception as a result of the diverticulum's serving as a lead point.

Barium studies usually fail to outline a Meckel's diverticulum. The imaging modality of choice for detection of ectopic gastric mucosa in a bleeding Meckel's diverticulum is nuclear scintigraphy. A well-defined focal accumulation of radionuclide (99m-technetium pertechnetate) usually appears at or about the same time as activity in the stomach and gradually increases in intensity (Fig. 118.16). A duplication cyst with gastric mucosa shows the same focal accumulation of radionuclide. Preoperative differentiation between two lesions as a cause of GI bleeding is not important. The accuracy of scintigraphy in detection of ectopic gastric mucosa in Meckel's diverticula is approximately 95%. False-negative results may rarely occur in patients with rapidly bleeding Meckel's diverticula and with those diverticula that do not contain gastric mucosa. Ultrasound and magnetic resonance imaging (MRI) are of no use in finding a Meckel's diverticulum.

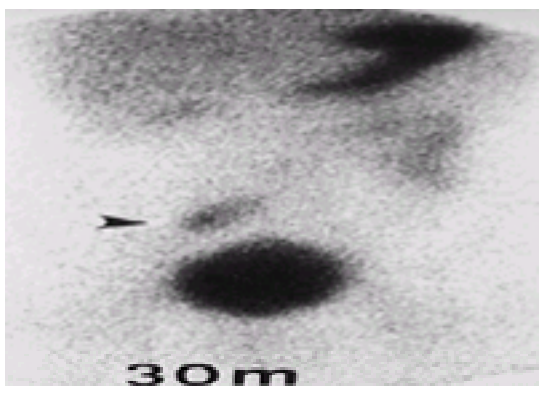

FIGURE 118.16. Meckel's diverticulum. Anterior image at 30 minutes shows an oval focal accumulation of ^{99m}Tc-pertechnetate in the right lower quadrant of the abdomen *(arrowhead).*

In any child with a major rectal bleed and a negative scan, further workup, including an arteriogram if the bleeding continues to be active or colonoscopy when the bleeding is not active, is required.

Henoch-Schönlein Purpura

Henoch-Schönlein purpura (see Chapter 87) is a vasculitic disorder that can produce asymptomatic rectal bleeding or abdominal pain and hematuria. Usually there is visible evidence of vasculitis on the skin surface, but a patient initially may have only abdominal pain. Occasionally, a child will develop a small bowel intussusception from a submucosal hemorrhage that is acting as a lead point. Other common manifestations are purpuric rash, fever, and joint pains (see

Chapter 87).

Other Causes of Rectal Bleeding

Other causes of rectal bleeding include intestinal vascular malformations, intussusception, duplications, inflammatory bowel disease, peptic ulcer with bleeding, and portal hypertension with bleeding varices. These topics are covered elsewhere in this chapter, in Chapter 93 and in Chapter 30.

INTRA-ABDOMINAL MASSES

Background

Intra-abdominal masses in children may be benign, but unfortunately, there are also a number of malignant ones. Abdominal masses may be silent, even after the tumor has reached a large size. Often, they are first recognized by the parent or the child's caretaker while the child is being undressed or bathed.

It is difficult to feel an intra-abdominal mass and outline its limits and its degree of mobility if an infant or child is crying. If the child is fed a bottle with his or her head turned to one side, the abdominal musculature will relax. The physician should then make an effort to palpate the intra-abdominal contents carefully. These masses are fragile and prone to rupture. Therefore, palpation of the mass should be done gently and should be strictly limited to as few examiners as possible.

Retroperitoneal masses tend to be fixed, whereas masses attached to the mesentery or omentum are mobile and may be shifted to different locations by the examiner. Pelvic masses are commonly fixed and often can best be felt by rectal examination. A presacral mass may narrow the rectum and produce constipation. Abdominal masses present with various characteristics and may be smooth, nodular, cystic, or rock hard.

Initial evaluation in the ED may include flat and upright abdominal films. If, after such an examination, the origin of the mass is unclear or suggests a neoplasm, the patient should be admitted and a workup done without delay. Observation has no place in dealing with unexplained abdominal masses in children.

The role of diagnostic imaging is to identify the precise anatomic location and extent of the pathologic process with a minimal number of procedures. It should be stressed that ultrasonography, nuclear scintigraphy, CT, and MRI have dramatically changed the traditional approach to pediatric imaging. The general location of a mass, with or without calcification, can be confirmed by plain abdominal roentgenograms. Real-time ultrasonography has become increasingly important initial imaging because it does not use radiation and yet is diagnostically accurate. Ultrasonography can differentiate a cystic flank mass (Fig. 118.17) that could be a hydronephrotic kidney from a solid tumor such as an adrenal neuroblastoma and thus facilitate the proper referral of the child to either a urologist or a pediatric surgeon. CT is superior to other modalities for anatomic detail and obtains an entire anatomic section of tissue, which aids in determining the precise extent of disease. CT provides anatomic and physiologic information about organs and vascular structures despite overlying gas and bones. Nuclear scintigraphy has a limited role in the evaluation of pediatric abdominal masses. Renal scintigraphy is superior to excretory urography for quantitating renal function. Angiography is indicated for an abdominal mass only if a precise knowledge of segmental vascular anatomy is required or if interventional techniques are contemplated.

FIGURE 118.17. Ureteropelvic junction obstruction. A newborn with left flank mass. Ultrasonography of the left flank shows dilated pyelocalyceal system. The communicating dilated collecting systems are seen in the periphery of the significantly dilated renal pelvis.

Excretory urography has traditionally been the radiologic choice for abdominal masses in children. However, ultrasound and CT have forced reassessment of this classic approach. In approaching abdominal masses in infants and children, the plain film with either real-time ultrasonography and excretory urography or CT can define the origin of abdominal masses.

Sacrococcygeal Teratoma

The presacral sacrococcygeal teratoma is the most common tumor of the caudal region in children and is more common in females than in males (4:1). Most tumors are benign and are noted at birth. However, tumors in patients beyond neonatal age have a higher incidence of malignancy. Radiography shows a soft-tissue mass that arises from the ventral

surface of the coccyx. Calcifications are present in 60% of presacral sacrococcygeal teratoma and are more common in benign tumors. Ultrasound confirms whether presacral sacrococcygeal teratomas are cystic, solid, or mixed. Also, ultrasonography is valuable to determine impingement on the urinary tract. CT is helpful in confirming the diagnosis, particularly in older children, and demonstrates the content of a tumor as well as its extent and bone anomalies. Tumors with more solid components are more often malignant than those with more cystic components (Fig. 118.18).

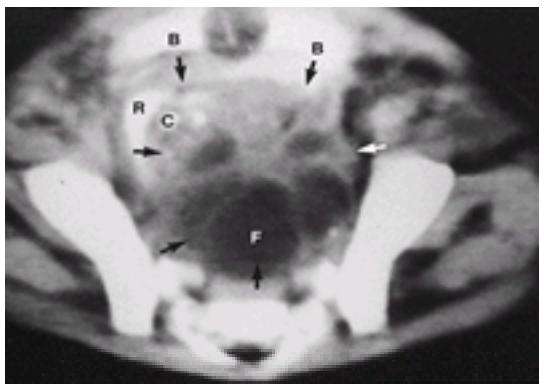

FIGURE 118.18. Presacral teratoma. Computed tomographic section of pelvis with contrast medium enhancement shows a large cystic mass *(arrows).* The mass contains both fat and calcification, and displaces the rectum anteriorly and laterally, and the bladder anteriorly. *B,* bladder with Foley catheter; *C,* calcification; *F,* fat; *R,* rectum.

Nonmalignant Intra-Abdominal Masses

Fecaloma

A lower abdominal mass, particularly one on the left side, is most often related to retained stool and is more often associated with chronic functional constipation than with Hirschsprung's disease. If a mass is found, a careful review of the bowel habits is important. If an abdominal mass is a fecaloma, a large bolus of stool usually can be felt on rectal examination just inside the anus. The evaluation of the impaction, and irrigation of the upper sigmoid colon, should cause the mass to disappear. See Chapter 14 for the causes of constipation.

Ovarian Masses

Simple ovarian cysts and solid teratomas are not uncommon and may be asymptomatic even though they have reached a large size. Occasionally, the child presents with urinary complaints from the pressure on the bladder or urethra. Granulosa cell tumors of the ovary produce precocious puberty because they are hormonally active tumors. They may be malignant. The sudden onset of severe abdominal pain may indicate a torsion of an ovarian mass on a slender pedicle, with resultant infarction. Granulosa cell tumors tend to give the impression of rising up from the pelvis and on occasion lie in the midabdomen or even the upper abdomen. When they are still partially within the pelvis, they usually can be felt by rectal examination. Most ovarian masses are smooth and nontender. Radiographs may show calcification in about half of patients with teratomas (Fig. 118.19). Because an occasional ovarian tumor is malignant in children, children with ovarian masses should be promptly evaluated and prepared for surgery (see Chapter 94).

FIGURE 118.19. Ovarian dermoids. Note calcification *(arrows)* in superior aspect of a large pelvic mass in a 12-year-old girl.

Omental Cysts

Omental cysts are rare, are usually asymptomatic, and can reach gigantic size. It is often difficult to differentiate an omental cyst from ascites. There are a number of cases on record in which omental cysts have been tapped, on the assumption that they were ascitic fluid. Smaller cysts are more mobile and can be pushed freely into all quadrants of the abdomen. If a cyst volvulizes on its pedicle or has bleeding within it, it may cause abdominal pain or tenderness. Elective surgical excision is indicated.

Mesenteric Cysts

Mesenteric cysts can occur anywhere in the mesentery but are most common in the mesentery of the colon. They tend to be multilocular and are often discovered during a routine examination or after an episode of abdominal trauma with enlargement from bleeding. They are benign, but surgical therapy is indicated, both to confirm the diagnosis and to prevent complications. They can usually be removed with sparing of the bowel, or they can be marsupialized into the general peritoneal cavity where the fluid is absorbed.

Duplications

GI duplications within the abdomen can occur anywhere along the greater curvature of the stomach, the lesser curvature of the duodenum, or the mesenteric side of either the small or large intestines. They can also be pararectal, rising up out of the pelvis. Duplications that produce abdominal masses are either noncommunicating, and hence gradually enlarge, or communicating in that their secretory lining has a distal communication with the true lumen of the bowel. Except for the rare occurrence of massive rectal bleeding in a child with a communicating duplication, most duplications do not present as emergencies. Instead, they present in children either as unexplained abdominal masses or with symptoms of intermittent colic, resulting from partial obstruction of the true lumen of the adjacent bowel. The exact diagnosis is often unclear until the time of laparotomy.

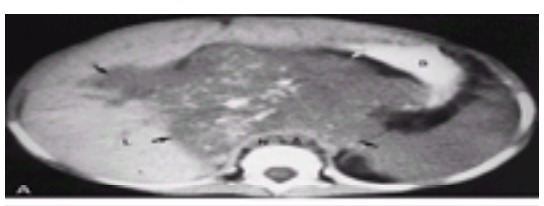
Malignant Intra-Abdominal Masses

About 50% of the solid malignant tumors seen in children occur within the abdominal cavity. They generally occur in the retroperitoneum. The most common is neuroblastoma, followed by Wilms' tumor and rhabdomyosarcoma. Other unusual tumors, such as embryonal cell carcinomas (yolk sac tumor) and lymphosarcoma, also occur in young children. Chapter 100 covers oncologic emergencies. As with most malignant tumors, early diagnosis and treatment provide the best prospects for a cure. Therefore, the physician must have a high index of suspicion for malignancy in any child with a mass or unexplained GI or genitourinary symptoms.

Neuroblastoma

Neuroblastoma most often occurs as a tumor in the left or right adrenal gland, but it can develop anywhere along the sympathetic chain or in the pelvis. It has even been found intrarenally. It has the ability to grow extensively, often crossing the midline of the abdomen, and enveloping key vascular and visceral structures. The best cure rates are generally in children who are less than 1 year of age at the time of diagnosis and in whom the tumor is still localized to the point of origin. In such favorable cases, the tumor can be totally excised. When widespread dissemination occurs, complete resection is unwarranted because of the risk to other vital structures.

CT is superior to ultrasonography for clearly defining morphologic details of neuroblastoma, such as calcifications, and precise extent of tumor by direct spread or lymphatic metastasis. CT with contrast enhancement demonstrates precise anatomy, as well as renal function and organ vascularity. The CT characteristics of neuroblastoma include irregular shape, irregular margins, lack of well-defined capsules, and mixed low-density center. Neuroblastoma often displaces surrounding organs and encases vessels. Prevertebral midline extension is common. There are calcifications in at least 75% (Fig. 118.20). Ultrasonography has limitations in accurately determining tumor margins or local extension. Therefore, CT is the modality of choice for imaging neuroblastoma.



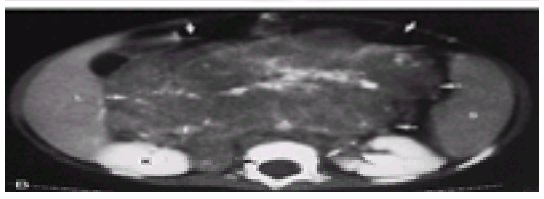


FIGURE 118.20. A. Celiac axis neuroblastoma. Computed tomographic (CT) section of the abdomen shows a large lobulated mass with multiple flake of calcification displacing stomach and the liver *(white arrows).* Note presence of retrocrural node *(black arrows). A,* aorta; *L,* liver; *N,* node; *S,* stomach. **B.** Celiac axis neuroblastoma. Enhanced CT section of the abdomen at level of the kidney shows a large lobulated mass with irregular margins and calcification displacing the right kidney inferoposterior and laterally. Note encased inferior vena cava (IVC) and aorta. The IVC is displaced laterally and ventrally and to the right the superior mesenteric artery and celiac axis are completely surrounded by the mass. *A,* aorta; *I,* IVC; *K,* kidney; *L,* liver; *S,* spleen; *white arrows,* mass.

Wilms' Tumor

Wilms' tumor is the most common intrarenal tumor seen in children. Great progress has been made in the last several decades in its management. The tumor can reach a gigantic size before its discovery. Wilms' tumor should be considered

in any child who has hematuria even if he or she has a history of trauma.

A solid renal mass demonstrated by ultrasound in infants and children is usually a Wilms' tumor. Because of the high frequency of tumor extension into the renal veins and inferior vena cava, these vascular structures should be examined by real-time ultrasound. Venous extension is diagnosed when echogenic filling defects are identified within a renal vein, the inferior vena cava, or the right heart. Because Wilms' tumors are usually large and expansive, the inferior vena cava often is extrinsically displaced by the tumor mass. CT with bolus contrast enhancement may be required for confirmation of equivocal invasion in a patient suspected of having Wilms' tumor. After abdominal real-time ultrasound, excretory urography should be performed to evaluate the function of the kidneys. Angiography seldom provides additional diagnostic information. CT defines the presence of an intrarenal mass and extent of tumor, visualizes vascular structures, identifies nodal involvement, defines internal hemorrhage and necrosis, evaluates the presence or absence of liver metastases, and images the opposite kidney. Also, CT can define whether a tumor is initially nonresectable or bilateral (Fig. 118.21). CT may be extremely helpful in following the response to chemotherapy. Chest CT is also performed at the initial evaluation to identify pulmonary metastases. Bone scintigraphy is helpful in diagnosing metastases. Surgical removal of Wilms' tumor should not be delayed. Postoperative management with chemotherapeutic agents and selective irradiation is important. These youngsters should be cared for by a team of specialists with thorough knowledge of ancillary forms of therapy.

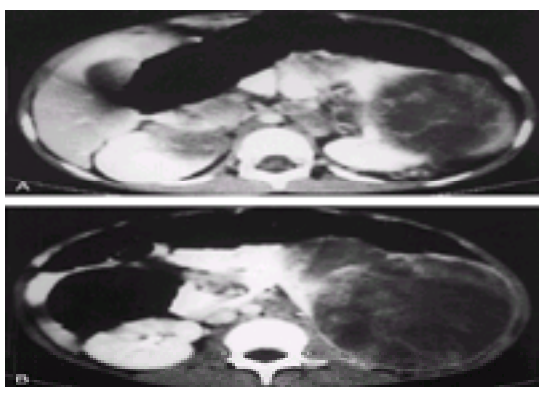

FIGURE 118.21. A. Bilateral Wilms' tumor. A 5-year-old girl with left flank mass. Computed tomographic (CT) sections of the upper abdomen with contrast medium enhancement show a necrotic mass arising from superior aspect of the left kidney. Note a small mass in the superior medial aspect of the right kidney. **B.** Bilateral Wilms' tumor (same patient as in **A** CT section of the abdomen with contrast medium enhancement shows extent of the large necrotic left Wilms' tumor with periaortic adenopathy.

Rhabdomyosarcoma

Rhabdomyosarcoma can occur anywhere in the abdomen or pelvis where there is striated muscle. Tumors are particularly common in the pelvis, involving the prostate, uterus or vagina, and retroperitoneal structures, but they have also been found in the common bile duct and other unusual sites. These tumors can reach a large size before they become symptomatic and each must be managed individually, depending on the site of origin, extent of growth, and the degree of spread. Modern selective therapy has greatly improved the survival rate of this highly malignant tumor.

Hepatoma

Hepatomas are fortunately rare. They are usually seen in older infants and young children. Hepatoblastoma, more common than hepatoma, is often discovered accidentally when the child is undressed for a bath. The child may feel and act well, yet the tumor is already of a formidable size when first noted. Differential diagnosis should include hemangioendothelioma, hamartoma, and renal and adrenal tumors, especially if they occur on the right side.

An important application of CT in the examination of patients with hepatomas involves a complementary role with MRI and angiography in the assessment of potential resectability. The ability of CT to show the location and extent of a tumor's relation to the intersegmental fissure makes it a useful procedure to determine the feasibility of this operation. MRI without IV contrast is more sensitive than dynamic CT for the detection of liver lesions. It possesses the imaging qualities of both ultrasound and CT scan in that it can image the liver in any plane and displays the vascular structures without the need for contrast media (Fig. 118.22A). Angiography is required before surgery to provide the surgeon with knowledge of the vascular supply of the tumor and the arterial anatomy of the liver. More recently, a new tool for angiographic imaging is magnetic resonance angiography (Fig. 118.22B). This method eliminates the need for arteriography and gives the surgeon an excellent view of the extent of the tumor with its vasculature and possibility of resection. CT and MRI are reliable methods to observe the response or progression of tumors in patients who undergo nonoperative therapy (Fig. 118.23).

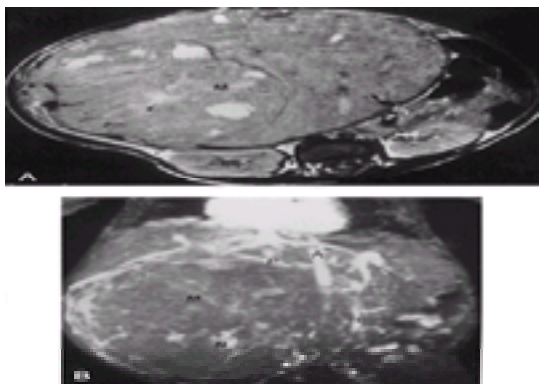

FIGURE 118.22. A. Hepatoblastoma in a 2-month-old boy. Axial T1 magnetic resonance imaging (MRI) shows a solid mass *(M)* occupying entire liver, gallbladder *(arrow),* and right kidney *(K).* **B.** Coronal magnetic resonance angiography shows liver mass *(M),* with stretching of the hepatic vessels and multiple area of neovascularity *(N).* Note marked stretching and displacement of the inferior vena cava *(I)* with patent portal vein *(P). A,* aorta.

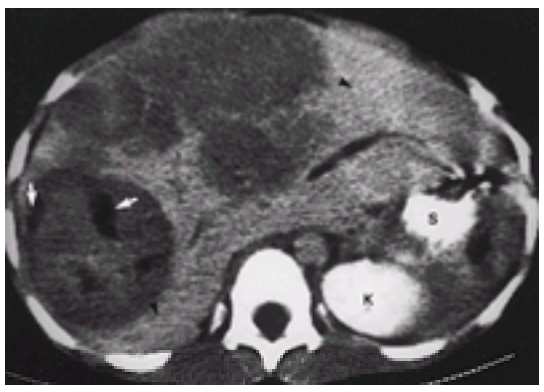

FIGURE 118.23. Hepatocellular carcinoma. Computed tomographic (CT) section of the abdomen with contrast medium enhancement shows multiple area of nonuniform lower density than the adjacent normal liver occupying most of the liver. The area of more lower density is representative of focal necrosis *(arrows).* Only small part of the left lobe and right lobe of the liver is normal *(arrowhead). K,* kidney; *S,* stomach

Survival depends on both complete resection of the primary tumor before metastases have occurred and intensive prolonged chemotherapy postoperatively. As much as two-thirds of the liver may have to be removed.

ABDOMINAL WALL DEFECTS

Inguinal Hernias and Hydroceles

Indirect inguinal hernia is the most common congenital anomaly that is found in children. It is approximately 10 times more common in males than in females. There is a strong familial incidence.

Clinical Manifestations

The child with a hernia may present in different ways. The presentation is determined by the extent of obliteration of the processus vaginalis before birth. A child may have a completely open hernia sac, which extends from the internal ring to the scrotum, or a segmental obliteration producing a sac that is narrow at its proximal end, creating a hydrocele of either the tunica vaginalis or the spermatic cord. The narrowing of the processus allows the abdominal fluid to seep into the distal portion of the sac. It then becomes entrapped and produces what is clinically recognized as a hydrocele. It is often difficult for this fluid to egress through the narrow patent processus vaginalis back into the abdominal cavity.

At the time of the embryologic closure of the processus vaginalis, many fetuses will have some fluid trapped around the testicle in the tunica vaginalis. This is called a physiologic hydrocele, which is a normal newborn finding. In such cases, the fluid gradually is absorbed in the first 12 months of life. If, however, an infant or child develops a hydrocele along the cord in the tunica vaginalis sometime after birth, it must be assumed that the processus vaginalis is still patent and in communication with the peritoneal cavity. This patent processus vaginalis represents a hernia sac. Surgical closure of the sac and drainage of the hydrocele are then indicated.

Many infants and children manifest the classical bulge in the inguinal canal that occurs during straining or crying. This is caused by a loop of intestine distending into the hernia sac. Usually, the hernia sac contents reduce into the abdominal cavity when the straining ceases. If the prolapsing loop of intestine becomes entrapped in the hernia sac, an incarceration has occurred. This is a true emergency that could eventually lead to intestinal obstruction and possibly strangulation of the bowel (p. 1521).

Elective herniorrhaphy should be done shortly after the hernia is diagnosed. One always worries about incarceration. It is an outpatient procedure in all term infants at 44 weeks' gestational age. If the operation is urgent and the infant is less than 44 weeks' gestational age, the child should be admitted for overnight monitoring. All premature babies are admitted

for 1 night because of the high incidence of postoperative apnea.

Hydroceles of the spermatic cord with associated communicating hernias are sometimes difficult to differentiate from an incarcerated hernia. If an empty hernia sac can be felt above the hydrocele, the physician can be assured that this is an asymptomatic hernia with an associated hydrocele. However, if there is a fullness above the hydrocele and the mass cannot be reduced, the child should be taken to the operating room on the assumption that it probably is an incarcerated hernia that needs to be managed surgically.

Management

Fortunately, strangulation of the entrapped loop of bowel in an incarcerated hernia occurs relatively late so that, contrary to adult practice, efforts to reduce the incarceration without surgery are usually warranted. When a child with an incarcerated hernia presents in the ED, the child should be given nothing to eat or drink, sedated if necessary with morphine 0.1 mg/kg, and placed in a Trendelenburg position. Often, this alone will reduce the incarceration. If it does not, bimanual reduction should be attempted. If the child is warm and, preferably, asleep as a result of the sedation, the reduction is facilitated. The fingers and thumb of one hand should compress the internal ring area while an effort is made with the other hand “to milk” either gas or fluid out of the entrapped bowel back into the abdomen. This relieves the pressure and usually allows the entire loop of bowel to reduce back into the abdominal cavity. Once the incarcerated hernia is reduced, the child should be admitted or scheduled for elective surgery at the preference of the surgeon. A day or two should be allowed to pass to lessen the edema of the area and allow an easier and safer elective herniorrhaphy.

Epiploceles (Epigastric Hernias)

If a discrete mass occurs intermittently about one-third of the distance from the umbilicus to the xiphoid, it is usually the result of a weakness of the linea alba through which properitoneal fat protrudes. This defect is called epiplocele. Such defects are fairly common in infants and usually close spontaneously. In older children, the mass may occasionally be tender. If it becomes excruciatingly tender, it is a sign that fat has become incarcerated in the hernia. Although there is no great urgency, these small midline defects should be repaired surgically when they become symptomatic.

Umbilical Hernias

Umbilical hernias are common in small infants, particularly in African-Americans. Fortunately, most of the hernias tend to close spontaneously and only rarely does incarceration occur. Umbilical hernias can be large and unsightly and families need reassurance that watchful waiting is the best course. However, if the umbilical hernia fails to close by the age of 5 to 6 years, surgical repair is indicated. Umbilical hernias may be repaired earlier if there is a large ring that shows no signs of diminishing in size over 1 to 2 years, if there is a thinning of the umbilical skin, or if an incarceration has occurred. Hernias that have a supraumbilical component tend not to close spontaneously and may be operated on at an earlier time of life.

Other Umbilical Defects

Omphalomesenteric duct remnants may persist in either of two forms. When the duct is patent from the ileum to the umbilicus, there is a release of small bowel contents via an opening in the umbilicus. A second form involves a remnant of the omphalomesenteric duct that contains a secreting mucosal patch that is attached to an opening in the center of the umbilicus. Passage of a sterile blunt probe or instillation of contrast dye under fluoroscopy via the umbilical opening will usually confirm either of these conditions. Once identified, these remnants must be excised surgically. By contrast, some infants present with umbilical granuloma in which an excessive amount of granulation tissue has built up after separation of the umbilical cord. In these patients, no opening in the granulation tissue can be seen or felt by means of a probe. These granulomas are usually best treated by application of silver nitrate to the granulation tissue. Occasionally, two or more treatments are required. After each treatment, the area should be rinsed thoroughly to prevent burning of adjacent skin. If the granuloma is allowed to persist, it will eventually epithelialize and become an umbilical papilloma (Fig. 118.24).

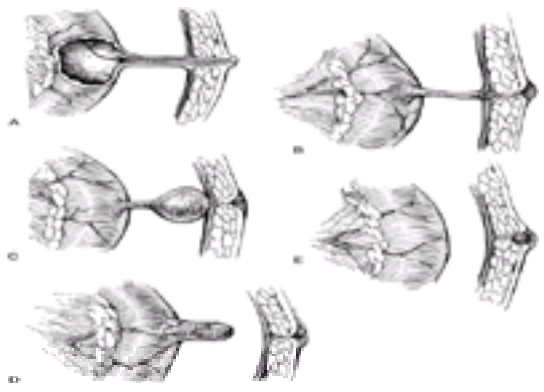

FIGURE 118.24. Omphalomesenteric remnants. Patent omphalomesenteric duct from terminal ileum to umbilicus **(A);** closed omphalomesenteric duct with mucosal patch at umbilicus **(B);** omphalomesenteric cyst below umbilicus **(C);** Meckel's diverticulum **(D);** umbilical granuloma **(E).**

If the urachus persists after birth, it can form a urinary fistula that drains at the umbilicus. This problem is ordinarily noted in the newborn period. Older infants or children may present with drainage at the umbilicus caused by persistence of part of the urachus even though connection with the bladder may be obliterated. These urachal remnants also require

surgical excision.

FOREIGN BODIES OF THE GASTROINTESTINAL TRACT

When a child ingests a foreign body, it causes great family concern. Most swallowed foreign bodies move through the GI tract without complication. Occasionally, a foreign body lodges in the esophagus, necessitating removal. Plain film roentgenograms for suspected foreign body should focus on the suspected area initially but then expand to include the base of the skull to the anus if the object is not seen. Once an esophageal foreign body has been identified, it should be removed promptly to prevent complications such as edema, ulceration, aspiration, pneumonia, or perforation.

Foreign bodies that reach the stomach, whether pointed or sharp-edged, usually pass completely through the intestinal tract and are evacuated. Cathartics and other efforts to hurry their transit should not be used.

Occasionally, a long, thin foreign body such as a bobby pin may not be able to traverse the turn where the duodenum joins the jejunum at the ligament of Treitz. If a foreign body is trapped in this area, perforation with local or generalized peritonitis may occur. When entrapment occurs anywhere beyond the pylorus, surgical removal is indicated either to prevent or to treat local perforation. Occasionally, objects such as straight pins, toothpicks, and broom straws become entrapped in the appendix. When this occurs, the appendix should be removed. Coins may remain in the child's stomach for considerable time, and if they do not become imbedded in the gastric mucosa, they eventually pass, even after a month or more. With the aid of modern flexible endoscopic equipment, foreign bodies in the stomach can usually be removed with ease. Chapter 121 covers pharyngeal foreign bodies.

CHAPTER 119

Thoracic Emergencies

***ROBERT E. KELLY Jr, MD and †DANIEL J. ISAACMAN, MD**

**†Departments of Surgery and Pediatrics, Eastern Virginia Medical School, and *Department of Surgery, †Division of Pediatric Emergency Medicine, Children's Hospital of The King's Daughters, Norfolk, Virginia*

INTRODUCTION

Thoracic emergencies in children often result in life-threatening alterations in cardiorespiratory physiology. A rapid, yet organized approach to the child with a thoracic emergency may represent the difference between life and death. This chapter is aimed at guiding the emergency physician toward evaluation and stabilization of children presenting with surgical diseases involving the thorax. Congenital abnormalities usually diagnosed at birth are not included. Thoracic trauma is discussed in Chapter 107.

This chapter reviews the pathophysiology and clinical manifestations of thoracic emergencies. The general principles of physical and laboratory assessment are detailed. Subsequent sections cover specific entities within the following categories: 1) airway obstruction, 2) violations of the pleural space, 3) circulatory impairment, 4) intrinsic pulmonary lesions, 5) mediastinal tumors, 6) diaphragmatic defects, and 7) chest wall tumors.

PATHOPHYSIOLOGY

Thoracic conditions of surgical significance usually present because of a mechanical or infectious complication of an anatomic abnormality. Responding to these problems requires thinking about the patient on a gross anatomic level. These anatomic distinctions may be conveniently grouped into conditions resulting in airway compromise, violations of the pleural space, circulatory compromise, intrinsic lesions of the lung, mediastinal masses, and diaphragmatic defects.

Within each of these categories, it is particularly useful to consider *fluid pressure* changes and their effect on normal physiology. Fluids, including air, move in the body down pressure gradients. Air moves through the oropharynx, through the trachea, and into the lungs *only if the pressure in the lungs is less than atmospheric pressure.* Accumulation of air or fluid around the lungs in the pleural space may need to be removed if it is preventing lung expansion. Obstructions to flow caused by masses compressing the airway or esophagus may make it impossible for fluids to flow down the pressure gradient.

Infectious problems requiring surgical care usually have an underlying *anatomic abnormality.* Examples include an infected bronchogenic cyst or pulmonary sequestration, and an H-type tracheoesophageal fistula producing aspiration

pneumonia. Empyema, the accumulation of infected pleural fluid, which complicates pneumonia in childhood, is an example of an exception to this rule. The pathophysiology of this condition and its predilection for younger children remain poorly defined.

Whereas in most conditions of surgical significance, it is important to view the patient at the anatomic level, in some cases masses are important because of their *cellular* makeup rather than their compressive or displacing effects. Because the cellular morphology of tumors often guides therapy and relates to prognosis, biopsy is often indicated for thoracic masses. Appropriate referral of such patients is imperative.

The emergency physician evaluating the child with a thoracic problem must attempt to determine whether the patient has evidence of airway compromise, circulatory compromise, or components of both.

Airway Compromise

Airway compromise can occur anywhere in the respiratory tract from the nose to the alveoli. Obstructive emergencies relating to the oropharynx, larynx, and proximal trachea are discussed in Chapter 112 and Chapter 121.

Compromise of the more distal tracheobronchial tree may be caused by lesions in the lumen, in the wall, or outside the wall of the bronchus. Examples of intrinsic obstruction include tumor within the bronchial lumen (e.g., carcinoid tumor), foreign body, and a mucous plug. Obstruction from lesions in the wall of the bronchus include collapse from tracheomalacia and stenosis after tracheostomy. Extrinsic lesions make patients symptomatic by producing impingement on a bronchus by some adjacent structure such as a bronchogenic cyst or inflamed lymph nodes. Table 119.1 lists intraluminal, mural, and extrinsic conditions that produce airway obstruction.

Intraluminal
Foreign bodies
Aspiration (esophageal reflux, tracheoesophageal fistula, bronchial fistula, biliary fistula, or esophageal fistula)
Mucous plugs (cystic fibrosis)
Granuloma (chronic intubation, tuberculosis)
Hemoptysis (vascular malformations, cystic fibrosis, tuberculosis, sarcidosis, hemosiderosis, lupus)
Acute infection (tracheitis)
Mural
Tracheomalacia
Lobar emphysema
Bronchial atresia
Bronchial tumors
Extrinsic
Lymphadenopathy
Bronchogenic cyst
Cystic hygroma
Esophageal duplication
Mediastinal tumors

Table 119.1. Tracheobronchial Conditions Associated with Airway Compromise

The anatomic level of the obstruction correlates with its effects: an obstruction of the distal tracheobronchial tree may lead to segmental lung overdistension, or segmental infection. An obstruction of the proximal trachea affects both lungs, with a much greater likelihood of catastrophe for the patient. Similarly, greater degrees of obstruction, as a rule, lead to greater effects on gas exchange. Infection commonly follows obstruction of bronchial drainage because the clearance of bacteria or inhaled foreign materials by the mucociliary elevator is prevented.

Circulatory Impairment

Hemorrhage has somewhat different effects on the circulation in children than in adults. The ability of the child to support blood pressure in the face of significant blood loss has particular implications in the chest. Significant amounts of blood loss may be hidden in the large volume of the chest. It is important to recognize the early signs of shock before significant decreases in blood pressure occur, as this may represent a loss of 20% or more of the blood volume. Fortunately, non-traumatic causes of intrathoracic major blood loss are uncommon in children.

Collections of fluid in the pleural space and mediastinum, whether the result of bleeding or other causes, may produce obstruction of the venous return by *tension phenomena:* the child's mediastinum is mobile, and kinking of the great veins occurs much more easily than in adults. In a patient who requires positive-pressure ventilation, the positive inspiratory pressure inside the chest may be greater than the venous pressure returning blood to the heart. Thus, major intrathoracic bleeding may produce more than one difficulty: the central venous pressure and systolic arterial pressure are decreased because of loss of blood volume, and in addition, the pressure inside the chest of a ventilated patient may collapse the veins returning blood to the heart. Both of these problems require rapid administration of volume to the patient.

Rarely, the heart itself can be obstructed by primary tumors such as rhabdomyosarcoma or metastatic Wilms' tumor. Tamponade of the heart can be caused by pericardial effusion, hemopericardium, or, even more rarely, by pneumopericardium or pneumomediastinum. These topics are addressed in Chapter 82.

CLINICAL FINDINGS

Physical Examination

Evaluation of the child with a thoracic emergency requires a calm, orderly assessment of the ABCs. The physician must first address whether the patient's problem is currently causing or likely to cause imminent impairment of the airway,

breathing pattern, or circulatory status.

In assessing the airway, the physician must evaluate the adequacy of air movement and gas exchange. Pulse oximetry should be done upon the patient's arrival. Anxiety or confusion in a patient with a thoracic emergency may be evidence of hypoxemia. The work of breathing can be evaluated by assessing the use of intercostal, subcostal, and supraclavicular accessory muscles.

Breathing is best evaluated by palpation and auscultation of the chest. The trachea should be palpated to make sure that it is midline. Any lateralization of the trachea is evidence suggestive of a pneumothorax. The neck and chest should be palpated for signs of subcutaneous emphysema, suggestive of an ongoing air leak. Finally, breath sounds should be assessed via auscultation for symmetry, and adequacy of inspiratory and expiratory air flow.

Evaluation of the cardiovascular system should include an assessment of the patient's pulse for quality, rate, and regularity. The peripheral skin should then be assessed for color, temperature, and capillary refill. Signs of poor perfusion often precede that of pressure instability. The neck should be assessed for signs of jugular venous distension. Finally, the heart should be examined for signs of displacement of the point of maximal impulse (PMI); shift or alteration in the heart tones; or new murmurs, gallops, or friction rubs.

Laboratory Studies

The most important study when evaluating any patient with a thoracic emergency is a good quality chest radiograph. A radiograph of the chest should include posteroanterior (PA) and lateral views done in an upright position, unless contraindicated by the patient's condition (e.g., possible injury to the spine). The width of the mediastinum and the degree of mediastinal shift are much better seen in the upright chest radiograph. Moreover, abnormalities in the lung, pleural cavity, and diaphragm are also best appreciated in this view. For example, in the patient with a traumatic rupture of the diaphragm, the true nature of the patient's respiratory distress may not become clear until an upright chest radiograph is obtained. When a pulmonary effusion exists, lateral decubitus anteroposterior (AP) views of the chest can be obtained to determine whether the effusion layers freely or is loculated.

In interpreting the chest radiograph, the physician should distinguish between a diffuse pulmonary problem and a focal lesion. Hyperaeration of one portion of the lung suggests air trapping in the involved lobe. Hyperaeration of the entire lung field on one side is usually the result of compensatory enlargement of the lung because of atelectasis and loss of lung volume on the opposite side.

Other studies that should be considered in a patient with a thoracic emergency include a complete blood count (CBC), blood urea nitrogen (BUN), serum glucose, electrolytes, CO_2 concentration, and an arterial blood gas or measurement of oxygen saturation. Depending on the patient's specific problem, a crossmatch, blood cultures, and an assessment of any sputum by Gram stain and bacteriologic culture may be helpful. Clinical evidence of a bleeding problem, but not need for operation alone, mandates evaluation of platelet count, prothrombin time (PT) and partial thromboplastin time (PTT). Other more involved studies, such as pulmonary function tests, barium contrast studies, sonograms, computed tomography (CT) scans, and magnetic resonance imaging (MRI), can be utilized as needed.

AIRWAY OBSTRUCTION

Tracheal Obstruction

Tracheal obstruction may be produced by lesions within the lumen of the trachea, in the wall of the trachea, or extrinsic to the tube. Intrinsic obstruction most commonly occurs in children because of an aspirated foreign body. Intrinsic obstruction may also occur because of a subglottic stenosis after tracheostomy. A hemangioma may also occur, but is rare. Tracheomalacia, sometimes complicating lung disease of prematurity, is characterized by a floppy trachea that collapses during expiration, when the intrathoracic trachea is compressed by the positive intrathoracic pressure. Laryngomalacia, or tracheomalacia outside the thoracic inlet, may produce obstruction during inspiration, when the negative intraluminal pressure transmitted from the chest causes the floppy wall to collapse. Tracheomalacia often occurs in infants born with tracheoesophageal fistula. Extrinsic compression may occur both from mass lesions (Table 119.1) and as a result of anomalous arteries. Bacterial tracheitis may produce sufficient inflammation that the mucosa effectively obstructs the airway.

Clinical Findings

Tracheal compromise produces symptoms that vary from mild to severe, depending on the amount of obstruction present. When symptoms are mild, the underlying cause may not be evident. Occasional episodes of respiratory infection that are thought to result from croup or bronchitis may be the only symptom. Stridor, wheezing, or cough occur in patients with more significant obstruction, and a history of previous hospitalizations for treatment with mist tent, antibiotics, and chest percussion may be given.

Severe tracheal compromise usually is manifested by a history of stridor at rest. Progressive cyanosis and apneic episodes occur. On examination, a child with obstruction caused by extrinsic compression often has wheezing or stridor throughout the respiratory cycle. In contrast, a patient with the floppy trachea of tracheomalacia often wheezes only during expiration.

Management

If the patient has a life-threatening airway obstruction, he or she should receive airway management as outlined in Chapter 1 and Chapter 5. Intubation of the airway to within a short distance of the carina supports most patients with

lesions extrinsic to the trachea or in the tracheal wall with a critical obstruction. Such a patient requires admission to an intensive care or other unit with ventilator capability. Lesions within the lumen will likely require endoscopic management in an operating theater.

Radiographic evaluation of the stable patient should begin with PA and lateral chest radiographs, ideally obtained at full inspiration and again at full expiration. Mass lesions will usually require CT to evaluate them. Bronchoscopy is often indicated to evaluate obstructive lesions, whether in the lumen, the wall, or extrinsic to the wall of the trachea (Fig. 119.1).

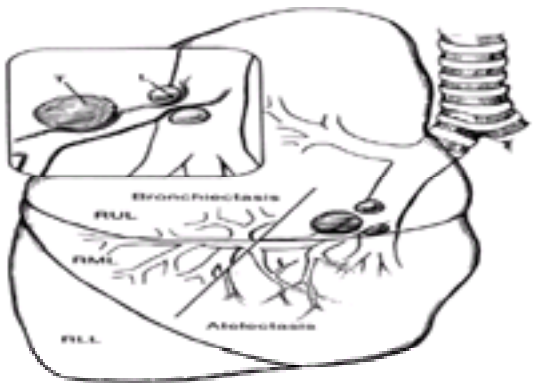

FIGURE 119.1. Acute and chronic obstruction of a bronchus owing to tumor or cyst *(T)* or lymph nodes *(L).* When the obstruction is acute, there may be bronchiectasis caused by recurrent pneumonia. The right middle lobe as shown here is particularly prone to bronchial obstruction caused by pressure from encircling lymph nodes. *RUL, RML, RLL,* right upper, middle, and lower lobes, respectively.

Vascular Rings

Vascular rings are developmental anomalies of the aorta and great vessels. They may produce obstruction of the esophagus, trachea, or both. Many anatomic types of rings are produced by failure of the normal involution of the appropriate segments of the six embryologic aortic arches. The number of possible variants is at least 36; 16 or more have been seen in humans. The level of obstruction is usually at the trachea, but compression of a bronchus by the ductus arteriosus, or by a pulmonary artery sling may produce compression more distally. The reader is referred to standard texts of pediatric or thoracic surgery for further details.

Clinical Findings

Vascular rings should be suspected in infants with stridor, dysphagia, failure to thrive associated with difficult feeding, or recurrent pneumonia. The wide variety of anomalies produce varying degrees of symptoms. Esophageal obstruction produces difficulty swallowing, designated *dysphagia lusoria* by Bayford in 1794. Often, diagnosis is delayed by failure to consider these anatomic obstructions. Chest radiographs may be supplemented by a variety of diagnostic tests: angiography, echocardiography, MRI, and digital subtraction angiography are needed in some combination to define the anatomy.

Management

Although a few patients with constricting anomalies improve as they grow, the usual situation is for a poor prognosis with medical therapy. Surgical treatment is usually indicated to relieve the obstruction. This is accomplished by dividing the vascular ring and preserving the blood supply to the aortic branches. This is usually accomplished by a left thoracotomy.

Bronchial Lesions

Bronchial Atresia

Congenital bronchial atresia is a rare anomaly characterized by a bronchocele caused by a mucus-filled, blindly-terminating segmental or lobar bronchus, with hyperinflation of the obstructed segment of lung. Hyperaeration is thought to result from communication via the pores of Kohn and the channels of Lambert with the normally aerated lung. First reported in 1953, a 1986 review of the literature reported a total of 86 cases.

Clinical Findings

Neonates and infants with the lesion usually are seen for respiratory distress. In older patients, a history of episodic upper respiratory infection and wheezing may be elicited. Some older patients may complain of dyspnea on exertion or unilateral chest pain. Physical findings seldom suggest the diagnosis, but often unilaterally decreased breath sounds are evident.

Management

Chest radiographs make the diagnosis most of the time. Chest CT scan is indicated to help define the anatomy. Bronchoscopy is the most efficient way to identify the atretic opening to the involved bronchus. Bronchography has been

used in the past, but high-resolution CT scan can often provide the same anatomic information non-invasively.

Right Middle Lobe Syndrome

The right middle lobe is anatomically predisposed to compression of its bronchus by the lymph nodes in its vicinity, which tend to encircle it. Because the right middle and lower lobes are favored sites for aspirated material, recurrent inflammation caused by pneumonia leads to adenopathy. Previously, especially in the era before antituberculous chemotherapy, this tended to result in compression of the right middle lobe bronchus alone, which produced eventual bronchiectasis. Often, right middle lobectomy was necessary. Presently, it is more common for the right middle and lower lobes to be involved together.

Clinical Presentation

Recurrent episodes of pneumonia and associated atelectasis in the right middle (and often lower) lobes occur in these patients, and are not responsive to chest percussion, postural drainage, or antibiotic treatment. The mechanical compression of the bronchus leads to a sequestered infection, which may require resection of the right middle or right middle and lower lobes. Although the need for resection is far less common than in the past, acute pneumonia in these anatomic locations should prompt a discussion of previous pneumonias and treatment. Close follow-up is indicated in such patients.

Esophagus-Related Causes of Airway Difficulties

Tracheoesophageal Fistula

Tracheoesophageal fistula (TEF) occurs in children both as a congenital lesion and as an acquired problem after suppuration of mediastinal nodes. The congenital fistula is accompanied by atresia of the esophagus in more than 85% of patients. However, in about 3% of all patients with TEF, the connection between the tracheal tube and the esophagus creates the shape of the letter “H” (Fig. 119.2). In these, there is no accompanying esophageal atresia.

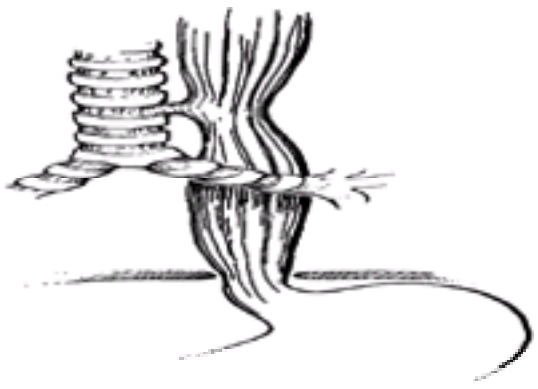

FIGURE 119.2. H-type tracheoesophageal fistula.

It is this “H-type” fistula that is most likely to be seen in the ED. The acquired form is usually in the distal trachea or proximal bronchial tree, and is extremely uncommon.

Clinical Findings

These fistulae are notoriously difficult to diagnose. Children generally develop recurrent pulmonary infections for which no source is evident. The characteristic history of choking or gagging when swallowing that accompanies esophageal atresia with TEF may not be present.

Management

Contrast esophagram may identify the lesion. Most of these fistulae are small in diameter (much less than 1 cm), and short (also less than 1 cm), making radiographic identification difficult. Even when contrast appears in the tracheobronchial tree, it may be difficult to know whether primary aspiration of orally administered contrast is responsible. Placing a feeding tube in the esophagus and injecting contrast while pulling the tube from the lower esophagus up under fluoroscopic observation may be helpful. High-resolution CT scanning may identify the anatomy. Bronchoscopy and esophagoscopy may be both diagnostic and may aid the repair if a small catheter can be passed across the fistula to aid its identification by enabling palpation at operation. Most such fistulae are cervical, and can be repaired without a thoracotomy.

Gastroesophageal Reflux

Introduction/Pathophysiology

The mucosal lining of the trachea and bronchial tree tolerates periodic soilage relatively well; even witnessed aspiration of gastric contents does not reliably produce infection or pneumonia. Ongoing irritation by gastric acid, bile, or contaminated secretions will eventually overcome the mucociliary elevator that transports contaminants to the pharynx, and the other barriers to infection of the tracheobronchial mucosa, and bronchitis or pneumonia will result. Common

causes of repetitive soilage of the tracheobronchial tree include primary aspiration of oropharyngeal secretions, often in children with impaired swallowing mechanisms, and gastroesophageal reflux (GER). GER is universal in babies, and is usually outgrown. Particularly in the neurologically impaired patient, however, GER may require medical or surgical treatment.

Clinical Presentation

GER presents with symptoms of spitting up or vomiting after eating. Aspiration may lead to presentation with recurrent pneumonia. Complications that follow prolonged GER include failure to thrive because of inadequate nutrition, esophagitis, esophageal ulceration and esophageal stricture (Fig. 119.3). Some patients present with an acute life-threatening event (ALTE) in which laryngospasm or bronchospasm precipitated by aspiration of gastric contents produces profound hypoxia and even respiratory or cardiac arrest.

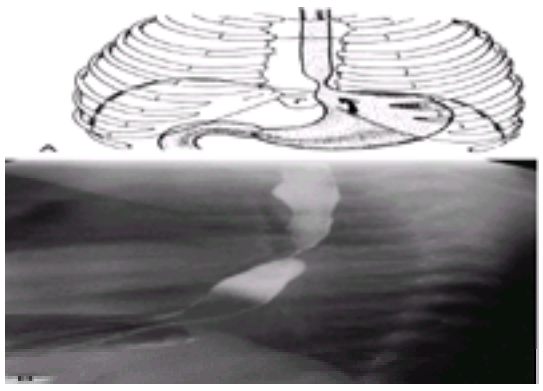

FIGURE 119.3. A. Distal esophageal stricture caused by prolonged reflux esophagitis. Note the loss of the normal angle between the esophagus and the stomach and propensity for gastric contents to reflux into the esophagus. **B.** Esophageal stricture. Lateral barium esophagram shows narrowing of midesophagus in an infant with gastroesophageal reflux.

Management

Management of GER begins with establishing the diagnosis. If this is evident clinically, and the child responds to medical management, no further evaluation may be needed. Recalcitrant GER may be an indication for an upper gastrointestinal contrast study (UGI series) to establish that there is no anatomic obstruction to gastric emptying such as a duodenal web or annular pancreas. Recording the esophageal pH over a 24-hour period with a pH probe may help quantify the severity of the problem.

GER is managed by a three-tiered approach. Initially, elevating the head of the bed, thickening the feeds, and decreasing the volume of individual feeds are useful to allow gravity and mechanical effects to help. Medical management (second tier) of this problem includes efforts to decrease gastric acidity, including antacids, H_2-receptor antagonists such as ranitidine, and proton-pump inhibiting drugs. Many clinicians add prokinetic medications to improve the gastric motility such as metoclopramide or cisapride. Recently, concerns regarding the association between cisapride and ventricular tachycardia have led to a decrease in the utilization of this medication. Surgical indications, the third tier, are failure of nonoperative management or occurrence of a complication that cannot be tolerated, such as esophageal stricture or repeated ALTEs without other evident cause. Presently, the favored operative treatment in North America is fundoplication: wrapping the fundus of the stomach either partially (a Thal operation if anterior to the esophagus, or Toupet operation if posterior) or completely (the Nissen operation) around the esophagus just above the gastroesophageal junction. The procedure may be performed laparoscopically in appropriate patients.

Esophageal Web

Introduction/Pathophysiology/Management

Rarely, a patient presents with GER that is caused by an esophageal web (Fig. 119.4). The membranous, congenital narrowing of unclear origin is usually able to transmit liquids, and symptoms often arise when the child begins to eat solid food. Recurrent aspiration pneumonia may also develop. An esophagram is usually diagnostic. Often, a thin membranous web may be split by a hydraulic balloon placed endoscopically across the stenosis. If this approach is unsuccessful because the lumen is too small to transmit the dilator or the tissue is unyielding, segmental esophageal resection may be necessary via thoracotomy.

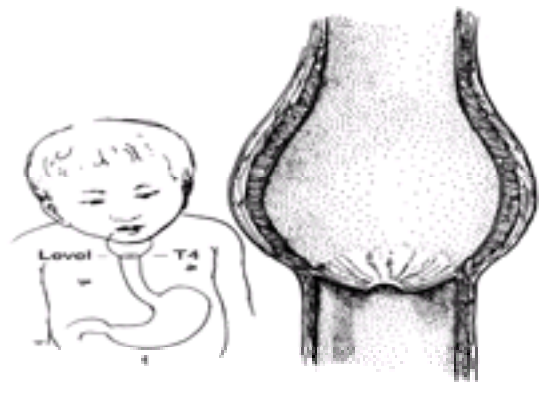

FIGURE 119.4. A child with chronic partial obstruction of the esophagus caused by a congenital web. Similar bulbous enlargement of the proximal esophagus can occur with any type of stricture and result in pressure on the trachea and recurrent regurgitation with aspiration.

CIRCULATORY IMPAIRMENT

Circulatory collapse, or shock, is often classified as hypovolemic, cardiogenic, neurogenic, or septic. Hypovolemic shock results from massive loss of blood or fluid. Cardiogenic shock follows impairment of the pump function of the heart. Neurogenic shock follows spinal cord transection or spinal anesthesia and results from loss of vascular tone with attendant pooling of blood in the lower body, reducing cardiac preload. Similarly, septic shock is, in large part, caused by decreased peripheral resistance. Trauma-producing shock is reviewed in Chapter 3, Chapter 103, and Chapter 107. Thoracic causes for each of these categories may be enumerated, but the important task for the emergency physician is to classify the cause of the patients problem in a way that will direct management.

Cardiogenic shock results from decreased cardiac preload, failure of the heart as a pump, increased afterload, or loss of heart rate. Preload may be reduced by tension pneumothorax causing kinking of the great veins bringing blood to the heart in the child's mobile mediastinum; by massive intra-abdominal hemorrhage compressing the inferior vena cava; by cardiac tumor obstructing one of the atria; or by tamponade of the heart from mediastinal pressure caused by blood, pericardial fluid, or air. Hypertension resulting from coarctation of the aorta, pheochromocytoma, or other causes, may increase afterload so greatly that cardiac output is impaired. Failure of the heart as a pump occurs in viral myocarditis, or after infarction. Drug ingestions and hypoxia may slow the heart sufficiently to decrease cardiac output.

The causes, presentation, and management of cardiogenic shock are reviewed in detail in Chapter 3.

Clinical Findings

Findings are dependent on the type of shock and the primary lesion. Whether caused by tension pneumothorax, intracardiac tumor, or tamponade, hypovolemic (or decreased preload) shock is accompanied by tachycardia. Usually blood pressure is maintained until perhaps 20% of the blood volume is lost to hemorrhage; predicting the onset of hypotension with tension pneumothorax or compressive phenomena is difficult. Characteristically, the extremities are cold and poorly perfused as peripheral vasoconstriction compensates for loss of central venous pressure. Tamponade is accompanied by muffled heart tones, often difficult to recognize in a noisy ED, especially in the setting of trauma. Distended neck veins are often present. Once tamponade has reached a critical compression pressure, it often does not respond to intravenous (IV) fluid. Pulsus paradoxus may not accompany acute tamponade.

Clinical findings suggestive of cardiogenic shock are discussed in Chapter 3. Septic and neurogenic shock are “warm shock” in which the extremities are well-perfused because of loss of vascular tone; tachycardia commonly accompanies them. Fever in septic shock, and flaccid extremities with loss of bladder control and rectal tone in neurogenic shock may aid diagnosis.

Management

IV support with two large-gauge peripheral catheters, electrocardiogram monitoring, pulse oximetry, and oxygen supplementation are indicated for any type of circulatory collapse. Stable patients should undergo a chest radiograph immediately. Afterward, management is directed to relieving the condition that produced shock.

If acute cardiac tamponade is suspected, emergency pericardiocentesis is indicated immediately (see Section VII, Procedures). If the patient is not improved by pericardiocentesis, the pericardium may be filled with clotted blood that will not drain through the inserted needle. In this circumstance, pericardial drainage will require a larger opening in the pericardium. In a patient with shock and incipient cardiac arrest, a vertical subxiphoid incision should be made in the ED. After opening the linea alba, the pericardium can be opened widely enough to digitally clear hematoma from the pericardium.

PLEURAL DISEASE

The lung is covered by the densely adherent visceral pleura, which moves smoothly over the parietal pleura of the chest wall because of a thin film of pleural fluid, allowing lubricated motion of the chest during respiration, and contributing to the full expansion of the lung mechanically. When air, excess fluid, or pus comes between the two layers of the pleura, the lung tends to collapse, and consideration needs to be given to removing the interloper.

Pneumothorax

Air can collect in the pleural space acutely or chronically, statically or progressively. Because atmospheric pressure is always greater than intrapleural pressure, any mechanism that allows even momentary communication between the atmosphere outside the chest wall or the atmosphere within the tracheobronchial tree, can result in a rapid shift of air into the pleural space. Penetrating wounds of the chest are the most common cause for pneumothorax. The penetrating object (a knife, a bullet, or a doctor's needle) may cause injuries of both the parietal pleura and often the lung parenchyma. Therefore, many patients with penetrating trauma to the chest will have not only an initial pneumothorax but also an expanding pneumothorax, as more and more air leaks from the surface of the lung.

Nonpenetrating trauma to the thorax can also result in a pneumothorax. For example, a fracture of one or more ribs may result in puncture of the visceral pleura and lung, causing an escape of air from the lung into the pleural space. If the intrapleural pressure increases, air may leak out through the hole in the parietal pleura and into the chest wall tissues, resulting in subcutaneous emphysema. Another form of nonpenetrating trauma is barotrauma, which can occur in infants and children who have been ventilated with high inflating pressures via a tight-fitting endotracheal tube. A particularly hazardous form of pneumothorax occurs when severe blunt trauma to the chest results in partial or complete tear of a bronchus or the trachea. Usually, patients with more peripheral bronchial tears will immediately develop symptoms of a pneumothorax. If the tear is more central, the patient may first develop mediastinal and even cervical emphysema before a secondary rupture occurs into the pleural cavity.

Seemingly spontaneous episodes of pneumothorax may occur in children or adolescents. For example, a patient with one or more emphysematous blebs on the surface of the lung may develop spontaneous rupture, resulting in an acute pneumothorax often associated with nearly complete collapse of the involved lung (Fig. 119.5). In patients with cystic fibrosis, spontaneous pneumothorax is the second most common pulmonary complication of this condition. It usually occurs in teenage or young adult patients with far-advanced, diffuse bilateral cystic fibrosis. Another group of children with a high incidence of spontaneous pneumothorax are those with pulmonary metastases, for example, those with osteogenic sarcoma. Many of the metastases occur just below the pleural surface of the lung and, thus, may be the foci for the pneumothorax. Children with staphylococcal pneumonia are especially prone to develop unilateral or bilateral pneumothorax.

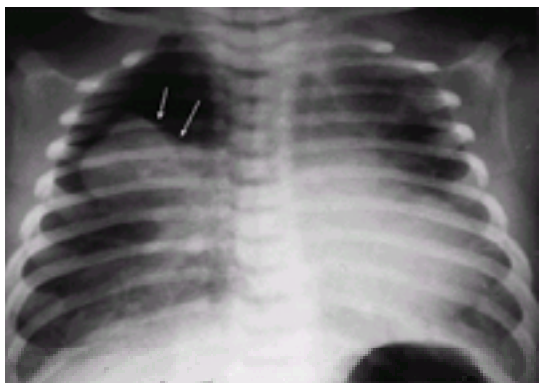

FIGURE 119.5. Radiograph revealing obvious pneumothorax. Note the collapsed right upper lobe segment borders *(arrows).*

If the site through which air enters the pleural cavity seals quickly, and no fluid or blood collects in the pleural space, a small or moderate pneumothorax will resolve spontaneously. However, some patients may have what appears to be a chronic or static pneumothorax. This usually occurs when there is a slow, persistent leak of air from the surface of the lung. A patient with osteogenic sarcoma metastases to the lung, for example, might continue to have a small, but clinically significant, separation of the lung from the parietal pleura.

Two special forms of pneumothorax require emphasis because these conditions may result in the death of the patient if not recognized early and attended to rapidly. The first is a tension pneumothorax, which results not only in total collapse of the lung but also in progressive tension across the mediastinum (Fig. 119.6). The development of a progressive tension pneumothorax is a result of air accumulating in the hemithorax with each inspiration. Whether the site of entry of the air into the pleural space is through the chest wall, a torn bronchus, or an injured portion of lung, the physiologic result is a one-way valve effect, whereby air continues to accumulate in the pleural cavity with inspiration but cannot be extruded on expiration. This phenomenon continues until the intrathoracic pressure on the involved side is so high that no further air can enter the pleural space. This is often the point at which venous return from below the diaphragm is impeded and circulatory failure ensues.

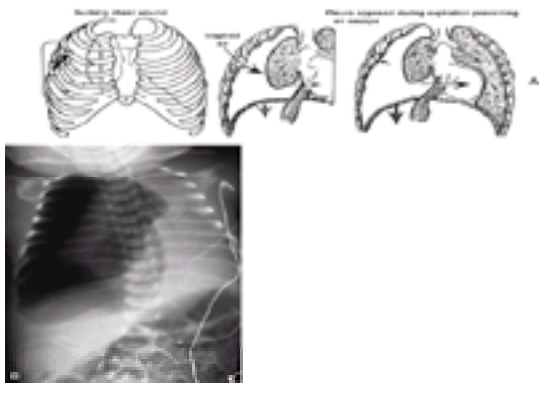

FIGURE 119.6. A. The development of a progressive tension pneumothorax as a result of air accumulating in the hemithorax with each inspiration. **B.** Severe pneumothorax causing marked hyperaeration of the right lung field and shift of the mediastinum to the left side.

The second life-threatening form of abnormal collection of air in the thorax is massive pneumomediastinum with or

without an associated pneumothorax. In extreme cases, the tension produced in the mediastinum can be great enough to impair both circulation and ventilation. This phenomenon is particularly likely to occur in a patient who is receiving positive-pressure ventilation, which enhances escape of air from the bronchial tree into the mediastinum. See Chapter 107 for trauma-related causes such as rupture of a major bronchus or the trachea.

Clinical Findings

The symptoms and signs of pneumothorax depend on the size of the pneumothorax and how rapidly it occurred. A patient with spontaneous rupture of an emphysematous bleb may complain of sudden acute pain on the involved side of the chest followed by tachypnea, pain at the tip of the ipsilateral shoulder, and a sense of shortness of breath. Such patients usually have a small to moderate pneumothorax (less than 20% of the lung volume).

In general, a patient with a pneumothorax has signs and symptoms of ventilatory impairment: dyspnea, tachypnea, pain, splinting on the involved side, agitation, increased pulse rate, diminished breath sounds, and increased resonance on the involved side, and possibly, displacement of the trachea and heart away from the involved side. See Chapter 107 for evaluation of traumatic pneumothorax.

Management

The essential components of management involve confirmation that a pneumothorax exists and reexpansion of the lung. If the patient's condition is not severe, an immediate upright PA and a lateral chest radiograph should be taken. These radiographs are important to determine not only the site and extent of the pneumothorax but also any complicating features such as tumor; fluid within the pleural space; or abnormalities of the lungs, diaphragm, or mediastinum.

Once a pneumothorax is diagnosed on radiograph, the urgency for treatment of the pneumothorax depends on the patient's signs and symptoms, clinical circumstances, and the extent of the pneumothorax. If the pneumothorax is greater than 20% of the lung volume or if the patient is symptomatic, a controlled, sterile chest tube insertion should be considered (see Section VII, Procedures). In the ED, the percutaneous, guidewire “pigtail” catheters (sometimes called “Fuhrman tubes”) are ideal for pneumothorax not associated with blood in the chest or empyema. In the case of a patient who requires surgery but who has only a small pneumothorax, a chest tube should be inserted because of the risk that the pneumothorax will expand under anesthesia and therefore complicate the course of surgery.

If the child's condition is so severe that there is not time for a chest film and if a pneumothorax is suspected, immediate therapy includes 1) tamponading and obliterating any sucking or open chest wound, and 2) inserting an angiocath, percutaneous central line, or pigtail catheter into the pleural space and evacuating air. Placement of whichever tube is used is usually best done in the midaxillary line over the top of a rib about level with the nipple. Once the plastic cannula enters the pleural space, it can be advanced further inside and then attached to sterile IV tubing and placed to underwater seal. Alternatively, a stopcock can be attached to the same setup and an attempt made to aspirate enough air and/or fluid to improve the patient's pulmonary dynamics. In a patient with a tension pneumothorax, the insertion of the needle and catheter will immediately result in release of the tension on the mediastinum and diaphragm.

Many infants can be effectively managed in this way if the amount of air present in the pleural space is small. However, these temporary catheter devices are small gauge and thus tend easily to develop fibrin plugs. Therefore, in any infant or older child who requires a tube within the pleura for more than 1 hour, it is best to proceed with a standard or pigtail chest tube insertion. Patients with pneumothorax should be admitted to a hospital, even if no chest tube is thought necessary, so that the stability of the air collection can be monitored in a setting where tension pneumothorax may be rapidly treated should it develop.

Pleural Effusion

Pleural fluid in excess amount is not a disease per se, but it indicates the presence of pulmonary or systemic illness. The classification of the fluid into *transudate,* which accumulates when the normal pressure relationships between the capillary pressure in the lung, the pleural pressure, and the lymphatic drainage pressure are disturbed, or *exudate,* an inflammatory collection, has less utility today than in previous years because of other diagnostic tools presently available. Nevertheless, an awareness that an increased pulmonary capillary pressure (as in congestive heart failure), a decreased colloid osmotic pressure (as in renal disease), increased intrapleural negative pressure (as in atelectasis), or impaired lymphatic drainage of the pleural space (e.g., from surgical trauma to the thoracic duct) may result in transudative effusion is important. In children, the inflammatory cause of effusion is often evident as a pneumonia. The accumulation of blood in the pleural space because of trauma is discussed in Chapter 107. Hemothorax may result from non-traumatic conditions as well. Necrotizing pulmonary infections; tuberculosis; pulmonary arteriovenous malformation; torn pleural adhesions with spontaneous pneumothorax, hemophilia, thrombocytopenia, systemic anticoagulation; and pleural tumors all have been reported to cause hemothorax. Chylothorax, or the accumulation of lymphatic fluid in the pleural space, has become more common as thoracic, especially complex cardiac, surgical operations, have become more common in children.

Clinical Findings

Pleuritic chest pain is a sharp, intense pain on deep inspiration that is often not present on quiet breathing. Small, sterile collections, as well as large, chronic collections, tend to be asymptomatic. Acute collections produce symptoms by compressive effects on the lung, with resultant atelectasis and right-to-left shunting, which produces oxygenation and ventilation compromise. Respiratory distress may follow, with attendant dyspnea, tachypnea, increased use of accessory muscles of respiration, and even cyanosis. Except for huge effusions, the examination, using auscultation and percussion to define the amount of fluid, is not nearly as useful as a chest radiograph. Almost all effusions are detected on this basis. Bilateral decubitus chest radiographs help define the presence of pleural fluid in patients in whom it is difficult to see because of adjacent parenchymal disease. This examination also demonstrates whether the fluid is free to move

about in the chest.

Management

If the presence of a significant effusion is evident by examination and radiograph, no further radiographic studies may be needed. A CT scan, or in some institutions, an ultrasound examination of the chest helps determine whether opacity seen on a chest radiograph is parenchymal disease or pleural fluid. All patients should have a CBC and differential and blood culture. Analysis of the fluid itself is the most useful diagnostic test. The technique for thoracentesis is given in Section VII.

Aspirated fluid should be sent for cell count, differential, Gram stain, acid-fast bacillus (AFB) stain, total protein, lactate dehydrogenase (LDH), protein, specific gravity, and a complete set of cultures (aerobic, anaerobic, AFB, and fungal). The normal protein concentration is 1.5 gm/dL. Classically, an exudate was said to have a total protein of more than 3.0 gm/dL and a specific gravity of more than 1.016. An accuracy rate of more than 99% in classification is obtained by noting that fluid is an exudate if any one of the following criteria are present: 1) Pleural fluid protein divided by serum protein is greater than 0.5; 2) pleural fluid LDH divided by serum LDH is greater than 0.6; or pleural fluid LDH greater than two-thirds of the upper limit of normal for serum LDH. The studies ordered should clearly be tailored to the clinical setting: in patients with hemothorax with an evident cause, little is to be learned by studies of the pleural fluid. Suspected chylothorax may be identified by measurement of triglycerides and cholesterol; a fat stain such as Sudan black or oil red “O” may be done on the fluid. Empyema can appear similar to chylothorax. Centrifuging the specimen can differentiate the two because in empyema the supernatant is clear.

Draining the pleural fluid must then be considered. Thin fluid may sometimes be managed by intermittent thoracentesis. If the underlying medical problem can be managed, the effusion may take care of itself. If not, a small-diameter tube, such as an 8-Fr pigtail percutaneous tube, may suffice. Thick fluid, such as blood, pus, and sometimes chyle, requires a large-diameter chest tube to drain it. Either tube must be attached to a pleural drainage system. When the drainage decreases significantly, to approximately 1 mL per pound of body weight per day, the drain may be removed. The drain should not be removed in the presence of an accompanying “air leak” caused by a bronchopleural connection.

Empyema

Empyema or pus within the pleural cavity is a particularly serious and, at times, life-threatening situation. The predominant organism is *Streptococcus pneumoniae* with *Staphylococcus aureus* and group A streptococcus also meriting consideration. Empyema is usually the result of septicemia or direct or lymphatic extension from an associated pulmonary infection. When empyema follows accidental trauma or surgery, other bacterial organisms may be involved.

Clinical Findings

Empyema is most common in children 2 to 9 years of age. Presentation with a pneumonia that does not respond to antibiotic treatment for many days should lead to consideration of decubitus chest radiographs or CT scan for diagnosis. High fever is common, as are the symptoms of pneumonia: cough, pleuritic chest pain, and lassitude.

Management

Empyema in healthy children may respond to prolonged (3 to 4 weeks) IV antibiotic therapy and chest tube drainage. Recovery may be hastened to less than a week in most cases by thoracoscopic debridement of the pleural space of the infected fibrinous peel that encases the lung and prevents its full expansion in many cases. Under a general anesthetic, a fiberoptic high-resolution camera placed within the pleural space via a short (2-cm) incision between the ribs allows removal of the purulence and the fibrinous peel that often encases the lung, restricting its expansion. The peel may be removed under direct visualization via other thoracoscopic instruments placed through two or three small incisions. A chest tube is then placed to drain the pleural cavity through one of these incisions and is left in place for a few days. Because sedation approaching the depth of general anesthesia is needed for placement of a chest tube, many surgeons and infectious disease consultants recommend thoracoscopy as the initial approach to a child with empyema. Seldom is open thoracotomy now necessary to resolve empyema.

Solid Pleural Lesions

Solid lesions in the pleural space occur uncommonly in children. A localized pleural-based mass should suggest neoplasm, which may be primary or metastatic. Diffuse collections usually are the sequelae of bleeding into the pleural space in the distant past or of empyema. They may encase the lung and produce restrictive lung disease.

Clinical Presentation/Management

It is impossible to generalize on the mode of presentation of such rare processes. Focal lesions may be expected to be found in investigation of symptoms caused by local compression or erosion; because of the large functional pulmonary reserve of children, restrictive lung disease caused by a diffuse process is distinctly uncommon. A full radiographic evaluation, including CT scan, should be obtained; admission to the hospital should be strongly considered, and appropriate consultation sought. Focal lesions should be considered malignant until proven otherwise, so operation for biopsy or excision will likely be required.

LUNG LESIONS

The lung is often affected in childhood illness. Asthma, pneumonia, and other conditions that do not require surgical management are addressed elsewhere in this text. Mass lesions and cystic lesions of the lung include congenital cystic

adenomatoid malformation (CCAM), congenital lobar emphysema, bronchogenic cyst, congenital pulmonary arteriovenous fistula, and bronchopulmonary foregut malformations. Acquired conditions of the lung that require surgical management are distinctly uncommon because of the control of tuberculosis in North America. Bronchiectasis—the chronic dilation of the bronchi resulting from the chronic infection of the lung in cystic fibrosis, tuberculosis, or other chronic pneumonic infection—may require pulmonary resection.

Bronchogenic Cyst

Bronchogenic cysts are thought to result from aberrant budding from the primitive foregut or tracheobronchial tree. They may occur along the trachea, along the bronchi, in the lung substance, or adjacent to the esophagus (Fig. 119.7).

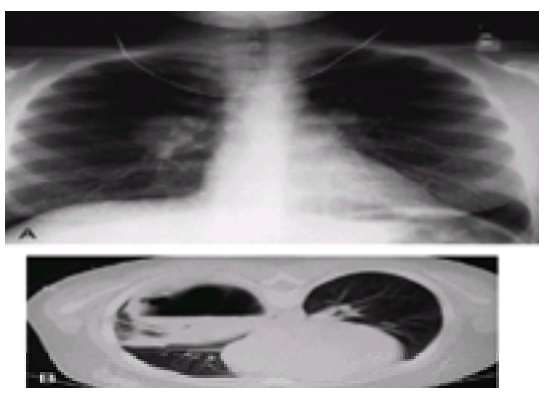

FIGURE 119.7. A. Plain film of patient with bronchogenic cyst arising off the right mainstem bronchus. **B.** Computed tomography scan of similar lesion reveals large fluid-filled cyst compressing adjacent lung tissue.

Clinical Presentation

Centrally located cysts may present with symptoms caused by compression of an airway. Wheezing, cough, fever, and recurrent pneumonia may result in such children. In contrast, patients with peripherally located cysts develop respiratory symptoms only 50% of the time. Physical examination is often unrewarding.

Management

Detection of bronchogenic cysts almost always occurs radiographically. Chest radiograph often suggests the process, but CT scan is usually indicated to clarify the anatomy. Plain-film findings include a homogeneous, water-density mass without sharply-defined borders. CT scanning usually shows a water-density mass as seen by Hounsfield or other density units. Cysts with turbid, mucoid fluid may appear solid on CT scan.

Treatment of bronchogenic cysts is by surgical resection. Active infection should be brought under control. Thoracoscopy may be used for some lesions, depending on the location of the mass. Asymptomatic cysts should be removed to establish the diagnosis and to prevent the complications of secondary bronchial communication, bleeding, or perforation into the pleural cavity. Carcinoma and fibrosarcomas have been reported to arise in benign-appearing bronchogenic cysts.

Congenital Cystic Disease of the Lung (Congenital Cystic Adenomatoid Malformation and Sequestration)

Grouping the several pathologic entities included in congenital cystic disease of the lung makes particular sense for the emergency physician. From a single giant unilocular cyst, to a mixed lesion composed of multiple cysts and solid tissue, or a lesion composed predominantly of solid tissue with only an occasional small cyst, these lesions are all congenital processes that present with pulmonary infection, an abnormal chest radiograph, or possibly, a mass or tension effect. Cystic adenomatoid malformations are the result of an excessive overgrowth of bronchioles (Fig. 119.8) and an increase in terminal respiratory structures and mucous cells lining the cyst walls. Pulmonary sequestrations arise from an accessory bronchopulmonary bud of the foregut. Histologically they are portions of pulmonary tissue; however, they are not connected with bronchi or vessels to the rest of the lung (and hence the pulmonary tissue is “sequestered”). Usually, there is a systemic rather than pulmonary blood supply. Sequestration can be intralobar (like cystic adenomatoid malformation) or extralobar.

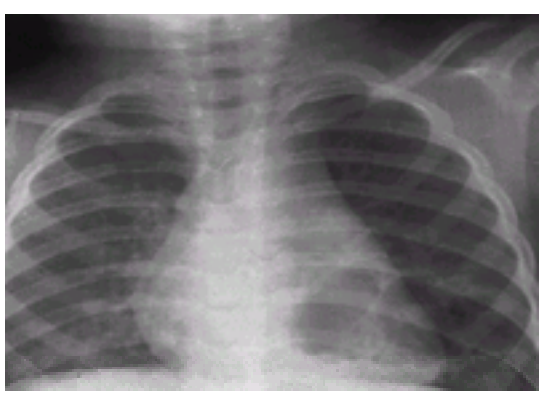

FIGURE 119.8. Cystic adenomatoid malformation in a 12-month-old girl with recurrent episodes of apparent left lower

lobe pneumonia.

Clinical Findings

Recurrent respiratory infections often lead to the chest radiograph, which confirms the condition. Clinical findings may be identical to those of a lobar pneumonia. Occasionally, a lesion is discovered after failure of resolution of an empyema by chest tube placement.

Management

Chest radiographs in the PA, lateral, and bilateral decubitus positions should be obtained to evaluate any areas with air-fluid levels. Any pathogens identified in the sputum should be treated with appropriate antibiotics (see Chapter 84). After control of superimposed infection, the lesion should be resected to prevent recurrent infection. Attempted aspiration of the cystic lesions or placement of a chest tube is to be avoided because it may lead to spread of infection into the pleural space. When the lower lobe seems to be involved, a CT scan with IV contrast should be obtained to identify any possible systemic blood supply. Because the blood supply may arise from below the diaphragm, the scan should include both the chest and abdomen. Arteriography is seldom necessary with currently available imaging techniques. The CT scan will likely exclude other conditions that may be misdiagnosed, such as a diaphragmatic hernia, postpneumonic pneumatoceles, or esophageal duplication.

Congenital Lobar Emphysema

Congenital lobar emphysema, also known as infantile lobar emphysema or congenital segmental bronchomalacia, is caused by overexpansion of the air spaces of a segment or lobe of the lung (see Fig. 119.9). There is no significant parenchymal destruction. This entity accounts for about half of all congenital lung malformations. Bronchial obstruction caused by a variety of entities produces the condition.

FIGURE 119.9. Congenital lobar emphysema of the left upper lobe in a 3-month-old girl who presented with decreased breath sounds and rales in this area. Note the secondary compression atelectasis of the left lower lobe.

Clinical Findings

Infants with congenital lobar emphysema are often normal in appearance at birth, but develop tachypnea, cough, wheezing, dyspnea, and/or cyanosis within a few days. The onset of symptoms may be more gradual; nevertheless, 80% of patients are symptomatic by 6 months of age. The upper lobes are involved in about two-thirds of patients, and in less than 1% are the lower lobes involved. Chest radiographs show striking radiolucency in the involved lobe with mediastinal shift to the opposite side. The diaphragm is usually flattened on the affected side. It can be difficult to tell whether pulmonary markings are present at all in the involved lobe, and pneumothorax may be suspected. The compressed normal lung may be erroneously thought to be atelectatic with the emphysematous lobe compensatory.

Management

Treatment should be given to patients with life-threatening pulmonary insufficiency from compression of normal pulmonary tissue. If a bronchial obstruction such as a mucous plug or foreign body can be relieved, no further treatment may be necessary. Pulmonary lobectomy may be needed acutely if symptoms are progressive. The diseased lobe is evident at thoracotomy because of its overdistended state, which often pushes this part of the lung out of the chest. Lobectomy is curative if the cause of the obstruction is also relieved.

Congenital Pulmonary Arteriovenous Fistula

Congenital pulmonary arteriovenous (AV) fistula, a congenitally occurring communication between a major pulmonary artery and a vein within the lung, is usually an aneurysmal sac. Fistulae vary in size from a few millimeters to several centimeters, and can be multiple. At times, a systemic artery may also be involved. Direct right-to-left shunting leads to hypoxemia, and the size of the fistula correlates with the degree of desaturation.

Clinical Findings

As the initial presentation of this disorder is frequently that of wheezing and desaturation, the child may be misdiagnosed as having asthma. Clubbing and cyanosis may suggest chronic hypoxemia. Examination of the chest may demonstrate a palpable thrill or murmurs. If there are symptoms of hemoptysis and epistaxis, one may find telangiectasias or hemangiomas of the skin and mucous membranes. Evaluation of the family may also reveal the presence of hereditary hemorrhagic telangiectasis (Rendu-Osler-Weber disease), which is present in more than half the patients with congenital pulmonary AV fistula.

Management

Children who are symptomatic from this condition should be evaluated by means of CT scan, contrast echocardiography, perfusion scintigraphy, and arteriograms of the pulmonary artery and aorta. Chest films may demonstrate the aneurysmal areas as rounded or lobulated discrete lesions in the parenchyma. Often, tortuous vessels trace from these rounded areas to the hilum. Resection of the fistula, often involving lobectomy, is indicated if the lesion is localized. Unfortunately, some patients have such diffuse disease that this is impossible.

Rare Lesions

There are a variety of rare lesions of the lungs, including rare tumors and uncommon infections. Rare tumors, often identified on radiographs obtained for nonspecific symptoms, include primary sarcoma, pulmonary blastoma, hamartomas, and teratomas. Fungal infections, including actinomycosis, histoplasmosis, mucormycosis, and coccidioidomycosis, may look like tumors on chest radiograph. Atresia of the bronchus or pulmonary artery rarely occurs and produces differences in the lucency of the two lungs. The reader is referred to texts of pulmonary medicine or thoracic surgery for further discussion.

MEDIASTINAL TUMORS

Mediastinal Mass

At least one-third of all mediastinal masses occur in children younger than 15 years of age. Half of these masses are symptomatic, and 50% of the symptomatic masses are malignant tumors. More than 90% of the asymptomatic masses are benign. More than 95% of biopsied mediastinal masses in children are secondary to cysts or tumors. The mediastinum is commonly divided into anterior, superior, middle, and posterior compartments (Fig. 119.10). If only the anterior and middle mediastinal compartments of children are included, between 40 and 90% of the masses are malignant or cystic in origin. Neurogenic tumors are the most common cause of mediastinal masses, with lymphomas and germ cell tumors being second and third in frequency. Infection is an uncommon cause of mediastinal node enlargement, but, when present, is largely caused by histoplasmosis. Thymic enlargement may mimic an anterior mediastinal mass.

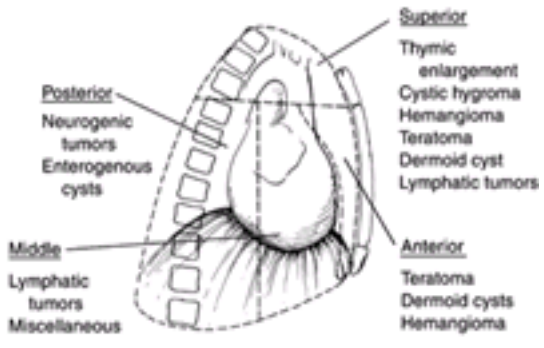

FIGURE 119.10. Mediastinal tumors in children. Differential diagnosis is based on anatomic location within the mediastinum.

Clinical Presentation

Mediastinal masses usually present with respiratory symptoms secondary to airway obstruction or erosion. As a result, patients may present with cough, wheezing, recurrent respiratory infections, bronchitis, atelectasis, hemoptysis, chest pain, or sudden death. Dysphagia and hematemesis may occur with compression of the esophagus. Superior vena cava syndrome is a rare complication, usually in association with a rapidly growing tumor. If the recurrent laryngeal nerve is compressed as a result of the mass, hoarseness and inspiratory stridor may result. Spinal cord compression syndrome and vertebral erosion can be seen with a posterior mediastinal tumor.

Management

Children with tumors of the anterior or superior mediastinum should be admitted to a hospital to undergo urgent evaluation. CT scan of the chest is almost always needed to supplement plain radiographs.

When biopsy of a large mediastinal mass is necessary, the logistics of biopsy require careful, thoughtful evaluation, ideally involving the pediatrician, surgeon, and anesthesiologist. Airway compression by large mediastinal masses is

often significant. If a general anesthetic is administered, the thoracic trachea may be occluded by tumor because the anesthetic eliminates the negative intrathoracic pressure caused by expansion of the chest wall. This situation can be difficult to manage; passage of a rigid bronchoscope may be necessary to stent the trachea open to allow gas exchange. Large mediastinal masses should be evaluated by CT scans to assess the likelihood of tracheal compression. MRI may be a better diagnostic tool for posterior mediastinal masses, because many of them are neurogenic in origin and extradural with extension into the spinal canal. Consideration should be given to the feasibility of biopsy under local anesthesia. The anesthesiologist should be apprised of the nature of the tumor, and a bronchoscope should be at hand if a general anesthetic is needed. Tissue may be obtained in a number of ways: 1) with a mediastinoscope, inserted via an incision above the sternal notch and passed behind the sternum; 2) a video-assisted thoracic surgery (thoracoscopy); or 3) a thoracotomy, usually a limited thoracotomy, often through an anterior interspace. In some cases, mediastinal masses can be accurately diagnosed by biopsy of supraclavicular or other extrathoracic adenopathy.

DIAPHRAGMATIC PROBLEMS

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) is the presence of intestinal viscera in the chest through an opening in the diaphragm not caused by trauma. About 90% occur on the left. They occur through the foramen of Bochdalek, which is at the back of the thoracic cavity. Herniation may occur through the foramen of Morgagni, which lies just posterior to the sternum and is even more rare than Bochdalek's hernia, comprising 2 or 3% of all diaphragmatic hernias. Traumatic diaphragmatic rupture may occur through any portion of the diaphragm and may present in a delayed time frame.

Pathophysiology

Most babies with congenital diaphragmatic hernia become symptomatic as newborns, when profound respiratory compromise leads to diagnosis. Until recent years, it was thought that the respiratory difficulties of babies with CDH were caused by mechanical compression of the lung by the intestinal viscera extruded through the diaphragmatic opening into the chest. It has become clear that this is not the case: pulmonary hypertension; surfactant deficiency; and a vicious cycle of hypoxia, acidosis, and intrapulmonary shunting lead to the death of about half of newborns with this diagnosis. CDH may be also identified after the neonatal period. These pathophysiologic situations are not present in older infants and children with the condition, who present with features of bowel obstruction, visceral ischemia, or pleural inflammation arising from sudden shift of abdominal viscera into the chest.

Clinical Presentation

When found in older babies and children, identification usually is by a chest radiograph obtained for nonspecific symptoms such as fever, cough, chest or abdominal pain, or vomiting. The presence of loops of intestine on the chest radiograph may be confirmed by passing a nasogastric tube, which will often end up with its tip in the thorax. The chest radiograph may suggest pneumonia with pneumatocele formation; in fact these “pneumatoceles” may be loops of bowel (Fig. 119.11). A gastrointestinal contrast study or chest and abdominal CT scan may clarify confusing findings. Potential intestinal or visceral ischemia caused by strangulation obstruction is one of the reasons operative repair is undertaken, and this possibility should be considered.

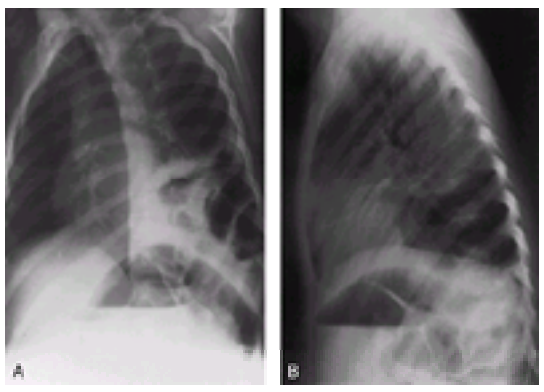

FIGURE 119.11. A 4-year-old boy admitted with 1-day history of recurrent severe upper abdominal colicky pain with dyspnea and decreased breath sounds in left base. Posteroanterior **(A)** and lateral **(B)** chest films demonstrate multiple bowel loops in the lower, posterior left chest, indicative of a foramen of Bochdalek hernia that was subsequently repaired without difficulty.

Management

Surgical repair should be undertaken soon after the diagnosis is made but may be elective in the asymptomatic patient. Because diagnosis is often made incidentally during evaluation for a condition such as pneumonia, which would increase risk of elective operation, the timing of surgery must be tailored to the individual situation. Certainly the pediatric surgeon should be consulted as soon as the diagnosis is suspected. If a patient is symptomatic from an acute ischemia of the herniated viscera, an urgent operation may be required. Usually, a subcostal abdominalincision is used, because it permits easier manipulation or resection of compromised intestine or other abdominal viscera, and allows for correction of the malrotation that usually accompanies this condition.

Foramen of Morgagni Hernias

Usually asymptomatic, an opening in the diaphragm just behind the sternum allows protrusion of abdominal viscera, usually including the colon, into the pericardium (Fig. 119.12). Described by Morgagni in 1769, this defect was also noted and repaired by Larrey, Surgeon General to Napoleon, and is sometimes called Larrey's hernia. Substernal or epigastric pain and bowel obstruction resulting from the narrow neck of the sac may occur spontaneously or be precipitated by any condition that increases intra-abdominal pressure.

FIGURE 119.12. Diaphragmatic defects in infants and children. The nature of these defects are often better appreciated on a lateral view of the chest. Eventration of the diaphragm **(A);** foramen of Morgagni hernia **(B);** and left foramen of Bochdalek hernia **(C).**

Clinical Findings/Management

A lateral chest radiograph should define the herniation as anterior, and suggest that the protrusion is not at the esophageal hiatus. A barium enema in stable patients should be considered. Surgical repair, indicated to prevent incarceration of bowel even in asymptomatic patients, may be performed through an upper abdominal incision.

Diaphragmatic Eventration

Often presenting to the emergency physician as an unexpected finding on a chest radiograph obtained for another reason, eventration of the diaphragm may be congenital or acquired. Acquired forms result from some form of phrenic nerve paralysis, which may be caused by birth, operative, or other trauma. Absent movement of the attenuated muscle produces atelectasis by decreasing the volume of the hemithorax.

Clinical Findings

Symptoms vary from mild wheezing to profound respiratory distress and are directly correlated in most cases with the size of the defect. Examination showing findings of non-aerated lung, including absent breath sounds and dullness to percussion, are investigated by chest radiograph. Chest radiographs usually confirm the presence of a high, rounded diaphragm shadow filled with bowel and other viscera involving more than 50% of the thoracic cavity on the involved side (Fig. 119.13). This study may be elucidated by observation of a diaphragm that does not move with respiration, which may be confirmed by fluoroscopy or ultrasound. Mediastinal shift may occur. Eventrations may be bilateral, but are more commonly on the left.

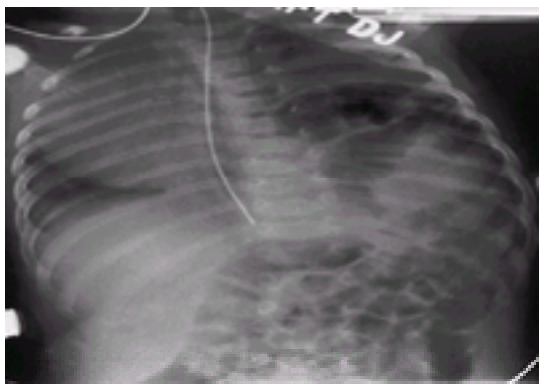

FIGURE 119.13. This 2-month-old girl was well until 4 days before admission. She developed congestion and an apparent upper respiratory tract infection. She slowly developed increasing dyspnea and was admitted in acute respiratory distress. A chest radiograph revealed a high left diaphragmatic eventration with a significant mediastinal shift to the right.

Management

Small degrees of eventrations incidentally identified and asymptomatic may be observed. Major diaphragmatic eventrations should be referred for repair, even in asymptomatic patients, to avoid collapse of the ipsilateral lung.

Acquired Diaphragmatic Malfunction

Clinical Findings

Paralysis of the diaphragm can occur as a result of injury to the phrenic nerve during birth or during a cervical or thoracic operation. In most cases, the paralysis is complete and the symptoms present shortly after the injury occurs. In the

newborn, a paralyzed diaphragm is particularly debilitating as air exchange is greatly impaired. The mediastinum is so mobile that a pressure differential allows the paralyzed diaphragm to rise paradoxically on inspiration, resulting in a shift of the mediastinum toward the normal side. Infants with only partial paralysis of the diaphragm may develop respiratory distress or pulmonary infections.

Management

As in a child with eventration of the diaphragm, an upright PA and lateral radiograph indicate the degree of diaphragmatic compromise (Fig. 119.14). Fluoroscopy may demonstrate the paralyzed portion of the diaphragm. If a trial of keeping the child in an infant seat at 60- to 75-degree elevation does not significantly improve the symptoms, resection and plication of the attenuated portion of the diaphragm should be performed. In selected cases, an implanted pacemaker can be used to stimulate the phrenic nerve and produce diaphragmatic motion.

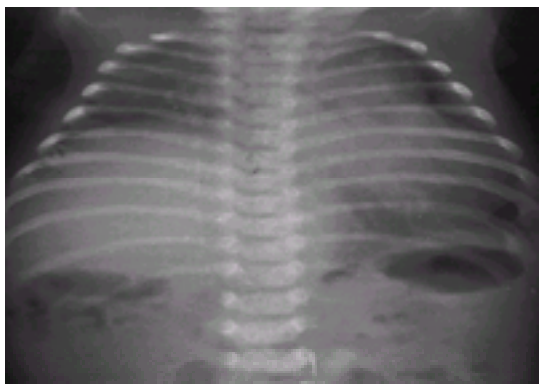

FIGURE 119.14. A 2-month-old girl with a brachial palsy at birth. She initially did surprisingly well but subsequently developed respiratory distress with cyanosis when out of oxygen. A chest radiograph showed a high attenuated right diaphragm.

Paraesophageal Hernia

Paraesophageal hernia is the protrusion of the stomach through an opening in the diaphragm that is not the diaphragmatic esophageal hiatus. It is extremely uncommon in children. When a part of the stomach migrates into the chest, it may become strangulated or kinked. Symptoms of vomiting and upper abdominal pain, tachypnea, and tachycardia may accompany the condition as the herniated stomach distends with swallowed air inside the chest.

Clinical Findings/Management

Chest radiographs show an air and fluid-filled mass in the left lower chest. A nasogastric tube may not pass into the stomach because of angulation of the gastroesophageal junction (Fig. 119.15). Surgical consultation should be sought because immediate laparotomy is likely necessary for reduction of a potentially strangulated stomach.

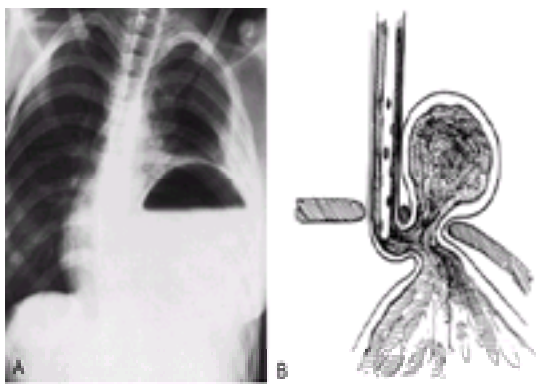

FIGURE 119.15. A. A 13-year-old girl developed first right and then left epigastric pain with retching but little or no vomitus. She had grunting respirations. A radiograph revealed a large air- and fluid-filled mass in the left lower chest. **B.** As shown in the diagram, a nasogastric tube would not pass into the stomach.

CHEST WALL TUMORS

Tumors of the chest wall occurring in childhood are likely to be malignant. Tumors at this site are uncommon in adults, and rare in children. Benign tumors, arising from the ribs in many cases, include aneurysmal bone cysts, chondromas, lipoid histiocytosis, osteochondromas, and osteoid chondromas. If the clinical and radiologic picture clearly indicates a benign, self-limited process, observation may be appropriate. However, if this is unclear and there is any concern that the lesion is not benign, even a small chest mass in a child should be considered malignant. Many malignant tumors may be present at birth and have been identified early in the first year of life.

Clinical Findings

Benign tumors of the chest wall are usually asymptomatic until trauma or fracture brings them to light. Malignancy is signaled by a rapid increase in size, pain, tenderness, or local inflammation. The site of the lesion may give a clue (Fig. 119.16). Ewing's tumor typically involves the lateral aspects of the ribs. Chondrosarcoma typically involves the costal cartilages between the sternum and the distal rib end. The sternum is a favored site for anaplastic sarcomas. These last two tumors may extend intrathoracically, as well as outside the chest cage. Chest radiographs may show pleural effusion, a mass adjacent to the pleura, or direct involvement of the lung.

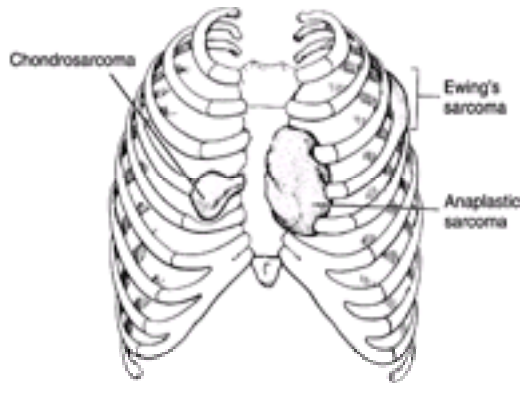

FIGURE 119.16. Malignant chest wall tumors in children. Most common lesions and their usual site of origin.

Management

Radiographic evaluation of these areas should include a CT scan of the pertinent area, bone scans of the entire body, and a metastatic bone survey. Multiple modality, coordinated treatment is usually required involving surgery, chemotherapy, and radiotherapy. If biopsy is anticipated before definitive wide resection, the route of the biopsy should be designed to avoid compromise of the subsequent chest wall reconstruction. Preoperative chemotherapy and radiotherapy may be useful to shrink particular lesions. Resection of the tumor and even subsequent recurrences have resulted in disease-free survivals of 15 years or more.

CHAPTER 120

Ophthalmic Emergencies

ALEX V. LEVIN, MD

Departments of Pediatrics, Genetics, and Ophthalmology, University of Toronto, and the Hospital for Sick Children, Toronto, Ontario, Canada

There are a number of ocular disorders in children that may be seen by the emergency physician. Although ophthalmology consultation may be necessary in some cases, many problems can be treated by the emergency physician. The goal of this chapter is to provide the emergency physician with a basic foundation for the diagnosis and treatment of some common pediatric eye emergencies.

EXAMINATION

Many children regard eye examinations and eye drops with the same fear that they harbor for injections. Therefore, it is important to gather as much information as possible before touching the patient or instilling eye drops. This can be accomplished by turning the initial parts of the eye examination into games, using toys and distracting stimuli, and exploiting the full potential of the direct ophthalmoscope, the main instrument for ophthalmic examination available to the pediatric emergency physician.

A detailed history can be an invaluable tool in focusing the examination and making a diagnosis. Questions regarding the unilaterality/bilaterality, acute/chronic onset of symptoms, and prior ophthalmic care are particularly helpful. Perhaps the child is known to have an eye with poor vision. Even if the parent does not know that this is the case, a history of having one eye patched for a visual problem suggests that the unpatched eye had amblyopia. However, if a child has previously passed his or her visual screening examination at school, this does not necessarily imply that the vision was normal because, false-negative tests are known to occur. The child may also be unaware of having poor vision in one eye because the pediatric brain is able to suppress recognition of the blurred image, allowing the child to proceed with normal activity unaware of the unilateral visual deficit (see the following).

The examiner may start the evaluation either by testing visual acuity in children who are readily verbal and interactive, or by using other techniques in children who need to be “warmed up.” In the latter case, it is often useful to start with assessment of the extraocular muscle movements. This procedure is discussed in Chapter 25. By using a toy or another interesting hand-held object, the physician can distract the child to look in the direction in which the object is placed. Both eyes should move equally, quantitatively and qualitatively, in all directions. The examiner should test gaze in all directions: up, down, left, and right.

After the eye movements have been assessed, the examiner can then use the direct ophthalmoscope as a tool to accomplish several tasks without touching the child. The direct ophthalmoscope light may be useful as a fixation target in testing eye movements. It can also be used to assess whether the eyes are aligned (Hirschberg light reflex test, see Chapter 25) and to test for a red reflex (see Chapter 111). In addition, the ophthalmoscope can be used as a simple hand-held magnifier by viewing through the ophthalmoscope and dialing the focusing wheel in the direction of the black or green numbers. This allows the eyeball to come into focus regardless of the distance between the examiner and the patient. The closer one gets, the greater the magnification.

Visual acuity testing is usually performed at a distance of 20 feet (6 meters) or 10 feet (3 meters). Most standard wall charts are calibrated to be read at 20 feet. However, if space does not permit this distance to be used, the patient can be placed 10 feet in front of the chart and the results interpreted with an adjustment for this system. For example, the line marked 20/60 on the chart (a line that a person with normal sight can see at 60 feet, but a person with that visual acuity would need to stand at 20 feet to see) becomes a 20/30 line at a distance of 10 feet.

Chart selection is important when trying to obtain an accurate visual acuity. Letter charts should be used only for patients who clearly can recognize all of the alphabet. If there is any question by parental report, a “tumbling E” or picture chart (Fig. 120.1) should be used. The patient may be asked to walk right up to the chart to identify the letters or pictures. If the patient can perform this task, the chart may be used for distance testing. Some children give remarkably unique interpretations of the pictures (e.g., calling the birthday cake a bag of French fries). When using picture charts that have colored figures, the examiner should avoid using those figures that are yellow because the bright illumination of the emergency department (ED) lessens the contrast between these figures and the white chart background, thus making recognition more difficult.

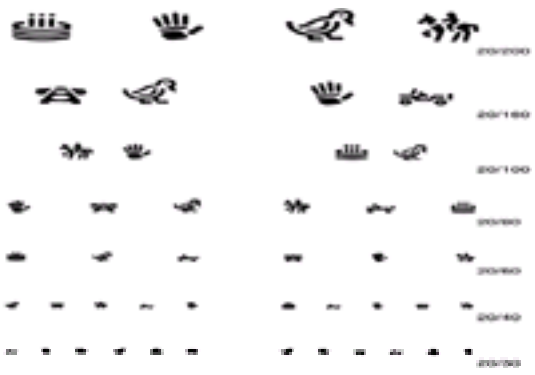

FIGURE 120.1. Picture visual acuity chart.

When using the tumbling E chart, it is important to give clear directions to the child. Otherwise, a falsely low visual acuity may be obtained. The child should be asked to point his or her fingers in the direction of the E (or call it table legs). Do not ask the child to use the words left and right because this can sometimes be confusing. The examiner may ask the child to perform this test up close to be sure that the instructions are clearly understood.

When using any visual acuity chart, it is not necessary to start with the largest symbol and have the patient read every symbol on every line thereafter. Doing so risks losing the child's attention. Rather, one can start with the 20/20 line and then go to larger lines if the child is having trouble. The child needs to recognize only a few letters on each line. Minor errors such as the substitution of the letter F for the letter P, or the letter C for the letter O, may be tolerated.

It is almost an instinct for young children to use the better eye and suppress the vision in the lesser eye. Therefore, if the good eye is covered inadequately, the patient will naturally try to read the chart with what the examiner thought was the covered eye. Children should never be allowed to cover their eye with their own hand because the small cracks between the fingers can actually allow vision out of the “covered” eye and even improve that vision by the pinhole effect (see Chapter 111). Children may also look around commercially available occluders for the same reasons. Perhaps the best way to obstruct the vision in the eye not being tested is to use a broad piece of tape, being sure that the tape also covers the depression at the bridge of the nose (Fig. 120.2). To help ensure that the patient is not “cheating,” the examiner should stand by the chart indicating the letters or pictures while simultaneously looking back at the child.

FIGURE 120.2. A broad piece of tape can be used to obstruct the vision of the eye not being tested. However, if the tape is not adherent to the bridge of the nose, the child can peek out by turning the face to the side *(right frame)*.

Any child who shows a reduced visual acuity should be offered the pinhole test as described in Chapter 111. If the patient is unable to identify any object or picture on the chart, the examiner should at least try to determine whether vision is present (see Chapter 111). After external examination and visual acuity are completed, the examiner can then proceed with other procedures as indicated, such as upper lid eversion and dilating the pupil. These techniques, along with the proper methods of examining the retina and optic nerve using the direct ophthalmoscope, are also discussed in Chapter 111.

One circumstance that may present an obstacle to proper examination of the eye is the situation in which the eyelids are swollen or the patient refuses to voluntarily open the eyelids. The techniques described in Chapter 111 for opening the traumatized eye may be useful. Commercially available speculums, when used in association with a topical anesthetic, are a painless and efficient way of opening the eyelids (see Fig. 111.5). If these are not available, either a Desmarres retractor (see Fig. 111.6) can be used or a similar device can be fashioned out of paper clips (Fig. 120.3). These types of single-blade retractors are most helpful when used on the upper eyelid (see Fig. 111.6). A retractor also can be applied simultaneously to the lower eyelids, although this often requires an extra assistant if there is a problem holding the child still while the eyelids are retracted. When paper clips are used, it is important to inspect the paper clip after bending the “blade.” Some paper clips have a coating that may become fragmented, potentially causing particles that could be dispersed on to the conjunctiva or cornea. Eyelid speculums and retractors should be sterilized between patients. Paper clip speculums are designed for single usage and may be prepared by cleansing with an alcohol swab.

FIGURE 120.3. Paper clips can be bent into a tool to open the eyelids.

In infants, the eyelids may be separated by using cotton swabs. The swabs should be placed at the midbody of the upper and lower eyelids. As they are separated, pressure should be applied against the eyelid and the swab should be rotated inward toward the eyelashes. This will keep the eyelids in place so that they do not spontaneously evert and further obstruct the examiner's view. When long cotton swabs are used, the stick should be grasped close to the patient to prevent breakage when pressure is applied. The cotton swab technique should not be used in patients being evaluated for eye trauma because pressure on the eyeball from this technique could cause further injury.

COMMON EYE EMERGENCIES

The pediatric emergency physician is called on to care for a number of eye problems. The reader is referred to other sections of this book for discussions of eye injuries (see Chapter 111), disorders of the eye muscle movement and strabismus (see Chapter 25), iritis (see Chapter 24 and Chapter 111), and unequal pupils (see Chapter 26).

Periorbital and Orbital Cellulitis

Clinical Manifestations

The primary concern when making the diagnosis of periorbital cellulitis (preseptal cellulitis) is to rule out the possibility of orbital cellulitis. The cardinal signs of orbital cellulitis include decreased eye movement, proptosis, decreased vision, and papilledema. Both orbital and periorbital infection may be associated with fever, pain, swollen eyelids, and red eye. If orbital cellulitis is suspected, computed tomography (CT) scanning of the orbit is indicated. However, the diagnosis of orbital cellulitis can be made clinically if the initial CT scan taken in the first 24 to 48 hours of infection is normal and clinical signs are present. Ophthalmology consultation is indicated in all cases of suspected or proven orbital cellulitis. Surgical intervention may be required. Otorhinolaryngology consultation should also be considered when orbital cellulitis is secondary to contiguous sinus infection.

Historical and clinical information can also be helpful in establishing the probable bacterial source of the infection. Infection secondary to a bug bite or other skin lesion that may have served as a route of entry for local bacteria is more often caused by staphylococci or streptococci. The bluish hue of the periorbital skin that is sometimes attributed to *Haemophilus-influenzae* is not a specific or sensitive indicator. In fact, since the introduction of the *H. influenzae* type b vaccine in 1985, the incidence of this pathogen as a cause for periorbital or orbital cellulitis has dropped substantially. It is now an uncommon cause.

One must rule out other conditions that can simulate a periorbital cellulitis. Insect bites and allergic reactions can cause dramatic acute periorbital swelling. However, these conditions are not usually associated with fever. Often, close inspection of the skin with magnification (using the direct ophthalmoscope) can localize the site of an insect bite. Allergic swelling is often bilateral, whereas periorbital cellulitis is rarely bilateral. Underlying sinusitis can also cause periorbital swelling. Some authors have argued that CT scan evaluation of the sinuses is indicated in all cases of presumed periorbital cellulitis. Severe conjunctivitis, especially adenoviral infection and neonatal gonorrhea conjunctivitis, can also result in significant lid swelling. The presence of conjunctival discharge is helpful in making these diagnoses. Contiguous spread of conjunctival infections to the periorbital tissues can occur and one must be careful about falsely eliminating the diagnosis of periorbital infection based on the presence of conjunctivitis.

Management

There is some controversy about the appropriate route of antibiotic administration in periorbital cellulitis. When *H. influenzae* was more common, with the risk of hematogenous spread, it seemed prudent to use intravenous (IV) antibiotics. Some clinicians are now becoming more liberal with oral antibiotic treatment now that the risk of *H. influenzae* has declined. In otherwise well children who are beyond infancy and have mild periorbital cellulitis and no systemic signs or symptoms, particularly when the cause of the cellulitis is believed to be a skin wound, intramuscular and/or oral antibiotics may be tried. The patient should be seen again (or with phone follow-up) within 24 to 48 hours, at which time improvement should be documented. If no improvement occurs, the patient should then be admitted for IV antibiotics. Periorbital cellulitis is a potentially fatal disease because complications such as meningitis may develop if inadequately treated. All cases of orbital cellulitis must be treated with IV antibiotics.

The choice of antibiotics should reflect the probable causative organism. Antibiotic coverage that would be used for presumed sepsis in an immunocompetent host with an unknown organism is usually appropriate. Before starting IV antibiotics, blood culture should be taken. Other systemic cultures (e.g., cerebrospinal fluid, urine) may be indicated if signs of systemic toxicity are present. Percutaneous aspiration from the area of cellulitis is not recommended.

Conjunctival cultures do not necessarily identify the causative agent of the cellulitis, but it may be reasonable to treat a predominant organism, particularly if purulent conjunctivitis is present. The patient should be monitored daily for signs of orbital cellulitis if improvement is not occurring.

Chalazions and Styes

Clinical Manifestations

Chalazions (internal hordeolum) and styes (external hordeolum) represent blocked glands within the eyelids. Both may present acutely with localized lid swelling, erythema, and tenderness. Styes are associated with swelling and purulent drainage at or near the lid margin (Fig. 120.4). More than one lesion may occur simultaneously and more than one lid may be involved. Acute chalazions cause swelling and redness in the body of the eyelid and may be associated with drainage on the conjunctival surface of the eyelid with or without a red eye. They may also point and drain via the skin (Fig. 120.5). Chalazions may enter a chronic phase in which there is a nontender, noninflamed, mobile pea-sized nodule within the body of the eyelid (Fig. 120.6). History can be helpful in establishing these diagnoses because patients often have had recurrent lesions at varying sites.

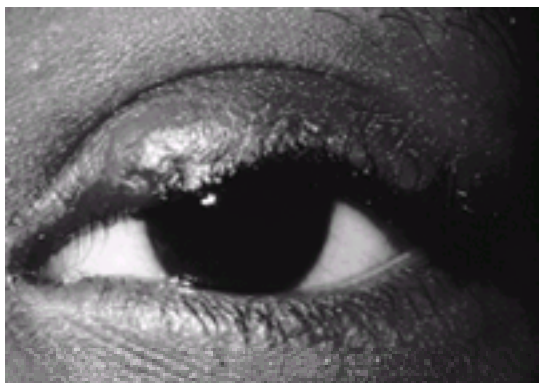

FIGURE 120.4. Acute sty (external hordeolum). *Please see the color-tip insert (Color Plate 120.4).*

FIGURE 120.5. Chalazion draining spontaneously via skin. *Please see the color-tip insert (Color Plate 120.5).*

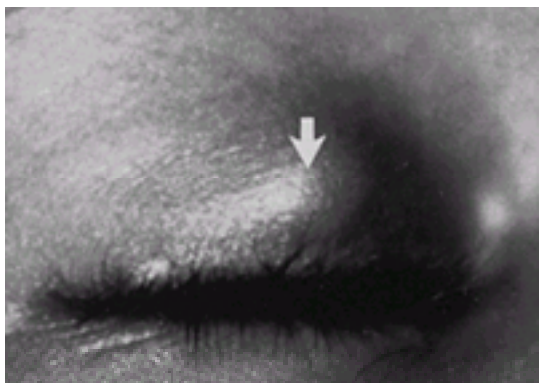

FIGURE 120.6. *Arrow* indicates chronic chalazion within upper lid.

Management

The treatment for both chalazions and styes is essentially the same. Eyelash scrubs with baby shampoo once or twice daily are helpful in mechanically establishing drainage. Baby shampoo is applied to a washcloth and then used to scrub the base of the eyelashes. Warm compresses are also useful, but rarely tolerated well by younger children. Optimally, warm compresses should be applied four times daily for 10 to 20 minutes at each sitting. The eyelid should be closed for both lid hygiene and warm compresses. Antibiotics probably play a minimal role in the treatment of styes and chalazions. If desired, a topical antibiotic ointment (Table 120.1) can be given twice daily following eyelash scrubs. If medical treatment has failed to cause adequate resolution after at least 4 weeks, surgery can be offered either for cosmesis or for

uncomfortable lesions. In severe recurrent cases, particularly when associated with red eye, oral erythromycin or tetracycline (8 years old) may be tried, although at this stage, ophthalmic consultation should be obtained.

Use	Avoid
Dilating drops	
Phenylephrine 2.5%	Scopolamine
Tropicamide 1%	Atropine
Cyclopentolate 1%	Homatropine
	Cyclopentolate 2%
Antibiotics	
Bacitracin	Neomycin
Erythromycin	Sulfacetamide
Polysporin	Aminoglycosides (except neonate)
Polytrim (trimethoprim/polymyxin B)	Quinolones
Lubricants	
Artificial tears/ointment	
Vasoconstrictors/antihistamines	
Albalon A, Naphcon A, Vasocon A	
Diagnostic Agents	
Topical fluorescein	
Anesthetic Agents	
Proparacaine, tetracaine	Cocaine
AVOID ALL ANTIVIRALS, MIOTICS (see Chapter 26), STEROIDS,* and ANTI-GLAUCOMA AGENTS	

*Including steroid-containing preparations, such as combination antibiotic-steroids.

Table 120.1. Pediatric Emergency Department Ophthalmic Drug Guidelines

Chemical Injury

Clinical Manifestations

When the child has a clear history of a noxious substance coming in contact with the ocular surface, it is important to determine whether this substance is an acid or an alkali. Alkali injuries tend to be much more severe. It is also important to determine whether particulate matter may have been deposited on the ocular surface. Smoke can also cause chemical conjunctivitis, particularly in house fires when chemicals are liberated into the air from the burning of plastics and other substances. The examiner must also assess the degree of exposure. If a child has no symptoms (pain, photophobia) or signs (red eye, epiphora, conjunctival swelling) and a weak history of actually getting the chemical into the eye, it may be acceptable to avoid lavage.

Management

Chemical injury to the eyeball is a true ocular emergency. Immediate intervention by ED personnel is essential to improving the patient's prognosis. Any patient with sufficient history should be immediately placed in the supine position so that ocular lavage may be started. Although a drop of topical anesthetic can make this procedure more comfortable, the physician should not wait for this to become available if it is not immediately handy. Usually, the irrigating solution itself will induce cold anesthesia. If a speculum, Desmarres retractor, or paper clip (see previous discussion) is readily available, this may be used to help obtain optimal exposure of the ocular surface. Again, the physician should not wait for these to become available. Virtually any IV solution can be used for ocular lavage, although normal saline solution or Ringer's lactate is perhaps preferable. A standard IV bag and tubing set is used without a needle on the end. Rather, the solution is allowed to flow, with the system at its maximum flow rate, across the surface of the open eye from medial to lateral. If both eyes have been exposed, they should both be lavaged simultaneously with two separate setups. Lavage should be continued until the involved eye(s) has received either 2 L of fluid or until approximately 20 minutes has elapsed. Lid eversion should be performed (Fig. 111.12) and lavage should be continued with the lid in this position so that the conjunctiva under the upper lid may also be cleansed. Mechanical debridement should be limited to the removal of visible particles from the ocular surface.

It is useful to have a strip of standard litmus paper available in the ED. The litmus paper is touched against the surface of each conjunctiva before beginning lavage. The pH is noted and the lavage is continued if, after the required minimum time/volume, the pH has not become normal (6.5 to 7.5) or equal between the two eyes. The end point of equality should only be used if one eye has not been exposed to chemical injuries. The conjunctiva under the upper lid may also be tested separately because noxious material can be harbored in the recess above the eye under the lid.

Ocular lavage can often be frightening to a child. If sedation can be administered promptly, it may be helpful. However, the physician should never wait for the effects of sedation before proceeding with lavage.

Ophthalmology consultation is usually indicated in cases of significant chemical injury. The consultant should be notified while lavage is ongoing. In cases of minor exposure to substances that are clearly not alkaline or strongly acidic, and when the eye is not injected, an ophthalmology consultation may be deferred. However, the physician must be cautious about the absence of conjunctival injection because alkali burns can cause blanching of the conjunctiva, which is a poor prognostic sign.

Conjunctivitis

Clinical Manifestations

Chapter 24 provides an approach for eliminating other causes of red eyes from the differential diagnosis. Table 120.2 is designed to give some additional help in differentiating causes of conjunctivitis. The patient's age is often useful in determining a diagnosis. Neonates presenting in the first 3 days of life can have a chemical conjunctivitis caused by silver nitrate used for ocular prophylaxis perinatally. Most hospitals have now discontinued this practice and many are using erythromycin ointment. However, this is not completely effective in eliminating subsequent gonorrheal or chlamydial conjunctivitis in the neonatal period. These two forms of conjunctivitis, as well as bacterial conjunctivitis secondary to enteric organisms, can be difficult to distinguish clinically. Each can present as either a mild purulent form or chronic

purulent conjunctivitis. A dramatically hyperacute conjunctivitis with significant lid swelling and copious purulent ocular discharge is more characteristic of gonorrhea (Fig. 120.7). In view of the risk of spontaneous corneal perforation associated with gonorrheal conjunctivitis, infants should be presumed to have this infection until proven otherwise. Immediate Gram stain should be performed looking for Gram-negative diplococci. If present, treatment for gonorrheal conjunctivitis should be started while awaiting culture results. In this age group, *Chlamydia* studies may be useful as well. Conjunctival scrapings are useful to look for inclusion bodies of chlamydial conjunctivitis. However, the sensitivity of this test depends on sampling, and the techniques may not be readily available or properly performed. Other methods to detect *Chlamydia* must always be used. Although rapid slide methods are approved for conjunctival samples (Syva), *Chlamydia* cultures are preferred because they increase diagnostic sensitivity. Even if *Chlamydia* is detected by Giemsa staining, this does not rule out the presence of concomitant gonorrheal infection.

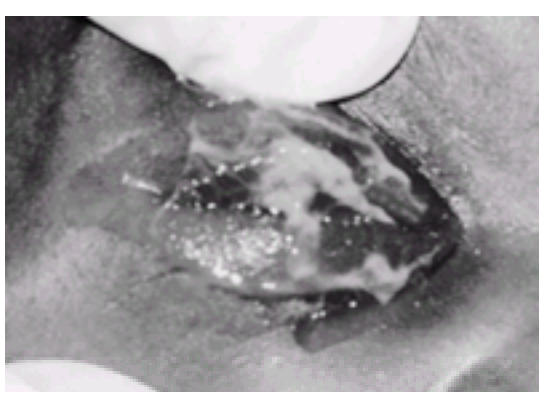

FIGURE 120.7. Neonatal gonorrheal conjunctivitis. Note the dramatic lid swelling and severe purulent discharge. *Please see the color-tip insert (Color Plate 120.7).*

	Bacterial	Viral (Nonherpetic)	Herpetic	Chlamydial	Allergic

Table 120.2. Differential Diagnosis of Conjunctivitis

In children beyond the neonatal period, a wide range of organisms, both viral and bacterial, as well as *Chlamydia,* can cause conjunctivitis. Clinically, these entities may appear to be similar. In general, purulence is more characteristic of bacterial infections, whereas clear serous discharge is more characteristic of viral infection. Although both viral and bacterial conjunctivitis may be unilateral or bilateral, a history of multiple infected contacts argues in favor of a viral etiology. Likewise, dramatic lid swelling, associated with preauricular adenopathy; mucoid or serous discharge; and perhaps an uncomfortable, sandy, foreign body sensation that affects one eye followed closely by the other, is strongly suggestive of epidemic keratoconjunctivitis secondary to adenovirus. This fulminant viral infection is easy to recognize (Fig. 120.8).

FIGURE 120.8. Patient with right epidemic keratoconjunctivitis infection. Note the lid swelling, red eye, and absence of purulent discharge. Patient also has right preauricular adenopathy (not visible). Note the early injection of left eye, representing sequential involvement. *Please see the color-tip insert (Color Plate 120.8).*

Viral culturing is rarely necessary. Bacterial cultures should be considered in all cases of purulent conjunctivitis, particularly when antibiotic treatment is going to be instituted. Gonorrheal conjunctivitis has been reported in prepubertal

children and in sexually active adolescents. Gram stains should be done in children with severe or persistent purulent conjunctivitis to rule out this infection.

Allergic conjunctivitis is usually a hyperacute conjunctival injection associated with tearing and a blister-like swelling of the conjunctiva (chemosis) (Fig. 120.9). Itching is often a prominent symptom, although this may also be a symptom of blepharitis (see Chapter 24). Conjunctival smears stained with Gram or Wright methods may reveal abundant eosinophils.

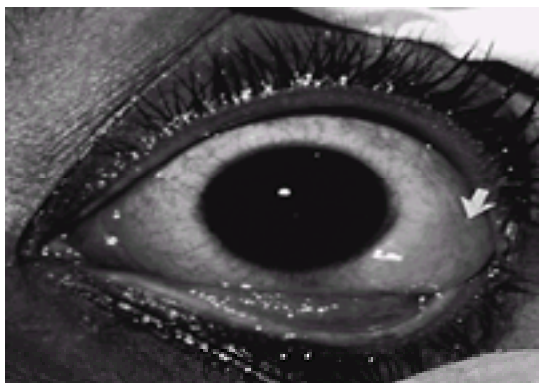

FIGURE 120.9. Allergic conjunctivitis.

Nasolacrimal duct obstruction is often confused with conjunctivitis because discharge may be present. However, the conjunctiva is rarely inflamed, indicating the absence of true conjunctivitis. The eye is white. The discharge is mostly mucus that has precipitated out of the tear film because of stagnation of tear flow. Patients are usually less than 1 year old, with a history of symptoms dating back to the first weeks of life. The discharge is usually worse on waking. Crusts may form on the lashes. Tearing may become more prominent after the first few months of life. Older children often have epiphora without discharge. The diagnosis can be confirmed by placing pressure on the lacrimal sac, which lies under the skin against the lacrimal bone between the medial canthus and bridge of the nose. This maneuver may cause an increase in the amount of discharge as it is forced out of the sac back onto the surface of the eye.

Management

Until proven otherwise, and in the presence of Gram-negative diplococci, neonatal purulent conjunctivitis should be treated as gonorrheal conjunctivitis, pending the results of cultures. The patient should be admitted for IV antibiotic therapy with cephalosporin (ceftriaxone 25 to 50 mg/kg, maximum 125 mg, intramuscularly or intravenously as single dose, or cefot1axime 100 mg/kg intramuscularly or intravenously as single dose), particularly in areas where penicillinase-producing strains are common. Ophthalmology consultation is indicated. Saline ocular lavage on an hourly basis may be helpful in decreasing the amount of organisms having access to the cornea. Topical erythromycin ointment is helpful because it will also treat *Chlamydia.* However, topical treatment alone is insufficient for either organism. If *Chlamydia* is laboratory proven, then the child must receive a 14- to 21-day course of oral erythromycin as well. This is necessary to eradicate carriage of *Chlamydia* in the nasopharynx, which can subsequently lead to pneumonia. The mother and father should be tested.

Any of the local antibiotics suggested in Table 120.1 would be appropriate for empiric coverage in treating a presumed bacterial conjunctivitis other than gonococcal while awaiting culture results. Gram stain can be helpful when narrowing down the possible causes, particularly when sheets of one predominant type of organism are seen. In the first 3 months of life, topical aminoglycosides might be a reasonable choice because Gram-negative and enteric organisms are more common.

If the patient clearly has a viral conjunctivitis, antibiotic treatment is probably not needed. Some physicians use antibiotics to “prevent secondary infection”; however, this is not a clinically significant problem in immunocompetent children. Rather, these patients are best soothed with cool compresses and artificial tear preparations. Depending on the virus, symptoms may last for weeks. Patients with symptoms that appear to be getting worse or persisting for longer than 1 week may benefit from ophthalmology consultation.

Allergic conjunctivitis is also helped by topical lubricants and cool compresses. The combination vasoconstrictor/antihistamine preparations listed in Table 120.1 may also be prescribed. Patients with recurrent allergic conjunctivitis, atopy, or asthma may benefit from long-term or seasonal topical mast cell stabilizers. Ophthalmology consultation may be useful, especially when symptom relief is not obtained or pain and red eye are present.

Any patient with a history of herpetic ocular infection and any patient who wears contact lenses and has conjunctivitis should be referred immediately for ophthalmology consultation. Herpetic corneal infection is usually painful. Patients may or may not have a history of skin lesions. Characteristic fluorescein dendritic staining patterns can be seen on the cornea or conjunctiva (Fig. 120.10). However, even if there is no staining but a history of herpetic (varicella-zoster or simplex) corneal infection, urgent ophthalmology consultation is essential. However, skin lesions on the lids without any conjunctival injection does not require ophthalmology consultation.

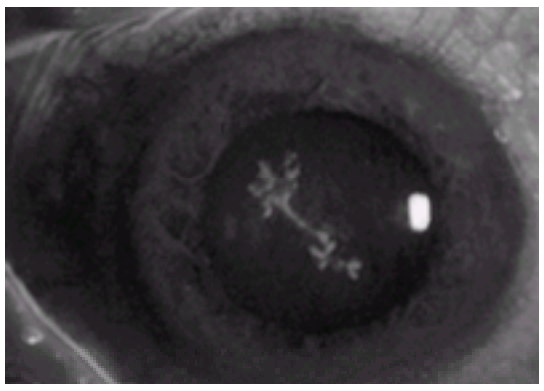

FIGURE 120.10. Fluorescein staining pattern of herpes simplex virus corneal infection. Eye is illuminated with blue light to demonstrate yellow/green branching staining pattern of herpetic dendrite. *Please see the color-tip insert. (Color Plate 120.10)*

DRUGS

Table 120.1 is designed to give emergency physicians some guidelines regarding the prescription and use of ophthalmic medications. Those drugs that should be avoided are listed because of problems with ocular toxicity, systemic toxicity, undesirable selection of resistant organisms, or the need for ophthalmology consultation and management regarding the problem that those drugs are designed to treat. In addition, the following guidelines should be adhered to:

1. No local drugs should be prescribed to patients who wear contact lenses without the supervision and consultation of an ophthalmologist.
2. Topical anesthetics must never be prescribed for outpatient use. These are strictly diagnostic agents. Prolonged use of topical anesthetics may result in corneal ulceration.
3. Steroids should never be prescribed by the emergency physician. Inappropriate use of steroids may lead to glaucoma, cataract, increased severity of corneal viral infection, or rebound symptoms when the drug is discontinued.

Instillation of eye drops can sometimes be difficult because of swollen eyelids or noncompliance from the patient. It will sometimes be noted that some of the drop is expelled upon blinking after drop instillation. This is not an indication for repeat instillation because only approximately 20% of an eye drop is actually absorbed for use. Most ophthalmic solutions are designed for a one-drop dose. Drops are most efficiently delivered by pulling down the lower eyelid and placing the drop in the inferior fornix. In patients who are extremely resistant, forced eyelid opening is needed to expose just a small strip of palpebral conjunctiva. The same techniques as described previously and in Chapter 111 for opening the eyelids may be used for the administration of eye drops in the ED. The eyeball itself need not be visualized. An alternative technique involves placing the eye drop in the sulcus between the medial canthus and the bridge of the nose while the patient is in the supine position. Every child must eventually open his or her eyes and when this happens the eye drop will naturally flow onto the conjunctiva.

Topical anesthetics do sting for approximately 10 to 20 seconds before taking effect. This may still be more desirable than the severe sting associated with dilating drops. In addition, the placement of a topical anesthetic before instillation of dilating eye drops increases the effectiveness of the latter.

When an eye drop and ointment are to be used simultaneously, the solution should always be instilled before the ointment. Ophthalmic ointments are applied by placing a strip of ointment along the conjunctiva of the lower lid. When treating styes and chalazions located within the eyelid, ointment can be placed on the lashes or conjunctiva.

CHAPTER 121

Otolaryngologic Emergencies

WILLIAM P. POTSIC, MD and STEVEN D. HANDLER, MD

Department of Pediatric Otorhinolaryngology: Head & Neck Surgery, The University of Pennsylvania School of Medicine, and Pediatric Otolaryngology & Human Communication, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

The ear, nose, and throat are common sites for infection and neoplasms and may be the sources of acute pain. This makes the head and neck region one with which the emergency medicine specialists must be familiar because they are called on to evaluate this area frequently. Although the presenting complaints may seem extremely distressing to the patient and cause considerable anxiety for the parents, the diseases prompting the visit are rarely life-threatening. This chapter includes discussion of disorders of the ear, nose, nasal sinuses, oral cavity, pharynx, esophagus, larynx, trachea, and neck.

EAR

Methods of Examination

Every emergency department (ED) should have an otoscope with good illumination, wax loop (curette), illuminated head light, and otologic forceps.

Examination of the ear begins by inspection of the auricle and surrounding areas. The external meatus should be visualized directly with a bright light after it is fully opened by pulling the pinna posteriorly and superiorly. The tragus may be displaced forward by traction on the skin in front of the ear with the examiner's other hand (Fig. 121.1). The ear canal can then be examined with a pneumatic otoscope, using the largest speculum that will fit in the meatus without discomfort. Wax or debris occluding the ear canal should be removed with a curette or by repeated irrigation with body-temperature water (see Procedure 5.3 in Section VII). Irrigation of the canal should not be done if a ventilating tube is in place or if a perforation of the tympanic membrane (TM) is suspected.

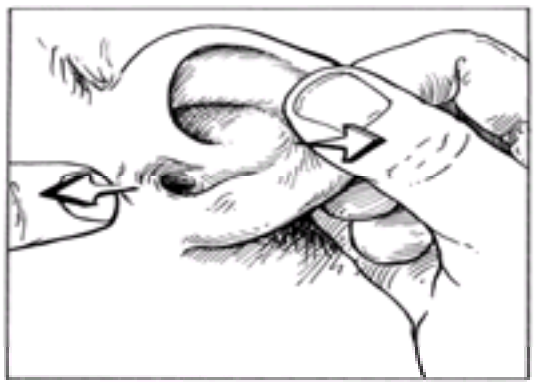

FIGURE 121.1. The external meatus is opened by pulling the auricle in the posteriorsuperior direction and placing traction on the skin immediately in front of the tragus.

The TM should be evaluated for its appearance, but the examination should not stop there. Part of the middle ear contents can often be seen through a translucent ear drum (Fig. 121.2). Mobility should be assessed with the pneumatic otoscope. Pneumatic otoscopy is performed by applying positive and negative pressure to the TM with the pneumatic otoscope fitted snugly into the ear canal. The ear pressure can be varied by squeezing a rubber bulb or blowing through a tubing connected to the otoscope head (see Procedure 5.1 in Section VII).

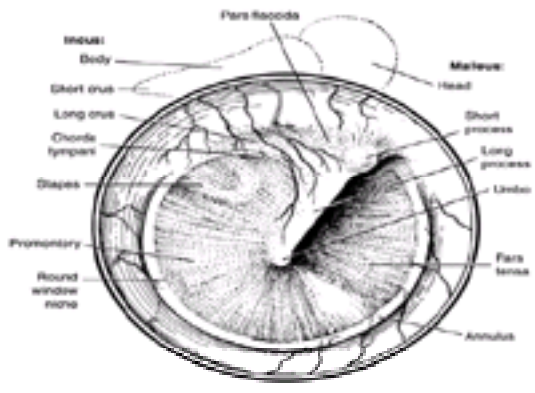

FIGURE 121.2. Right tympanic membrane.

The ear of a neonate requires special attention to perform an adequate otologic examination. The ear canal itself is narrow and collapsible. Often, the otoscopic speculum can only be inserted as positive pressure from the pneumatic bulb distends the canal ahead of the advancing speculum. The canal may be filled with vernix caseosa, which must be removed or irrigated out of the canal to permit visualization of the TM. The neonate's TM lies at a more oblique angle to the ear canal (compared with older children) and may make recognition of the TM and its landmarks more difficult.

Crude hearing acuity can be tested with a ticking watch or a 512-Hz tuning fork. The sound should be heard equally in each ear. However, this does not rule out a symmetric bilateral hearing deficit. If the tuning fork is applied to the forehead, it should be heard equally in both ears. If it is heard only in one ear, it signifies either a conductive loss in the ear that hears the tone or a sensorineural loss in the opposite ear. Audiometry (behavioral or evoked response) is required for an accurate evaluation of hearing.

Infections

Acute Otitis Media

Acute otitis media (AOM) is one of the most common head and neck infections in children and is the second most common diagnosis in the ED. It may occur as an isolated infection or as a complication of an upper respiratory infection (URI). Otitis media with effusion (OME), which is noninfected fluid in the middle ear (also called serous otitis media or secretory media), and immunodeficiency states predispose children to recurrent AOM.

The most common organisms causing acute otitis at all ages are *Streptococcus pneumoniae, Haemophilus influenzae,* and less often, *Moraxella catarrhalis,* group A b-hemolytic streptococcus, and various upper respiratory viruses. Gram-negative organisms may occur in hospitalized patients who are younger than 8 weeks of age or immunosuppressed.

Clinical Manifestations

AOM should be suspected in any child who is irritable or lethargic. The pain develops rapidly and is often severe. Spontaneous perforation of the TM with serosanguineous drainage may occur in less than 1 hour after the onset of pain. AOM is best diagnosed by pneumatic otoscopy. The TM is hyperemic, and mobility is decreased. As the drum becomes more edematous, it bulges outward and the landmarks may become unrecognizable. Infection with *Mycoplasma pneumoniae* and other bacteria may cause blebs on the lateral surface of the drum. The vesicles of bullous myringitis are filled with clear fluid and are painful. The appearance of the TM in AOM secondary to bacterial pathogens does not differ

significantly from AOM of viral etiology.

Complications

The following complications of AOM may be encountered in the ED:

1. The purulent exudate that fills the middle ear space causes a conductive hearing loss. The congealed exudate may organize and stimulate hyalinization and calcification, leading to tympanosclerosis (white patches on the undersurface of the TM).
2. Spontaneous perforation of the TM usually produces a small hole that heals rapidly; however, large perforations may occur that do not heal even after the infection has cleared.
3. Ossicular necrosis may also occur, causing a persistent conductive hearing loss.
4. As the TM heals after a perforation, skin from the lateral surface of the TM may be trapped in the middle ear to form a cyst (cholesteatoma) that can expand and destroy the structures of the middle ear and surrounding bone.
5. Facial nerve paralysis may occur suddenly during AOM. The nerve paralysis may be partial or complete when the child is first examined. The facial nerve usually recovers complete function if appropriate systemic (intravenous [IV] followed by oral) antibiotic therapy is administered and a wide myringotomy for drainage is carried out as soon as possible.
6. AOM may cause inflammation in the inner ear (serous labyrinthitis). This causes mild to moderate vertigo without a sensorineural hearing loss.
7. Bacterial invasion of the inner ear (suppurative labyrinthitis) causes severe vertigo and sensorineural hearing loss.
8. Pus always fills the mastoid during AOM, causing radiographic opacification , but acute suppurative mastoiditis (acute coalescent mastoid osteomyelitis) may develop, causing destruction of the mastoid air cell system. As the infection spreads to the postauricular tissues, subperiosteal collection of purulent material displaces the auricle laterally and downward from its normal position. The pus may extend through air cells to the medial portion of the temporal bone, causing sixth cranial nerve paralysis, deep retro-orbital pain, and otorrhea (Gradenigo's syndrome). Pus may also break through the mastoid tip and extend into the neck (Bezold abscess).
9. The most common intracranial problem associated with AOM is meningitis, which may be associated with severe sensorineural deafness and irreversible vestibular damage. Less commonly associated problems are cerebritis, epidural abscess, brain abscess, lateral sinus thrombosis, and otitic hydrocephalus. The child with overt or impending intracranial complications should be stabilized and have a computed tomographic (CT) or magnetic resonance imaging (MRI) scan.

Management

The treatment of uncomplicated AOM is oral antibiotic therapy with amoxicillin (25 to 50 mg/kg per 24 hours in three divided doses for 10 days). Systemic or local antihistamine–decongestant preparations are of no proven value. Patients with complicated AOM should also be treated with a wide inferior myringotomy for drainage, usually best performed by an otolaryngologist. Alternatively, in neonates, in immunosuppressed patients, and in cases in which antibiotic therapy is not effecting resolution of the infection, tympanocentesis (see Procedure 5.2 in Section VII) may be performed for Gram stain and culture. Patients treated on an emergency basis for AOM should be referred for follow-up examination in 2 weeks after therapy is started. Children with persistent OME, complications of middle ear disease, or recurrent bouts of AOM that do not respond to a 6- to 8-week course of antimicrobial treatment/prophylaxis should be referred to an otolaryngologist for evaluation for possible surgical treatment.

External Otitis

External otitis usually follows swimming and is often called swimmer's ear. Ear canal trauma or foreign bodies may also contribute to the development of external otitis.

Otitis externa may be localized or diffuse. Localized external otitis is the result of an abscessed hair follicle in the outer two-thirds of the ear canal. These abscesses are caused by *Staphylococcus aureus.*

Diffuse external otitis is caused by *Pseudomonas aeruginosa,* staphylococci, fungi, or a mixture of Gram-negative and Gram-positive organisms. Viral external otitis is usually caused by herpes simplex or herpes zoster.

Clinical Manifestations

External otitis usually begins with itching and fullness that progress to severe pain. The pain is worsened by chewing or by touching the ear. The external canal is red, edematous, and narrowed. The diagnosis of external otitis is usually readily made by external inspection and otoscopy. Otoscopy may be painful, and visualization of the eardrum may be impossible because of edema of the canal walls. A foul-smelling, purulent discharge is usually present. Surrounding cellulitis and regional cervical adenitis may also be present. Malignant external otitis occurs rarely in debilitated patients who have diabetes or are immunosuppressed. It may cause extensive tissue necrosis and can be rapidly fatal if not treated immediately with antibiotics and surgical debridement.

Management

If the abscess in localized external otitis is about to drain spontaneously, it should be opened where it is pointing with an 18-gauge needle, or a No. 11 scalpel blade. Drainage results in immediate relief of pain. Antibiotic therapy with an antistaphylococcal antibiotic (e.g., erythromycin, dicloxacillin, or a cephalosporin) should be administered for 10 days. The treatment of diffuse external otitis is to use antibiotic ear drops containing neomycin, polymyxin, and hydrocortisone (4 drops, three times daily) in the affected ear for 10 days. Before the drops are started, the pus and debris should be cleaned from the ear canal with gentle suction, a curette, or cotton-tipped applicators. If the meatus is so swollen that drops can not enter the external canal, a wick of gauze or Merocel sponge should be gently advanced into the ear canal

with a forceps (Fig. 121.3) to facilitate instillation of the topical medicine. The wick should be left in place for 24 to 48 hours, by which time the canal swelling should resolve to permit entrance of the drops. Broad-spectrum systemic antibiotics should be used if cellulitis or regional cervical adenitis is present. No water should be allowed to enter the ear canal during the 10 days of therapy.

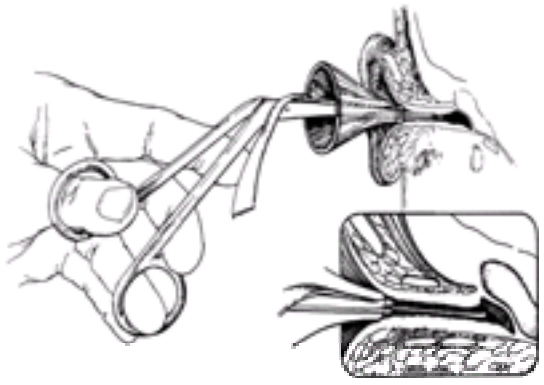

FIGURE 121.3. Gauze wick (¼ × 1½ inch) being placed in ear canal to facilitate topical treatment of otitis externa.

Chronic Otitis Media

Chronic otitis media (COM) is a persistent perforation of the tympanic membrane of more than 3 months' duration; the perforation may be acquired (from AOM or trauma) or iatrogenic (by tympanostomy tube) and may or may not be associated with active infection. When infection is present, the causative organism is usually *P. aeruginosa* or *S. aureus,* and it presents with a profuse, foul-smelling discharge. Any perforation may be associated with a cholesteatoma (white skin-lined cyst) that can destroy the structures of the ear as it expands.

Clinical Manifestations

COM is usually diagnosed by otoscopy. A perforation of the eardrum is readily seen and the white, pearly, flaky debris from a cholesteatoma may also be present.

Management

Dry perforations require no active treatment. When otorrhea is noted, antibiotic-containing ear drops (4 to 5 drops, three times daily) should be placed in the ear canal. Systemic antibiotics are of limited value unless regional cellulitis or cervical adenitis is present. In those cases, an antistaphylococcal antibiotic (e.g., erythromycin, dicloxacillin, or cephalosporin) should be administered for 10 days. Chronic perforation and cholesteatoma require surgical correction. All cases should be referred to an otolaryngologist for definitive management.

The complications of COM with infection are the same as those that occur in AOM, including intracranial spread of the infectious process. In addition, with repeated infection, a progressive high frequency sensorineural hearing loss may develop.

Infection of the Pinna

The pinna may become infected in a fashion similar to skin surfaces anywhere else on the body (see Chapter 84). Preauricular cysts and sinuses may occasionally be infected with *S. aureus* and should be treated with antistaphylococcal penicillin or cephalosporin for 10 days. If an abscess forms, it should be drained surgically. Infected preauricular sinuses/cysts require surgical excision once the acute infection has been treated.

Sudden Hearing Loss

Sudden hearing loss is not a common complaint in the ED, but it requires prompt attention, especially if the loss is determined to be sensorineural. Sudden conductive losses almost never occur without a known antecedent event such as head trauma, ear infection, or wax occlusion of the ear canal. History and otoscopy can usually establish the cause of the conductive hearing loss. However, the cause of sensorineural sudden hearing loss is obscure when the history is unrevealing and otoscopy is normal. Tuning fork testing helps confirm the presence of a sensorineural hearing loss.

Sudden sensorineural hearing loss that occurs after an airplane trip, scuba diving, straining, or head trauma is highly suggestive of a perilymph fistula. A perilymph fistula occurs when inner ear fluid leaks out into the middle ear through a rupture in the round window or stapes footplate (oval window). The leaking fluid causes a fluctuating sensorineural loss and vertigo. Urgent surgical exploration of the middle ear is required for repair.

Sudden sensorineural deafness may occur without a history suggestive of a fistula and without otoscopic abnormalities. This is often secondary to a viral infection of the cochlear labyrinth. Measles, mumps, and cytomegalic viral illnesses are common causes of sudden sensorineural deafness. Other viruses may injure the cochlea as well. There may be no systemic symptoms or signs of such a viral infection. These patients may have partial or complete recovery of hearing over several weeks. There is no proven effective treatment for sudden hearing loss. Aspirin has been recommended (in older children) to decrease platelet aggregation and to maintain patency of the cochlear blood vessels, and corticosteroids have been recommended by some authors. Other treatments have been proposed (e.g.,

cyclophosphamide, hyperbaric oxygen, inhaled CO_2), but are of uncertain efficacy. Antivertigo medications may be prescribed for patients experiencing dizziness. All patients with a sudden sensorineural hearing loss should be referred to an otolaryngologist.

Vertigo

Sudden vertigo is a disturbing and sometimes confusing symptom. A child may be brought to the ED because the parents think he or she is having a seizure. Vertigo may follow dysfunction of any part of the vestibular system from the labyrinth to the vestibular cortex.

Vertigo may be associated with a number of conditions affecting the middle ear:

1. Serous labyrinthitis may develop in a child with OME, AOM, or COM. Pressure and infection in the middle ear may cause inner ear inflammation and vestibular dysfunction. The conductive hearing loss and the dizziness resolve when the middle ear pressure is normalized or the inflammation subsides.
2. Suppurative labyrinthitis may occur when bacteria invade the inner ear. Severe vertigo and a profound sensorineural hearing loss result.
3. When a cholesteatoma arises in association with COM, it may invade the bony wall of the labyrinth. Pneumatic otoscopy may produce the sensation of vertigo by transmitting the pressure directly to the inner ear.
4. A common cause of sudden vertigo is vestibular neuronitis. The origin of this entity is uncertain, and the vertigo resolves spontaneously over several weeks. There are no accompanying signs or symptoms.
5. Trauma can be associated with vertigo in several ways. Perilymph fistulae, which occur most often after barotrauma, blunt head trauma, or straining, produce vertigo that fluctuates in severity. However, head trauma may also cause labyrinthine concussion or hemorrhage (hemorrhagic labyrinthitis), resulting in vertigo. Cerebral injuries involving the temporal lobe (with or without temporal bone fracture) can also cause vertigo.
6. Measles and mumps may also infect the inner ear and cause vertigo.
7. Meniere's disease (endolymphatic hydrops) is rare in children. Its origin is unknown. The symptoms are intermittent vertigo, tinnitus, a feeling of fullness in the ear, and fluctuating hearing.
8. Miscellaneous causes of sudden vertigo in children include benign paroxysmal vertigo of childhood and retrolabyrinthine lesions such as tumors, demyelinating diseases, and temporal lobe seizures.

The emergency physician should be reminded that vertigo is only a symptom of an underlying disease. Emergency treatment should consist of searching for the underlying disease, as well as providing symptomatic relief. Vertigo is rarely associated with a life-threatening illness. Because sensorineural hearing loss usually accompanies serious causes of vertigo, its absence can provide some level of confidence that no life-threatening disease is present. (See Chapter 21 for further discussion.)

Neoplasms

Neoplasms of the external ear are as varied as the tissue types of the auricle and are not difficult to diagnose because they are so visible. Neoplasms of the middle and inner ear are rare, but bear mentioning because they are often missed until they are far advanced. External canal and middle ear tumors are most often brought to the physician's attention because of painful secondary infection that does not respond to conventional treatment of topical and systemic antibiotics. The examiner may overlook a tumor, assuming that it is granulation tissue caused by an infection or related to a ventilating tube. If an ear infection does not respond to appropriate treatment or is associated with any abnormal-appearing tissue, a tumor should be suspected; otolaryngologic consultation should be made to obtain a biopsy of the abnormal tissue.

Inner ear tumors are deceptive in their early stages and are rarely detected until they cause either hearing loss, vertigo, or focal neurologic signs. The most common of these tumors are neural sheath tumors of the eighth nerve that cause progressive sensorineural hearing loss, vertigo, and fifth nerve anesthesia.

Facial Nerve Paralysis

Facial nerve paralysis is a frightening occurrence in children. Bell's palsy (idiopathic facial paralysis) is the most common cause of facial paralysis. (See Chapter 83 for management of this presumed viral infection.) A child presenting with facial paralysis must have a careful examination to detect any other treatable cause for the nerve dysfunction. Facial paralysis secondary to AOM requires a course of systemic (24 to 48 hours of IV followed by oral) antibiotics and an urgent wide-field myringotomy for drainage. Temporal bone or facial trauma and neoplasms of the middle ear and parotid area can also present with facial nerve paralysis. A child with a facial nerve paralysis should be referred to an otolaryngologist for a complete evaluation of the head and neck, audiogram, and radiographic imaging.

NOSE AND PARANASAL SINUSES

Methods of Examination

The external nose and anterior portion of the nasal cavities can be examined by direct visual inspection. A nasal speculum and directed light source are necessary to permit good visualization of the anterior septum and inferior and middle turbinates. In younger children, the examiner's thumb can elevate the mobile nasal tip to allow adequate inspection of the anterior nasal structures. Vasoconstrictors such as 0.25% phenylephrine or 0.05% oxymetazoline (2 or 3 drops) can be applied to the nose to shrink the mucosa and allow a more complete examination. The posterior nasal structures and nasopharynx can be seen with the aid of a flexible fiberoptic endoscope placed in the nose or the posterior oropharynx (see Procedure 7.5 in Section VII). Patency of the nasal cavities in the neonate can be assessed by the passage of small rubber catheters through the nose and into the pharynx. Palpation is also important in the

evaluation of nasal and facial trauma. Tenderness to palpation over the sinuses is a common sign of acute sinusitis.

A careful examination of adjacent areas is important when evaluating a child with sinus disease. Dental pathology must be detected in the search for a possible cause of a bacterial maxillary sinusitis. An examination of the orbit with assessment of visual acuity and ocular mobility should be performed to detect possible orbital complications of sinus disease.

Radiographs are indispensable in evaluating diseases of the nose and sinuses. Plain films (sinus or facial series) are used as screening devices to evaluate a mass or fluid in a sinus, but CT scans are indicated for more precise and detailed evaluation of sinusitis or tumors of this area.

Infections

Infections of the nose and paranasal sinuses are most often a component of the common URI. The symptom complex of fever, nasal congestion/rhinorrhea, and headache is most often caused by a viral agent. Physical examination often reveals swollen, erythematous nasal turbinates. The rhinorrhea can be clear or white in color. Facial tenderness is usually absent. Viral rhinitis requires little more than supportive care with hydration, rest, and antipyretics; oral antihistamines and/or decongestants are thought by some to provide additional relief. Topical decongestants are to be avoided because of their tendency to cause rebound congestion as their vasoconstricting effect on the nasal mucosa wears off.

Bacterial infection of the nose and paranasal sinuses is a more serious condition and requires a careful examination and prompt treatment. Bacterial sinusitis should be suspected when the nasal discharge lasts more than 7 days and is thick yellow to yellow–green. Tenderness over the face may indicate clinical involvement of one or more of the paranasal sinuses. The diagnosis is usually confirmed radiographically. Gram stain of the material reveals many polymorphonuclear leukocytes (PMNs) and the causative organism. Because the most common organisms responsible for bacterial rhinosinusitis are *H. influenzae* and group A streptococcus, amoxicillin 25 to 50 mg/kg per day for 10 days is the treatment of choice.

Complications of acute sinusitis, such as orbital cellulitis, facial cellulitis/abscess, and meningitis, require admission to the hospital for appropriate IV antimicrobial therapy and possible operative intervention. Otolaryngologic consultation should be obtained in the evaluation of these patients with complicated acute sinusitis; surgical drainage may be needed.

One complication of chronic sinusitis, the sinus mucocele, can cause a child to present to the ED with acute symptoms. Mucoceles are expansile cystic lesions that occur secondary to a long-standing blockage of a sinus ostia. Although the lesion evolves over several months or even years, the child usually presents with the sudden onset of signs and symptoms usually related to an acute infection of the mucocele. These include pain and swelling secondary to osteomyelitis of the frontal bone, inferior and lateral displacement of the globe with proptosis, limitation of ocular mobility, and chronic nasal/postnasal discharge. Radiographs (plain films and CT) are often needed to determine the presence and extent of a mucocele. The patient should be referred to the otolaryngology service for appropriate IV antimicrobial therapy and surgical drainage.

Any child presenting to the ED with a history of persistent (after what would appear to have been an adequate course of appropriate treatment) rhinosinusitis should have a careful search for predisposing causes. Foreign bodies, choanal atresia, neoplasms, septal deviation, dental disease, adenoid hypertrophy, allergic polyps, or immunodeficiency states may all present with recurrent or persistent rhinosinusitis.

Chronic Nasal Obstruction

Obstruction to the normal passage of air can occur with a variety of conditions, and gives the sensation of a blocked or “stuffy” nose. Temporary partial obstruction of one nasal cavity at a time occurs normally in the nasal respiratory cycle. However, prolonged blockage, is not physiologic, and the physician should search for a cause.

Although most instances of nasal obstruction cause only mild feelings of discomfort, some children may present with a history of obstructive apnea (Pickwickian syndrome—see Adenotonsillar Hypertrophy, p. 1578) and even cor pulmonale. A history of trauma or foreign body may lead one to the reason for the obstruction. A careful examination of the nasal cavities and pharynx is necessary to determine the cause of the obstruction. Septal deviation, nasal tumor, and turbinate hypertrophy related to allergy and/or infection are common causes. Adenoid hypertrophy, nasopharyngeal tumor (lymphoma, rhabdomyosarcoma), and choanal atresia (unilateral or bilateral) can all present with nasal obstruction. Flexible fiberoptic examination (see Procedure 17.5 in Section VII) and radiographs (usually CT scan) of the nose and nasopharynx may be useful in the evaluation of the blocked nasal airway. If the source of the obstruction is not apparent after these maneuvers, referral should be made to an otolaryngologist to perform a complete examination of the nose and nasopharynx.

Epistaxis

Epistaxis is relatively common in children, and may cause significant anxiety in both the child and the parent. Although bleeding occasionally occurs secondary to the mucosal maceration caused by URIs, nose-picking accounts for most cases of recurrent epistaxis. (A more complete discussion on the differential diagnosis is presented in Chapter 23.) The usual site of bleeding is the anterior nasal septum, Kiesselbach's or Little's area (Fig. 121.4).

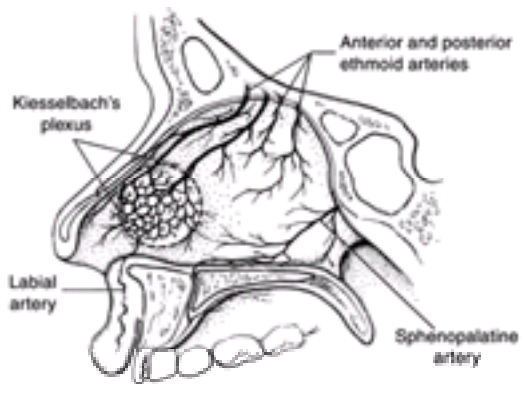

FIGURE 121.4. Vascular supply of nasal septum. Note confluence of vessels that forms Kiesselbach's plexus.

A complete history is an important step in the proper management of epistaxis. Site of bleeding (one or both sides of the nose), frequency, bleeding from other places, history of trauma, and family history of bleeding are all important factors to know in this evaluation. Figure 121.5 presents an algorithm for the management of epistaxis. A careful examination of the nose should be performed to identify the site and cause of the bleeding. Good lighting, suction, and material for cauterization and packing should be readily available (see Procedure 7.1 in Section VII). Topical vasoconstrictors such as phenylephrine (0.25%), oxymetazoline (0.05%) or epinephrine (1:1000) on a cotton pledget can be placed in the nose to shrink the nasal mucosa, allowing better visualization of the nasal cavity; vasoconstrictors may slow or even stop the bleeding. Simple pressure by squeezing the nostrils together is usually sufficient to stop most epistaxis. Occasionally, a roll of cotton placed under the upper lip will stop bleeding by compression of the labial artery. If pressure is not successful, cauterization with silver nitrate sticks or packing of the nose is performed (see Procedure 7.1 and Procedure 7.2 in Section VII). Absorbable packing such as oxycellulose (Surgicel) or gelatin (Gelfoam) is usually adequate for most epistaxis and has the advantage of not requiring removal.

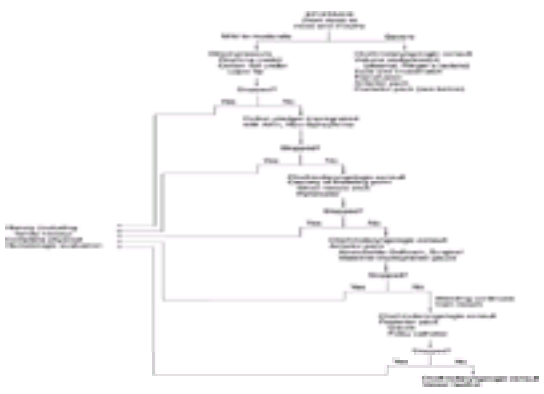

FIGURE 121.5. Algorithm for management of epistaxis.

Further treatment should also be directed toward preventing the child from continuing to traumatize his or her nose, resulting in further bleeding. Using a vaporizer to increase the humidity in the child's room and applying petroleum jelly to the anterior septal areas twice daily can aid in healing the irritated nasal mucosa and preventing recurrent epistaxis. Fingernails should be cut short.

Severe or recurrent episodes of epistaxis require the assistance of an otolaryngologist in their diagnosis and management. Epistaxis that does not stop with simple pressure or oxycellulose or gelatin packing may require a more substantial anterior nasal pack of petroleum jelly-impregnated gauze. A posterior nasal pack (using gauze or a Foley catheter) may be necessary in managing severe epistaxis that originates in the posterior nasal cavity or nasopharynx (see Procedure 7.2 in Section VII).

If the epistaxis recurs despite the above treatment, an otolaryngologist should be consulted to look for other causes for the epistaxis. Nasal septal deviation or perforation, sinusitis, tumor (nasal, nasopharyngeal or sinus), Rendu-Osler-Weber disease (hereditary hemorrhagic telangiectasia), and nasal foreign body can all present with epistaxis. Blood dyscrasias such as hemophilia, idiopathic thrombocytopenia purpura, von Willebrand's disease, and those hematologic conditions associated with leukemia or the administration of chemotherapeutic agents may lead to severe epistaxis. Treatment consists of correcting the underlying hematologic problem in addition to the previously described local measures. Recurrent or severe bleeding may require more extensive cauterization or even ligation of dilated vessels on the septum.

Neoplasms

Neoplasms of the nose and sinuses are uncommon in children. They may present as mass lesions or as chronic/recurrent rhinosinusitis. When a neoplasm is suspected, the child should be referred to an otolaryngologist for a complete evaluation of the nose and sinuses and appropriate radiographic imaging that is a prerequisite to the proper treatment of these lesions.

Hemangiomas are the most common benign neoplasms of the head and neck in children and often occur on the skin near or on the nose. Because hemangiomas often go through a period of rapid growth for the first 12 to 18 months of life

before they begin to involute, a period of observation is recommended before corticosteroids or surgical excision is considered. Recurrent bleeding, thrombocytopenia, skin breakdown, obstruction to vision, respiratory distress and cardiac failure are some indications for early intervention. Papillomas are viral-induced verrucous growths that are the most common neoplasms of the aerodigestive tract. When they appear in the nose, they are most often found on the nasal septum. Simple excision or fulguration is the preferred treatment for these lesions. In addition to these conditions, there are a variety of benign and malignant mass lesions of the nose. Early consultation with an otolaryngologist should be obtained for any tumor of the nose, especially one with recent changes in size or character.

ORAL CAVITY, PHARYNX, AND ESOPHAGUS

Methods of Examination

The oral cavity and oropharynx are directly visible with the aid of a tongue blade. A headlight or brightly lighted flashlight is required for this examination. The tongue should be displaced down and forward with the tongue blade placed on the anterior two-thirds of the tongue to avoid gagging. The examination of the nasopharynx, hypopharynx, and esophagus requires special instrumentation. The nasopharynx and hypopharynx can be examined using a flexible nasopharyngoscope. Nasopharyngoscopy requires special skills and may be best left to the otolaryngology consultant (see Procedure 17.5 in Section VII). Examination of the esophagus requires direct visualization with an esophagoscope, under general anesthesia. Palpation of the hypopharynx and nasopharynx should not be performed because it is uncomfortable to the child and potentially dangerous.

Radiography contributes minimally to the examination of the oral cavity and oropharynx because these areas are visible by direct examination. The lateral neck radiograph is useful to evaluate the nasopharynx and hypopharynx because there are good air–tissue interfaces. The esophagus can be coated with barium contrast.

Infections

Stomatitis

The most common infectious lesion of the oral cavity is the aphthous ulcer. The ulcers are often recurrent, may appear as a single lesion or a confluence of many lesions, and can cause severe stomatitis. The exact cause of aphthous ulcerations is unknown, but it is believed to be infectious.

Herpes simplex can cause severe gingivostomatitis, whereas the pharynx is relatively spared. On the other hand, Coxsackievirus infection (herpangina) causes severe ulcerative lesions of the pharynx, but not the anterior mouth. These viral infections cause severe oral pain and inability to eat. They are self-limited and require only symptomatic relief (see Chapter 84 and Chapter 124).

Candida albicans oral infection (thrush) usually appears as white patches with surrounding inflammation on the oral mucosa. It often occurs in newborns, immunosuppressed patients, and patients receiving antibiotic therapy. Nystatin is an effective treatment. The dosage is 200,000 units (2 mL) four times a day for 14 days.

Acute necrotizing, ulcerative gingivitis (trench mouth) causes painful, bleeding gums. Vigorous brushing of the teeth and gums with a soft brush promotes rapid healing. Antibiotics are of limited value.

Pharyngitis/Tonsillitis

Pharyngitis/tonsillitis (pharyngotonsillitis) may be caused by viral or bacterial organisms. Differentiating viral pharyngotonsillitis from an infection of bacterial origin is difficult on clinical grounds. A throat culture may be helpful in identifying an infection of bacterial origin. The degree of erythema and exudate may vary on the pharynx and tonsils. Bacterial pharyngotonsillitis is treated with a 10-day course of penicillin or amoxicillin. Patients with repeated debilitating bouts of pharyngotonsillitis that do not respond to a 6- to 8-week course of antimicrobial therapy/prophylaxis should be referred to an otolaryngologist for consideration for tonsillectomy and adenoidectomy.

Pharyngeal infections may spread to the peritonsillar area, causing cellulitis. The affected tonsil bulges forward and medially to touch the uvula. If pus localizes in the peritonsillar space, a peritonsillar abscess is formed. The peritonsillar abscess causes trismus. Suspected abscess formation requires immediate consultation with an otolaryngology specialist. Acute treatment of peritonsillar abscess requires systemic (24 to 48 hours of IV followed by oral) antibiotics and needle aspiration or incisional drainage (if possible) of the abscess. Occasionally, a “hot” or quinsy tonsillectomy may be required to treat the acute infection. Later elective tonsillectomy is indicated if there is a previous history of tonsillar or peritonsillar infections.

Retropharyngeal and Parapharyngeal Infection

Retropharyngeal and parapharyngeal lymph nodes may also be involved during pharyngitis and progress to abscess formation. Retropharyngeal abscess is usually easily seen on the lateral neck radiograph (Fig. 121.6). Peritonsillar, retropharyngeal, and parapharyngeal abscess must be treated with IV antibiotics and surgical drainage. (See also Infections under the section on Neck and Associated Structures.)

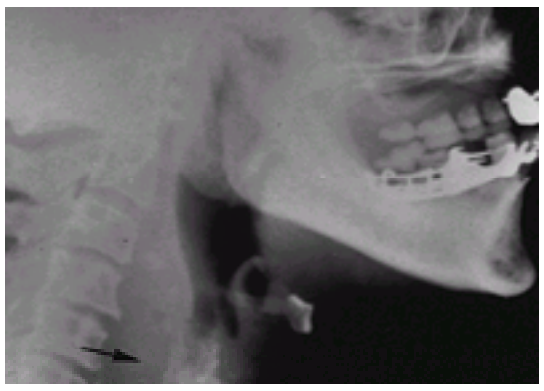

FIGURE 121.6. Lateral neck radiograph demonstrating retropharyngeal abscess *(arrow).*

One must always keep in mind that unusual infections like actinomycosis, mucormycosis, and syphilis may appear in the oral cavity. Actinomycosis appears with oral–cervical fistulas, and *Mucor* causes necrosis of the palate. Syphilis is visible in many ways (e.g., ulceration or raised lesion), and has no one characteristic appearance.

Adenotonsillar Hypertrophy

Lymphoid hyperplasia (enlarged tonsils and adenoids) can cause airway obstruction that can range from mild snoring to severe sleep apnea with right heart strain. Young children with obstructive sleep apnea are often in the lower 25th percentile by weight (failure to thrive). Older children with severe obstructive sleep apnea are often obese, and present with daytime somnolence (Pickwickian syndrome). If right heart strain or daytime somnolence is present, a tonsillectomy and adenoidectomy may be required urgently.

Neoplasms

Benign and malignant neoplasms occur in the oral cavity, pharynx, hypopharynx, and esophagus. Benign neoplasms in the oral cavity may rise from the mucosa or underlying tissues. Minor salivary gland tumors, hemangiomas, lymphangiomas, pyogenic granulomas, and neurofibromas are found in the oral cavity, but they are rarely an emergency.

Nasopharyngeal angiofibromas occur in prepubescent males and cause nasal obstruction. They may appear in the ED with massive epistaxis. Posterior packing is usually required to control the hemorrhage that may be life-threatening (see Procedure 7.2 in Section VII).

Malignant neoplasms are rare but can occur throughout the oral cavity, pharynx, and esophagus. Rhabdomyosarcoma, lymphoma, and squamous cell carcinoma (lymphoepithelioma) are the most common lesions and are rarely seen as emergencies unless there is extensive hemorrhage or a compromised airway.

Biopsy of oral, pharyngeal, and esophageal tumors is best done in the operating room where adequate exposure and control of hemorrhage is most effectively obtained.

LARYNX AND TRACHEA

Methods of Examination

Examination of the larynx is often difficult in the young child. Commonly, however, the tip of the epiglottis may be visualized when the tongue is protruded during the examination of the oropharynx. Examination of the larynx can be performed using a flexible fiberoptic endoscope. Vocal cord mobility, the structures of the larynx, and the presence of laryngeal masses can usually be assessed in this manner in a cooperative child 4 years of age or older (see Procedure 7.5 in Section VII). The otolaryngologist may need to be consulted to perform this examination for the child presenting in the ED with symptoms related to the larynx.

Lateral and anteroposterior plain radiographs of the neck can provide significant information about the larynx and upper trachea. Although xeroradiographs offer more precise detail of the airway by virtue of their property of edge enhancement, the extra radiation exposure inherent in this study makes this a less desirable imaging modality. CT and MRI scans are useful in examining the fine detail of laryngeal and tracheal structures, but the general anesthetic required to keep the child still for these examinations restricts their use to specific situations. Fluoroscopic examination of the larynx is one method of evaluating the movements of the vocal cords during phonation and respiration. Vocal cord paralysis and laryngomalacia can often be identified in this manner. Contrast studies can also be used in the evaluation of laryngeal function. A barium swallow is useful in detecting aspiration related to vocal cord paralysis, posterior laryngeal cleft, or tracheoesophageal fistula.

Infections

Viral laryngitis is often a component of the common URI described previously in this chapter. Laryngitis is manifest by a hoarse, raspy voice as a result of inflammatory edema of the vocal cords. Airway obstruction is rare in viral laryngitis. Symptomatic treatment with humidification, antipyretics, analgesics, throat gargles, and voice rest are recommended while the disease runs its natural course. When the viral infection involves the subglottic space, a more serious clinical problem appears. Laryngotracheobronchitis (croup) is a common, and potentially life-threatening, infection occurring in early childhood. The diagnosis and management of croup is discussed in other chapters of this book (see Chapter 72

and Chapter 84).

Bacterial laryngotracheobronchitis does occur, but is not nearly as common as its viral counterpart. Children age 3 to 6 years are more commonly affected by bacterial tracheitis compared with the infection of viral origin that usually appears in children less than 3 years of age. It may be difficult to distinguish bacterial laryngitis on clinical grounds from a similar infection of viral origin. Etiologic agents responsible for bacterial laryngitis include staphylococci and *H. influenzae.* Severe airway obstruction is a common symptom of bacterial laryngotracheobronchitis. This is caused by thick, inspissated secretions that fill the trachea and are difficult for the child to clear. Treatment consists of the same measures recommended for viral laryngitis with the addition of the appropriate antimicrobial agents. The otolaryngologist is usually required to perform a direct laryngoscopy and bronchoscopy to confirm the diagnosis and to aspirate the thick secretions for therapeutic and diagnostic purposes.

Diphtheria may involve the larynx, in addition to other areas of the upper aerodigestive tract. The diagnosis is suspected by the presence of a membrane covering the pharynx and larynx that leaves a raw, bleeding surface when it is removed. The diphtheria membrane can obstruct the laryngeal airway to cause respiratory distress. Endoscopic removal of the membrane and/or tracheostomy may be required, in addition to antimicrobial therapy.

Bacterial infection of the supraglottic larynx can cause a symptom complex with potentially life-threatening airway obstruction. Epiglottitis (more appropriately called supraglottitis) is an infection of the supraglottic larynx that is caused most often by *H. influenzae* type b. The diagnosis and management of epiglottitis is discussed in other chapters of this book (see Chapter 72 and Chapter 84).

Neoplasms

Neoplasms of the larynx and trachea are uncommon in children. The otolaryngologist should be consulted to assist the emergency physician in the management of these patients.

The most common neoplasm of the larynx in children is the laryngeal papilloma. This is believed to be a viral-induced neoplasm that has a predilection for the upper aerodigestive tract and the larynx in particular. The disease is usually diagnosed in the child between 2 and 5 years of age and presents with persistent or worsening hoarseness and, occasionally, airway obstruction. If papillomas are suspected as the source of hoarseness in a child, the otolaryngologist should be consulted to perform the indirect or direct laryngoscopy required to confirm the diagnosis. A lateral neck radiograph may demonstrate a soft-tissue mass in the area of the larynx (Fig. 121.7). The course of the disease is characterized by multiple cycles of growth and regression until a spontaneous remission occurs, usually around puberty. The otolaryngologist's goal in managing these patients is to maintain an adequate voice and unobstructed airway by frequent repeated excision (with cup forceps or CO_2 laser) of the papillomas. A tracheostomy may be required in cases of severe airway obstruction.

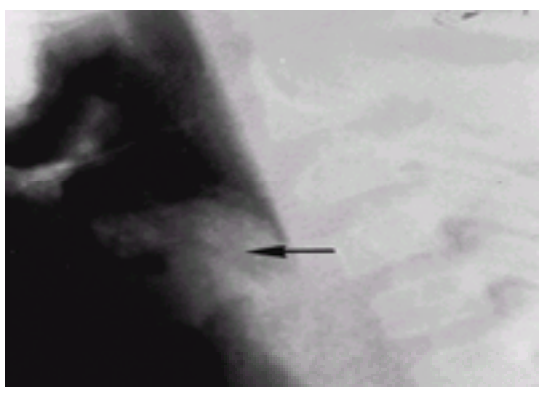

FIGURE 121.7. Lateral neck radiograph demonstrating soft-tissue density *(arrow)* at level of larynx. Direct laryngoscopy revealed this to be papilloma.

Hemangiomas may occur in the larynx, primarily in the subglottic area. As with most juvenile hemangiomas, these lesions present in the second to sixth month of life and can enlarge over several months to cause significant airway obstruction. Episodes of stridor may be precipitated by a URI. Of children with subglottic hemangiomas, 50% have other cutaneous lesions. Therefore, the presence of cutaneous hemangiomas in an infant with stridor should suggest to the emergency physician the possibility of a subglottic hemangioma. Hemangiomas may appear as posterior subglottic masses on lateral neck radiographs, but the diagnosis must be confirmed by laryngoscopy performed by an otolaryngologist. Because most hemangiomas of infancy tend to involute after an initial period of rapid growth during the first 1 to 2 years of life, close observation is the only treatment required for those lesions that are causing minimal symptoms. If there is severe, persistent, or recurrent respiratory distress, intervention is indicated. Systemic corticosteroids, CO_2 laser or direct surgical excision, and tracheostomy are some of the modes of treatment presently being advocated.

Malignant neoplasms of the larynx are uncommon. They include rhabdomyosarcoma, chondrosarcoma, and lymphoma. These tumors are seen with varying degrees of hoarseness and respiratory obstruction. If a laryngeal malignancy is suspected, the otolaryngologist should be asked to perform indirect and direct laryngoscopy to confirm the laryngeal problem and to obtain tissue for histologic identification of the tumor.

Stridor

The differential diagnosis and emergency management of a child presenting with stridor is discussed in detail in Chapter 72.

NECK AND ASSOCIATED STRUCTURES

Methods of Examination

Visual inspection and palpation provide the basis for examination of the neck and its enclosed structures. The head should be erect during the examination, with the normal prominence of the sternocleidomastoid muscle on each side. Anterior projection of the thyroid cartilage or “Adam's apple” is seen in postpubescent males. Palpation of the neck is performed to assess the normal structures in the neck and to detect the presence and nature of any cervical masses. Examination of the two sides is done simultaneously so they can be compared with one another. The examiner should be able to grasp the thyroid cartilage and move it gently from side to side without any discomfort to the patient. Immobility or significant pain may indicate the presence of laryngeal pathology. Crepitance of the neck indicates free air in the tissue planes of the neck from perforation of a hollow viscous. Passive and active range of motion of the neck should be complete in all directions. Restriction in movement may be caused by tender cervical adenopathy, cervical spine disease, spasm or fibrosis of the sternocleidomastoid muscle or meningeal irritation (Brudzinski's sign). Arterial pulses of equal strength should be palpable in the carotid artery on each side of the neck. The carotids can also be auscultated for evidence of bruits.

Radiographs are often invaluable in the examination of the neck. Plain anteroposterior and lateral views provide significant information in the evaluation of cervical problems. The presence of masses projecting into and compromising the airway can be detected. Air between the muscle planes of the neck indicates a perforation of a hollow viscous such as the pharynx, esophagus, larynx, trachea, or pulmonary alveolus. Sinus films, by identifying a neoplasm or sinusitis, are often helpful in determining the cause of a neck mass.

Infections

Cervical adenitis is the most common cause of a neck mass in a child. The lymphatic system of the neck drains the internal cavities of the head and neck (ear, nose, mouth, pharynx, sinuses, and larynx), as well as the skin and associated adnexal structures of the face and scalp. Regional cervical lymph nodes respond when there is a primary infection in any area of the head and neck. Because certain groups of nodes drain specific sites in the head and neck, the location of the swollen and infected lymph node can often help the practitioner to identify the area of the primary infection. Ear infections most often drain to the infra-auricular nodes, pharyngeal infections (e.g., tonsillitis) usually are seen with jugulodigastric node involvement, and posterior cervical nodes often accompany nasopharyngeal infections (e.g., adenoiditis).

Cervical adenitis is uncommon secondary to a brief, uncomplicated viral URI. Tender and enlarged nodes occur more often as a result of bacterial infection of the head and neck, with the ears and throat responsible for a large portion of these. Because *Streptococcus* species are the causative agents in the majority of bacterial infections in the head and neck, the infected lymph nodes usually contain the same organisms. Treatment with oral penicillin (or amoxicillin) usually clears the primary infection and causes regression of the enlarged lymph nodes. Culture of the nasopharynx, throat, or aspirate of the cervical node can assist the physician in the choice of antimicrobial agents.

Although most children will respond to the therapy just described, there is a small group of children whose nodes progress to suppurative cervical adenitis. Studies of children hospitalized with cervical adenitis have shown a predominance of *S. aureus* as the causative agent. This high incidence of staphylococci is probably the result of selecting patients who have not responded to oral antimicrobials effective against the more commonly occurring *Streptococcus* species. Therefore, if cervical adenitis has not responded to the primary antimicrobial treatment, agents should be added that are effective against *S. aureus* (erythromycin, dicloxacillin, clindamycin, or cephalosporins).

A child who has demonstrated rapid enlargement of cervical nodes, poor response to oral antimicrobials, cellulitis of the overlying skin, abscess formation, or signs of toxicity (high fever, malaise, dehydration) should be admitted to the hospital for treatment with IV fluids and antimicrobials. Surgical consultation should be obtained in the management of these complicated cases in which needle aspiration, incisional drainage, or biopsy (for possible neoplasm) may be required.

Retropharyngeal or parapharyngeal nodes are uncommonly involved with inflammatory processes that originate in the pharynx. Sore throat, dysphagia, and stiff neck are some of the symptoms that can accompany significantly enlarged pharyngeal nodes. Retropharyngeal nodes can be overlying the cervical spine during examination of the oropharynx. They also appear as widening of the retropharyngeal soft tissues on lateral neck radiographs. Parapharyngeal nodes are seldom detected clinically unless they enlarge sufficiently to deviate the tonsil and pharyngeal wall medially. Treatment of enlarged pharyngeal nodes consists of IV antimicrobials (usually penicillin) and observation of the child's airway. Biopsy of the mass is indicated if resolution does not occur with treatment or if a malignancy is suspected.

A collection of purulent material within the tissues of the neck, a neck abscess, requires prompt and specific treatment. The most common cause of a neck abscess is breakdown or necrosis of an infected lymph node. Purulent material may be located within a single node or may accumulate between several adjacent nodes. Once the process of cervical adenitis has progressed to the point of abscess formation, treatment involves evacuation of the infected material and the prevention of further spread of the infection. The child is hospitalized, and IV antimicrobials are administered that are effective against *S. aureus* (antistaphylococcal penicillin). Otolaryngologic consultation is obtained to perform a needle aspiration or incision and drainage to evacuate and culture the infected material.

Deep neck abscesses are uncommon in children, but can be extremely dangerous when they occur. Parapharyngeal abscess occurs when purulent material collects in the parapharyngeal space lateral to the pharyngeal constrictors and

medial to the vascular compartment of the neck. Necrosis of parapharyngeal lymph nodes or lateral extension of a peritonsillar abscess are the two main sources of this infection. The child with a parapharyngeal abscess presents with a stiff neck, high fever, malaise, dehydration, and other signs of toxicity. The child usually has dysphagia and may not be able to swallow his or her own saliva. Physical examination reveals diffuse swelling and tenderness of one side of the neck, but fluctuance is seldom appreciated. Intraoral examination may demonstrate medial displacement of the lateral pharyngeal wall and tonsil. Lateral neck radiographs are usually not helpful in evaluating this disease process. CT or MRI scans provide the best evaluation of suspected deep neck abscesses. If left to progress, the parapharyngeal abscess can involve the adjacent vascular structures in the neck, descend into the mediastinum, or spontaneously rupture into the pharynx, causing aspiration of purulent material.

Otolaryngologic consultation should be obtained to assist the emergency physician in the evaluation of a patient with a parapharyngeal abscess. Appropriate treatment consists of hospitalization, IV fluids, antimicrobials effective against *S. aureus* (antistaphylococcal penicillins, clindamycin, cephalosporins), and external drainage of the abscess.

Retropharyngeal abscess occurs as a result of the necrosis of retropharyngeal lymph nodes or secondary to perforation of the pharynx or esophagus. Purulent material collects between the retropharyngeal and prevertebral layers of the cervical fascia, also called the danger space. This potential space extends from the base of the skull to the mediastinum, thus allowing extensive spread of the infection. A child presents with symptoms similar to those associated with parapharyngeal abscess. Lateral neck radiographs demonstrate widening and bulging of the retropharyngeal space (Fig. 121.6). Treatment consists of hospitalization, IV fluids, antimicrobials effective against *S. aureus,* and drainage (either intraoral or external) of the abscess.

Nontubercular mycobacterial (NTM) infection is a common cause of chronic cervical adenitis in children. Also called atypical mycobacteria, the ubiquitous agent is thought to gain access to the cervical lymph nodes through oral mucosal breaks (e.g., teething, minor trauma). The usual presentation of NTM cervical adenitis is that of a non-tender, slightly fluctuant cervical mass with overlying skin that has a characteristic violaceous hue. Chest radiographs are usually normal and purified protein derivative (PPD) tests are most often reported as negative or intermediate in their response. NTM infections do not respond to anti-tubercular antibiotics. The child should be referred to an otolaryngologist to perform surgical excision that is required to cure this condition. Incision and drainage is discouraged because this will lead to a chronic draining sinus.

Salivary gland infections should be considered in the differential diagnosis of a cervical mass suspected to be infectious in origin. Both viral and bacterial agents can be responsible for the infection, with the former being more common. Mumps (endemic parotitis) is the most common salivary infection in children. Although the parotid gland is involved in more than 85% of the cases, the submandibular gland may also be involved with the viral infection. The infection appears with acute painful swelling of the involved gland or glands. There is erythema around the intraoral orifice of the salivary duct and the saliva expressed is generally clear. Treatment is supportive with clear fluids, antipyretics, and analgesics as necessary.

Bacterial infections of the salivary glands are seen with signs and symptoms similar to those associated with cervical lymphadenitis. Neonatal parotitis and, less commonly, submandibular sialadenitis usually occur in a 3- to 4-week-old child after a systemic illness has caused dehydration. The affected gland is swollen and abscess formation may occur. Purulent material may be expressed from either Stenson's or Wharton's duct by massage of the affected salivary gland. Otolaryngologic consultation should be obtained. The child is hospitalized for treatment with IV antimicrobials effective against *S. aureus* (antistaphylococcal penicillin) and surgical drainage of any collection of purulent material. Recurrent or chronic infections of the salivary glands are usually related to some predisposing factor such as stones, ductal stenosis, or secretory immunodeficiency. Management should include the detection and correction of these conditions.

Neoplasms

Neoplasms of the neck, both primary and metastatic, occur in children. If a cervical neoplasm is suspected, an otolaryngologist should be consulted to perform a complete examination of the head and neck, including endoscopy of the nasopharynx, larynx, and hypopharynx.

The hemangioma is the most common neoplasm of the head and neck in children. Although they are more common on the skin of the face and scalp, lesions can occur on the skin of the neck and involve deeper structures, such as the parotid gland. The diagnosis of cutaneous hemangiomas of the cervical skin is usually obvious on physical inspection; the lesions are red to reddish-purple, flat or raised, blanch with pressure, and increase in size with crying or straining. Deep-seated lesions without cutaneous manifestations may require special diagnostic aids such as CT or MRI scans and, rarely, biopsy to confirm the diagnosis.

These juvenile hemangiomas demonstrate a cycle of rapid growth for the first 12 to 18 months of life. Slow regression and even total disappearance occurs over the next year or two. Because of this natural history, once the diagnosis of hemangioma is made, the preferred treatment is close observation. Lesions that grow rapidly to produce complications such as airway obstruction, skin necrosis, hemorrhage, high-output cardiac failure, or thrombocytopenia require more active intervention. The child should be admitted and otolaryngologic consultation obtained. Treatment modalities presently advocated include systemic corticosteroids, cryotherapy, CO_2 laser excision, interferon, sclerosing agents, and surgical excision.

Lymphangiomas are uncommon benign lesions of the neck. Cystic hygroma is the most common type of lymphangioma found in the neck. These lesions consist of multiple cystic spaces filled with lymph and, occasionally, blood. They appear most commonly as large lateral neck masses in neonates. The diagnosis is often obvious on physical examination of a large cystic lesion that transilluminates. The natural history of these lesions is usually one of progressive growth and enlargement. Lymphangiomas can fluctuate in size secondary to a concurrent infection of the head and neck or hemorrhage into a cyst. Small, stable, asymptomatic lesions can be managed by close observation. Surgical excision is the treatment of choice for all large symptomatic lesions, with several staged procedures often being required. Aspiration

of a large cyst (or cysts) can temporarily decompress a lesion, but it is not a substitute for definitive surgical excision. Large cystic hygromas may cause feeding difficulties or respiratory distress in the newborn and may necessitate early surgical intervention, which can include tracheostomy and gastrostomy.

Less common benign neoplasms of the neck in children include teratomas, paragangliomas (carotid body tumors, glomus tumors), neural sheath tumors (neurofibromas, neurolemmomas), and thyroid and salivary gland neoplasms.

The sternocleidomastoid “tumor” of infancy is an unusual lesion that appears as a discrete mass within the substance of the sternocleidomastoid muscle in a child 4 to 8 weeks old. The cause of this localized area of fibrosis is unknown. The lesion usually resolves with range-of-motion exercises. Surgical intervention is indicated in those cases in which the fibrosis progresses to cause torticollis (see the section on Neck Stiffness, Chapter 46) or if there is suspicion of a malignancy.

The most common malignant neoplasm of the neck in children is lymphoma, being almost equally divided into Hodgkin's and non-Hodgkin's types. The disease may be localized in the neck or be a part of a more generalized disorder. Physical examination often reveals multiple firm, rubbery, unilateral, or bilateral nodes. If the diagnosis of lymphoma is suspected, otolaryngologic consultation should be obtained for a careful examination of the oral cavity, pharynx, and paranasal sinuses to look for a primary or associated lesion. This not only aids in the evaluation of the extent of the lymphoma but may also locate a site from which a biopsy can be obtained without the morbidity of a neck exploration.

Cervical lymph nodes may appear as neoplasm metastatic from a nonlymphogenous primary tumor. Thyroid carcinoma, squamous carcinoma (lymphoepithelioma) of the nasopharynx, and malignant melanoma may all be seen first with enlarged cervical lymph nodes. These nodes tend to be hard, singular, and may be fixed to underlying structures. Otolaryngologic consultation should be obtained for a complete examination of the head and neck to search for a primary lesion. Biopsy of the node is usually required for diagnosis.

Rhabdomyosarcoma is the most common soft-tissue sarcoma of the head and neck in children, and its frequency of occurrence in the neck is second only to that in the orbit. The child usually presents with a history of rapid enlargement of a painless neck mass. The mass itself is hard, often diffuse, and poorly mobile. Although the diagnosis of rhabdomyosarcoma may be suspected from the history and physical examination, biopsy is always required for confirmation.

Many other malignant neoplasms can also occur in the neck. These include soft-tissue sarcomas other than rhabdomyosarcoma, malignant fibrous histiocytoma, and neuroblastoma.

Neck Mass

The differential diagnosis and ED management of the child with a neck mass is presented in detail in Chapter 45.

Torticollis (Wryneck)

The differential diagnosis and ED management of the child with torticollis or stiff neck is presented in detail in Chapter 46. For further details, see Chapter 110 and Chapter 112.

CHAPTER 122

Urologic Emergencies

HOWARD M. SNYDER III, MD

Department of Surgery in Urology, The University of Pennsylvania School of Medicine, and Pediatric Urology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Early in their lives, children become familiar with the act of voiding and the appearance of their genitals. Disturbances of either are a great source of concern to them and their parents. This may result in an anxious trip to the emergency department (ED), requiring the emergency physician to be familiar with the problems to be discussed in this section (see Chapter 58). This chapter discusses 1) penile problems, 2) testicular problems, and 3) urinary tract infections. Renal trauma is covered in Chapter 108 and Chapter 109.

PENILE PROBLEMS

Penile Care in the Uncircumcised Male

Although the data of Wiswell and Roscelli have suggested that the presence of the foreskin may make ascending urinary infection an increased risk in newborn males, the overall low incidence of problems associated with the foreskin and the benefits from its removal lead us to continue to discourage routine circumcision. This view is common and increasing numbers of uncircumcised children are seen in EDs. Surprisingly, few physicians know how to care for uncircumcised boys. It is important to realize that, in male infants, adhesions between the glans and the foreskin are normal (Fig. 122.1). The foreskin is not normally retractable in this age group. No effort should be made to strip the foreskin back in infants because that not only produces undue pain for the child, but also may result in a raw surface, with consequent inflammation and scarring. Between ages 2 and 4, lysis of the adhesions is spontaneous in 90% of children. It is rare for the young male to have any adverse hygienic consequence from leaving the foreskin in place until spontaneous lysis of the adhesions takes place. The small, whitish lumps that may be seen and felt beneath the foreskin represent only desquamated epithelium and need not be removed. When toilet training has occurred, it is wise to teach a boy to retract the foreskin enough to expose the meatus when he voids. Not only does this facilitate better aiming, but it also avoids leaving the inner foreskin wet with urine. Ammoniacal irritation can lead to inflammatory adhesions and may create a portal of entry for a bacterial balanoposthitis. When a boy is able to retract his foreskin, usually between 4 and 6 years of age but sometimes later, he may be taught to withdraw the foreskin and carry out normal hygiene as part of bathing.

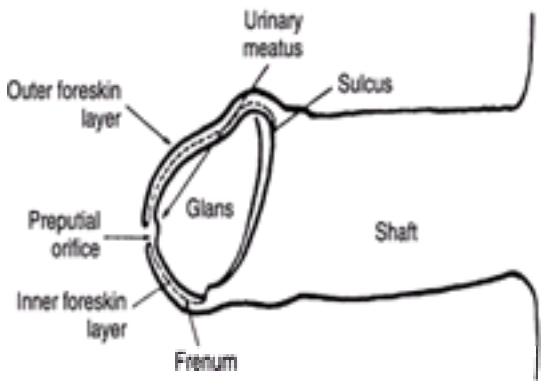

FIGURE 122.1. Anatomy of normal uncircumcised male. Adhesions between inner foreskin layer and glans are normal in newborns and prevent retraction of the foreskin. (Reprinted with permission from Wallerstein E. Circumcision: An American Health Fallacy. New York: Springer, 1980: 201.)

Phimosis and Paraphimosis

Phimosis exists when tightness of the distal foreskin precludes its being withdrawn to expose the glans. Although inflammation of the foreskin from severe chronic ammoniacal rash or infection may lead to scarring and a true phimosis, this is uncommon in children. More often, normal penile adhesions are confused with phimosis.

In the uncircumcised male, if the foreskin is retracted behind the glans and left in that position, venous congestion and edema of the foreskin results, making it difficult to reduce the foreskin to a normal position. This condition of a swollen, retracted foreskin is called paraphimosis (Fig. 122.2). The application of ice and steady local manual compression usually reduces the edema and permits manual reduction of the paraphimosis. A local anesthetic penile block of the dorsal nerve of the penis at the base of the shaft will reduce the discomfort experienced by the child during compression of the edematous foreskin. Once a portion of the edema has been reduced, pressure on glans (like turning a sock inside out) usually permits reduction of the foreskin back to its normal position (Fig. 122.3). If manual reduction fails, a surgical division of the foreskin to permit reduction is indicated (Fig. 122.4). That usually may be accomplished with sedation and local anesthetic. If surgical reduction of the foreskin is required, it should be followed a few weeks later by a circumcision. Education in the care of the uncircumcised male will reduce the incidence of this condition.

FIGURE 122.2. Paraphimosis: a foreskin that is left in a retracted position leads to venous congestion and edema of the foreskin.

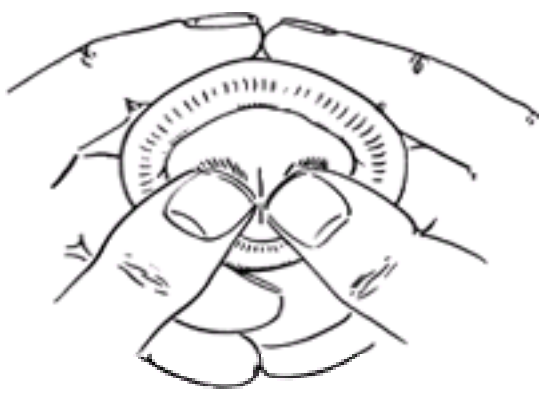

FIGURE 122.3. Manual reduction of paraphimosis. After a local anesthetic block of the dorsal nerve of the penis, the foreskin is manually compressed to reduce edema. The foreskin can be reduced by pressure on glans—like turning a sock inside out. (Reprinted with permission from Klauber GT, Sant GR. Disorders of the male external genitalia. Philadelphia: WB Saunders, 1985:827.)

Balanoposthitis

Balanoposthitis is an infection of the foreskin that may extend onto the glans (Fig. 122.5A). It is a form of cellulitis and has its origin from a break in the penile skin, commonly associated with ammoniacal dermatitis. It may be the result of local trauma or may, in the older boy, be associated with poor penile hygiene. Scarring after the inflammatory reaction may lead to true phimosis. The acute infection is dealt with adequately by warm soaks and the administration of an appropriate antibiotic, usually ampicillin (50 to 100 mg/kg every 24 hours in four doses) (Fig. 122.5B). It is unusual for a child to be unable to void as a result of this condition, although he may be more comfortable voiding while in a tub of warm water. After resolution of the acute infection, the youngster should be examined again, and, if true phimosis is present, a circumcision is advisable. One episode of balanoposthitis with a normal retractable foreskin does not indicate a need for a circumcision. However, if a child has recurrent infections, a circumcision is in order.

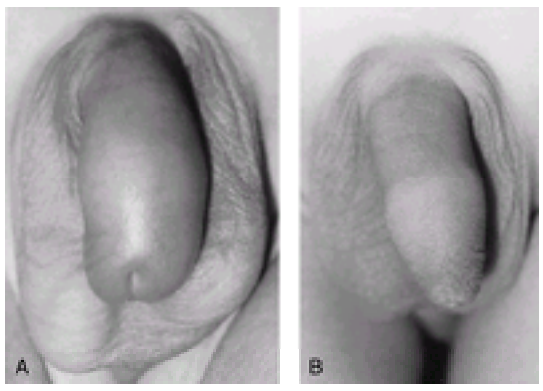

FIGURE 122.5. A. Balanoposthitis: cellulitis of normal foreskin with erythema, edema, and tenderness. **B.** Normal foreskin after treatment of balanoposthitis with antibiotics and warm soaks.

Penile Swelling

Although most penile swelling is painful and the result of either infection, as described previously, or trauma, to be described later, occasionally a child has isolated penile edema that is either nontender or minimally tender. This may result from an insect bite, with local edema secondary to histamine release. A history of a bite or the finding of a small punctate lesion may give the clue to diagnosis. Painless penile edema may be present with a generalized allergic reaction or as part of the manifestation of a general edematous state secondary to renal, cardiac, or hepatic problems. Here, the diagnosis is suggested by evidence of dysfunction in these organ systems on general examination. It is also important to remember that penile swelling may be caused by a strangulation injury (see the following).

Priapism

Prolonged, painful penile erection unaccompanied by sexual stimulation is called priapism. In the pediatric age group, this entity may be caused by trauma or leukemic infiltration, but it is most often seen in African-American males with sickle cell disease. A sickling crisis that involves the corporal bodies does not necessarily need to be related to symptomatic sickling elsewhere in the body. Sickling of the erythrocytes produces sludging and stasis in the erectile tissue of the corporal bodies. This stasis leads to further hypoxia, acidosis, and more sickling. The thick, dark sludge that is formed prevents detumescence of the erectile tissue and thus causes priapism. Pain results from ischemia. It is speculated that an inflammatory reaction to this material may lead to fibrosis of the erectile tissue. Impotence may result.

Although recommendations for treating priapism have ranged from ice or hot packs, estrogens, and spinal anesthesia to radiation therapy, the best treatment for priapism associated with sickle cell diseases now appears to be hydration and irrigation of the corporal bodies with saline in combination with vasoactive substances. This is best carried out with urologic consultation. Although priapism has been documented to lead to impotence in some cases, impotence is rare in priapism related to sickle cell disease, unless the patient has been subjected to a surgical procedure. It may be that the more difficult cases are the ones most likely to come to surgical treatment, and impotence thus may reflect more the basic disease, rather than the type of treatment.

Meatal Stenosis

Meatal stenosis is a problem almost exclusively of circumcised males and follows an inflammatory reaction around the meatus, usually the result of the lower edge of the meatus rubbing against a wet diaper with inflammation of the meatus resulting from mechanical and ammoniacal chemical dermatitis. Meatal stenosis is rare in the boy who has a circumcision after becoming continent. Appearances are often deceiving. The meatus may appear to be stenotic, but may be functioning adequately. Significant meatal stenosis causes spraying of the urinary stream or more commonly, dorsal deflection of the stream. Surgical treatment of the meatus is warranted only if these symptoms are present. Meatal stenosis is not a cause of frequency, enuresis, or urinary tract infection. When it is indicated, we carry out a meatotomy in our office after application of topical penile anesthesia with EMLA Cream and the infiltration of a small amount of Xylocaine with epinephrine into the ventral edge of the meatus. A general anesthetic usually is neither necessary nor indicated.

Penile Trauma

Direct Injury

The most common cause of direct injury to the penis comes from the toilet seat's falling on the penis of a little boy who is learning to stand at the toilet to void. Although the resulting penile edema may be notable, significant injury to the corporal bodies or urethra is rare. Although parents may be concerned that the child will be unable to void, this generally is not a problem, but the child may be more comfortable voiding in a tub of warm water. The only treatment required is warm soaks and expectant observation.

After blunt or sharp trauma, if blood is seen at the urethral meatus, urethral injury must be considered and a retrograde urethrogram carried out. Pediatric urologic consultation is appropriate, as is follow-up for possible stricture formation (see Chapter 109).

If a child is seen for a laceration of the shaft of the penis, it is important to be certain that the corporal bodies and urethra have not been injured concurrently. When a question exists, pediatric urologic consultation, retrograde urethrogram, and exploration under anesthetic may be needed. For simple lacerations of the penile skin, repair with chromic catgut suffices. It should be recalled that a child who has any form of a genital injury may be a victim of sexual abuse (see Chapter 128).

Zipper Injury

Boys often seem to be in a hurry and sometimes fail to get their penis or foreskin completely back in their pants before they pull up the zipper. This results in the entrapment of penile skin or foreskin in the teeth of the zipper. The teeth may be so engaged that it is impossible to simply unzip the zipper. Often, the problem may be dealt with simply, as shown in Figure 122.6. The median bar of the zipper may be cut with a pair of wire cutters, which will permit the two halves of the zipper to fall apart, releasing the entrapped skin. Mineral oil has also been used to allow the tissue to slide free of the metal zipper. Local infiltration of Xylocaine makes this procedure less traumatic to the child. Only rarely is a general anesthetic required. After the zipper is removed, the penis may become edematous, but generally nothing more than warm soaks is required for further treatment.

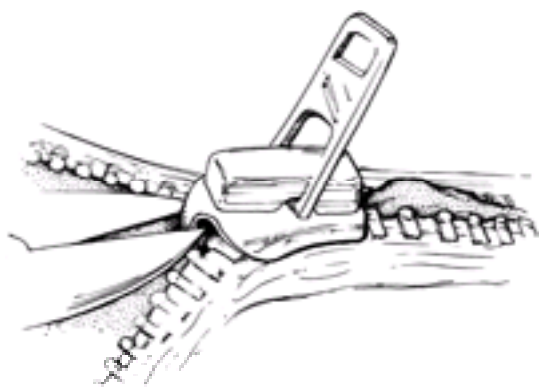

FIGURE 122.6. Penile zipper injury. A wire cutter may be used to cut the median bar of the zipper, releasing the two sides of the zipper and freeing the penis.

Strangulation

The penis may be encircled by a constricting ring formed by hair or a fiber or a thread, just as occurs with digits. Many times the cause of the problem is not immediately evident, because local edema may hide the ring of hair. The edema is produced by venous engorgement, which takes place early, after the development of this type of constriction around the penis. Once the source of the problem has been identified, therapy requires the division of the hair and the release of the constriction. This may require a general anesthetic. Pediatric urologic consultation is advisable. A urethrocutaneous fistula or even the loss of the penis has been reported, but is rare. How the hair comes to encircle the penis is generally unknown, but it should be remembered that such constriction occasionally has been reported as a form of sexual abuse.

TESTICULAR PROBLEMS

Background

Primordial germ cells have their origin in the entoderm of the yolk sac. By the fifth week of intrauterine life, they have reached the ventromedial portion of the urogenital ridge, the portion destined to form the testes. A mesodermal cord, the gubernaculum, becomes attached to the bottom of the testis at the epididymis and runs to the bottom of the scrotum. With rapid growth of the trunk, the testes lie adjacent to the internal ring by the third month of gestation. The testes remain at this location until the seventh month when, preceded by a fold of peritoneum (the processus vaginalis), the testes move down the inguinal canal and reach their final scrotal position shortly before birth. This fact accounts for the higher incidence of undescended testis in premature boys.

The gubernaculum appears to have an important role in testicular descent, although the exact nature of that role remains incompletely understood. Acute conditions involving the testes are discussed in Chapter 58.

Retractile Testis

In the physical examination of the child in the ED, an empty scrotum on one or both sides is a common finding. Although the testis may be found to be truly undescended, more often it is merely a retractile testis. In a boy with a retractile testis, the active cremaster muscle attached to the small prepubertal gonad is able to draw the testis up into a position near the pubic tubercle. There is no evidence that this causes any harm to the gonad. When the testis enlarges at puberty, it will assume a scrotal position permanently because the cremaster is no longer able to draw it out of its more normal position. The diagnosis of a retractile testis is made when one is easily able to milk the testis down into a position in a dependent portion of the scrotum where the testis stays, at least briefly, after overstretch of the cremaster muscle. In an obese youngster, it may be difficult to grasp the testis to pull it down. It is worthwhile putting a youngster in a “catcher's position,” in which the testis is pushed down to where it can be grasped and drawn into the scrotum. If the testis can be pulled into the scrotum but, regardless of how much the cremaster is overstretched, the testis “pops up” when released, this is a low form of a true undescended testis and not a retractile testis. This is a common diagnostic difficulty and pediatric urologic consultation should be sought if the situation is questionable.

Undescended Testis

True undescended testes are seen in 4% of newborn males. That instance decreases to 1.6% by 1 year of age, indicating that some undescended testes do descend after birth. Spontaneous descent rarely occurs after 6 months of age. Although it may be appropriate to continue for a few months to observe an infant who has an undescended testis, the child older than 6 months of age should have urologic consultation.

Testicular malignancy and infertility are increased in the male with an uncorrected undescended testis. By electron microscopy, it is possible to demonstrate degenerative changes in the undescended testis by 1 year of age. Early referral to a urologist for orchiopexy (before age 2 and preferably near age 1) appears advisable because data are now accumulating that indicate early surgery may decrease the incidence of both testicular malignancy and infertility.

Usually, an undescended testis is asymptomatic. However, in a position against the abdominal wall, it may be more subject to trauma than when freely mobile in the scrotum. The undescended testis also is malfixed and may undergo torsion more easily than a normally descended one. The boy who presents with an acutely tender groin mass with an ipsilateral empty scrotum may have a torsion of his undescended testis. The physician must consider the differential diagnosis of an incarcerated inguinal hernia or acute hydrocele of the cord. Prompt surgical treatment is required.

Varicocele

Varicoceles are abnormal dilations of the cremasteric and pampiniform venous plexuses surrounding the spermatic cord (Fig. 122.7). They generally present as an asymptomatic scrotal swelling about the time of puberty and are rare in the prepubertal boy. Almost all are of congenital origin and affect the left testis. The anatomic problem is a defect in the valves of the left spermatic vein that, on the left, drains directly into the left renal vein. Why varicoceles often are not noted until a boy approaches puberty is unclear, but they are common in that age group, affecting about 15% of adolescent boys. If the varicocele does not disappear when the child lies down, it suggests a varicocele secondary to obstruction of the left renal vein, and a renal and bladder ultrasound is appropriate. Varicoceles are rarely symptomatic; a heavy or tugging sensation is occasionally reported.

FIGURE 122.7. Varicocele: abnormal dilation of cremasteric and pampiniform venous plexuses surrounding the spermatic cord, giving scrotum the appearance of a “bag of worms.”

Approximately 15% of these boys with a varicocele will have an adult problem with infertility, although the exact mechanism of injury to the spermatogenic elements remains to be defined. Thus, periodic examination of these boys as they progress through pubertal change is recommended. As in the postpubertal testis, more than 80% of testis volume is a result of the spermatogenic elements; testis size is generally accepted as an indication of the effect of the varicocele on testis function. Although testicular asymmetry is common during pubertal change, a progressively smaller ipsilateral testis over 2 years or more of follow-up is an appropriate indication for surgical or radiographic treatment of the varicocele. “Catch-up” enlargement may occur after treatment of the varicocele. In our experience, any form of treatment is needed in only a small minority of cases. However, controversy exists on this point and long-term follow-up of adolescent boys with a varicocele is insufficient to permit firm conclusions.

URINARY TRACT INFECTIONS

Background

Urinary tract infection (UTI) ranks behind upper respiratory problems as the second most common form of bacterial infection in children. Between 1 and 2% of infants and children have bacteriuria at any given time, and 5% of all girls have UTI during their school years. Most UTIs result from fecal bacteria on the perineal skin ascending the urethra. The short female urethra, with resultant ease of bacterial contamination of the bladder, accounts for the higher incidence of UTIs in girls. The uncircumcised male infant appears also to be at increased risk of ascending urinary infection because foreskin bacterial colonization may lead to increased meatal contamination. However, as the absolute risk of UTI in infant males is in the order of 1%, it is questionable to suggest the risk of UTI is an indication for routine circumcision.

It is now recognized that the major risk factor in the development of UTI is the physical nature of the uroepithelium lining the urethra and bladder. In some children and adults, adherence factors in the mucosa lead to recurrent episodes of symptomatic infection. In addition, some bacteria (piliated ones) have increased adherence characteristics that add to the risk of invasive infection. Because voiding dysfunction may also contribute to recurrent infection, this is another reason to consider pediatric urologic consultations, especially in the older child who persists with wetting after appropriate treatment of infection.

A UTI may be defined as the multiplication of bacteria in the urinary tract. Normally, urine from the bladder and upper urinary tract should be sterile. The concept of “significant bacteriuria” (³$10^5$ organisms per milliliter of one colony type) in a cleanly voided midstream specimen is based on the statistical likelihood that this colony count is associated with the actual presence of bacteria in the bladder. A colony count of 10^5 or more organisms per milliliter of a single type suggests infected urine, with an 80% confidence level. Reliability can be increased to 95% if a second culture confirms the presence of the same bacteria type with identical antibiotic sensitivity; 10^4 to 10^5 bacteria per milliliter is an equivocal result and requires repeat culture. Less than 10^4 organisms per milliliter or the presence of several different organisms, suggests no infection or contamination of the specimen (see Chapter 84).

Clinical Manifestations

Particularly in the infant, UTIs may produce nonspecific findings. The urine may be cloudy or have a foul odor. There may be a history of unexplained fevers, general irritability, or failure to thrive and gain weight normally. Gastrointestinal (GI) symptoms are common, and many times the youngster with a UTI is believed to have gastroenteritis or a food allergy. A high index of suspicion is required. If a urine culture is not obtained, the source of the child's problem will be missed.

In the older child, symptoms may point more directly at the urinary tract. Frequency, urgency, and dysuria are produced by inflammation of the bladder and urethra. A previously toilet-trained child may begin to have “accidents.” Particularly in girls, hematuria may be seen. Although symptoms do not provide a completely reliable way of differentiating cystitis from pyelonephritis, the presence of systemic findings such as a high fever and malaise or abdominal/flank pain suggests renal involvement. A UTI, especially when chronic, may also have few or no symptoms. It is important to emphasize that in children, anything that irritates the urethral meatus may produce dysuria and occasionally urgency and frequency (see Chapter 54). The source of the irritation may be a tight or moist bathing suit or underwear or an ammoniacal rash. Bubble bath or other soap in contact with the urethral meatus may not only produce these symptoms, but, by producing inflammation, contributes to the ascent of bacteria up the urethra and the development of true infection. To avoid being confused by a noninfectious cause of symptoms, it is important that UTIs be proven by urine culture and not diagnosed by history and urinalysis alone.

Escherichia coli is the most commonly isolated organism responsible for UTI in children, constituting 80 to 90% of the total. This is because of the prevalence of the organism in GI tract flora, as well as its short mean-generation time, which enables it to multiply rapidly once it has entered the bladder. The other organisms commonly found can be seen in Table 122.1.

Escherichia coli	*Proteus* species
Klebsiella pneumoniae	*Pseudomonas aeruginosa*
Streptococcus faecalis (enterococcus)	*Staphylococcus epidermidis*

Table 122.1. Bacteria Commonly Causing Urinary Tract Infections

Management

The first step in management is to make an accurate diagnosis. The presence of pyuria does not provide an accurate criterion for the diagnosis of UTI. At least 20% of children with pyuria do not demonstrate significant bacteriuria. In any febrile illness, mobilization of the peripheral leukocyte pool may be adequate to produce the presence of white cells in the urine. Conversely, a child with bacteriuria occasionally does not demonstrate pyuria. Bacteria demonstrated by Gram

stain of an unspun urine specimen are more reliably indicative of a UTI. However, it is difficult to determine whether one type of bacteria or several different contaminants are present. Thus, culture of the urine must continue to be the benchmark for the diagnosis of a UTI in children. Obtaining an adequate urine specimen for bacterial culture is the most critical step in diagnosing UTI. A cleanly voided specimen obtained as a midstream catch after washing of the periurethral area is the preferred technique in the toilet-trained child. Simple soap and water washing of the periurethral area is preferred because antimicrobial soaps or solutions may become mixed with a voided specimen and lead to a false-negative result.

In the infant, obtaining an adequate urine specimen is more difficult. Specimens collected in a plastic bag (U-bag) attached to the perineum are rapidly contaminated by perineal bacterial skin flora. If a culture from a bag is sterile, it is acceptable. However, the demonstration of bacterial growth must be confirmed by some other means before a bona fide UTI can be presumed to be present. The most reliable way to obtain a confirming specimen of urine is by suprapubic aspiration of urine from the bladder, a procedure that is not dangerous and that has a reliability approaching 100%. The procedure for performing suprapubic aspiration is covered in Section VII. A specimen obtained by urethral catheterization is an acceptable alternative. If it is essential that the first specimen be the definitive one for diagnosis of UTI, as in the infant undergoing septic workup, the primary use of these techniques is justified. When symptoms strongly suggest the possibility of a UTI, beginning antibiotic therapy as soon as an adequate urine specimen for culture has been obtained is recommended. The matter of just 1 or 2 days before the institution of antibiotics may make a difference in the degree of eventual pyelonephritic scarring. If the urine culture turns out to be negative, the antibiotics may be stopped. Table 122.2 lists the most commonly used outpatient antibiotics for urinary tract infections.

Drug	Oral Dosage	Number of Doses
Trimethoprim–sulfamethoxazole	1 mL suspension/kg/day	2
Sulfisoxazole	120 mg/kg/day	4
Nitrofurantoin	5–7 mg/kg/day	4
Amoxicillin	50–100 mg/kg/day	3
Cephalexin	50–100 mg/kg/day	4

Table 122.2. Antibiotic Agents for Urinary Tract Infections

Although any of these antibiotic choices is acceptable in the initial therapy of a urinary tract infection, trimethoprim–sulfamethoxazole has become most commonly used in recent years because of its acceptance by children and high efficacy. Nitrofurantoin, although effective, can produce GI upset (lessened by taking with meals) and is less well tolerated by most children. Methenamine mandelate is not useful unless there is urinary stasis and acid urine, and accordingly has little role in most childhood UTIs. Tetracycline is not recommended for the child less than 10 years of age because of its potential for discoloration of the teeth. When the organism causing UTI is sensitive to the antibiotic selected, the urine is usually sterilized rapidly. It is advisable to repeat a culture 48 hours after starting an antibiotic. The continued presence of infection suggests inaccuracy of the sensitivity, noncompliance, or obstruction.

If a child is sufficiently toxic to warrant hospitalization, the intravenous administration of antibiotics is appropriate. The drugs of choice while cultures are pending are a cephalosporin or aminoglycoside, singly or in combination.

The duration of therapy has been a subject of recent debate. For uncomplicated cystitis, 1 to 3 days of therapy is usually adequate. For children who have not been radiographically evaluated or for any child with a congenital anomaly, a 10-day course of antibiotics continues to be recommended.

Other factors in the treatment of UTI involve high fluid intake with regular and frequent voidings to promote bladder washout of bacteria. If the child has a history of wetting, infrequent voiding, or frequent urge episodes, the possibility of dysfunctional voiding, which can contribute to recurrent infections, should be considered and appropriate consultation obtained. Avoiding constipation helps ensure better bladder emptying. Good perineal hygiene, including wiping from front to back after a bowel movement, is important. Eliminating pinworms prevents a source of inflammation, excoriation, and secondary increase in perineal skin flora. Bubble bath, by producing inflammation at the meatus, may promote the ascent of bacteria and should be avoided. Acidification of the urine with oral vitamin C or juices high in citric acid content may be useful to produce an acid urine in which bacteria multiply less rapidly.

Urologic Follow-Up and Radiographic Investigation

A suppressive dose of antibiotics should be begun after the acute phase of full-dose treatment. It is customary to use one-third to one-half the dose of antibiotic used for acute treatment, usually administered in a once-a-day evening dose. Suppressive antibiotics reduce the likelihood of recurrent infection, pending urologic consultation and radiographic investigation.

The routine radiographic evaluation of a urinary tract infection is by means of a voiding cystourethrogram (VCUG), followed by an ultrasound examination of the kidneys and bladder. These studies are usually carried out about 2 to 4 weeks after the acute treatment of a UTI; however, failure of a child to respond promptly to appropriate antibiotic therapy should lead to the urgent performance of an ultrasound examination to rule out urinary obstruction. The cystogram must include a voiding phase, or significant pathology may be missed, particularly vesicoureteral reflux, which may be evident

only on voiding films. In the usual child with a UTI, cystoscopy contributes little to the initial investigation; therefore, it is not recommended.

All boys should be investigated after their first UTI. In girls, the usual recommendations have been to wait until a second infection before recommending urographic investigation. However, Kunin's data demonstrate that after one UTI, there is an 80% likelihood of a second episode of bacteriuria and that half of these children will be asymptomatic. Thus, it appears justified to carry out radiographic studies after a first documented infection in girls, as well as boys, or at the least to follow girls who have recovered from a first UTI with repeat cultures at regular intervals.

In approximately 50% of infants and 30% of older children, an anatomic abnormality is found in association with a UTI. The most common finding is vesicoureteral reflux. Reflux permits infected urine to ascend to the kidney, where pyelonephritic damage may occur. With linear growth of the child, many milder cases of reflux may spontaneously resolve, leaving surgical management primarily for the more severe cases. These decisions are best made in consultation with a pediatric urologist.

As for the child who has no abnormality demonstrated by ultrasound and VCUG, the parents can be reassured that although the child may have a symptomatic problem from cystitis, there is little likelihood of renal damage. Occasionally, if a child has frequent episodes of symptomatic cystitis, suppressive antibiotics are justified in order to reduce the morbidity of these infections. The primary factor responsible for the development of urinary infection appears to be an adherent uroepithelium, which leads bacteria that ascend the urethra to stick to the bladder lining and become invasive. Children, like adults, who have such bladder lining may experience several UTIs per year. Surgical manipulations, such as urethral dilation, do nothing to change the basic bladder problem and are no longer performed. When infections recur in rapid sequence, this may indicate the colonization of the GI bacterial flora by organisms with increased adherence characteristics. Fortunately, during 3 to 6 months of suppressive antibiotic therapy, these organisms tend to modulate to less adherent bacteria. It should also be borne in mind that children with dysfunctional voiding patterns also tend to be troubled with frequent UTIs. Thus, if a child has an abnormal voiding pattern when uninfected (wetting, infrequent voiding), a pediatric urologic assessment is in order.

ACUTE URINARY RETENTION

A patient with acute urinary retention is unable to empty the bladder even though it is full. In children, as in adults, the cause may be a urethral obstruction. Congenital lesions, such as urethral valves, or acquired lesions, such as posttraumatic strictures, may lead to urinary retention. In such cases, a careful history often elicits symptoms of a weak stream or difficulty initiating the stream. Children who have any form of urethral irritation and dysuria may voluntarily retain urine. That is a different situation and needs to be separated carefully from organic obstruction causing retention. For the child with voluntary retention, gentle massage of the lower abdomen combined with a soak in a warm tub usually leads to spontaneous evacuation of the bladder. Rarely does a child's bladder become so distended, as after an outpatient surgical general anesthetic, that the child is unable to void. A simple one-time emptying of the bladder by catheterization with a feeding tube usually corrects the problem. It should be remembered that a child is able to hold urine voluntarily for longer periods than would be suspected; up to 12 hours is not unusual. Unless the child has a history suggestive of an organic obstruction or has a palpably enlarged bladder that cannot be emptied by massage and warm tub soaks, instrumenting the child's urethra should not be considered. Urologic consultation would be advisable before undertaking such maneuvers.

CHAPTER 123

Orthopedic Emergencies

***MARK D. JOFFE, MD and †JOHN LOISELLE, MD**

**Department of Pediatrics, The University of Pennsylvania School of Medicine, and Pediatric Emergency Medicine, Community Pediatric Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania; †Emergency Services, A. I. duPont Institute, Wilmington, Delaware*

ORTHOPEDIC CONDITIONS

Most orthopedic emergencies are related to trauma (see Chapter 115). Anecdotes abound, however, of non-traumatic orthopedic problems that present as injuries. A history of a recent fall is prevalent, perhaps ubiquitous, in active young children. Parents, seeking to understand their child's complaint, assume a painful extremity is the result of a recent mishap. Physicians must not be misled. The non-traumatic orthopedic conditions described in this chapter are especially important to consider when a reported injury mechanism is minor, or onset of symptoms is delayed. Evaluation of children with complaints such as limp (see Chapter 43), joint pain (see Chapter 57), and back pain (see Chapter 51) to name a few, requires consideration of traumatic and non-traumatic causes. Overuse syndromes may occur at any age and can present as trauma. Children train more intensively and at younger ages than in previous years, resulting in overuse syndromes. With knowledge and appropriate suspicion, physicians caring for children can identify non-traumatic orthopedic problems, begin treatment, and make intelligent recommendations about referral.

Osteomyelitis

Background

Osteomyelitis is an inflammation of the bone, most commonly of infectious origin. Infection is confirmed by the presence of two of the following: pus on an aspirate of the bone, clinical findings consistent with the diagnosis, positive blood or bone aspirate cultures, and radiologic imaging. Osteomyelitis is more common in boys, and several studies have found the highest incidence among infants and preschool children. Age and underlying disorders are associated with an increased risk for contracting osteomyelitis, as well as for the particular pathogens involved.

Pathophysiology

Infection occurs by one of three routes: hematogenous, direct spread, or inoculation through a penetrating wound. Hematogenous spread is the most common route in children. A transient bacteremia is believed to be the initiating event in the infection. Bacteria enter the bone at the level of the metaphysis through the predominant vascular supply of the bone. The sluggish blood flow within the microvasculature of the marrow predisposes to infection. Local trauma has been suggested as a possible cause of micro-thrombotic events further predisposing bone to infection. This is supported by the preponderance of infection occurring within the long bones, especially those of the lower extremities. In sickle cell patients micro-infarcts within the more tenuously supplied area of the diaphysis may explain the increased occurrence in this region of the bone. As infection progresses, pressure increases, and organisms penetrate up through the cortex to the subperiosteal space. If left untreated, the infection may spread along this space or rupture through the periosteum into the surrounding soft tissue.

Differences in the underlying bony structure in the neonate and young infant predispose them to a higher incidence of multi-focal osteomyelitis and concomitant septic arthritis. The periosteum is less adherent in these ages and less

effective in limiting the spread of infection. Transphyseal vessels, which are present up to 18 months, allow bacteria to gain access to the adjoining epiphysis and joint space.

A less common source of osteomyelitis in children is penetration of the periosteum by local infections. Inoculation of the bone from stepping on a nail, surgical instrumentation, or intraosseous line placement, provides a third means for infection to gain entrance to the bone. With either mechanism of infection, osteomyelitis can progress to chronic osteomyelitis that may have deleterious effects on growth.

Clinical Findings

Physical signs of osteomyelitis are age dependent. The older child is more likely to have localized infection and is more capable of expressing or identifying a site of localized point tenderness. The neonate or young infant may present with a pseudoparalysis of the affected limb. Another common, although nonspecific, finding in this age group is paradoxic irritability in which the infant exhibits pain or distress upon handling, and is more comfortable when left alone.

Fever and pain are highly sensitive findings but not universally present. Fever is described in up to 90% of children with osteomyelitis upon presentation and may be quite elevated. Pain is expressed through limp, refusal to bear weight, or a decreased range of motion when a limb is involved. Erythema and swelling are less common, but can also be observed at the site and usually suggest more advanced periosteal involvement.

Diagnosis

In addition to clinical findings, the diagnosis of osteomyelitis depends on culture results. Blood cultures and bone aspirates should be obtained in suspected cases of osteomyelitis before the initiation of antibiotics. Isolation of the causative organism is important not only in diagnosis, but also in antibiotic selection and the possibility of eventual outpatient therapy. Reports of positive blood cultures range from 30 to 57%. An organism is recovered from a bone aspirate in 51 to 90% of cases. The combination identifies a pathogen in 75 to 80% of cases. Bone aspirates may remain positive for several days after antibiotic use, whereas blood cultures are often sterile within 24 hours of antibiotics.

Laboratory tests vary in sensitivity. The white blood cell (WBC) count is elevated in only a third of the cases of osteomyelitis, whereas both the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are elevated in more than 90%. The latter tests are useful both in diagnosis and for monitoring the response to therapy.

The plain radiograph is the initial imaging study of choice. It is useful both in detecting early signs of osteomyelitis and excluding other diagnostic possibilities. The earliest radiograph changes suggestive of osteomyelitis include deep soft-tissue swelling with elevation of the muscle planes from the adjacent bone (Fig. 123.1). These may be seen as early as 3 to 4 days after the onset of symptoms. Lytic bone changes are not detectable until 7 to 10 days. Periosteal elevation, when present, is not generally visible until 10 to 21 days after infection (Fig. 123.1). A negative radiograph in the first 10 days of illness does not rule out osteomyelitis. When suspicion remains high in the setting of a negative radiograph, a bone scan should be obtained. The triple phase technetium bone scan has a reported sensitivity and specificity of more than 90%, and detects osteomyelitis within 24 to 48 hours of symptom onset. A bone aspirate preceding a bone scan will not cause a false-positive result.

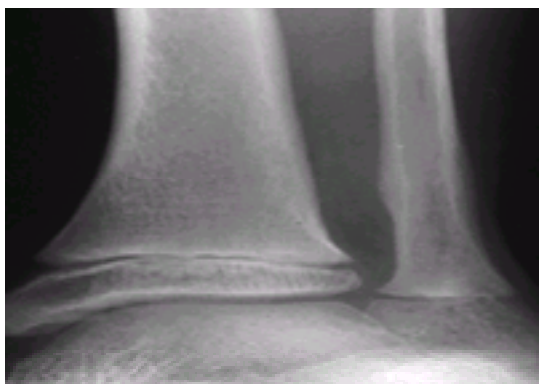

FIGURE 123.1. Periosteal activity in distal fibula in child with *Staphylococcus aureus* osteomyelitis; day 20 of illness.

Other imaging modalities, including magnetic resonance imaging (MRI), computed tomography (CT), and ultrasound, may have a limited role in certain complicated cases or to obtain further details of the infection, but they should not replace the plain film or bone scan in the acute setting.

Microbiology

Organisms responsible for osteomyelitis differ according to the patient's age and the route of infection. *Staphylococcus aureus* is the most common pathogen across all age groups. Epidemiologic data gathered before availability of the *Haemophilus influenzae* type b (Hib) vaccine showed *H. influenzae* to be a common organism in children less than 2 years of age. Although there is evidence of a dramatic decline in the incidence of invasive *H. influenzae* disease since the advent of the Hib vaccination, most experts still recommend that initial antibiotic coverage include *H. influenzae* for children less than 5 years of age. Bacterial isolates from neonates less than 2 months include *S. aureus,* group B streptococcus, and *Escherichia coli,* and antibiotic coverage should reflect this.

Certain groups are at risk for particular organisms. Patients with sickle cell disease have a high incidence of osteomyelitis caused by *Salmonella. Pseudomonas aeruginosa* is the predominant organism found in osteomyelitis of the foot, resulting from a nail penetrating a sneaker.

Management

Initial therapy for osteomyelitis includes intravenous antibiotics. Antibiotic coverage should be based on the predominant organisms in each age group, the mechanism of infection, and Gram stain results. Suggested agents are listed in Table 123.1. Early aggressive antibiotic therapy often prevents the need for surgical intervention.

Age	Pathogens	Antibiotics
Neonate <2 mo	*Staphylococcus aureus*, group B streptococcus, Gram-negative bacilli	Nafcillin and Gentamicin
<5 yr	*S. aureus*, group A streptococcus, *Streptococcus pneumoniae*, *Hemophilus influenzae*	Cefuroxime or Ampicillin/sulbactam Nafcillin and chloramphenicol
>5 yr	*S. aureus*, group A streptococcus, *S. pneumoniae*	Nafcillin or Cefazolin
Special Cases		
Sickle cell disease	*S. aureus*, Salmonella	Nafcillin and ceftriaxone or Nafcillin and chloramphenicol
Foot puncture wound	*Pseudomonas aeruginosa*, *S. aureus*	Nafcillin and ticarcillin or Ticarcillin/clavulanate or Nafcillin and ceftazidime

Table 123.1. Initial Antibiotic Therapy Osteomyelitis [a]

Septic Arthritis

Background

The presence of bacterial pathogens within the articular capsule presents a true surgical emergency. Delay in the identification and treatment of an infected joint in a child can result in severe and permanent sequelae. The urgency associated with this diagnosis has given rise to the maxim, “The sun should never rise or set on an untreated septic hip.” In many cases, the pediatric emergency physician is the initial point of contact, and must maintain a high index of suspicion to recognize and appropriately treat these patients at the time of the initial visit.

Pathophysiology

Bacteria gain entry to the joint space through one of three means. The synovium is most commonly infected through hematogenous seeding. The role of local injury in predisposing joints to infection is unclear. Adjacent areas of infection may invade the joint, or direct inoculation can occur through penetrating injuries. Infection secondary to penetrating objects may be delayed from the actual time of injury. External wounds may be small or healed at the time of presentation. Undetected penetration of the knee joint, for example by a sewing needle in a crawling infant, may give rise to a septic knee. A metatarsal joint infection may be the result of a nail puncture wound to the foot that occurred several weeks earlier.

Eighty to ninety percent of septic joints occur in the lower extremities. The knee and hip are most commonly afflicted. The same distribution is found in the preambulatory child. Infections involve only a single joint in more than 90% of cases. Multifocal infections are more common in neonates.

Once established within the joint, bacteria release proteolytic enzymes that directly damage the intra-articular cartilage. Pressure elevation within the minimally distensible capsule can lead to dislocation of a joint, and compromised vascular flow, resulting in ischemic injury to the bone. This is a particular concern in the hip, where avascular necrosis of the femoral head is a well-described complication of septic arthritis. Prognosis is worse in children less than 1 year old, with involvement of the hip joint, with delay to the initiation of therapy, and with infection by *S. aureus.*

Clinical Findings

Pain is the most common presenting complaint in the child with a septic joint. This may be expressed in many ways. The older child is better able to localize the area of discomfort. Because of the predominance of septic arthritis in the lower extremities, the younger child will often present with a limp, abnormal gait, or inability to bear weight.

Range of motion around the affected joint is dramatically reduced. Any degree of movement causes great distress and is vigorously resisted. Many orthopedic surgeons rely on this aspect of the evaluation more than any other in differentiating infection from alternative causes of joint pain.

Clinical signs are more subtle in the neonate or young infant with a septic joint. Nonspecific findings such as septic appearance, irritability, and pseudoparalysis of a limb are common presenting findings in these ages. Parents may note excessive irritability associated with diaper changes in the infant with a septic hip. The child with a septic hip will typically hold the lower extremity in abduction and external rotation in order to maximize the volume of joint space (Fig. 123.2). A high degree of suspicion, close observation, and isolated manipulation of each extremity help locate the particular area of

involvement.

FIGURE 123.2. Five-month-old infant with septic arthritis of the right hip. Hip joint is held in flexion, abduction, and external rotation.

The skin surface should be closely evaluated for local signs of injury. Most involved joints have obvious erythema, warmth, and swelling. The exception is the hip joint because of its deep-seated location. Swelling may be less obvious in the pudgy infant. Fever is a commonly associated sign, but is absent in up to one-third of patients.

Diagnosis

The diagnosis of septic arthritis is confirmed by the presence of purulent fluid within the joint space. Arthrocentesis is a mandatory procedure in all suspected causes of septic arthritis. The level of suspicion and decision to perform this procedure is based on the degree of clinical suspicion in combination with results of laboratory tests and imaging studies. None of these in isolation are 100% sensitive in detecting or excluding septic arthritis from other conditions. A sample of synovial fluid is essential in discriminating septic arthritis from less serious inflammatory processes.

The mean WBC count is elevated in children with septic arthritis; however, more than one-half of patients will have a WBC count less than 15,000/mm^3. The ESR and CRP are more sensitive markers and are elevated in 90 to 95% of patients.

Plain radiographs may demonstrate signs of an effusion ranging from subtle blurring or displacement of fascial planes to complete dislocation of the joint. The main role of the radiograph in the evaluation is to exclude fractures or other bony abnormalities that may mimic septic arthritis. Ultrasound is increasingly used to evaluate questionable joints, especially the hip. It is much more sensitive than the radiograph in detecting a joint effusion. Some have suggested that the absence of an effusion on an ultrasound scan effectively excludes the diagnosis of septic arthritis. However, the ultrasound cannot distinguish between infected and sterile inflammatory effusions. The bone scan localizes areas of inflammation and is unaffected by prior arthrocentesis. It cannot differentiate infection from other causes of inflammation. A bone scan may be helpful in excluding osteomyelitis. Inflammation is found symmetrically across a joint in septic arthritis, whereas in osteomyelitis, it is limited to one side. The reliability of a bone scan in differentiating joint from bone involvement decreases in the neonatal age group.

The isolation of a bacterial pathogen is important in diagnosis and in directing subsequent management. Cultures of joint fluid and blood should be performed on all patients with a possible septic joint. When indicated, cultures from additional sites should be obtained to increase the potential isolation of a pathogen. Cultures of the joint fluid demonstrate the highest yield, and are positive in 50 to 80% of cases. Blood cultures identify an organism in 15 to 46% of patients with septic arthritis, and are positive in many cases in which the organism is not isolated from the joint fluid. Cerebrospinal fluid (CSF) cultures have been helpful in the past in identifying *H. influenzae.* Cervical or urethral cultures in sexually active adolescents with septic arthritis may provide the responsible organism. A causative organism is not recovered in 20% of cases.

A Gram stain should be performed on joint fluid and occasionally provides additional assistance in identifying both an infection and the infecting organism. Although elevation of the WBC count in the synovial fluid above 100,000/mm^3 is considered strong evidence of infection, the actual counts are often much lower.

A differential with greater than 90% neutrophils is also highly suggestive of infection. Presence of purulent fluid, a positive Gram stain, and an elevated WBC count with a left shift in the synovial fluid are often used as indications for operative intervention when there is a concern of a septic hip.

Microbiology

With a few exceptions, the bacteria found in septic arthritis are the same as those in osteomyelitis. *S. aureus* is the most common reported isolate in children older than 5 years, followed by group A *streptococcus* and *Streptococcus pneumoniae.* Before the introduction of the Hib vaccine, *H. influenzae* type b was the leading cause of septic arthritis in the 6 months to 5-year-old age group. *S. aureus* is the predominant pathogen in neonatal patients. Gram-negative coliforms are also found in this age group. *Neisseria gonorrhoeae* is found in the neonatal ages and is a common pathogen in sexually active teenagers. *Kingella kingae* is a fastidious Gram-negative rod, susceptible to b-lactam antimicrobials, which has recently been isolated as a pathogen in a number of childhood bone and joint infections.

Management

The management of septic arthritis consists of parenteral administration of antibiotics (Table 123.2), joint immobilization, and joint irrigation in selected cases. Empiric antibiotic therapy is dictated by the common organisms in the age group and results of the synovial fluid Gram stain. An anti-staphylococcal agent consisting of a b-lactamase–resistant penicillin or a first-generation cephalosporin is effective in most cases. Gram-negative coverage should be added in neonates and adolescents. Until further evidence of the eradication of *H. influenzae* type b from the younger age group, appropriate coverage is recommended for children less than 5 years.

Age	Pathogens	Antibiotics
Neonate	*Staphylococcus aureus*, group B streptococcus, Gram-negative bacilli	Nafcillin and Gentamicin or cefotaxime
≤5 yr	*S. aureus*, *Hemophilus influenzae*, group A streptococcus, *Streptococcus pneumoniae*	Cefuroxime or Ampicillin/sulbactam
>5 yr	*S. aureus*, group A streptococcus	Nafcillin
Adolescent	*S. aureus*, group A streptococcus, *Neisseria gonorrhea*	Nafcillin Ceftriaxone[b]

[a]Common pathogens and empiric antibiotic coverage by age.

Table 123.2. Initial Antibiotic Therapy Septic Arthritis[a]

Surgical intervention for joint irrigation is generally indicated for all cases involving the hip joint, infections in which large amounts of fibrin, debris, or loculations are found within the joint space, or when the patient fails to improve after several days of intravenous antibiotic therapy. Expeditious and aggressive management limits, but does not eliminate, potential sequelae of septic arthritis.

Toxic Synovitis

Background

Toxic or transient synovitis is a benign, self-limiting inflammatory process of the hip. It afflicts males more often than females and is the most common cause of acute hip pain in children 3 to 10 years of age. The underlying cause is unknown, although a post-infectious inflammatory response has been suggested. Its presentation can mimic that of septic arthritis of the hip (Fig. 123.3), a distinction that is as crucial in management as it is difficult in diagnosis.

FIGURE 123.3. Seven-year-old child with toxic synovitis of the left hip. Hip joint is held in same position of comfort as in septic arthritis.

Clinical Findings

The onset of symptoms is abrupt with unilateral hip pain and limp (Fig. 123.3). Fever is rare, occurring in less than 10% of cases, and, when present, is usually low grade. Although patients complain of discomfort with movement of the limb, it generally remains possible to put the hip through a full range of motion. This contrasts with the septic hip in which pain and spasm are more extreme, and patients resist a full range of motion. Additional signs of systemic illness are absent and, despite the title, the child is nontoxic appearing.

Laboratory

Laboratory tests are generally useful only in attempting to distinguish toxic synovitis from more serious conditions. The WBC count and ESR are generally normal or only slightly elevated. The mean WBC count and ESR are significantly lower than in septic arthritis; however, sufficient overlap exists between values in toxic synovitis and septic arthritis such that they cannot be relied on to distinguish between them in individual patients.

Radiographs may demonstrate an effusion, but its principal role is in excluding pathologic osseous conditions. Ultrasound is more sensitive than plain films at detecting joint effusions, although accuracy declines in patients under a year. Reports of an effusion of the hip by ultrasound in toxic synovitis vary from 50 to 95%. Although patients often report relief of pain after aspiration, the procedure is unnecessary except to exclude the presence of a bacterial infection. When obtained, synovial fluid is sterile.

Management and Prognosis

Treatment occurs on an outpatient basis and emphasizes rest and analgesics. Traction is of unproven benefit and is potentially harmful. Nonsteroidal anti-inflammatory medications are the first-line therapy for pain. Pain duration is typically 3 to 4 days but may last as long as 2 weeks. Exacerbations can occur if activity is resumed too early.

There is no evidence of serious sequelae resulting from toxic synovitis. The relationship between toxic synovitis and Legg-Calve-Perthes disease is unclear. Studies have been unable to demonstrate cause and effect. Some suggest that these patients are at increased risk for developing Legg-Calve-Perthes, and others only that the clinical presentations are similar.

Penetrating Intra-Articular Wounds

Penetrating intra-articular wounds are not specific to children, but they are injuries that the pediatric emergency physician must recognize and treat on an urgent basis to prevent serious and potentially permanent sequelae. Knees are the most commonly injured joints. Motor vehicle accidents are the cause in the overwhelming number of cases.

An open joint may be detectable on direct visualization or by palpation through a periarticular laceration. Injuries that extend below the skin surface adjacent to a joint effusion should raise a high level of suspicion that the joint space has been violated. The presence of air in the joint on radiograph is diagnostic for joint penetration (Fig. 123.4). In less obvious cases, disruption of the joint capsule can be demonstrated by the saline load test. Arthrocentesis is performed through an uninjured site on the skin surface and saline is injected. Extravasation of saline from the joint into the wound is diagnostic for penetrating injury. A volume of 60 mL of saline is generally adequate to evaluate knee joint integrity, 20 mL for elbow or ankle joints, and 1 to 2 mL for finger joints. The addition of a small amount of methylene blue to the saline may improve visualization of extravasated fluid. Voit et al. found that clinical evaluation had poor sensitivity in identifying penetrating wounds compared with saline injection. If a question still remains regarding the integrity of the joint after such testing, then further imaging studies or surgical exploration is necessary.

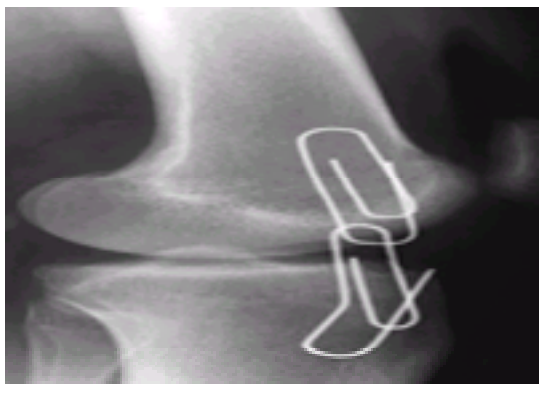

FIGURE 123.4. Intra-articular air in knee joint following penetrating injury sustained in a motor vehicle accident. Center of paper clips mark entrance and exit sites.

The treatment of an open joint wound is similar to that of an open fracture. Open wounds of the joint are considered contaminated and broad-spectrum antibiotics should be administered. Surgical intervention consists of vigorous irrigation and debridement, often in the operating room. Attention should be given to appropriate tetanus prophylaxis, splinting, wound dressing, and pain control while the patient remains in the emergency department.

The prognosis of penetrating intra-articular wounds depends on the degree of overlying soft-tissue injury and the extent of intra-articular damage. Infectious complications are the most common. Septic arthritis with a variety of both Gram-positive and Gram-negative organisms is an early and common outcome of inadequate early intervention. Delayed synovitis, often necessitating synovectomy, has been described after unidentified penetration of small foreign bodies.

Radial Head Subluxation

“Nursemaid's elbow” is the most common joint injury in pediatric patients, usually occurring in children between 6 months and 5 years of age. The left elbow is more often affected because adult caretakers prefer to hold the child's left hand with their dominant right hand. Subluxation of the radial head occurs as a result of abrupt traction on a pronated hand or wrist. The annular ligament slides over the radial head and becomes interposed between the radius and capitellum. The radial head is not abnormal and the annular ligament need not tear for this injury to occur.

In up to half of cases, a history of traction on the arm is not obtained, which may suggest other mechanisms for this injury, or perhaps caretakers who are reluctant to provide self-incriminating information. Astute clinicians should suspect

this injury even in the absence of an appropriate history.

Subluxation of the radial head can be strongly suspected from across the room. The child holds the arm slightly flexed and against his or her body. When left alone, the child does not appear to be in significant pain. Parents may report a problem with the wrist or shoulder because, in their attempts to check these joints, inadvertent movement of the elbow causes pain. Physicians can be similarly fooled, especially when a classic history is not obtained.

Evaluation and Management

The young child must be approached in a slow and non-threatening way. Point tenderness of the clavicle, humerus, radius, and ulna can be excluded with a deliberate examination that does not move the elbow at all. True tenderness and swelling at the elbow are usually absent. When disuse of the elbow is present without pain or bony tenderness, the clinician should perform the reduction maneuver to confirm the diagnosis of radial head subluxation. Radiographs of the elbow are unnecessary unless the physician suspects another injury. Swelling and localized tenderness are usually apparent with supracondylar fractures, the next most common elbow injury in this age group.

Reduction of a subluxed radial head is one of the most gratifying procedures for physicians and parents alike. Several effective maneuvers are described. The clinician holds the elbow with his or her thumb over the radial head (Fig. 123.5). Supination of the affected arm rotates the flared aspect of the radial head, snapping the annular ligament back to its original position with a telltale click. Flexion or extension of the elbow may add to the success rate. If no click is felt, a second attempt can be made, perhaps exerting a little traction to disengage the annular ligament from between the radial head and capitellum. In the absence of a click, the child should be observed for return of function of the arm because many successful reductions occur without a perceptible click. Excessive failed attempts at reduction should be avoided. Radiographs may be useful for patients who fail reduction maneuvers.

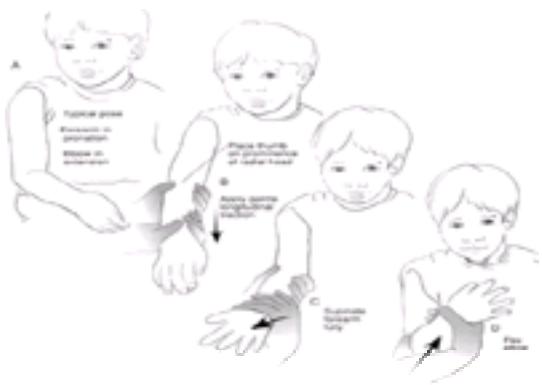

FIGURE 123.5. A–D. Supination–flexion maneuver for reduction of radial head subluxation (nursemaid's elbow).

Return of function after successful reduction is usually prompt, but not immediate. Toys, bottles, or interesting objects can be used to encourage the child to use the affected arm. Voluntary use of the arm will return in less than 15 minutes in almost 90% of patients. Younger children generally take longer to begin reusing the arm. Despite common belief, duration of subluxation was not associated with time to return of function. Many clinicians relate experiences with “failed” reductions in children whose arms are better the following morning. If disuse of the arm persists, and radiographs are normal, a sling should be placed and the child should be seen in follow-up by an orthopedist.

Recurrent radial head subluxations are common, occurring in about one-third of cases. Caretakers should be counseled to lift the child from the axillae, avoiding traction on the extremities.

Shoulder (Glenohumeral) Subluxation/Dislocation

Shoulder dislocation is extremely uncommon in young children. Shoulder dystocia at delivery can lead to displaced Salter I fractures. These injuries may look like dislocations because the unossified proximal humeral epiphysis remaining in the glenoid fossa is not visible radiographically. True dislocations become more common in adolescence and their management is described in Procedures, Section VII.

Glenohumeral subluxation/dislocation may be recurrent, especially if the anterior glenoid rim is avulsed (Bankhart lesion). Patients may report that the shoulder “pops out” and reduces spontaneously. Some disturbed individuals intentionally dislocate their shoulder. Patients with recurrent shoulder dislocation need to be evaluated by an orthopedist. If a rehabilitation program is unsuccessful, a reconstructive procedure may be beneficial.

Slipped Capital Femoral Epiphysis

Background

Slipped capital femoral epiphysis (SCFE) is the most common hip disorder in adolescent patients and should be familiar to all who care for children in this age group. It is twice as common in males as females, and more common in African-American patients. Obesity is a risk factor, although not all patients with SCFE are overweight. For unknown reasons, it is diagnosed far more often in the eastern portion of the United States, with a reported incidence of 3.41 per 100,000 in Connecticut and 0.71 per 100,000 in New Mexico. Cases are usually sporadic, but some familial tendency has been noted. Most children with SCFE are early adolescents in their growth spurt. Boys are most commonly affected

between 13 and 15 years of age; girls are most commonly affected between 11 and 13 years of age because of their earlier pubertal development. SCFE onset after menarche is extremely rare.

Slippage of capital femoral epiphysis is almost always posterior and inferior relative to the proximal femoral metaphysis. Displacement anteriorly or superiorly has been reported. The epiphysis maintains a normal relationship with the acetabulum. The left hip is affected more often than the right. Radiographic evidence of bilateral SCFE is common, even though symptoms are usually unilateral. Plain radiographs document bilateral slippage in about 25% of cases, CT scans in approximately 50%.

Pathophysiology

The pathogenesis and biomechanics of SCFE have been the subject of some research and much reasoned speculation. The perichondrium is primarily responsible for the strength of the proximal femoral physis. SCFE differs from a displaced Salter I fracture in that the perichondrium remains intact in most cases of SCFE and is disrupted with acute Salter I fractures. Collagenous bridges traverse the physeal cartilage and also contribute to the shear strength of the physis. The undulating convexity of the physis toward the epiphysis further stabilizes the interface. It takes an enormous shearing force to produce acute slippage of an initially normal hip joint. SCFE is usually a gradual, chronic process because of the viscoelasticity of the physis. Acute presentations, with radiographic evidence of chronic slippage, are common.

Several factors contribute to slippage of the capital femoral epiphysis in early adolescence. The perichondrial ring thins, probably in response to hormonal changes, reducing its support of the physis. The increased height of the physis lengthens the lever (moment) arm, increasing shearing forces on the growth plate. The geometry of the proximal femur changes during the growth spurt in adolescence such that the vector of body weight is more perpendicular to the femoral neck, adding to the shearing force across the physis. Increasing body weight, especially in obese children, obviously contributes to the forces on the physis. The combination of unfavorable changes in geometry, weakening of the physeal–epiphyseal complex, and increasing weight explains the characteristic age distribution of patients with SCFE.

Most patients with SCFE do not have identifiable endocrinologic problems. However, several hormonal abnormalities have been associated with increased risk. Elevated growth hormone and somatomedin, hypogonadism, hypothyroidism, and secondary hyperparathyroidism from renal failure (renal osteodystrophy) have been associated with SCFE. Short children receiving exogenous growth hormone therapy and tall, thin, rapidly growing children with high levels of endogenous growth hormone are both at increased risk. Children outside of the usual age range for SCFE, and those with other signs and symptoms that suggest possible endocrine abnormalities, should be referred for endocrine evaluation.

Clinical Presentation

Pain and/or limp are the most common chief complaints in patients with SCFE. Physicians may be misled when the pain is referred to the thigh, knee, or groin. It is often dull, vague, intermittent, and chronic in nature. Many patients have had symptoms for weeks or months at the time of presentation. A history of trivial injury is sometimes obtained, perhaps causing the additional slippage that precipitates a medical evaluation. Acute onset of severe symptoms suggests acute or acute-on-chronic slippage. These patients are often unable to bear weight and may be in significant pain. Major trauma can cause SCFE, but these presentations are rare.

Examination findings in patients with SCFE include a resting position with hip flexion and some external rotation. Range of motion of the hip, especially full flexion, medial rotation, and abduction, is decreased and tender. Patients with significant displacement may have evidence of limb shortening. Occasionally, there is tenderness of the hip anteriorly. Patients with more acute presentations should not be forced to walk as part of the evaluation. Testing for full range of motion is potentially injurious and unnecessary once a decision to obtain radiographs has already been reached.

Diagnosis

Plain radiographs of the hip should include two views because SCFE may be missed on an anteroposterior (AP) view alone (Fig. 123.6). On the AP view, widening of the physis is usually seen, even if the displacement is inapparent. The epiphysis is almost always displaced posteriorly; therefore, a frog leg or lateral view is best for documentation of the slippage. External rotation of the hip in the frog view turns the posterior aspect medially. Following the medial margin of the femur proximally reveals a step off between the metaphysis and epiphysis. New bone formation is often visible, suggesting a chronic slip. When radiographic findings are equivocal, comparison with the contralateral, asymptomatic hip should be done with caution, given the frequency of bilateral slippage with unilateral symptoms.

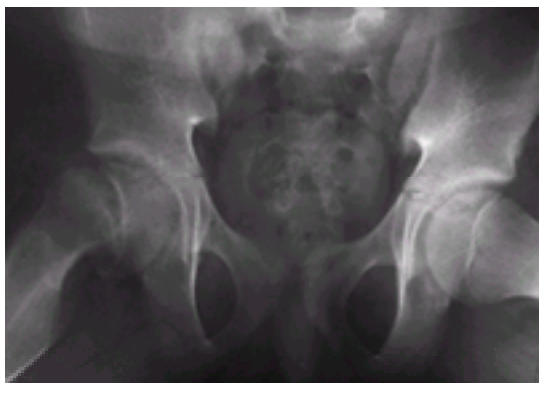

FIGURE 123.6. Slipped capital femoral epiphysis of right hip. Epiphysis is displaced medially on the frog view.

SCFE is classified by symptom duration, stability and degree of displacement. Patients with acute SCFE have symptoms for less than 3 weeks; with chronic SCFE, symptoms are present for more than 3 weeks. Acute-on-chronic SCFE describes patients with symptoms for more than 3 weeks with a recent exacerbation. An acute slip with severe symptoms is unstable. Acute or chronic slips with mild symptoms are stable, and have a more favorable prognosis. The degree of slippage is expressed with a grading system; grade I or preslip with widening of the physis but no displacement; grade II with displacement less than one-third of the width of the metaphysis; grade III with displacement of one-third to one-half of the metaphyseal width; and grade IV with displacement of greater than one-half the metaphyseal width.

Management

Treatment of SCFE is primarily surgical. Screws are usually placed through the femoral neck into the epiphysis. Reduction of the displacement is not performed because there is some evidence that it may increase the likelihood of avascular necrosis of the femoral head and chondrolysis. Chondrolysis is the most common complication of SCFE, occurring in about 8% of patients. Pain and persistent decreased range of motion after pinning are the usual presenting symptoms. If the pins extend into the joint space, the risk of chondrolysis is increased. Two-thirds of patients with chondrolysis have a progressive course. Ankylosis may ensue, leading to long-term disability.

Legg-Calve-Perthes Disease

Legg-Calve-Perthes Disease (LCPD) is a hip disorder that generally has onset between the ages of 4 and 9 years. Males outnumber females by a ratio of 4:1. Genetic factors play a minor role. Most children with LCPD are short, with average or above-average weight. They often have delayed skeletal maturation.

LCPD begins with repeated episodes of ischemia of the femoral head, leading to infarction and necrosis. Theories about the cause of the circulatory insufficiency include increased blood viscosity and elevated intracapsular pressure caused by synovitis, but these theories remain unproven. Patients may remain asymptomatic despite varying degrees of necrosis and resorption of the femoral head. Some children recover completely without developing symptoms. Symptoms generally begin when minor trauma causes stress fracture of the subchondral bone. Rarefaction of the femoral head with subluxation and deformity may ensue. The process of reossification and remodeling takes 2 to 4 years.

The onset of symptoms in LCPD is usually insidious. Presentation as an acute emergency is rare. Mild hip pain and limp have usually been present for weeks to months before diagnosis. Pain is often referred in the distribution of the obturator nerve to the knee, anteromedial thigh or groin. Physical findings include decreased hip abduction and medial rotation. Thigh muscle atrophy, and in advanced cases, limb shortening may also be noted.

The sequence of radiographic changes in LCPD have been described in detail (Fig. 123.7). At diagnosis most patients have widening of the articular cartilage with a small, dense proximal femoral epiphysis. Subchondral fracture may be visible. Irregularity and flattening of the epiphysis develops over time. The differential diagnosis includes various bone tumors and skeletal dysplasias. As the disease progresses, anterolateral subluxation may be quantitated radiographically.

FIGURE 123.7. Legg-Calve-Perthes disease of left hip. Epiphysis is narrowed and radio-dense. A subchondral fracture is also visible.

Management of LCPD requires a pediatric orthopedist who will follow and treat the child through the various stages of the disease. Prompt referral may influence long-term prognosis. Older children, obese children, girls, and those with more severe disturbance of the epiphysis on radiographs have a poorer prognosis.

Discitis

Background

Discitis is an inflammatory condition involving the intervertebral disc space that has also been called acute osteitis of the spine, spondylitis, and spondylarthritis. The variety of diagnostic terms is an indication that the pathophysiology of this condition is poorly understood. Vertebral osteomyelitis with involvement of the disc space is a distinct diagnostic entity with different epidemiology and pathophysiology from discitis.

Discitis is a disease of childhood, with about 75% of patients being less than 10 years of age. No gender or racial predilection has been noted. The involved disc space is usually lumbar or lower thoracic. Most authorities believe discitis results from infection. A history of trauma is obtained in some patients with discitis, but whether the injury plays a role in cause or is a “red herring” is unclear. The vascular anatomy of the disc space supports the notion that organisms reach the disc space via the hematogenous route. In children, the blood supply of the disc space comes from adjacent vertebral body end plates. These vascular connections are absent in older adolescents and adults, which is consistent with the age distribution of discitis.

Bacteria are cultured from a minority of children with discitis. *S. aureus* is the predominant isolate from disc space aspirates and occasionally blood, but other organisms have also been recovered.

Diagnosis

Children with discitis are a diagnostic challenge for clinicians. Symptoms are often nonspecific and vague, especially in the younger child. They have usually been present for more than 1 week at the time of diagnosis. Back pain is not always described. Limp, refusal to walk, leg pain, hip pain, and abdominal pain are common presenting complaints. Low-grade fever and irritability may be reported.

Physical findings suggesting discitis will be missed if this entity is not considered, because careful examination of the spine is not performed routinely by most clinicians. Many children assume a recumbent position of comfort from which they do not want to be moved. Decreased range of motion of the spine and paravertebral muscle spasm are usually present. There is often a change in the lumbar lordosis, which may be decreased or increased. Tenderness to palpation of the disc space can usually be demonstrated. Range of motion of the hips is essentially normal, but inadvertent movement of the lumbar spine during hip examination may cause pain that is misinterpreted to suggest hip pathology. Straight leg raising may be limited by muscle spasm in the hamstrings. Neurologic assessment of the lower extremities is normal. Abnormalities in strength, sensation, and/or deep tendon reflexes suggest a spinal cord lesion, tumor, epidural abscess, or herniation of the disc (rare). Signs of discitis may vary, depending on the location of the inflamed disc. Patients with lesions of the upper spine may have meningismus.

Imaging studies can be useful in the diagnosis of discitis. Plain radiographs are initially normal. Intervertebral disc space narrowing develops after 2 to 3 weeks of illness (Fig. 123.8). Bone scan is the most sensitive imaging modality early in the course of this disease. Increased uptake at the level of the involved disc can confirm the diagnosis. MRI has also proven sensitive in the early phase. CT scanning can demonstrate the degree of bony erosion of the vertebral end plates and paravertebral soft-tissue involvement.

FIGURE 123.8. Discitis. L3–L4 intervertebral disc space is narrowed. Anteroposterior **(A)** and lateral **(B)** views.

Laboratory testing plays a minor role. Elevation of the WBC count is sometimes noted at the time of diagnosis. ESRs of 40 to 60 mm/hour are usually noted in patients presenting with discitis, and decrease with resolution of the disease. Skin testing for tuberculosis, and serologic testing for brucellosis and salmonellosis are often performed. Discitis can usually be diagnosed and treated without biopsy or aspiration of the involved disc space. If the presentation is atypical, signs and symptoms severe, or response to therapy unsatisfactory, obtaining a guided needle aspiration can be helpful.

Management

Discitis is a self-limited disease and need not be treated aggressively. Virtually all children in reported series return to normal function in a few months. Resting the spine usually results in improved symptoms in days to weeks. Immobilization with plaster has not been shown to improve outcome over bed rest alone, but therapeutic decisions should be individualized with input from an orthopedist. Although there are no data to suggest that they speed recovery or improve outcome, antistaphylococcal antibiotics seem prudent, given the frequency of documented staphylococcal infection. When cultures demonstrate particular organisms with known antimicrobial susceptibilities, antibiotic therapy can be individualized.

SPONDYLOLYSIS AND SPONDYLOLISTHESIS

Spondylolysis and spondylolisthesis occur in 2 to 5% of children, but most are asymptomatic. In older children with low back pain, especially adolescents, it is a condition that should be considered. Spondylolysis is a defect in the pars interarticularis of the vertebral body. Spondylolisthesis is displacement of the vertebral bodies, usually involving L5

slipping anteriorly on S1. Spondylolisthesis may result from structural abnormalities of the vertebral bodies (dysplastic type) or acquired defects of the pars interarticularis (isthmic type) that allow slippage. There is a genetic predisposition to spondylolysis and spondylolisthesis. Parents of children with spondylolisthesis are found to have this condition in 28% of cases.

The cause of the defect of the pars interarticularis in spondylolysis is not fully understood. Repeated stress, such as occurs in gymnasts with frequent hyperextension of the spine, causes stress fracture. One side of the pars interarticularis fractures overtly, which adds to the stress on the contralateral side. Fracture becomes bilateral. Displacement may or may not occur. Children who play sports that stress the spine, such as gymnastics, football, rowing, diving, weight lifting and high jumping, are at particular risk.

Patients who develop symptoms generally present during the adolescent growth spurt. Back pain worsens with activity and improves with rest, and usually has an insidious onset. Over time, there may be pain in the buttocks and posterior thighs. Symptoms radiating down the legs suggest significant nerve root irritation. Parents may describe an increase in the lumbar lordosis or a change in the child's gait.

Physical examination shows tenderness with hyperextension of the lumbar spine in the prone position, and with deep palpation. The hamstrings are usually tight, with decreased range of motion on straight leg raise and flexion of the trunk. Children seldom have motor (10%), sensory (15%), or reflex (10%) deficits in the legs.

Plain radiographs should include AP, lateral, and oblique views. The “scotty dog” of the oblique view will have a collar on the neck if spondylolysis is present. Spondylolisthesis can be diagnosed on the lateral view, and the degree of displacement can be quantitated relative to the width of the vertebral body (Fig. 123.9).

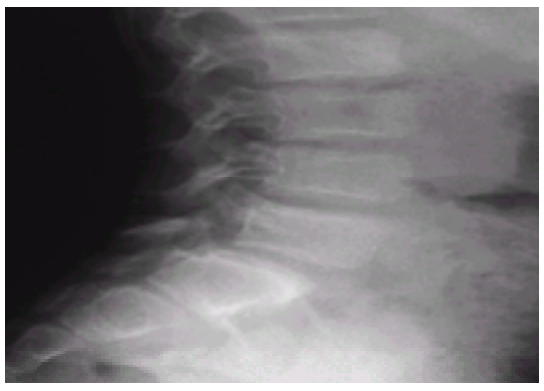

FIGURE 123.9. Spondylolisthesis with slippage of L5 anteriorly on S1.

Treatment varies depending on symptoms and degree of displacement, if any. Most cases of asymptomatic spondylolysis, and spondylolisthesis with mild displacement will not progress. Children with displacement greater than 25% should avoid rough sports. Symptomatic children with displacement may benefit from immobilization. Decisions about treatment should be made in consultation with an orthopedic surgeon.

OVERUSE SYNDROMES

Overuse syndromes is a general term that encompasses a variety of injuries that result from excessive and repetitive forces on susceptible structures. Children are at unique risk for such injuries, which are particularly common in adolescent athletes. There is an increased susceptibility during the growth spurt when skeletal growth exceeds the growth of the muscle–tendon unit. This results in increased stress at the apophysis, the musculotendinous origin or insertion. In children, cartilage is interposed between tendon and bone and is most prone to injury from repetitive forces. Repetitive tensile forces at these sites result in chronic irritation and microfractures or avulsions of the apophysis. If allowed to progress, there is evidence that the repetitive microtrauma may weaken the bone and predispose to major avulsion fractures. Traction apophysitis is unique to the growing child. By adulthood, fusion of tendon to bone leads to tendinitis rather than apophysitis as a result of repetitive forces. The late childhood, early teenage years coincide with increased participation in organized sporting activities. There is a tendency in high-intensity programs to over-train young athletes, and at times to wrongly encourage them to work through or ignore the early warning signs of pain.

General therapy for these injuries must emphasize several areas. Rest is crucial for the specific area involved until pain has completely resolved. The athlete should be actively encouraged to use alternative activities to maintain conditioning during this time. The role of inflammation in overuse injuries is controversial, but the application of ice and use of antiinflammatory agents is generally recommended. Directed stretching exercises are encouraged to reduce tension on affected areas. Biomechanics should be assessed and corrected when necessary. When returning to full activity, an appropriate training regimen should emphasize a slow gradual buildup in intensity and duration and should include explicit limitations. The sudden increase in intensity and duration of training that occurs with a change of sporting seasons is a major culprit in overuse injuries.

A number of overuse syndromes have acquired popular eponyms. Among the most common overuse syndromes in children are Osgood-Schlatter disease, Little Leaguer's elbow, and Sever's disease.

Little Leaguer's Elbow

Little Leaguer's elbow refers to a group of disorders resulting from repetitive valgus stress applied to the skeletally underdeveloped elbow. Its cause is a combination of excessively repetitive pitching and poor throwing biomechanics. Valgus force places tension on the medial collateral ligaments, which is translated to the medial epicondyle. A medial epicondylitis or apophysitis is the most commonly resulting lesion. An avulsion fracture of the medial epicondyle may result from an acute valgus force once the site has become weakened from repetitive microtrauma. As expected, Little Leaguer's elbow occurs most commonly in boys ages 9 to 12. Patients complain primarily of elbow pain that is exacerbated by throwing. Tenderness is localized over the medial elbow. Flexion of the wrist or finger against resistance also elicits pain. In advanced cases, extension of the elbow becomes limited.

Radiographs may reveal nonspecific changes such as an irregular or widened medial epicondylar physis, but in general, an apophysitis is not visible. An avulsion fracture may appear as a bony fragment separated from the medial epicondyle.

Treatment emphasizes rest for at least 1 month, application of ice, and return to activity only after all pain is gone. Once activity is resumed, the athlete must concentrate on limiting the total amount of pitching, as well as minimizing stress on the medial epicondyle by employing an overhand rather than side-arm pitching motion. Routine stretching and range of motion exercises will reduce the risk of recurrence. Displacement of an avulsion fragment may require surgical repair to restore full elbow function.

Osgood-Schlatter Disease

Osgood-Schlatter disease is an apophysitis of the tibial tubercle. Repetitive stress imposed by the patellar tendon on its site of insertion results in a series of micro-avulsions of the ossification center and underlying cartilage. The condition is most common in running and jumping athletes between the ages of 11 and 15. Girls are less commonly affected than boys. Most cases are bilateral, although symptoms are commonly asymmetric.

The physical examination is notable for localized tenderness at the tibial tubercle. Any action that applies tension to the patellar tendon elicits pain. Placing the patient prone and flexing the knee so that the heel contacts the buttocks typically triggers pain at the tibial tubercle. Additional maneuvers likely to cause pain include forced extension of the knee, jumping, or squatting. In advanced cases, callus formation occurs, resulting in further prominence of the tubercle. Some experts have suggested a relationship between Osgood-Schlatter disease and acute avulsion fractures of the tibial tubercle (Fig. 123.10). The diagnosis is based on the clinical features. Radiographs are not indicated in typical cases. Radiographic findings of soft-tissue swelling and irregularities of the tubercle are nonspecific.

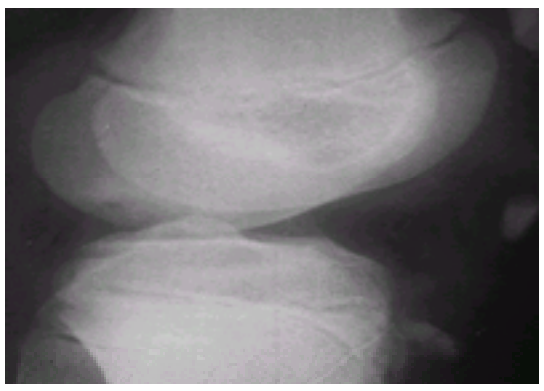

FIGURE 123.10. Acute tibial tubercle avulsion fracture in child with history of Osgood-Schlatter disease.

Management consists first and foremost of avoiding activities that place stress on the tibial tubercle. This is perhaps the most difficult instruction to enforce in young athletes. A brief period of immobilization or non–weight bearing is recommended by some as a means of ensuring compliance. Application of ice reduces pain and swelling. Non-steroidal anti-inflammatory medications are commonly recommended. Activity may be resumed when the patient is free of pain. Flexibility exercises concentrate on stretching the quadriceps and hamstrings to alleviate stress on the tubercle and avoid recurrences. A neoprene sleeve on the knee reduces patellar mobility and reduces forces on the tubercle.

Osteochondritis Dissecans

Background

Osteochondritis dissecans is a lesion involving separation of the osteochondral segment from underlying healthy bone. A variety of articular lesions are often lumped together under this term, including acute osteochondral fractures and epiphyseal dysplasias. This results in confounding descriptions of the natural course and outcome of the true condition. Adults are often diagnosed with osteochondritis dissecans; however, it remains primarily a condition of the adolescent age group, with the highest incidence occurring among male athletes between 12 and 16 years of age. The primary sites of osteochondritis dissecans include the medial femoral condyle in the knee, the posteromedial aspect of the talus in the ankle, and the capitellum in the elbow. It is less commonly reported in the hip, feet, and wrist. Involvement of multiple sites is rare.

Pathophysiology

The underlying cause of osteochondritis dissecans remains controversial and may differ based on the anatomic location

of the lesion. Trauma, vascular insult, genetic predisposition, and abnormalities of ossification have all been proposed as possible causes. The greatest evidence supports repetitive trauma as the sole or major contributory cause of the pathology. Overuse injury is most clearly associated with osteochondritis dissecans of the capitellum, where most cases come from Little League pitchers. Higher incidences of osteochondritis dissecans of the knee and ankle are seen in participants of activities that place increased stress on these areas, such as distance running, ballet, and basketball. Focal necrosis is suspected to follow the initial insult. Spontaneous resolution may occur at this point, or it may progress with the subchondral bone undergoing various degrees of separation from the underlying epiphysis. In advanced stages, complete separation of the osteochondral fragment results in a free floating body within the joint, which can disrupt normal mechanical function.

When the disease occurs in the second decade of life, long-term outcome is generally good. Progression to osteoarthritis or other degenerative joint diseases is rare. A worse prognosis is associated with a diagnosis after skeletal maturity, larger lesions, and complete separation of fragments.

Clinical Findings

The onset of symptoms occurs over several months. Joint pain and swelling typically occur after strenuous exercise and improve over several hours with rest. When a free body is present, patients describe intermittent, abrupt locking of the joint. Locking in the knee or elbow prevents full extension of the extremity. This is in contradistinction to buckling, stiffness, or pain with extended range of motion.

The physical examination of the joint is often normal. Occasionally, a small effusion may be detectable. Lesions in the medial femoral condyle may be directly palpated and pain elicited when the knee is held in 90 degrees of flexion. The typical location of lesions in the talus are not accessible on examination. Osteochondritis dissecans in the femoral condyle may give rise to an abnormal gait with external rotation of the affected limb.

Diagnosis

A plain film of the joint should be obtained, and is often diagnostic when osteochondritis dissecans is suspected (Fig. 123.11). Radiographs reveal a crescentic-shaped defect within the subchondral bone. The avascular segment of subchondral bone may have increased density. A radiolucent line may demarcate the separation from the remainder of the epiphysis. A free body often includes a portion of dead subchondral bone, which appears as a radio-dense object within the joint space. Standard AP and lateral views, as well as tunnel and sunrise views, of the knee are recommended for lesions within the femoral condyle. Lateral, AP, and mortis views of the ankle are adequate when a lesion of the talus is suspected, and AP and lateral views of the elbow are sufficient when the capitellum is involved.

FIGURE 123.11. Osteochondritis dissecans of the medial femoral condyle. Crescentic lesion with radiolucent margin in a 14-year-old girl.

Early lesions may not be detected on plain films and alternate imaging modalities may improve overall sensitivity. When correlated with arthroscopic or surgical findings, MRI has been shown to have better ability to detect osteochondritis dissecans and accurately define the extent and stage of the lesion. MRI is increasingly used to guide therapy and monitor healing. Arthrograms have also been used to detect changes in the surface of the cartilage before bony changes occur, but these studies require intra-articular injection of dye and subject patients to additional radiation.

Management

The management of osteochondritis dissecans depends on the age and skeletal maturity of the patient, the location of the lesion, and the stage of the lesion. Conservative therapy consisting of restricted activity and relief of stress on the joint is the first-line treatment in children who have not reached skeletal maturity, and for those diagnosed at an early stage of the disease. Immobilization in a cast or non–weight bearing for lower extremity lesions is unnecessary. Patients should be followed closely by an orthopedic surgeon both for resolution of clinical symptoms and evidence of healing on serial radiographs or MRIs. Most stable lesions occurring in patients before physeal closure go on to heal; however, a few will progress to separation. Lesions occurring in adults generally do not heal without surgery.

Surgical intervention is generally recommended when lesions fail to improve clinically or radiographically after 6 months of rest. The presence of a loose or free body is also considered an indication for surgery. Many surgical procedures can now be performed arthroscopically. Fine drilling through the articular cartilage and subchondral bone into healthy bone appears to stimulate revascularization and promote healing. Loose fragments and larger free bodies may be reduced and fixed in place with the use of screws or Kirschner wires. Other free bodies need to be removed from the joint space.

Resulting defects may be repaired with the use of a bone graft or through stimulation of fibrocartilage or scar tissue formation to restore congruity to the articular surface.

Chondromalacia Patellae

Chondromalacia patellae is a pathologic diagnosis referring to damage of the articular cartilage of the patella. Specific changes include softening, fissures, and erosions. Patellofemoral pain syndrome, a term often used interchangeably with chondromalacia patellae, more accurately describes a constellation of symptoms, principally anterior knee pain arising from the patellofemoral joint. Whether the two conditions are actually related is the subject of debate. They share a number of symptoms and precipitating factors. Patellofemoral pain syndrome may represent the early end of the spectrum of injury, which ultimately may or may not progress to true pathologic changes within the cartilage.

Patellofemoral pain syndrome and chondromalacia patellae are first seen in early adolescents. The rise in incidence tends to parallel the growth spurt. A number of underlying causes or associated factors have been identified. Malalignment of the patella and an abnormal tracking of the patella over the femoral condyles appear to be the major contributors to patellofemoral disorders. The quadriceps or Q angle is the angle between a line from the center of the tibial tubercle to the center of the patella, and a second line from the center of the patella to the anterior superior iliac spine. A Q angle greater than 20 degrees has been found in a significant number of affected individuals and results in disproportionate lateral traction applied to the patella during extension. The wider pelvic bones in females result in a generally wider Q angle, which may account for the higher proportion of patellofemoral problems in females. Another contributing anatomic factor is a relative strength imbalance of the four muscles composing the quadriceps. A shallow femoral intra-condylar sulcus has also been associated with the disorder.

Chondromalacia patellae and patellofemoral pain syndrome are often classified as overuse syndromes because individuals exposed to repetitive trauma are at higher risk for these disorders. Runners are particularly predisposed to develop these conditions. Poor training regimens, rapid increases in duration or intensity of training, hard or uneven running surfaces, and inadequate shoes have been blamed.

Symptoms consist mainly of anterior knee pain often described as arising from beneath or on the sides of the patella. Pain is usually of gradual onset and is exacerbated by exercise. Activities that involve loading of the knee when it is in flexion, such as climbing steps, are particularly painful.

The physical examination is notable for tenderness along the patellar margins or the posterior surface, which is accessible when the patella is manually displaced medially or laterally. Pain, and occasionally crepitus, are elicited with flexion and extension of the knee, or tightening the quadriceps while compressing the patella against the femoral condyles. Range of motion is not limited and swelling is rare. The presence of an effusion is suggestive of significant cartilaginous damage. Provocative tests that reproduce the pain include climbing steps, squatting, or knee extension against resistance.

Radiographs are generally insensitive but may show changes to the patella in advanced cases. Radiographs may also be obtained to more accurately measure the intracondylar sulcus or Q angle, or to rule out alternative diagnoses. MRI, with a sensitivity greater than 80%, is considered the best noninvasive diagnostic modality for chondromalacia patellae. True confirmation of lesions requires arthroscopy.

Treatment is conservative. More than 90% of cases of patellofemoral pain syndrome resolve after instituting a program of rest, anti-inflammatory medications, and ice followed by physical therapy. Exercises that begin once the initial pain has resolved emphasize strengthening of the quadriceps muscles. Recommended exercise regimens include isometric contractions of the quadriceps with the knee in extension, straight leg raises, and knee extensions, first without and then with weights. Training routines for athletes may need modification and should emphasize soft, even running surfaces; proper biomechanics; and shoes with appropriate cushioning and support. Surgery is recommended only as a last resort in the most recalcitrant cases because results have been generally less than satisfactory. Surgery is directed at either correcting unequal tension applied to the patella or removing loose or nonviable cartilage from the posterior patellar surface.

Sever's Disease

Sever's disease is a calcaneal apophysitis occurring at the insertion of the Achilles' tendon at the posterior aspect of the calcaneus. It afflicts predominantly runners, jumpers, and soccer players. Sever's disease is often bilateral, is more common in males, and has its peak incidence between 10 and 12 years of age.

Localized tenderness occurs at the insertion of the Achilles' tendon on the calcaneus. A maneuver such as hanging the heels over the edge of a step, climbing steps, or hopping applies tension to the Achilles' tendon and exacerbates the pain. Patients are often found to have a tight gastrocnemius-soleus muscle complex and limited dorsiflexion of the foot. Radiographs of the site are usually normal and are unhelpful except to exclude bony injuries such as stress fractures.

Management includes rest, ice, and anti-inflammatory medications. Heel padding or lifts may be helpful in relieving tension in the area. Flexibility exercises should concentrate on both the hamstrings and the calf muscles. When therapy is initiated early in the disease, most patients are able to return to normal activity by 2 months.

Bursitis

Bursa sacs are both the shock absorbers and the ball bearings of the musculoskeletal system. They disperse forces from blows on bony prominences and reduce friction where tendons or ligaments are in frequent motion.

Trauma, either in a single blow or by repetitive forces, can inflame the bursa, which responds with increased production

of synovial fluid. The bursa sac subsequently swells and a cycle of swelling, irritation, and inflammation ensues. Bursitis is most commonly an overuse syndrome seen in adolescents and adults, and is less common in young children.

Injury or cellulitis of the skin overlying a bursa sac can predispose to infection. Aspiration and culture are necessary for definitive diagnosis. The organisms found in septic bursitis are the same as those in septic arthritis, with *S. aureus* accounting for more than 90% of cases. There is no consensus on the need for parenteral versus oral antibiotics. The prepatellar bursa and olecranon bursa are most commonly infected.

Bursae are located throughout the body, but bursitis occurs only in a few. Prepatellar bursitis, commonly called “housemaid's knee” results from frequent or prolonged kneeling. Pens anserinus bursitis occurs on the lateral aspect of the knee, where the tendons of the hamstring muscles overlie the tibia. Retrocalcaneal bursitis occurs between the calcaneus and Achilles' tendon and often is caused by direct pressure from ill-fitting footwear or high-heeled shoes. Olecranon bursitis most often results from a single direct blow to the elbow. Shoulder or subacromial bursitis is often associated with calcifications and produces severe pain with abduction. Other commonly affected bursae include the inferior calcaneal bursa and the trochanteric bursa.

An unusual form of bursitis is known as a popliteal or Baker's cyst. This occurs in the bursa, which cushions the tendons of the gastrocnemius and semimembranous muscles from the distal femur. The presence of this condition in adults is highly suggestive of intra-articular knee damage. In children with a Baker's cyst, there is often a congenitally wide opening joining the bursa sac with the knee joint itself. One-way flow of synovial fluid into the bursa produces swelling just below the popliteal fossa on the medial side. Patients with chronic inflammatory conditions of the knee, such as juvenile rheumatoid arthritis (JRA), are at increased risk of developing popliteal cysts. The swelling limits full flexion of the knee and produces the sensation of tension with extension. An arthrogram or bursagram may outline the cyst, document the articular connection, and detect ruptures of the cyst. Ultrasound is a useful noninvasive diagnostic modality. MRI is more accurate than ultrasound, but not as essential in children given the lower incidence of accompanying intra-articular injury.

Bursa inflammation produces swelling and localized pain with direct palpation. Any movement of the tendons overlying the site will reproduce the pain.

Conservative therapy consisting of restricted activity, frequent application of ice, and regular use of non-steroidal anti-inflammatory medications is successful in most cases. Resistant cases respond well to aspiration of synovial fluid and injection of corticosteroids. Often, recurrent cases may require surgical removal of the bursa sac. A new bursa will be generated.

COMPARTMENT SYNDROME

Compartment syndrome refers to vascular insufficiency caused by elevated tissue pressures. It usually occurs after an injury causes hemorrhage or edema within an enclosed fascial compartment. Tight circumferential bandages or casts can also limit expansion of swollen tissues and result in elevation of tissue pressures. Fluid extravasation from intravenous or intraosseous lines, especially pressure-driven extravasation, may significantly elevate compartment pressures. Direct injury to a vessel is less common as the cause of vascular insufficiency after injury. When compartment pressures approach the perfusion pressure of muscle, which is approximately 30 mm Hg, arterial inflow is reduced and veins and capillaries are collapsed. Ischemia of muscle leads to further swelling, and an ischemia–edema cycle can lead to complete cessation of tissue perfusion. Muscle necrosis is irreversible after 6 to 8 hours of tissue anoxia. Fibrosis develops and ischemic contracture results in permanent disability. The emergency physician must identify patients at risk for compartment syndromes and consult with an orthopedist, who can monitor tissue pressures and treat compartment syndromes before irreversible injuries occur.

Knowledge of the common pediatric injuries that are associated with compartment syndromes can raise the clinician's index of suspicion appropriately (Table 123.3). Displaced supracondylar fractures may lead to Volkmann's contracture, which involves the distribution of the anterior interosseous artery and the flexor compartment of the forearm. Forearm fractures may also cause compartment syndromes, affecting either the flexor or extensor musculature. Fractures of the tibia and/or fibula can lead to compartment syndrome of the lower leg. Compartment syndromes may occur from crush injuries and other soft-tissue trauma that does not necessarily involve a fracture.

Fractures	Ischemic Compartments
Supracondylar fractures of the humerus (displaced)	Deep flexor (anterior) compartment
Radius/Ulna fractures (diaphyseal)	Anterior tibial and peroneal compartments
Tibia/fibula fractures (diaphyseal)	
Femur fractures	

Table 123.3. Compartment Syndromes

Compartment syndromes are diagnosed clinically by assessing the “Five Ps”: pain, paresthesia, pallor, paralysis, and

pulselessness. All five need not be present for a compartment syndrome to exist.

Pain is the hallmark of compartment syndromes, but it can be difficult to distinguish the pain of the injury itself from that related to the vascular insufficiency. Pain that increases over time after the injury suggests muscle ischemia. Compartment syndrome must be suspected when the pain seems out of proportion to the injury itself. Stretching ischemic muscles exacerbates the pain. Increased pain with extension of the fingers or toes is an important clinical finding in patients with compartment syndromes.

Paresthesia may be noted in the distribution of the nerves that traverse the ischemic compartment. When the flexor compartment of the forearm is involved, the median nerve is usually affected. Over time, paresthesias may progress to complete anesthesia, and pain may decrease.

Pallor from decreased perfusion may be noted distally. Sluggish circulation may cause cyanosis. Paralysis is a late finding and is probably the least sensitive marker for compartment syndrome. Pulselessness is a useful finding if present, but some physicians are falsely reassured when distal pulses are palpable. The ischemia in compartment syndromes results from vascular occlusion of small vessels. Pressures seldom exceed systolic blood pressure. Larger arteries may not be occluded, and pulses often remain intact.

Treatment of a compartment syndrome should begin when it is suspected. All circumferential bandages should be removed. If symptoms persist, orthopedic consultation should be obtained for measurement of compartment pressures. Reduction of displaced fractures can improve blood flow to affected compartments. Fasciotomy in the operating room is indicated if compartment pressures remain high.

REFLEX SYMPATHETIC DYSTROPHY

Reflex sympathetic dystrophy (RSD) is a poorly understood disorder characterized by pain, abnormal sensation, and circulatory irregularities. Over time, atrophic changes of the extremity develop. *Causalgia, algodystrophy,* and *Sudeck's atrophy* are also terms that have been used for this mysterious disorder, first reported in gunshot victims during the American Civil War. The average time from onset to diagnosis of RSD in children is 1 year. Emergency physicians play an important role in the early diagnosis and treatment of RSD, which may prevent prolonged disability.

RSD is well known in adults, but children with RSD as young as 3 years have been described. The average age of children with RSD is approximately 12 years, girls outnumbering boys by as much as 6:1. Most cases in children involve the lower extremity. RSD usually follows minor trauma, but some cases develop without an identified precipitant.

The pathophysiology of RSD is not understood. Early theories suggested abnormal synapses develop between sensory afferent nerves and sympathetic efferents after an injury. “Sympathetic” dystrophy may be a misnomer, however, because local epinephrine and norepinephrine levels are lower, not higher than normal, and vasodilation, not sympathetic vasoconstriction, may predominate. Theories of sympathetic receptor hypersensitivity or central, self-exciting pathways in the substantia nigra remain unproven.

Pain is usually the presenting complaint with RSD. The pain is continuous, often burning in quality, with exacerbations but no complete remissions. Abnormal sensitivity is distinctive, with severe pain provoked by normally non-tender touching (allodynia). The extremity is usually swollen and cool to the touch, although warmth has also been reported. Dusky discoloration of the skin with hyperhidrosis or anhydrosis may be present. The arm or leg is not used, and atrophic muscle, skin, and bony changes develop in some patients over time. There is some evidence that demineralization of bone occurs more rapidly than would be expected from disuse alone.

Psychiatric and personality problems have been suspected in many patients with RSD, but controlled prospective studies are lacking. Factitious illness or conversion reactions may be considered, given that symptoms are out of proportion to the inciting injury.

The characteristic history and physical examination, including pain, loss of function, and evidence of autonomic dysfunction, allow for a clinical diagnosis of RSD in most cases. Radiographs in children may not demonstrate the osteoporosis described in adults, especially early after the onset of symptoms. Radionuclide bone scans generally show increased blood flow and periarticular uptake in adults, but in children with RSD the blood flow and osseous uptake is more often reduced. Thermography may document decreased temperature in the affected extremity. Treatment of RSD focuses on early mobilization of the extremity through physical therapy to avoid atrophic changes. Physiotherapy may initially exacerbate symptoms, but experienced clinicians believe it both prevents atrophy and decreases the duration of pain. The knee-jerk response to splint for comfort may be counterproductive with RSD. Referral to a pediatric pain program is advisable should symptoms persist. Intravenous regional block with guanethidine, sympathetic block, transcutaneous nerve stimulation, and, with intractable cases, sympathectomy have all been performed, reportedly with some success.

CHAPTER 124

Dental Emergencies

LINDA P. NELSON, DMD, MScD and STEPHEN SHUSTERMAN, DMD

Department of Pediatric Dentistry, Harvard School of Dental Medicine, and Pediatric Dentistry, Children's Hospital, Boston, Massachusetts

Nontraumatic orofacial emergencies can appear suddenly and can be frightening for pediatric patients and their families. The major task in evaluating a child with a nontraumatic orofacial emergency is to identify the cause of the problem. In cases of facial swellings, the first step in treatment is determining that a tooth is the causative agent. In cases of postextraction complications, historical information suggesting a preextraction infection, fractured tooth, or overlying chronic systemic problem may be elicited. Therefore, initial assessments must be performed in the same manner as traumatic orofacial emergencies (see Chapter 113).

POSTEXTRACTION COMPLICATIONS

Hemorrhage

It is expected that any extraction site may ooze for 8 to 12 hours and perhaps longer for a permanent site. However, it is important to check the history for any prior bleeding episodes to rule out a systemic hematologic abnormality. A complete blood count and coagulation profile would be indicated.

Emergency treatment may include the following steps:

1. Apply pressure, using folded gauze sponges that are placed over the socket with biting pressure applied for 30 minutes. If unsuccessful, proceed to the second step.
2. Physically close the socket by suturing. Administer local anesthesia (2% Xylocaine with 1:100,000 epinephrine infiltration), approximate the extraction site with the appropriate sutures. Alternatively, the socket may be packed with Gelfoam.

A possible home remedy before coming to the emergency department (ED) might include the use of a tea bag. A tea bag is dipped in hot water and allowed to cool, then placed over the socket with pressure. The tannic acid in the tea bag may accelerate or initiate coagulation.

Infection

Postextraction infection is rare in children. If it occurs, it may present as localized swelling or edema surrounded by an erythematous zone. A purulent exudate may be evident from the socket. Emergency treatment includes the application of moist heat, oral saline rinses (if the age is appropriate), and antibiotic therapy. Penicillin remains the drug of choice. (See the section on “Dentoalveolar Abscess” for dose and duration.)

Alveolar Osteitis

Alveolar osteitis, or “dry socket,” is a painful postoperative condition produced by a disintegration of the clot in the tooth socket. This condition usually is seen in adults and only rarely in children less than 12 years of age. It usually follows

(approximately 72 hours) mandibular extractions and is painful. Emergency dental treatment is variable, but the immediate goal is relief of pain. Under local anesthesia, the socket may be debrided and then packed with ¼-inch iodoform gauze or Bipp's paste (bismuth, iodoform, benzocaine, and petrolatum). Oral analgesic medication should be prescribed along with antibiotics.

ORAL INFECTIONS

In a retrospective analysis of pediatric dental patients presenting to the ED and dental clinic at The Children's Hospital, Boston, from 1989 to 1990, toothaches, pain, and facial swellings accounted for 44% of the chief complaints. This is consistent with other studies. It is important to remember that the infant or small child who may be in pain often cannot localize the discomfort. It may be the first opportunity for many children to receive dental care. A complete history from the parents and a thorough oral examination are mandatory. Figure 124.1 is a diagram of the normal tooth.

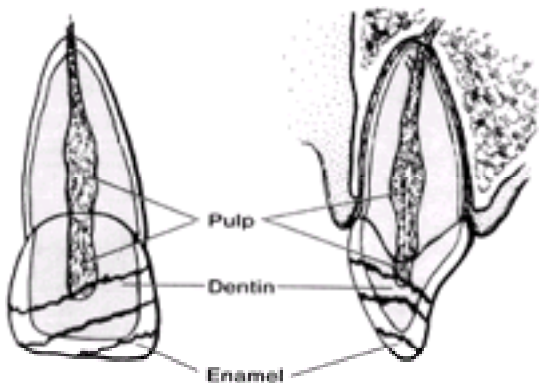

FIGURE 124.1. The anatomy of a tooth that should be considered during a traumatic injury. Enamel fracture, no emergency treatment; dentin fracture, emergency treatment as soon as convenient; and pulpal fracture, emergency treatment as soon as possible.

Odontalgia—Simple Toothache

The child with a simple toothache often complains of diffuse mouth pain and may not be able to point to a specific tooth. The emergency physician may note a grossly carious tooth or large restoration. Swelling or inflammation in the surrounding soft tissue may be present. The tooth may be sensitive to percussion and may exhibit excessive mobility. A dental consultation is necessary, especially if swelling is noted. In the case of swelling, the tooth may be opened for drainage to relieve the pressure, in a manner similar to the management of any abscess.

Dentoalveolar Abscess

Dental abscesses are common in children because of the morphologic characteristic of the primary tooth and immature permanent tooth. In the dentoalveolar abscess, the causative factors are gross or recurrent decay, trauma, or perhaps, chronic irritation from a large restoration. Suppuration is usually confined to the bone around the tooth. If the infection is long-standing, it can perforate the thin buccal bony plate adjacent to the root of the involved tooth and spread into the subperiosteal area and then to the surrounding soft tissues. In a child, the dentoalveolar abscess usually perforates the buccal plate of bone because of the position of the tooth and the thinness of the overlying bone. If it does not drain intraorally, the infection can spread rapidly through the fascial planes of the face or neck.

The following are clinical manifestations of a dentoalveolar abscess in a child:

1. Pain: The tooth may be painful to percussion, or may exhibit spontaneous painful episodes.
2. Mobility: The tooth may have a greater than normal degree of movement in the socket when palpated.
3. Swelling: The soft tissues surrounding the tooth may be edematous and erythematous.
4. Temperature elevation: The child may be febrile (greater than 37.5°C [99.5°F]), have general malaise, and a decrease in appetite.
5. Fistulous tracts: These appear clinically as a pustule-like lesion on the gingiva (rarely on the face) when the infection has been present for a long time.
6. Extrusion: The tooth may become extruded because of the presence of fluid in the periradicular space.
7. Lymphadenopathy: Major lymph node enlargement can occur at any time during the infective process.

The first step in treating a perioral abscess is to determine whether a tooth is the causative agent. This can be accomplished by clinical examination and available radiographs. Corroboration of dental origin can be established by reviewing intraoral radiographs. The location and extent of any swelling and/or fistulous tracts, both intraorally or extraorally, should be noted.

It is important that the treatment of choice for a localized dentoalveolar abscess is local in its focus (e.g., drainage, moist heat). In cases of facial cellulitis with lymphadenopathy caused by acute dentoalveolar abscess, the antibiotic of choice is penicillin (or erythromycin, if there is a known allergy to penicillin). The initial dose for children who weigh more than 60 pounds (27 kg) is 1 g orally, followed by 500 mg every 6 hours until the patient can be seen by a dentist. For children who weigh less than 60 pounds (27 kg), the initial penicillin dose is 500 mg, followed by 250 mg every 6 hours.

Penicillin-sensitive streptococci and anaerobic organisms predominate as the cause of acute dentoalveolar abscesses. If

there is a facial cellulitis over the maxilla extending toward the inferior border of the orbital rim or if there is a mandibular cellulitis, which might be a potential cause of airway compromise, the child should be admitted to the hospital where intravenous antibiotic therapy can be managed. Treatment for facial cellulitis is covered in Chapter 84.

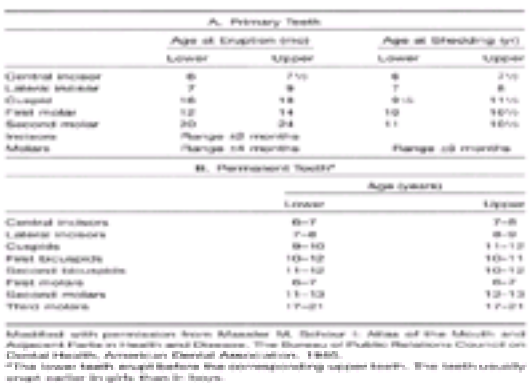
Other factors to consider in determining the need for hospital admission include the child's ability to take fluids and the likelihood of the parent's cooperation for follow-up dental care. Obviously, if the child is toxic, a hospital admission is indicated. In addition to antibiotics, warm oral saline rinses should be used and heat should be applied extraorally. There is some feeling that extraoral heat will cause the abscess to point extraorally and thus produce an exterior fistula. This has not proven true in our experience. Mild analgesic therapy such as acetaminophen is usually sufficient. Dental consultation should be obtained in order to vent the offending tooth, to establish drainage, to incise a fluctuant mass, or to remove the tooth.

As with infection elsewhere in the body, the basic surgical principles of treatment must be used: 1) establish drainage and 2) remove the cause. An abscessed primary tooth must be vigorously treated because such infections can affect the developing unerupted permanent tooth bud. A facial cellulitis can have severe systemic consequences, including cavernous sinus thrombosis, airway obstruction, brain abscess, and septicemia.

In some cases, there may be a need for additional consultation with infectious disease experts, especially in a situation in which systemic disorders render the child more susceptible to infection.

Pericoronitis

Pericoronitis is a localized infection surrounding an erupting tooth. It is usually associated with erupting molars in the adolescent patient, although a mild form may be associated with the eruption of the first permanent molar at age 6 (Table 124.1). Symptoms usually include pain distal to the last erupted tooth in the dental arch, along with erythema and edema localized to the gingiva in the retromolar area. Lymphadenopathy, trismus, and dysphagia may accompany these symptoms. An elevated body temperature is an occasional finding. It is not unusual to see or palpate the cusps of the erupting tooth. The patient may complain of an inability to completely close his or her mouth, as a result of the edematous gingiva. Otalgia is an uncommon complaint.



A. Primary Teeth

	Age at Eruption (mo)		Age at Shedding (yr)	
	Lower	Upper	Lower	Upper
Central incisor	6	7½	6	7½
Lateral incisor	7	9	7	8
Cuspid	16	18	9½	11½
First molar	12	14	10	10½
Second molar	20	24	11	10½
Incisors	Range 6–9 months			
Molars	Range 12 months		Range 2 months	

B. Permanent Teeth*

	Age (years)	
	Lower	Upper
Central incisors	6–7	7–8
Lateral incisors	7–8	8–9
Cuspids	9–10	11–12
First bicuspids	10–12	10–11
Second bicuspids	11–12	10–12
First molars	6–7	6–7
Second molars	11–13	12–13
Third molars	17–21	17–21

Modified with permission from Wheeler M, Schour I: Atlas of the Mouth and Adjacent Parts in Health and Disease. The Bureau of Public Relations Council on Dental Health, American Dental Association, 1960.

*The lower teeth erupt before the corresponding upper teeth. The teeth usually erupt earlier in girls than in boys.

Table 124.1. Eruption Schedule for Specific Teeth

Emergency treatment includes local curettage, oral rinses, heat, and scrupulous oral hygiene. Penicillin may be necessary (for dose, see “Dentoalveolar Abscess”) when there are systemic symptoms or facial swelling. Antibiotics should be continued until the tooth has erupted or treatment is completed.

Primary Herpetic Gingivostomatitis or Herpes Simplex Virus Type 1

Primary herpetic gingivostomatitis, or herpes simplex virus type 1 is a communicable childhood disease that is not a true dental emergency, but is a common cause of ED visits. The child is usually an infant or toddler who stops eating, drinking, or talking and is extremely irritable. The child usually has had an elevated temperature for 3 to 5 days before any clinical oral findings. A higher incidence of primary herpes has been noted after other viral illnesses. Older children may complain of headaches, malaise, nausea, regional lymphadenopathy, and/or bleeding gums. The physical examination reveals fiery red marginal gingiva with areas of spontaneous hemorrhage. Within 1 or 2 days, yellowish, fluid-filled vesicles develop on the mucosa, palate, or tongue and coalesce. The vesicles rupture spontaneously, leaving extremely painful ulcers, covered by a yellow or gray membrane and surrounded by an erythematous zone. Ulcers, especially on the lips, may become encrusted, as seen in Figure 124.2.

FIGURE 124.2. A child with typical crusted extraoral lesions of late primary gingivostomatitis.

If necessary, a definitive diagnosis can be made by isolation of herpes simplex virus in tissue culture (although this is rarely indicated). Emergency treatment includes reassuring the parent and rehydrating the patient. The disease, like recurrent herpes labialis, is self-limiting, with a duration of 7 to 14 days. Dehydration and weight loss are the major concerns; therefore, milk shakes, ice cream, and liberal quantities of clear fluids should be encouraged. The young child with extensive lesions may require hospitalization for intravenous hydration.

Viscous Xylocaine rinses and “magic mouthwash,” Kaopectate and Benadryl, may be unrealistic for children in this age range. The unpleasant taste sometimes negates any benefit that the topical anesthetic gives, and makes administration difficult.

Secondary infection, although rare, is of concern for those children who may be immunosuppressed and, in those cases, antibiotic therapy may be indicated.

Acute Necrotizing Ulcerative Gingivitis, Vincent's Disease, Trench Mouth

Acute necrotizing ulcerative gingivitis (ANUG), Vincent's disease, or trench mouth is characterized by increases in the fusiform bacillus and *Borrelia vincentii,* a spirochete, which usually coexist in a symbiotic relationship with other oral flora. Adolescents complain of soreness and point-tenderness at the gingiva and often tell the physician that they feel as if they “cannot remove a piece of food that is painfully stuck between their teeth” (a wedging sensation). They may also complain of a metallic taste in their mouth and of bleeding gums. Upon examination, the breath has an obvious fetid odor. The gingivae are hyperemic and the usually triangular gingiva between the teeth is missing, or “punched out” (Fig. 124.3). Intense pain is produced with probing, and a gray, necrotic pseudomembrane may cover some areas of gingiva.

FIGURE 124.3. A child with typical “punched out” gingiva—pathognomonic for acute necrotizing ulcerative gingivitis. (Courtesy of Dr. Mark Snyder.)

It is extremely rare to find ANUG in a young child, but a mistaken diagnosis is often made by physicians, confusing this disease with primary herpetic gingivostomatitis. Primary herpes is usually seen in infants and toddlers, and ANUG is characteristically seen in adolescents and young adults (ages 15 to 35). Emotional stress has been linked to the onset of the disease process. The adolescent should be advised to maintain better oral hygiene and to use frequent hydrogen peroxide mouth rinses. Diluted 1:1 with warm water, the hydrogen peroxide is vigorously swished and forced between the teeth as often as possible throughout the acute phase. Because of the rapidity of tissue destruction and sensitivity of the organisms, as well as risk of secondary infection, penicillin should be prescribed for the first week. When the acute phase is over, the patient should be sent to the dentist for a thorough debridement of the area.

ORAL AND PERIORAL PATHOLOGY PRESENTING AS DENTAL EMERGENCIES

Erythema Multiforme

Erythema multiforme is primarily a dermatologic disease characterized by macular, papular, vesicular, or bullous lesions on the skin or oral mucosa (Fig. 124.4). The lips may appear crusted, as in primary herpes. Lesions arise from an erythematous area that enlarges and develops a central vesicle or “target lesion.” Oral lesions arise at about the same time as skin lesions and are also variable in their clinical appearance, producing painful, bleeding, crusting erosions. These symptoms may occur as an acute drug reaction, but can be precipitated by herpes simplex. Stevens-Johnson syndrome is a more disseminated form of erythema multiforme in which conjunctival and genital lesions are seen concomitant with the oral and cutaneous lesions (see Chapter 99). Identifying and eliminating the precipitating drug is the first step in treatment. Immediate care may include caloric and fluid support. Steroids may be of help in severe cases.

FIGURE 124.4. Intraoral view of erythema multiforme.

Epidermolysis Bullosa

Epidermolysis bullosa is a hereditary vesiculobullous condition affecting the skin, mucous membranes, and teeth. There are several forms of the disease. In the dominant form, oral bullae have been documented. In the recessive dystrophic form, the teeth have hypoplastic enamel, have an increased susceptibility to dental caries, and delayed eruption. Oral mucosal involvement appears soon after birth with vesicles from the negative pressure of the sucking reflex. The labial mucosa and lips can appear scarred and taut. Even routine dental management such as toothbrushing may cause the eruption of bullae on the mucosa and lips. Emergency visits may result from pain or bleeding from oral lesions. Treatment should palliate pain and support nutritional requirements.

Pyogenic Granuloma

Pyogenic granulomas develop as granulation tissue in response to an irritant or trauma. Clinically, they are red, elevated, and usually ulcerated. Initial growth is rapid. Pyogenic granulomas are most common on the gingivae and may remain static for a time before becoming fibrotic. Treatment consists of simple excision, but recurrence is common unless the causative agent (calculus or foreign body) is removed.

Epstein's Pearls

Epstein's pearls are keratin-filled cystic lesions located along the midpalatine raphe in the newborn. Often, only a few can be visualized, but sometimes there are too many to count. They are thought to arise from embryologically trapped epithelium. They are present in about 80% of neonates and should be considered a variation of normal. No treatment is necessary because they disappear within several weeks.

Bohn's Nodules

Bohn's nodules are remnants of the dental lamina that appear as cysts on the buccal or lingual aspect of the maxillary and mandibular dental ridges in the newborn. They may appear in the palate but are far removed from the midpalatine raphe and should not be confused with Epstein's pearls. No treatment is necessary because they disappear in several weeks.

Dental Lamina Cysts

Dental lamina cysts are multiple, or occasionally solitary, nodules on the alveolar ridge of newborn (Fig. 124.5) or young infants. They represent trapped remnants of the dental lamina. They are soft and spongy, asymptomatic, and tend to disappear with time or the eruption of teeth.

FIGURE 124.5. Dental lamina cyst in a neonate.

Eruption Cysts

Eruption cysts arise from the pre-eruptive dental sac and appear as a swelling of the alveolar ridge. They are associated with the eruption of primary (Fig. 124.6) and permanent teeth. Occasionally, they fill with blood and may be termed

eruption hematomas (Fig. 124.7). Treatment is unnecessary because the erupting tooth usually emerges within several days. If treatment is necessary because of the size of the lesion, excision of the overlying soft tissue to expose the erupting tooth eliminates the problem.

FIGURE 124.6. An eruption cyst associated with an erupting primary central incisor.

FIGURE 124.7. Erupting hematoma over erupting maxillary permanent central incisor.

Riga-Fede Disease

Riga-Fede disease is a condition observed in infants with natal or neonatal teeth. It is characterized by ulcerations on the ventral surface of the tongue from irritation caused by the incisal edges of lower incisors during nursing or suckling. Treatment should be avoided, but extraction may be necessary if they interfere with feeding.

Orofacial Neoplasms

Orofacial neoplasms in children are rare, but may be frightening to the patient and their family. Common benign and malignant neoplasms may result in emergency visits and, therefore, are included. Identification is central to the triage process.

The oral papilloma is a benign epithelial neoplasm that is an exophytic elevation of the surface epithelium with small fingerlike projections from its surface. These lesions, which rarely become malignant, constitute about 8% of all oral neoplasms in children. Slightly more than a third of the lesions occur on the tongue and (in decreasing order of frequency) palate, buccal mucosa, gingiva, and lip. If spontaneous involution does not occur, the usual treatment is surgical removal.

The fibroma is a common smooth-surfaced lesion with a sessile base. Its consistency varies from soft to firm, and its size ranges from a few millimeters to a centimeter or more in diameter. It may become whitened secondary to the overlying hyperkeratosis caused by trauma. Fibromas occur during the first and second decades of life and are usually found on the palate, tongue, cheek, and lip. Surgical removal is sometimes indicated and recurrence is rare if the source of the irritation is removed.

The mucocele appears as a soft, raised, fluid-filled and well-delineated nodule, most commonly on the lower lip (Fig. 124.8). Superficial lesions appear translucent and are bluish, whereas deep-seated lesions have a normal color. A mucocele in the floor of the mouth is termed a ranula and is seen as a dome-shaped, fluid-filled lesion. Mucoceles are thought to result from severance or obstruction of a salivary gland duct, with pooling of mucin in the lamina propria. Complete excision of the mucocele or marsupialization of the ranula is indicated.

FIGURE 124.8. Mucocele associated with minor salivary gland of the lower lip.

CHAPTER 125

Neurosurgical Emergencies, Nontraumatic

DALE W. STEELE, MD

Department of Pediatrics, Section of Emergency Medicine, Brown University, and Emergency Department, Hasbro Children's Hospital, Providence, Rhode Island

Patients with non-traumatic acute neurosurgical problems come to the emergency department (ED) with a variety of non-specific signs and symptoms, including headache, vomiting, seizures, changes in mental status, weakness, and coma. Because headache and vomiting are common, a high index of suspicion is required. This point is amplified by a case series from a large center that reports seven children who died unexpectedly from acute hydrocephalus associated with a previously undiagnosed intracranial tumor, most of whom had been managed as presumed acute gastroenteritis and treated with intravenous hydration.

Because most of the acute problems that result in an ED visit for non-traumatic neurosurgical problems are related to the onset of increased intracranial pressure (ICP), this chapter opens with a general discussion of ICP. A detailed description of the specific congenital, infectious, vascular, and neoplastic entities that may result in intracranial hypertension follows.

INCREASED INTRACRANIAL PRESSURE

Pathophysiology

The functions of the buffering systems that maintain ICP at normal levels have been detailed in Chapter 105. The relatively rigid cranium contains three components: 1) brain tissue predominantly, 2) cerebrospinal fluid (CSF), and 3) blood. An abnormal increase in volume of any of these components (by means of edema or mass lesion of the brain tissue, increased production or diminished absorption of CSF, or increased cerebral perfusion pressure related to increased blood flow) may result in elevated ICP. This closed space has limited capacity to compensate for increased volume from hydrocephalus, cerebral edema, hemorrhage, mass lesions, or pus.

ICP levels normally rise and fall over the course of the day. ICP is at its peak during sleep, because the horizontal posture and the relative hypoventilation that increases arterial P CO_2 result in increased cerebral blood flow. This condition is especially true during rapid eye movement (REM) sleep, which usually occurs just before awakening. Headaches that awaken a child during the night or that occur on awakening are always significant, because they may be caused by ICP waves elevated beyond the normal nighttime peaks. With the improved ventilation and the assumption of upright posture on arising, P CO_2 is lowered and cerebral vasodilation is lessened. If vomiting occurs, the accompanying hyperventilation also decreases cerebral blood flow. As a result, the severity of the headache may then lessen significantly in the awakened child.

Clinical Manifestations

A careful history must be taken with respect to the timing and severity of headaches, vomiting, changes in behavior, visual changes, and episodic decreases in level of consciousness (Table 125.1). Nighttime and morning headaches that improve on arising are always ominous suggestions of elevated ICP, as is recurrent vomiting without fever, abdominal pain, or diarrhea.

Symptoms	Signs
Headache	Papilledema
Nocturnal, episodic severe	Cranial nerve palsies
Vomiting	Meningismus
Stiff neck	Head tilt
Double vision	Retinal hemorrhage
Transient visual loss	Macewen's (cracked pot) signs
Gait difficulties	Decorticate/decerebrate posturing
Dulled intellect	Coma
Irritability	Progressive hemiparesis
	Bradycardia

Table 125.1. Signs and Symptoms of Elevated Intracranial Pressure

The clinical examination can help confirm the presence of intracranial hypertension, but a normal examination cannot reliably exclude it. Funduscopic examination should be performed to look for papilledema or optic atrophy. Visual fields and visual acuity should be checked. Cranial sutures may split in infants and young children with chronic elevation of ICP, resulting in a hyperresonant note when the skull is percussed, a “cracked pot” sound known as Macewen's sign. Cranial nerve palsy may occur, usually affecting the third and sixth nerves, resulting in dilated pupil, diplopia, and strabismus. When the fourth nerve is affected, the child may exhibit a “cock robin” head tilt. Cerebellar herniation may also cause head tilt; if herniation is bilateral, the neck may be held in an extended position.

The possibility of cerebral herniation should be considered and aggressively treated in the presence of an evolving pattern of diminishing level of consciousness, unexplained bradycardia, pupillary changes, or abnormal asymmetric motor responses to stimuli. Abnormal motor posturing in this setting may be confused with seizure activity. Cushing triad (hypertension, bradycardia, and irregular respirations) is a near terminal event, with bradycardia usually the first and most sensitive indicator.

Other diagnoses must be considered, but some can be ruled out by the history and examination. Migraine headaches are rarely present on waking and are usually relieved by rest. Children up to at least 7 years of age do not have frontal sinuses, ruling out the possibility of frontal headache caused by sinusitis in this younger age group. However, frontal sinusitis in adolescents has a significant rate of intracranial complications, warranting meticulous evaluation for this possible cause. The headaches of school phobia do not usually occur during sleep nor do they lessen on arising.

Management

The emergency treatment of increased ICP depends on the patient's clinical state and the cause of the intracranial hypertension (Table 125.2). However, the first priority in all patients is to follow the ABCs (airway, breathing, and circulation) of resuscitation and to prevent hypoxemia, hypercarbia, and systemic hypotension with oxygenation, ventilation, and appropriate fluid therapy. Seizures should be prevented if possible and treated aggressively when they occur, because the ICP spikes during seizures aggravate intracranial hypertension. Phenytoin (15 to 20 mg/kg) and fosphenytoin are the preferred drugs.

Prevent hypoxia and hypercarbia
Tracheal intubation/controlled ventilation
Seizure treatment and prophylaxis
Maintain adequate cerebral perfusion pressure and cerebral perfusion
Treatment of shock
Limitation of excessive hyperventilation
Decrease cerebral blood volume
Acute hyperventilation
Decrease brain tissue volume
Mannitol
Dexamethasone for vasogenic edema
Decrease cerebrospinal fluid (CSF) volume
CSF drainage
Acetazolamide
Removal of mass lesion
Surgical removal/decompression

Table 125.2. Treatment of Increased Intracranial Pressure

When the clinical picture suggests intracranial hypertension, computed tomography (CT) of the head should be performed without contrast material as soon as the patient is stable. Lumbar puncture should be withheld until the scan has been read for fear of precipitating herniation. The temptation to give sedative agents to the agitated patient to accomplish head CT or to facilitate transport should be avoided. Sedative agents given without controlled ventilation may result in hypercarbia, causing an increase in cerebral blood volume and, therefore, in ICP. Sedatives may also block protective airway reflexes, increasing the risk of aspiration. Therefore, inserting an endotracheal tube before CT scan or before transport is often preferable.

However, intubation should not be attempted without appropriate expertise and use of proper medications to blunt the increases in ICP associated with the procedure. Rapid sequence intubation (Chapter 5 and Chapter 105) should be accomplished after pre-oxygenation by giving a sequence of atropine (0.02 mg/kg), lidocaine (1.5 mg/kg), and thiopental (2 to 5 mg/kg), followed by a neuromuscular blocker. Succinylcholine (1 to 1.5 mg/kg) has rapid onset and short duration, but the fasciculations related to its depolarizing effects may cause transient increases in ICP. Rocuronium (0.6 to 1.2

mg/kg) and vecuronium (0.1 to 0.2 mg/kg) are non-depolarizing blockers that provide adequate alternatives.

In the absence of signs of impending herniation, P_{CO_2} should be controlled by mild hyperventilation in the range of 30 to 35 mm Hg. Prolonged excessive hyperventilation may cause cerebral ischemia. Continuous, portable capnometry may be useful as a monitor to avoid excessive hyperventilation during transport or diagnostic imaging.

Acute hyperventilation (hand ventilation) is used as an attempt to reverse signs of acute herniation. The head of the bed should be elevated to 30 degrees and the head maintained in a neutral position to promote venous drainage. Also, when the child exhibits acute herniation, drainage of CSF, either from a shunt reservoir or by a ventricular tap via an open fontanel, a split suture, or a burr-hole, allows controlled reduction of CSF volume. A ventriculostomy catheter may also be used to directly measure ICP, to direct medical therapy, and to allow drainage of CSF. Mannitol (0.25 to 2.0 g/kg) is the most useful drug to acutely decrease ICP in the deteriorating patient. Acetazolamide and furosemide have a limited role in acute management. Dexamethasone (1 mg/kg) is of controversial benefit, has slow onset, and appears to be most useful in treating vasogenic brain edema associated with tumors and brain abscess and non-traumatic hemorrhage. Surgical removal of collections of blood or pus may be indicated to lower ICP, as discussed later in this chapter.

HYDROCEPHALUS

Hydrocephalus is characterized by dilated cerebral ventricles that contain an excessive amount of CSF, resulting from imbalance between production and absorption. Production, which is accomplished in the choroid plexus, almost always remains stable and is only rarely excessive. In non-communicating hydrocephalus, CSF in the ventricular systems is blocked from communicating with CSF in the subarachnoid spaces and basal cisterns by a congenital or acquired defect. In communicating hydrocephalus, the block in absorption is on the meningeal surfaces, outside the ventricular system. Congenital hydrocephalus may result from aqueductal stenosis or in association with Dandy-Walker or Arnold-Chiari malformations. Acquired hydrocephalus may follow bacterial meningitis, be secondary to tumor (particularly in the posterior fossa), or result from the inflammatory response to subarachnoid or intracranial hemorrhage.

Previously Undiagnosed Hydrocephalus

Children with undiagnosed hydrocephalus rarely present first to the ED, but hydrocephalus must be considered in all children with symptoms suggestive of increased ICP. A careful history should be taken of all previous illnesses and traumas. In a child with unexplained headache, chronic vomiting, and irritability, head circumference should be recorded and the fontanel, if open, evaluated. The skull should be transilluminated and dilated scalp veins should be noted. A “cracked pot” sound may be noted on percussion if the sutures are split. The pupils and extraocular movements should be examined. Difficulty with upward gaze (“sunset” sign) may be seen. Muscular spasticity, particularly in the lower extremities, may develop as cortical motor fibers are stretched by the ventricular dilation.

Management

Non-contrast head CT demonstrates enlarged ventricles. The urgency with which either insertion of a ventricular shunt or ventricular drainage needs to be performed depends on the child's condition. Ventricular puncture through an open fontanel or coronal suture may be lifesaving in a child with evidence for impending cerebral herniation who is unresponsive to hyperventilation and mannitol.

Previously Shunted Hydrocephalus

The placement of CSF shunts is currently the most commonly performed neurosurgical procedure. These shunts allow diversion of CSF into another area of the body outside the brain, most commonly the peritoneal cavity, thereby relieving pressure on the brain. Unfortunately, placement of shunts is accompanied by complications, including malfunction, obstruction, infection, malposition, and migration. Children who have shunts represent a heterogeneous group with multiple causes for hydrocephalus, including: congenital defects, intraventricular hemorrhage, myelodysplasia, central nervous system (CNS) infection, and brain tumor.

Pathophysiology

Many different types of shunts are in use; therefore, emergency physicians must become familiar with those commonly used in their area. All shunts share three common features 1) a radiopaque ventricular catheter; 2) a one-way valve; and 3) a long distal tubing that is palpable subcutaneously and that enters, most commonly into the peritoneal cavity, but rarely into the right atrium or pleural cavity. Many shunts also include a pumping mechanism and a reservoir, which enables percutaneous sampling of CSF without damage to the shunt.

Shunt malfunctions are the most common complication of CSF shunts. The risk for shunt failure is greatest in the first months after placement, with a mean survival time of 5 years. Approximately 80% of patients require a revision by 10 years. Obstructions occur most commonly (approximately 80%) at the proximal (ventricular) end as a result of occlusion by tissue or migration of the shunt tip into the brain parenchyma. The valve may occasionally become blocked. Distal obstruction also may result from disconnection of the shunt tubing, migration of the catheter outside the peritoneum, perforation of the bowel, or pseudocyst formation. Shunt infections eventually result in obstruction.

Shunt Malfunction

Clinical Manifestations

Patients with shunt malfunction commonly present with manifestations of increased ICP. Children may complain of headache (often worse in the morning), screaming episodes, lethargy, and other behavioral changes and/or visual

symptoms. Vomiting is common. Parents, particularly those who have witnessed prior episodes of shunt malfunction, are perceptive to subtle, and often intermittent symptoms that herald shunt malfunction. On physical examination, unilateral or bilateral cranial nerve palsies, especially a non-localizing sixth nerve palsy, may be present. Intermittent downward gaze (sunset sign) may be reported or observed. Swelling from CSF tracking along the shunt tract is indicative of obstruction. The fontanel may be full and tense, even when the infant is upright. Rapid enlargement in head circumference or increase in the prominence of scalp veins may occur. Infants and young children with split sutures have a characteristic hyperresonant sound when the skull is percussed (“cracked-pot” sound) known as a positive Macewen's sign. Papilledema is uncommon in acute shunt malfunction. Head tilt may be seen as a result of fourth cranial nerve palsy or cerebellar tonsillar herniation.

Of particular concern are waves of severe headache with or without visual changes, loss of consciousness, decerebrate posturing, or new third nerve palsy. Although seizures are common in patients with CSF shunts, one reported series revealed that only 2.9% of ED visits for seizures in patients with shunts culminated in shunt revision. Thus, a seizure alone is seldom an indication of shunt malfunction. Most shunts have a pumping mechanism, but pumping the shunt correlates poorly with shunt obstruction. In one series, shunt pumping in patients with suspected shunt malfunction had a sensitivity of 18% with a positive predictive value of only 17%. The shunt should not be routinely pumped because the negative pressure generated in a small ventricle may occasionally result in obstruction. However, if the ventricular catheter is shown on CT scan to be in the center of a dilated ventricle and the shunt umbilicates on depression with slow refill, shunt obstruction is likely.

Management

If the history or physical examination suggests shunt malfunction, early neurosurgical consultation is strongly recommended. A plain radiographic “shunt series” should be done, consisting of anteroposterior and lateral views of the skull, neck, thorax, and abdomen. These radiographs allow the type, location, connections, and intactness of the system to be evaluated. Occasionally, split sutures on the skull film suggest increased ICP. Noncontrast head CT should also be taken and compared, if possible, with previous scans taken when the shunt was functioning. In most cases (approximately 80%), these studies identify shunt malfunction.

Shunt tap may also be useful in patients in whom the function of the shunt is questionable. This procedure should be completed under sterile conditions with a knowledge of the anatomy of the patient's shunt. A small, but significant risk of causing a shunt infection by performing a shunt tap exists. Therefore, diagnostic shunt taps are usually performed selectively by the neurosurgical consultant. Three pieces of information can be obtained. First, assuming the ventricular end is patent, the pressure in the system can be estimated by the level to which CSF rises when the butterfly tubing is held erect. A falsely low reading results if the ventricular end is obstructed. If the pressure is high, CSF may be withdrawn until a pressure of approximately 10 cm of water is reached. Second, downstream drainage is checked by permitting CSF to flow distally, observing the height at which the CSF column ceases draining. Third, the fluid is sent to the laboratory to evaluate for CSF infection.

The urgency of shunt revision depends on the patient's status. Patients with evidence of obliteration of the perimesencephalic cistern appear to be at particularly high risk for sudden deterioration. Patients with proximal obstructions may worsen quickly, and if the child suddenly deteriorates, CSF cannot be quickly withdrawn from the shunt reservoir to relieve pressure. Because fluid cannot be drawn from the shunt, the ventricle must be tapped through the fontanel, if open, through the sutures if they are split, or through the shunt burr hole. This latter maneuver usually damages the shunt and is therefore simply a temporizing measure to lower the ICP before operative shunt revision.

When the distal end of the shunt is blocked, the ICP can be immediately lowered by removing CSF through a shunt tap. The need for emergency shunt revision is less in this setting because the ICP can be easily controlled by tapping the shunt. Acetazolamide and dexamethasone may be used as temporizing measures if shunt revision is to be delayed, but may not be effective.

In some patients, ventriculomegaly may persist despite a functioning shunt. In these patients, prior CT scans are particularly helpful. Conversely, some patients have symptoms and signs of increased ICP despite small or unchanged ventricules, which is called the “slit ventricle” syndrome. This condition may be the result of intermittent proximal obstruction, poor ventricular compliance, or overdrainage of CSF. A history of onset or worsening of symptoms with upright posture suggests overdrainage. These children require careful further evaluation, which may include ICP monitoring, to determine the functions of their symptoms.

Shunt Infection

About 70% of all shunt infections occur within 2 months of surgery.

Pathophysiology

Infections are caused by low virulence organisms found in skin flora. *Staphylococcus epidermidis* accounts for approximately 75% of shunt infections, followed by Gram-negative organisms and *Staphylococcus aureus. S. epidermidis* recovered from CSF fluid shunt devices secrete an extracellular polysaccharide “slime” substance that coats the shunt, making the enclosed colonies of organism highly resistant to phagocytosis and systemic antibiotics.

Clinical Manifestations

In the post-operative period, erythema and warmth along the course of the shunt are highly predictive of early wound infection. Later, signs of indolent infection are often variable and nonspecific. Signs of shunt malfunction occur commonly. The adage, “an infected shunt is an obstructed shunt” is well remembered. Although fever raises concern for shunt infection, documented shunt infections were associated with fever in only 42% of patients in one series. Meningeal

signs have been reported in only about 33% of patients. Abdominal symptoms from an associated peritonitis may predominate in cases of pseudocyst formation with distal obstruction.

Management

A definite diagnosis of shunt infection is made by tapping the shunt and obtaining a CSF specimen. A definite, although small, rate of infection occurs as a result of a tap, and in someone with the potential for bacteremia, the blood carried into the shunt reservoir on the tip of the needle may be contaminated and produce a shunt infection. Thus, shunt tap is not indicated in all children with a shunt who present with fever. A diligent search for alternative explanations of fever should be undertaken. Urinary tract infections are a particularly common cause of fever in children with myelomeningocele. Debilitated patients with severe developmental delay are at risk for pneumonia. These potentially occult sources should be excluded. Fever without localizing signs in those patients in whom the current shunt was placed or revised many months to years ago and who lack signs and symptoms of shunt malfunction may be appropriately managed with close follow-up and observation without shunt tap.

In patients with noncommunicating hydrocephalus, if the shunt tap is negative but a CNS infection is a likely clinical diagnosis, a lumbar puncture is required because ventriculitis may not accompany meningitis. CSF obtained from the shunt tap is sent for Gram stain, cell count, glucose and protein, and culture. If the CSF contains more than 100 cells/mm^3, cultures are positive in about 90% of patients. However, most infected shunts have only modest pleocytosis (less than 200 white blood cells/mm^3), slight decrease in glucose, and modest protein elevation. The Gram stain is positive for Gram-positive cocci in clusters in approximately 50% of infections caused by *S. epidermidis.* Blood cultures are positive in only a minority of patients. The peripheral white blood count is of little use in predicting patients with infected shunts.

In patients with abdominal symptoms, neurosurgical consultation should be obtained before exploratory laparotomy for suspected appendicitis. Abdominal ultrasonography is especially useful for diagnosing abdominal pseudocyst, which is always secondary to infection. If shunt infection is diagnosed and appropriate cultures are obtained (including CSF via shunt tap, blood culture, and possibly urine and soft-tissue aspirate cultures from areas of local inflammation), treatment with intravenous vancomycin (15 mg/kg) may be started, pending growth on the cultures. Patients require complete removal of the entire shunt and a period of external drainage, followed by placement of a new shunt into a different anatomic location.

STROKE

Stroke denotes a sudden onset of a persistent focal neurologic deficit, resulting from interruption of blood flow to a localized area of the brain. Pediatric stroke has a wide range of causes and risk factors distinct from those in adults, thus limiting comparison to stroke in adults.

Hemorrhagic Stroke

In children and adolescents, rupture of an arteriovenous malformation is the most common cause of spontaneous intracranial hemorrhage. (General causes of hemorrhagic stroke are listed in Table 125.3.) These lesions are within the cerebral parenchyma; therefore, when they bleed, the hematoma is intracerebral and the bleeding is arterial. Arterial intraparenchymal bleeding results in progressive surrounding edema and focal mass effect. Congenital or acquired coagulation disorders, such as severe factor VIII deficiency or severe thrombocytopenia, may result in spontaneous intracranial bleeding with minimal or no preceding head trauma.

Secondary hemorrhage into ischemic brain
Vascular malformations
Arterio-venous malformations
Sickle cell disease
Saccular (berry) aneurysms
Hemorrhage into intracranial tumor
Coagulopathy
Hemorrhagic disease of the newborn (vitamin K deficiency)
Clotting factor deficiency (VIII, IX, XI)
Thrombocytopenia
Arterial hypertension
Renal vascular or parenchymal disease
Coarctation of the aorta
Pheochromocytoma
Illicit drugs with sympathomimetic effect
Amphetamines, cocaine

Table 125.3. Causes of Hemorrhagic Stroke

Ruptured aneurysms are rare, accounting for only 10% of intracranial hemorrhage in children. Congenital ruptured aneurysms rarely may be seen as early as the first week of life. The bleeding occurs from an aneurysm located at branching points of the major arteries coursing through the subarachnoid space at the base of the brain. The incidence of aneurysm is increased in several inherited conditions, including autosomal-dominant polycystic kidney disease, Ehlers-Danlos type IV, neurofibromatosis type 1, and Marfan's syndrome.

Other vascular abnormalities associated with intracranial bleeding include cavernous angiomas and hemangioblastoma associated with von Hippel- Lindau syndrome. Cavernous angiomas are low-flow lesions that can occur anywhere in the cerebrum, brainstem, cerebellum, or spinal cord. Because they lack large arterial feeders, onset of symptoms is usually subacute. The greatest danger is of acute hydrocephalus caused by occlusion of the fourth ventricle, resulting from

posterior fossa hemorrhage and/or swelling.

Ischemic Stroke

Ischemic injury to the brain occurs as a result of embolism from the heart or proximal arterial circulation, or from thrombosis in the arterial or sinovenous system. The most common risk factor (in about 25% of patients) is congenital heart disease.

Although it is difficult to separate risk factors from causes, several conditions have been associated with embolic or thrombotic stroke (Table 125.4). Embolic sources are primarily from the heart (dilated or abnormal chambers), from abnormal or infected heart valves, or from “paradoxical” emboli via lesions associated with right-to-left cardiac shunts. Other risk factors include congenital or acquired vascular disorders and factors that result in hypercoagulability, such as 1) oral contraceptive use, 2) anticardiolipin antibodies, and 3) deficiencies of protein S, protein C, or antithrombin III. Stroke occurs in 6 to 9% of patients with sickle cell disease (SCD). In children with SCD, most strokes are ischemic, resulting from occlusion of intracranial carotid and middle cerebral arteries. An important cause of stroke is arterial dissection, which may be spontaneous or associated with minimal trauma. This condition often results in acute thrombosis and has been treated with anticoagulation and endovascular thrombolytic treatment.

Cardioembolic
Cyanotic congenital heart disease
Right-to-left shunts (e.g., patent foramen ovale)
Congenital or acquired valvular defects
Contractile dysfunction
Rhythm disturbance
Vascular disease
Sickle cell disease
Arterial dissection
Homocystinuria
Vasculitis
Moyamoya
Migraine
Thrombotic (arterial and sinovenous)
Hypercoagulable state, *congenital or acquired*
Hyperviscosity (polycythemia, dehydration)
Genetic/metabolic

Table 125.4. Causes of Ischemic Stroke

Clinical Manifestations

Diagnosis of stroke syndrome in children is often delayed by the failure to consider it. Focal weakness in association with headache or after a seizure should not be dismissed as hemiplegic migraine or post-ictal Todd's paresis. Presenting symptoms are non-specific as to the cause, but several patterns exist. Depending on the location and nature of the intraparenchymal lesion, stroke in children may present with sudden onset of hemiplegia or hemiparesis, aphasia, and sensory symptoms. These focal signs are frequently accompanied by seizures, fever, acute change in mental status, and signs and symptoms of increased ICP. Arterial dissection commonly presents as stroke with the patient complaining of sudden ipsilateral pain in the head, neck, or eye. It may be associated with Horner's syndrome if cervical sympathetic chain is involved, and a bruit may be heard over the involved carotid. The posterior circulation can also be involved, resulting in vertebro-basilar insufficiency resulting in cranial neuropathies, difficulties with balance and coordination, and tremor. Subarachnoid hemorrhage causes sudden severe headache and meningismus caused by the breakdown of blood products in the subarachnoid space, leading to meningeal irritation. As CSF circulates, symptoms of lower back pain and radicular leg pain may subsequently predominate.

Management

After initiation of supportive care to prevent secondary hypoxic ischemic injury and to ameliorate increased ICP, the next priority is to exclude an acute intraparenchymal or subarachnoid hemorrhage. Non-contrast head CT is sensitive for acute bleeding and should be obtained emergently. Noncontrast CT is a good test to exclude hemorrhagic causes of stroke, but it may be normal or near normal soon after the onset of symptoms of ischemic stroke. If subarachnoid hemorrhage is thought likely but not documented by CT, a lumbar puncture may be performed to enumerate red blood cells in the CSF. Xanthochromia from breakdown of blood products may also be seen, particularly if lumbar puncture is performed after the acute episode. Lumbar puncture has been associated with herniation in the setting of increased ICP and should be deferred until after a mass lesion or noncommunicating hydrocephalus has been excluded.

If intraparenchymal hemorrhage is found, most children with bleeding from suspected rupture of an arteriovenous malformation require early angiography to localize the bleeding and the arterial feeders. Medical therapy of associated edema and increased ICP may include dexamethasone (0.5 to 1.0 mg/kg; maximum 16 mg/day) and mannitol (0.25 to 2.0 g/kg). Seizures should be treated aggressively, and prophylactic administration of phenytoin (15 to 20 mg/kg) or fosphenytoin may play a role in this treatment. Coagulation defects should be corrected as appropriate (see coagulation emergencies, Chapter 87). Emergent splenectomy is indicated for intraparenchymal bleeding associated with idiopathic thrombocytopenic purpura (ITP).

Hemorrhagic stroke or secondary gross hemorrhage into an area of ischemic infarction may produce a rapidly expanding intracranial mass. Depending on the site of the hemorrhage, emergency surgical evacuation of the hematoma may be indicated to reverse cerebral herniation and lower ICP.

The management of ischemic stroke remains largely supportive. Acute carotid occlusion may result in significant hemispheric swelling sufficient to produce elevated ICP. This condition may require ICP monitoring and intensive medical

and perhaps surgical therapy to prevent or reverse transtentorial herniation. Invasive angiography and possibly endovascular thrombolytic therapy may be needed for definitive diagnosis and should be considered early in the diagnostic workup of ischemic stroke. Magnetic resonance imaging (MRI) permits visualization of brain infarction. Magnetic resonance angiography (MRA) yields further information about blood flow and the structure of cervical and intracranial vessels. Ultrasound may be used to evaluate the extracranial carotid circulation. Cardiac lesions are often found and may be evaluated with transthoracic or trans-esophageal echocardiography.

The decision to use anticoagulation must balance the likelihood of either extension of infarction or a second embolus with the risk of inducing hemorrhage. Anticoagulation is often used in children with arterial dissection, dural sinus thrombosis, or coagulation disorders, in those at high risk of embolism; or in response to progressive deterioration during the initial evaluation of a new cerebral infarction. The loading dose of heparin is 75 units/kg intravenously, followed by 20 units/kg per hour for children older than 1 year of age (or 28 units/kg per hour for children less than 1 year of age) titrated to a target activated partial thromboplastin time (aPTT) of 60 to 85 seconds. Alternately, low-molecular-weight heparin (Enoxaparin 1 mg/kg subcutaneously twice daily) has also been used.

Stroke in a patient with SSD is treated with simple or partial exchange transfusion to achieve a hemoglobin SS fraction of less than 30% and a hemoglobin level not greater than 10 g/dL to avoid problems of hyperviscosity.

The use of thrombolytic agents for ischemic stroke, administered intravenously, or locally utilizing angiographic catheters, is currently receiving significant attention. A single controlled trial of intravenous recombinant tissue plasminogen activator (t-PA) resulted in overall better outcomes in carefully selected adults treated within 3 hours after onset of symptoms. This therapeutic success has led to the concept of stroke as a “brain attack” analogous to a heart attack. In adults, placebo-controlled studies of intra-arterial thrombolysis are under way. However, as yet, no clinical efficacy trials of intra-arterial thrombolysis, nor a direct comparison between intravenous and intra-arterial thrombolysis, has been reported. The relative infrequency of childhood stroke and the heterogeneous patient population has hindered clinical trials of the sort possible in adults. There are anecdotal reports of successful endovascular thrombolysis in children. Intravenous thrombolytic therapy in children using t-PA (0.5 mg/kg) mostly for non-cerebral thrombotic complications has resulted in successful clot lysis, but at the expense of serious bleeding complications. If the diagnosis is delayed beyond 3 to 6 hours, risk of hemorrhage into ischemic infarcts clearly precludes any attempt at clot lysis. Some pediatric patients with acute ischemic stroke may benefit from thrombolytic therapy, when administered with caution, in a highly individualized manner using guidelines defined by ongoing randomized studies in adults.

CENTRAL NERVOUS SYSTEM INFECTIONS (SEE CHAPTER 84)

Infection of the CNS, including subdural empyema, brain abscess, bacterial and viral meningitis, and viral encephalitis, are often associated with some degree of increased ICP. Acute hydrocephalus may complicate tuberculous, fungal, amebic, and rarely bacterial meningitis. Subdural empyema occurs as a complication of parameningeal infections, such as sinusitis, orbital cellulitis, or mastoiditis, and is a true neurosurgical emergency, often progressing to death if not recognized early. Children with CNS infectious processes may present with fever, evidence of meningeal irritation, seizures, and increased ICP, which may progress to herniation and focal neurologic findings.

Management

Supportive care and antibiotics are the first priority in treatment of meningitis. Lumbar puncture should be deferred in the patient with cardiorespiratory instability. When an increase in ICP or mass lesion is suspected, the clinician must use extreme caution, and should not perform a lumbar puncture before excluding these diagnoses with an appropriate imaging study. A contrast-enhanced CT is necessary if a subdural empyema or brain abscess is suspected. Subdural empyemas require immediate neurosurgical drainage. Brain abscess is treated with dexamethasone, antibiotics, general management of intracranial hypertension, and often surgical drainage. An ICP monitor may assist in the medical management of intracranial hypertension associated with meningitis or encephalitis.

BRAIN TUMORS

Brain tumors in children usually present with a chronic history, but these signs and symptoms may have been attributed to benign causes. Neurologic abnormalities may be subtle. Children with brain tumors may develop the following four major symptom complexes: 1) cerebellar ataxia, 2) acute deterioration in the level of consciousness, 3) acute onset of cranial nerve palsies, and 4) severe recurrent headaches or vomiting. Headaches on awakening may be ominous, but many of the headaches associated with intracranial mass lesions are nonspecific.

Physical examination should include funduscopy to look for papilledema, cranial nerve examination for palsy, and search for focal motor deficits and ataxia. Acute symptoms may result from seizure, acute intracranial hypertension with pressure waves, or acute obstructive hydrocephalus or hemorrhage into tumor.

Management

Most children with dramatic acute symptoms requiring emergent management (obstructive hydrocephalus, mass effect, hemorrhage into tumor) are recognized on non-contrast CT, which is readily available to most EDs. Subsequent MRI with contrast is required for definitive management and evaluation of subtle abnormalities. The probability of elevated ICP should always be considered. Children with headache, papilledema, and altered levels of consciousness, which may suggest herniation, are at risk for sudden deterioration; therefore, early neurosurgical consultation should be obtained. Dexamethasone is useful in treating increased ICP before surgery. Patients are best managed by a multidisciplinary team that incorporates pediatric neurosurgery, neurology, and oncology.

SPINAL CORD COMPRESSION

Nontraumatic acute spinal cord dysfunction occurs in 4% of children undergoing treatment for cancer, usually because of spinal cord compression. Many children undergoing treatment for cancer develop back pain, which should raise concern for cord compression until proven otherwise.

Pathophysiology

Spinal cord compression may be the presenting sign of neuroblastoma, lymphoma, or sarcoma. Other causes of acute spinal cord symptoms include spinal epidural and, more rarely, subdural abscess, epidural hematoma, and congenital tethered cord.

Clinical Manifestations

Back pain in children commonly signals an important diagnosis. A history of localized or radicular back pain or refusal to walk mandates a careful evaluation. A history of change in gait or difficulty with bowel or bladder control should be sought. Localized tenderness to palpation is commonly found, and the level of maximal spinal tenderness is usually the site of pathology. A detailed neurologic examination should be documented with attention to extremity strength, reflexes, anal tone, and evaluation of sensory level. Compression of the spinal cord above the conus may be associated with increased or absent deep tendon reflexes, an extensor Babinski's reflex with symmetric (and profound) weakness, and a symmetric sensory level. Sphincter tone is spared until late, and progression is characteristically rapid. Compression of the conus medullaris results in increased knee and decreased ankle reflexes, extensor Babinski's reflex with a symmetric saddle distribution of weakness, and early sphincter involvement. Compression of the cauda equina typically results in asymmetric, often mild weakness, and asymmetric and radicular sensory distribution. Deep tendon reflexes are decreased with a plantar Babinski's response.

Management

Evidence for progressive cord dysfunction in the presence of significant neurologic deficits mandates immediate high-dose corticosteroid therapy with methylprednisolone 30 mg/kg or dexamethasone 2 mg/kg. Plain radiographs of the spine may be helpful, but emergency MRI is necessary to view the anatomic cause and degree of spinal compression. A previously unknown primary tumor is a clear indication for immediate decompressive surgery because it offers the benefit of decompression plus identification of the tumor type. Radiation therapy or chemotherapy may be indicated if the tumor type is known. Abscess formation, subdural or epidural hemorrhage, and symptoms related to cord tethering are usually indications for surgical intervention.

†Department of Pediatrics, The University of Pennsylvania School of Medicine, and †Renal Transplantation, ‡The Liver Transplant Program, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Solid organ transplantation provides many children with a second chance at life, whether that means freedom from the disabling effects of end-stage liver, heart, or lung disease, or from the burden of chronic dialysis. However, transplant recipients differ significantly from other children, because of their susceptibility to infection, risk for organ rejection, and risk for early and late postsurgical complications. Most post-transplant problems encountered follow a pattern in terms of their timing and presentation, but others are dangerously subtle and insidious. Aggressive workup and compulsive examination are the rule when complications and emergencies arise in a child who has had a transplant. A thoughtful and focused approach is necessary for proper care. Although these children are naturally susceptible to the usual illnesses and injuries of childhood, their abilities to handle even minor infections or wounds may be compromised. Many illnesses and emergencies are unique to this patient group. The goal of this chapter is to provide the necessary background information and tools for the management of the transplant recipient presenting to the emergency department (ED). The focus is on recipients of kidney and liver grafts, but many of the problems discussed are germane to all transplant recipients.

OVERVIEW OF RENAL TRANSPLANTATION

End-stage renal disease is uncommon in children, with an incidence of 11 per 1 million population, less than 20 years of age. Renal transplantation is the preferred treatment for most children with end-stage renal disease because it restores the potential for optimal growth and development. Congenital structural abnormalities are the most common cause of renal failure in pediatric renal transplant recipients (Table 126.1). Renal transplantation is indicated when there are significant complications of chronic renal failure, including symptoms of uremia unresponsive to medical management, failure to thrive because of inadequate dietary intake, hypervolemia, metabolic bone disease, hyperkalemia, or delayed development. The absolute contraindications to renal transplantation include active malignancy, chronic human immunodeficiency virus (HIV) infection, chronic active infection with hepatitis B, and severe multi-organ failure. The relative contraindications are uncommon and would be decided on a case-by-case basis. These conditions similar to those listed for the liver transplant patient in Table 126.2.

Cause	Percentage
Obstructive uropathy	16%
Renal dysplasia/hypoplasia	16%
Focal segmental glomerulosclerosis	12%
Chronic glomerulonephritis	10%
Reflux nephropathy	6%
Systemic immunologic disease	5%

Table 126.1. Most Common Causes of Renal Failure in Children Undergoing Renal Transplantation

Indications	Contraindications
Poor or arrested growth	Untreated bacterial or fungal infection outside of the liver
Intractible coagulopathy	Malignant disease outside of the liver
Progressive hypoalbuminemia (<2.5 g/dL)	Irreversible brain damage
Intractible hepatic encephalopathy	Other irreversible organ failure
Refractory ascites	Poor or no psychosocial support
Recurrent esophageal variceal bleeding	Chronic human immunodeficiency virus infection
Spontaneous bacterial peritonitis	
Others: Intractable pruritus, pathologic fractures	

Table 126.2. Indications and Contraindications for Liver Transplantation in Pediatric Liver Disease

Approximately half of pediatric renal transplant recipients receive a kidney from a living donor, most often a parent, and the other half receive a kidney from cadaver donors. The transplant procedure is the same for either donor source. In larger children, the kidney is placed extraperitoneally in the iliac fossa with vascular anastomoses to the iliac vessels. In smaller children (less than 20 kg), the kidney is placed intraperitoneally with vascular anastomoses to the aorta and vena cava. Because of these vascular anastomoses, many centers recommend antibiotic prophylaxis after transplantation for dental procedures and other procedures that are likely to produce bacteremia, such as colonoscopy, to decrease the risk of arteritis, following the current recommendations for endocarditis prophylaxis. The ureter is implanted into the bladder in most children. An intestinal conduit is used in uncommon circumstances when no other options for urinary drainage are available (Fig. 126.1). The native kidneys remain in situ in 75% of patients. Indications for native nephrectomy include severe hypertension, chronic or recurrent pyelonephritis, risk of malignancy (Wilms' tumor in Denys Drash syndrome), or young recipient age. Because the native kidneys remain in place, the possibility of urine production by these kidneys must be kept in mind when assessing renal transplant recipients.

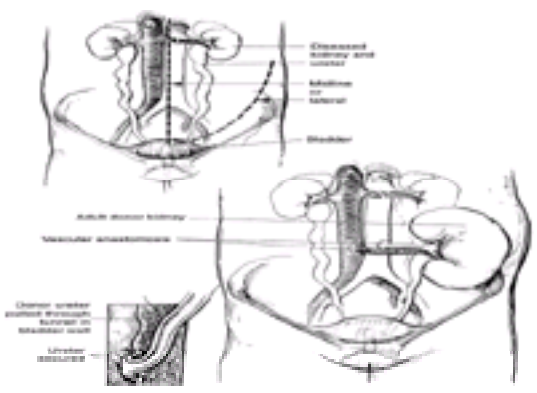

FIGURE 126.1. Anastomoses in renal transplantation

OVERVIEW OF LIVER TRANSPLANTATION

Human orthotopic liver transplantation is a reliable life-saving technique for patients with acute or chronic liver failure. Since 1963, when Starzl performed the first liver transplant, the technique and success of transplantation has grown exponentially. Presently, most transplant centers report 5 year survival rates of at least 80 to 90% in children after liver transplant. The most common indication for liver transplantation in the pediatric age group is biliary atresia with chronic liver failure after a failed hepatoportoenterostomy (Kasai procedure). The second most common indication is the metabolic disorder-a-antitrypsin deficiency. Smaller percentages of children receive transplants to treat other metabolic diseases, chronic liver disease secondary to hepatitis, and acute liver failure resulting from viral or toxic causes. The main indication for transplantation is end-stage organ dysfunction and failure (Table 126.2). The timing of the transplant procedure is crucial to the outcome and is based on the severity of the disease. The risks of the procedure make it inappropriate to operate on a child who has a good quality of life, but it is essential not to delay until end-stage liver failure with associated multi-organ involvement occurs. The aim of the pretransplant evaluation of the potential transplant recipient is to detect any likely surgical problems, assess the extent of any extrahepatic problems, and prepare the child and the family for the operation. Patients are listed with The United Network for Organ Sharing (UNOS), which administers the national organ procurement computer-matching network according to blood group, weight range of the donor, and medical urgency of the recipient.

Pediatric patients may receive transplants from reduced-size adult cadaver livers, whole cadaver organs from a donor of similar size, or donated left-lateral segments from a living donor. The transplantation operation in children differs from the procedure in adults based on the accommodations made for small sizes of the vessels and biliary ducts, which need to be anastomosed between the donor and recipient. A Roux-en-Y jejunal limb is usually used in most children for the biliary anastomosis in children, which changes the dynamics of biliary drainage. The operation involves the anastomosis of the donor and recipient portal veins, hepatic arteries, hepatic veins and bile duct–to–bile duct or biliary–enteric (Roux-en-Y) (Fig. 126.2A) anastomosis. After the transplant, any of these anastomotic sites may be a source of complications or emergencies. Despite these potential complications, liver transplant recipients generally have an excellent quality of life and return to a normal lifestyle shortly after receiving their graft.

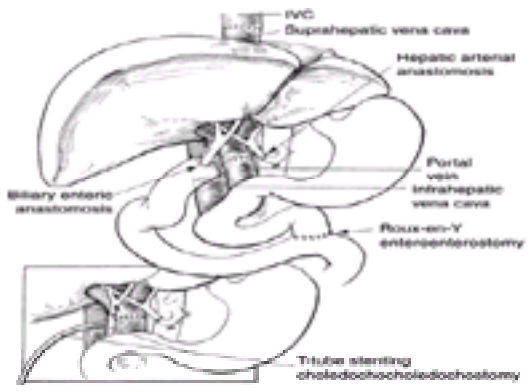

FIGURE 126.2. Anastomoses in liver transplantation.

IMMUNOSUPPRESSIVE AGENTS

The outcome of transplantation in children has improved progressively with the introduction of new immunosuppressive agents. The goal of immunosuppressive therapy is to down-regulate the immune response. Failure to attain an adequate degree of immunosuppression is associated with a high incidence of graft rejection. Acute and chronic allograft rejection remains a significant cause of morbidity and a contributing factor in mortality after solid organ transplantation. Post-transplant immunosuppression varies among transplant centers, organs transplanted, and individual patients. In all cases, however, a combination of agents is used to optimize immunosuppressive effects while minimizing adverse effects, such as opportunistic infection and renal toxicity. Initial immunosuppression for some transplant recipients includes induction with monoclonal or polyclonal anti-lymphocyte antibodies. Most long-term immunosuppression regimens consist of varying combinations of cyclosporine or tacrolimus, azathioprine or mycophenolate mofetil, and corticosteroid. The immunosuppressive agents are generally administered at high dosages in the early post-transplant period and are then weaned progressively if the patient is doing well. Many post-transplant complications observed are related to adverse effects of these medications. Immunosuppression remains complicated by the resultant increased incidence of major infections and malignancy in transplanted patients (Fig. 126.3).

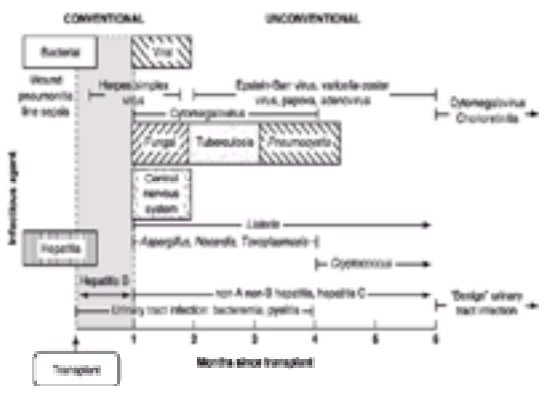

FIGURE 126.3. Timing of posttransplantation infections.

OKT3/Antilymphocyte Globulin (ALG)/Antithymocyte Globulin (ATGAM)

Polyclonal (ALG, ATGAM) and monoclonal (OKT3) antibodies against lymphocytes generally or effector T cells specifically are often effective in reversing established rejection refractory to high-dose steroid pulse therapy. These antibodies may also be used as part of initial immunosuppressive regimens at some centers and are particularly useful in the early postoperative management of the anuric kidney transplant or the liver recipient with poor renal function. Polyclonal antibodies are used in 37% of living donor kidney recipients and 47% of cadaver donor recipients. OKT3, a monoclonal mouse anti-human antibody to the CD3 epitope of lymphocytes, and a potent T-cell inhibitor, is used in 12% of living donor kidney recipients and 19% of cadaver donor recipients. These preparations are administered intravenously on an inpatient basis. The use of these agents increases graft survival in some situations but also increases the risk of infection (e.g., cytomegalovirus [CMV]) and malignancy (e.g., Epstein-Barr virus [EBV]-related lymphoproliferative disease). A patient who has received a recent course of OKT3 or ALG may be profoundly immunosuppressed for several weeks after administration and is at increased risk for opportunistic infections.

Cyclosporine (Neoral®/CyA)

Cyclosporine is the backbone of many immunosuppression regimens. Cyclosporine primarily affects the T-cell immune response by blocking the production of interleukin-2 (IL-2), thereby inhibiting T-cell activation. Cyclosporine also inhibits gene transcription for interferon-g, IL-3, IL-4, and other genes required for the differentiation and proliferation of T and B lymphocytes.

Empiric initial dosing of cyclosporine is modified on the basis of trough cyclosporine levels drawn just before the next dose or analysis of area-under-the-curve by formal pharmacokinetic studies. Blood or plasma levels may be measured by high-performance liquid chromatography (HPLC) or radioimmunoassay techniques. The target level varies by organ, assay method, and the time interval since transplant. For liver transplant recipients, cyclosporine trough levels of 250 to 400 ng/mL (HPLC of the parent compound) are recommended with slow reduction to half that level over time. The dosage

required to achieve these levels may range from 2 mg/kg to 30 to 40 mg/kg per day in young infants with decreased drug absorption. This variation has decreased with the advent of the microemulsion preparation of cyclosporine (Neoral ®), which has more predictable dosing and absorption/metabolism kinetics. Cyclosporine is highly lipid soluble and is only poorly soluble in water. Its absorption from the gastrointestinal (GI) tract is variable and depends in part on good bile flow for solubilization by bile salts and in part on the small intestinal length available for absorption. Therefore, any factor that impairs bile flow (i.e., bile duct stricture, external T-tube drainage of bile, allograft rejection, or cholestasis) may decrease absorption of cyclosporine. Similarly, any factor that decreases the small intestinal length available for absorption of the drug (i.e., long Roux-en-Y jejunal limb) or that increases transit time through the small intestine (as in diarrhea) may impair the absorption of cyclosporine. Higher dosages of the drug may be required in such cases to achieve therapeutic levels. The absorption of the Neoral ® preparation that is currently used is more consistent than that of the earlier non-microemulsified preparation. Cyclosporine is metabolized by the cytochrome P-450 liver microsomal system into multiple metabolites. Most metabolites are excreted in bile and undergo enterohepatic circulation. With severe liver dysfunction, in which the liver is unable to metabolize the cyclosporine or excrete the metabolites, the potential for toxicity of the drug is increased. Many drugs can alter the metabolism of cyclosporine by inhibition or stimulation of the P-450 system (Table 126.3).

Agents That Decrease Cyclosporine/Tacrolimus Metabolism (Increase Levels)
Erythromycin
Chloramphenicol
Ketoconazole
Fluconazole
Diltiazem
Verapamil
Nicardipine
Metoclopramide
Agents That Increase Cyclosporine/Tacrolimus Metabolism (Decrease Levels)
Phenytoin
Phenobarbital
Carbamazepine
Rifampin
Isoniazid
Agents That Cause Synergistic Nephrotoxicity
Aminoglycosides
Amphotericin B
Sulfonamides

Table 126.3. Medications That Alter Cyclosporine and Tacrolimus Metabolism

The major short-term and long-term side effect of cyclosporine is nephrotoxicity, which can cause particular confusion to the physician caring for the renal transplant patient. Some degree of renal dysfunction is present in 25 to 40% of transplant recipients. Acute, reversible renal dysfunction caused by intrarenal vasoconstriction secondary to cyclosporine may be manifested by hypertension, oliguria, azotemia, and hyperkalemia. These effects may be reversed with a decrease in the drug dosage. Chronic cyclosporine nephrotoxicity can result from interstitial fibrosis. Some drugs may act synergistically to amplify the nephrotoxic effect (Table 126.3). Other common side effects of cyclosporine include gingival hypertrophy, hirsutism, tremor, seizure, headache, hepatotoxicity, and hyperuricemia with occasional clinical gout (Table 126.4). Over time, the risk of de novo malignancy, such as lymphoma, is also increased. Seizures associated with cyclosporine occur in more than 20% of children, whether from high levels of the drug or in association with drug-induced hypomagnesemia caused by excessive magnesium wasting in the urine. To some degree, these side effects can be lessened by decreases in dosage, but their occurrence in any given patient is unpredictable and often idiosyncratic.

Adverse Effect	Cyclosporine	Tacrolimus	Azathioprine	Corticosteroids	Sirolimus
Systemic increased risk of infection	+	+	–	+	–
Increased risk of malignancy	+	+	–	+	–

Seizures	+	+	–	–	–

*Does not include adverse effects rarely encountered with a medication.

Table 126.4. Adverse Effects of Immunosuppressive Agents[a]

Tacrolimus (Prograf®/FK506)

Tacrolimus is a potent immunosuppressive agent that, in the last 5 years, has been established as an effective drug for both primary immunosuppression after pediatric liver transplantation and as rescue therapy for the management of refractory and chronic rejection. An analysis of graft survival in pediatric liver transplant recipients showed 4-year graft survival of 86% in those patients receiving tacrolimus-based immunosuppression compared with 66% in those patients receiving cyclosporine. Tacrolimus in combination with prednisone alone has replaced cyclosporine in many liver transplant immunosuppressive regimens. Presently, tacrolimus may be used for induction and maintenance immunosuppression, usually in combination with steroids, which are often subsequently successfully withdrawn. Tacrolimus was developed as a macrolide antibiotic but functions in immunosuppression similarly to cyclosporine. It inhibits IL-2, interferon-g, and IL-3 production, transferrin and IL-2 receptor expression, mixed lymphocyte reactions, and cytotoxic T-cell generation.

Tacrolimus is administered at initial oral dosages of 0.1 to 0.3 mg/kg per day divided in two doses, with the dosage adjusted to maintain target whole blood trough levels. The target level varies from 5 to 20 ng/mL, depending on the organ transplanted, the transplant center, and the time since the transplant. Higher levels are used in the early post-transplant period and to treat acute rejection. Unlike cyclosporine, the oral absorption of tacrolimus is not dependent on solubilization by bile acids. The absorption of tacrolimus is enhanced on an empty stomach. Like cyclosporine, tacrolimus is primarily metabolized in the liver through the cytochrome P-450 system and its metabolism can be altered by concurrent administration of a number of medications (Table 126.3). Therefore, in the setting of liver dysfunction, decreased excretion may occur, which may lead to toxic levels of the drug.

The adverse effects of tacrolimus are similar to those associated with cyclosporine and include nephrotoxicity, hypertension, renal tubular acidosis, neurotoxicity, and hyperglycemia (Table 126.4). Acute nephrotoxicity and neurotoxicity (in the form of headaches, tremors, and seizures) are as frequent and severe as those seen with cyclosporine and are generally controllable with dosage reduction. Hyperglycemia may require therapy with insulin and does not appear to be dose dependent. Unlike cyclosporine, hirsutism and gingival hypertrophy are not a problem with this agent.

Corticosteroids

Corticosteroids were the first immunosuppressive agents used in solid organ transplantation. They are potent immunosuppressive and anti-inflammatory agents. Low-dose prednisone is a key component of mainstay post-transplant immunotherapy, whereas larger doses of both prednisone and methylprednisolone are often used as the first-line treatment for acute allograft rejection. Corticosteroids decrease inflammatory response by preventing inflammatory cell chemotaxis and recruitment and inhibition of extravascular migration of cells and plasma protein via microvascular constriction. In addition, steroids inhibit macrophage secretion of IL-1. At high dosages, steroids are lympholytic. Steroid activity is primarily inactivated by liver metabolism through reduction and conjugation with urinary excretion. Thus, changes in the liver function may significantly influence activation, metabolism, and elimination of the steroids.

The dosages of prednisone vary from 0.1 to 2 mg/kg per day, with higher dosages used in the early post-transplant period, in younger children, and in recipients of renal transplants. Some patients are treated eventually on an alternate day schedule or have steroids withdrawn entirely.

The adverse effects of corticosteroids are diverse and include both short-term and long-term toxicities. The most common short-term effects include sodium and fluid retention, hypertension, hyperglycemia, poor wound healing, gastritis, and central nervous system (CNS) changes (depression, euphoria, or rarely psychosis). The adverse effects of chronic steroid treatment include Cushing's features with truncal obesity, acne, striae, dermal atrophy, and hirsutism. Additional consequences include osteoporosis and aseptic necrosis of bone (particularly of the vertebral bodies and the femoral heads), glucose intolerance, cataracts, and growth retardation. The effect of steroid therapy on the immune system may render the transplant recipient susceptible to lethal bacterial, viral, or fungal infections.

Azathioprine (Imuran®/AZA)

Azathioprine (AZA) has been a key component of antirejection immunotherapy for more than 30 years. In many programs, it is used in a triple drug regimen with cyclosporine and prednisone. AZA is an antimetabolite that inhibits purine nucleotide synthesis and metabolism. The alteration in RNA synthesis caused by the drug prevents mitosis and proliferation in rapidly dividing cells such as B and T lymphocytes. AZA is administered intravenously or orally at dosages of 1 to 2 mg/kg per day as a single daily dose. The metabolites of AZA are primarily excreted by the kidneys, necessitating a dosage reduction patients with in renal failure to avoid increased toxicity.

The most common adverse effect of AZA therapy is myelosuppression, especially granulocytopenia with an increase risk of infection. The myelosuppression is dose-dependent and generally occurs within 1 to 2 weeks after the initiation of therapy. Monitoring of the peripheral blood counts, particularly during the early stages of therapy, is critical. Idiosyncratic reactions, such as fever, hepatotoxicity, and pancreatitis, occur but are relatively rare. Toxicity may occur during periods of renal insufficiency from diminished metabolite elimination and the increased sensitivity noted in uremic patients. AZA may also contribute to the risks of infection and late neoplasia in transplant recipients.

Mycophenolate Mofetil (MMF/Cellcept®)

The active metabolite of mycophenolate mofetil (MMF), mycophenolic acid, is a potent inhibitor of lymphocyte proliferation. It may also interfere with the binding of lymphocytes to activated endothelial cells, decreasing the migration of lymphocytes into the allograft. MMF may also inhibit arterial smooth muscle proliferation and thereby decrease the arteriopathy associated with chronic rejection. MMF is typically used in combination with cyclosporine and prednisone, or less commonly added to tacrolimus and prednisone as rescue therapy for rejection. The usual pediatric dosage is 600 mg/m^2 body surface area (BSA) per day administered in two divided doses or 20 mg/kg per day in two divided doses up to an adult dose of 1 g twice daily. The absorption is decreased by concurrent administration with antacids, and the blood level may be decreased if cholestyramine is also taken. As is the case for other immunosuppressive agents, MMF treatment increases the risk of serious infections and malignancy. GI complaints, including esophagitis, gastritis, diarrhea, and emesis, are common. These symptoms may be ameliorated with treatment with an H_2 blocker or proton-pump inhibitor (e.g., omeprazole). Bone marrow suppression, including leukopenia, anemia, and thrombocytopenia, is dose related and may necessitate a decrease in dosage. Isolated anemia associated with MMF treatment is more common in patients with decreased renal function. Adverse fetal effects have been reported in animal studies, but no studies have been conducted in pregnant humans. Therefore, MMF should be used with caution during pregnancy.

INFECTION PROPHYLAXIS

The immunosuppressed transplant recipient is susceptible to a wide variety of infections (Fig. 126.3). Therefore, antimicrobial prophylaxis is used to decrease the risk of serious infection with the most common pathogens (e.g., *Pneumocystis, Candida,* CMV, herpes simplex virus [HSV], and urinary pathogens). The agents used and the dosing schedules vary with the organ transplanted, the transplant center, and the infection risk of the individual patient.

Most programs consider *Pneumocystis carinii* to be an important pathogen. Prophylactic regimens may include trimethoprim–sulfamethoxazole as a single dose (at half the therapeutic dose) daily or full dose (10 mg/kg per day trimethoprim) in two divided doses three times per week. Other regimens include monthly intravenous (IV) pentamidine and monthly aerosolized pentamidine. Trimethioprim–sulfamethoxisole may also serve as a urinary tract infection suppressant in renal transplant recipients. These patients are also at increased risk for oral and esophageal candidiasis as a result of steroid and antibiotic treatment. Therefore, oral nystatin is given for 6 to 12 months after the transplant.

Both primary and reactivated CMV infections can be serious threats to transplant recipients. The risk is particularly high in CMV-negative recipients who have received CMV-positive allografts. CMV infections may be asymptomatic or may present with symptoms such as fever, leukopenia, pulmonary disease, hepatic dysfunction, intestinal bleeding, or diarrhea. Prophylactic therapy for CMV infections may include CMV hyperimmunoglobulin, oral acyclovir, and IV or oral ganciclovir for the first 4 to 6 months after the transplant and during treatment with monoclonal or polyclonal antibodies. Some programs monitor the presence of CMV antigen in the blood and treat intermittently with IV ganciclovir.

ANTIHYPERTENSIVE MEDICATIONS

Hypertension is a common problem in pediatric transplant recipients, with an incidence of at least 50% in liver transplant recipients and 85% in renal transplant recipients in the early post-transplant period. A number of factors may contribute to post-transplant hypertension, including medications (cyclosporine, tacrolimus, and corticosteroids), acute or chronic renal allograft rejection, renal artery stenosis, high renin production by native kidneys, and recurrence of primary renal disease.

Several agents are effective in treating hypertension in this group of patients. Long-acting agents that can be dosed once or twice a day are optimal. Calcium channel antagonists may be optimal because they can counteract some of the intrarenal vasoconstriction caused by cyclosporine or tacrolimus and ameliorate their nephrotoxicity. However, they may also increase gingival hypertrophy. Long-acting preparations, such as amlodipine or nifedipine, provide the most consistent blood pressure control and are dosed daily or twice a day. The amlodipine tablet, which maintains its pharmacokinetic profile when dissolved in water, may be administered to children more than 1 year of age. The total oral daily dose of the two formulations is the same (0.25 to 1.0 mg/kg). Other vasodilators, such as minoxidil, may also be used. Diuretic treatment is usually necessary in concert with the vasodilator. The most commonly used agent is furosemide (1 to 5 mg/kg per day in one to two divided doses). b-Adrenergic antagonists are useful second-line agents. They are also effective when added to a vasodilator. Several selective b-blocker drugs have a greater effect on cardiac b-receptors than on bronchial b_2-receptors. One such agent is atenolol, which is administered daily or twice a day (1 to 2 mg/kg per day).

Angiotensin-converting enzyme inhibitors are used in a number of programs. In renal transplant recipients, they may be helpful if renin-mediated hypertension caused by high levels of renin secretion by the native kidneys is present. However, these agents should be used with caution in renal transplant recipients because they can cause profound graft dysfunction if renal artery stenosis is present and can exacerbate graft dysfunction in the presence of cyclosporine or tacrolimus therapy and volume depletion. The available agents vary in half-life; therefore, the dosing interval is shortest with captopril (0.3 to 5 mg/kg per day divided into two to three doses per day) and longer with enalapril (starting dosage 0.08 mg/kg per dose once or twice a day) or ramipril (once a day).

Severe hypertension is most commonly a complication of renal transplantation. When a child presents to the ED with severe hypertension, it may be important to rapidly reduce the blood pressure in a symptomatic patient to avoid the sequelae of hypertensive encephalopathy. In an emergency setting, sublingual nifedipine (0.25 to 0.5 mg/kg) is often effective. It can be repeated after 20 minutes if blood pressure is not adequately reduced. The dose is difficult to accurately administer to small children, but the capsule can be punctured and the liquid aspirated into a tuberculin syringe and the appropriate amount (0.035 mL corresponds to about 1 mg) administered. After the nifedipine is administered, IV access should be obtained for further treatment. Sublingual nifedipine should be used with caution to avoid too rapid a drop in blood pressure or frank hypotension. Hydralazine can be an effective agent administered intravenously or intramuscularly (0.1 to 0.2 mg/kg). The dose can be doubled and repeated every 20 minutes. A more effective agent is IV labetalol, which can be administered as a bolus (0.25 mg/kg) and repeated in escalating doses (0.5 to 1.0 mg/kg). Blood pressure control may be maintained by the constant infusion of labetalol at 1 to 3 mg/kg per hour. If this agent is inadequate, the blood pressure can be controlled with infusion of nitroprusside (0.5 to 3.0 µg/kg per minute). A child who requires an infusion is typically cared for in the intensive care unit.

IMMUNIZATIONS

When possible, children should be fully immunized before transplant with all age-appropriate vaccines, including vaccines for varicella, pneumococci, and hepatitis B. In general, live virus vaccines are contraindicated after transplant, and oral polio, measles, mumps, and rubella vaccines should be avoided. Limited experience exists with the use of the varicella vaccine after transplant. Immune response to vaccines administered after transplant may not be as complete as they might be in a non-immunosuppressed (non-transplant) patient.

GENERAL PRINCIPLES OF MANAGEMENT

Hospitalizations in the first 6 months after transplant are common. As an example, 60% of recipients of cadaver donor renal allografts and 50% of living donor recipients are hospitalized in the first 6 months after transplant. The most common causes for hospitalization include treatment of acute rejection, viral and bacterial infections, and treatment of hypertension. These reasons are also the most likely for presentation to the ED. The encounter in the ED with the renal or liver transplant recipient need not provoke a sense of uneasiness in the nontransplant physician if the following pertinent principles of evaluation and treatment are applied:

1. The transplant center should be regarded as a valuable source of information and assistance, and dialog with the center should be recognized as critically important to patient care. The transplant center should be contacted during the ED visit and should be contacted immediately if the patient has abnormal laboratory tests. No changes in immunosuppressive medication should be undertaken independent of input from the transplant center. A copy of the ED record should also be forwarded to the transplant center.
2. If the transplant patient is critically ill or hemodynamically unstable, the patient should be stabilized in the usual manner with attention to the ABCs of resuscitation. The primary focus should be on the patient and not on graft survival. The same life-saving interventions used for any critically ill individual should be used in these acute situations, and specific considerations regarding the graft should be secondary. A critically ill transplant patient should be stabilized and then transported to a transplant center.
3. All symptoms require thorough evaluation because a patient receiving immunosuppressive medications may have blunted or atypical presentations of severe disease, particularly when infection is involved.
4. Conditions that impair the patient's ability to take or absorb medications (e.g., vomiting, diarrhea), necessitate hospital admission for parenteral administration of the immunosuppressive medications and careful monitoring. Simple conditions, such as gastritis with vomiting or gastroenteritis with diarrhea, may lead to significantly diminished cyclosporine levels and the potential for rejection and graft loss.
5. Children and adolescents with renal transplants can become dehydrated more readily than healthy children with what appear to be trivial illnesses. The volume of the urine output cannot be used as an indication of adequate hydration in renal transplant recipients. Maximal urinary concentrating ability may not be present; therefore, the patient more readily becomes dehydrated. Volume depletion increases the acute nephrotoxicity potential of cyclosporine and tacrolimus, resulting in an increased serum creatinine. Therefore, renal transplant recipients often require IV fluids to maintain hydration. These patients also require IV hydration if the serum creatinine is increased above baseline levels and if ability to maintain oral intake is in question. Home trials of oral rehydration therapy are not appropriate for these children.
6. Fever in the immunocompromised patient requires aggressive investigation because it could be a manifestation of a wide spectrum of disease from severe opportunistic infection to acute graft rejection. If the patient is obviously septic, blood cultures should be drawn and broad-spectrum antibiotics administered expeditiously. Headache, seizures, or neurologic changes in the setting of a fever are indications for a lumbar puncture with cerebrospinal fluid cell count, and comprehensive stains and culture for bacteria, viruses, fungi, and acid-fast organisms, to be performed as a part of the primary evaluation. The transplant center should be notified of the patient's condition as soon as possible.
7. Abdominal pain may represent a surgical emergency even when mild in nature. Steroid therapy may blunt the inflammatory response in a transplant patient such that visceral perforation, urine or bile leak, or infectious peritonitis may not be accompanied by classic peritoneal signs. All complaints therefore warrant full investigation.
8. Renal or liver allograft dysfunction may be secondary to causes other than rejection. Problems such as bile duct or ureter obstruction, infection, drug toxicity, and rejection may mimic each other but require different therapy. In addition, volume depletion can significantly increase the serum creatinine level in renal transplant recipients. Therefore, these patients must be fully evaluated in a transplant center where they may have prompt immunosuppressive drug levels, graft-specific imaging studies, and possibly graft biopsy before antirejection therapy is initiated.
9. Cyclosporine and tacrolimus have several drug interactions (listed in Table 126.3) that alter patients' metabolism and may lead to dangerously high or low levels. A number of medications can act synergistically with these agents to increase their nephrotoxic effects. The effects of these medications on the levels of cyclosporine and tacrolimus are not absolute contraindications to their use, but an alternative medication should be used if possible. Levels of cyclosporine or tacrolimus should be carefully monitored.
10. Upper extremity cut-down IV access should be avoided in the renal transplant patient because these veins may be required for future hemodialysis access. Established arteriovenous fistulas should not be used for IV access, blood pressure monitoring, or blood drawing.
11. Non-steroidal anti-inflammatory agents should be avoided in renal and liver transplant recipients, if possible. These agents can increase the nephrotoxicity of cyclosporine and tacrolimus.

INFECTIONS

In general, the onset and type of infection and the responsible agent is related to the intensity and type of immunosuppression, and the time since the transplant procedure (Fig. 126.3). In the first few weeks after transplant, the most common infections are urinary tract infection and wound infection with bacterial pathogens. After this period, the incidence of opportunistic infections increases.

Pneumocystis carinii *Pneumonitis*

P. carinii pneumonia (PCP) is becoming increasingly uncommon in transplant patients as a result of routine prophylaxis. However, although most common within the second to sixth months after transplant, infection may occur at any time. In most cases, a patient with PCP presents with dry cough, dyspnea, diffuse interstitial infiltrates, and hypoxemia. Suspicion of infection with this pathogen necessitates a diagnostic intervention such as bronchoscopy with a bronchoalveolar lavage. The isolation of pneumocysts on the silver stain of the lavage fluid confirms the diagnosis. Infection is treated with IV trimethoprim–sulfamethoxazole (15 to 20 mg/kg per day of trimethoprim intravenously in three to four divided

doses) or pentamidine (4 mg/kg intravenously in a single daily dose).

Cytomegalovirus Infection

CMV infection is the single most important infection in the transplant recipient. CMV disease may represent 1) a primary infection in a CMV non-immune recipient who acquires the infection from the allograft or transfusion of CMV-positive blood products; 2) reactivation of latent virus as a consequence of immunosuppression (most recipients in this situation show some evidence of CMV infection, although only 20% become symptomatic); and 3) superinfection of a CMV-immune patient with a strain of CMV of donor or environmental origin. The course of CMV infection is influenced by the type and intensity of immunosuppression the patient has received. Steroids alone do not put the patient at great risk of reactivation of CMV disease. However, AZA and particularly OKT3 and ALG have the highest risk of reactivating CMV disease. CMV infection in an immunocompetent host is usually asymptomatic, whereas in a transplant patient, it may be devastating. CMV causes a syndrome characterized by anorexia, malaise, and myalgias and arthralgias usually heralded by the initial presentation of fever. These symptoms may be accompanied by an atypical leukocytosis and usually occur within 2 to 3 months of transplant but may occur at any time. In approximately one-third of febrile patients with CMV infection, pulmonary disease develops and may rapidly progress to adult respiratory distress syndrome (ARDS) and death. CMV may also cause localized disease, which in transplant patients may localize to the renal or hepatic graft (causing a picture of hepatitis) and mimic rejection. Another specific site of CMV involvement is the mucosal lining of the GI tract where the virus may cause ulceration and massive GI tract hemorrhage. The effects of the organ-specific infection are amplified by several of the systemic effects of the virus, including thrombocytopenia and leukopenia caused by bone marrow suppression, and impairment in alveolar macrophage function and cell-mediated immunity, which predispose the patient to further opportunistic infections by other viral agents or *Pneumocystis.* Diagnosis of CMV is made by culture, serology, or antigen detection. Treatment of active CMV includes lowering of the immunosuppression and administering IV ganciclovir (5 to 10 mg/kg per 24 hours in two divided doses).

Epstein-Barr Virus and Posttransplant Lymphoproliferative Disease

EBV is a ubiquitous virus and, similar to CMV, is associated with hepatitis as well as a more systemic illness. Acute EBV infection presents as a mononucleosis-like syndrome with diffuse B-cell hyperplasia. However, of particular concern is the risk of post-transplant lymphoproliferative disorder (LPD). This disorder is most common in children who are not immune to EBV at the time of transplant and develop EBV infection. The overall incidence in pediatric renal transplant recipients is less than 1%, but the risk increases with increasing exposure to immunosuppressive medications such as OKT3 and tacrolimus-based immunosuppression. LPD can present as early as 1 month after transplant or many years after transplantation. A high index of suspicion must be maintained because LPD can present at any lymph tissue site (e.g., tonsils, GI tract, cervical nodes, CNS). Patients may present with fever, upper airway obstruction, GI bleeding, or intestinal obstruction or perforation. In all cases, the first line of treatment is to discontinue immunosuppressive agents (prednisone may be maintained) even at the risk of possible rejection. Additional treatment with acyclovir or ganciclovir is added at most centers. In many cases, the LPD responds to discontinuation of immunosuppressive medications without ensuing allograft rejection. In other cases, cytotoxic chemotherapeutic agents, such as cyclophosphamide, are added.

Herpes Simplex Virus

Reactivation of latent HSV infection is common in transplant recipients. Patients presenting with an oral or genital lesion resembling herpes should have a scraping for immunofluorescence performed on the lesion. If herpes simplex is present, oral acyclovir is used for minor lesions without systemic symptoms. Extensive lesions, fever, or other systemic symptoms require IV acyclovir treatment (750 to 1500 mg/m^2 per 24 hours intravenously in three divided doses) to prevent disseminated herpes infection.

Varicella

Varicella is a highly contagious pathogen that is common among school children. In a transplant patient who is immunocompromised, it may become disseminated disease spreading to the liver, lungs, and CNS. If a patient has been exposed only to varicella (household contact or played in the same room with an infected individual), the patient should receive varicella-zoster immunoglobulin (VZIG). VZIG (125 units or one vial per 10 mg) should be given within 96 hours of exposure, but the sooner it is administered, the more efficacious it will be. If the transplant patient is diagnosed with varicella, he or she should be admitted to the hospital for IV acyclovir therapy (1500 mg/m^2 per 24 hours in three divided doses) and a sharp reduction in steroid dosage. Herpes zoster may occur in as many as 5 to 10% of adult transplant patients, representing reactivation of old varicella infection, although it rarely disseminates. Acyclovir may hasten resolution of lesions, but no change in immunosuppressive regimen is usually needed.

Adenovirus

This viral infection occurs in up to 7% of pediatric transplant patients and should be considered when the patient presents with high fever and liver and/or pulmonary dysfunction with or without diarrhea. A nasopharyngeal swab and stool for viral culture should be sent to screen for the virus in the febrile posttransplant patient.

Fungal and Nocardial Infections

Fungal infections in the posttransplant patient can have a variety of clinical presentations. They may present as a subacute respiratory illness with local or disseminated findings on chest radiograph. Alternatively, the patient may have a systemic illness with nonspecific symptoms of malaise and fever that may be acute or chronic. Fungal infections may also present with metastatic disease. Examples are the 20 to 30% of patients with cryptococcal infection who demonstrate skin lesions weeks or months before the development of CNS lesions and the 10 to 15% of patients with disseminated *Candida* infection who have skin lesions early on in its course. Similarly, *Nocardia* and *Mucor* species may show early skin lesions before evidence of more serious deep-seated infection presents itself. Another common fungal infection is

Candida esophagitis, which may present with dysphagia or odynophagia. CMV and HSV infection of the esophagus may also occur with similar symptoms.

Fungal infections generally do not occur in the first month after transplant but rather in the subsequent months. Between the first and sixth months, *Candida* species are the major fungal pathogens. Infections with *Aspergillus* are less common but are associated with high mortality.

Fungal infection of the CNS may be difficult to assess because the classic signs of CNS infection, such as meningismus, are often absent in immunosuppressed patients. The common presentation of headache, often without fever, may be the only indication that a CNS infection exists and warrants thorough neurological evaluation, lumbar puncture with fungal stains and cultures, and possibly an imaging study of the brain, preferably magnetic resonance imaging. Acute or subacute meningitis is most commonly caused by *Listeria monocytogenes,* whereas chronic meningitis is most often caused by *Cryptococcus neoformans* and focal brain abscess is often indicative of *Aspergillus* infection.

APPROACH TO FEVER

Fever is the most common reason for the pediatric transplant recipient to seek evaluation in an ED. A fever in a transplant patient may be a manifestation of any number of infections or processes from acute graft rejection to systemic sepsis. Assessing these patients is challenging because their immunosuppression may mask many of the typical physical findings associated with their disease process (e.g., peritoneal signs). All fevers and new symptoms in these patients require investigation. If the patient appears well, has normal laboratory evaluation and chest radiograph (if presenting with respiratory symptoms), and has an obvious minor source of infection, such as otitis media or an upper respiratory tract infection, the patient may be sent home with appropriate therapy. As previously mentioned, the transplant center should always be notified at the time of the visit that the patient had been seen and what the diagnosis was. Close outpatient follow-up is mandatory within 48 hours.

Patient assessment should include 1) a careful physical examination that includes examination of all wounds; 2) pulse oximetry, chest radiograph, and arterial blood gases if the patient has cough, dyspnea, tachypnea, or other signs of hypoxia; 3) a screen of graft function (liver function tests and creatinine) in addition to other routine laboratory tests, such as complete blood count and differential, disseminated intravascular coagulation panel, and prothrombin time/partial thromboplastin time, if the patient appears septic; and 4) a blood culture for bacterial and viral pathogens, blood buffy coat CMV antigen assay by rapid assay technique, urine for urinalysis, rapid CMV assay, and viral culture of the urine and a standard urine culture if the child has a fever or appears ill. Because some patients may have a central venous catheter, line sepsis should always be considered in the differential diagnosis.

In the liver transplant patient, elevated liver aminotransferases may be a sign of rejection, arterial or venous thrombosis of the graft, or even biliary stricture and obstruction with resultant cholangitis. The initial study required in this case is an ultrasound examination with Doppler flow study to view arterial and venous blood flow to the graft and to assess the biliary tree for evidence of dilation, which suggests obstruction. If obstruction is suspected from the ultrasound, percutaneous transhepatic cholangiography is usually necessary to image the biliary tree and biliary–enteric anastomosis. Recent progress has been made with magnetic resonance cholangiography to obtain clear non-invasive imaging of the biliary tree. The patient is given broad-spectrum antibiotic coverage for the common biliary pathogens (e.g., Gram-negative enteric organisms). Ampicillin (200 mg/kg per day) and cefotaxime (100 mg/kg per day) are usually adequate. If the ultrasound is normal and no source for the fever or increased liver function tests is found, the patient requires admission and liver biopsy to rule out rejection or viral infection. If the ultrasound is abnormal, the situation could require surgical revision of the biliary anastomosis or biliary stent placement (Fig. 126.2), either by the interventional radiologists or by open procedure by the transplant surgeons.

In the renal transplant recipient, particular attention should be paid to the graft site because fever, tenderness over the transplanted kidney, poorly controlled hypertension, diminished urinary output, and recent weight gain may all be signs of rejection. A rise in the blood urea nitrogen and creatinine levels also suggests rejection. However, ascending urinary tract infection, infected perinephric collections (lymphocele, seroma, and urinoma), ureteral stenosis or obstruction, and renal vascular thrombosis may also present with similar findings. These emergencies require in-hospital workup, beginning with urine culture, blood culture, Doppler and conventional ultrasound, nuclear renal scan, antegrade or retrograde pyelogram when indicated, and possible renal biopsy.

GASTROINTESTINAL EMERGENCIES

Transplanted patients may develop GI complications that are secondary to many different causes, ranging from infection to post-surgical complications. Perforation and bleeding may occur secondary to necrotic lymph nodes from LPD or because of small bowel ulcerations from CMV infection. Intussusception or luminal obstruction may occur secondary to enlarged lymph nodes from post-transplant lymphoproliferative disease (PTLD), and peritonitis may be caused by any of the aforementioned conditions, including bile leak from an anastomotic breakdown or bile duct ischemia, particularly in the early post-transplant period. Severe variceal bleeding is also seen in the liver transplant patient with portal venous thrombosis and consequent pre-hepatic portal hypertension. Pancreatitis may be seen as a complication of taking AZA.

The approach to these patients in the ED is the same as for the non-immunocompromised patient: 1) fluid resuscitation; 2) nasogastric intubation 3) blood products as needed; and 4) frequent monitoring of vital signs while transfer to the transplant center is arranged. In the evaluation of abdominal pain, a number of processes should be considered. Tacrolimus toxicity can produce complaints of severe epigastric pain or diffuse abdominal pain. MMF can cause gastritis, esophagitis, and diarrhea. In addition to viral involvement of the GI tract, infectious processes that are most common in transplant recipients include *Clostridium difficile* colitis and candidal esophagitis.

MISCELLANEOUS EMERGENCIES

Transplant recipients may also experience many of the usual childhood emergencies, including hydroceles and herniae. Scrotal edema on the side of the renal transplant is a common finding and is generally self-limiting and not a problem. Other possible complications include deep venous thrombosis on the side of the transplanted kidney, which is confirmed by noninvasive venous imaging and managed with anticoagulant therapy. Less common complications are suture-line disruption with subsequent “blow-out” or aneurysmal rupture at the anastomotic site in both liver and renal transplants.

Careful attention should be paid to a transplant recipient with a headache. In addition to usual causes of headaches, meningitis, pseudotumor cerebri, malignancy, and malignant hypertension must be considered. In a patient with papilledema, the most likely cause is pseudotumor cerebri, which is a complication of steroid treatment and may be related to changes in steroid dose.

CONCLUSION

Emergencies in the pediatric transplant patient are common, consequent to the complex nature of the procedures and the depressed state of the immune system. With the ever-increasing number of organ transplants being performed each year in children, more of these patients are likely to be seen in the ED. Therefore, a working knowledge of the nature of these procedures and the common emergency situations that may arise in this patient group is essential to proper assessment and management of these patients' problems.

CHAPTER 127

Approach to the Care of the Technology-Dependent Child

***JOEL A. FEIN, MD, †KATE CRONAN, MD, and *JILL C. POSNER, MD**

**Department of Pediatrics, The University of Pennsylvania School of Medicine, and Division of Emergency Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania;*
†Department of Pediatrics, Thomas Jefferson University, Philadelphia, Pennsylvania, and Department of Pediatrics, A. I. duPont Hospital for Children, Wilmington, Delaware

Up to almost one-quarter of the visits to a pediatric emergency department (ED) are for complaints associated with chronic illness. Many children with chronic illness have indwelling hardware, such as cerebrospinal fluid (CSF) shunts, venous catheters, and gastrostomy tubes. Medical technology has enabled these children, who in the past would have required specialized inpatient or intensive care, to thrive at home. Emergency physicians must be able to diagnose and treat the common problems associated with these new technologies and recognize when it is appropriate to consult other specialists familiar with these children.

Devices most commonly found in the pediatric population include CSF shunts, tracheostomy tubes, venous catheters, and percutaneous gastrointestinal (GI) and urologic catheters. The goal of this chapter is to familiarize the emergency clinician with the equipment and with the clinical manifestations and management of the problems related to these apparatuses. In addition, the clinician can advocate more effectively for the patients if he or she is aware of the emotional and social issues accompanying these patients and families.

APPROACH TO THE CARE OF THE TECHNOLOGY-DEPENDENT CHILD

The technology-dependent child who visits the ED may pose a challenge for the practitioner. Because of several factors, the evaluation of these children may, at times, seem overwhelming. These children often present with several pieces of equipment, the history can be difficult to obtain because of its inherent complexity, and a thorough physical examination may be impeded by the technology. When a common illness is superimposed on a chronic condition, the illness may appear more complex, misleading the examiner. In addition, the ED visit may have been necessitated by multiple reasons. The more involved the equipment and problems, the more challenging the situation becomes.

When a technology-dependent child arrives in the ED, contacting the primary care provider early on during the evaluation of the patient may be helpful. The primary care provider may be able to offer suggestions about the management of the child, potentially avoiding unnecessary tests and admission. In many situations, a home health nurse may accompany the patient and family to the ED and can be a valuable source of information.

In recent years, developments have led to the facilitation of medical history gathering in the ED. For example, “Pedistat” is a computerized program used in Rhode Island that allows families and physicians of children with special needs to provide information about their child, which is entered into the database in the state's children's hospital ED. The American College of Emergency Physicians (ACEP) now provides a data set for children with special health care needs that can be accessed at the time of the ED visit. When the aforementioned approaches are not immediately available, checking for a Medi-Alert bracelet, which provides a patient identification number that can be used to obtain information about the patient, is always prudent. By accessing the Medi-Alert hot-line, relevant medical information about the patient can be faxed rapidly to the ED for immediate use. Deriving an accurate history in these scenarios is imperative and greatly improves the quality of care administered.

When caring for the technology-dependent child in the ED, several important points emerge and should be used in approaching these children in the acute care setting (Table 127.1).

Common pediatric illnesses can afflict chronically ill children.
The presence of foreign bodies or hardware predisposes the patient to infection.
Families are the experts in their children's problems—rely on them for important information.
Consider altering the usual criteria for admission.

Table 127.1. Approach to the Technology-Dependent Child in the Emergency Department

First, *common things are common;* common pediatric illnesses may afflict these children as they do others. This point is always important to remember when evaluating a seemingly complicated child who presents with the routine signs and symptoms characteristic of typical childhood diseases. For example, a child with a CSF shunt may have vomiting caused by gastroenteritis.

Second, the presence of indwelling devices *predisposes the patient to infection.* When a child presents with symptoms associated with a specific piece of equipment, the clinician must be suspicious of infection of that equipment. For example, if a child with a tracheostomy presents with fever, cough, and increasing secretions, it is crucial to evaluate for the possibility of tracheitis. At the same time, the equipment has a tendency to become colonized with commensal organisms. Therefore, all bacterial growth does not indicate acute infection, and other sources of infection should be considered.

Above all, *families should be relied on* for important information because the parents or caretaker of technology-dependent children have become sophisticated in their knowledge of specific illnesses and equipment. This information becomes crucial when an acutely ill patient presents to the ED with several forms of technology and an involved medical history. Parents are sensitive to subtle changes in their children because they provide most of the home medical care. *Families are experts* and should play an integral role in the evaluation, management, and ultimate disposition of their child in the ED setting.

Children with chronic illnesses have a higher likelihood of being admitted to the hospital, resulting in longer lengths of stay in the ED. The practitioner should realize that the families of technology-dependent children often have sufficient equipment and trained personnel available in the home setting to care for an exacerbation of a chronic problem or an unrelated acute problem. For example, a family whose child has a chronic respiratory illness often has supplemental oxygen in the home and is facile with its use. Knowing that families of technology-dependent children are compliant and likely to return to the ED if their child's degree of illness exceeds the capabilities of the home care is reassuring. Thus, the practitioner should consider *altering the usual criteria for admission* in this specific population.

Having a technology-dependent child in the home creates a stressful situation for family members and other caretakers. A visit to the ED for an acute problem exacerbates this level of stress. These families may be more likely to question the diagnostic tests and therapies offered during the evaluation of their child because of their level of medical knowledge as well as the constant illness-related anxiety that intrudes upon their lives. The ED visit is more effective if the practitioner recognizes the psychosocial issues associated with this population of patients.

Tracheostomy Care

Background

Advances in neonatology and pediatric critical care medicine have enabled children to survive the complications of premature birth, congenital anomalies, and severe life-threatening illnesses. Yet a significant number of children are unable to be weaned immediately from respiratory support. As home care has become more widely recognized as an alternative to prolonged and costly hospitalization, the number of children managed at home with tracheostomies and mechanical ventilation has increased dramatically. Consequently, these children seek care more often in the ED when acute problems arise. To approach these situations calmly and systematically, the emergency physician should 1) appreciate the physiologic differences in a patient with chronic respiratory insufficiency (CRI); 2) be familiar with the equipment used in the care; and 3) understand the commonly encountered complications and their management.

Pathophysiology

In healthy people, respiration is maintained via a complex mechanism involving the alveolocapillary network, the diaphragm and intercostal musculature, and the central centers in the brainstem. Respiratory compromise results when one or more components of this mechanism are affected by disease. Approximately 65% of patients with CRI have bronchopulmonary dysplasia and congenital airway anomalies. Another 30% have neuromuscular disorders such as muscular dystrophy or spinal cord injuries. The remaining 5% require mechanical ventilation to overcome central disorders such as a brain tumor or Chiari malformation. Many children are successfully weaned from ventilator-assisted to independent breathing. Survival and decannulation rates depend on the nature and severity of the underlying disease.

Equipment

The complexity of the many tubes and attachments extending from the patient's airway can be overwhelming, especially

in the emergent situation. Familiarity with the equipment used in caring for a patient with a tracheostomy ensures the emergency physician's adept management of these situations. Starting from the patient's neck, each piece of equipment can be easily identified (Fig. 127.1).

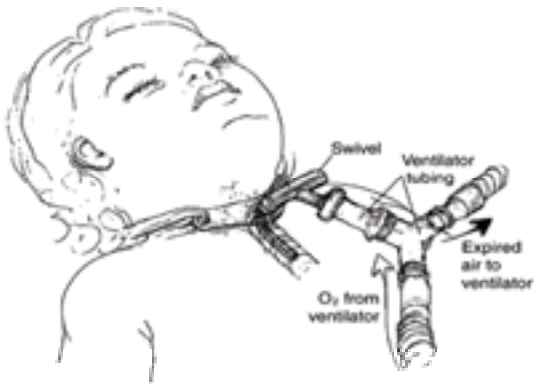

FIGURE 127.1. Tracheostomy parts.

Tracheostomy Tubes

Modern tracheostomy tubes are made of polyvinylchloride, a soft substance that conforms to the shape of the trachea, but is rigid enough to avoid collapse. Unlike their metal predecessors, they have little tissue reactivity, causing less tracheal wall irritation. Tracheostomy tubes are packaged by several manufacturers under sterile conditions for one-time use. Intensivists directing the long-term airway management of their patients may prefer one manufacturer over another, but the emergency physician does not need to know the minor differences among the products. The emergency physician should, however, know what types of tracheostomy tubes are stocked by the ED's facility and how to convert from the patient's brand and size to an available tube with suitable dimensions.

The size of a tracheostomy tube is determined by three dimensions: the inner diameter, the outer diameter, and the length. The inner diameter refers to the same measurement used in describing the size of an endotracheal tube, ranging from 2.5 to 10 mm. This measurement is generally imprinted on the flanges of the tracheostomy tube and is standardized among manufacturers. The outer diameter and length often are not identified on the tube and can vary considerably among manufacturers. The chart in Table 127.2 lists the dimensions of various tubes. When a tracheostomy tube change is indicated and an identical replacement is not available, this chart can be used in selecting the appropriate size tube of an available type.

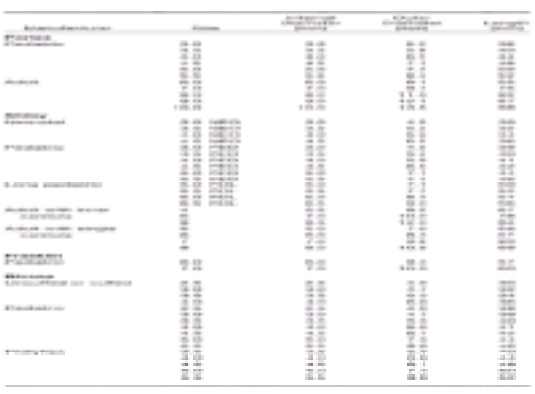

Table 127.2. Tracheostomy Tube Dimensions

A tracheostomy tube may be cuffed or uncuffed. Contrary to the general guideline that cuffed endotracheal tubes are used only for older children, an infant or young child may have a cuffed tracheostomy tube, especially if he or she has an airway anomaly or has developed tracheomegaly. Checking for the presence of a cuff in all patients, and deflating it before removing the tube is important.

Some tracheostomy tubes are fenestrated. The hole in the posterior aspect of the tube facilitates retrograde movement of air through the larynx, allowing vocalization. In addition, some tracheostomy tubes have an inner cannula. In patients with this type of tube, the inner cannula can be removed for cleaning while maintaining the airway with the outer cannula. Importantly, the proximal portion of the inner cannula is required to connect the tracheostomy to the manual resuscitator bag; therefore, the inner cannula must be in place when bag-valve ventilating.

Swivel

A swivel is often attached to the end of the tracheostomy tube. Some unique characteristics of children make the swivel particularly useful. First, children have a natural inclination to move and explore. The swivel device accommodates movement in the ventilator-assisted child so that traction is not placed on the ventilator tubing or on the tracheostomy tube. Second, the short neck and bulky soft tissues of young children can obstruct the tracheostomy tube opening. The swivel provides additional length so the tube extends beyond the soft tissues of the neck.

Heat–Moisture Exchanger

Air inspired directly into the trachea through a tracheostomy tube bypasses the important warming and humidification mechanisms provided by the natural upper airway. Therefore, a humidification system is an important component of the equipment used in a patient with a tracheostomy. The stationary humidification system in a home ventilator setup is used when the child is connected to the circuit. Similarly, a heat–moisture exchanger is attached to the end of the tracheostomy tube in patients who do not require the ventilator. The device is composed of a hydrophilic material that captures the patient's own heat and humidity on exhalation so that it can be inspired on inhalation. It should be placed between the tracheostomy tube and the manual resuscitator when prolonged bag-valve ventilation is performed.

Clinical Findings/Management

The approach to the ill patient with an artificial airway is the same as that for any patient who comes to the ED. The initial evaluation consists of a review of the patient's ABCDs (airway, breathing, circulation, and disability). Certainly, particular attention must be paid to the airway and breathing. An emergency physician who knows how to anticipate common problems and to recognize them early is able to institute appropriate therapy without delay.

Obstruction and Decannulation

The most life-threatening complication in a patient with an artificial airway is cannula obstruction or dislodgment. Younger children are more likely to experience accidental decannulation because of the short length of the trachea and tracheostomy tube. Some infant tubes are as short as 3 to 4 cm. In addition, the small lumen is more easily occluded by a mucous plug or by an accumulation of secretions. Infants with less developed intercostal muscles and children with neuromuscular disorders may be unable to generate an adequate cough to keep the airway clear of debris.

The presentation is similar to that of other children with respiratory compromise. The child may appear distressed with tachypnea, cyanosis, accessory muscle use, and nasal flaring. Alternatively, the child may be lethargic or obtunded as a result of prolonged respiratory effort or an elevated carbon dioxide level.

Any child with an artificial airway and respiratory distress is assumed to have an obstruction. The patient should be placed immediately on high-flow humidified oxygen. The physician should determine whether the tracheostomy tube appears to be in place, recognizing that a tube in the stoma does not necessarily indicate a tube in the trachea. If a cannula change was attempted before the child's arrival in the ED, a false passage into the paratracheal soft tissues may have occurred. Auscultation for the presence and symmetry of bilateral breath sounds should be performed and the quality of the patient's respiratory effort should be assessed. Immediate suctioning is appropriate in an attempt to assess tube patency and to clear the airway of secretions.

The physician should not hesitate to change the cannula. All the necessary equipment for the change should be present, including a replacement tracheostomy tube, an endotracheal tube one-half size smaller, a bag-valve-mask ventilation circuit with oxygen flow, scissors, and tracheostomy ties. The change is best accomplished with the participation of two people; one secures the patient and removes the old tube while the other inserts the new tube (see also Section VII).

Infection

Bacterial colonization of the trachea usually occurs in a child with a tracheostomy. Common colonizing organisms include Gram-positive cocci (*Staphylococcus aureus, Staphylococcus epidermidis, Streptococcus pneumoniae,* a- and b-hemolytic streptococcus), Gram-negative bacilli *(Klebsiella, Pseudomonas, Escherichia coli, Serratia marcescens, Haemophilus influenzae),* and anaerobes *(Peptostreptococcus, Bacteroides).* These same organisms can become pathogenic, causing tracheitis or pneumonia.

A peristomal cellulitis can result from infection with skin flora. Good tracheostomy care and regular cleaning with dilute hydrogen peroxide solution can prevent most peristomal infections. Similarly, inadequate padding of the neck area beneath the tracheostomy ties can result in a contact or monilial dermatitis.

Differentiating between bacterial colonization of the trachea and clinical infection can be difficult. The physician should elicit a history of any changes in the quantity, thickness, or odor of the tracheal secretions, and any systemic signs of infection or respiratory distress. Along with physical examination, there should be a determination of oxygenation by pulse oximetry. A Gram stain and bacterial culture, and a rapid viral detection assay of the tracheal secretions may be helpful in determining the presence and cause of an infection. Leukocytosis in the tracheal secretions and a predominant organism by Gram stain may be suggestive of bacterial tracheitis; radiographic evidence of a new infiltrate indicates pneumonia.

If the child appears well and follow-up can be ensured, outpatient antibiotic therapy may be appropriate. For children with increased oxygen or ventilatory requirements, hospitalization should be considered for intravenous (IV) antibiotic therapy, aggressive pulmonary toilet, and close monitoring.

Erythema of the peristomal skin is usually caused by irritation and should be managed by increasing the frequency of the tracheostomy care at home. The additional findings of warmth, tenderness, purulent drainage, or fever may suggest the presence of a peristomal cellulitis. Depending on its severity, this condition should be treated with oral or IV antibiotics.

The skin of the neck under the ties securing the tracheostomy tube also can become inflamed. Generally, this situation can be treated by increasing the amount of padding and by keeping the area dry. An erythematous rash with satellite

lesions classic for a monilial dermatitis should be treated with topical antifungal creams.

Asthma

The incidence of asthma in children with chronic lung disease has increased. Many children are maintained at home on inhaled b-agonists, inhaled steroids, and cromolyn sodium therapy. The usual viral and environmental triggers, such as dust, pets, and smoke, precipitate exacerbations of asthma in these children.

The presentation is similar to that of other asthmatic patients, with varying amounts of respiratory distress, wheezing, and hypoxemia. As previously mentioned, the physician must consider the possibility of cannula obstruction or dislodgment in all cases. Treatment with oxygen, bronchodilators, and steroids should be initiated promptly. Therapeutic options are the same as those used with other asthmatic patients, as described in Chapter 80 and Chapter 95. Emergency clinicians should recognize, however, that children with chronic lung disease have less pulmonary reserve. Chest radiography and arterial blood gas analysis should be performed as clinically indicated. Increased ventilatory support or continuous positive airway pressure (CPAP) may be required to overcome fatigue and atelectasis.

Bleeding and Granuloma

The tracheal mucosa located adjacent to the stoma, the cuff, and the distal tip of the tracheostomy tube are prone to bleeding or granuloma formation. The most common reason for bleeding is inadequate humidification causing drying and friability of the tracheal mucosa. Infection or granuloma formation can also result in small amounts of bleeding. Large amounts of blood coming from the tracheostomy tube opening can signify erosion of the tube into the innominate artery. This complication is rare, but life-threatening.

Small amounts of bleeding from the tracheal stoma usually resolve with increased humidification of the inspired air. The persistence of minor bleeding might indicate an intratracheal granuloma, which should be evaluated by direct visualization. This procedure is best performed by an otorhinolaryngologist.

A large amount of bleeding is a surgical emergency. IV access should be obtained immediately and volume replacement should be initiated. The tracheostomy tube should not be removed because it may be the best way to ensure an airway. Frequent suctioning aids in preventing aspiration. If the site of bleeding can be identified, direct pressure should be applied to the area. Overinflating the cuff may tamponade a bleeding vessel and provide a temporary treatment until it can be ligated.

Peristomal granulomas can usually be treated with topical antibiotics. In refractory cases, cauterization with silver nitrate is indicated.

Cerebrospinal Fluid Shunts

Background

CSF shunt placement is the most common neurosurgical procedure performed in children. CSF shunts are placed to divert CSF from the brain to another area of the body, most commonly the peritoneal cavity. The clinician evaluating a child with a CSF shunt should be aware of associated complications such as infection, obstruction, and overdrainage. Certain complications can be disastrous if unrecognized and untreated. Children with CSF shunts often may exhibit symptoms of their chronic illness that are unrelated to shunt placement.

Pathophysiology

CSF is an ultrafiltrate of plasma produced at a rate of 500 mL/day by the choroid plexus and various extrachoroidal sites within the brain. CSF travels from the lateral ventricles into the third ventricle through the foramen of Monro, and then again through the aqueduct of Sylvius to the fourth ventricle. The CSF then enters the subarachnoid space via the foramina of Magendie and Luschka, and travels through the brain and spinal canal. CSF is reabsorbed and enters the venous system through the “one-way valves” of arachnoid villi that penetrate the dura.

Hydrocephalus can result from oversecretion, impaired absorption, or blockage of CSF pathways. *Oversecretion* can occur in some choroid plexus tumors. *Impaired absorption* can occur as a result of increased CSF protein (e.g., subarachnoid hemorrhage, Guillain-Barré syndrome), severe congestive heart failure, or any other condition that raises venous pressure. Impaired absorption is the cause of communicating hydrocephalus, in which flow from the lateral ventricles to the foramina of Luschka and Magendie is not obstructed. *Blockage of CSF pathways* is the most common cause of hydrocephalus in children and is often located at the narrow aqueduct of Sylvius proximal to the fourth ventricle. Conditions that can cause obstruction are intraventricular bleeding or scarring, tumors, or congenital malformations. Dandy-Walker cysts cause obstruction of the foramina of Magendie and Luschka and therefore result in enlargement of all four ventricles.

Equipment

Different types of CSF shunts, which vary mostly by the location of the distal tubing and the type of reservoir or valve system, are available. The choice of CSF shunt depends on the individual patient's anatomy and cause of hydrocephalus, and the experiences and preferences of the neurosurgeon performing the procedure. Commonly, the patient or caretaker knows the location and type of shunt and is able to provide details regarding prior shunt placement and problems. Palpation of the hardware and plain radiographs may be used to acquire more information regarding the specific location of the shunt components. All CSF shunts have the following three components: 1) proximal shunt tubing,

2) reservoir system, and 3) distal shunt tubing (Fig. 127.2).

FIGURE 127.2. Diagram of typical ventriculoperitoneal shunt.

The *proximal shunt tubing* has a fenestrated tip that is usually located in the ventricle but may also be located inside a non-communicating cyst. This tip allows free passage of CSF into the shunt system. More than one proximal catheter may be present if multiple, noncommunicating areas of the brain require shunting. The *reservoir system* consists of one or two “domes” or “bubbles” and may contain a one-way internal valve unit. “Double-bubble” shunts provide selective access to (and assessment of) proximal or distal portions of the shunt system. Reservoirs may be placed directly over or slightly distal to the burr hole. This information is crucial when emergent access to the burr hole is needed. The *distal shunt tubing* leads from the reservoir unit to a part of the body that can accept the drained CSF, usually the peritoneum. The distal tubing may also be located in the vascular system or pleural cavity. Ventricular–atrial shunts are less commonly inserted because of the serious infectious complications that have occurred with these types of shunts. All modern shunt tubing is made of $^{1}/_{8}$-inch diameter Silastic, which causes less omental reaction and suffers less cracking than did prior materials.

CSF shunt systems contain a one-way valve to prevent backflow of CSF into the ventricles. These valves are designed to operate at high, medium, or low pressure, and may rarely incorporate an on–off control switch. An anti-siphon device may be inserted into the system to prevent overdrainage of CSF and concomitant low-pressure complications.

Clinical Findings/Management

Mechanical Malfunction

Malfunction of a CSF shunt can be caused by obstruction of the catheter lumen or disconnection of the various components. The proximal catheter lumen can be obstructed by fibrosis, debris, or choroid plexus; the distal catheter can be obstructed by the surrounding omentum or kinking of the catheter. Both proximal and distal portions can be occluded by the products of infection or by migration of the catheter tip into the brain parenchyma or intraabdominal structures. Particularly in neonates, poor absorption of excess fluid in the peritoneum can create the appearance of luminal obstruction. In addition, as the child grows, the tension on the shunt system can lead to disconnection of the distal tubing.

Almost 70% of patients with CSF shunts experience a shunt malfunction in their lifetime. Parental history is paramount in deciding whether a child is experiencing symptoms of shunt malfunction. The parent often notices that the child “just isn't acting right,” or is less active or thinking less clearly than usual. The statement, “This is exactly how he acted the last time his shunt was obstructed” is suggestive of another malfunction, regardless of the presence or absence of the symptoms listed in the following section.

Common signs and symptoms of mechanical shunt failure include headache, visual disturbances, vomiting, lethargy, and irritability (Table 127.3). The astute parent or clinician may note mild ataxia, increased head circumference or bulging fontanelle in an infant, poor cognition, or abnormal behaviors. Less subtle signs include paralysis of the fourth (sunsetting) or sixth cranial nerves (lateral gaze preference) and decreased level of consciousness. Increased tone, hyperreflexia, or Babinski's reflex represents stretching and disruption of the corticospinal fibers originating from the motor cortex and can suggest shunt malfunction in a patient with a previously normal examination. Patients with any component of Cushing's triad (hypertension, bradycardia, and abnormal respiratory pattern) require immediate maneuvers to decrease intracranial pressure (ICP) and guide them quickly toward operative repair of the shunt. Seizures are uncommon as the sole manifestation of CSF shunt malfunction. However, seizures can occur in children who have predisposing brain lesions, and many patients with CSF shunts have epilepsy. Shunt infection must be considered in the child with symptoms of shunt malfunction, especially if the child has a history of recent shunt revision. Ronan et al. reported that more than one-third of patients with shunt infection presented with symptoms of malfunction.

Symptoms
Fever
Headache
Altered mental status
Irritability
Lethargy/difficult arousal
Confusion
Vomiting
Visual disturbances
Seizures (rare to be only manifestation)
Signs
Papilledema
Bulging fontanelle/enlarged head
Engorged head veins
Macewen's sign (cracked pot sound during percussion)
Abnormal neurologic examination
Increased deep tendon reflexes (DTRs) or lower extremity tone
Positive Babinski's sign
Cranial nerve palsy—lateral (6th) or upward (4th) gaze (sunsetting)
Respiratory compromise

Table 127.3. Concerning Findings in Patients in Cerebrospinal Fluid Shunt Malfunction

If the history and physical examination of the ill child with a CSF shunt suggest a possible shunt malfunction, further evaluation includes a non-contrast computed tomography (CT) scan with comparison to the most recent prior study, if available. A plain radiograph of the skull, chest, and abdomen (“shunt series”) is helpful in assessing the integrity of the shunt connection and in identifying the components of the working system. The clinical suspicion of a shunt malfunction based on history and physical examination may outweigh the data obtained from radiographic studies.

Much discussion and controversy surround the clinician's ability to assess CSF shunt function by “pumping” the shunt reservoirs. In a single reservoir system, this procedure involves depressing the reservoir bubble. Resistance to depression suggests distal catheter malfunction. Poor filling suggests either proximal catheter malfunction or small ventricles. The maneuver in a double-bubble shunt requires the initial depression of the proximal bubble, depression of the distal bubble to check for resistance, and subsequent release of the proximal bubble to check for poor filling. Pumping the shunt to test for obstruction is not always reliable. Piatt found that this maneuver had a positive predictive value of 21% and a negative predictive value of 78% in patients for whom the diagnosis of shunt patency or malfunction was definite. In addition, frequent pumping of the shunt can cause entrapment of choroid plexus in the proximal shunt tubing and lead to proximal catheter obstruction where none previously existed.

If subsequent evaluation is still necessary to diagnose malfunction, a neurosurgeon should be consulted. It may be necessary to “tap” the shunt (Fig. 127.3). The patient's hair is either shaved or trimmed. The scalp is cleansed first with alcohol, then with three applications of Betadine that are allowed to dry after each application. The shunt tap is performed by inserting a 23- or 25-gauge butterfly obliquely into the reservoir and holding the butterfly tubing perpendicular to the floor. The height that the CSF rises into the butterfly tubing, measured in centimeters, is the ICP. Normal pressure is between 5 and 10 cm; pressure more than 20 cm is indicative of distal shunt malfunction requiring urgent revision. Slow or absent flow from the proximal reservoir (especially with occlusion of the distal reservoir of a double-bubble shunt) suggests proximal shunt obstruction. In this case, the physician may notice that the reservoir collapses when gentle suction is applied to the butterfly with a syringe.

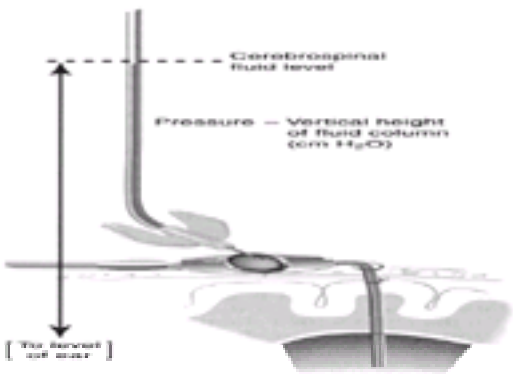

FIGURE 127.3. Tapping the cerebrospinal fluid shunt.

The shunt tap can be therapeutic as well as diagnostic. The child with a distal shunt obstruction or partial proximal obstruction may be eligible for urgent, rather than emergent, shunt revision if symptoms of increased ICP are alleviated after the tap. However, removal of too much fluid should be avoided because abrupt fluid shifts within the cranial vault can lead to disruption of subdural vessels. It is prudent to remove just enough fluid to decrease the ICP below 20 cm and repeat the procedure if symptoms return before definitive surgical management.

The child with complete obstruction of the proximal catheter does not obtain relief of symptoms after a shunt tap, because the obstruction prevents adequate aspiration of fluid from the ventricles. In most cases, these children may respond to medical management of increased ICP. This treatment includes the administration of acetazolamide (Diamox) 30 mg/kg per day and Decadron 1.0 mg/kg per day, and hyperventilation in the relatively unstable patient. If the child is experiencing life-threatening symptoms from proximal obstruction, is unable to undergo immediate surgical repair, and is unresponsive to medical management, a burr-hole puncture procedure may be performed (Fig. 127.4). Although the role of burr-hole puncture is clear in the patient who is in impending or existing neurologic failure, the procedure has many risks, including disruption of intraparenchymal vessels and tissue. By nature of the procedure itself, the proximal shunt catheter is torn and urgent revision is therefore mandatory. The burr hole is located either directly below or slightly proximal to the reservoir, depending on the type of shunt. For example, a Rickham reservoir is located directly over the

burr hole, whereas a double-bubble reservoir is located slightly distal to the burr hole. A 3½-inch spinal needle is inserted perpendicular to the skull through the burr hole to a depth of no more than 5 cm. After the stylet is removed, fluid should drain spontaneously and should be removed until flow slows down. The patient's condition should stabilize sufficiently for transport to an operating suite or tertiary care institution.

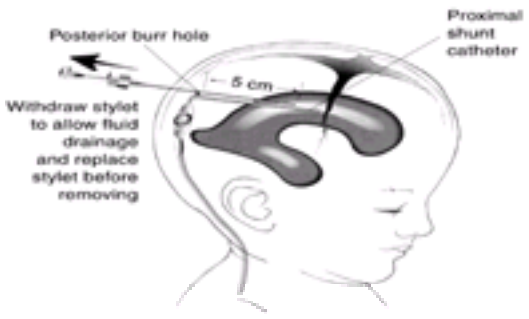

FIGURE 127.4. Burr-hole puncture.

Another method of temporarily relieving a lumen obstruction is to flush a small amount of sterile saline through the clogged tubing in an attempt to dislodge the obstruction. This method can be used for distal or proximal obstructions, with the caveat that instilling a few more milliliters into the ventricles may in fact worsen the patient's condition. In a double-bubble shunt, the reservoir that is not being used must be compressed to allow the fluid to go in only one direction.

In an infant with an open fontanelle, the physician can aspirate fluid through a direct ventricular puncture (Fig. 127.5). This procedure carries as great if not greater risk of parenchymal injury as the burr-hole puncture procedure, and likewise should be performed only when prompt surgery is impossible.

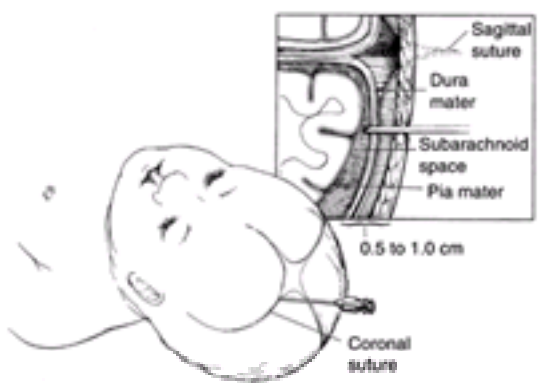

FIGURE 127.5. Ventricular tap through open fontanelle.

Infection

The reported incidence of CSF shunt infections ranges between 2 and 20% and depends on the center performing the study and the criteria used to define infection. The chance of infection is directly related to the timing of shunt placement. Infections generally occur within a few months of shunt placement, many of which occur within the first few weeks. The common organisms cultured from infected CSF shunts are Gram-positive (Table 127.4). Staphylococci adhere well to Silastic tubing, and these infections are often difficult to eradicate without removal of the catheter. Infection with staphylococci is common within the first 2 weeks after surgery. Gram-negative infections tend to occur later in the perioperative course. Fungi are rare pathogens seen occasionally in premature infants.

Table 127.4. Common Organisms Involved in Cerebrospinal Fluid Shunt Infections

External infection of skin and subcutaneous tissue overlying the shunt hardware can occur; however, these superficial infections may not lead to shunt infection if treated promptly. Necrosis of the area around the reservoir can occur as a result of the constant pressure in infants or non-ambulatory patients. Skin breakdown leading to visualization of the shunt mechanism is, by definition, a shunt infection, and must be treated accordingly.

The peritoneal portion of the shunt may become infected through the shunt mechanism or via a primary peritoneal

infection. Peritoneal infection can result in loculated, cystic pools of infection around the terminal portion of tubing (pseudocysts). These infections may be indolent in their presentation, and the shunt tap from the reservoir may not show evidence of infection.

Shunt nephritis is a rare but serious complication of ventricular–atrial shunts. Renal deposition of antigen–antibody complexes leads to complement activation, which damages the renal tissue.

Unfortunately, the child with an infected CSF shunt may present with nonspecific signs and symptoms (Table 127.5). Children commonly develop symptoms of shunt malfunction, such as lethargy or irritability. However, infection may also manifest as abdominal complaints, such as pain or vomiting. Fever is present in a little more than half of patients with shunt infections, and is rarely the only sign. As previously mentioned, infection is most common within a few months of the shunting procedure and is rare more than 1 year afterward. These rules are less applicable in patients with Gram-negative infections, which can occur later after shunt placement. Children with Gram-negative infections are often bacteremic, if not septic appearing.

Change in sensorium	Shunt malfunction
Fever	Vomiting
Irritability	Abdominal pain

Modified with permission from Odio C, McCracken GH, Nelson JD. Am J Dis Child 1984;138:1103-1108.

Table 127.5. Signs and Symptoms of Shunt Infection in Patients without Wound Infection

A wound infection overlying any portion of the shunt mechanism manifests as erythema and tenderness or swelling along the shunt tract or over the reservoir.

In the absence of overlying infection, aspiration of a small amount of CSF from the shunt system should be performed to identify the presence of a bacteriologic cause of shunt infection. This procedure is usually performed by a neurosurgeon, if possible. The white blood cell (WBC) count can range from 0 to 2600 if the shunt is infected, and patients without evidence of infection can have up to 500 WBC/mm^3. Many clinicians use greater than 50 WBC/mm^3 in the presence of clinical signs or symptoms of infection to secure the diagnosis. Gram stain of the fluid may be helpful in broadening antibiotic coverage if Gram-negative organisms are present. However, the Gram stain should not be used to narrow the usual antibiotic coverage until the culture and sensitivities of the causative organisms are obtained.

Various permutations of medical and surgical therapy have been suggested for treatment of CSF shunt infections. Medical therapy alone has been found to have a relatively low success rate compared with the surgical approach. Potential surgical interventions include immediate shunt replacement, or the insertion of an extraventricular drainage (EVD) catheter followed by delayed shunt revision. This latter method improves the bacteriologic cure rate significantly, although it must be performed in an institution that is facile in managing and preventing infection of EVD catheters. This procedure also requires the patient to visit the operating room twice.

Medical therapy provided in the ED for children with suspected CSF shunt infections is limited to the administration of broad-spectrum IV antibiotics. The antibiotics should be effective against the most common infecting organisms, as well as any organisms identified from previous infections. A reasonable choice of empiric therapy is vancomycin and ceftazidime. Therapy can be narrowed based on culture results of the shunt fluid. In patients with Gram-negative or fungal infections, intrathecal antibiotics may be used; however, this procedure is not considered appropriate in an ED.

Overdrainage

Occasionally, children with CSF shunts experience symptoms related to the system working too well, resulting in low ICP. One consequence is the slit ventricle syndrome, in which the ventricles collapse around the proximal catheter port and block further drainage. The best means of diagnosing this condition is the patient's history, rather than physical examination or radiographic analysis.

Until fluid increases to the point that the proximal catheter becomes patent, the child may exhibit symptoms of headache, nausea, vomiting, and lethargy. The drainage of CSF shunts increases when the patient is upright and decreases when supine. In contrast to the classic timing of symptoms related to increased ICP, patients with slit ventricle syndrome are often worse when in the standing position or after they are awake for several hours. Lying supine for a few hours tends to relieve symptoms of slit ventricle syndrome. Many patients with CSF shunts have CT scans that reveal small ventricles; however, only a small proportion of these patients have slit ventricle syndrome. Therefore, the CT scan is best used to differentiate between shunt malfunction and other causes of symptoms, rather than to diagnose an overdrainage problem.

Chronic or recurrent episodes of slit ventricle syndrome can be addressed surgically by upgrading the resistance of the valve or by insertion of an antisiphon device. Oral analgesics may be helpful in managing mild cases.

Other Complications

A number of other complications related to CSF shunts deserve mention. The most common of these complications is a benign postoperative leakage of CSF around the proximal shunt tubing into the subgaleal space around the reservoir. The resulting boggy mass, often called a “bumble,” resolves spontaneously, so drainage of this fluid should be avoided.

Patients with CSF shunts have an increased risk of seizures compared with the general population. These seizures often begin years after shunt placement and are caused by epileptogenic scars. They are more common in patients with other abnormalities correlated with seizures, such as porencephalic cyst or intracranial hemorrhage.

Overdrainage can lead to shrinkage of brain tissue and concomitant subdural accumulations (hematomas or effusions). Similarly, a decreased rate of head growth because of overdrainage can result in craniosynostosis in the infant.

Some important, albeit rare, complications are related to specific types of CSF shunts. The distal portions of a ventriculoperitoneal shunt can migrate and cause perforation of the colon or genital tract. This section of tubing can act as a fulcrum for intestinal volvulus. Ascites and abdominal cysts can form as a result of drainage of excess fluid into the peritoneum. Increased intra-abdominal pressure can precipitate the formation of an inguinal hernia through a patent processus vaginalis.

Ventricular–vascular shunts can be associated with an increased risk of bacteremia. Shunt nephritis can result from complement activation renal deposition of bacteria. Patients with ventriculo-atrial shunts can experience cardiac arrhythmias or atrial perforation, usually perioperatively. Bacterial endocarditis, cardiac foreign body, and mural thrombus are rare but notable complications of vascular shunts.

Indwelling Venous Access Devices

Background

Broviac designed the first Silastic indwelling central venous catheter in 1973. These devices provide children with relatively permanent and secure venous access during chemotherapy, total parenteral nutrition, or prolonged IV antibiotic therapy. Pediatricians, family practitioners, and emergency physicians have increasingly been called on to access and assess these catheters. Clinicians must be familiar with the procedures for establishing patency, drawing blood, dealing with catheter occlusion or breakage, and assessing for infection.

Pathophysiology

The distal tip of indwelling venous catheters is located in the right atrium or at the junction of the right atrium and the superior vena cava. The site of venous entry is usually the subclavian or internal jugular vein; however, access is occasionally obtained through the external jugular, cephalic, and brachiocephalic veins. The catheter is tunneled under the skin to a site in the chest away from the venous entry site, and then either externalized or connected to a subcutaneous reservoir.

Equipment

Partially implantable central venous catheters (CVCs) are also known as *externalized* CVCs (Fig. 127.6). They come in various types, such as Broviac, Hickman, Leonard, Raaf, Hermed, Groshong, and Corcath. All of these catheters are made of Silastic and are tunneled under the skin a few centimeters before externalization. A Dacron cuff located around the catheter at the skin line anchors the catheter after it fibroses. The most proximal portion of the catheter contains a female Luer lock tip, allowing a direct and solid connection to most syringes and IV tubing. A clamp is present just before this tip, under which a reinforced sleeve protects against catheter breakage. The catheters can vary in length, diameter, and numbers of lumen and access ports. The Groshong type catheter is valved at the distal tip to keep blood out of the lumen and therefore requires only saline flushes and does not require clamping. A kit is available that contains the equipment necessary to repair broken external catheters (Evermed, Inc.).

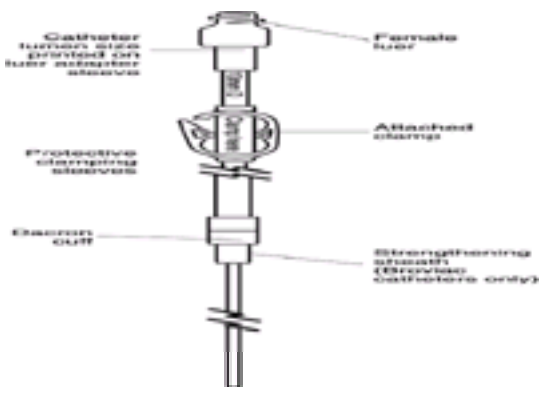

FIGURE 127.6. Partially implantable (externalized) venous catheter.

Implantable venous access devices (Infusaport, Port-A-Cath) are also called *internalized* CVCs (Fig. 127.7). Like the externalized CVCs, they use a Silastic catheter with the distal tip located in the right atrium. However, the proximal end is

tunneled and connected to a subcutaneous reservoir chamber. The reservoir has a self-sealing silicone septum and a hard back surface. The chamber is accessed using a tapered 20- or 22-gauge Huber noncoring needle (solid tip with side ports). The needle is angled at 90 degrees for ease of insertion and stabilization. If emergency access is required, a 19-gauge straight needle can be used.

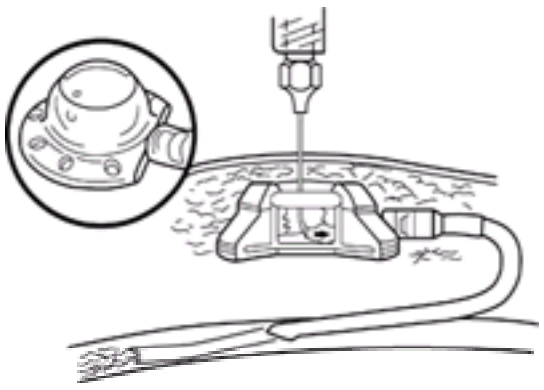

FIGURE 127.7. Implantable (internalized) venous access device.

Specific equipment is available for accessing externalized and internalized indwelling CVCs (Table 127.6). The medical office or ED that occasionally sees these children should have a prepared kit containing these items at hand.

Clamp or hemostat without teeth, possibly with rubber tips	Povidone-iodine ointment
T-extension tubing with clamp	Alcohol swabs
10-mL syringe of normal saline	Sterile drapes and gloves
10-mL syringe of heparin 100 U/mL	Dressing gauze and tape
(4) Injection caps	Tegaderm sterile dressing
Povidone–iodine solution with sterile gauze	(2) Tapered Huber non-coring needles, 20- and 22-gauge

Table 127.6. Equipment Needed to Access Central Venous Catheters

Procedures that can be accomplished by the generalist or ED personnel include establishing access, performing phlebotomy, and infusing fluids or medications. The general procedure for establishing access and patency is similar for both externalized and internalized devices (Table 127.7). Aseptic technique is mandatory. Because tincture of iodine solution can damage Silastic catheters, povidone–iodine solution is used. Clamps or hemostats with teeth can also damage the external portion of the catheter. In addition, smaller (less than 3 mL) syringes can generate too much pressure inside the catheter, causing catheter breakage. Therefore, 5- or 10-mL syringes are recommended to flush the system. Fluid or medications should never be infused until patency is established because the risk of administering these solutions into a non-vascular space is high. To prevent air emboli from occurring, all clamps must remain closed when any part of the circuit is open. For accurate blood test results, the amount of blood that needs to be withdrawn unused is 5 mL from an externalized CVC and 3 to 5 mL from an internalized CVC.

Aseptic technique
Do not use:
Clamps or hemostats with teeth
Tincture of iodine solution
Small (≤3-mL) syringes
Flush entire intravenous circuit before accessing system.
Always close clamps when any part of the circuit is open.
Do not infuse fluids or medications until patency is established.
Flush the catheter with 10 mL of saline between medications.
Flush cap or reservoir with heparin when procedure is complete.

Table 127.7. Tips for the Routine Use of Indwelling Venous Access Devices

When an externalized CVC is accessed, these steps should be followed:

1. Before accessing the system, flush the intended IV circuit, including T-connectors, with saline to remove air. Clamp the T-connector closed.
2. Clamp any external portions of tubing 3 cm from tip.

3. Connect to the system.
4. Flush the system with 3 to 5 mL of saline in a 5- to 10-mL syringe, then aspirate 3 to 5 mL of blood to check patency.
5. Draw off blood needed for laboratory analysis, and administer medications or fluids as needed.
6. When these steps are completed, clamp the line.
7. Inject 1 mL of 100 U/mL heparin solution into the cap after the procedure is completed. The recent advent of "needleless" systems have decreased the need for puncturing the caps of external catheters. If this type of system is used, remember to discard the old cap and replace it with a new one using sterile technique.

The procedure differs slightly when accessing an internalized CVC. Because intact skin is penetrated, the use of EMLA at least 60 minutes before access should be considered when feasible. If used, the EMLA should be wiped off and the skin should be cleansed using povidone–iodine, allowed to dry, and followed by an alcohol swab. Instead of connecting to an external catheter, a Huber needle should be inserted through the skin directly into the reservoir diaphragm but stopped if resistance is met at the back of the reservoir. The needle should be taped in place and patency should be established with aspiration and flushing. After use, the internalized device must be flushed using 1 mL of heparin diluted in 4 mL of saline or similar solution.

Complications resulting from accessing CVCs include occlusion, air embolus, catheter breakage or displacement, and infection. Although most of these complications can be avoided if care is taken to maintain aseptic technique, the clinician should be aware of their diagnosis and management.

Clinical Findings/Management

Catheter Occlusion

Difficulty in drawing blood or infusing fluid through a CVC can be the result of catheter malposition or occlusion. The catheter may be positioned against a vessel wall or fibrin or blood may be clotted in the lumen. In addition, various precipitates can occlude the lumen of the catheter. Waxy precipitates can result when parenteral nutrition solutions contain combinations of fat, protein, and carbohydrate, and particulate precipitates can result from the poor solubility of calcium and phosphorus. IV phenytoin (especially when administered in a glucose-containing solution) and diazepam can precipitate as well.

Children who require IV medications or fluids at home may present for acute management of catheter occlusions. The problem is often noted only when the acute-care nurse or physician cannot access the line during the evaluation of another problem.

Phlebotomy can be facilitated by increasing the venous pressure gradient along the catheter. These maneuvers include having the patient hold his or her arms above the head, cough or Valsalva, and placing the patient in reverse Trendelenburg position. If blood still cannot be drawn, 3 mL of saline should be used to gently irrigate the clot and aspirate it into the syringe. Two to three mL of fluid should be used in a back-and-forth motion to avoid forcing the clot into the venous system. A number of complications can result from this maneuver. The pressure can force the clot into the bloodstream or rupture the catheter, particularly if the practitioner uses too much force or too small a syringe. Care should be taken to observe the catheter for a balloon "aneurysm," a sign of impending rupture.

Internalized systems are much less likely to clot than are externalized catheters. This situation is fortunate because irrigating the clot is admittedly more difficult, if not impossible, to perform on an internalized system.

Specific agents may help dissolve precipitates or clots. For waxy precipitates, 70% ethanol should be used, and for particulate precipitates, 0.1 normal hydrochloric acid (HCl) should be used. Fibrinolytic agents such as urokinase (0.5–1 mL of a 5000 U/mL solution) may dissolve a blood clot, and similar to HCl may be used up to three times if necessary. Ethanol should only be used one time per episode. Urokinase infusions may be started at the suggestion of the surgical consultants, who should be involved in the treatment plan if initial attempts are unsuccessful.

Air Embolism

Failure to maintain a closed system during manipulation of indwelling venous catheters can result in embolism of air into the chambers of the heart. Passage of the embolus to the systemic or pulmonary circulation can result in severe and irreversible tissue damage.

Air embolus can cause a patient to experience sudden onset of tachypnea, tachycardia, hypotension, or loss of consciousness. Other diagnoses that should be considered in patients with these symptoms are pneumothorax, liberation of septic emboli, and direct cardiac insult. If an air embolus is suspected, the patient should be placed in the left-sided Trendelenburg position, and oxygen should be administered. In addition, the indwelling catheter should be clamped and remain unused as other peripheral access is obtained.

Catheter Breakage

The family members and physicians caring for the child with an externalized catheter may have considered the nightmare of catheter breakage and subsequent exsanguination. Although catheter breakage is a distinct possibility, most events occur during routine care rather than during playtime, and therefore the blood loss is easily apparent and correctable. An external catheter can acquire a small hole from inadvertent needle puncture or even ordinary wear and tear. Internalized catheters, on the other hand, are less susceptible to local events or wear and tear. However, trauma to the area can result in detachment of the proximal portion of the catheter from the implanted port.

Leakage of blood or fluid from the externalized portion of an indwelling catheter is easily noticed. Externalized catheters

must be immediately clamped proximal to the break, cleaned with povidone–iodine solution, and covered with sterile dressing until repair can be made. Repair kits are available for each catheter size (Fig. 127.8). These kits contain a new external catheter segment with a hollow male connector that fits into a cleanly sliced proximal end. The kits also contain a syringe and needle to apply the glue to the male connector. Optimally, a person familiar with the procedure will be available within a short time of clamping the catheter. If the externalized portion is too small to clamp, hemostasis may be achieved by putting pressure on the site of venous entry. A scar is usually apparent at this site. However, if the scar is not apparent, the catheter should be palpated from the exit site on the skin to the location at which it can no longer be palpated, and pressure should be applied at that site.

FIGURE 127.8. Repair kit for externalized catheters

If an implantable catheter leaks, fluid or blood that collects subcutaneously may cause a bulge or painful swelling at the site. A broken internalized catheter must undergo prompt surgical management.

Catheter Displacement

Occasionally, the patient or caretaker inadvertently pulls on the externalized portion of an indwelling catheter. The venous portion of the catheter may eventually be displaced from the venous system. Externalized catheters are at higher risk for dislodgment within a few weeks of insertion, because the cuff is not fully anchored by fibrosis. Exsanguination after catheter dislodgment is a rare event because of the advancement of the tip inside the vein and the natural tendency toward venous hemostasis. However, children with clotting disorders are at increased risk of life-threatening blood loss after catheter displacement. Internalized devices are at risk of dislodgment at both ends; however, few events aside from major thoracic trauma place enough tension on the catheter to dislodge it from the vein. Migration of the venous catheter tip is rare but can lead to cardiac arrhythmias, pneumothorax, cardiac tamponade, and superior vena cava syndrome.

Detecting catheter dislodgment is easier in patients with externalized catheters. If the Dacron cuff is noted outside of the skin surface, the catheter must be considered dislodged and should not be used. Failure to draw back free-flowing blood from the device increases the suspicion that the catheter is no longer in the central vein. In this situation, the catheter should be clamped and secured close to the skin, and immediate surgical consultation should be obtained. As previously mentioned, hemostasis is obtained by putting pressure on the site of venous entry. A dye study may be necessary to locate the catheter tip. For internalized devices, dislodgment of the catheter from the vein should be suspected if the device no longer functions after thoracic trauma. If the catheter is disconnected from the reservoir, fluid or blood may collect subcutaneously and cause a bulge or painful swelling at the site. Prompt surgical management is required.

Catheter migration should be considered in patients with indwelling venous catheters who experience respiratory distress or palpitations. Radiologic evaluation of catheter location should rapidly ensue, with subsequent surgical consultation if the catheter tip has migrated.

Infection

Fever in a patient with an indwelling venous catheter is usually caused by a routine viral or bacterial infection. However, certain clinical findings suggest a line infection. The presence of an indwelling venous catheter places a patient at higher risk for infection. Immunocompromised patients can exhibit rapid deterioration, and more commonly acquire fungal, Gram-negative, and polymicrobial infections. Patients receiving parenteral alimentation are also at higher risk for Gram-negative infections. Still, the most common pathogens in patients with indwelling catheters are Gram-positive organisms such as *S. epidermidis, S. aureus,* and *S. viridans.* Externalized catheters carry a higher overall risk of infection compared with internalized devices. Catheter infection can occur at the site of catheter exit or reservoir, at the subcutaneous tunnel, or at the site of venous entry. The signs of infection may be more subtle or absent in neutropenic patients. Catheter-related bacteremia can also occur without apparent skin manifestations.

The presence of erythema, tenderness, or purulent drainage at any skin site related to an indwelling catheter suggests a line infection. The entire dressing must be removed for all of these sites to be inspected. Fever is common in patients with catheter-related bacteremia or sepsis but may be absent in early localized infection.

Blood cultures should be obtained from the catheter, and in most cases from a peripheral vein as well. Fungal cultures are appropriate in immunocompromised patients or those who have had prior invasive fungal infections. Cultures of any purulent fluid are helpful. A complete blood count with differential is warranted, although a normal result should not dissuade the clinician from suspecting an invasive bacterial infection. Other blood tests, such as coagulation studies, should be considered if the patient is ill appearing.

Initial treatment consists of IV antibiotic therapy and supportive measures. Many catheter infections can be eradicated without catheter removal. Infection of the subcutaneous tunnel is a strong indication for catheter removal. Initial antibiotic therapy should include agents active against both Gram-positive and Gram-negative infections. Many centers use vancomycin and gentamicin as the first choice. If the patient is neutropenic, ceftazidime should be added for presumptive treatment of *Pseudomonas* infection. Local bacterial resistance patterns may alter these choices, such that centers may reserve the use of vancomycin for culture-positive resistant strains or use netilmicin in place of gentamicin. These issues should be discussed with the patient's personal physicians and the infectious disease consultants.

Other Complications

Other complications related to indwelling catheters can occur, albeit rarely. Direct injury to the exit site can be a result of erosion of tissue by the Dacron cuff of an externalized catheter, or of breakdown of the skin site from vigorous cleansing. This condition can lead to a localized infection. On physical examination, excoriation, erythema, tenderness, or purulent drainage is present at the exit site of the catheter. Select patients with a localized site infection who are afebrile and well appearing, have a normal leukocyte count, and have pre-arranged follow-up may be managed as outpatients with oral antibiotic therapy.

As previously mentioned, phenytoin and diazepam can interact with the silicone lining of the catheters, and the administration of these medications through silastic catheters should be avoided if possible. In addition, a large volume of saline flush should be administered between medications that are incompatible with each other, such as calcium and bicarbonate.

Enteral Feeding Tubes

Background

A stoma, derived from the Latin word for “mouth,” is an opening from the GI or urinary tract to the outside of the body. A gastrostomy is a surgically created stoma that brings the stomach to the level of the skin. A jejunostomy is a surgically created stoma that brings the jejunum to the skin surface. Gastrostomy is performed most typically in children who are predicted to be unable to take adequate oral nourishment for a prolonged period. The inability to tolerate sufficient oral feedings can be related to several conditions, including esophageal atresia, chronic malabsorptive syndromes, significant craniofacial abnormalities, neurologic impairment, severe gastroesophageal reflux, and esophageal burns. Jejunostomy feedings are used when post-pyloric feeding is required, such as patients with delayed gastric emptying, recurrent aspiration pneumonia, and severe gastroesophageal reflux. Gastric feedings are much more common than jejunal feedings.

Enteral feeding via gastrostomy and jejunostomy tubes has become more common in recent years. Therefore, ED physicians should become comfortable with the various types of G-tubes and jejunal tubes, the supporting types of apparatus, and the complications inherent in the use of these lifesaving enteral feeding devices.

Pathophysiology

Gastrostomies tubes are inserted via open gastrostomy, or percutaneous endoscopic gastrostomy (PEG). In the open gastrostomy technique, a left upper quadrant or midline incision is used to place the gastrostomy tube through the abdominal wall. The G-tube then passes through a purse string silk suture placed on the anterior wall of the stomach and into the lumen of the stomach at the level of the fundus. The purse string suture is then tightened around the tube to prevent gastric leakage, and the wall of the stomach around the suture is sewn to the abdominal wall where the tube makes its exit. PEG is the most popular of the non-surgical procedures for placing a gastrostomy tube. This technique involves placing a tube into the stomach through a percutaneous hole in the anterior abdominal wall. An endoscope is used to provide light at the exact site on the anterior abdominal wall as a guide for needle puncture. A long guidewire with a feeding tube and pointed dilator is then passed through the mouth and distally until the pointed dilator is seen pushing its way through the skin of the anterior abdominal wall. A cuff system is used to bring the stomach and anterior abdominal wall closely together.

Jejunostomy can be performed via an open technique or percutaneously. Jejunal feeding can also be accomplished by placing a jejunal tube via the gastrostomy. This method allows jejunal feeding and enables venting of gastric air.

Equipment

Gastrostomy Tubes

Several types of gastrostomy tubes are available. Most are made of polyurethane, silicone, or rubber. These devices may vary in length, the number of ports, the type of catheter tip, the number of lumens, and the manner of securing to the patient's skin (Fig. 127.9). The *mushroom* types (Button by Bard Interventional Products Division, Billerica, Massachusetts) have soft flexible tips that require an obturator or stylet to stretch the tip. These devices have a single lumen. The *collapsible wings* tubes (Malecot, St. Louis, Missouri) are not as available but function in a similar manner. The *balloon tip devices* (MIC-KEY, Medical Innovations Corporation, Draper, Utah) have become popular and have begun to replace the mushroom tip and collapsible wings devices. The inflatable balloon is located at the tip, similar to a urinary Foley catheter. They are easy to secure and do not dislodge as easily. These tubes may have multiple ports and lumina. The most recent advance in gastrostomy tubes is the introduction of the low profile G-tube, commonly referred to as buttons (Fig. 127.10). The advantage of this type of apparatus is that no long piece of tubing arises from the stoma. They may have either mushroom or balloon tips. Replacement devices need to be matched for both the size of the stoma (the external diameter of the tube) and the length of the stoma tract. These buttons have uni-directional anti-reflux valves

that are fragile.

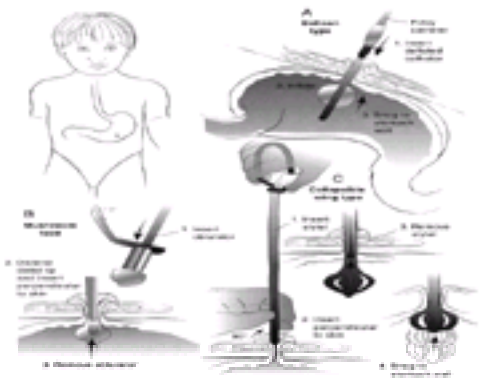

FIGURE 127.9. Gastrostomy tube replacement for balloon-type **(A),** mushroom-type **(B),** and collapsible **(C)** wing-type catheters.

FIGURE 127.10. The button: replacement gastrostomy device.

Jejunal Tubes

Jejunal tubes that pass through the gastrostomy are usually small diameter tubes (8 Fr), an example of which is the Frederick Miller feeding tube set manufactured by Cook (Bloomington, Indiana). These tubes have a small mercury weight at the distal tip and are placed under fluoroscopy. Several types of surgical jejunostomy feeding tubes are available, including Malecot and MIC-KEY jejunal tubes.

Clinical Findings/Management

Patients with gastrostomy tubes (G-tubes) or jejunostomy tubes (J-tubes) who present with symptoms that seem to be related to the tube still require a full evaluation. If the problem is directly related to the G-tube or J-tube, the emergency physician can offer efficient evaluation and therapy if he or she is familiar with potential complications. Complications related to gastrostomy and jejunostomy can be divided into mechanical tube-related problems and stomal problems.

Tube-Related Problems

Dislodgement. Dislodgement is one of the most common complications of gastrostomy tubes. This situation can occur as a result of a traumatic event, such as accidental tension on the external tubing, occult balloon deflation, or rupture of the balloon leading to extrusion of the entire tube. When G-tube dislodgement precipitates an ED visit, many parents either remember the size of the tube or bring one along to the ED. If neither of these events occurs, the patient's medical record usually provides the most recent tube size.

The patient with tube dislodgement may present with a benign stoma or with active bleeding secondary to trauma. If the tube size is unknown or if various tube sizes are not available, the most common temporizing method of replacement is insertion of a Foley catheter. A crucial consideration is the interval of time since the dislodgement. If hours have elapsed, the stoma may be constricted and require insertion of a smaller replacement tube.

The interval since *initial* placement of the gastrostomy is important. Peri-operative displacement (within 1 month of initial placement) is treated differently than dislodgement of a mature stomal tube. If a G-tube dislodges, temporary replacement with a smaller Foley catheter may prevent pushing the recently fixed stomach away from the anterior abdominal wall. A series of progressively larger Foley catheters, beginning with one to two sizes smaller than the original tube, may be used to dilate the stoma if it is partially closed. A gastroenterologist or surgeon should then be consulted for definitive care. An older tube that has dislodged should be replaced urgently with the same size and type of tube to avoid narrowing of the stoma. The physician must use caution when reinserting a G-tube because extreme force can lead to tube insertion into the peritoneal cavity through a false tract.

A jejunal tube that has dislodged needs to be replaced by the subspecialist who placed it initially. For example, a J-tube that was inserted via the gastrostomy should be replaced by the interventional radiologist under fluoroscopy. A surgical

jejunostomy tube should be replaced by a surgeon.

Clogging. Clogging or obstruction of the lumen of the G-tube or J-tube can occur as a result of dried, solidified formula or twisting or kinking of the tube. Tube obstruction is discovered when the caretakers cannot infuse fluids. If formula is suspected as the cause, aspiration of the clot should be attempted as well as gentle flushing of the lumen. Warm water is recommended as the most effective fluid. Despite reports of the success of various carbonated drinks in this situation, their effectiveness is controversial. When the G-tube becomes clogged, insertion of a stylet is not recommended because this technique may result in perforation of the tubing beneath the skin level. Repositioning of the tube should be attempted next; if this procedure is not effective, removal and replacement are necessary. If the gastrostomy is fresh (within 1 month), the surgeon or gastroenterologist should be consulted before removal of the clogged tube. Caretakers should be reminded of the need for proper flushing with each use.

Leaking. Leaking can occur directly from the lumen of the tube or from the peristomal area. Leaking from the stoma often indicates that the stoma has widened and now exceeds the size of the tube. Determining whether the leaking substance is formula, pus, or gastric fluid is crucial. If purulent drainage is coming from the stoma, the physician needs to look further for signs of stomal cellulitis or peristomal abscess (see following section). If formula is leaking from the lumen of the tube, the physician must assess the tube position and check the balloon. In the case of a leaking button, problems with valve patency could occur. If fluid is leaking from the stoma, the stoma may have become larger than the tube. One approach to this problem is removing the tube for a short period, allowing constriction of the stoma to occur. Alternatively, the existing tube can be replaced with a larger one. The stoma may also have become disrupted and, therefore, requires surgical evaluation.

Reflux. Gastroesophageal reflux may be a complication of gastrostomy placement. An increase in prior reflux disease can occur when a Nissen fundoplication is not performed simultaneously. The patient may present with an increase in vomiting and symptoms of esophageal irritation after gastrostomy placement. Patients in this category may benefit from continuous enteral feedings. If continuous feedings are not effective in reducing symptomatic reflux, fundoplication may be indicated.

Gastric Ulceration. Gastric irritation leading to ulceration may occur as a complication of gastrostomy in several scenarios. If the tip of the gastrostomy tube is too long, it may abrade the opposite surface of the stomach mucosa, resulting in traumatic ulceration. Similarly, the balloon may accidentally become overinflated and cause friction, especially when the stomach is empty. Balloon overdilation can occur if medications or flushes are erroneously administered via the balloon port.

A patient with gastric ulcer caused by mechanical trauma presents with symptoms similar to other ulcer patients. Common findings are abdominal pain, irritability, hematemesis, hematochezia, and coffee ground gastric drainage from the G-tube lumen. Saline lavage should be performed. If the fluid obtained is non-bloody, medications such as H_2-blockers, antacids, and Carafate may be administered, and upper endoscopy should be scheduled. The gastrostomy tube should be changed and the patient's symptoms should be monitored carefully.

Gastric Outlet Obstruction. Gastric outlet obstruction is a rare but serious complication of gastrostomy tubes. It is usually the result of the migration of the tube tip into the pyloric channel. Occasionally, the gastrostomy tube can migrate superiorly and block the esophagus. In rare cases, the entire apparatus can migrate distally, resulting in gastric outlet obstruction. The child complains of retching or sudden onset of emesis, and appears uncomfortable. The G-tube needs to be pulled back to its proper location until it is snug against the abdominal wall. If this procedure is not successful, the tube must be removed completely.

Stomal Complications

Irritant Dermatitis/Allergic Hypersensitivity. Skin irritation around the stoma may result from chronic leakage of gastric or jejunal fluid around the tube. If the stoma widens, the leakage may become excessive, resulting in more significant dermatitis. Various brands of adhesives and cleansing solutions may result in an allergic rash around the stoma.

The peristomal skin should be thoroughly cleansed and dried before assessment. Small vesicular lesions with surrounding erythema suggest irritant dermatitis. Local treatment includes keeping the area as dry as possible and using barrier creams to protect the skin from further breakdown. Stomahesive Power (Convatec, Princeton, New Jersey) is useful to mold to the skin surface and keep the area dry and free of debris. In addition, identifying and treating the cause of the leakage is important. If the leakage is caused by an enlarged stoma, surgical intervention may be required in the near future.

Granulation. Children with gastrostomy tubes may develop granulomatous tissue in the peristomal area. These lesions are harmless but occasionally become infected or bleed. Granulomatous tissue typically appears in the borders of the stoma and may begin to cause occlusion of the stoma. The most effective treatment is silver nitrate swabs.

Cellulitis. When peristomal skin surrounding the G-tube or J-tube is irritated by recurrent or intermittent exposure to drainage, cellulitis may occur. The infection may begin as a superficial skin irritation or contact dermatitis and then evolve into a deeper infection. The surrounding peristomal area may become reddened, warm, tender, and edematous. These symptoms and signs may be accompanied by systemic symptoms and fever. The patient with a G-tube may become resistant to gastrostomy feedings because of the discomfort associated with manipulation of the apparatus. Once cellulitis is present, the patient requires systemic antibiotics for resolution of this infection. The common organisms, staphylococci and streptococci usually respond to a first-generation cephalosporin. Occasionally, the cellulitis can be complicated by a peristomal abscess, heralded by a localized area of fluctuance. This abscess requires incision and drainage before antibiotic administration.

Fungal Infection. Recurrent moisture caused by gastric or jejunal leakage in the stomal area can predispose the patient

to fungal infection. The most common causal organism is *Candida albicans,* appearing as fiery red plaques at the stoma site. Topical clotrimazole is curative in most situations. Keeping the area as dry as possible is imperative.

Gastrointestinal and Genitourinary Diversion

Background

Pediatric patients may have a GI or genitourinary diversion for one of many reasons. Congenital causes include Hirschsprung's disease, imperforate anus, cloacal exstrophy, bladder exstrophy, meningomyelocele with a neurogenic bladder, and posterior urethral valves. Acquired lesions may include ulcerative colitis, Crohn's disease, and necrotizing enterocolitis. Traumatic injuries leading to GI or genitourinary diversion include penetrating wounds and falls.

GI diversions consist primarily of colostomy and ileostomy. Colostomy brings the colon to the skin. Patients with colostomies usually have semi-formed stools because the absorptive and storage function of the bowel is preserved. An ileostomy brings the ileum to the skin. Ileostomy patients do not possess large bowel function and consequently have a watery, frequent stooling pattern.

The major forms of urinary diversions consist of ureterostomy, vesicostomy, nephrostomy, and ileal conduits. Ureterostomy brings the dilated ureter to the level of the skin, whereas an ileal conduit implies that the ureters are attached to the ileum, which is then externalized. A vesicostomy opens the bladder to the skin. Nephrostomy indicates that a tube is placed into the renal pelvis percutaneously, usually by an interventional radiologist. Urinary undiversion indicates that the patient has undergone a surgical procedure that internalizes the urine passage via a “neobladder.”

In general, a stomatherapist is crucial to the physicians and families of all patients with stomal sites and appliances. However, patients continue to present to the ED with ostomy-related problems and the emergency physician should become facile with the various types of GI and genitourinary diversions and their specific complications.

Pathophysiology

The nature of the disease and the location of the lesion(s) guide the surgeon when choosing the type of diversion to use. Ileostomy is usually performed in newborns for conditions such as meconium ileus, necrotizing enterocolitis, and intestinal atresia. It may be required in older children and adolescents because of ulcerative colitis or polyposis. The surgical method used depends on the predicted length of time required for the ostomy, as well as the location of the disease.

Colostomy in infants is required for complications of colonic atresia, high forms of imperforate anus, and Hirshsprung's disease. The level of the colostomy is related to the disease type and to anticipated future procedures. Some of the ostomy complications that occur in patients with genitourinary and GI diversions are similar. In both types of diversions, many complications relate to the actual stoma. These conditions are discussed in the previous enteral feeding section. Other complications are metabolic or mechanical in nature.

Vesicostomy is usually performed for patients with myelomeningocele, posterior urethral valves, prune belly syndrome, and spinal cord injury resulting in a neurogenic bladder. This procedure is protective of the upper urinary tract.

Ureterostomy is accomplished by bringing the ureter to the surface of the skin either in the groin (low) or in the flank (high). Most high ureterostomies are of the loop variety, in which a loop of ureter is incised on one side, and passed upward to allow the edges to be anastomosed to the skin. This path allows ureteral continuity from the kidney to the bladder, with a vent to the skin. Low ureterostomies are more common, performed for obstructed ureters such as ectopic ureters or megaureters. To decompress an obstructed system and prevent urinary tract infection, the ureter is divided, the distal end is ligated, and the proximal edges are anastomosed to the skin.

Ileal loop conduits are created using a resected 10 to 20 cm bowel segment of ileum and anastomosing both ureters to one end. The other end of the bowel loop is brought out to the skin. Ileal loop conduits are preferable in older children who can wear an appliance to collect the urine.

Equipment

Standard ostomies are commonly managed by placing an ostomy pouch over the stoma to collect the effluent. In young infants, sigmoid colostomies may be managed without an external pouch if the effluent is not caustic to the skin, and fluid is therefore collected in the diaper. Urinary flow can also be collected in a diaper, and may be preferable because some appliances do not adhere well to the skin for long periods.

Ostomy pouches for children are manufactured in a variety of sizes. One- and two-piece configurations are available, and pouches may be soft or rigid. Supplemental adhesives are crucial to enhance adhesion. In general, the more liquid the effluent, the greater the need for adhesive substances.

Clinical Findings/Management

Gastrointestinal Diversions

Patients with colostomies and ileostomies may present with complications that are common to both types of ostomies. Ileostomies also have metabolic complications that are specific to this type of ostomy.

Cutaneous Complications. Peristomal cutaneous complications are common in patients with ostomies, and stem from

the effect of chronic stool and other drainage on the peristomal skin. This chronic drainage compromises the skin integrity surrounding the stoma. The most effective management is the maintenance of a good seal between the ostomy pouch and the stoma. Contact dermatitis may occur from leakage around the stoma or from allergy to stomal materials such as tape or pouches. This condition is often successfully treated by removing the offending material. Infection with *C. albicans* is fairly common because of the persistent moisture and the frequent use of prophylactic antibiotics. Treatment with antifungal agents such as clotrimazole, especially powders, is effective. The powder can be mixed with a small amount of water and painted onto the skin to enhance adherence of the pouch. Ointments and creams should be avoided in fungal infections. Skin bleeding resulting from mechanical trauma from the stomal tube is usually minor. The cellulitis that can occur if the skin excoriation worsens is treated with systemic antibiotics.

Stomal Complications. Stomal stenosis is not always detectable to the parent or practitioner and may present with reduced or absent output, diarrhea, or cramping abdominal pain. When severe stenosis occurs, it usually presents as obstruction. To assess the degree of stenosis, the physician should gently examine the stoma digitally unless the stoma is too small. In this case, a catheter should be carefully passed. If abdominal obstruction is suspected, radiographs of the abdomen and urgent surgical consultation are indicated.

Prolapse of stoma occurs in greater than 20% of patients with stomas and is usually not an emergency. However, skin excoriation, bleeding, and incarceration of the bowel may occur. The situation becomes more urgent if the prolapse is associated with pain, decreased output, or a dusky stoma color that represents circulatory compromise. Management includes easing the prolapsed contents back into the stoma using both hands. This procedure may need to be done repetitively.

Retraction of the stoma because of excessive tension may cause the stoma to recede beneath the skin. This condition occurs more often than prolapse in patients with ileostomies. Stomal retraction makes it difficult for a pouch to adhere to the skin. Retraction can also result in cellulitis or even peritonitis depending on the location of the detachment and the flow of the effluent. Management usually includes antibiotics. Surgical correction may be required if the stomal detachment reaches the fascial layer.

A hernia of the peristomal contents occurs when there is a protrusion of the colon or ileum into the subcutaneous layers of skin surrounding the stoma. This complication may impede adherence of the ostomy pouch but does not represent an emergency.

Complications Specific to Ileostomy. Patients with ileostomies occasionally develop metabolic derangements. In the face of large volume losses, children tend to become salt and water depleted. If large fluid losses persist, the biochemical profiles of these patients are significantly altered. Determining the cause of the exceptionally high fluid losses from the ileostomy is crucial. Some possibilities are obstruction, gastroenteritis, and dietary indiscretion. Treatment is aimed at restoring normal fluid and electrolyte balance and may require hospital admission.

Patients with ileostomies are prone to acquiring urinary stones. The chemical composition of stones in this scenario is different than that in normal patients; uric acid stones constitute 60% and calcium oxalate makes up the remainder. Treatment is directed at decreasing ileostomy output and increasing urine output.

Urinary Diversions

Vesicostomy. In patients with vesicostomy, eversion of a large portion of the bladder can occur and appear like an exstrophy. When the posterior aspect of the bladder prolapses through the stoma, the patient presents with a red mass, which may progress to purple if not treated promptly. This condition may be managed by applying an index fingertip to the bladder and gently pushing inward. Non-latex gloves are used because children with urologic abnormalities are often allergic to latex. Sedatives may be required to facilitate reduction of the prolapse. A prolapsed vesicostomy should be surgically revised if the manual reduction is unsuccessful.

Patients with stomal stenosis of the vesicostomy usually present with a palpable bladder, a history of unwanted urethral voiding, or with symptoms of urinary tract infection. As the bladder fails to empty at low pressures, the mean storage pressure rises and the chance for seeding bacteria into the upper urinary tract increases. These patients often have a pinpoint opening to the bladder, and the parents usually comment on how much smaller the stoma has become over time. If possible, these patients should have a catheter placed via the vesicostomy using a small (6 or 8 Fr) catheter. The urethra should be catheterized for urine to establish a diagnosis of urinary tract infection. If the vesicostomy is successfully catheterized, the catheter should be left in place until surgical revision may be carried out.

All vesicostomies are colonized with bacteria via stomal contamination. Therefore, a catheterized specimen through the stoma is unreliable. Patients with constitutional symptoms such as fever are treated. Otherwise, a positive culture may represent asymptomatic bacteriuria and is not always of concern.

Skin irritation in the area of the vesicostomy is unusual. The most important preventive measure is frequent diaper changes, even if highly absorbent diapers are used. If urine seeps onto the patient's clothes repetitively, skin breakdown may ensue. In severe cases, temporary urinary diversion with a Foley catheter while applying a barrier ointment allows time for healing.

Ureterostomy. Stenosis is the most common complication in the patient with a ureterostomy. These patients often present with fever and symptoms suggestive of pyelonephritis. The stoma should be catheterized with an 8-Fr catheter, and urine should be sent for culture. Ureterostomy prolapse is rare.

Ileal Loop Conduits. Inflammation of the peristomal skin arises when the appliance fits poorly around this bud of ileum, allowing urine to seep under the protective wafer. Prolonged contact with skin causes irritation and ulceration. The use of paste to create a better seal around the bud is often all that is needed to avoid such a complication. In some cases,

surgical revision is necessary, especially when the bud has retracted.

Prolapse of the ileum occurs occasionally and can be striking, especially if too long of a segment was used in creating the loop initially. Prolapsed segments 20 to 30 cm long have been seen and require surgical revision. If the prolapse is minor, the clinician should perform the same gentle manual reduction technique described in the previous section on stomal complications of GI diversions.

Peristomal hernia can occur when fascial defects adjacent to the ileal loop allow loops of bowel to herniate outside the abdominal wall. This condition requires urgent surgical consultation.

Stenosis of the ileal stoma may occur in these patients. Symptoms may include pain, but the usual presenting complaint for these patients is fever. This finding necessitates a workup for pyelonephritis. Stomal stenosis can also lead to formation of urinary calculi.

Urinary Undiversions. As the child with a vesicostomy or ileal loop grows older, the social stigma of a diaper motivates many of these patients to seek urinary continence. For patients with spina bifida or exstrophy, this goal may be achieved by the use of an intestinal segment to augment bladder capacity as well as a procedure to tighten the bladder neck and create a resistance to leakage. For all spina bifida patients, and most exstrophy patients, continence comes at the expense of daily clean intermittent catheterization for the rest of their lives. Careful patient and family selection is necessary for this procedure; compliance with clean intermittent catheterization is crucial. Nevertheless, the enhanced self-esteem and improved quality of life these patients report is gratifying.

Perforation is the worst complication of intestinal augmentations to create neobladders. Most bladder perforations result from overdistension of the augmented bladder, which then diminishes perfusion to the bowel segment. In addition, the urine in these neobladders is chronically colonized secondary to the use of intermittent catheterization. Patients may present anywhere from 1 month to many years after surgery with a history of acute abdominal pain. Fever may be present within a few hours of perforation. Because many spina bifida patients have decreased or absent abdominal sensation, peritonitis may be fairly advanced before pain is experienced. The presence of abdominal pain in a patient with a urinary diversion should prompt an immediate call to the patient's urologist. The urologic evaluation generally consists of a fluoroscopic gravity cystogram with views during filling and emptying. Small perforations may be obscured with the full bladder and become apparent only during bladder emptying. Prophylactic antibiotics should be administered before the cystogram. Once this diagnosis is established, the patient is prepared for emergency laparotomy.

Patients may present to the ED with a sudden inability to pass a catheter into their neobladder. This situation may be because the appendiceal conduit through which they pass their catheter contains a false passage. A fluoroscopic study is warranted to delineate the passage and allow catheterization under radiographic control. The same situation is often true for patients catheterizing per urethra. In some cases, the urologists may opt to take a patient to the operating room for emergency endoscopy to define the obstruction point. When all else fails and the patient's bladder continues to distend, it is safest to pass a suprapubic drainage catheter into the neobladder.

Because the creation of a neobladder is an intraperitoneal operation, these patients are all at risk for developing small bowel obstructions. A patient with abdominal pain and a neobladder merits radiographic evaluation.

Up to 30% of patients with a neobladder develop stones within their pouch and require either endoscopic or open surgical removal. These stones rarely cause pain by obstruction, but rather they produce a foul urine that can be so irritating to the neobladder that the patient presents with a vague lower abdominal pain. These stones are calcified and show up on an abdominal radiograph. Treatment with antibiotics is palliative until surgical removal is undertaken.

The insertion of bowel segments into the urinary tract carries with it certain fluid and electrolyte complications that may not be a problem under normal circumstances. However, with a GI virus and superimposed diarrhea and dehydration, the patient may not be able to compensate. For example, a patient with a gastric augmentation who presents with diarrhea and lethargy may prove to have a severe hypochloremic hyponatremic metabolic alkalosis. Thus, any patient with a bladder augmented with bowel who is obtunded requires careful consideration of an electrolyte disturbance as the underlying cause.

CHAPTER 128

Child Abuse

STEPHEN LUDWIG, MD

Departments of Pediatrics and Emergency Medicine, The University of Pennsylvania School of Medicine, and Division of Pediatric Emergency Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Child abuse is the single diagnostic term used to describe a range of behaviors from somewhat harsh discipline to intentional repetitive torture. This phenomenon is complex and results from a combination of individual, familial, and societal factors. The common pathway for all these factors is parental behavior destructive to the process of normal growth, development, and well-being of the child. Abuse may be subdivided into four broad categories: 1) physical abuse, 2) sexual abuse, 3) neglect, and 4) emotional abuse. Each form of abuse has individual characteristics of family dynamics, clinical manifestations, and management.

The task of the emergency physician is difficult. The physician must first maintain an open mind to the possibility that abuse not only occurs, but occurs commonly. Thus, abuse should be included in the differential diagnosis of any injury or any unusual physical or psychological complaint. Second, the physician must identify signs and symptoms of suspected abuse. Next, the family crisis must be managed to protect the child yet maintain the abusive parents' motivation for help. Finally, the legal requirements for reporting abuse to the proper social service or police authority should be thoroughly understood.

The demands of managing a case of child abuse may be lessened by sharing the responsibility with other health care professionals. The skills of nursing and social work staff are invaluable. The child abuse field has been a model for multidisciplinary collaboration, which is most productive if begun in the initial phases of case management in the emergency department (ED). Establishing an institutional or departmental protocol for the management of abuse cases is also helpful. This protocol relieves the emergency physician from having to reconstruct a complete management plan for each new case. Having a standard protocol to follow allows the physician more time to concentrate on the individual needs of the patient and parents.

To the unfamiliar observer, the easy solution to all abuse cases is to “take away the child and put the parents in jail.” This commonly held treatment philosophy would be practiced more if it were truly a panacea. However, the alternative forms of child care (i.e., institutional care, foster care, extended family care) are each fraught with their own hazard. With the use of well-organized community services, abusive behavior can be controlled while the child and family receive therapy.

There may be support for the notion that parents who bring their abused child to the ED are motivated to seek help for their child and for themselves. Most parents remorse about their abusive behavior. The severity of injuries inflicted is often overestimated as a result of parental guilt. The emergency physician must neither overlook nor mismanage the opportunity to identify abuse and control the parent's behavior. Sharp focus must be maintained on the dual goals of case management—protect the child and use the crisis to strengthen and preserve family life.

PHYSICAL ABUSE

Background

Physical abuse is the most often reported form of child abuse. Definitions of physical abuse vary from state to state. Operationally, the definitions vary from institution to institution, and indeed from person to person. Even the definition of physical abuse is a definition in transition. Over the past century, many advances in the “rights of the children” have been made. For example, the enactment of child labor and compulsory education laws has been an important step forward. As the history of abuse is traced through the centuries, the forms and the definitions of abuse have changed. Definitions currently used are likely to continue to change with time. The present widespread medical interest in abuse was stimulated by C. Henry Kempe with the introduction of the term *“battered child syndrome”* in 1962. It was only as recently as 1968 that the last of the 50 states enacted child abuse legislation. Many states are now using their second or third generation of child abuse laws.

The Child Abuse Prevention and Treatment Act (CAPTA), as amended and reauthorized in October 1996 (Public Law 104-235, Section 111;42 U.S.C. 5106g), defines child abuse and neglect as, at a minimum, any recent act or failure to act:

- Resulting in imminent risk of serious harm, death, serious physical or emotional harm, sexual abuse, or exploitation
- Of a child (a person under the age of 18, unless the child protection law of the State in which the child resides specifies a younger age for cases not involving sexual abuse)
- By a parent or caretaker (including any employee of a residential facility or any staff person providing out-of-home

care) who is responsible for the child's welfare.

There are four major types of child maltreatment: 1) physical abuse, 2) child neglect, 3) sexual abuse, and 4) emotional abuse. Physical abuse is the infliction of physical injury as a result of punching, beating, kicking, biting, burning, shaking, or otherwise harming a child. The parent or caretaker may not have intended to hurt the child, but rather the injury may have resulted from over-discipline or physical punishment.

The true incidence of abuse is unknown. Many cases go unrecognized and unreported. Estimates for all forms of abuse vary from 500,000 to 4 million, cases per year in the United States. Three national incidence studies have been conducted. The incidence across the three studies is shown in Figure 128.1. The incidence rates for abuse and neglect is 15 per 1,000 American children. A Gallup poll estimated as many as 49 per 1,000 children were physically abused and 19 per 1,000 were sexually abused. Physical abuse accounts for 25% of reported cases. Several studies have estimated that 10% of children less than 5 years old brought to the ED with traumatic injury are victims of child abuse. There may be as many as 2000 abuse-related deaths per year in the United States.

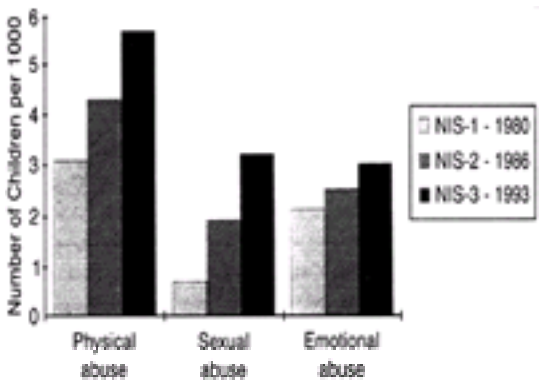

FIGURE 128.1. Incidence of child abuse per 1000 children by abuse type determined on three National Incidence Studies. (Reprinted with permission from the U.S.

Homicide is now the fifth leading cause of death in children aged 1 to 4 years and the fourth leading cause of death in children aged 5 to 14 years. There are 2,000 to 5,000 deaths annually or an incidence of 5.4 per 100,000 children aged 4 and younger. The incidence of child homicide has steadily increased. The rate of homicide in the 1- to 4-year-old age group has increased sixfold since 1925, according to a review by the Centers for Disease Control and Prevention. The perpetrators in these cases of child homicide are most often adults who are known by their child victims.

Although the true incidence of abuse is in question, the number of reports has certainly escalated. Figure 128.2 shows the number of substantiated cases from 1976 to 1997 in Pennsylvania. Pennsylvania established a statewide reporting registry in 1975. Most authorities believe the increase in reports is attributable to an increase in awareness and ease of reporting, as well as to a rise in the true incidence of abuse.

Dynamics

Many factors contribute to the reasons a parent abuses a child. Helfer's formulation of the necessary elements is shown in Figure 128.3. The factors include a parent who is capable of abuse, a child who actively or passively becomes the target, and a crisis that triggers the angry response. Frederick Green has added to this triad the concept that the process must exist in a society that unknowingly condones or even encourages violence, and in particular violence against children. Some of the factors that contribute to the parents' abusive potential are listed in Figure 128.4.

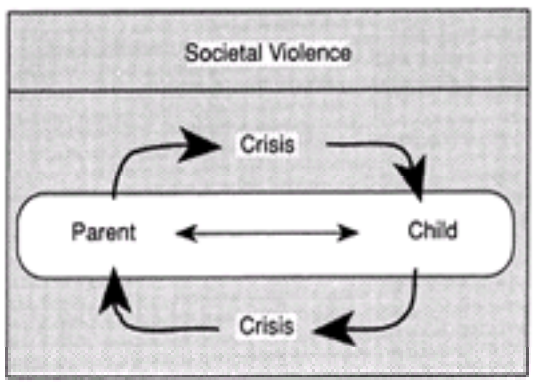

FIGURE 128.3. Essential elements of child abuse. (Modified with permission from Helfer RE. Why most physicians don't get involved in child abuse cases and what to do about it. Child Today 1975;4:28.)

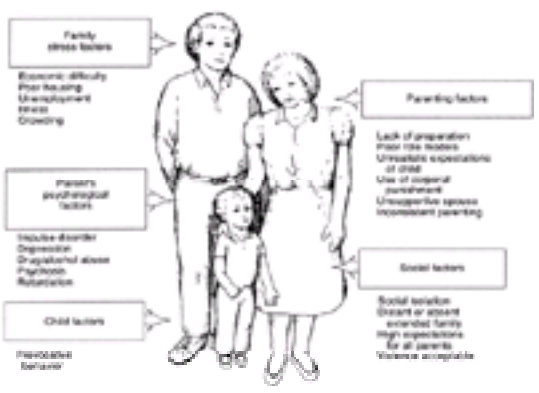

FIGURE 128.4. Risk factors that contribute to abuse and neglect.

Stress and lack of specific child-rearing information and experience play dominant roles. The combination of these factors causes many parents to misread normal childhood behavior as defiant or provocative and to react with a violent, destructive response. The typical example is the parent who is angered by the 1-year-old child's refusal to become toilet-trained. The child's contribution to abuse may be real, as in the case of negative behavior or disparate temperament, or imagined by the parent (e.g., “he's just like his father”). Children with prolonged neonatal hospitalization, handicapping conditions, or developmental delays are at increased risk. Living situations in which nonbiologic parents are present are also high risk. For example, the adopted child or the child living with a parent's paramour may be the target of abusive behavior. The crisis that initiates abuse varies tremendously. It may be unrelated to the child, such as the stress of a family member's death or economic disappointment. However, crisis often occurs because the child's behavior does not meet parental expectations. The crisis is identifiable as the spark that ignites the existing potential for abuse.

Manifestations

The manifestations of physical abuse may affect any body system. Thus, the emergency physician must be prepared to recognize a variety of signs and symptoms. Abuse may also be seen by any specialist physician. National data show neglect to be most common (Fig. 128.5). Injuries seen at The Children's Hospital of Philadelphia between 1976 and 1979 are shown in Figure 128.6. These proportions have remained constant.

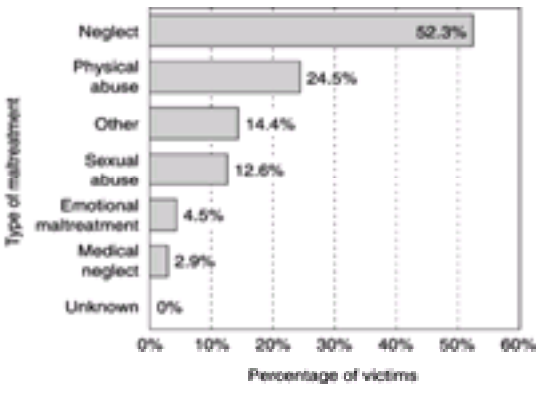

FIGURE 128.5. Types of maltreatment as a percentage of victims (1995) based on surveys in 49 states. *N* = 1,000,502 victims in 49 states. (Note: Percentages total more than 100% because some states reported more than one type of maltreatment per victim.)

Integument

The skin is the most commonly injured body organ. Cutaneous injuries may be divided into nonspecific and specific traumatic lesions, burns, and hair loss. Of the nonspecific traumatic injuries, the bruise or contusion is the most commonly seen. Although bruises are also common in children who are not abused, accidental bruises usually have a different distribution and appearance. Accidental injuries occur most commonly on the extremities and forehead. As bruising moves centrally and becomes extensive, the likelihood of abuse rises. Contusions undergo recognizable stages of healing. In the first 24 hours, the size of the bruise increases slightly if careful measurements are made. The process of resolution is variable. The bruise should be dated and compared with the history provided. A prothrombin time, partial thromboplastin time, bleeding time, and platelet count should be obtained if the issue of “easy bruisability” has been offered as a possible explanation.

Other nonspecific cutaneous injuries include lacerations, punctures, and abrasions. The following criteria are important for the evaluation of any nonspecific injury: 1) the history of injury, 2) the child's age and developmental level, 3) the presence of other old or new injuries, 4) the interaction between the parents and child, and 5) the interaction between the parents and the ED staff.

Specific skin injuries are those that clearly reflect the method or object used to inflict the trauma. Loop-shaped marks are readily seen after a beating with an electric cord or wire. Linear marks may be seen from a belt or paddle injury. Rope burns result in circumferential marks on the wrists, ankles, or around the neck when a child has been bound. Another common specific integument lesion is a hand print on the side of the face or symmetrically on the upper arms. The lesion produced by a slap leaves ecchymotic areas in the location of the interphalangeal spaces. Human bites appear as circular lesions 1 to 2 inches in diameter. Forensic dentistry is able to match the skin lesion with the dentition of the alleged perpetrator. Some specific skin lesions are shown in Figure 128.7.

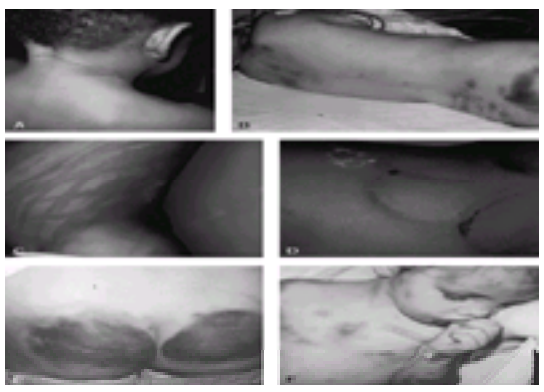

FIGURE 128.7. Cutaneous manifestations of child abuse. **A.** Strangulation mark. **B.** Bruises at various stages of healing. **C.** Linear loop-shaped marks. **D.** Multiple loop-shaped marks. **E.** Buttocks bruises as a cause of myoglobinuria. **F.** Multiple bruises in a central pattern.

Burns of the skin may be caused by abuse or neglect. Burns account for 5% of cases of physical abuse. In particular, tap water scald burns that occur in an immersion pattern (Fig. 128.8A) are often the result of intentional trauma. Immersion burns are likely to be inflicted by an abusive parent when they occur on a child who is being toilet-trained. Other indications of abuse are 1) a delay in seeking treatment, 2) a history of the child being unsupervised, and 3) the child being brought to the hospital by the parent who was not present at the time the burn occurred.

FIGURE 128.8. A. Hot water burn in an immersion pattern. **B.** Pattern burn from cigarette lighter.

In attempting to match the physical findings of the burn with the available history, several factors must be appreciated. The extent of the burn depends on the temperature of the water, duration of exposure, thickness of the skin involved, and presence or absence of clothing. Water temperature 54°C (130°F) or greater causes a full-thickness burn with less than a 30-second exposure. Because palms and soles are thick, they are often spared. Clothing tends to keep the hot water in contact with the skin and causes more severe burns. Burns presumably caused by falling or thrown fluids should produce a droplet or splash pattern. When the child has several small bullous lesions, the main differential diagnosis is a second-degree burn versus bullous impetigo. This differentiation is easily made by Gram stain and culture of a bulla.

Other burns may occur through contact with a hot solid rather than a hot fluid. Cigarette burns are the most common of this type. If the history given is of a child brushing against a cigarette or of hot ashes falling on the child, the resulting injury should be a nonspecific first- or second-degree burn. When a cigarette is extinguished on the child's skin, the injury is a burn that is 8 to 10 mm in diameter and indurated at its margin. A healed cigarette burn is indistinguishable from any other circular skin lesion such as impetigo, abscess, or vesicles. Burns from radiators, hot plates, cigarette lighters (Fig. 128.8B), curling irons, or standard irons imprint the shape of the hot object. Recently, there have been reports of children burned by microwave ovens.

The final category of integumental injury is injury to the hair. Traction alopecia is seen when a parent pulls the child by the hair. The scalp is usually clear, differentiating this lesion from tinea capitis, seborrhea, and scalp eczema. Alopecia areata produces a lesion in which the hair is uniformly absent. In the cases of traction or traumatic alopecia, patches of broken hair remain.

Skeletal System

The skeletal system is also commonly traumatized when children are physically abused. As previously mentioned, matching the history of injury with the physical findings is important. Considering the mobility and strength of the child is also important to identify suspicious injuries. The radiologist needs to review the patient's past radiographs to identify the child with multiple visits to the hospital for fractures. When suspicion of abuse is high, a radiographic skeletal survey should be obtained to ascertain the condition of the entire skeletal system.

Support for the use of radioisotope scans as a more sensitive and immediate way of demonstrating bone injury is increasing. However, radionuclide scans are still second-line studies. Some of the indications for a radiographic skeletal survey or bone scans are listed in the “Management” section of this chapter. Skeletal surveys are often performed on a young child with an obvious fracture that then reveal multiple old fractures. The skeletal survey is the preferred radiographic study because it provides information on the type, location, and age of fractures as well as presence or absence of bone diseases.

Bone injuries may be of several types, including simple transverse fractures, impacted fractures, spiral fractures, metaphyseal fractures, or subperiosteal hematomas. Radiographs of some of these injuries are shown in Figure 128.9. To explain a transverse fracture, the history should be that of direct force applied to the bone. Differentiating the true cause of this type of fracture is often difficult. The impacted fracture should have an accompanying history of force along the long axis of the bone, such as the child's falling on his or her outstretched hand. In the case of a spiral fracture, a history of twisting or torque during the traumatic event should be present. Metaphyseal chip fractures occur when the extremity is pulled or yanked; the periosteum is most tightly adherent at the metaphysis, causing small bone fragments to avulse. Metaphyseal chip fractures are almost exclusively caused by abuse. Subperiosteal hematomas produce a characteristic radiograph. The elevation of the periosteum is seen as a linear opacification running parallel to the bone surface. Subperiosteal hematomas are produced by direct trauma to the bone. However, in up to 10% of small and premature infants, symmetric periosteal elevation that is not caused by abuse may occur along the tibia or humerus. The reason for this finding is unknown, but it should not be confused with abuse.

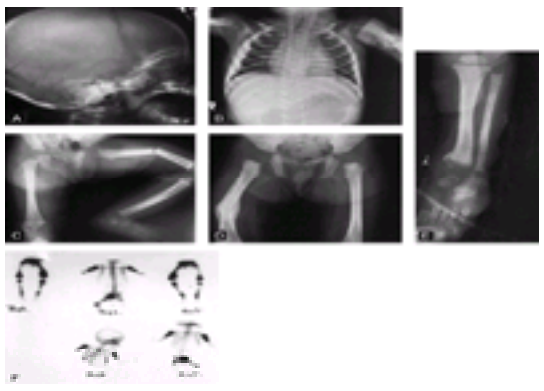

FIGURE 128.9. Radiographic findings of child abuse. **A.** Multiple skull fractures in an infant. **B.** Left humerus fracture and multiple old healing rib fractures. **C.** Left femur fracture and metaphyseal chip avulsion fractures of the right distal femur. **D.** Healing fracture of the right femur with callus formation, and new periosteal bone formation. **E.** “Bucket-handle” deformity of healing distal tibial epiphyseal fracture. **F.** Bone scan showing multiple areas of increased uptake caused by trauma. Some of these areas appeared normal on the original radiographs.

The location of the fracture is important in the identification of abuse. The fracture of a clavicle or the dislocation of a radial head are common noninflicted injuries. However, when the femur of a young child is fractured, or when ribs are fractured, the suspicion of abuse increases. Anderson reported on a series of children with femur fractures. Of 24 children who were less than 2 years old, abuse was proved in 19 cases. In two-thirds of these children, the fracture was the only sign of abuse. Feldman et al. reported on a series of children with rib fractures and noted an obvious history of trauma; for example, motor vehicle accident, an obvious bone disease such as osteogenesis imperfecta, or that the child was abused.

Feldman also reports examining several children who received external cardiac compression and finding that none of them had sustained rib fractures as a result of their cardiopulmonary resuscitation. In a confirmatory report, Schweich and Fleisher found that when the parents could not provide a history for rib fractures, the cause was abuse. The mean age of the group of children who had inflicted trauma was 3 months, whereas the group having accidental rib fractures had a mean age of 8.5 years. Ribs that are fractured along the axillary line are broken by an anterior-posterior force. Ribs that are fractured anteriorly or posteriorly are injured by a side-to-side compression of the thorax. The history of injury must be matched to the physical finding.

Other uncommon and, therefore, suspicious fractures are located in the vertebrae, sternum, pelvis, or scapulae. Uncommon fractures need to be carefully evaluated unless a clear history of significant trauma, such as an automobile injury, is reported.

The age of a fracture may be estimated from the amount of callus formation and bone remodeling seen on the radiograph. Table 128.1 lists fracture landmarks by date. Dating of fractures is not an exact science because, many confounding variables, such as the child's age, location of the fracture, and nutritional status, must be considered. Nonetheless, the child who presents with an acute fracture, and has a second fracture with a callus, stands out as having sustained more than one episode of trauma. The usual long-bone fracture may take 8 to 10 days to form callus and several months to heal completely. In the acute stages of injury, soft-tissue swelling should be seen for 2 to 5 days. Soft-tissue swelling may be clearly seen on standard radiographs. Skull fractures or fractures of other flat bones cannot be dated in the same way.

0–10 Days
Soft-tissue edema
Joint fluid
Visible fracture fragments
Visible fracture lines
10 Days–8 Weeks
Periosteal new bone (layered)
Callus (first subtle and then heavy)
Bone resorption along fracture line makes fracture line more visible
Metaphyseal fragments often more visible
8 Weeks and Over
Periosteal new bone matures, becomes thicker
Callus formation becomes more dense and smoother
Metaphyseal fragments are incorporated into metaphyseal callus and become smoother
Fracture line less visible and then invisible
Deformities and cortical bumps persist

Table 128.1. Dating Fractures

When a young child sustains multiple fractures, the differential diagnosis must be widened beyond accidental trauma and abuse to include osteogenesis imperfecta, infantile cortical hyperostosis, scurvy, syphilis, osteoid osteoma, neoplasms, rickets, hypophosphatasia, and osteomyelitis. Table 128.2 details the distinction between child abuse and osteogenesis imperfecta. All of the other conditions are much more rare than abuse and can be ruled out by the appearance of the bone on the radiograph and by the levels of calcium, phosphorus, and alkaline phosphatase in the serum.

Finding	Osteogenesis Imperfecta	Child Abuse
Incidence	Rare	Common
Positive family history	Common	Common
Blue sclerae	Common	Rare
Abnormal teeth	Common	Rare
Hearing impairment	Common	Uncommon
Osteoporosis	Common	Rare
Abnormal fracture healing	Common	Rare
Wormian bones	Common	Rare
Joint laxity	Common	Rare
Short stature	Common	Occasional
Fracture recurrence in protected environment	Common	Rare
In utero fracture	Occasional	Rare
Biochemical studies	Abnormal	Normal

Table 128.2. Osteogenesis Imperfecta versus Child Abuse

Central Nervous System

Injuries to the central nervous system (CNS) are the main cause of child abuse deaths. These injuries may be subdivided into two categories: direct trauma and shaking injuries. Direct trauma is inflicted by striking the child with an object or by dropping or throwing the child against a wall or onto the floor. The extent of the resulting trauma depends on the amount of force used, the surface contacted, and the child's age. The child may be brought to the ED with a small subgaleal hematoma or in coma. Injuries may vary from scalp contusions to intracerebral hematomas.

A history of a young infant's falling off a bed or dressing table is often presented. The precise extent of injury from this type of fall is unknown, but several reports suggest that even uncomplicated skull fractures are as uncommon as 1 to 2% of cases. If the injury is more severe and the only history is of a fall from less than 8 to 10 feet, abuse should be suspected. Another scenario is that of a child who sustained trauma 1 week before the ED visit. The visit is prompted by the parent's noticing a soft spot on the child's cranium. This sequence may occur when the initial scalp hematoma so rapidly expanded that it had a bony consistency. Only with degradation and softening of the mass does the parent now perceive the hematoma. Although a delay in seeking treatment is a well-recognized red flag for child abuse injuries, this case provides a plausible exception. In all children younger than 1 year of age who have a history of head trauma, skull radiographs are recommended. Infants tend to sustain skull fracture more easily and are more vulnerable to serious sequelae. If a fracture does exist and abuse is suspected, a skeletal survey should also be obtained. For the diagnostic methods to be used for more serious head injuries, refer to Chapter 105.

Shaking injuries characteristically cause serious central nervous system damage without evidence of external trauma. The infant's relatively large head size and weak neck muscles are predisposing factors for whiplash injury. Whether the injury is caused by shaking alone or shaking followed by an impact is controversial. In most fatal cases, minor bruising to the scalp is apparent, although such scalp injuries may not be apparent until the scalp is reflected during the autopsy.

The shearing and contusive forces that result from shaking the infant produce this type of injury. Specific lesions that occur include hematomas, subarachnoid hemorrhages, or brain contusions, particularly in the frontal and occipital lobe. The child may present with lethargy and a “septic” appearance, with seizures, or in a coma. The physical examination is otherwise unremarkable except for retinal hemorrhages (Fig. 128.10A). Occasionally, bruises on the upper arms or shoulders indicate the sites where the child has been grasped. Lumbar puncture produces grossly bloody or xanthochromic spinal fluid. If computed axial tomography is available, it shows the characteristic findings of occipital contusion and intrahemispheric blood (Fig. 128.10B). This form of abusive behavior by the parent is usually triggered by the infant's persistent crying. Occasionally, excessively rough forms of play or misguided resuscitative efforts may result in shaking injuries.

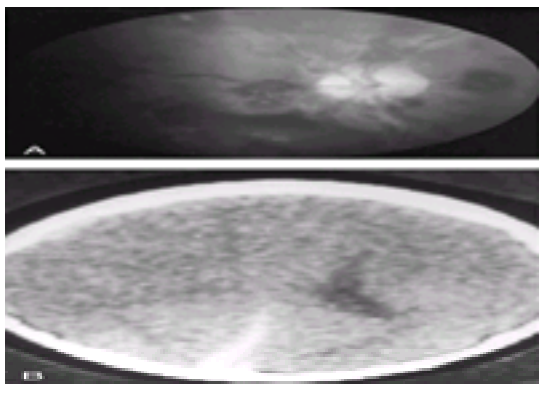

FIGURE 128.10. Manifestations of the whiplash shaking injury. **A.** Retinal hemorrhages as seen on fundoscopic examination. **B.** Computed tomogram showing intrahemispheric subdural bleeding and right cortical brain swelling.

Gastrointestinal System

Gastrointestinal (GI) injuries are relatively uncommon abuse manifestations but, similar to CNS injuries, account for a significant percentage of fatal injuries. Of all GI injuries, mouth trauma is perhaps the most common. Small infants may sustain a tear of the frenulum resulting from “bottle jamming.” In the older child, dental trauma may be a sign of abuse.

Other GI system manifestations are more medically serious and generally result from blunt trauma to the abdominal contents. Rupture of the spleen or laceration of the liver causes the child to present with elevated liver enzymes, with an acute abdomen, or in shock, with no external source of bleeding and with absent or only minor bruising of the abdominal wall. The identification and management of these emergencies is covered in Section IV. A less acute presentation is the afebrile child with persistent bilious vomiting from a duodenal hematoma with small-bowel obstruction. Documenting an elevated serum amylase or lipase or increased liver enzymes is important in providing tangible evidence of abdominal trauma in cases that lack any radiographic finding or abdominal wall bruising. Elevation of the serum amylase may also identify those cases that should be followed for possible development of a pancreatic pseudocyst.

Cardiopulmonary System

Abuse may be manifested in cardiac or pulmonary trauma with no injuries that are characteristically induced by abuse. Pulmonary contusion, pneumothorax, hemothorax, cardiac tamponade, and myocardial contusion may all occur occasionally. Specifics of identification and management of these problems are covered in Chapter 107.

Genitourinary Systems

Common genitourinary complaints, such as hematuria, dysuria, urgency, frequency, and enuresis, may be the initial sign of abuse. These problems may result from direct trauma, sexually transmitted infections, or emotional abuse. Some aspects of genitourinary manifestation are covered subsequently under the “Sexual Abuse” section. As for direct trauma, any part of the genitourinary system may be involved, from the renal parenchyma to the urethral meatus. Penile trauma that does not have an adequate explanation may be an alerting sign of abuse. Traumatic hematuria is managed as described in Chapter 109.

A life-threatening renal manifestation may be the occurrence of rhabdomyolysis and myoglobinuria. With extensive deep soft-tissue and muscle trauma, myoglobin may be liberated in quantities sufficient to cause acute renal failure. Such children have dark or tea-colored urine that tests positive for blood with urine dipstick, but has no visible red blood cells on microscopic examination. Serum myoglobin levels confirm the diagnosis, and the serum creatine phosphokinase reaches extremely high values. Before using hypertonic intravenous contrast materials in the child with heme-positive urine, myoglobinuria should be considered and ruled out. The patient with possible myoglobinuria and acute renal failure must not be given potassium-containing intravenous solutions.

Sensory

All of the sensory organs are vulnerable to physical abuse, including ocular, nasal, and otic injuries. The eye may sustain several different forms of injury, including periorbital ecchymosis, corneal abrasion, subconjunctival hemorrhage, hyphema, dislocated lens, retinal hemorrhages, or detached retina. Each of these lesions is discussed in Chapter 110, Chapter 111, Chapter 112 and Chapter 113. A careful history of injury is important when treating any of these conditions. Injury to the nose may result in simple hemorrhage or fracture and disfigurement of the nasal structures. The external ear may show evidence of contusion. In particular, ecchymosis on the internal surface of the pinna may result from “boxing” the ear and crushing it against the skull.

A direct blow to the ear may also cause hemotympanum and perforation of the tympanic membrane. In such cases, hemotympanum on the basis of basilar skull fracture should also be considered. The presence of discoloration behind the ear (Battle's sign) may be a further indication of a basilar skull fracture. Refer to Chapter 105, which deals specifically with these aspects of emergency care.

Unusual Manifestations

Rarely, the emergency physician is confronted by one of the unusual abuse manifestations. Cases of toxic and nontoxic ingestions, electrolyte disorders such as hyponatremia and hypernatremia, foreign bodies, bathtub drowning, and multiple serious infections may be the result of abuse. In all these situations, the parent actively abuses the child by feeding, instilling, or injecting harmful substances or objects into the child's body. Some children with a toxic ingestion reveal that their parents forced them to ingest the substance. The most common toxic ingestants of this type are alcoholic beverages that are given to or forced on the child to either quiet the child or to demonstrate “manly” qualities. Other drugs may be used to poison the child. Most recent reports are of cocaine ingestions.

Several cases of parents who have placed their children on high-salt, water-only, or pepper diets as a form of punishment have been reported. Such children may present with signs of hypernatremia or hyponatremia, possibly with seizures. Foreign bodies have been found in every orifice, as well as under the skin and in fingernail beds. Several cases of Munchausen syndrome by proxy have occurred in which a parent has inflicted illness on the child rather than feigning or inducing illness (Table 128.3). Cases of fictitious fever, hematuria, and even sepsis have resulted from this form of abuse. Although rare, the unusual manifestations of abuse should be considered when more common causes of these problems cannot be identified.

Difficult to understand medical situation with recurrent episodes
Failure of other centers to arrive at diagnosis—doctor shopping
Unsupportive or "absent" marital relationship
Compliant, cooperative, overinvolved mother
Medical knowledge in parent's background
Findings abort with surveillance of child
Findings correlate to presence of parent
Extensive medical care in parent's background

Table 128.3. Characteristics of Munchausen Syndrome by Proxy

Management

The management of a child abuse case is difficult unless the emergency physician has a previously prepared, well-structured protocol. If reports of abuse are not a daily occurrence, an institutional policy serves as an important guide to the mechanics of management. Consultants from different disciplines, such as nursing and social work, provide invaluable assistance. A multidisciplinary approach simplifies the initial decision-making and subsequent case management. The steps in the protocol are shown in Figure 128.11.

FIGURE 128.11. Procedure for emergency department management of suspected physical abuse.

Suspect Abuse

The first step is to decide whether a reasonable likelihood of abuse exists. Many shades of suspicion make the term *abuse* imprecise. Although every traumatic injury should be suspected as abuse, the physician has the onerous task of deciding how much suspicion is necessary to take some action (i.e., report). To establish the level of suspicion, data are gathered by obtaining a complete history, performing a thorough physical examination, comparing the history and physical examination, observing interactions, and obtaining laboratory studies and/or radiographs. Then, the physician can formulate a differential diagnosis and assign a rank to abuse. Indications of abuse in the history and physical examination and observational data must be used like building blocks that are added until they achieve a certain threshold of suspicion. As demonstrated in Figure 128.12, when the threshold is reached, a report of suspected abuse must follow. In the example of case 1, all of the building blocks must be used to build a level of suspicion; in case 2, the physical injury is sufficient to make the diagnosis.

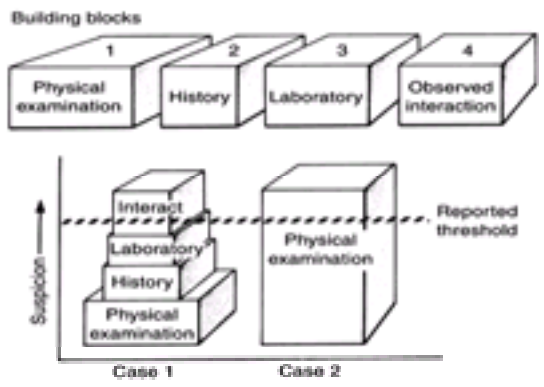

FIGURE 128.12. Building a level of suspicion.

A detailed history is always important. As in many other medical situations, this process is initiated by asking some general open-ended questions about “what happened?” If the child has sufficient verbal skills, the first questions are directed at him or her. General inquiries must then be followed with specific requests for information; however, a harsh

interrogation only alienates the family. Some specific historical indications are listed in Table 128.4.

1. Is the history one of inflicted injury?
2. Is there an absence of history, a "magical" injury?
3. Could the injury have been avoided by better care and supervision?
4. Are there inconsistencies or changes in the history?
5. Is there a history of repeated injury or hospitalization?
6. Was there a delay in seeking medical care?
7. Does the history overestimate or underestimate the injury?
8. Is there a medical history of prematurity, failure to thrive, failure to receive adequate medical care such as immunization?

Table 128.4. Historical Indicators of Abuse

As with the history, the physical examination must be thorough. The signs of physical abuse have been detailed in the section on “Clinical Manifestations.” A thorough examination serves as a means to uncover these findings. Although the clinician may be tempted to merely glance at a small contusion on a child's face, such a cursory examination fails to reveal possible linear and loop-shaped marks on the upper thighs and buttocks. Table 128.5 lists some of the important physical examination features that are indicators of abuse.

1. Does the injury match the history of injury?
2. Are there pathognomonic injuries such as looped wire marks, cigarette burns, and so on?
3. Are there multiple injuries?
4. Are the injuries at various stages of healing?
5. Are there different injury forms, for example, burns and fractures?
6. Is there evidence of overall poor care?
7. Has poisoning been documented in a young child?
8. Is there evidence of failure to thrive without a history of symptoms or physical findings?
9. Are there any visual or unexplained physical findings?

Table 128.5. Physical Indicators of Abuse

After completion of the history and physical examination, the next step is to compare them. Does the stated history match the physical findings? Does the history make sense? Does the history correlate with the developmental level of the child? Answers to these important questions may add further elements of suspicion.

This step of comparing history and physical examination is completed subconsciously by most practitioners. Physicians often attempt to match the patient's degree of symptoms with the presence or absence of physical findings, particularly in patients with psychosomatic complaints. In child abuse cases, this step should be a conscious and well-defined step because it is vital to establishing suspicion. In some cases, a lack of consistency is obvious, such as a parent's claim that burns on the child's buttocks occurred when the child inserted his or her finger into an electric socket. Other situations may be less clear, such as the injury being attributed to hot plastic seat covers on an automobile. Although the latter explanation has in fact been reported as a case of accidental injury, it rarely explains burns on the buttocks.

Laboratory data and radiographs are another source of indicators of abuse. The laboratory studies used are few and, for the most part, document the obvious or rule out other disease states. Biochemical, hematologic, and urinary studies that are used appear in Table 128.6 along with their indications. Radiographs document a specific bony or soft-tissue injury. They may provide a comprehensive and longitudinal record of osseous injury at any site in the skeletal system. Although no precise indications for ordering a skeletal survey exist, some relative indications are: 1) any child less than 1 year old presenting with a fracture, 2) any child with severe or extensive fractures, 3) any child who has a history of more than one fracture, and 4) a history in the child or the family of “soft” or easily broken bones.

Table 128.6. Laboratory/Diagnostic Evaluation of the Physically Abused Child

During the time occupied by the history, physical examination, and performance of laboratory studies, the physician should be cognizant of the interactions among family members and between the parents, the child, and the ED staff. Such an awareness often uncovers subtle indicators of abuse. The observation of parents arguing vehemently on the way to the radiology department may be a clue. The parent who appears to be distant from both the child and the physician is also suspect. Although the parent who is intoxicated or incoherent never fails to gain staff attention, such individuals are in the minority of abusive parents. Observation of the child is important as well. All abused children are not withdrawn, passive, and depressed. On the contrary, some are competent, outgoing, or “pseudomature.”

The observed state of the child depends on several factors: 1) the length, frequency, and severity of abuse; 2) the child's developmental level and age; and 3) the amount of positive interaction the child's parents and extended family have had between abusive episodes. Physicians are often surprised that the child does not immediately state the nature and extent of the abuse and ask for asylum. Such statements by children are actually rare and occur mainly in adolescent patients. Children are loyal to their parents. Abusive parents may be only episodically abusive and at other times nurturing and loving. Young children may have no framework for comparison and may accept the abuse as the norm. Somewhat older children may understand and dislike the abuse, but may fear the consequence of reporting it even more. In the child's mind, it may be better to live with the pain of abuse than to face the unknown of institutional or foster placement.

The final step in establishing a threshold level of suspicion is to review the differential diagnosis. At this point in the management scheme, the physician must add up the indicators and arrive at a judgment. If the process does not lead to a clear determination, most state laws imply that reporting suspected abuse is more prudent than not. Physicians are asked to report suspected, not proven, abuse. The major differentiation is between accidental and nonaccidental trauma. The other elements of the differential diagnosis are all uncommon diseases, including: 1) bone diseases such as osteogenesis imperfecta, osteoid osteoma, hypophosphatasia; 2) hematologic disorders such as idiopathic thrombocytopenic purpura and hemophilia; 3) neoplasms; 4) metabolic disorders such as rickets or scurvy; 5) infections such as syphilis or osteomyelitis; and 6) syndromes in which pain sensation is absent, such as spina bifida or congenital indifference to pain. All of these diseases occur with much less frequency than abuse, but deserve consideration; simple laboratory and radiographic studies confirm or deny these diagnoses.

A special note should be made concerning the child less than 6 months old who is brought to the hospital dead. In this situation, the central differential diagnosis exists between sudden infant death syndrome (SIDS) and child abuse. Other rare causes of sudden death include hypoglycemia, medium-chain fatty acid defects (MCAD), mitochonrial defects, intoxication, and smothering. Victims of SIDS may appear to have bruising as a postmortem change. Clearly, their parents have no adequate explanation for the death. In this situation, the presumption should always be SIDS. Most localities require an autopsy to be performed. If not required, the physician should insist on a postmortem examination and wait for the autopsy to ultimately make the differentiation. Interrogating parents in cases of SIDS about the possibility of abuse can produce unnecessary psychological harm. With the death of a child, supportive ED treatment becomes paramount and suspicions of abuse can be pursued by the medical examiner and law enforcement personnel if warranted. If two or three SIDS deaths have occurred in the immediate family, the level of suspicion for abuse should be elevated.

Multidisciplinary Consultation

If consultation with a nurse, social worker, or physician with more extensive experience in the management of child abuse is available, it should be obtained. The advantages of consultations are many. They allow for: 1) information sharing, 2) joint decision-making, 3) planning, and 4) mutual support. Planning an approach to the family and subsequent case management is useful. This brief consultation enables the physician to be more secure in making decisions about matters that are generally unfamiliar and often value-laden. Joint interviewing is not only time-efficient, but gives the family a uniform approach from the professional staff.

Reporting

Once the suspicion of abuse has been established and consultations obtained, the next step is reporting. Although laws vary from state to state, most have common elements. The emergency physician should become familiar with his or her current state law. The definition of abuse is central to each of the reporting laws. A stated age defines a child. The laws also specify who must report (mandated reporters) and who may report (nonmandated reporters). For most mandated reports, the law requires a specific penalty (as well as malpractice liability) for failure to report, and provides protection from liability if the report of suspected abuse turns out to be unfounded once investigated. Finally, the law dictates to whom and how the report should be made. Generally, reports are made to child protective services (CPS) agencies, to police departments, or to some combination of law enforcement and social work personnel. Many states now have statewide central registries for receiving reports.

Notifying the Parents

An important, but often avoided, step in case management is notification of the parents. This step is often forgotten because it is a difficult interpersonal task; nonetheless, it must be done. Nothing makes parents more resistant to change than completing a “routine” ED visit, only to later receive notification that the physician has filed a suspected child abuse report. Some specific guidelines are helpful in avoiding this breech of trust. The overall approach to the parents must be based on concern for the child. Concern for the child, not accusation should be stressed. The physician should not confront the parents or attempt to seek an admission of guilt. Many times, the parent in the ED may not be the abusive

parent and may know as little about the episode as the hospital staff. The physician should explain the requirement for a mandated reporter to report all suspected cases. However, stating the requirement should not be used as an excuse. The desire to report should also be stated.

In many states, the reporter is required to report all injuries that are not fully explained. This requirement may also be stated to the parent. Using the words *"child abuse report"* is important. This situation is not a time to "soft pedal." However, child abuse does represent a range of behaviors, from the parent who overvigorously disciplines to the parent who sadistically tortures. Parents often have not seen themselves as abusers, and an explanation of the range of abuse is helpful in demonstrating how a child abuse report applies to them. Parents are fearful of what a child abuse report means and of what will happen. Therefore, the consequences of the report should be explained (e.g., "a social worker will call and come visit you in 1 or 2 days"). The physician's natural fear is that the parent will have a dramatic and hostile reaction.

The emergency physician can expect a wide variety of reactions, from hostility to appreciation. To minimize the angry reactions, the physician should stress the focus as being concern for the child. This perspective puts the physician on common ground with the parent. An angry reaction is more likely if guilt or fear is increased. This reaction may be seen as a feedback relationship. Stoking the fire by increasing the parents' guilt or fear results in a flare of angry emotion directed at the staff, the child, or the other spouse. Figure 128.13 illustrates this relationship.

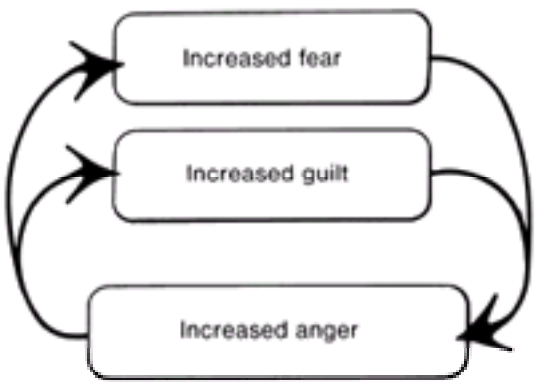

FIGURE 128.13. The cycle of fear, guilt, and anger.

Although the child does not need to be formally notified, the child may often be aware of what is happening and may even ask some pointed questions. The physician may wish to discuss the report with the child. The physician should stress the outcomes of protection and help for the child and family. The ED staff should never be accusatory or belittling of the parent.

Crisis Hospitalization

In some cases of abuse, the family crisis is at such an acute level that hospitalization is necessary. The physician must ask, "Is the home safe?" If the child's environment poses a potential danger, the child should be admitted, no matter what the extent of injury. Some state laws have included protective custody sections that allow physicians virtual police powers in detaining a child for protection. In other states, the physician may need to obtain parental consent for admission.

This task is also difficult. As with reporting, the approach to the parents must be honest and nonaccusatory. The reasons for admission are to observe the child and allow time to evaluate the possibility of such an injury happening again. The focus must be the physician's concern for the child's health. In hospitalizing the child, the physician also makes a statement about the seriousness of the situation and the depth of his or her concern. Most hospitals do not have the resources to hospitalize every abused child, nor is it necessary or advisable to do so in every case. Factors that favor sending the child home are: 1) a concerned relative or neighbor available to support the family, 2) a solution to the inciting crisis, 3) parental acceptance of responsibility, 4) prompt (less than 24 hours) (CPS) or police response, 5) a first episode or minor degree of abuse, and 6) an alternative environment (e.g., grandmother's house). If the physician is unable to hospitalize the child and has lingering doubts, a specific agreed-upon return appointment for the next day may be a solution. If the family is unable to keep the appointment, there should be grave concern, and emergency CPS or police involvement should be requested.

Documentation

Throughout each step of case management, documentation is important. The record of this visit is both a medical and a legal document. A precise description of the injuries enhances the document's value, and small sketches are also helpful. Photographs are invaluable in documenting extensive injuries. Some states require parental permission for photographs, whereas other jurisdictions allow photographs to be taken without parental consent. Photographs may be used in court to illustrate, for a judge or jury, injuries that would be difficult for most witnesses to describe. Even if the photographs are not admissible in court, they refresh the memory of the physician for testimony. Often, court proceedings may not take place for several months after the ED visit. If photographs are taken, their quality must be good. Poor-quality photographs can damage a case by failing to show all of the pertinent findings.

Written descriptions of an injury are adequate for less extensive trauma, but as much detail as possible should be included. The record of the history should be as factual as possible; conclusions or impressions should not be listed. For example, rather than recording "the child looked fearful," describing the physical components or behaviors that prompted that judgment, under standard courtroom procedure, is more appropriate. Direct quotes from the child or parents should

be included because quotes from another person are generally considered hearsay and are disallowed. When such quotes are included in the text of a business (medical) record, they may become more acceptable. General legibility and, in particular, a clearly written signature are always important record requirements. At the time of the ED visit, detailed record-keeping seems to be a burden and waste of time. When a case record requires review before court testimony, good documentation is a necessity. Upon completion of the record, the physician should read it again as if he or she were the defendant's attorney.

Staff Reactions

Child abuse triggers many emotions in the physician and in the ED staff. Sadness and pity for the child and, often, anger for the parent are exhibited. The staff may have a general feeling of disbelief, “How can this happen?” The case management plan previously described requires that each ED staff member be professional and in control of these emotions. The offhand comment of a clerk or the whispering between nurses can undermine the work being done with the family. If a staff member is too upset by abuse, he or she should be relieved of the responsibility of working in such situations. Physicians or nurses who openly attack the family or who are blatantly accusatory should not be involved in these types of cases. Only after having experience with large numbers of cases can an ED staff member develop an appreciation of abuse as a negative, but understandable human response. With such a perspective, the physician can become less angry and more zealous in attempting to provide constructive case management.

If problems relating to the staff reaction exist, as they often will, several corrective actions should be taken. At times, a brief meeting of the involved staff members can be called after the family has been discharged from the ED. This meeting allows the staff an immediate opportunity to ventilate their feelings. In-service education serves the same purpose, providing a forum for the staff to discuss their personal feelings about abuse, as well as their past experiences. ED staff are always involved in the negative aspects of identifying and reporting abuse and never see the long-term treatment and rehabilitation phase. If a therapist, or better yet, a family member, can present this side of abuse to the staff, it engenders more positive attitudes. Without learning about the successes, the staff often displace this anger, charging “incompetence” of the CPS agency or “leniency” of a family court judge. Scapegoating should be put into the proper perspective. Again, in-service education and case reviews are useful. The integrity of the entire treatment team, both in the hospital and in the community, must be maintained to accomplish the difficult goals of protecting the child and preserving family life.

SEXUAL ABUSE

The sexually abused child is another difficult psychosocial emergency for the emergency physician. The state-of-the-art method in identifying and managing cases of sexual abuse has developed rapidly in the last decade. Most child abuse centers are reporting dramatically increasing numbers of sexually abused children. The Children's Hospital of Philadelphia currently sees more than 10 times the number of sexually abused children than were reported 10 years ago. The number of sexual abuse cases reported now equals the number of physical abuse cases. Of all societal taboos, those that prohibit incest are the strongest. This belief leads to denial and makes even basic recognition of the problem more difficult.

As with the physically abused, the sexually abused child engenders a great deal of emotion from the health care professionals in the ED. Treatment issues for both the child and the perpetrator are more complex. Working in a multidisciplinary fashion with nursing and social work staff is important. The effects of this form of abuse may clearly be profound, but may not be expressed as symptoms for many years. Prompt diagnosis, humane emergency management, and referral to long-term treatment resources are the goals of the emergency physician. Many centers have adopted strategies to use the ED for recognition and screening of acute (less than 72 hours) episodes of sexual abuse as well as developing programs for comprehensive evaluation outside the ED.

Background

The term *“sexual abuse”* conjures up images of a violent, forced sexual attack and rape. Although most people may think of the psychopathic criminal luring children on their way home from school by offering them candy, such stereotypes are the exception. This situation has prompted Sgroi et al. to suggest that the term *“sexual abuse”* be changed to *“sexual misuse.”* This new term presents a more realistic image of what occurs in most sexual abuse cases. Commonly, a relationship exists between the perpetrator and the victim. The misuse of that relationship is central to the sexual abuse of the child. The relationship may be a familial one, such as father–daughter, or a household relationship, such as mother's live-in paramour and child, or a more casual relationship, such as that with a neighbor, teacher, or friend of the family. Most often, no overt violence is perpetrated, although harsh threats of violence as a consequence of the child's revealing the act to another person may be issued. The term *sexual misuse* is also more encompassing because it includes the misuse of children for prostitution and pornography. Although the suggested terminology change is based on several sound points, most state laws use the term *“sexual abuse”;* thus, this chapter conforms to that tradition.

CAPTA defines sexual abuse as: (1) employment, use, persuasion, inducement, enticement, or coercion of any child to engage in, or assist any other person to engage in, any sexually explicit conduct or any simulation of such conduct for the purpose of producing any visual depiction or such conduct; or (2) rape, and in cases of caretaker or inter-familial relationships, statutory rape, molestation, prostitution, or other form of sexual exploitation of children, or incest with children. Sexual abuse includes fondling a child's genitals, intercourse, incest, rape, sodomy, exhibitionism, and commercial exploitation through prostitution or the production of pornographic materials. Many experts believe that sexual abuse is the most underreported form of child maltreatment because of the secrecy or “conspiracy of silence” that so often characterizes these cases. Sexual abuse has traditionally been more the domain of police and other law enforcement personnel. Several specific legal definitions should be understood and used precisely. Each state defines these terms independently as well as legislates the age of consent. Emergency physicians must be aware of their local laws. In Pennsylvania, for example, the age of consent is 18 years. Sexual abuse terms are defined as follows:

Rape

A person commits a felony when he or she engages in sexual intercourse with another person not his or her spouse:

1. By forcible compulsion
2. By threat of forcible compulsion that would prevent resistance by a person of reasonable resolution
3. Who is unconscious
4. Who is so mentally deranged or deficient that such person is incapable of consent

Statutory Rape

A person who is 18 years of age or older commits a felony when he or she engages in sexual intercourse with another person not his or her spouse who is less than 14 years of age.

Involuntary Deviate Sexual Intercourse

A person commits a felony when he or she engages in deviate sexual intercourse per anus, or per os, or any form of sexual intercourse with another person:

1. By forcible compulsion
2. By threat of forcible compulsion
3. Who is unconscious
4. Who is mentally deranged or deficient
5. Who is less than 16 years of age

Indecent Assault

A person who has indecent contact (any touching of the sexual or other intimate parts of the person for the purpose of arousing or gratifying sexual desire in either person) with another not his or her spouse, or causes such other to have indecent contact with him or her is guilty of indecent assault.

Incest

A person is guilty of incest if he or she knowingly marries or cohabits or has sexual intercourse with an ancestor or descendant, a brother or sister of the whole or half blood, or an uncle, aunt, nephew, or niece of the whole blood. These relationships include blood relationships without regard to legitimacy and relationship of parent and child by adoption.

Promoting Prostitution

A person who knowingly induces or encourages a child to engage in prostitution is guilty of promoting prostitution.

The true incidence of sexual abuse is unknown. There is a recent documented upward trend in number of reports. The National Center on Child Abuse/Neglect estimates that the current annual incidence of sexual abuse is between 75,000 and 250,000 cases per year. Most estimates do not include children who are victims of pornographic exploitation and child prostitution.

Dynamics

Sexual abuse encompasses several different sexual acts committed by different perpetrators for different reasons. Thus, no single theory can explain the dynamics. In an effort to simplify the interactions and make them understandable in light of behaviors seen in the ED, the physician should consider intrafamilial versus extrafamilial sexual abuse. The intrafamilial category includes incest in all of its forms as well as sexual abuse by significant, although perhaps not legal, members of the family. Sexual abuse between a girl and her mother's paramour would be included in this category. Extrafamilial abuse occurs between adults and children of adolescents and children who have no familial relationship.

The dynamics of intrafamilial abuse are controversial. Professionals are divided into at least two theoretical camps. One group theorizes that sexual abuse is the sole responsibility of the perpetrator, usually a male adult. Advocates of this position contend that the abuse results from an inability of the individual to control his sexual impulses or to establish age-appropriate adult relationships. This perpetrator is the pedophile. A second group sees the problem more as a family responsibility. In this model, the disturbed relationship between the adults expresses itself in the male parent's (or parent equivalent's) crossing generational lines for sexual gratification. Theorists in this camp often point to the mother's passive sanction of the abuse, even to the point of being informed about the incest and still allowing it to continue over long periods.

Obviously, the two theories point to different treatment strategies. According to the first, the solution is to simply remove the male perpetrator to jail or a mental hospital and to concentrate rehabilitation efforts on the perpetrator. The second group would prescribe therapy for the entire family to reorder the relationships so that the adults are able to meet their own needs and the children are protected. These professionals would contend that, when the male adult is removed, the mother soon finds a replacement.

The dynamics of extrafamilial abuse are less well understood. In some cases, the rape of a child by a stranger, similar to the rape of an adult, is a crime of violence. Such attacks are triggered by extreme anger, and a child may be selected as more easy prey. In other cases of extrafamilial abuse, some of the dynamics are still based on the misuse of a

relationship, although in this case the relationships are more casual. Perhaps the most common extrafamilial sexual abuse occurs between neighbors or between a babysitter and the child being watched. These episodes often involve adolescent perpetrators. The abuse dynamic may be an abuse of a power relationship, an uncontrolled sexual curiosity, or a combination of these factors. As the age difference between the child and the perpetrator widens, the more pathologic the dynamic becomes. As the perpetrator increases in age, socialization is expected to instill more self-control. Certainly, the sexual exploration that occurs between children of the same age is not sexual abuse, although on occasions, an uninformed parent may consider it as such.

Clinical Manifestations

The manifestations of sexual abuse may occur at a time shortly after the abuse has occurred or at a time more distant from the event. The manifestations may be influenced by a single episode or by a pattern of repeated encounters. Finally, the manifestations may depend on the child's age and maturity. The manifestations may be divided into four categories, as shown in Table 128.7. These categories are specific physical findings, specific behavioral manifestations, nonspecific physical complaints, and nonspecific behavioral complaints.

Physical Complaints	Behavioral Complaints
Specific	*Specific*
Genital injury	Explicit assertions of sexual contact
Bruises	Inappropriate knowledge of adult sexual behavior
Lacerations	Compulsive masturbation
Rectal laceration, fissures	Excessive sexual curiosity, sexual acting out
Sexually transmitted disease	*Nonspecific*
Pregnancy	Excessive fears, phobias
Nonspecific	Refusal to sleep alone, nightmares
Anorexia	Runaways
Abdominal pain	Encopresis
Enuresis	Aggressive behavior
Dysuria	Attempted suicide
Evidence of physical abuse in genital area	Any abrupt change in behavior
Vaginal discharge	
Urethral discharge	
Rectal pain	

Table 128.7. Identification of Sexual Abuse

Specific Physical Complaints

Bruising on the upper thigh, lower abdomen, or genitalia is a rare finding in childhood sexual abuse. The child is not usually injured because he or she is often used for stimulation, masturbation, or genital contact that involves no force. Nonetheless, a physical injury to the genitalia should elicit a suspicion of sexual abuse. For children with even small vaginal lacerations, a detailed history of injury should be obtained. Straddle injuries do produce genital trauma and are the most common form of accidental genital injury to young girls. In males, accidental penile trauma may occur from zipper accidents or from a toilet seat that falls. Beyond these common accidental situations, the emergency physician should scrutinize the history given. The premenstrual child who presents with vaginal hemorrhage may be bleeding from a vaginal laceration that is not visible on external examination. Accidental injuries such as straddle injuries are always able to be seen. Prompt surgical or gynecologic consultation should be obtained to identify and repair unseen sites of trauma.

The presence of sexually transmitted disease in a prepubertal child is a specific finding of sexual abuse until proven otherwise. Studies by Branch and Paxton and others have shown that when instances of prepubertal gonorrhea were carefully investigated for cause, the source of the infection was through sexual contact, most often in the child's home or in a relative's home. Gonorrhea may occur in the genitourinary tract, rectum, or oropharynx. When gonorrhea is culture proven, it should be pursued as sexual abuse, according to the Centers for Disease Control and Prevention. The American Academy of Pediatrics has issued guidelines for the diagnosis of gonorrhea. Parents may bring their child to the ED for the complaint of vaginal discharge. Gonorrhea may also appear in cases of less well-defined symptoms, such as vaginal pain, itching, urinary frequency, or enuresis. Recent studies indicate that only children with vaginal discharge need to be cultured.

The Centers for Disease Control and Prevention indicate in their treatment guidelines that “Any sexually transmitted infection in a child should be considered as evidence of sexual abuse until proven otherwise.” At present, knowledge about sexually transmitted diseases is limited. Any sexually transmitted disease in a prepubertal child is suspicious of abuse; however, basic understanding about disease transmission places these infections in three categories (Table 128.8). In the first category are those infections that virtually always are transmitted through sexual contact; for example, syphilis and gonococcal infections. In the second category are those infections that to the best of clinical knowledge are usually transmitted sexually. It must be noted, however, that exact scientific information is not present. For example, Kaplan reported on six cases of genital herpes simplex, but in only four cases could sexual abuse be documented. Category three includes diseases that are suspicious of abuse but that may be transmitted by nonsexual contact. The pregnant adolescent may be a victim of incest. The physician should try to obtain a specific history of conception. Often, the focus of case management centers on how the adolescent plans to notify her parents or whether she considers abortion or adoption as options. If the issue of paternity is not pursued, instances of sexual abuse escape detection.

Always	Usually	Possibly
Neisseria gonorrhoeae	Herpes simplex	Condylomata
Syphilis	*Chlamydia trachomatis*	Scabies
	Trichomoniasis	Pediculosis
		Gardnerella vaginalis

Table 128.8. Sexually Transmitted Diseases and Their Probability of Being Caused by Child Sexual Abuse

Specific Behavioral Complaints

The most common clinical manifestation of sexual abuse is a positive history. The child who gives a clear detailed story of sexual encounter with an adult has a specific behavioral manifestation. Reports of suspected sexual abuse may be based on history alone because, children do not make up such allegations. Most children who are not abused are not knowledgeable in the details of sexual encounters. Thus, when a child offers the specifics of an encounter, he or she must be believed. The detail of the history varies with the child's age and language development, but even children of 3 or 4 years are able to make simple yet credible statements about someone touching their genitals.

Some children manifest behaviors in their play or in their conversation that indicate that they have been exposed to sexual experiences, and perhaps abused. These signs are less specific than a clearly stated history, but are significant enough to require further explanation. For example, the young child who discusses urogenital contact may be demonstrating a specific behavioral manifestation. Children who wish to fondle their parents' genitals as an expression of affection are cause for concern. These behaviors are usually learned. All children manifest sexual curiosity and may engage in some form of masturbation, but when either of these behaviors appears in excess, it deserves investigation. Sexual abuse may be the cause.

Recently, several films, videotapes, books, and school programs have been developed as prevention tools in sexual abuse situations. These instructional materials are also helpful in opening discussions between parents and children and thereby promote disclosure of past events experienced by the child.

Nonspecific Physical Complaints

The physician should keep sexual abuse in the differential diagnosis for many complaints. Sexual abuse may be related to cases that present with pain in the abdomen, thighs, or genitals; dysuria; pain on defecation; hematuria; or hematochezia. Abuse may manifest as a change in habits, such as urinary frequency, enuresis, constipation, or encopresis; other complaints may be vaginal discharge or chronic sore throat. The cause of each of these complaints may be any number of things. For example, in studying a group of children with enuresis, sexual abuse is an uncommon cause of the complaint. Nonetheless, sexually abused children are regularly brought to EDs with nonspecific complaints. If sexual abuse is not considered, it goes unnoticed.

Nonspecific Behavioral Complaints

The final group of clinical manifestations includes unexplained changes in the child's behavior. In this group are relatively minor behavioral changes, such as the recent acquisition of nightmares or phobias, or major changes, such as school truancy and adolescent runaways. Children who bear no physical evidence of their abuse and in whom no physical symptoms develop may express themselves behaviorally. Many children demonstrate change in one or more of the important spheres of their life: at home, in school, or with peers. This situation is exemplified by a 5-year-old girl who begins avoiding contact with her father and other male relatives after an abusive episode with a male friend of the family. A sudden change in school performance unexplained by the teacher, social withdrawal, and isolation may also be nonspecific behavioral manifestations. Similar to the nonspecific physical complaints, these behavioral complaints may be caused by several other things as well. Sexual abuse is likely to produce a behavioral change in children old enough to comprehend the wrongness and shamefulness of the situation.

Management

The primary goals in case management of the sexually abused child are to identify and report the abuse and to avoid the secondary abuse phenomenon. *Secondary abuse phenomenon* refers to the physical examination that is so overzealous that it assumes a rape-like quality in the mind of the child. Also to be avoided are parental or staff reactions that make the child feel responsible or blamed for the abuse. Many centers have moved to performing a screening function. If the child has been abused in the past 72 hours or more and no acute symptoms (e.g., bleeding, signs of sexually transmitted disease) are present, the child is referred to a sexual assault center provided such a community service exists. In places where no center is functioning, the entire evaluation must be done in the ED. The following sections offer techniques in management to identify suspected sexual abuse and to gather enough documentation for legal purposes in a manner that is humane for the child and supportive for the family. Chapter 130 details the management of adolescent rape victims.

Interviewing the Parent

Parents may present the problem of sexual abuse either directly or indirectly. For the parent who is direct (i.e., “My child's been abused”), it is important to provide a controlled, quiet environment because he or she will be upset and angry. It may be necessary to limit what is said in front of the child. With such parents, the interviewer's tasks are calming, limiting, and clarifying. In an example of the indirect presentation, the parent brings the child for complaints such as those detailed in the sections on nonspecific physical or behavioral manifestations. With this parent, the task of the interviewer is to bring the possibility of sexual abuse into the open. Once the topic is nominally broached, it becomes apparent that the parent has often already given it consideration. With both types of parents, exploring both their concerns and their information in detail is important.

Recent public media attention to the problem of child sexual abuse has contributed significantly to raising the level of awareness about this problem. The increased number of reported cases may be directly linked to growing public and parental concern. Most of the parents bringing their child to the ED initiate their visit based on a real observation or a strong feeling that something has happened to their child. The emergency physician must help clarify what the initiating cause may have been. In a rare situation, the parent may have responded to pure anxiety that their child may have been abused; however, these parents can provide no substantive cause for their concern. Arrangements should be made for parents in this latter group to have at least one follow-up visit to a sexual abuse center to again explore their motivation before putting their concerns to rest.

Interviewing the Child

Beyond standard history-taking from the parents, the emergency physician must always obtain a history from the child. This task is difficult for several reasons: 1) the child's level of language development, 2) the child's level of psychosexual development, 3) the desire not to contaminate what may be important evidence, 4) the apprehension of the child and the parent, and 5) the awkwardness and apprehension felt by the interviewer in discussing sexual matters with a child. The first steps are for the physician to obtain a quiet, private place and to decide whether he or she wishes the parent to be present. If possible, the physician may wish to defer the comprehensive examination to a more appropriate time and place. Based on previous history-taking from the parent, the physician can gauge the parent's level of emotional composure. This criterion is useful to decide whether parents should be present. If the parents are excluded, another third party (e.g., a nurse or social worker), should be present. An initial discussion of topics, other than the alleged abuse, comforts the child and encourages him or her to talk to the interviewer. Information about school, peers, and family adjustment is important in looking for nonspecific behavioral manifestations, and this preliminary conversation also helps evaluate the child's developmental level. Table 128.9 briefly outlines normal sexual developmental stages and appropriate interviewing techniques for each level.

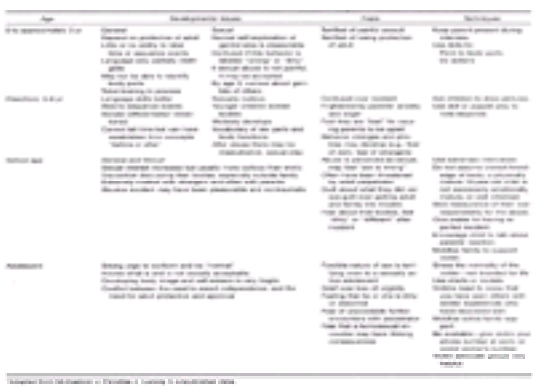

Table 128.9. Developmental Issues in Managing the Sexually Abused Child

In focusing the conversation on the abuse, one technique may be to ask the child why his or her parents brought him or her to the hospital. Another approach that is more appropriate for younger children is to establish common vocabulary by asking the child the term used for his or her genitalia. Children offer a rich variety of terms and may have no understanding of the words *“vagina”* and *“penis.’* One 4-year-old girl stated “He tried to put his pencil in my pocketbook.” In eliciting and using common language, the physician gets to the point of the interview more easily.

If the parental history and surrounding circumstances are credible, inquiries should be phrased to obtain the details of the abuse rather than to ask the child to make the initial allegation. For example, the physician may want to directly ask “How did Uncle Tommy touch your pee pee (vagina)?” rather than “Did Uncle Tommy touch you?” If questions are phrased in a yes-or-no format, a one-word response will be given. Obtaining detail is important to add credibility to the history. The history is also important in guiding the physician to significant aspects of physical examination, evidence collection, and treatment.

With a preverbal child, using anatomically correct dolls may be helpful (Table 128.9). These dolls allow the child to play out the episode. Similarly, some children may choose to draw a picture that tells the story or that may be used by the interviewer to initiate the interview. These techniques are fraught with hazard as far as legally sound methodology, but when simple interviewing fails, making a diagnosis and protecting the child is more important than protecting the legal process.

Emotional Support

Throughout the interview and in all contacts with the child, the rightness of his or her decision to discuss the abuse should be stressed. A child experiences conflict about revealing a secret, especially a long-standing secret. The patient

may also feel conflict in sensing that his or her actions may be provoking a great deal of emotional turmoil. Often, the child has a relationship with the perpetrator and realizes that this admission may alter or end the relationship. At times, the child is aware or is made aware of getting the perpetrator “in trouble.” Reaffirm the importance of what the child has revealed and focus the wrongdoing on the perpetrator. The child may have been threatened not to tell. Thus, bringing the nature of the threats into the open and offering protection to the child are important concerns. Finally, many children have fears about the abuse. Common fears are shown in Table 128.9. The physician may anticipate and address these fears based on the child's development.

Physical Examination

The physical examination may be a point of significant trauma for the child. The examination should be conducted in a standard fashion with all parts of the body examined. The position of the child depends on age and comfort. Many young children want to be examined while sitting in their parent's lap. In examining the genitalia of young girls, two positions are recommended. One is a frog-leg posture while sitting on an adult lap. Alternatively, the child can lie prone with knees tucked under the thorax (i.e., the knee–chest position).

In the prepubertal girl, only the external genitalia need be examined. If even minimal vaginal bleeding appears to be coming from a more internal source, exploration and possible surgical repair is best done under general anesthesia in the operating room. Examination in the ED should be deferred. In the pubertal child, a full genital examination should be performed. This examination may be modified if it is a girl's first speculum examination and it proves too difficult. Chapter 94 details physical examination techniques.

Examination of the rectum and oropharynx needs to be carefully performed, particularly if the history suggests that these were sites of sexual contact. Other physical findings to note carefully are any contusions, abrasions, or lacerations in nongenital areas. Common sites for these signs of trauma are the upper thighs, buttocks, and upper arms. Figure 128.14 shows some of the visible findings of child sexual abuse.

FIGURE 128.14. Physical signs of child sexual abuse. **A.** Rectal dilation and multiple lacerations after sodomy. **B.** Multiple vaginal and paraclitoral lacerations. **C.** Herpes virus infection in perirectal area. **D.** Herpes virus vaginitis. **E.** Syphilis in a sexually abused adolescent.

If the physical examination proves too traumatic for the child, the physician is faced with a significant dilemma. The choices are to further traumatize the child or to perform an incomplete examination and collect inadequate evidence. As with all dilemmas, the best choice is not obvious. Physically or psychologically traumatizing the child should be avoided. Often, no physical evidence is present, and the history, if detailed enough, may be sufficient. The guiding principle should be primum non nocere (first do no harm).

Evidence Collection

The type of evidence to be collected, the collection methods used, and the procedures for processing the results vary by locale. The specimen-collecting procedures at the Children's Hospital of Philadelphia have been reviewed by the Philadelphia Police Department and District Attorney. The protocol is listed in Table 128.10. Whatever the specifics of a particular jurisdiction, some general principles should be followed. Establishing a standard protocol is important so that each new case does not force the emergency physician to reformulate the entire process. The ED should have on hand either standard “rape kits” or some modification thereof. The kits should contain all of the necessary tubes, slides, swabs, and supplies. Evidence collection should be performed with another health care professional present, either a nurse or a social worker. A standard for marking the specimens should be established, including the patient's name and medical record number. Finally, the protocol should include a procedure for a specified person to take the specimens to the laboratory and to officially have them received or logged in by the laboratory. This detail becomes important in the court proceedings against the perpetrator. For example, nothing is more unsatisfying than seeing an alleged perpetrator go unconvicted because the hospital cannot be legally sure that a positive gonorrheal culture belongs to the victim in question.

1. Child's history in detail
2. History of observers
3. Documentation of general physical examination; note signs of force (e.g., bruises)
4. Documentation of genital injury (colposcopy)
5. Documentation of sexual contact
   - Presence of sperm or semen (e.g., on patient's clothing, linens)
   - Sexually transmitted disease
   - Pregnancy
   - Foreign material
6. Documentation of perpetrator
   - Sperm: motile/nonmotile
   - Seminal fluid
     - Genetic marker (blood group antigens)
     - Acid phosphatases
   - PSG glycoprotein
   - Blood
   - Hair analysis
   - DNA matching

Table 128.10. Evidence for Child Sexual Abuse

Consider a Differential Diagnosis

In any consideration of abuse, the physician must always consider the question, “What else could it be?” There may be plausible explanations such as accidental injuries to the genitals as in straddle injuries. Other important alternatives to consider are: 1) infections such as streptococcal, *Haemophilus influenzae,* and monilial; 2) congenital anomalies such as hydrometrocolpos, hemangioma, and perineural clefts and pits; 3) foreign bodies of the rectum and vagina; and 4) dermatologic conditions such as lichen sclerosus et atrophicus, diaper dermatitis, contact dermatitis, Ehlers-Danlos syndrome, and phytodermatitis. Perhaps the most common mistaken perineal finding is prolapsed urethra, which appears as a hemorrhagic mass covering the upper vaginal area.

Documentation

Careful record-keeping cannot be stressed too strongly. As with the collection and processing of evidence, ED records can make or break a case. The Children's Hospital of Philadelphia has developed a separate form that guides the examining physician to include all of the pertinent information (Fig. 128.15). All of the aspects of record-keeping mentioned in the section on physical abuse apply. In particular, what the child said in his or her own words should be carefully recorded. Such questions may be the mainstay of any legal actions to be taken. Good records not only help the police and lawyers involved, but also help the physician review the case before a hearing that may not take place for 6 months. In some jurisdictions, legal provisions allow videotaping patient interviews. This tool is particularly helpful to the victim in that he or she may not have to repeat the history so many times. It may also be helpful to the physician by serving as another form of documentation. When such tapes are shown during court proceedings, they are most helpful.

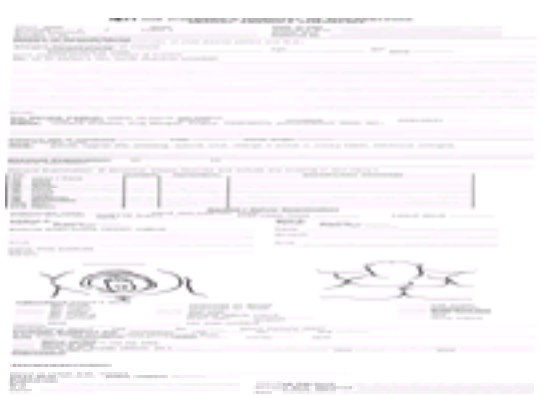

FIGURE 128.15. Sexual assault checklist.

Diagnosis

The diagnosis of sexual abuse should be based on a composite of the history, physical examination, and laboratory findings. Many centers have begun to use a four-category classification of assessment developed by Adams and Harper (Table 128.11) using a classification of physician findings noted in Table 128.12.

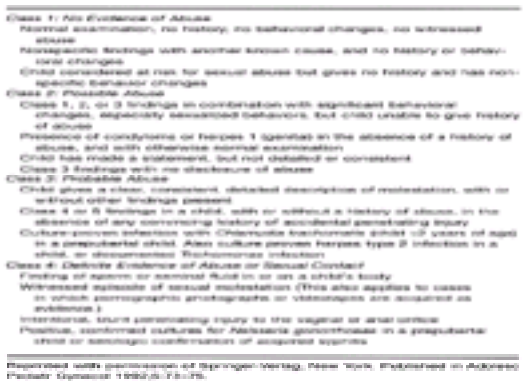

Table 128.11. Overall Assessment of the Likelihood of Sexual Abuse

Table 128.12. Proposed Classification of Anogenital Findings in Children

Reporting

In most jurisdictions, sexual abuse is a criminal offense. Thus, all cases are reported to the police department. In some jurisdictions, when the abuse has occurred in the home or during a time when parental supervision was lax, a civil report to the CPS agency may also be required. This detail needs to be specified according to local guidelines and included in an ED procedure. In the event of a criminal (police) report, a civil (child abuse) report, or both, the parent needs to be informed that such reports are being made. The physician or social worker must spell out the practical consequences of the reports for the parent.

Preparing the Parent

Beyond notifying the parent about reporting the sexual abuse, additional preparation must be given. Many workers believe that, for the young child, the parental reaction to sexual abuse may have as important a role as the abuse itself in producing subsequent manifestations. Long-term follow-up studies of sexually abused children performed using a case control methodology show that the sexually abused child is at long-term risk for a variety of psychological and behavioral consequences. Parents need to be aware of this correlation. All parents will be upset. All parents will be angry. Some parents may express disbelief or the feeling that “this could not be happening to me.” Parental reactions vary depending on whether the abuse is intrafamilial or extrafamilial. Social worker consultation and collaboration for this aspect of case management are essential.

The first step is to focus the parent's attention on the child. Especially in situations of father–daughter incest or surrogate father–daughter incest, the maternal reaction may initially be more self-centered. In directing the parent's attention to the child, the physician returns the parent to a more comfortable traditional role and raises many important issues to which the parent must attend. The physician should review with the parent that manifestations of sexual abuse may be physical and/or psychological. The physical manifestation may seem minor to the physician, but parents must be specifically told that whatever the injury, it can be repaired with no impairment of the victim's sexual functions as an adult. The physician should stress that soft tissues can be repaired, and gonorrhea, if present, can be treated.

Parents must be told that the psychological outcome, in part, relates to their reactions to the situation. Their role must be to provide comfort, support, and reassurance to the child. Methods of supporting the child have been raised previously in this section. These techniques must be used by the parents. Unfortunately, parental anger and blame may sometimes be displaced onto the child, who has set off an emotional time bomb by revealing the abuse. For example, parents may openly say, “I told you not to play with those children down the street,” in a case of extrafamilial abuse. In cases of intrafamilial abuse, the parent may have an even more damaging perception that the child lured the adult into the abuse. Statements such as “I knew she would end up no good” or “I told her never to walk around the house in her underwear” are not uncommon. All attempts to place responsibility or blame on the victim need to be eliminated. The ultimate responsibility was that of the perpetrator, no matter what the behavior of the child.

Some parents may focus their anger clearly on the perpetrator but wish to “take the law into their own hands.” Parents should be cautioned about leaving the ED to find and confront the perpetrator. This action is a police responsibility. The parental role is to provide safety for the child. Parental ire can be cooled by pointing out that a parent's arrest for assault of the perpetrator will not benefit the child.

Yet another common parental reaction is to want to institute several lifestyle changes. Parents may want to change their place of residence, change the child's school, or quit their jobs to be able to guard the child 24 hours a day. The ED staff should stress that returning to as normal a lifestyle as possible is best for the child. Change is always difficult for children, and the stress of entering a new school or meeting a new set of friends is a burden the sexual abuse victim does not need. Parents should be cautioned about limiting the amount of open conversation with friends and relatives that the child may overhear. The victim's desire to discuss the abuse should regulate how much abuse-related conversation should take place between family members. Some children may want repeated reassurances about their parents' approval and about their future safety. Other children may wish to let the episode be forgotten and return to school and play. If the sexual abuse triggers disruption and chaos in the parents' life and disapproval of the child, it will surely have psychological ramifications. The best prognosis results if the parents can show their concern in a way that assures the

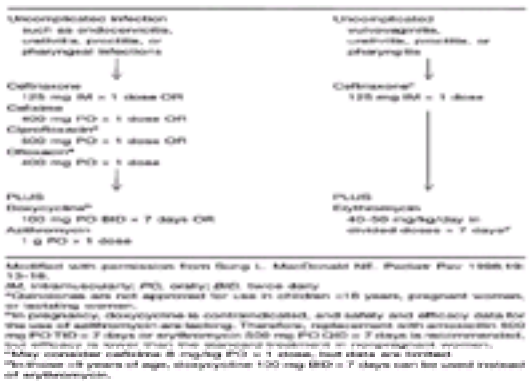
child of approval, protection, and resumption of a normal lifestyle.

Hospitalization

Two indications for hospitalizing the sexually abused child are: 1) severe injury requiring treatment and 2) an unsafe home. However, outpatient management of sexual abuse victims is always preferable. The rationale is to avoid victimizing the child twice. If an adult male has been the intrafamilial perpetrator, he should be removed from the home so that the child may return. Children who are hospitalized because the home is unsafe believe that they are being sent away for their wrongdoing. Another message hospitalization may transmit is that the parent is incapable of providing protection. Both of these messages are harmful to the child's psychological adjustment.

Treatment

Whether the child is hospitalized or discharged from the ED, three additional issues should be considered: 1) gonococcal prophylaxis, 2) human immunodeficiency virus (HIV) testing, and 3) pregnancy prevention. If the abuse has occurred less than 48 hours before the hospital visit, gonococcal prophylaxis is recommended. Within this time period, cultures for *Neisseria gonorrhoeae* may prove negative, even if a true infection is incubating. In abuse that has occurred more than 48 hours before the visit, the choices are either to treat all children prophylactically or to culture the genitalia, anus, and throat and await culture results. This choice depends in part on the reliability of the microbiology laboratory in recovering *N. gonorrhoeae* (which is a fastidious organism) and the ability to provide follow-up treatment for positive cultures. Recommended treatment regimens are shown in Table 128.13 (see also Chapter 94).



Modified with permission from Sung L, MacDonald NE. Pediatr Rev 1998;19:13–18.
IM, intramuscularly; PO, orally; BID, twice daily.
*Ciprofloxacin are not approved for use in children <18 years, pregnant women, or lactating women.
†In pregnancy, doxycycline is contraindicated, and safety and efficacy data for the use of azithromycin are lacking. Therefore, replacement with amoxicillin 500 mg PO TID × 7 days or erythromycin 500 mg PO QID × 7 days is recommended, but efficacy is lower than the standard treatment in nonpregnant women.
‡May consider cefixime 8 mg/kg PO × 1 dose, but data are limited.
§In those <8 years of age, doxycycline 100 mg BID × 7 days can be used instead of erythromycin.

Table 128.13. Treatment Guidelines—Gonorrhea

HIV testing is already an issue on the minds of most parents of sexual abuse victims. Transmission of HIV during child sexual abuse contacts has been reported. Routine testing for HIV may depend on the nature and extent of sexual contact, regional rates of HIV infection, ability to test the alleged perpetrator, and parental desires for testing. All HIV testing should be preceded by written consent and should be done in a manner that results in proper notification, counseling, and follow-up. See Chapter 85 for more on HIV infections.

Most children can be eliminated from consideration for pregnancy prophylaxis if they have not yet reached menarche. Another group may be eliminated based on the nature of the abuse. If the abuse took the form of fondling, and no ejaculate was produced by the perpetrator, prophylaxis does not need to be used. In the pubertal child not using contraception, in whom active penetration occurred at a midmenstrual cycle time, pregnancy prophylaxis should be offered. Documenting that the patient does not have an existing pregnancy is always important. The Children's Hospital of Philadelphia's current therapy is a singleday treatment with oral contraceptive pills (see Chapter 130).

Referral and Follow-Up

All sexually abused children need some form of referral and need careful follow-up care. Referral may initially be to the hospital social worker for monitoring of the child's symptoms and the family's ability to cope with this stress. In some locales, volunteer self-help groups organized for women who have been raped may provide support to the child victim and parent. Referral for more in-depth mental health counseling depends on the 1) symptoms manifested by the child, 2) state of family organization, 3) length of time the abuse has occurred, and 4) the child's age. In general, the older the child and the longer the abuse has occurred, the more likely he or she may have or may develop a serious mental health problem. All children should be referred to mental health services. Follow-up health care visits should be arranged with an informed and sympathetic practitioner who can continue the humane and supportive care initiated in the ED.

False Allegation and Unfounded Reports

At times, the emergency physician is called on to establish the diagnosis of sexual abuse without adequate data. Two situations may be at play: a false allegation or an unfounded report. False allegations refer to situations in which a child sexual abuse complaint is being used by one adult against an estranged wife or husband. These situations are extremely difficult to manage from the ED. Beyond taking a detailed history and performing a physical examination to rule out acute injury, these cases are best referred to a child abuse center. False allegations are often identified by weekend presentation, lack of both history from the child and physician findings, upcoming custody hearing, and bitter divorce situation. Unfounded reports often occur because of undue parental concern stimulated by a media presentation or public discussion of sexual abuse or an unwarranted fear stemming from a parent's own childhood sexual abuse experience. Historical indications by the child or physical findings may be absent. Unfounded reports should also be referred to the

local child sexual abuse center for further evaluation if parental concerns cannot be satisfied.

NEGLECT

Child neglect is by far the most prevalent form of child abuse. When neglect is blatant, it is easily recognized and reported. More often, neglect is not obvious and goes undetected for long periods. Although the manifestations of neglect are less dramatic than those of physical abuse, the long-term effects may be more destructive to the child. The indolent nature of child neglect makes it a serious public health problem. For the ED staff, neglect cases are difficult because they require that certain value judgments be made. The balance between supporting the independent rights of the child and maintaining the privacy and sanctity of family rights is delicate. With neglected children, the questions are: 1) How much should the family be doing? 2) How much are they capable of doing? 3) How much support from the community or society do they require? and 4) How much support or help are they willing to accept on behalf of their child? As with the other forms of child abuse, the management of child neglect cases is made easier by working with a multidisciplinary team. In the ED, the team would generally consist of the physician, nurse, and social worker. Particularly in situations in which the line between adequate child care and neglect needs to be drawn, the diversity of personal and professional opinions adds credibility to decision making and lessens the burden on the single practitioner.

Background

The definition of child neglect is difficult because no societal standards for child care are explicitly stated. This vagueness creates a situation in which parents and professionals are left to define their own standards that produce many problems. Defining *"abandonment"* (the ultimate neglect) is an excellent example of the difficulties encountered in setting standards. No societal norm is established for either the age of the child left alone or the duration of time. Thus, if a parent leaves a 3-year-old child unattended in a home for several hours, most neighbors and professionals would consider that neglect. But what if the child were 10 years old, and the parent was gone for 20 minutes? Then the situation becomes less clear.

Many states have tried to partially define the condition by making it depend on a physical manifestation in the child. Thus, the child left alone who stays out of trouble is not neglected; the one who burns himself or herself and cries to the point that the neighbors become aware is neglected. The National Center for Child Abuse and Neglect uses the following definition: child neglect is characterized by failure to provide for the child's basic needs. Neglect can be physical, educational, or emotional. Physical neglect includes refusal of or delay in seeking health care, abandonment, expulsion from the home or refusal to allow a runaway to return home, and inadequate supervision. Educational neglect includes the allowance of chronic truancy, failure to enroll a child of mandatory school age in school, and failure to attend to a special educational need. Emotional neglect includes actions such as significant inattention to the child's needs for affection, refusal of or failure to provide needed psychological care, spouse abuse in the child's presence, and permission for drug or alcohol use by the child. The assessment of child neglect requires consideration of cultural values and standards of care as well as recognition that the failure to provide the necessities of life may be related to poverty.

Other apparent societal conflicts are inherent in defining neglect. One conflict centers on the relationship between neglect and poverty. This situation relates to the questions asked previously and the issue of what the family should be doing versus what they are financially capable of doing. Certainly, at times, poverty may be coincident with neglect, but the issues are distinctly separate. Most poor families find a way to provide the material essentials and, more important, the emotional essentials for their children. The contrasting example is that of families who are in the middle or upper socioeconomic scale and who could provide for their children but who are neglectful. Another conflict is based on the failure to recognize the evils of excess. The child who is underfed and wasted is promptly labeled *"failure to thrive."* The child who is overfed to the point of obesity may face as many serious consequences. The child who is developmentally delayed from understimulation may be labeled *neglected.* The child who has psychosomatic illness from being stressed to overachieve also deserves identification and help. The term *neglect* generally refers to underprovision on the part of the parent. Overprovision may be as deleterious, which presents a serious conflict to the definition of neglect. The true incidence of neglect is not ascertainable.

Dynamics

The dynamics of child neglect have been explained by several different theorists. Some theories are based on purely individual dynamics and point to the immature, overwhelmed, overstressed parent who responds by withdrawal. Polansky has well documented and labeled this condition as the "apathy futility syndrome." Theories that have a more social orientation point to the societal pressures and to the existence of poverty. David Gil considers all children existing on a welfare stipend as neglected and recommends a change in the distribution of societal resources as a solution. Most theories would support the notion that the neglectful parent does not see himself or herself as such. Most parents are caught up in a neglectful lifestyle that is self-perpetuating. Most neglect is not purposeful, it just happens. Studies have clearly shown that women who fail to seek prenatal care are also likely to not obtain health care for their children. In the parents' view, it is a pattern of living that seems to be the norm. This facet of the dynamics of neglect is important to the ED management.

Manifestations

The manifestations of neglect are countless. The manifestation may be tangible, such as the weight loss of a child whose diet has been inadequate, or intangible, such as the psychological effects of unsatisfactory relationships. A categorization of neglect can be made by looking at the standard functions of the family and then considering the failure to fulfill these functions. A family must 1) provide and distribute material goods—food, clothing, and shelter; 2) ensure health; 3) promote safety; 4) socialize and educate; and 5) provide emotional support, security, and love. The manifestations of neglect may occur in one or more of these functional areas. The most commonly reported manifestations are: 1) nonorganic failure to thrive—a lack of food and feeding skills; 2) medical neglect—a failure to provide needed health care; 3) abandonment—total neglect, generally viewed as a lack of supervision and as a safety

hazard; and 4) truancy and school avoidance.

Failure to Thrive

The term *failure to thrive* has been used as a diagnostic term to group several diseases and disorders that result in growth failure. Growth failure is generally measured in weight, length, and head circumference as compared with standard growth curves for these parameters. Growth failure may be defined as measurements that fall below 2 standard deviations for age or patterns that cross percentile lines (i.e., move 2 standard deviations) and do not follow the normal lines of growth. Patients diagnosed as failure to thrive may be subcategorized into three groups: 1) organic, 2) nonorganic, and 3) mixed group. *Organic* refers to children whose failure to thrive is based on a physical cause such as congenital heart disease, renal disease, or a genetic abnormality. *Nonorganic* refers to the group whose growth failure is environmentally related. When these children are hospitalized and fed standard diets, they grow rapidly and thrive. The group of patients with nonorganic failure-to-thrive includes a substantial number of neglected children who may be brought to the ED for care. The mixed group refers to patients who have a combination of physical and environmental factors. An example might be a physical condition that so overstresses a family that they cannot function, and thus neglect the child in some aspect of the feeding process.

In recognizing the patients with nonorganic failureto-thrive, the following factors are suggestive: History: 1) an idealized feeding history; 2) a chief complaint and history that do not identify the child's growth pattern as a problem; 3) no description of losses, such as vomiting or diarrhea; and 4) failure to give a history of a schedule or scheduled pattern of feeding (e.g., baby eats about every 4 hours). Physical examination: 1) measurements in which weight is more depressed than length, which is more depressed than head circumference; 2) other signs of neglect such as poor hygiene, diaper rash, and flat and balding occiput; 3) dull, apathetic facies; 4) body posture of an understimulated child; 5) excessive oral self-stimulation; and 6) developmental delay, particularly in the social adaptive and language areas. Parental observation: the parent who 1) has an uninterested attitude; 2) does not respond to child's needs (e.g., react to crying); 3) lacks concern about health issues; and 4) appears to be a drug or alcohol abuser. These factors are shown in Figure 128.16.

FIGURE 128.16. Physical signs of failure to thrive. **A.** Dull, apathetic eyes that avoid eye contact. **B.** Oral self-stimulatory behavior. **C.** Wasted extremities and protuberant abdomen. **D.** Severe diaper rash as a sign of overall neglect.

Medical Neglect

The differentiation between medical neglect and noncompliance is often difficult. The key to differentiating them is to ask, “Has identifiable harm come to the child?” If a parent fails to complete a course of therapy prescribed by a physician, noncompliance exists. However, if the failure to give medication results in further illness in the child, medical neglect exists. The manifestations of medical neglect can be documented and reported as such. Noncompliance merely results in a worsening doctor-patient relationship. Proving that the failure to give medication, attend follow-up appointments, or obtain a procedure directly resulted in damage to the child's health may be difficult. Intervening variables, such as the complexity of the disease (e.g., the exacerbations of an asthma attack), or the proven efficacy of the treatment often exist. The ED is often the central place for identifying the manifestations of medical neglect. Good documentation of prescribed treatments and good communication with the source of the child's ongoing health care are important.

Abandonment

Local jurisdictions may dictate the length of time a child must be without supervision before he or she is declared legally abandoned. These cases often come to the ED as the result of a neighbor's call or the initiative of a relative who is aware of the neglect. At times, the situation may become apparent as the ED attempts to obtain permission to treat a child and has difficulty locating a parent or responsible adult. Manifestations of abandonment include: 1) physical findings such as excessively dirty diapers, poor hygiene, or hoarse cry; 2) excessive hunger documented by unusual intake; and 3) dehydration as documented by urine specific gravity or blood urea nitrogen. Other manifestations may relate to lack of supervision and protection and may include burns, ingestions, or repeated accidents. Children with all of these manifestations may be brought to the ED for treatment. Good case management results in their identification.

Truancy

Truancy as a manifestation of neglect may be less commonly recognized in the ED. The section on school avoidance (see Chapter 129) details many of the aspects of this complex psychosocial emergency. The emergency physician may recognize truancy as a neglect problem when the truant child presents with multiple somatic complaints. As the complaints are explored and no organic basis is found, the parent may be instructed to return the child to school. A

failure to comply with this aspect of treatment constitutes medical neglect. For the child who makes frequent visits to the ED, neglect needs to be considered.

Management

The management of cases of child neglect follows the principles detailed in the “Physical Abuse” section. The steps are to: 1) suspect and recognize neglect manifestations; 2) obtain multidisciplinary consultation; 3) report the neglect; 4) inform the parents; 5) determine the need for hospitalization; and 6) arrange follow-up. These steps are reviewed in the following sections to underscore those aspects unique to neglect.

Suspect Neglect

As with other forms of abuse, the open mind of the physician allows neglect to be recognized. Because the manifestations are more subtle than with physical abuse, recognition is more difficult. The physician can overcome this difficulty only by obtaining a more detailed history and observing the parent-child interaction. In-depth social work evaluation can often uncover previous reports of neglect or involvement with child welfare agencies. Piling the building blocks of suspicion to the height of a threshold point may be more difficult because the size of each block may be smaller and less dramatic than in physical abuse.

Multidisciplinary Consultation

Because much of defining neglect is value laden, using a multidisciplinary consultation is vital. Such consultation can broaden perspectives on “normal” lifestyles and child-rearing practices. The difficulty any one professional feels in making a value judgment can be shared by a group. The multidisciplinary consultation may be made with someone outside the ED. Speaking with a school teacher, nurse, or counselor may be informative. A public health nurse or visiting nurse may have worked in the family's home and have excellent insights. Any multidisciplinary consultations are of value.

Reporting

Most states provide that reports of child neglect go to the CPS agency. Some states have joint police and social work (CPS) reporting. Criminal charges under the rubric of “endangering the welfare of another” may be brought against some neglectful parents. However, the greatest number of neglect cases come under the supervision of CPS. Police involvement becomes almost essential in cases of abandonment, and police have special skills in locating a missing parent.

Informing Parents

Informing the parents is more difficult in cases of neglect. Responses may be either active or passive. The term *neglect* often triggers an active and angry response. This reaction occurs because neglectful parents believe they are trying to parent as best as they can. Their perceptions of the neglect are different from those of the ED staff. This difference invariably creates conflict and evokes guilt and anger. When informing the parents, the focus should be on the child. The physician may need to verbally recognize the positive efforts of the parent. Nonetheless, if the result in the child is inadequate, action needs to be taken to help the child. Taking this approach often directs the parents' energy toward the child and sufficiently quiets emotional reactions.

The passive response may be equally disquieting to the physician. It may be seen in parents who are overwhelmed, have inadequate personalities, or are depressed, intoxicated, or retarded. Separating these parental problems from each other may be difficult. The physician may incorrectly assume that the parent does not care what happens to the child because of the lack of any response. With extremely passive parents, even engaging them in conversations may be difficult. Approaching the withdrawn parent with simple questions that do not directly relate to the neglect may be helpful. Often, by initiating a neutral conversation, the physician can learn about the parental problem. Asking the parent to perform a task that requires reading or writing may also be instructive. When informing the parent of the neglect report does not trigger active resistance, the physician may be left with an uneasy feeling that the communication was not clearly understood. However, repeat explanations may not stimulate more parental response.

Hospitalization

The need for hospitalization depends on several factors. Certainly, if the child's physical condition warrants treatment, hospitalization is indicated. For example, a child failing to thrive in the first 6 months of life should be hospitalized. Another indication relates to the degree of parental dysfunction. If the parents are assessed as being so overwhelmed, withdrawn, depressed, or inadequate that they are unable to assume parental responsibility, the child should be protected regardless of his or her current physical status. A third indication stems from the chronicity of neglect. Because of the indolent nature of neglect, the physician may need to make a point of hospitalizing a child to dramatize a chronic or recurrent situation. The final factor in determining the need for hospitalization is the time required for community agency response. If the report of neglect triggers an immediate investigation and institution of therapeutic services, the need for hospitalization is diminished. The response to neglect reports varies by community.

Follow-Up

In cases of neglect, arranging follow-up care by a physician or clinic is important. Often, the step of informing the receiving physician is overlooked. The staff providing the long-term care is expected to have the capacity to closely monitor patients and to become aggressive about correcting failure to keep appointments. The treatment of neglected children is often a long and frustrating process. Thus, special referral resources should be sought. Attempts to provide treatment in standard health care facilities may be doomed because the passive and indolent character of neglect may

escape health care providers and thereby injure the child.

EMOTIONAL ABUSE

Emotional abuse is the form of child abuse that most seriously and most often affects children. With every episode of physical or sexual abuse, a negative psychological message is being inflicted. The child is told, “You are bad!” and often comes to believe this statement. When the bruises, burns, and broken bones are healed, psychological injury may remain untreated. The neglected child also feels devalued and unloved. Emotional abuse always accompanies other forms of abuse and at times is inflicted independently.

Yet, this form of abuse is the least well understood. Furthermore, a report of suspected abuse is rarely based solely on emotional abuse. Gathering enough objective data to prove that emotional abuse has occurred is difficult. Courts and legal authorities remain unconvinced that a given parental behavior or set of behaviors can be shown to be responsible for effects in the child. Emotional abuse rarely results in a psychosocial emergency. More often, similar to neglect, it is a chronic impediment to normal growth and development.

Background

Emotional abuse has been defined in many different ways. The National Center for Child Abuse and Neglect defines it simply: “Child abuse which results in impaired psychological growth and development. Frequently occurs as verbal abuse or excessive demands on a child's performance and results in a negative self-image on the part of the child and disturbed child behavior.” The Pennsylvania Child Abuse Law provides for reporting serious mental injury, which is defined as “…a psychological condition determined by a psychologist, psychiatrist, or pediatrician, and caused by the acts or omissions of a parent or person responsible for the child's welfare, which: (1) renders the child chronically and severely anxious, agitated, depressed, socially withdrawn, or in reasonable fear of his/her life; (2) makes it extremely likely that the child will be chronically and severely anxious, agitated, depressed, socially withdrawn, or be in reasonable fear that his/her life is threatened; or (3) seriously interferes with the child's ability to accomplish age-appropriate developmental milestones or school or community tasks or peer relations.”

The Pennsylvania law identifies some of the potential manifestations of emotional abuse, but does not define the difficult issue of a child's behavior as “caused by” an act or omission on the part of the parent. The issue of causality hampers the reporting of emotional abuse. The incidence of emotional abuse is unknown, and reasonable estimates of its frequency are not available. Although neglect is reported most often, emotional abuse is the most common form of abuse because it occurs along with all other forms of abuse and neglect as well as independently.

Dynamics

Emotional abuse occurs when a parent attacks, belittles, humiliates, or devalues a child. Such behavior is not the infrequent reaction of a normal angry parent, it is an often repeated message to the child. An emotionally abusive parent appears to be determined to verbally destroy his or her child. The reasons for this behavior are many. All of the dynamics responsible for physical abuse may be operative for emotional abuse. Often, poor parental self-image is a strong component. The child either threatens the parent or reflects unwanted parental characteristics. In either case, the parent is unable to withstand the stress and attacks the child. When there are many children in a family, a parent may scapegoat the one child with whom he or she most identifies. At times, the child may be identified with another family member, such as an estranged father or a grandparent.

Helfer has capsulized the intergenerational nature of emotional and physical abuse in his “World of Abnormal Rearing” formulation (Fig. 128.17). The child who is told repeatedly that he or she is “bad” and “worthless” eventually accepts it. Once the belief that “I'm no damn good” exists, the child's behavior matches the expectation. Ultimately, the poor self-image is reflected in the inability to choose friends or a mate and to accept help. The cycle is completed with poor parenting and emotional abuse of the next generation of children. The intergenerational potential for emotional abuse makes it a serious public health problem.

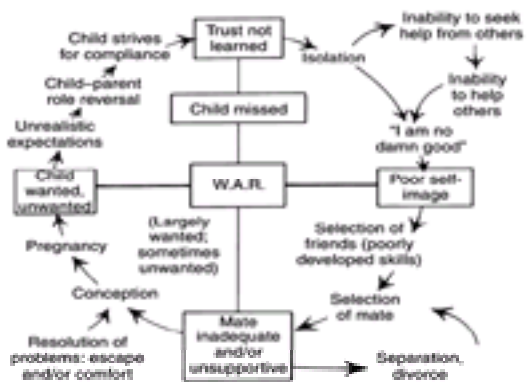


FIGURE 128.17. World of Abnormal Rearing (W.A.R.). (Modified with permission from R.E. Helfer.)

Manifestations

Emotional abuse manifests in many forms, including children who are excessively withdrawn and passive and those who are aggressive and act out. The manifestations are so varied that it is difficult to identify any constant characteristics of

the emotionally abused child. To identify emotional abuse, the physician must witness family interactions on repeated occasions; however, the emergency physician does not often have the opportunity for such comprehensive evaluation.

Rarely, more direct presentations of emotional abuse may be seen in the ED. Some children may seek hospital asylum because of excessive fear of their parents. Adolescent “runaways” may include a subset of children who are emotionally abused (see Chapter 129, Chapter 130, and Chapter 131). Developmental delay may be recognized in the ED, but the cause of the delay can rarely be identified. Finally, children with drug or alcohol abuse may be in a high-risk group for prior emotional abuse. The effects of emotional abuse closely parallel the findings in children with substance abuse (e.g., poor self-image, difficulty in establishing relationships).

Another group of emotionally abused children frequently seen in the ED is youngsters caught in the conflict between estranged parents. These victims have been called “yo-yo” children because they are pulled between arguing parents. Sometimes the children are virtually kidnapped by one parent. These presentations to the ED are based on one parent's attempt to document the poor parenting or neglect of the other. The misuse of the child as a pawn in the marital dispute constitutes emotional abuse. Despite the credibility and motivation of the parent in the ED, emotional abuse should be reported to remove the child from the middle.

Management

The management principles for emotional abuse are the same as those for other forms of abuse. To substantiate emotional abuse, documentation of behavior must be precise. The physician, nurse, and social worker must record observed interactions in behavioral terms using a minimum of subjective assessments and personal conclusions. Recording significant statements from the parents and child is good documentation. Citing a pattern of abuse or repeated episodes of abuse may be necessary to strengthen a report.

It is often difficult and painful for parents to see themselves as emotionally abusive. Thus, informing the parent in a constructive and sensitive way is also difficult. The informant must keep the discussion child-focused and nonaccusatory. Child welfare agencies and the family court system also have difficulty in identifying and treating emotional abuse. As the rights of children become more well-established and standards for child care more widely accepted, management of cases of emotional abuse will become less difficult.

CHAPTER 129

Psychiatric Emergencies

[*]GORDON R. HODAS, MD AND [†]JOHN SARGENT, MD

[*]*Department of Psychiatry, University of Pennsylvania School of Medicine, and Office of Mental Health and Substance Abuse Services, Pennsylvania Department of Public Welfare, Philadelphia, Pennsylvania*; [†]*Department of Psychiatry, Karl Menninger School of Psychiatry and Mental Health Sciences, and Education and Research, The Menninger Clinic, Topeka, Kansas*

INTRODUCTION

In contemporary American society, the emergency department (ED) of the hospital has become a major community resource. It is open 24 hours each day, professionally staffed, and used by the community for assistance in dealing with many physical, social, and emotional problems. The ED is the setting for the initial evaluation of a variety of difficulties of children and their families, including acute and chronic illnesses with their emotional sequelae, psychophysiologic conditions, family crises, and the entire spectrum of emotional and behavioral disorders. ED visits of children with social and emotional difficulties continue to increase, especially for families without a designated primary care physician. Although the medical staff and the community may disagree concerning appropriate uses of the ED, the ED staff must, nevertheless, respond to the problems that are brought to it. Therefore, physicians working in EDs must master the skills of psychiatric diagnosis, crisis intervention, and disposition planning.

Crisis and Crisis Intervention

Psychiatric emergencies are best understood as crisis situations. Crisis involves the acute development of circumstances or events that render the usual coping and adaptive patterns of an individual or social unit inadequate. Most crisis situations during childhood are handled effectively by the child's family. However, in some instances, the child's behavior or the overall situation becomes unmanageable. At this point, professional help is sought, and the child may be brought to the ED. Typically, the family members appear overwhelmed and helpless. Severe anxiety, disagreements among various caretakers, and disruption of previously stable family relationships may have occurred and be ongoing. In other cases, relationships may have been unstable for some time, with the acute superimposition of a crisis.

Psychiatric emergencies in childhood may be defined as crises in which the adults around the child are no longer able to help the child control his or her anxiety and can no longer provide adequate support and control of the child's emotional reactions and behavior. Any psychiatric emergency in childhood implies a limitation of effective interaction of the child and his or her caretakers. For example, the suicidal child is seen by his or her family as being uncontrollably self-destructive and needing professional help. However, the child's suicidal state also reflects the family's inability to assist him or her in developing alternatives other than suicide. Comprehensive assessment and treatment of psychiatric emergencies in children should involve the participation of the child's family. In this way, the family, with professional support, can resume its role in guiding the child's emotional and behavioral development.

Psychiatric crises are not just times of intolerable stress for the family, but also unique opportunities to bring about

change. When a family brings a child to the ED with an emotional problem, the crisis created by the problem has overcome the usual tendency to deny difficulties and maintain the status quo. Because family coping patterns are failing and denial is lessened, intervention at this time can be used to modify nonadaptive patterns and to create alternative solutions. Thus, family crises are nodal points at which the possibility for family change is maximized and during which interventions can extend beyond the amelioration of the concern at hand to have lasting impact.

It follows that the goal of the emergency physician is not to merely alleviate the crisis per se, but to use the crisis to create meaningful change. The physician needs to maintain within the family a sense of urgency that enables it to respond positively. Therefore, the emergency physician needs to be able to assess the immediate crisis and to appreciate through observation and history-taking how the family has become ineffective. Crisis intervention techniques in the ED address not only the complaint, but also the underlying problems that have given rise to it.

Requirements of the Emergency Department

The ability to respond effectively to psychiatric emergencies of children and families requires special capacities of the ED staff. Clinicians in the ED should have a preexisting relationship with a mental health team that is committed to providing child psychiatric consultation at all times. The emergency staff must be capable of collaborating effectively with this mental health team. Requests for psychiatric consultation should provide a clear statement of the problem and the goal of the consultation. To enable adequate response, the degree of urgency of each request should be clearly stated. When the consultant arrives, the ED staff should describe in detail its findings and any interventions made thus far. The emergency physician and the consultant should discuss how to proceed throughout the remainder of the ED visit. Such clarification not only is useful in the current situation, but also fosters mutual respect in the future.

Adequate physical space is another requirement of the ED. A place where interruptions are uncommon should be designated for psychiatric emergencies to be assessed. This room should have seats for each family member and the emergency physician. The availability of a separate room for psychiatric emergencies enables a mood of concern and deliberation to be achieved. The ED should also have a holding or observation room where certain children, such as those recovering from overdoses or those being stabilized with psychotropic medication, can be observed and evaluated regularly. Such a room should be adequately staffed by nurses as well as security personnel, when indicated, and the capacity for using restraints should also be present.

The ED should also have relationships with various psychiatric inpatient units so that hospitalization, when needed, can be arranged efficiently. Relationships with brief, crisis-oriented inpatient units that involve the child and the family in problem-focused treatment are of particular value. The staff should be thoroughly familiar with the procedures for psychiatric hospitalization, including the specific legal requirements for involuntary commitment. In certain situations, such as children recovering from medically serious suicide attempts, medical hospitalization may be necessary. The hospital should have specific guidelines for the management of psychiatric patients on medical floors.

Finally, the ED should have relationships with other social agencies and an awareness of relevant laws. The police should be aware of which children to bring to the ED for psychiatric assessment and should be prepared to remain in the ED until adequate security has been arranged. Relationships should be developed with mental health base service units, temporary shelters, and other crisis intervention centers, ensuring effective referrals when necessary. Staff should be aware of child protection laws and the procedures for emergency intervention in situations of abuse and neglect.

Physician Responsibilities and Skills

The responsibilities of the emergency physician with psychiatric emergencies are shown in Table 129.1. To effectively fulfill these responsibilities, the physician must possess a variety of clinical skills and the ability to block out other concerns when responding to psychiatric emergencies. The physician must be able to display empathy for the child's and family's distress. Once the family senses the physician's concern, it will be more responsive. The physician needs to handle the family's anxiety and uncertainty by approaching the family crisis calmly and systematically. In doing so, the physician establishes the leadership and authority that enables the family to discuss its problems freely and to consider and act on recommendations. Throughout the ED visit, the physician needs to foster the belief among family members that improvement in their situation will be achieved through appropriate changes in family members' behavior and relationships.

Obtain necessary information for database	Develop specific crisis interventions
Rapidly identify crisis situation	Acute medical management
Assess nature and degree of child and family stress	Acute psychiatric management
	Psychiatric consultation
	Independent disposition planning

Table 129.1. Childhood/Adolescent Psychiatric Emergencies: Emergency Physician Responsibilities

Another important skill of the emergency physician involves the ability to obtain and assess relevant information about the child, family, and their community supports. This topic is covered subsequently in the section “Evaluation of

Psychiatric Emergencies.”

Family Responsibilities

A childhood psychiatric emergency implies a limitation of effective interaction between the child and his or her caretakers. In our society, the child's caretakers have the major responsibility for promoting growth and development. In many instances, the child's caretakers are his or her parents, but, in some situations, grandparents, extended kin, foster families, and state agencies have legal custody of the child. The emergency physician must establish who the child's actual caretakers are and try to involve as many of them as possible in the ED. When evaluating the child, the caretakers, and their relationships with each other, the emergency physician should assess the degree to which the parents (or other caretakers) are meeting the following responsibilities:

1. Ensure the physical and emotional safety of the child. Parents need to protect the child, as much as possible, from external danger (e.g., getting lost, walking into traffic, going off with strange adults) and from internal family danger (e.g., neglect, physical and emotional abuse, sexual abuse). If safety is not provided, the existence of the child may be jeopardized.
2. Provide support and nurturance, especially to younger children, such that an emotional bond is established between child and parent. When such an attachment is present, the child desires parental approval and usually responds to parental authority.
3. Provide enough socialization to set limits on the child's behavior. The physician should assess whether the limits chosen are appropriate, too rigid, or too weak.
4. Promote the child's efforts in age-appropriate tasks, including consistent school attendance and performance, learning to relate to peers, and assuming greater autonomy within the family as the child grows older.
5. Instill a sense of competence and mastery in the child at each developmental level. This accomplishment allows the child to successfully integrate new knowledge and new experiences.
6. Assist the child in coping with unexpected failures and losses, including academic disappointment, family disruption, and disability resulting from physical illness.

By keeping these family responsibilities in mind, the emergency physician can assess families in crisis, determining which functions are being met and which need to be supported.

Working with Strengths

The emergency physician working with a family in crisis must look for problem areas, as well as areas of competence in both the child and family. These areas of strength form the basis for a successful treatment plan that enables the family to master the crisis. Typically, families in a crisis do not use their existing abilities enough as they pursue a narrow range of responses to the problem at hand. Through history-taking, observation of family interaction, and assessment of the way that the family relates to the physician, the physician can identify the family's assets. Once recognized, these skills enable the parents to be more confident and competent in dealing with their child. A family that has successfully reared its children until now should also be able to respond effectively to new challenges that the children present. A family that has successfully dealt with aggressive behavior in a child in the past can use some of that previous experience in responding to the current crisis. A family with a disruptive or destructive child that successfully has brought the child to the ED, where he or she sits quietly, has more parenting skills than members may realize. The emergency physician should help the family recognize its capabilities at a time when confidence is at its lowest level.

EVALUATION OF PSYCHIATRIC EMERGENCIES

The evaluation of acute psychosocial emergencies can be divided into five sections (Table 129.2). Orienting data and relevant history indicates the general living situation and previous psychosocial adaptation of the child or adolescent patient. It also provides a complete description of the current crisis, including apparent precipitants. Medical history and physical evaluation determine the child's current physical status. The mental status examination of the child provides information about the patient's current psychological well-being. A family evaluation, using both history and observation of the family's behavior during the ED visit, enables the physician to determine the family's ability to respond to the child's distress. By integrating these sources of information, the emergency physician is well-equipped to understand the crisis and to pursue appropriate treatment alternatives.

1. Orienting data
2. Relevant history
3. Medical history and physical examination
4. Mental status of the child
5. Family evaluation

Table 129.2. Childhood/Adolescent Psychiatric Emergencies: Categories of Necessary Information

Orienting Data and Relevant History

Psychosocial orienting data, as shown in Table 129.3, provide information that enables the physician to appreciate the basic living situation of the child and family. This information can be quickly obtained and includes the child's age, sex, and race; the child's grade in school and type of classroom setting; and the address and type of neighborhood where the family lives. Family composition includes who lives at home, what their relationships are to each other and to the identified patient, and who are the primary and secondary caretakers.

Age of child, sex, race
Grade in school, name of school, classroom setting
Family address, type of neighborhood, parental occupations
Family composition
One- or two-parent family; approximate ages of parents
Siblings of patient and their ages
Other family members, if any, living in the home
Other significant relatives and caretakers

Table 129.3. Childhood/Adolescent Psychiatric Emergencies: Orienting Data

Relevant history, as shown in Table 129.4, builds on identifying information to provide a more complete description of the problem at hand. Historical information should include a thorough understanding of the current crisis and its apparent precipitants, as well as similar problems in the past and previous psychiatric involvement for either child or family. The recent school performance of the child and the adequacy of his or her relationships with peers and with family members should also be determined.

History of presenting crisis and apparent precipitants
Past episodes or other major psychosocial problems
Psychiatric treatment, past or current, for child or family member
School performance of child
Child's relationships with siblings and peers

Table 129.4. Childhood/Adolescent Psychiatric Emergencies: Relevant History

The history of the current crisis should be obtained directly by asking family members in turn to give their account. Usually, beginning with the parents and other adults in the room is easiest. The physician must also obtain the child's version of the current difficulties. If the family does not provide a coherent history, the physician should guide the interview by interrupting respectfully and asking relevant questions. The physician can ensure a more complete understanding of the problem by periodically summarizing what family members have said and then checking for accuracy. When accounts and opinions differ among family members, this disparity should be made explicit. When important issues such as suicidal thinking and severe depression are not brought up, the physician should inquire about them directly. This inquiry reassures the family that its distress is understood and enables the emergency physician to have all of the relevant information needed for assessment. As the physician gains control of the interview and obtains the necessary information, his or her own sense of confidence in dealing with the crisis will increase.

Medical History and Physical Examination

The child's physical status must be determined during the emergency assessment. Many diseases, as well as acute intoxications, can mimic psychiatric disorders. In addition, psychiatrically impaired children may also have concomitant medical problems. Therefore, the emergency physician must obtain a thorough medical history of the child, including current medication and possible medicines available to the child, followed by a complete physical examination, including assessment of neurologic functioning. This information is used in conjunction with the psychological aspects of the assessment to provide a complete picture of the child.

Mental Status of the Child

Evaluation of the child's mental status takes place throughout the entire ED visit. The mental status examination provides a psychological profile of the child at the same time that it assists in determination of a psychiatric diagnosis. Generally, the physician does not need to perform a formal mental status examination of the child because most of the relevant data emerge from history, the physical examination, and the interactions that the child has with family members and with the physician during the emergency assessment. However, the emergency physician should have a systematic and thorough understanding of the mental status examination, and should follow up areas of concern with more specific questions.

Table 129.5 lists the major categories of the mental status examination. These categories are described as they apply to emergency psychiatric assessment.

Orientation	Speech
Appearance	Affect
Memory	Thought content and process
Cognition	Insight and judgment
Behavior	Strengths
Relating ability	Synthesis of evaluation

Table 129.5. Childhood/Adolescent Psychiatric Emergencies: Child Mental Status Examination

Orientation

The level of consciousness and orientation of the child is the first area of assessment. The child not under the influence of drugs or with severe organic illness should be oriented in all spheres: person, place, time, and situation.

Appearance

The physical appearance of the child reveals important information about both the way the child feels about and cares for himself or herself and the supervising care by the family. The examiner should carefully observe factors such as physical size, personal hygiene, choice of clothes, neatness, grooming, posture, and gait.

Memory

The child's memory can be evaluated while listening to the history and through direct questioning. Impairment of memory in a child is a strong indication that his or her emotional and behavioral disturbance may have an organic cause.

Cognition

Intelligence, fund of knowledge, and the ability to think and reason are evaluated while talking with the child. Intelligence and fund of knowledge need be categorized only as adequate or inadequate for the child's age.

Behavior

The child's behavior can be observed throughout the visit. Activity level may be at the appropriate age level and goal-directed, too rapid and random (hyperactive), or too slow and diffuse (psychomotor retarded). The child may appear well-focused, or may be distractible. Behavioral tendencies are revealed in the child's talking with the examiner and in interactions with various family members. Psychotic youngsters may respond to people as objects and use objects in non-directed, bizarre ways. Nonpsychotic children may behave in angry, aggressive ways that can usually be distinguished from the behavior of psychotic children by its negative or resistant nature. The child's ability to control his or her behavior in response to the examiner's or family's request should be carefully noted.

Relating Ability

The child's capacity to relate to the examiner is a key element in the mental status evaluation. In a sense, the examiner is a window to the outside world, and the degree to which a positive relationship can develop during the assessment suggests the child's current capacity for forming relationships in general. The examiner should be concerned with what occurs at any moment during the evaluation and, even more important, how the interaction evolves during the course of the visit. The following questions should be considered: 1) To what degree does the child offer eye contact and speak spontaneously? 2) How trusting does the child appear to be, and to what degree does the child appear to desire the examiner's approval? and 3) On the other hand, is the child too friendly and open, suggesting extreme neediness? The child's cooperativeness and tendency to alter his or her mood in response to the examiner's encouragement are important components of his or her capacity to relate.

Speech

Speech includes elements such as spontaneity, coherence, articulation, and vocabulary. As such, the category of speech overlaps with the capacity to relate, the quality of thought processes, and the level of intelligence. Poor vocabulary and articulation may suggest mental retardation, psychosocial deprivation, specific language disabilities, or combinations of these.

Affect

The child's affect, as the external manifestation of predominant feeling states, is assessed informally during the course of the interview. Fluctuations of affect according to changes in content and interactions should be carefully observed, with

more serious concern raised by children whose affect does not change as different subjects are discussed. Depressed children may show both sad and angry affect, which suggests the way in which the child sees both self and the external world. Some angry children express their anger directly, even in the form of rage. Other children become so well-defended that their affect appears flat and constricted. Frankly psychotic children, in addition to blunted affect, show an inappropriate response to internal and external events, such as smiling while serious topics are discussed.

Thoughts

Thoughts include both thought processes and thought content. The evaluation of the preceding categories necessarily yields much information on thinking. Thought process involves the coherence and goal directedness of verbal communication. Evasiveness and guardedness must be distinguished from the looseness of associations of the psychotic child or adolescent. Loose associations have no logical coherence or connection with previous statements. Flight of ideas, as found in bipolar disorder, involves rapid shifting from one topic to another, often triggered by the patient's ongoing monologue. Thought content involves the major themes that emerge as the child talks spontaneously and responsively to the examiner. If themes of violence and insecurity are present, are other more hopeful and positive themes also present? Such information can often be obtained by eliciting fantasy material, such as three wishes, personal goals, and views of the future. Self-concept, when low, may become apparent as persistent themes and fantasies are pursued. Thorough screening also involves determining the possible presence of psychotic phenomena (hallucinations, delusions, grandiosity, and ideas of reference) and present or past tendencies toward suicide or homicide.

Insight and Judgment

Insight involves the degree of recognition and acknowledgment of current problems by the child. A child with a high degree of insight can also identify possible precipitating factors. Judgment involves the child's ability to think before acting. Over the course of the interview in the ED, the examiner can assess these elements informally.

Strengths

The purpose of any child's mental status examination is not only to screen for possible deficits, but also to search for strengths and areas of competence in the child. Thus, the examiner must determine areas of interest, competence, and motivation of the child. These strengths may go undiscovered unless specifically looked for. Thus, the role of the evaluation extends beyond assessment; it also involves, through the identification of strengths, the beginnings of positive interventions.

Synthesis

After the component parts of the mental status examination have been determined, the physician should integrate them into a comprehensive picture of the child. For example, a 14-year-old boy presents to the ED fully alert and oriented, but disheveled and malnourished. His cognitive abilities appear to be intact, but his actions are slow and labored. The child's thinking shows no evidence of incoherence, but themes of disappointment emerge from the conversation. The boy relates to the physician in a withdrawn manner, and appears to be preoccupied. The data from this mental status examination suggest that the adolescent described is depressed. This impression should then be integrated with historical, medical, and family information as the examiner plans appropriate treatment.

Family Evaluation

Physicians, while performing emergency assessments, explaining results of evaluations, and developing treatment plans, typically deal with both the ill child and his or her family. Recommendations depend in part on the physician's impression of the family and of how effectively the family will carry out the required treatment. To assess families, the physician needs to have an organized framework to guide the evaluation process (Table 129.6). The goal of a family evaluation for childhood psychiatric emergencies is to determine the methods that the family uses to help its members when distressed, the adequacy of these efforts, and the possibilities for new alternatives that will help the family cope successfully with the current crisis. In obtaining the history from the family and proceeding with the assessment, the emergency physician should keep in mind these specific aspects of family functioning so that he or she can evaluate the family systematically during the ED visit. When conducting the interview with child and family, the emergency physician is encouraged to remember that, despite the disruption caused by the crisis, families know their child the best and can often collaborate effectively with the medical staff. When the physician approaches parents as partners, the likelihood of positive outcomes is maximized.

Signs of Competence and Strength	*Danger Signs with Parents/Caretakers*
Level of concern	Psychosis
Verbal communication	Intoxication/drug abuse
Problem-solving ability	Depression
Relationships	Violence
Parents and child	History of abuse (physical, emotional, sexual) and/or neglect
Parents or caretakers	
Parents and physician	

Table 129.6. Child Adolescent Psychiatric Emergencies: Family Assessment

Family Mental Status

Just as it is important to know the child's mental status, the emergency physician must also determine the mental status of the rest of the family. This task can be accomplished as the physician observes the family members and listens to their presentation of the history. The history should be coherent and logical, and should follow a temporal sequence. Families that do not present an organized history may have serious difficulties resolving crises. Family members under the influence of drugs or alcohol may not be fully alert and oriented. Their history may not be clear. Depressed parents appear withdrawn and downcast. They may be so preoccupied with their depression that they do not focus effectively on the child's problem, or they may describe the problem in extremely hopeless terms.

Although anxiety, distress, and even anger may be appropriate responses to a psychiatric emergency, parents should be able to use the physician's support to control these responses so that the crisis can be approached systematically. When this cooperation does not occur, the emergency physician should consider psychiatric consultation. Other indications for psychiatric consultation include the presence of psychosis or other severe psychiatric disturbance in a parent or caretaker. When the family presents a disorganized history, the physician can indicate that he or she is confused and ask for clarification. The physician can also suggest that only one person talk at a time, and can repeat the history given and ask the family to confirm it. When these attempts to provide structure to the family fail, psychiatric consultation is needed.

Hierarchy and Leadership in the Family

The family is a social system that requires acknowledged leadership that is consistent and whose direction is followed. In American nuclear families, the parents are generally the acknowledged leaders, with the responsibility to set rules that are respected and followed by the children. In many families, grandparents live nearby and help with the children, but they are expected to defer to the parents' plans and approaches. In other families, however, especially single-parent families, a grandparent may function as caretaker while the parent is away at work and the parenting responsibility is shared. For effective collaboration to occur, the specific roles for each caretaker must be explicit and agreed on.

In two-parent families, specific parental roles and expectations must also be made explicit. In this way, undermining of one parent by the other is avoided and family rules are enforced consistently. Children are allowed to voice complaints, with the understanding that the parents are the final arbiters. In providing leadership, the parents use both closeness and distance in relation to the child at different times. The relationship between any parent and child involves closeness—the ability to be loving, nurturing, and supportive—and also involves distance—the ability to set and enforce limits and the willingness to allow the child some independence.

The emergency physician should be concerned when either excessive closeness or excessive distance characterizes the relationship between parent and child. An overly close relationship between parent and child may interfere with the parent's ability to establish and enforce rules. The parent may hold back either because he or she is unable to get angry at the child or because he or she fears upsetting the child by taking a firm stand. Overly close relationships are common in single-parent families, but may occur in two-parent families as well. Such relationships may be revealed in the ED when child and overinvolved parent are sitting close to each other (and apart from other family members, if present), when the parent answers for the child or describes how the child feels rather than encouraging the child to speak for himself or herself, and when the parent uses the pronoun “we” while describing difficulties pertaining to the child individually.

The emergency physician can assess an overly close parent–child relationship in several ways. He or she can suggest that child and parent not sit so close to each other or can have the child switch seats with another family member. The physician can ask parental permission to speak with the child in the presence of the family, with only the child speaking for himself or herself. The physician can point out the nature of the overly close relationship to the other parent and ask whether this situation is of concern to the less involved parent. When these interventions fail, psychiatric consultation is in order.

Excessively distant relationships occur in some disorganized families when parents are so involved with their own problems that the needs of the child are overlooked. In such families, the child is given more autonomy or responsibility than is appropriate for his or her age, and rules are either nonexistent or enforced inconsistently. Such families may be unable to focus on the child's problem. The parents may be primarily concerned about the effect of the child's problem on their lives, and less concerned about the child's distress. The child may be scapegoated by the parents as the source of all the problems. Statements by such parents include, “Why are you doing this to me?” “I have better things to do than to be in the emergency room with you,” and “If it weren't for you, things would be going smoothly.” Disengaged or underinvolved parents may also appear apathetic and unresponsive to the child's disturbed behavior.

In responding to an underinvolved family, the emergency physician should create an intensely serious mood and emphasize the gravity and danger of the situation. The physician can appeal to positive parental instincts, conveying a belief that the parents want to do what is best for their child. In some cases, this approach creates a tone that enables family members to actively respond to the child's distress. In other situations, however, the caretakers remain unresponsive. When this happens, psychiatric consultation is required and hospitalization may be necessary.

Protectiveness versus Autonomy

All relationships can be placed on a continuum of involvement, with intimacy at one pole and disengagement at the other. Effective parenting requires avoidance of the extremes and the capacity to shift from one position to another at different times and in different situations. As previously described, some families have an overly close relationship between the child and one parent. This situation may occur in any family in which significant conflict occurs between the parents or between parent and other caretakers (e.g., grandmother). In addition, overinvolvement with a child may occur in families

with a special child, such as one with a physical handicap or chronic physical illness. Parents in such families may be overprotective of the child, assuming functions and speaking for the child. Overprotectiveness toward the child may involve primarily one parent or may involve the entire family. In such families, conflict is often avoided so the child does not get upset. The child also may avoid disagreement out of concern for his or her parents. A consequence of parental overprotectiveness is diminished autonomy on the part of the child, who tends to be more involved with adults than with peers. In such situations, the child's development of independence is often significantly delayed.

Underinvolved families, on the other hand, provide insufficient protection and support for the child. The child learns not to expect parental support and may present as under-socialized, with a conduct disorder, or as depressed and possibly suicidal. The child may also present as an overwhelmed “little adult.”

With overprotective families, the emergency physician can assess the family's flexibility by suggesting that the child speak for himself or herself and that the parents increase their expectations. When the overprotectiveness is rigid and severe, the physician may request psychiatric consultation as a way of initiating ongoing therapy for the family. With disengaged families that fail to respond to the physician's statement of urgency, psychiatric intervention should be pursued.

Conflict Resolution versus Conflict Avoidance

All families have disagreements among their members. In some families, disagreements are acknowledged and confronted directly, whereas in others, potential conflict is consistently avoided. Other families disagree openly, but are unable to reach a constructive resolution. The capacity of the family for conflict resolution is an important area for the emergency physician to assess because unresolved disagreements typically lead to chronic hostility, undermining of relationships, and ineffective parenting. Families that tolerate and resolve disagreements are usually more open in their discussion of family problems, whereas conflict-avoiding families use a great deal of denial. In some families, the presence of conflict becomes apparent as the history is given. Family members provide differing accounts of the history and may interrupt and contradict each other. The tension in the room increases, and the physician may start to feel anxious. In such circumstances, the emergency physician can indicate the need to hear from each family member one at a time and suggest that everyone take a turn. The physician can also summarize the family's account as he or she goes along, confirming information at the same time that tension in the room is controlled.

Families that are unable to resolve conflict often have significant marital problems. The parents, unable to deal effectively with each other, instead become overinvolved with one of the children. The child may have a chronic illness, may be either the oldest or the youngest, or may be chosen for another reason. The child gets caught in the marital struggle of the parents, in part through their efforts and in part through his or her own desire to remain close to the parents and keep them together. This child often develops physical and psychiatric symptoms and may present to the ED with the family.

The emergency physician may observe several possible patterns of conflict avoidance. The parents may agree that the only problem in the family is the child, and that, were it not for him or her, everything would be fine. However, the physician notes that the parents do not look at each other or talk to each other. Their one common ground of agreement is the scapegoated child and his or her symptoms. In a related pattern, the parents suppress all conflict by focusing excessive concern on the symptomatic child, who is seen as vulnerable and weak. This reaction often occurs in families with a child with psychosomatic symptoms, where the child is overprotected and his or her symptoms are typically exacerbated by family conflict. The third pattern involves parental focusing on the child and his or her symptoms as the battleground for overt parental and spouse disagreements. The parents deny the existence of any disagreements except those related to the identified patient, about whom they disagree openly and angrily.

The emergency physician should request psychiatric consultation when inability to resolve conflict has seriously impaired the functioning of the family and the child. Psychiatric involvement should also be sought when patterns of conflict avoidance occur in conjunction with other aspects of family adaptational problems described in this section.

Capacity for Problem Solving

Families in crisis usually try to solve their problems by attempting the same solutions over and over again. They perceive other remedies as currently inaccessible or impossible. As a result, the family's repertoire of behaviors becomes extremely limited and responses to problems become stereotyped and rigid. As the physician pursues historical information and observes the family, he or she looks for signs of flexibility and strength. The physician asks about the family's previous attempts to solve the presenting problem and seeks the family's ideas on how to approach the difficulty now. When offering observations, the physician notes whether the ideas are accepted or rejected. When asking family members to behave differently now, the physician observes how hard they try to change and evaluates the probability that these changes will enable the family to manage the crisis.

Disagreeing parents must find a way to put aside their differences in the interest of the child and the family. These parents must develop a mutually acceptable plan for responding to their child's problematic behavior. Thus, the parents must soften rigid and polarized positions, when these are present. For example, a father who harshly states that the child needs strong punishment and a mother who is adamant about not upsetting the child must both change their positions. The emergency physician tries to help the parents find an acceptable middle ground so that they can resume control of their family. When these attempts fail, psychiatric consultation should be sought.

Relating to the Physician

The emergency physician should rely substantially on his or her overall impression of the family and how members relate to him or her. Do family members maintain eye contact with the physician, or do they avoid looking at her or him and display guardedness or a sense of hostility? Families that accept the physician's expression of interest and concern are more likely to benefit from the ED visit. Families that are suspicious of the physician's motives and unresponsive to his or

her input probably gain less from emergency interventions. Emergency physicians need to recognize that those families that antagonize them the most may also be the families most in need of the physician's (and the psychiatrist's) interventions. When feeling anger toward the family, the physician must decide if these feelings should be expressed. For example, the physician may feel offended by a family that repeatedly criticizes a child whom he or she likes. He or she may want to rebuke the family for being unfair and want to defend the victimized child. However, such feelings, if acted on, would only compound the problem because the family might disqualify the physician and single out the scapegoated child even more when the physician is no longer present. On the other hand, in other circumstances, expressing feelings may be extremely helpful. For example, the physician can convey to parents a concern that his or her ideas are being disregarded and suggest that they be considered more fully. Such a statement may lead the family to reconsider the validity of the physician's statements.

Using Social Support

Some families come to the ED feeling isolated, overwhelmed, and exhausted. Often, such families have not used all of the family and community resources available to them. Effective crisis intervention for psychiatric emergencies involves not only emergency treatment but also effective disposition planning for the family. The ED staff should determine what community resources are available, or potentially available, to the family. The parents should be asked about relatives or neighbors who might be able to help them. Families that have previously mobilized community supports should be commended by the emergency physician for their competence and resourcefulness. This support by the physician often stimulates the family to recognize its capacity to address the crisis.

Integration

In following the aforementioned guidelines for family evaluation, the emergency physician obtains the necessary data for understanding the family in crisis. By integrating the history, the physical examination, the child's mental status, and the family assessment, the emergency physician is better able to understand the nature of the current crisis and the appropriate responses. However, effective intervention involves more than understanding. The emergency physician needs to offer information and recommendations in a respectful manner that conveys his or her recognition of the family's competence and its desire to help the child.

DEPRESSION

Background

The appreciation of depression in children and adolescents as a highly significant problem has increased greatly in recent years. *Depression* can refer to the symptom of feeling sad but most appropriately describes a symptom complex or syndrome that includes cognitive and physiologic components in addition to affective ones. Depression implies more than momentary sadness, and involves a pervasive inflexibility of sad mood, accompanied frequently by self-deprecation and suicidal ideation. Depression also implies a change in functioning from an earlier state of relatively good adjustment, rather than a temperamental or personality type.

Because no generally agreed-on definition of depression exists, incidence figures vary according to the definition used, as well as the nature of the population studied. In one study of high school students aged 11 to 15 years in suburban Boston, 33% of these early adolescents were believed to have moderate to severe symptoms of depression. Other estimates put the incidence of depression in children and adolescents in the 20% range. The incidence of depression is higher in children with school problems (including learning disabilities and attention deficit disorder), and in children with significant medical problems. Because most children with depression come to the ED with another chief complaint (e.g., somatic symptoms, school problems, behavior problems), the physician must keep in mind the possibility of depression in all children seen with recurrent or vague somatic complaints.

Considerable evidence suggests that a genetic predisposition exists for depression, particularly severe depression. Depressive episodes may be triggered by environmental events of significance to the child.

The depressed child typically experiences a profound sense of helplessness, feeling unable to improve an unsatisfactory situation. The child may be experiencing frustration and failure at home, at school, and with peers. Negative outcomes reinforce the child's negative self-image, which contributes in circular fashion to more negative outcomes.

Clinical Manifestations

Depression appears differently at different stages of development. In infancy, depression is usually the result of loss of mother and/or lack of nurturance, and is seen as a global interference of normal growth and physiologic functioning. Thus, some of the manifestations of depression in infancy include apathy and listlessness, staring, hypoactivity, poor feeding and weight loss, and increased susceptibility to infection.

During latency, depression can appear as part of a syndrome, or may be masked by other symptoms. Petti describes the two key features in childhood depression as dysphoric mood and self-deprecatory ideation. Dysphoric mood is manifested by looking or feeling sad and forlorn, being moody and irritable, and crying easily. Self-deprecatory thoughts are reflected by low self-esteem, feelings of worthlessness, and suicidal ideation. Depression in this age can also appear as other common symptoms, including multiple somatic complaints, school avoidance or underachievement (including learning-disabled children or children with attention deficit disorder), angry outbursts, runaway behavior, phobias, and fire-setting.

Depression during adolescence is more similar to adult-onset depression. The major symptom is a sad, unhappy mood, and/or a pervasive loss of interest and pleasure. Other symptoms may include a change in appetite, change in a sleep behavior, and psychomotor retardation or agitation. Also present in many depressed teenagers are loss of energy,

feelings of worthlessness or excessive guilt, decreased ability to concentrate, indecisiveness, and recurrent thoughts of death or suicide. Depressed teenagers can also present with somatic complaints, academic problems, promiscuity, drug or alcohol use, aggressive behavior, and stealing. Many teenagers with behaviors such as these are unaware of their depression because it is not on the surface. Others simply deny the painful depressive affect. In talking with these patients about their lives at home, at school, and with peers, the underlying depression usually becomes apparent.

Management

Once any initial medical concerns have been dealt with, the three major goals in the management of depression involve 1) determining suicidal potential, 2) uncovering acute precipitants, and 3) making an appropriate disposition.

The emergency treatment of depression can usefully be thought of as the prevention of suicide attempts. The task of the physician is to carefully determine whether any suicide attempts have been made and whether suicidal ideation is present. The physician should not be hesitant about asking the child about suicidal deeds, thoughts, or wishes. Such questions represent a positive confrontation of the problem of depression and are unlikely to catalyze a subsequent suicide attempt. In fact, questions about suicide may actually provide a sense of relief for the depressed child.

The physician should attempt to determine possible acute precipitants of the current depression to guide subsequent recommendations. The duration of the depression should be determined, as well as the family response. Assessing overall adjustment at home, in school, and with peers is important, as well as looking for the strengths of child and family for use in the treatment plan.

When suicidal ideation is present, the emergency physician should request psychiatric consultation. A decision can then be jointly made regarding outpatient or inpatient treatment. Whether or not suicide is an imminent danger, the task of the physician is to create a sense of hope that things will improve. To achieve this goal, the physician must form a solid doctor–patient relationship with child and family. Outpatient management can be used when adequate social support is present. The parents must first acknowledge the existence of depression in the child and then come to understand that the solution involves a strong commitment on their part, including at times their participation in family therapy. The physician can begin the process by helping the family create a list of areas involving child and family that need to be addressed. Another area commonly needing attention with a depressed child is school. School consultation as therapy begins may provide valuable information about the child and can help the child obtain academic remediation when needed. The emergency physician can inform child and family that school difficulties will be addressed in outpatient therapy.

Psychotropic medication, although not approved by the Federal Drug Administration (FDA) for use in children and adolescents, has been increasingly used in the treatment of childhood and adolescent depression. As an acute intervention, however, the emergency physician should not prescribe antidepressant medication because its desired mood-elevating effects generally require up to 1 month to take effect, and the act of prescribing medication in the ED may decrease the likelihood of successful referral for follow-up mental health treatment.

The emergency physician should be familiar with commonly used antidepressants, which are sometimes used adjunctively in the treatment of depression. In recent years, use of the selective serotonin reuptake inhibitors (the SSRIs) has displaced the tricyclic antidepressants as first-line medications. SSRIs include Prozac (fluoxetine), Paxil (paroxetine), Zoloft (sertraline), and Luvox (fluvoxamine). Advantages of these agents over tricyclic antidepressants include a decreased likelihood of cardiotoxicity, the absence of anticholinergic side effects, and the relative safety of these medications when used in overdose. These medications all require approximately 1 month to take effect. Another commonly prescribed antidepressant is Wellbutrin (bupropion), which is chemically distinct from other agents. A side effect of potential concern with Wellbutrin involves seizures.

Because the older tricyclic antidepressants are still prescribed at times for children and adolescents, and may more commonly be prescribed to a parent by a family physician, emergency physicians should be familiar with these medications, which include Tofranil (imipramine), Elavil (amitriptyline), Pamelor (nortriptyline), Norpramin (desipramine), and Anafranil (clomipramine). If the emergency physician learns that any of these medications have been used in overdose, especially in doses exceeding 10 mg/kg of body weight of the child, the possibility of cardiac arrhythmias should be considered. Other common side effects of tricyclic antidepressants are drowsiness and those resulting from the anticholinergic effects of these drugs, which include dry mouth, constipation, and blurred vision. Cardiac arrhythmias are reportedly less common with Sinequan (doxepin), Ascending (amoxapine), and Ludiomil (maprotiline), none of which are tricyclic compounds. However, drowsiness and variable amounts of anticholinergic effects may occur. Chapter 88 covers the management of specific toxic ingestions.

SUICIDE ATTEMPTS

Background

Suicidal behavior involves thoughts or actions that may lead to self-inflicted death or serious injury. A distinction is made between suicidal ideation and suicidal attempts in which a deliberate attempt to take one's own life occurred.

The increasing trend toward suicidal behavior by children and adolescents is alarming. Table 129.7 provides information on the nature and scope of this problem.

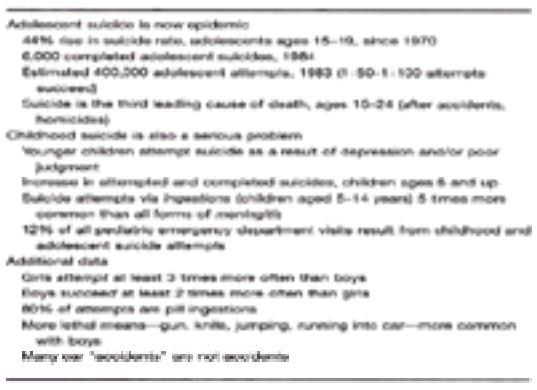

Table 129.7. Childhood and Adolescent Suicide: Nature of the Problem

Suicide can be seen as the final common pathway for a variety of situations in which the child experiences a pervasive sense of helplessness, with a perceived absence of alternative solutions. To the distressed child, suicide appears to be the only solution to his or her problems and also to the family's problems. Most suicide attempts occur in depressed children. Others occur with children experiencing major losses, such as serious illness or death in the family. Still others occur in children with depression in association with problems of impulsivity. A small but significant percentage of suicide attempts occur in psychotic children and adolescents. These attempts may be deliberate (stemming from hopelessness) or accidental (impaired judgment and reality testing). Table 129.8 outlines the potential sources of adolescent suicide attempts.

Table 129.8. Potential Sources of Adolescent Suicide Attempts

A factor that complicates the discussion of suicide in children is their differing conceptions of death at various ages. Up to age 5, death is seen as a reversible process in which the activities of life still occur. From 5 to 9 years, the irreversibility of death is beginning to be understood but death is personified, rather than seen as an independent event. It is not until about age 9 that death is seen as irreversible in the adult sense of being both final and inevitable. Even then, however, the child may imagine his or her own death as being reversible. Under such circumstances, a suicide attempt may have a different meaning from an adult, where suicide corresponds to a definite end of one's life.

Clinical Manifestations

In latency-aged children, certain risk factors have been identified that distinguish children with suicidal behavior from other children with emotional problems (Table 129.9). Suicidal children are likely to be depressed and hopeless. Self-esteem is low, and they see themselves as worthless. The wish to die is present, as are preoccupations with death. The family history may include past episodes of parental depression and suicidal behavior. Suicidal children tend to view death as temporary and pleasant rather than irreversible.

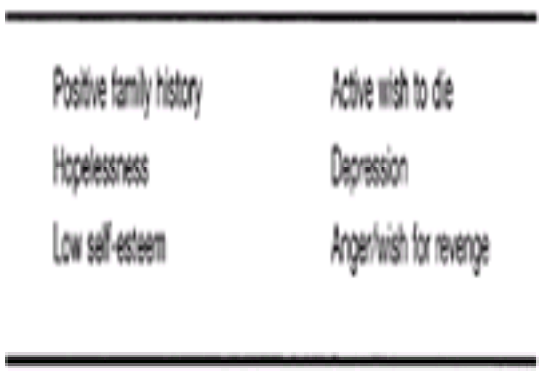

Table 129.9. Characteristics Associated with Childhood and Adolescent Suicide Attempts

Teicher has offered a longitudinal perspective of adolescent suicide attempts, which are usually not simply impulsive

acts. Before the suicide attempt, problems have been present in the family for at least 5 years. These problems include a parent or close relative attempting suicide, many residential and environmental changes, and unexpected separations from meaningful relationships (divorce, separation, or death). With the onset of adolescence, an escalation phase occurs in which frustration results from the teenager's desire for autonomy and the belief that his or her parents do not understand. The teenager withdraws or rebels, becoming alienated from his or her parents at a time when they are really still needed. The scene is then set for the final stage, in which some precipitating event leads to the suicide attempt. The precipitating event may be a peer rejection, the breakup of a romance, an unwanted pregnancy, or problems in school. (It was found that 36% of children attempting suicide were not enrolled in school at the time of the suicide attempt.)

Table 129.10 indicates the high-risk situations for suicidal behavior in which direct questioning about suicide should occur. The first two situations immediately alert the physician to the danger of suicidal behavior. The other situations involve a different chief complaint, masking possible suicidal ideation or behavior. All accidental ingestions should be screened for the possibility of a suicide attempt. Overtly depressed children are at risk for suicide, as are depressed children who present with somatic complaints. Children who have acted violently are also at risk because violence can be turned inward. Psychotic children present a special problem and may present with inadvertent suicide attempts as the result of impaired judgment, hallucinations, and delusions of persecution. The isolated, withdrawn child may harbor suicidal thoughts that are uncovered only by direct questioning.

Suicide attempt just made	Aggressive violent behavior
Suicidal threat made	Psychotic child
"Accidental" ingestion	Significant withdrawal by child
Child complains of depression	
Medical concerns, but child appears depressed	

Table 129.10. Childhood and Adolescent Suicide: High-Risk Situations for Suicide Attempts

Management

Assessment

The emergency physician should specifically ask about suicidal thinking in all high-risk children. When an actual attempt has taken place, the physician should attend to any medical needs such as suturing, lavage, and managing physical repercussions of overdoses. Then he or she should conduct an assessment as well as requesting psychiatric consultation.

The dichotomy sometimes drawn between suicide "attempts" and suicide "gestures" is ill conceived. All suicidal behavior should be regarded as suicide attempts, which are best evaluated by appreciating the medical lethality of the act, the suicidal intent of the child, the impulsivity of the act, and the strengths and supports within the family (Table 129.11). The lethality of a suicide attempt by itself may be misleading because suicidal children may miscalculate, causing at times greater harm than was intended and at other times less harm than was intended (Table 129.12). As an example, the child who takes 10 tablets of his mother's tricyclic antidepressant medication, Tofranil 100 mg, could make a fatal miscalculation, as 1000 mg of Tofranil can cause fatal arrhythmias in children. On the other hand, a child who takes 10 aspirins may be far more suicidal than the lethality of his or her ingestion would suggest. In general, more violent methods of attempted suicide (e.g., hanging, shooting, jumping) usually reflect greater suicidal intent. However, the physician cannot conclude that attempts with low lethality are not serious attempts until he or she has specifically asked about and assessed the child's suicidal intent, that is, just how seriously the child wanted to end his or her life (Table 129.13).

Medical lethality	Impulsivity
Suicidal intent	Strengths/supports

Table 129.11. Assessing Childhood/Adolescent Suicide Attempts: Four Major Dimensions

Vital signs
Level of consciousness
Evidence of drug/alcohol intoxication (e.g., pupils, smell on breath)
Need for emesis, lavage, or catharsis
Acute medical complications (cardiac, respiratory, renal, neurologic)
Indications for medical hospitalization, including intensive care
Residual abnormalities

Table 129.12. Childhood and Adolescent Suicide: Assessing Medical Lethality

Circumstances of Suicide Attempt
Nature of suicide attempt (pills versus violent means)
Use of multiple methods
Method used to extreme (all versus some pills ingested)
Suicide note written
Secrecy of attempt (attempt concealed versus revealed)
Premeditation (long-planned versus impulsive attempt)
History of prior attempts
Child Self-Report
Premeditation of attempt
Anticipation of death
Desire for death
Attempt to conceal attempt
Nature of precipitating stressors
Child's Mental Status
Orientation/cognitive intactness
Presence/absence of psychosis
Manner of relating to physician
Current suicidality
Response to being saved/being unsuccessful in attempt
Active plan for another attempt
Readiness to discuss stressors
Readiness to accept external and family support
Nature of orientation toward future

Table 129.13. Childhood and Adolescent Suicide: Assessing Suicide Intent

In addition to asking directly about suicidal intent (“When you took those pills, what were you hoping would happen?”), the physician should gather as much information as possible about the attempt itself to help infer the degree of suicidal intent on the part of the child. Did the child take all of the pills that were available; did he or she expect to wake up; did he or she tell anyone after taking the pills; did he or she leave a suicide note? Now that he or she is awake, is the child pleased or displeased to be alive? Does he or she intend to try again?

Children who threaten suicide without making an actual attempt should also be questioned carefully about suicidal intent. How long has the child considered suicide; what methods are planned; when will this take place? Has the child ever made previous attempts? How about other family members? Psychotic and depressed children, especially when the parents appear unable to supervise the child, should elicit particular concern.

Assessment of the child's level of impulsivity is also important (Table 129.14). Does the attempt appear to have been impulsive rather than planned? Is there a history of prior impulsive behaviors? Is there evidence of impulsivity during the ED interview?

Evidence of impulsive suicide attempt	Evidence of impulsivity during
History of prior impulsive behaviors	interview

Table 129.14. Childhood and Adolescent Suicide: Assessing Impulsivity

The physician should ask the child and family about possible precipitating events to determine what changes in the environment may be needed. The strengths of the family should be assessed to determine whether sufficient social support exists to allow for outpatient management (Table 129.15).

Strengths and Assets of Child	Nature of External Supports
Ability to relate to physician	Outpatient psychiatric/family physician
Ability to rely on parents in crisis	Extended family
Ability to acknowledge problem	Neighbors/other significant adults
Positive orientation toward future	Religious community
Strengths and Assets of Family	Self-help groups
Commitment to child	
Ability to unite during crisis	
Problem-solving abilities	
Capacity to supervise child (support and limits)	
Ability to use external supports	

Table 129.15. Childhood and Adolescent Suicide: Assessing Strengths and Supports

Evaluation for Hospitalization

No universally agreed-on criteria have been established for when to hospitalize a child with suicidal behavior and when to manage him or her on an outpatient basis. Garfinkel and Golombek have identified seven areas to assess to determine whether hospitalization is indicated (Table 129.16).

Social set	Stress
Intent	Mental status
Method	Support
History	

Table 129.16. Areas to Assess Following a Suicide Attempt

Social set involves the degree of privacy that the child arranged at the time of the attempt. Did he or she tell anyone before or after the attempt, or were pains taken to set up a situation in which detection was unlikely? Intent may be reflected in a suicide note left by the child, by the degree of detail of the suicide plans, and by direct questioning of the child regarding his or her suicidal intent at the time of the attempt and at the time of examination. The choice of method also helps in the assessment of the suicide attempter. Was a method with high lethality used or desired? Did the child understand the likely outcome of the method used? With an ingestion, were all available pills consumed? The history reveals both the presence of past suicide attempts by the child and past attempts by other family members. The evaluation of the stressful precipitating events is important in planning disposition, as is the mental status of the child in the present and in comparison with the past. Finally, the degree of support expected from within the family and outside the immediate family (extended family, neighbors, peers, and teachers) must be assessed. To what degree can the family unconditionally commit itself to support the child's safety and well-being? Are the resources present for the family and larger network to implement this commitment? The decision to hospitalize the child is made when the child's safety is still in doubt after these questions have been answered.

In general, any suicide attempt deserves a thorough assessment by the emergency physician and a complete psychiatric consultation. Hospitalization should be used in the circumstances listed in Table 129.17: 1) the physician has had difficulty in gaining the cooperation of the child and the family, 2) the child has made a serious suicide attempt, 3) the child is continuing to be actively suicidal, 4) the child is unwilling/unable to provide a no-suicide commitment to the parents, 5) the child is psychotic, 6) the family appears unable to provide necessary supervision and support to the child, and 7) the child and family rapidly deny the significance of a serious suicide attempt.

1. Failure of rapport among physician, child, and family
2. Serious suicide attempt (lethality and intent)
3. Continuing active suicidality
4. Inability to provide no suicide commitment to parents
5. Psychosis of child
6. Divisive/disturbed family, incapable of support and supervision
7. Rapid denial of significance of suicide attempt

Table 129.17. Indications for Psychiatric Hospitalization Following Childhood/ Adolescent Suicide Attempt

Initiating Treatment

The critical goal in dealing with suicidal behavior in a child is to create a context for living—an immediate response to the crisis that increases the likelihood that the child remains alive. The emergency physician creates a context for living through his or her thorough assessment of child and family, the eventual disposition, and the encouragement of family and child to increase communication and develop alternative solutions to problems that have arisen.

The parents should be encouraged to tell the child that they want him or her to live and that suicidal behavior is forbidden. Parents can be tender in expressing their love for the child, but they need to be firm in establishing the rule that self-destructive behavior is an unacceptable response to problems. The child should also be told that he or she has a responsibility to himself or herself and the family to keep himself or herself alive. The emergency physician may need to remind tentative parents that, whether or not hospitalization is used, they still have primary responsibility for their child.

A critical moment occurs when the parents, guided by the emergency physician, ask the child to make a no-suicide commitment, also known as a safety contract. This commitment signifies the child's promise to the parents that he or she will not try to harm himself or herself again, no matter how upset he or she is. Instead, the child will seek out the parents or another responsible adult for assistance.

The emergency physician should recognize the common tendency toward denial by the child in the ED after the actual suicide attempt. As a result of this denial, or in an effort simply to appease the parents, the child may make an insincere no-suicide commitment. Therefore, when this commitment is being made, parents and child should discuss it so that parents can determine the real intentions of the child and convey the urgency of the no-suicide commitment.

Although a no-suicide commitment is not always sufficient to avoid psychiatric hospitalization, sending any child home when an earnest no-suicide commitment has not been given and accepted is potentially hazardous.

If inpatient treatment is required, the child and family should be informed about how the hospital operates and what to expect. The goals of the hospitalization should be discussed, and the active role of the family in the treatment emphasized. In many states, voluntary consent forms need to be signed. In instances in which the child or parents do not agree to hospitalization, involuntary commitment may need to be used, although every effort should be made to enlist the concurrence of the parents first. When possible, the child and family should be accompanied to the psychiatric hospital by the consultant psychiatrist or an involved social worker so that the transition to the psychiatric facility is made smoother.

Outpatient management of suicidal behavior becomes feasible when 1) the child and family are cooperative and engageable; 2) the attempt is determined not to have been too serious, in terms of intent and medical lethality; 3) the child is not actively suicidal or psychotic at the time of the evaluation; 4) the child provides an earnest no-suicide commitment; and 5) the family can take responsibility for the child until formal psychiatric treatment is begun the next work day, and appears capable of managing the child within the home setting as mental health treatment is provided. Before sending a family home, the psychiatrist or emergency physician should have the family formulate a concrete plan concerning how it will manage the child. The expectations and responsibilities of each family member, including the suicidal child, should be spelled out.

Outpatient psychotherapy can begin immediately with emergencies that occur during the work day. When outpatient treatment cannot begin until the next day, the physician should give the family a therapist's name or the name of the “intake person” at the mental health agency. This information personalizes the agency and increases the chances that the family will follow through. The family should be instructed to use the physician's name as the source of referral and should be reassured that the physician will contact the agency before the family's call. At least one parent and the child, if an adolescent, should be asked to sign a release of confidentiality to authorize communication between the physician and the mental health agency. This release also enables the agency or the psychiatrist to contact the family if the family fails to follow through in making an appointment to be seen. Any discussion of suicide must contain careful consideration of prevention. Parents should be given guidelines for the prevention of suicide (Table 129.18) as well as instruction in the early warning signs (Table 129.19).

Understand nature of parent-child dilemma during adolescence
Maintain physical contact—be around, combat tendency toward isolation
Maintain emotional contact—stay involved, show positive regard
Listen to child before responding—promote safety in talking
Respond to child, once child has finished—take child seriously, do not dismiss or attack
Encourage choices by adolescent
Acknowledge child and provide respect

Table 129.18. Prevention of Childhood and Adolescent Suicide: Guidelines for Parents

Withdrawal (peers, parents, siblings)
Somatic complaints
Irritability
Crying
Diminished school performance
Sad or anxious appearance
Significant loss (rejection by peer group, break-up of romance, poor grades, failure to achieve important goal)
Major event or change within family
Casual mention of suicide or being "better off dead"
Explicit suicide threat
Minor, seemingly unimportant suicide "gestures"
Apparent "accidents"
Other unusual behavior pattern—housebound behavior, breaking curfew, running away, drug or alcohol abuse, bizarre or antisocial actions

Table 129.19. Prevention of Childhood and Adolescent Suicide: Warning Signs for Parents

PSYCHOSIS

Background

Psychosis is the term used to describe severe disturbances in a patient's mental functioning. It is manifested by significant aberrations in cognition, perception, mood, impulses, and reality testing. Thoughts and feelings are not well-integrated, and acted upon, perceptions may become distorted so that the world is seen as threatening, and mood may become ecstatic or despondent. Behavior may also become extremely agitated and potentially violent, or excessively withdrawn to the point where the patient does not recognize and attend to his or her physical needs. Psychotic patients are actively attempting to regain control over their mental capacities and are trying to understand and deal with highly unusual thoughts, perceptions, and impulses. Their subjective experience often is one of helplessness and extreme anxiety.

Psychosis in children and adolescents can be divided into two groups based on cause: organic psychosis and psychiatrically based psychosis. Psychiatrically based psychosis in children and adolescents has four major causes: 1) autism with onset before 30 months of age, 2) other pervasive developmental disorders with onset between 30 months and 12 years of age, 3) adult-type schizophrenia with onset in adolescence, 4) acute reactive psychosis, and 5) bipolar or manic–depressive illness with onset in late childhood or adolescence. Emergency management of organic psychosis and the four major types of psychiatrically based psychosis is described in the following sections.

Organic Psychosis

Differentiation of organic psychosis as a separate class does not imply that other (psychiatrically based) psychosis is completely independent of brain processes. On the contrary, all psychosis is assumed to be associated with aberrant brain function. The term *organic psychosis* merely implies that the cause of the aberrations in mental functioning is known and resolution of the psychosis depends on improvement in the underlying organic problems. Psychiatrically based psychoses, on the other hand, are those in which specific organic causes have not yet been determined (Table 129.20). The causes of organic psychoses can be acute or chronic illnesses, trauma, or intoxications with an exogenous substance (Table 129.21, Table 129.22 and Table 129.23).

Assessment Feature	Organic Psychosis	Psychiatrically Based Psychosis
History		
Nature of onset	Acute	Insidious
Past illness/drug use	Prior illness/drug use	Prior psychiatric history (self or family)
Medical evaluation		
Vital signs	May be impaired	Usually normal
Level of consciousness	May be impaired	Normal
Pathologic autonomic signs	May be present	Normal
Laboratory studies	May be abnormal	Normal
Mental status evaluation		
Orientation	May be impaired	Intact
Recent memory	May be impaired	Intact
Cognitive/intellectual functioning	May be impaired	Intact
Nature of hallucinations	Usually not auditory (e.g., visual, tactile)	Auditory
Response to support and reinstitution	Often dramatic	Often limited

Table 129.20. Organic versus Psychiatrically Based Psychosis: Major Differentiating Features

Medical conditions (acute and chronic)
Trauma (acute and chronic)
Prescribed medications (toxicity/side effects/withdrawal)
Drug intoxications
Accidental, including misuse of proprietary medication
Drug abuse/experimentation
Alcohol abuse (alone or with drugs)
Deliberate suicide attempt

Table 129.21. Causes of Organic Psychosis

Central Nervous System Lesions	Adrenal disease (hyper and hypo)
Tumors	Uremia
Brain abscess	Hepatic failure
Cerebral hemorrhage	Diabetes mellitus
Meningitis or encephalitis	Porphyria
Temporal lobe epilepsy	*Rheumatic Diseases*
Cerebral Hypoxia	Systemic lupus erythematosus
Pulmonary insufficiency	Polyarteritis nodosa
Severe anemia	*Infections*
Cardiac failure	Malaria
Carbon monoxide poisoning	Typhoid fever
Metabolic and Endocrine Disorders	Subacute bacterial endocarditis
Electrolyte imbalance	*Miscellaneous Conditions*
Hypoglycemia	Wilson's disease
Hypocalcemia	Reye syndrome
Thyroid disease (hyper and hypo)	

Table 129.22. Medical Conditions That May Lead to Psychosis

Alcohol	Quaalude
Barbiturates	Anticholinergic compounds
Antipsychotics (e.g., phenothiazines)	Heavy metals
Amphetamines	Cocaine and crack
Hallucinogens—LSD, peyote, mescaline	Corticosteroids
Marijuana	Reserpine
Phencyclidine (PCP)	Opiates (e.g., heroin, methadone)

Table 129.23. Exogenous Substances That Cause Psychosis Following Ingestion of Significant Quantity

Clinical Manifestations

The child or adolescent with an organic psychosis presents to the ED in an agitated and confused state. The child's orientation to time and place is often disturbed, and he or she may be highly distractible, with significant disturbance of recent memory. Evidence of bizarre and distorted thoughts is apparent, and disconnected ideas may be juxtaposed. The child may also have significant difficulty controlling behavior and may persist in activities without regard for personal safety. The child may get up to leave the room without saying where he or she is going or why he or she needs to leave. Intellectual functioning may also be impaired, and the child may be unable to concentrate on simple reading or arithmetic tasks.

The child with an organic psychosis may experience visual hallucinations, which may be frightening in nature. Tactile hallucinations may be present. Auditory hallucinations, more common in schizophrenia and manic–depressive illness, are rare in organic psychoses but may occur. As a result of impaired reality testing, organically psychotic children and adolescents are often extremely difficult to control and may strike out at family or staff when attempts are made to control their behavior.

An accurate and thorough history is essential in the evaluation of any child or adolescent for psychosis and is also helpful in appreciating its underlying cause. A complete medical history helps determine whether the organic psychosis is a concomitant feature of an already existing chronic illness (e.g., lupus cerebritis), a result of medication prescribed to treat an ongoing disease (e.g., steroids for lupus erythematosus), or a result of a drug ingestion (e.g., amphetamine psychosis). Typically, an acute intoxication or drug ingestion causes the acute onset of psychosis and represents an abrupt change from the child's previous psychological functioning. The possibility of alcohol use must also be considered in the cause of organic psychosis, and the history should explore the possibility of trauma. In general, no specific features of the mental status examination differentiate the various causes of organic psychosis.

The physical examination is often extremely helpful in both differentiating organic from psychiatrically based psychosis and in determining the underlying cause of an acute organic psychosis. Fever is likely to be present in infections, and tachycardia is often associated with chronic illness or intoxication. The general physical examination gives indications of pulmonary, cardiac, liver, or autoimmune disease, and the neurologic examination assists in the diagnosis of central nervous system disease. Abnormalities of reflexes or of motor, sensory, or coordination systems always require complete neurologic evaluation. Signs of increased intracranial pressure may be indicative of a cerebral vascular accident, central nervous system tumor, or cerebral edema. Signs of autonomic dysfunction, such as pupillary abnormalities, are often indicative of acute intoxication.

In instances of suspected organic psychosis, laboratory evaluation should include a complete blood count, urinalysis, serum electrolytes, calcium, blood urea nitrogen, blood glucose, and complete drug and alcohol screens. Serum, urine, and gastric aspirate should be obtained for toxicology screening. Other laboratory and radiologic studies depend on

abnormalities noted in the history and physical examination. If central nervous disease is suspected, skull radiographs, computed tomography, and a lumbar puncture may be necessary. Liver function studies, thyroid studies, and other specialized and specific laboratory tests may be obtained as required.

Management

Management of the child or adolescent with organic psychosis involves several steps (Table 129.24). First and foremost is diagnosing the underlying cause. Medical treatment is then pursued as indicated for the specific organic condition. Any child with a suspected organic psychosis should be admitted to a medical inpatient unit for diagnostic evaluation and treatment. This treatment is especially important because organic psychosis may be a transitory condition in a child or adolescent whose illness or intoxication is progressive and life-threatening.

Diagnose underlying cause.
Request *immediate psychiatric consultation*, with all psychiatrically based psychosis.
Use *medical hospitalization*, if clinically indicated, with organic psychosis.
Request *psychiatric consultation* with psychotic drug intoxications, either *immediately* or when mental status stabilizes.
Use *quiet room*, *family* and friends, and *constant medical supervision*.
Avoid administration of antipsychotic medication for psychiatrically based psychosis, in emergency department, when possible.
Use *restraints*, if necessary.
Recognize clinical variations of *extrapyramidal reactions* to antipsychotic medications (Table 122.26)

Table 129.24. Guidelines for Management of Acute Adolescent Psychosis

Other important components of the management of a psychotic child involve controlling the child's behavior, preventing injury to himself or herself or others, and alleviating the child's fear and anxiety. This goal should be attempted first through supportive statements indicating the physician's appreciation of the child's condition and his or her distress. Specific instructions to the child (e.g., “Try to relax and look at your mother”) may also be effective. Often, such interventions calm the child, but since the child is distractible and anxious, instructions may need to be repeated frequently.

Antipsychotic and sedative medications affect the child's neurologic status and should therefore be used only when the medical diagnosis is known with certainty and when it is clear that the medication will not worsen the underlying disease process or potentiate the intoxication. (Specific medications and dosages for psychosis are discussed under “Management,” see Table 129.25.) In most instances, when direct behavior control is essential, the child should be placed in arm and leg restraints. While in restraints, the patient should be attended by staff or family members and provided with frequent orienting statements and explanations of the need for restraint.

Generic Name	Brand Name	Estimated Equivalent Dosage (mg)	Total Daily Dosage
Phenothiazones			
Chlorpromazine	Thorazine	100	50–1000
Thioridazine	Mellaril	100	50–800
Trifluoperazine	Stelazine	5	5–30
Fluphenazine	Prolixin	2	1–20
Butyrophenone			
Haloperidol	Haldol	2	2–40
New Atypical Neuroleptics			
Clozapine	Clozaril	75	300–450
Risperidone	Risperdal	—	1–6
Olanzapine	Zyprexa	—	2.5–17.5
Quetiapine	Seroquel	—	150–300

Table 129.25. Antipsychotic Medications

Autism and Other Pervasive Developmental Disorders of Childhood

These disorders are extremely rare, and are approximately three times more common in boys than in girls. Because of the infrequency of these disorders and the chronicity of their course, it is unusual for children with either infantile autism or other pervasive developmental disorders to present in an ED undiagnosed. However, children with these disorders may present in the ED for the treatment of intercurrent illnesses or an acute exacerbation of the child's behavior.

Autism

According to the current psychiatric diagnostic nomenclature (*DSM* IV), autism is one specific type of pervasive developmental disorder (PDD) of childhood. The major differentiating feature between autism and other forms of PDD is the age of onset. Autism always has an onset before 30 months of age. Children with autism have a generalized lack of responsiveness to other people and a failure to develop normal attachment behavior. They do not develop relationships and instead play alone, often showing stereotyped behavior and using objects in bizarre, inappropriate ways. The autistic child becomes extremely upset if objects in his or her environment are disturbed or changed. Language development is

impaired or absent. Only 30% of autistic children have an IQ (intelligence quotient) greater than 70. Some autistic children have underlying illnesses, such as maternal rubella syndrome or previous encephalitis or meningitis, but in many cases the cause is unknown. Many autistic children have coexisting seizure disorders. The course of infantile autism is generally chronic, with two-thirds of all autistic children remaining severely handicapped throughout life.

A comprehensive educational and socialization program with psychiatric monitoring is essential for autistic children. If an autistic child seen in the ED is not participating in such a program, outpatient psychiatric referral is indicated. Medication management of autism at times may involve careful use of psychotropic medication, including neuroleptics, antidepressants, and a-adrenergic agents. Such psychotropic strategies should be used only in conjunction with ongoing psychiatric treatment. Clear justification must be present for psychotropic medication use, not just the diagnosis of autism. In general, acute psychiatric hospitalization is rarely necessary with autism. In instances of extremely disturbing behavior or acute agitation, sedation with either diphenhydramine (1 mg/kg) or chloral hydrate (30 mg/kg) may be helpful. If the parents are distressed by their child's immediate behavior and the child is receiving psychiatric treatment, phone contact with the psychiatrist may be helpful to both the emergency physician and the family. In the absence of ongoing care, a psychiatric consultation should be requested.

Other Pervasive Developmental Disorders

Pervasive developmental disorder of childhood is a generic term that includes other developmental impairments in which an incapacity to form reciprocal relationships with others results in severe, sustained impairment of attachment and social relationships. Other features may include extreme anxiety and severe emotional reactions to minor difficulties, with inappropriate affect and extreme mood lability. Abnormalities of speech, hypersensitivity to sensory stimuli, peculiar posturing, and self-mutilation may also occur. PDD other than autism has onset after 30 months and before 12 years of age.

The term *PDD* incompletely incorporates entities such as childhood schizophrenia, symbiotic psychosis, and atypical psychosis, as well as other recently added conditions. One type of PDD with which the emergency physician should be familiar is Asperger's disorder. Children with this disorder typically have normal or above average intelligence, with a well-developed capacity for speech and language. The impairment is in the capacity to form reciprocal relationships, and emotional rigidity, idiosyncratic thinking, and intense pursuit of a narrow range of interests may be present. Children with Asperger's disorder may be confusing to the emergency physician, because they present as higher functioning than other children with PDD and are not psychotic, yet they may appear to be significantly strange.

All children with PDD, including children with autism, require comprehensive psychiatric and educational treatment. Parents of children with autism and PDD should be given appropriate referrals, because children who receive services early in their development are believed to have an improved prognosis. When necessary, the same acute pharmacologic approaches for children with autism are also relevant for other PDDs. Low-dose thioridazine, a sedating neuroleptic, may also be used. With the acute exacerbation of a child with PDD, psychiatric hospitalization may be necessary, both to provide assistance to the parents and to develop or modify a comprehensive treatment program. Families with acute concerns about their child's behavior should receive psychiatric consultation.

Schizophrenia

Schizophrenia often has its onset in adolescence and occurs in approximately 0.5% of the population. This disorder is equally common in males and females, and is more prevalent among family members of known individuals with the disease. An excess of dopamine activity in the brain is believed to be one feature of schizophrenia.

Clinical Manifestations

Symptoms of schizophrenia involve impairment of basic psychological processes, including perception, thinking, affect, capacity to relate, and behavior (Table 129.26). Impaired thought content includes delusions (strongly held beliefs involving the self with no basis in reality), such as delusions of persecution and external control. For example, an adolescent with schizophrenia may think that others can read and insert thoughts into his or her mind. Significantly illogical thinking occurs. Speech is often characterized by loose associations, in which ideas shift from one subject to another entirely unrelated subject without the speaker recognizing that the topics are not connected. Auditory hallucinations are common and may include direct commands for suicide or for violence to others. Typically, but not always, the voices talk to the patient in the third person, with a highly critical and demeaning message. Affect may be blunted and flat, or inappropriate and bizarre. Sudden and unpredictable changes in mood may occur. These teenagers may appear extremely agitated or may be withdrawn, speaking only in monosyllables and describing only concrete objects. Schizophrenic patients typically have significant distortions of their identity and their abilities, and demonstrate behavior that is not goal-directed.

Flat affect
(Patient uninvolved and without emotion)
Auditory hallucinations
(Physician: "Have you been hearing voices even when no one is there?")
Thoughts spoken aloud
(Physician: "Can other people read your mind? Can you read their minds?")
Delusions of external control
(Physician: "Is anyone trying to kill you? . . . trying to control your mind or your body?")

Table 129.26. Acute Schizophrenia in Adolescence: Most Common Features

Although classified as a psychiatrically based psychosis, schizophrenia often has a strong family history and is considered to be an organic disorder. Families with schizophrenic adolescents may experience difficulties in communication, and relationships between parents and the affected teenager may be superficial and distant. Parents may have noted progressive emotional difficulties in the adolescent before seeking assistance and may be frightened by the teenager's bizarre behavior. At other times, the family may have been concerned about the child for many years, with no definitive understanding emerging before the acute onset of psychosis. Family members require clear explanations of the child's condition and proposed treatment, the longitudinal course of the disorder, and the essential need for their active participation.

The history often reveals a prodromal phase that includes social withdrawal, peculiar behavior, failure to look after one's appearance, and significant reduction in performance in school or work. This phase is followed by an acute phase in which the previously described symptoms develop, sometimes as a result of an acutely stressful event. The overall course of schizophrenia is often chronic and associated with remissions and exacerbations. Exacerbations often occur when treatment, including medication, is suspended. However, other individuals experience a schizophrenic-like acute psychosis and recover completely with appropriate treatment, experiencing no further deterioration.

Management

The management of an acute schizophrenic episode should always take place in collaboration with psychiatric consultation. Patients with suicidal or homicidal ideation should receive psychiatric hospitalization. Psychotic patients from disorganized home environments should also be hospitalized for initial treatment. In general, the approach to the psychotic patient in the ED depends on the condition of the patient and the anticipated site of the ongoing treatment. For agitation and dangerousness, approaches include reassurance and a quiet setting, psychotropic medication, and/or physical restraint. Medication involves a choice between a calming, sedating medication such as diphenhydramine or use of an antipsychotic medication. If the child requires an additional psychiatric assessment at a site different than the ED, such as at a designated psychiatric emergency facility as a precondition for psychiatric hospitalization, antipsychotic medication should be used sparingly, if at all, at the pediatric ED. Use of antipsychotic medication can alter the child's mental status such that, by the time of assessment at the emergency psychiatric facility, the child no longer appears in need of psychiatric hospitalization and instead may be inappropriately sent home.

If the ED is associated with a psychiatric inpatient unit where the child can be admitted, antipsychotic medication can be used in the ED, resulting either in psychiatric hospitalization or the child's return home with the parents with outpatient treatment, depending on the child's clinical response. Haldol (haloperidol) should be used in these circumstances. A conservative approach involves a single dose of 5 to 10 mg haloperidol orally or intramuscularly for adult-size adolescents (approximately 70 kg) or 2 to 5 mg haloperidol (orally or intramuscularly) for smaller children. A more aggressive approach involves the use of these same doses, administered every 3 to 60 minutes up to a maximum dose of 40 mg, until the patient's state of agitation lessens or until he or she becomes sedated. The patient's vital signs, general condition, and possible side effects should be monitored frequently. If the patient does not respond to this latter medication regimen, inpatient psychiatric hospitalization is necessary. If significant improvement occurs, suicidality and homicidality are absent, and side effects do not occur, the patient can be considered for discharge to outpatient psychiatric treatment with careful follow-up, so long as the parents or caretakers are well-organized, appreciate the child's condition, and feel capable of managing the child at home.

Commonly used antipsychotic medications, their trade names, relative potency, and usual dosage ranges are listed in Table 129.25. In addition to long-standing antipsychotic medications (now called typical antipsychotics), which include both phenothiazines such as Stelazine (trifluoperazine) and non-phenothiazines such as Haldol (haloperidol), a new class of antipsychotic medications, called atypical neuroleptics, is being used. Included in this growing class are Risperdal (risperidone), Clozaril (clozapine), Zyprexa (olanzapine), and Seroquel (quetiapine). Clinical advantages offered by this new class of medications include clinical effects on the “positive symptoms” of schizophrenia (e.g., an improvement in the ability of the individual to relate to the environment and to others, not just a positive effect on hallucinations and delusions) and a decreased likelihood of extrapyramidal side effects and long-term tardive dyskinesia. The emergency physician should become familiar with the use of antipsychotic medications in emergency situations. With typical antipsychotics, high-potency agents, such as haloperidol or trifluoperazine, rapidly reach therapeutic blood levels and produce less sedation than low-potency drugs, such as chlorpromazine and thioridazine. However, high-potency antipsychotics have a greater incidence of extrapyramidal effects that can be reversed by administration of the appropriate medication (see following section).

The major side effects of typical antipsychotic medications are extrapyramidal symptoms, including acute dystonic reactions (abnormal muscle tone or posturing), akathisia (motor restlessness), and parkinsonian effects (rigidity, tremor, slowed movement, and loss of balance). Acute dystonic reactions are best treated by the intravenous or intramuscular administration of diphenhydramine (25 to 50 mg), followed by a daily maintenance dose of benztropine (1 to 2 mg/day orally). Adolescents begun on high-potency antipsychotic medication on an outpatient basis should be treated prophylactically with benztropine (1 to 2 mg/day orally) to prevent side effects. Patients placed on antipsychotic medication should be clearly informed of possible side effects and instructed to return to the ED or to the responsible mental health professional should such symptoms develop. Attempts can be made later in treatment to lower the dosage of antipsychotic medication and discontinue use of the antiparkinsonian agent.

Acute Reactive Psychosis

Acute reactive psychosis, a relatively uncommon psychiatrically based psychosis, involves a time-limited loss of reality caused by the accumulated effects of externally imposed traumatic events. Although vulnerability may vary from child to child, children and teenagers can develop acute psychotic symptoms in response to trauma. The diagnosis of reactive psychosis can be made partly by history, but only after a complete medical and psychiatric evaluation has eliminated organic and other psychiatrically based psychoses. The acuteness of the clinical presentation and its precipitating events differentiates acute reactive psychosis from posttraumatic stress disorder.

The clinical picture of acute reactive psychosis varies, in some instances resembling schizophrenia and in others a less defined disorganized state characterized by loss of contact with reality, panic, and specific hallucinations (usually auditory or visual).

Different traumatic experiences, including physical or sexual abuse, rape, homelessness, and running away, may elicit a reactive psychosis. All such situations impose stress on the child and may also disrupt usual patterns of living. Confronted with a new environment and a new reality, the child's familiar cues are absent and confusion or frank psychosis may occur.

The emergency physician should appreciate that most children who present with acute reactive psychosis do not have a permanent psychiatric disorder. The emergency management is similar to that of other psychotic states. Physical and emotional protection of the child is the first priority. The child should be given support and time to reconstitute. Efforts to avoid antipsychotic medication should be made in the beginning, but, when necessary, low-dose antipsychotic medication can be used. When the parents or other caretakers are not implicated in the traumatic events, emergency staff should encourage their active involvement with the child. When the parents are implicated in the trauma or when the facts are unclear, immediate investigation should take place and contact made with appropriate child protection authorities, if indicated.

After emergency treatment, the prognosis of the child depends in large measure on the restoration—or creation—of a safe and dependable family support system. Referral for outpatient family therapy should be made unless the child requires psychiatric hospitalization for further evaluation or treatment. In the absence of adequate family support, some of these children may eventually require foster placement, residential treatment, or other placements.

Manic–Depressive or Bipolar Disorder

Manic–depressive or bipolar disorder occurs in approximately 0.5% of the population. Onset is usually before 30 years of age and occurs during late childhood and adolescence. Because depression is discussed in detail elsewhere in this chapter, this section deals only with manic psychosis, most commonly observed in adolescence, and with the childhood form of bipolar disorder.

Clinical Manifestations of Manic Psychosis

The patient with mania has a distinct period of predominantly elevated, expansive, and irritable mood (Table 129.27). The child has a significant decrease in need for sleep, high distractibility, hyperactivity and pressured speech, and emotional lability. These patients also exhibit what is called flight of ideas—a nearly continuous flow of accelerated speech with abrupt changes from topic to topic, usually based on understandable associations, distractions, or plays on words. Unlike the loose associations of the schizophrenic, the flight of ideas of a manic patient retains logical connection from one idea to the next, but moves quickly from one topic to another. The manic patient may at times have a remarkably inflated self-esteem, with uncritical self-confidence and significant grandiosity. This grandiosity may also include delusional ideas. The individual may be aggressive and combative. He or she may go on buying sprees or pursue other reckless behaviors. Sleep patterns may be significantly impaired, the individual reporting limited or no need to sleep. Manic patients usually have a history of previous depressive episodes, but an acute manic episode in adolescence may be the initial presentation of the disorder. A family history of psychiatric disturbance usually exists in patients with manic–depressive disorder. Typically, manic patients report feeling extremely well, and they are brought to the ED against their will. However, underneath this superficial presentation, the patient has extremely low self-esteem and self-confidence.

Pressured speech	Euphoria
Grandiosity	Anxiety/irritability
Apparent "high" (euphoria)	Combativeness/panic
Rapid shifts of emotion	

Table 129.27. Acute Mania in Adolescence: Most Common Features

The differentiation of mania and schizophrenia in an initial episode of psychosis in adolescence may at times be difficult. Hyperactivity, distractibility, and expansive and euphoric mood are often helpful in identifying manic individuals. Both groups may have auditory hallucinations and delusions, but someone listening to the speech of the manic adolescent

should recognize the flight of ideas and their connection with each other.

Clinical Manifestations of Childhood Bipolar Disorder

Bipolar disorder that occurs in childhood and early adolescence usually looks different than the later adolescent and adult form just described. The child typically presents in the beginning with depression rather than mania and with remarkable shifts in mood, involving sudden changes from depressed to irritable or happy, then back to irritable or depressed. These changes can be disorienting to parents, who cannot understand why the child changes so much and so dramatically, possibly even several times the same day. The sudden shifts in mood and functioning are the reason that childhood bipolar disorder is often referred to as “rapid cycling.” Unlike the older adolescent, the child often does not have a clear recovery from identified episodes but rather may continue to present in at least a mildly unstable way with irritability and anger for much of the time. Approximately 90% of children with bipolar disorder have concurrent symptoms of attention deficit hyperactivity disorder, which may in fact present before the onset of the mood instability.

Management

When an adolescent is suspected of having manic–depressive illness or an acute manic episode, psychiatric consultation should be obtained and psychiatric hospitalization initiated. Involuntary commitment may be necessary. Because the treatment of mania often includes the long-term use of lithium carbonate, which takes time to take effect and which requires careful blood monitoring to assure therapeutic levels, psychiatric hospitalization is necessary. Initial emergency treatment of the agitated manic patient may require the use of restraints and the acute administration of antipsychotic agents, such as haloperidol, in doses equivalent to those used for schizophrenic adolescents. The physician should also be aware that some patients receiving lithium may present with signs of lithium overdose, including nausea, vomiting, muscle weakness, ataxia, tremor, slurred speech, blurred vision, and confusion or somnolence.

Management of the childhood form of bipolar disorder, once suspected and diagnosed, is less likely to involve the need for psychiatric hospitalization, although this is not invariably the case. In the ED, psychiatric consultation should be obtained because these children do best when they receive ongoing individual and family psychotherapy with psychotropic medication. Younger children often respond more favorably to anti-seizure mood stabilizing medications, such as Depakote (valproic acid) and Tegretol (carbamazepine), than to lithium carbonate. However, some children respond more favorably to lithium, so the treatment must be individualized to the child, with careful longitudinal monitoring of blood levels and clinical responsiveness.

POSTTRAUMATIC STRESS DISORDERS

In part to acknowledge the accumulated effect of stress on individuals and also to avoid more invasive diagnoses, psychiatry has invoked the concept of posttraumatic stress disorder (PTSD) with increasing frequency in recent years. Used in the 1970s and 1980s to explain some of the maladjustments of some Vietnam War veterans, PTSD can also occur in childhood and adolescence, typically based on the experience of severe trauma during earlier years. Either the reemergence of the old trauma (or the emergence of a new similar one) or the recollection of the original trauma can activate a PTSD.

A summary of the official description of PTSD in the psychiatric nomenclature (*DSM*-IV) is helpful in understanding this concept:

> The person has been exposed to a traumatic event in which the person experienced, witnessed, or was confronted with an event that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others. The person's response involved intense fear, helplessness or horror, or, in children, disorganized or agitated behavior. In addition, the traumatic event is persistently re-experienced in one or more ways, there is persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness, and there are persistent symptoms of increased arousal.

Highly stressful situations that may precipitate severe emotional reactions by the child and PTSD include: physical beatings and other violence, repeated threats and belittling by adults, long-standing hunger and poverty, sexual abuse, and rape. In some cases, a separate dissociative reaction may occur instead (see following section). With the child, PTSD probably emerges through a combination of traumatic events along with a silent or nonaccepting environment that fails to provide the child with adequate protection and support.

Symptomatically, the child may persistently reexperience the traumatic event in many ways, including recurrent and distressing recollections of the event, which may be observed through repetitive play by young children in which themes or aspects of the trauma are expressed. Recurrent and distressing dreams of the event may also occur. Hallucinations and flashbacks may follow the child's sudden reliving of the experience. In addition, events that symbolize or resemble some aspect of the traumatic event may produce intense anxiety and distress; the connection between precipitating event and distress is not always evident to parents or child.

Other PTSD symptoms experienced by children include generalized numbing of responsiveness to events and people. Stimuli associated with the trauma may be consistently avoided. The emergency physician should also be alert for signs of increased arousal—anxiety and agitation, difficulty falling asleep, irritability or anger, suspiciousness, difficulty concentrating—and various physiologic complaints in response to events that resemble or symbolize the traumatic event.

The key task for the emergency physician is to recognize PTSD in the differential diagnosis of an agitated, confused, or even psychotic child or adolescent. A careful history usually provides clues to this diagnosis. Supportive management in the ED, including using family and friends, often is sufficient. Low-dose antipsychotic medication should be reserved for children who are frankly psychotic and who do not respond to reality-based support. Often, an antihistamine or anxiolytic

medication may suffice.

When parents dismiss or doubt the child's symptoms or worries, the emergency physician can encourage the parents to respond supportively to their child. When the physician suspects parental abuse, this concern must be addressed directly with the family with appropriate authorities brought in, if justified.

Many children with PTSD benefit significantly from individual and family therapy. If child and family are not already in treatment, a referral is appropriate.

DISSOCIATIVE DISORDERS

Some children develop a dissociative disorder in response to extreme trauma. In a dissociative disorder, the child separates the usually integrated functions of identity, memory, and consciousness. As a result, the child's affect appears split off from the rest of the person. Specific symptoms vary, but in most cases, the child appears distant, even weird, but is not psychotic. Dissociative disorders occur most commonly in females, with sexual abuse a common original trauma.

The function of dissociative reactions is believed to decrease the child's awareness of emotional pain caused by the trauma. The process of splitting off the affect from the body may help a severely traumatized child deal with and survive the assault. This response probably begins at the time of the trauma, especially if it occurs repeatedly, then is continued afterward as a form of coping. However, a consequence is that the child may continue to split off full emotional responsiveness to daily experiences, creating a profound isolation. This process may continue into adulthood.

The emergency physician may encounter a child with depersonalization, a feeling of detachment from one's self or a feeling of being an automaton or in a dream. Another dissociative response is psychogenic amnesia, the sudden inability to recall important personal information (or even know one's own identity). Some runaway adolescents may present with a psychogenic fugue, another dissociative disorder. In a fugue state, the individual leaves home unexpectedly with no apparent justification and may at times assume a partial or complete new identity.

The most extreme—and increasingly common—form of dissociative disorder is multiple personality disorder (MPD). In this condition, the child has two or more personalities and appears puzzling to parents, teachers, and physicians. At least two of these personalities recurrently take full control of the child's behavior, with the child unaware of the process. Children with MPD are aptly described as erratic, inconsistent, even mercurial.

The emergency physician should consider the possibility of MPD or other dissociative disorders in all children and adolescents who present in a confused and confusing way. None of these children are psychotic; in fact, an entirely different emotional process is operating. A thorough history is most rewarding and may reveal a female with repeated sexual abuse who often appears far off into her own world. Psychiatric referral is appropriate for patients with MPD. The emergency physician should also determine any possible ongoing abuse before releasing the child to the family.

SCHOOL REFUSAL

Background

School refusal, also called school avoidance and school phobia, entails a child's not attending school and expressing somatic complaints that keep him or her at home. Usually, some somatic complaint is used as the justification for school absence, with the child just “too sick” to be in school. School refusal involves the knowledge and complicity of the family. A parent, usually the mother, is aware of the child's school absence and has endorsed his or her being home, in part because the parent may consider the child to be physically ill.

School refusal is an important condition with which the emergency physician should be familiar. Usually, it is not the initial complaint. Typically, one or more physical complaints bring the child to the ED, and information about school attendance is not offered. The physician must maintain an “index of suspicion” in a child with recurring complaints for which no organic cause is apparent.

On rare occasions, school refusal may be the initial concern of a parent. The mother may bring her child, stating that for a specified time she has been unable to get her child to go to school. Attempts to force the child have been ineffective, either because the child refused to go, got sick in school and was sent home, or caused such family upheaval that eventually the parents gave in. In such a circumstance, school refusal represents a true emergency and should be responded to as such.

There are no specific prevalence figures for school refusal, but the condition is not uncommon. It probably occurs more often than it is diagnosed and may be easily missed. The problem is not confined to a specific population or socioeconomic group and can occur across ethnic, religious, and class lines.

Chronically ill children have been considered high risk for school refusal, although many physically ill children are determined to attend school regularly despite their disability. The child with vague, undiagnosable somatic complaints is more likely to fit the school refusal pattern. So-called vulnerable children and special children may also be in this category. Vulnerable children were ill at an earlier point in their lives, but parental overconcern remains. Special children, such as those born to an older couple who had problems conceiving, were wanted by their parents. The love and attention given to the child can easily yield to overprotectiveness, setting the stage for the development of school refusal. School refusal reportedly tends to occur in families with an orientation toward illness and disability, so it is not uncommon for one or more parents to have past or present illnesses, physical complaints, or hospitalizations. The presence of marital problems may also contribute to the development of school refusal.

Clinical Manifestations

Certain school attendance patterns are suggestive of but not necessary for the diagnosis of school refusal. More absences occur in the fall, when school begins, than in the spring. The child often exhibits a reluctance to return to school after weekends and holidays. There may be a lessening of somatic complaints on weekends and over the summer. Similar sporadic attendance patterns may often be elicited at some other time in the child's past. In other instances, however, school refusal may develop in a child who has previously given no cause for concern. Only specific questions asked routinely of every child and parent about school attendance yield the necessary information. Such questions should be specific, addressing not just recent school attendance but the pattern over the entire year. In this way, the diagnosis is made on the child who misses several days of school per week but still maintains good grades, as well as the more easily diagnosed child who has missed several consecutive weeks or months of school.

Schmitt has formulated a diagnostic triad of the clinical manifestations of school refusal: 1) vague physical symptoms, 2) normal physical and laboratory findings, and 3) poor school attendance. The child may have one or more complaints. Schmitt has also pointed out that many of the symptoms are reflective of depression and anxiety. This finding is consistent with the fact that many children with school refusal are also depressed. The symptoms that may be present include fatigue, insomnia, transient pallor, a smothering feeling (hyperventilation), palpitations, tension headaches, dizziness, syncope, and a variety of gastrointestinal complaints. Most common is nonspecific abdominal pain. Anorexia in the absence of weight loss may occur, as may diarrhea. Nausea may occur with or without associated vomiting. A clue to the psychogenic nature of the vomiting is that it sometimes follows stressful events. The serious complaint of vomiting should not mislead the physician into an overly extensive workup that iatrogenically reinforces disability. Similar considerations apply to the skeletal complaints that may occur—bone pain, joint pain, and back pain. Such tentative diagnoses as “possible rheumatoid arthritis” should be avoided. Other possible symptoms that may mask the school refusal syndrome include chest pain, dysmenorrhea, muscle weakness, coughing, tics, and recurrent sore throats.

Certain characteristics of the family with school refusal have been identified. Berger described four important elements: 1) An overprotective infantilizing attitude toward the patient exists. The child is excused from family responsibilities, and his or her wishes are quickly granted. 2) There is a belief in the physical or emotional vulnerability of the mother. This belief is fostered by the mother herself, who may voice fear of an emotional breakdown and complain of various physical symptoms. 3) The fathers in such families tend to be isolated and devalued. They are seen as disinterested and unreliable, perhaps even as violent. There may be underlying marital tension. 4) It has also been found that, in many families with school refusal, a major change in family composition, often the departure from home of an older sibling, has occurred. This situation focuses new attention on the identified patient.

Other characteristics of families with school refusal have been noted. An illness orientation is revealed by physical complaints in other family members as well as frequent somatic references in verbal communication. The closeness between the mother and child may be manifested by the mother's frequent use of “we” when talking about the child. Active undermining by the parents may at times be observed.

Management

The major responsibility of the emergency physician is the detection of school refusal. The diagnosis is made by having a higher index of suspicion for children with vague somatic complaints and by routinely inquiring about school attendance patterns.

Although the emergency physician cannot guide the entire treatment of school refusal, he or she can get the process going. The physical examination should be done in the presence of the parents in a thorough manner, with the physician emphasizing the absence of physical findings. Appropriate, but not excessive, laboratory work should be performed, and medication should not be prescribed. After acknowledging the genuineness of the child's symptom so that there is no misunderstanding that the child is “faking it,” the physician should provide a firm and unequivocal statement to the family that the child has no serious illness. He or she should then make sure that the family understands what has been said and accepts it. In this way, misunderstandings or disagreements can be confronted directly, thereby decreasing the likelihood of subsequent “doctor-shopping” by the family. The emphasis is then placed on the child's learning to function in spite of his or her symptoms.

Once school refusal is recognized and the possibility of organic disease ruled out, the principal goals in the treatment of school refusal are: 1) getting the child back to school as soon as possible, 2) ensuring continuity of medical care, and 3) addressing underlying individual and family issues that contributed to the development of the problem.

It may be helpful for the parents rather than the physician tell the child that he or she needs to return to school. In this way, the family takes responsibility for the resolution of the problem from the beginning of the intervention. The parents should be encouraged to work closely together to achieve their desired goal.

The emergency physician varies his or her recommendations concerning the child's return to school according to the severity of the problem. Uncomplicated cases of childhood or preadolescent school refusal can be addressed by the emergency physician and psychiatric consultant, and referred to the primary care physician or to a pediatric colleague. With severely depressed or psychotic teenagers, or in situations in which the problem has been long-standing, psychiatric consultation should be followed by a specific mental health referral. The emergency physician should ask the family to identify the responsible physician who will monitor the child's physical well-being over time and collaborate with the therapist. Ideally, minimally disturbed, younger children should return to school within several days' time. A follow-up appointment should be scheduled with either the primary care physician or the mental health professional for the day that the child returns to school. For longer term, more complicated cases of school refusal, careful planning of the child's return to school may be necessary. In all cases, the emergency physician should resist any request by child or family to

sanction or underwrite the child's continued absence from school.

CONDUCT DISORDERS

Background

A child with a disorder of conduct engages in repetitive, socially unacceptable behavior, without evidence of medical or other psychiatric disorder. The diagnosis of conduct disorder implies a continuing pattern of disruptive or deviant behavior, rather than isolated antisocial acts. The behavior may involve violence and aggression (e.g., vandalism, mugging, assault, and rape), or may involve behavior that is socially unacceptable but nonaggressive (e.g., truancy, running away, lying, stealing, substance abuse). Therefore, a disorder of conduct involves more serious behavior than ordinary mischief and pranks of children and adolescents. Because violent and other unacceptable behaviors may be performed by children with medical illnesses and intoxications, these causes must be ruled out before the diagnosis of conduct disorder can be made. Similarly, because children with psychosis and depression can also behave in socially unacceptable ways, these serious psychiatric disorders must also be considered and eliminated before diagnosing a conduct disorder (see Chapter 20). However, even with primary medical and psychiatric causes of socially unacceptable behavior ruled out, some youth with conduct disorder may have ill-defined physiologic predispositions that contribute to its emergence.

Viewed longitudinally, the incidence of youth violence has increased substantially since the 1970s, particularly among African-American males and females, and Hispanic- and Native-American males. The number of youth in detention facilities has increased proportionately. Approximately one in every nine children appear in juvenile court before their 18th birthdays. Delinquent behavior is five times more common in males than in females, and males are more likely to demonstrate violent behavior directed against others.

Society disagrees about whether to regard children and adolescents with conduct disorders as psychiatrically impaired and needing treatment, or as delinquent and needing detention or incarceration. Probably only a small percentage of violent and aggressive children are brought to the ED for psychiatric evaluation. Many are taken by police to detention centers and others engage in their unacceptable behavior without receiving legal or medical attention. No consistent agreement exists about the appropriate criteria for taking such children to an ED as opposed to a juvenile center. In actual practice, certain factors probably influence the choice of disposition, such as age (younger children are more likely to receive medical evaluation), socioeconomic level (middle- and upper-level income children are more likely to be taken to an ED), race (Caucasian children are more likely to be taken to an ED than African-American or other minority children), and nature of the infraction (children with aggressive acts directed outside the family are more likely to be taken to a detention center). Aggressive children should always undergo an emergency medical and psychiatric evaluation any time an intoxication, underlying medical condition, or other psychiatric disorder is suspected.

Clinical Manifestations

Children with conduct disorders typically have poor adjustment at home and in the community. Peer relationships are superficial, based more on what the child can get from the other person than on a sense of empathy. The child thinks primarily about himself or herself, trying to manipulate situations to personal advantage without significant concern for the feelings and needs of others. The child with a conduct disorder is unlikely to extend himself or herself for others when no immediate advantage can be gained. When the child is apprehended, little sense of remorse or guilt is exhibited, but rather a sense of anger at being detected and detained. Such children rarely accept responsibility for their own actions, and instead tend to blame others for their mistakes.

School attendance of children with a conduct disorder is often sporadic, and academic performance is often poor. This may be caused by a variety of factors, including lack of interest and discipline, but may also be caused by specific learning disabilities and a concurrent attention deficit disorder, diagnoses that are remediable but often missed.

The child or adolescent with a conduct disorder shows low frustration tolerance, irritability, and temper outbursts. He or she may be reckless in behavior and project an image of “toughness.” Smoking, drinking, drug use, and precocious sexual activity may all occur. In addition to possible legal difficulties, the child may have other problems, including school suspensions, drug dependence, sexually transmitted disease, pregnancy, and physical injury from accidents and fights.

The presence of a conduct disorder implies a failure of the child's environment to instill familial and societal values and to implement their rules effectively. As a result, the child comes to believe that he or she can act as he or she chooses and does not develop control of impulses. The specific pattern of inadequate limit-setting varies, but families share an inconsistency in enforcing rules and do not hold the child accountable for his or her behavior. In some families, discipline may fluctuate from being perfunctory at times to being harsh and even physically abusive at other times. Parental role models may show poor impulse control themselves and disregard societal norms. In some families, one parent is the enforcer and the other tends to protect and excuse the child; in other families, the parents may shift roles in protecting the child. In these situations, mutual parental undermining enables the child to persist in avoiding responsibility for his or her behavior. As a result, the child or adolescent comes to expect that, somehow, he or she will survive or be excused from any repercussions of his or her behavior.

In addition to inconsistent limit-setting, families of children with conduct disorders tend to be poorly organized, with the roles and expectations of various family members often unclear. Parental separations and divorce, mental illness, and alcohol or drug abuse may also be factors. Parental criminality and incarceration occur in some families. Families with aggressive and impulsive children often do not know how to effectively use social service resources and may consider themselves helpless in controlling their child and in dealing with the world at large.

When taken to the ED, predictably by some outside agent (police, parent, or other caretaker) against his or her will, children with a conduct disorder have variable presentations. For example, the child or adolescent may be angry, hostile,

uncooperative, and even violent, refusing to answer questions directed to him or her, but quick to interrupt to defend himself or herself when others speak. Alternatively, the child may present with a superficially smooth and pleasant facade, hoping to persuade the physician and authorities of his or her innocence. Often, once the child realizes that he or she will not be permitted to act out or manipulate in the ED, he or she may settle down and cooperate more fully. At other times, the child maintains an essentially impenetrable persona.

Management

The goals for managing aggressive and disruptive children in the ED are 1) to ensure the safety of the child, family, and staff; 2) to rule out possible medical conditions and severe psychiatric disorders before making the diagnosis of conduct disorder; and 3) to gather sufficient information to make an appropriate disposition.

The safety of the child and staff and control of the child's unacceptable behavior must be achieved in the ED. In many instances, the disruptive behavior occurred and ended before the child's coming to the ED and gaining the child's cooperation is not a problem. In other instances, however, the child may remain combative and aggressive in the ED. Dealing with such a problem requires the presence of adequate security staff and a quiet space where attempts to control the patient do not disrupt the remainder of the ED. The patient should be told firmly that he or she is in the hospital for medical and psychiatric evaluation and will not be permitted to harm himself or herself or others. The child should be informed of the need to cooperate with the staff and to control his or her behavior. The child's parents, if present, should be asked to assist in controlling the child. The child can be reassured that he or she will get a chance to tell his or her side of the story completely. These interventions usually are sufficient to gain the child's cooperation.

When the child remains aggressive and threatening in the ED, an adequate number of security staff should be summoned. If the child still cannot be calmed, physical restraints should be used. This task is accomplished by several security personnel laying the child down on a cart and applying leather arm and leg restraints with soft cuffs. Often, the external control established by the use of restraints helps the child or adolescent to feel safe and regain personal control. Nonpsychotic aggressive patients do not usually require psychotropic medication, and none should be given until possible medical conditions and intoxications have been ruled out. When needed for children 12 years and older, chlorpromazine (25 mg intramuscularly) can be used, and psychiatric consultation should be sought.

The history and physical examination assist in ruling out medical conditions and intoxications. The presence of ongoing medical conditions should be specifically asked about, as should any recent alcohol use or drug ingestion because substance abuse is common. As indicated, specimens for toxicologic screening should be obtained. Epilepsy can be ruled out as the cause of the abnormal behavior in the presence of a normal neurologic examination and the absence of an aura, abnormal neurologic signs, or postictal phenomena.

The history and mental status examination enables the diagnosis of psychosis or depression, when present, to be made. A history of withdrawal and social deterioration, including disregard of rules and possible cruelty or firesetting, suggests emotional antecedents of the current disturbed behavior. Hallucinations, delusions, and loose associations suggest psychosis, whereas sad affect, crying, and possible suicidal ideation indicate the presence of severe depression.

With this information available, the emergency physician can now consider appropriate treatment and disposition of the patient. Children with medical conditions and acute intoxications are best managed through medical hospitalization. The presence of psychosis or depression requires psychiatric consultation and possible psychiatric hospitalization. Psychiatric consultation should be obtained for children with presumptive conduct disorder and no underlying medical condition. Less severe and complicated cases can be managed through referral for outpatient therapy. More severe cases may require more intensive community-based services, such as partial hospitalization, or even psychiatric hospitalization, which should be considered in cases of severe, chronic conduct disorders, especially when the child's behaviors are escalating and treatment to date has been ineffective. For intervention to be effective with such children, the family must be willing to participate actively, with the goal of altering persistent patterns of disturbed behavior.

The child should agree to follow the rules of the institution and attempt to control violent impulses. The hospitalization can be explained as an opportunity for the child to learn to behave in more socially acceptable ways while the family learns to set limits for the child more effectively.

Involuntary hospitalization may be necessary when the child's condition continues to pose a threat to himself or herself or others, or when overt homicidal or suicidal ideation is present. When the child is not suicidal or homicidal and refuses to make a commitment to work in psychotherapy, and when the family does not support the proposed psychiatric hospitalization, problematic behaviors are more likely to continue and the child may eventually enter the juvenile justice system.

ATTENTION DEFICIT HYPERACTIVITY DISORDER

Background

Attention deficit hyperactivity disorder (ADHD) refers to a syndrome found in school-age children, characterized by a pervasive difficulty in maintaining attention and goal-directed behavior. The condition, previously called hyperkinetic syndrome and minimal brain dysfunction, has been relabeled, “ADHD” because the primary source of difficulty is believed to be inattention. ADHD has an incidence of between 5 and 10% of school-age children, occurring 10 times more often in boys than girls. It is presumed to have an underlying neurologic cause. Some cases of ADHD may be inherited, whereas others may be a consequence of prenatal or perinatal difficulties or of unknown cause. ADHD occurs in up to 50% of latency-age children receiving psychiatric treatment, making it the most common cause of chronic behavioral problems for this age group. The peak age range for referral of ADHD children is between the ages of 8 and 10.

The emergency physician should be familiar with ADHD, because many children so affected become depressed and may

make suicide attempts. ADHD is also common in children with bipolar disorder, and may in fact initially mask the bipolar disorder. During adolescence, ADHD may itself be masked by antisocial behavior, so the physician should always consider the possible concurrence of ADHD in the presence of conduct disorders. Because identification and treatment can produce significant improvements in the clinical picture, the diagnosis of ADHD should not be missed.

Clinical Manifestations

Although some children with attentional problems present without hyperactivity, most children have hyperactivity in association with inattention and impulsivity and therefore fit within the full ADHD umbrella. Wender has described the various possible components of the ADHD picture. Attentional difficulties occur both at home and in school, and are often more severe in school. The child has difficulty fixating attention. This problem manifests itself as an inability to persist for long periods in any activity and, in extreme form, may involve a frenetic movement from activity to activity. Rather than persisting in schoolwork and other tasks, the child often appears not to be listening to the teacher, and discipline may be a problem.

Impulsivity is another essential characteristic of ADHD. The child has difficulty with self-control, exhibiting behaviors that get him or her in trouble with parents, siblings, teachers, and peers. At home, the child typically has outbursts and temper tantrums, and enforcement of discipline may be difficult. Lack of self-control may also manifest through stealing, lying, playing with matches, and other forms of acting out.

Hyperactivity is usually part of the clinical picture, although some children with a subtype of attentional problems are inattentive but not hyperactive or impulsive. As with attentional difficulties and impulsivity, hyperactivity tends to be worse in a group situation than at home or in one-to-one interactions. This characteristic at times creates difficulty in the diagnosis of ADHD because the telltale signs are least likely to occur during an individual assessment by the physician. In one study, 75% of children referred for hyperactivity did not exhibit this behavior in the doctor's office. Therefore, the most important diagnostic clue is the history as related by parents, school teacher, and child. However, the aimless, non–goal-directed quality of the activity rather than the absolute amount of activity distinguishes the ADHD child from a normally active child.

The child with ADHD may have associated neurologic deficits or “soft signs,” but these signs are not necessary for the diagnosis. Up to two-thirds of children with ADHD may have motor incoordination as manifested by deficits in gross and fine motor skills. Impairment of fine motor skills may manifest in inability to tie shoelaces and poor handwriting. Poor eye–hand coordination may be reflected in difficulties with sports, and difficulty riding a bicycle suggests an impaired sense of balance. Various perceptual problems, including right–left discrimination problems, problems with spatial orientation, problems of sensory integration, and problems in processing various types of information, all may be present and may contribute to learning problems. Specialized psychological and educational evaluations are used to detect these deficits.

The child with ADHD may be labile, with fluctuations in mood and a tendency toward overreaction and temper tantrums, but such responses are not always extreme. Appreciating the low self-esteem and possible depression that may be present in these children, as a result of academic failure, conflicts at home, and peer and sibling rejection is important. In acute situations, the depression may find expression as suicide attempts or violent behavior. ADHD children are a high-risk group for self-destructive behavior. The physician often perceives the child's sense of sadness beyond a cocky bravado that masks feelings of frustration and inadequacy.

Family problems are typically found in the families of ADHD children, if only as a consequence of the child's impulsivity and challenging behaviors. The child may provoke the parents, interrupt family members, and fail to learn consistently from experience. The child is often difficult to discipline effectively. Conflicts with siblings may occur. If the parents become overly frustrated by the child, marital strain and blaming may also occur.

Management

The principal responsibility of the emergency physician is to recognize the possibility of ADHD in children who present with other problems—including depression, mood instability, and conduct disorder—and to consider the diagnosis. The physician is then in a position to clarify the meaning of this disorder with the family and to restore hope for the child's improved behavior and adaptation by making a psychiatric referral when indicated. The history is the most reliable diagnostic indicator. Once a presumptive diagnosis is made, appropriate referral and treatment can follow.

The treatment approach to ADHD should be comprehensive and multimodal and is best managed by a child psychiatrist who has a long-term relationship with the child and family. Psychostimulant medication is often helpful in alleviating the symptoms of ADHD. In addition, academic achievement and emotional well-being require attention to the child's individual style of learning and the maintenance of a supportive interpersonal environment. The child should be monitored carefully over time, since some children who present initially with behavior consistent with ADHD develop the childhood or adolescent form of bipolar disorder.

Although psychostimulant medication should not be prescribed in the ED, the emergency physician should have a familiarity with the commonly used drugs, including methylphenidate (Ritalin), D-amphetamine (Dexedrine), pemoline (Cylert), and Adderall (a mixed salt of a single-entity amphetamine product). Tricyclic antidepressants and Wellbutrin (bupropion) have also been successfully used in the treatment of ADHD, but constitute a second line of medication and are not approved by the FDA for this purpose. In general, response rates to the stimulant medications are higher than 75%. Methylphenidate may be given in median effective dosages of 40 mg/day, but dosages as low as 0.3 mg/kg per/day (10 to 15 mg/day) have been effective. A typical dose of D-amphetamine is 20 mg/day. The principal short-term side effects of the stimulants are appetite suppression and insomnia. The principal concerns of long-term use of stimulants are suppression of weight gain and linear growth. However, rebound growth appears to occur when the medication is discontinued. Because the best indicator of dosage adequacy is classroom performance and not behavior at home, close

communication must be maintained with the child's teacher.

Beyond the use of medication, the effective treatment of ADHD involves a multimodal approach with specific attention to identified areas of concern to child and family. If the child is far behind academically, tutoring or other remediation should be pursued. If a diagnostic evaluation discloses a specific learning disability, individualized educational approaches in the regular classroom or in a resource room may be indicated. Individual and family therapy can help the child learn to make accommodations to the ADHD and can help the parents more effectively normalize family functioning while also improving the child's self-esteem and social skills.

DISORDERS OF INFANCY

Excessive Crying

Excessive crying in an infant is a common presenting complaint in the ED. Parents usually learn to discriminate among the various cries of their baby and to respond with appropriate relief and comfort. By the age of 3 months, crying is generally of short duration and a baby is readily comforted. However, in a few infants, crying without underlying physiologic difficulty continues to be severe and intractable. Parents dealing with this symptom are often exhausted and frustrated, and may also describe difficulties in feeding their infants and significant disruptions in their child's sleep patterns.

An appropriate emergency evaluation includes complete medical history and physical examination to rule out underlying physical causes of distress for the infant, as described in Chapter 17. While examining the baby, the physician may note that the child is easily excitable and difficult to comfort.

In young infants, excessive crying has been called colic. Typically, colic can be expected to decrease with time, ceasing by 3 to 4 months of age. In some infants, however, the crying may persist, often with serious disruptions in parent–infant relationships. Parents in these families may be insecure, and their inability to effectively feed or calm their infants may lead to further insecurity, discouragement, and tension. Parents may be further troubled by impulses to physically harm their babies in response to their frustration. Prematurity and prolonged separation between mother and infant may have been underlying factors in the development of the symptom. Families presenting in the ED may feel isolated and have limited support. Other underlying parental difficulties may include disturbed marital relationships, parental depression, and unsupported single parenthood. The disorder itself is recognized by the child's excitability and the parents' anxiety and tension during the ED evaluation.

Management

Appropriate treatment involves first and foremost an appreciation of the situation and the level of difficulty felt by the parents. Supportive acknowledgment by the emergency physician of the stress confronting the parents and of their genuine desire to be effective with their child is usually greatly appreciated. Statements about the specific temperamental qualities of the child and about how common excessive crying is in infancy are also reassuring.

When the parents are not too exhausted and overwhelmed, or when alternative sources of support and caretaking are available to them, the problem can often be managed on an outpatient basis. Parents should be told not to overstimulate their baby and can be shown effective ways of handling and feeding the child. Follow-up well child care should be arranged so that the family receives intensive support from the primary care physician and allied professionals such as nurse practitioners, visiting nurses, and social workers. With this support, the family can become more effective in interrupting the vicious cycle of infant crying, parents becoming tense, and infant crying again.

In other cases, when a high degree of parental tension and exhaustion from the crying is present, a brief hospitalization of the infant may be necessary. Hospitalization should be proposed in a positive way rather than as a sign of parental defeat. The mother should be asked if she wishes to stay with her infant. If she feels an immediate need for rest at home, that is acceptable as long as the mother agrees to participate actively during the remainder of the child's hospitalization. In general, formula changes and the use of medication are not recommended in the emergency treatment of excessive crying.

Sleep Disorders

Infants and young children have varying patterns of sleeping. Whereas most children during infancy and early childhood sleep through the night, some are noted to wake easily and others to need only small amounts of sleep. It has been estimated that up to 20% of 1-year-old children wake regularly during the night. The exact causes of sleep disruption in young children remain undetermined, but low sensory threshold, high activity level, increased irritability, and adverse emotional factors in the home may lead to the development of disturbed sleep patterns. Concern about an infant's sleep pattern may be an underlying reason for ED visits with minor physical complaints. The emergency physician should be alert to the possibility of sleep disorders when evaluating young children in the ED. Because this problem causes significant anxiety and exhaustion in the parents and can lead to disruptions of maternal–infant attachment, sleep disorders should be appreciated and appropriate treatment should be initiated.

Infants with sleep disorders often have difficulties going to bed or getting to sleep and may often be found to sleep in the parents' bed. These children are also noted to be highly active, extremely intense, irregular in their behavior patterns, and difficult to comfort. The physical examination and medical history is noncontributory with an isolated sleep disturbance; however, when evaluating children with sleep problems, the physician must rule out any associated physical difficulties or underlying medical illness. In some cases, a history of perinatal difficulties or prolonged hospitalization following birth may be obtained. Parental depression and insecurity may also be noted during the ED evaluation.

Management

As in the case of persistent crying, the most important part of the emergency evaluation is identifying the problem and conveying to the parents that, with time and appropriate treatment, the child's sleeping behavior will become more regular and less disruptive to family living. Usually, the identification of the problem and the commitment to develop an effective treatment plan are extremely helpful to parents in the ED. Children with isolated sleep disorders rarely require hospitalization, and the initial approach to therapy should again be referral to ongoing primary care with effective social support. Underlying family difficulties or parental depression may require mental health treatment.

Most children with sleep disorders awaken during the night and return to sleep after comforting. Parents should be advised to avoid overstimulation of the child during the night, and sedative medication is rarely necessary. If extreme parental exhaustion is a problem, the possibility of using alternative caretakers should be investigated, and methods of the parents' sharing the care might be suggested. If sedation is viewed as an absolute necessity by the physician, chloral hydrate (30 mg/kg) or diphenhydramine (1 mg/kg) may be administered to the child. Sustained use of sedative medication should be used only as part of an ongoing treatment program for the infant and family. Chapter 131 includes a discussion of other sleep disorders.

Attachment Disorders

Occasionally, infants will be seen in the ED who are noted to be withdrawn and apathetic. These infants demonstrate severe disturbances of attachment with their primary caretakers, often have feeding disturbances, and may fail to thrive. The most significant disability of these children is a dramatic failure of social development. They do not track with their eyes, and they smile rarely. They do not interact with caretakers in age-appropriate fashion, and facial responsiveness may be entirely absent. The child may be noted to be weak, have poor muscle tone, and a feeble cry. The child demonstrates little spontaneous activity, sleeps excessively, and has a generalized lack of interest in the environment.

The cause of attachment disorders in infants is a continuing lack of adequate caretaking. Features that interfere with maternal-infant bonding are often noted in the history. These may include significant maternal depression and isolation, other maternal incapacitation including substance abuse, maternal indifference toward the infant, history of prolonged separation between mother and infant following birth because of perinatal difficulties, and actual physical abuse. Infants who are temperamentally placid, who make their needs known quietly, often have more difficulties in the presence of maternal depression or maternal preoccupation than more active and responsive infants.

Underlying chronic illness may also lead to the development of social withdrawal and apathy. Also, children with physical problems in infancy may be more difficult to care for and parental reactions to the child's illness may interfere with attachment. Children with mental retardation, although they develop slowly, do not generally demonstrate the profound apathy of the child with an attachment disorder. Furthermore, children with mental retardation receive generally adequate caretaking and do not fail to thrive.

Management

Children with attachment disorders require complete medical evaluation together with careful assessment of their environment. Such children are often seen in the ED for minor physical complaints and may not be receiving regular pediatric care. Thus, the emergency physician must recognize attachment disorders and make effective referrals for ongoing health care for child and family. When parental apathy accompanies severe failure to thrive, hospitalization may be necessary to initiate needed changes and to plan continuing treatment. The physician should recognize that attachment disorders and the associated failure to thrive are often reversible once adequate caretaking is instituted and maintained. If the physician suspects that the child's problems are a result of actual abuse or neglect, this belief should be reported to the appropriate agencies. (Child neglect is discussed in detail in Chapter 128.)

FIRE SETTING

Virtually all of the children in our society develop a fascination with fire and may experiment with it at a relatively early age. For most children, this experimentation is transient and consists mainly of playing with matches or lighting small fires. However, some children may persist with fire-setting behavior and may actually plan to set larger fires that are destructive to both people and property. At this point, the child is demonstrating evidence of a significant psychiatric disorder and requires intensive treatment. The exact incidence of fire setting is unknown, but serious repetitive fire setting is believed to be uncommon in children and adolescents. In general, fire setting is a symptom of serious underlying emotional difficulty and is often associated with other disturbances of behavior and impulse control. Fire setting is also associated with significant anger and aggressiveness on the part of the child. The background of fire-setting children is likely to be highly unstable. These children may have had multiple contacts with social agencies in the past, and some may have been placed outside the home in foster homes or institutions. Although the exact percentage of fire setters with underlying ADHD is unknown, many of these children are described as having been hyperactive, with significant learning problems and long-standing truancy from school.

Management

The clinical manifestations of fire setters in the ED are similar to those of other children with conduct disorders as previously described. Effective ED evaluation should always consider psychiatric hospitalization. As psychiatric hospitalization is arranged, the facility must be informed about the child's previous fire-setting behavior so that appropriate behavior monitoring and safety measures can be employed during the admission.

CHAPTER 130

Adolescent Emergencies

JANE M. LAVELLE, MD

Department of Pediatrics, The University of Pennsylvania School of Medicine, and Department of Pediatrics, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

OVERVIEW

The transition from childhood to adulthood is often a tumultuous process. Adolescents struggle to become independent from parents, to adopt a peer group identity, to think abstractly, and to adopt moral and philosophical values. In addition, they strive to accept a sexual identity, to establish meaningful interpersonal relationships, and to work toward long-term life goals. At the same time, dramatic physical growth occurs because of the complex changes in the hypothalamic–pituitary axis and subsequent increased production of the sex steroids. It is not surprising that when so many psychologic and somatic changes occur simultaneously in one individual presentation for emergency medical attention is likely. Although 80% of adolescents cope well with their development, having only occasional need of emergency medical services, 20% have serious behavioral or medical problems, including conditions that can cause serious injury and threaten their lives.

Adolescents account for approximately 10 to 15% of all emergency department (ED) visits; of these, 13% require acute hospitalization. In one report, 78% of these visits were triaged to the acute and urgent categories. A recent survey of hospital discharges revealed that more than half of all discharges in patients 15 to 24 years of age were a result of pregnancy and its complications, poisoning (substance abuse and suicide gestures/attempts), and trauma (including physical and sexual abuse). Other reasons for ED visits include minor trauma, sexually transmitted diseases, mental health disorders not associated with suicide, and routine visits for acute and chronic illness.

The changes in the health care needs of adolescents during the recent decades is reflected in the causes of their mortality. The death rate for adolescents is 150 per 100,000 with a male:female ratio of 2:1. A decrease in deaths caused by nonsexually transmitted communicable diseases has been accompanied by an increase in deaths associated with “social morbidities” (substance abuse, sexually transmitted diseases, accidents, homicides, suicides, mental health disorders, and eating disorders). As a result of this shift in cause, particularly the rise of violent deaths, no decrease in adolescent mortality has been observed.

Of all deaths of individuals between 15 and 24 years of age, 75% are the result of accidents, homicide, and suicide, with an additional 15 million or more nonfatal injuries. The last three decades have seen a doubling in adolescent homicide and a tripling in the number of suicides. The leading agents of these injuries include motor vehicles, drowning, poisoning, firearms, fires, and falls. Surveys of teens have revealed some insight about the extent they are at risk for some of these health problems. For example, 25% of 12- to 13-year-olds surveyed engaged in at least one health risk such as fighting or tobacco use. One-third of high school students smoke and one-third drink; 25% use marijuana and 3% use cocaine. Alcohol abuse plays a role in 20% of fatalities resulting from motor vehicle collisions, 25% of motor vehicle–pedestrian collisions, and 40% of drownings. In addition, teenagers are estimated to be the victims of 16 to 30% of all perpetrated physical abuse. Recent trends and changes in American family life, including increased incidence of unwed teenage pregnancy, high divorce rate, the deterioration of public education in some segments of our society, and unemployment, undoubtedly contribute to the health care problems of adolescents. These findings indicate that adolescent death and injury are not random events but have an epidemic cause that may be altered by timely appropriate interventions.

Another important influence on the acute medical problems of adolescents is their lack of access to the health care system. The National Health Interview Survey revealed that one in seven adolescents have no health insurance. Adolescents from families that are poor, near poor, or nonwhite families are more likely to be uninsured, as are those from families with little formal education. Economic reasons were most commonly cited for the lack of coverage.

Ten percent of adolescents have no regular source of health care, and 18% identify EDs, outpatient clinics, and city clinics as their only source of health care. When adolescents do have a regular physician, it is usually a family practitioner; the remaining are cared for by internists or pediatricians. Unfortunately, studies indicate that most of these primary care physicians perceive themselves to be deficient in experience, knowledge, and training in the care of

adolescents.

The adolescent may personally contribute to the poor access to health care. Inexperience, denial, and fear may delay the recognition of disease symptoms and the timely seeking of medical care. The anonymous setting of the ED is often preferred by adolescents because they can be treated in certain instances without parental consent and are rarely, if ever, refused. Although the adolescent's acute health care needs may be well served this way, proper follow-up and recognition of chronic problems may be less than adequate.

Thus, for multiple reasons ranging from the individual adolescent's development to physician availability and physician education and training to the adolescent's economic status, many teenagers have difficulty gaining access to the health care system. Adolescents are a medically underserved segment of our population.

Just as children are not just small adults, adolescents are not just large children. Adolescents are prone to a distinct group of diseases and have special medical needs that are much different from those confronted by younger children or adults. Tolmas has eloquently listed some important considerations for medical professionals preparing to care for this group of patients: “a knowledge of the growth and developmental tasks that young people address, a personal interest, respect for confidentiality, honesty and pragmatism in all aspects of behavior and conversation, and a genuine attempt to keep from projecting one's own moral code.” This chapter addresses these considerations by first briefly reviewing some special considerations in the history and physical examination of adolescents, then, in following sections, focusing on some of the specific adolescent problems, including eating disorders, pregnancy and its complications, rape and sexual abuse, suicide, substance abuse, psychosomatic complaints, and violence.

GENERAL CONSIDERATIONS FOR THE HISTORY AND PHYSICAL EXAMINATION

In taking the history, it is important to assess the developmental age of the adolescent and not to simply treat the adolescent on the basis of his or her “physical age.” As for all patients, anticipating the adolescent's fears is also important. Taking a moment to establish rapport, eye contact, patience, and a caring demeanor aids in conducting a successful interview. Medical staff often grossly underestimate patients' concerns regarding health, but more than 50% of adolescents worry about their health. Teens often seek care for health problems they define as physiologic. They avoid seeking care for social or psychiatric concerns, yet stress, depression, and nervousness associated with this period of physiologic change are often translated into somatic complaints. The reason for the visit is thus often intentionally or unintentionally disguised and presented in conventional or acceptable, nonspecific medical complaints because of the adolescent's embarrassment or inability to think abstractly. The clinician must be certain to find the “hidden agenda.”

Because nonspecific complaints may be the harbinger of pregnancy, sexual abuse or incest, physical abuse, significant depression, fear of sexually transmitted disease or homosexuality, or fear of serious illness, at some point during the patient evaluation, the patient should be interviewed without the presence of the parent or other caretaker. The physician must always assure the patient that confidentiality will be maintained but that openness and honesty between patient and physician is a prerequisite for good medical care. This is best accomplished by defining confidentiality at the start of the interview in front of the patient and parent/guardian. The clinician should be familiar with state laws regarding the treatment of minors. Confidentiality is not unqualified. If a teen is in imminent danger, he or she should be informed of the need to disclose this important information to a responsible adult either alone or with the clinician's help. Patients less than 14 years of age should be allowed to choose which responsible adult will be involved in their care plans. The primary physician and/or social work counselor should always be involved when possible to ensure necessary follow-up.

General questions about the adolescent's home and school life are helpful in assessing overall “wellness” of the teen. Table 130.I lists the components of the psychosocial interview, “HEADSS,” providing a framework to identify health risk behaviors. Reviewing components of this list may well be pertinent to the chief complaint that brings the teen to the ED.

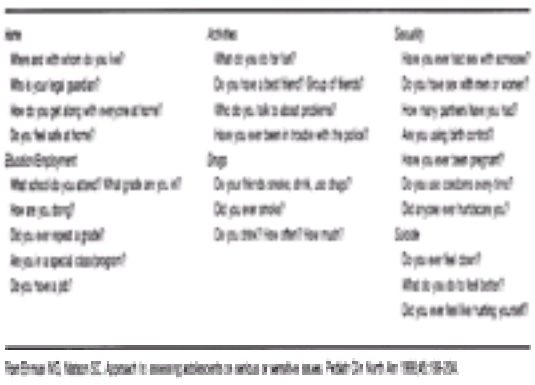

Table 130.1. The Psychosocial Interview

A brief sexual history must be taken for almost every complaint (see Chapter 85 and Chapter 94). Interviewers obtain more reliable information if questions are asked in a matter-of-fact fashion. For example, “What are you using for birth control?” is more likely to be effective in comparison to “Are you sexually active?” or worse, “Are you a virgin?” Adolescents may try to give the “proper” or perceived “desired” answer to such questions.

The physical examination pertinent to the chief complaint should be done with a low threshold for performing a pelvic examination (see Chapter 94). The sexual maturity rating of adolescents set forth by Marshall and Tanner is reviewed in Table 130.2. Figure 130.1, Figure 130.2, Figure 130.3 and Figure 130.4 show the normal progression of healthy adolescent growth. Abnormal progression is a sign of underlying organic disease and requires thorough evaluation.

Therefore, maturity rating becomes important in the evaluation of some adolescent complaints.

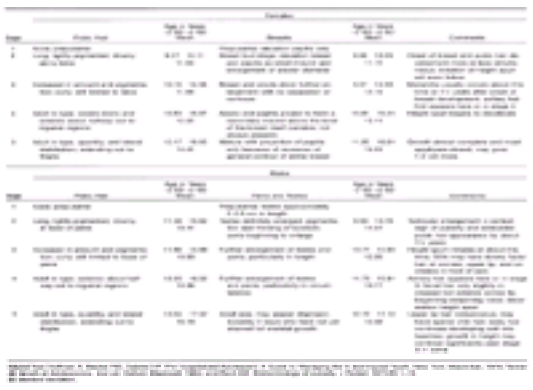

Table 130.2. Pubertal Development Scale

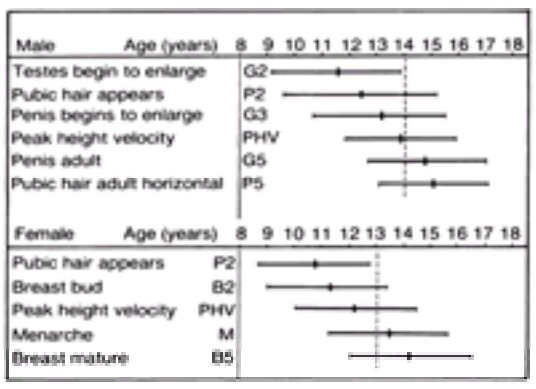

FIGURE 130.1. Normal timing of puberty in boy *(top)* and in girls *(bottom)* in the Zurich Longitudinal Growth study. *Horizontal bars* represent ±2 standard deviations; *vertical marks* represent mean age of stage. *PHV,* peak height velocity. Normal sexual maturation. J Pediatr 1973;83:1–19.)

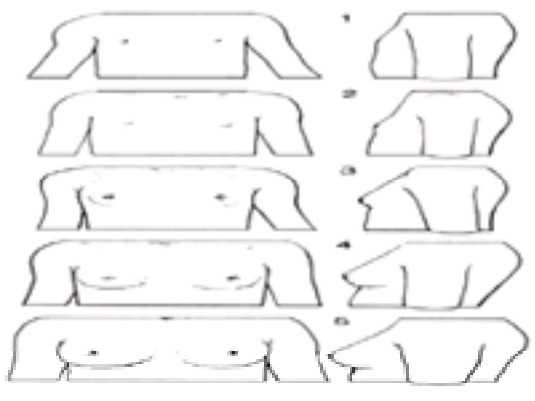

FIGURE 130.3. Stages of breast development in girls. Numbers refer to staging according to Marshall and Tanner. Description of stages: *1,* no breast development; *2,* breast budding widening or areola and elevation on mound of

subareolar tissue, erect papilla; *3,* continued enlargement of breast and widening of areola without separation of their contours; *4,* areola and papilla project above the plane of enlarging breast; *5,* mature breast, areola and breast in same plane, erect papilla. (Modified with permission from Marshall WA, Tanner JM. Variations in patterns of pubertal changes in girls. Arch Dis Child 1969;44:291–303; and Root AW. Endocrinology of puberty: 1. Normal sexual maturation. J Pediatr 1973;83:1–19.)

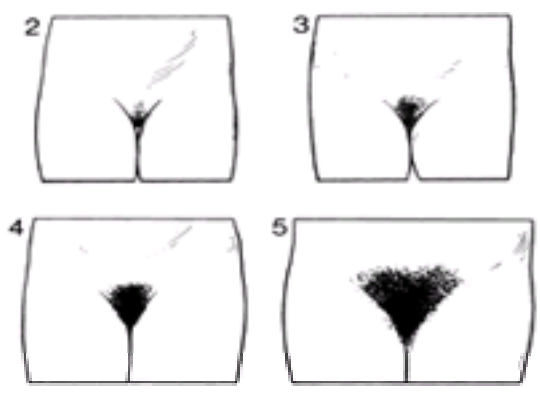

FIGURE 130.4. Stages of pubic hair growth in girls. Numbers in left-hand corner refer to staging according to Marshall and Tanner. Description of stages: *1,* no pubic hair (not shown); *2,* long, pigmented hair over mons veneris or labia majora; *3,* dark, coarse, curled hair spread sparsely over the mons veneris; *4,* abundant, adult-type sexual hair limited to the mons veneris; *5,* sexual hair is adult-type in quantity and distribution with spread to the medial aspect of the thighs. (Modified with permission from Marshall WA, Tanner JM. Variations in patterns of pubertal changes in girls. Arch Dis Child 1969;44:291–303; and Root AW. Endocrinology of puberty: 1. Normal sexual maturation. J Pediatr 1973:83:1–19.)

SPECIFIC DISORDERS

Eating Disorders (Anorexia Nervosa, Bulimia Nervosa)

Background

The prevalence of anorexia nervosa and bulimia among young women appears to be 0.5% and 2%, respectively. These disorders occur in males at one-tenth this rate. All socioeconomic, racial, and ethnic groups are affected.

Although the precise cause of these disorders remains unknown, they are likely a result of a combination of psychologic, social, and biologic factors. Predisposing factors include society's emphasis on thinness, family dysfunction and impaired conflict resolution, a history of sexual or physical abuse, obsessive–compulsive or schizoid personality traits, weight preoccupation, perceptual disturbances, and family history of obesity and/or eating disorders. Precipitating factors include family death, dieting, teasing about weight, demands of puberty, and diminished self-esteem or self-control. The vulnerable individual responds by dieting, which enhances low self-esteem. As starvation continues, performance in school, other activities, and relationships suffer, perpetuating dieting behavior and further reducing sense of control. Binge eating occurs as a response to dieting, reinforcing low self-esteem, loss of control, and more restrictive dieting. Attempts are then made to reduce weight gain from binge eating by self-induced vomiting, laxative and diuretic use, and exercise.

Anorexia nervosa and bulimia carry some of the greatest morbidity and mortality rates of all psychiatric illnesses. Pediatricians and emergency physicians must recognize these diagnoses and be familiar with the management of their medical complications, which are caused by starvation, malnutrition, hypovolemia, electrolyte abnormalities, and purging.

Clinical Manifestations

Anorexia nervosa is characterized by severe weight loss achieved through rigid caloric restriction, a disturbed body perception, and hyperactivity. Bulimia is characterized by secretive eating binges followed by purging (self-induced vomiting and abuse of ipecac, diuretics, and laxatives). In both disorders, the adolescent exhibits an intense preoccupation with food and body weight, fear of fatness, aggressive pursuit of thinness, and loss of normal appetite and impulse control. Diagnoses are confirmed through fulfillment of specific criteria, appearing in the *DSM* IV (1994), rather than through exclusion of other disorders (Table 130.3 and Table 130.4).

A. Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected).
B. Intense fear of gaining weight or becoming fat, even though underweight.
C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
D. In postmenarchal females, amenorrhea (i.e., the absence of at least three consecutive menstrual cycles; a woman is considered to have amenorrhea if her periods occur only following hormone, for example, estrogen, administration.)

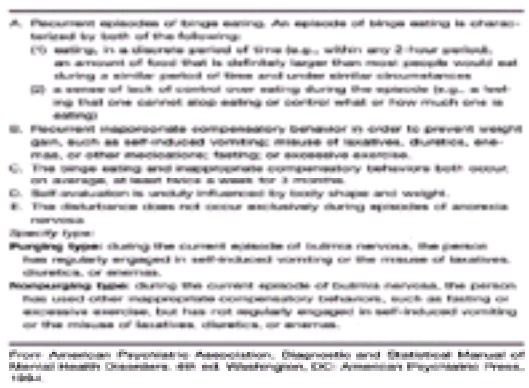
Specify type:

Restricting type: during the current episode of anorexia nervosa, the person has not regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas)

Binge-eating/purging type: during the current episode of anorexia nervosa, the person has regularly engaged in binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas)

From American Psychiatric Association. Diagnostic and Statistical Manual of Mental Health Disorders, 4th ed. Washington, DC: American Psychiatric Press, 1994.

Table 130.3. DSM-IV Diagnostic Criteria for Anorexia Nervosa



A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
   (1) eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances
   (2) a sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)
B. Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.
C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months.
D. Self-evaluation is unduly influenced by body shape and weight.
E. The disturbance does not occur exclusively during episodes of anorexia nervosa

Specify type:

Purging type: during the current episode of bulimia nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.

Nonpurging type: during the current episode of bulimia nervosa, the person has used other inappropriate compensatory behaviors, such as fasting or excessive exercise, but has not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.

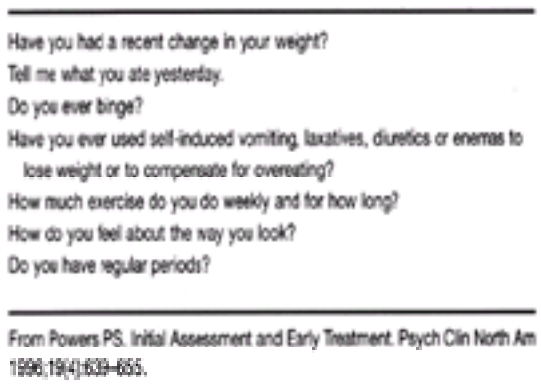
From American Psychiatric Association. Diagnostic and Statistical Manual of Mental Health Disorders. 4th ed. Washington, DC: American Psychiatric Press, 1994.

Table 130.4. DSM-IV Diagnostic Criteria for Bulimia Nervosa

Typically, anorexia nervosa begins in early adolescence; the mean age of onset is 13.75 years. Discrete onset occurs when the individual makes a conscious decision to lose weight, which is then followed by preoccupation with food and the development of profound changes in eating patterns. Classically, the anorexic adolescent is a white female from an upper middle-class family who could be described as intelligent and highly motivated but self-critical and living in a stressful family or social situation. These patients are asexual and detached and often deny their problem by hiding under layers of bulky clothing. The practice of bulimia appears later in adolescence and has a more insidious onset. Multiple attempts at weight reduction lead the patient to become aware of the role of purging in weight control. The bulimic patient is usually heterosexual and outgoing and is distressed by the disorder. Bulimics are more likely to exhibit other behavioral disturbances, such as promiscuity and substance abuse, but they are also more likely to seek and accept help.

Evaluation and Management

Anorexic patients present for medical evaluation with chief complaints related to parental concerns about their behavior and appearance, symptoms associated with the complications of the illness (e.g., syncope or weakness), or complaints that may seem unrelated, such as amenorrhea or pathologic fractures. Alternatively, bulimic adolescents most often seek medical care because of concern for their health, although these concerns are often hidden in a nonspecific complaint such as a mild gastrointestinal disturbance. If an eating disorder is suspected, the diagnosis can be made through careful history taking, focusing on evaluation of eating behavior and weight control. The diagnosis of eating disorders hinges on the presence of an intense fear of fatness and a relentless pursuit of thinness. Case reports of patients diagnosed incorrectly as having eating disorders have lacked these characteristics (Table 130.5).



Have you had a recent change in your weight?
Tell me what you ate yesterday.
Do you ever binge?
Have you ever used self-induced vomiting, laxatives, diuretics or enemas to lose weight or to compensate for overeating?
How much exercise do you do weekly and for how long?
How do you feel about the way you look?
Do you have regular periods?

From Powers PS. Initial Assessment and Early Treatment. Psych Clin North Am 1996;19(4):639–655.

Table 130.5. Important Historical Questions

Other important historical information includes family history of eating and affective disorders and screening for depression. The clinician should query about symptoms associated with purging, including abdominal pain, periodontal disease, sore throat, constipation, diarrhea, polyuria, palpitations, and abdominal discomfort. Other symptoms found in patients with eating disorders include hair loss, bruising, cold intolerance, and light-headedness. The differential diagnosis includes both medical and psychiatric causes. Medical causes of weight loss to be considered include occult malignancy, chronic infection, inflammatory bowel disease, malabsorption, hyperthyroidism, Addison's disease, and diabetes mellitus. Psychiatric causes include affective, obsessive– compulsive, and somatization disorders and schizophrenia.

Patients with eating disorders may manifest a wide variety of physiologic and metabolic derangements (Table 130.6). A complete physical examination is essential and should include height, weight, and orthostatic vital signs. Some physicians prefer the use of body mass index (weight in kg/m^2) for diagnosis in the older adolescent. Body mass index less than 18 is used as criteria for the diagnosis. Bradycardia (heart rate less than 60 beats/minute) and hypotension (blood pressure less than 90/60 mm Hg) is present in 90% of patients with anorexia. Hypothermia and cold intolerance

are not uncommon. The respiratory rate is usually normal.

Neuroendocrine	Delayed puberty Amenorrhea Anovulation Low estrogen state Euthyroid sick state Hypercortisolemia Hypothermia
Cardiovascular	Bradycardia Orthostatic hypotension/shock Arrhythmia Cardiomyopathy Dependent edema
Renal	Hypokalemia Hematuria, proteinuria Acidosis/alkalosis Decreased glomerular filtration rate, elevated blood urea nitrogen Hypercholesterolemia
Gastrointestinal	Constipation Delayed gastric emptying Enamel erosion, palatal trauma Enlarged parotids Esophagitis, Mallory-Weiss
Bone Marrow	Pancytopenia
Musculoskeletal	Weakness Osteopenia/osteoporosis

Adapted from Herzog DB. Eating disorders. N Engl J Med 1988;318:293.

Table 130.6. Physiologic Disturbances in Patients with Eating Disorders

Patients who induce vomiting may have evidence of palatal trauma as well as erosion of the enamel on the lingual surface of the teeth. Non-tender parotid swelling is common in bulimic patients. Skin changes include dry hair, hair loss, dry skin, brittle nails, carotenemia, lanugo, and pre-tibial edema. Patients who induce vomiting may have “Russell's sign,” calluses on the knuckles resulting from chronic trauma (Table 130.7).

	Anorexia	Bulimia
General Characteristics		
Incidence	0.5–1%	2–19%
Age	Early adolescence	Late adolescence
Sex	90–99% female	~80% female
Onset	Distinct	Insidious
Weight	>25% weight loss	Thin to above average
Personality	Model child	Behavioral problems
Social characteristics	Asexual, isolative	Heterosexual, gregarious
Menses	Absent	Absent, irregular
Death	Starvation	Hypokalemia, suicide
Physical Findings		
Skin	Dry, xanthemia	Edema
Hair	Lanugo, scalp and pubic hair loss	Hair loss
Mouth		Enamel erosion Palatal bruising, cuts Enlarged parotid glands Diminished gag reflex Pyorrhea
Endocrinologic	Low estrogen state	
Neurologic		Neuropathy Muscle cramping

Adapted from Herzog DB. Eating disorders. N Engl J Med 1988;318:293.

Table 130.7. Differences In Anorectics and Bulimics

Suggested screening laboratory evaluation includes a complete blood count with indices, electrolytes, blood urea nitrogen and creatinine, calcium, magnesium, phosphates, thyroid function tests, and a baseline electrocardiogram (ECG). More extensive evaluation is dictated by the individual patient's history and physical examination findings. Hematologic abnormalities are common and include leukopenia, normochromic, normocytic anemia, and thrombocytopenia. Electrolyte disorders, including hypokalemia, hypomagnesemia, and hypophosphatemia, are also common. Metabolic alkalosis is present in patients who vomit. Those patients who abuse laxatives may have a metabolic acidosis. Elevated amylase of salivary origin is seen in patients who vomit. ECG abnormalities include sinus bradycardia, non-specific ST-T wave changes, atrial tachycardia, interventricular conduction delay, premature ventricular contractions (PVCs), and prolonged QTc.

Patients who abuse ipecac may develop myopathy as well as cardiomyopathy. Myopathy manifests as weakness, stiffness, and tenderness in peripheral muscles and is reversible. Cardiomyopathy presents as chest pain, tachycardia, hypotension, ECG changes, including T-wave and ST-segment changes, and alterations in the QRS, P-R, and QTc intervals.

Acute medical management includes restoring the intravascular volume with saline solution, correcting symptomatic electrolyte imbalance, and closely monitoring vital signs. Once the diagnosis is confirmed, psychiatric evaluation is necessary with referral to a definitive, multidisciplinary treatment program. Guidelines for hospitalization appear in Table 130.8. This treatment may occur in a pediatric or psychiatric ward, depending on the patient's needs and ward capabilities. Treatment is a multifactorial endeavor, including medical, behavioral, personal, and family therapy. The first and most difficult task is to convince the adolescent that he or she needs help and that treatment will relieve the fears and obsessions, making it easier to return to normal activities.

A. Presence of severe or persistent medical complication that threatens life or health. Presence of at least one major and three minor, or at least six major complications.	
Major Complication	Weight <75% ideal body weight (IBW) Hypoglycemic syncope Severe fluid/electrolyte imbalance Cardiac arrhythmia Severe dehydration
Minor Complication	Weight <85% IBW Recalcitrant vomiting Bradycardia Hypothermia Hypotension Lanugo Amenorrhea for three consecutive cycles Acute starvation Vasomotor instability Minor electrolyte imbalance or hypoglycemia Hypophosphatemia Nutritional anemia Exercise-induced injury Impaired anal function Intestinal atony Failure of 2 months weekly outpatient management

From: Herzog DB, Bierach EV. Anorexia nervosa. In: Mash Lewis, ed. Child & Adolescent Psychiatry: A Comprehensive Textbook. 2nd ed. Baltimore: Williams & Wilkins. 1996.

Table 130.8. Guidelines for Hospitalization of Anorexic Patients

Mortality remains significant. In a 5-year post-hospitalization follow-up of anorexic women, 70 to 75% had moderate symptomatic improvement, 20% were chronically ill, and 5% had died. Depression, suicide attempts, perfectionism, and obsessive thinking and compulsive behaviors were seen. A significant number have affective or anxiety disorders at follow-up.

Pregnancy

Background

Fifty-five percent of 15 to 19 year olds and 8% of girls less than 15 years of age have had sexual intercourse, leaving them at risk for pregnancy and sexually transmitted diseases. In the latter half of the 1980s, there were 95.9 pregnancies per 1000 teenaged girls 15 to 19 years, representing a 9% increase. Abortion rates remained stable at 36.0 per 1000 and birth rates increased by 18% to 59.9 per 1000. Most of these pregnancies are unplanned and unexpected. The United States continues to have one of the highest rates of teenage pregnancy and birth rates of all developed countries.

Pregnancy in the adolescent years has tremendous health and socioeconomic effects on the mother as well as the child. Teen mothers are less likely to complete school and more likely to have low-paying jobs or be unemployed, and they are more likely to live at or below the national poverty level. Children of teen parents are at risk for adverse cognitive and psychologic effects as well as abuse. Health risks to the mother and fetus are most likely a result of inadequate prenatal care secondary to late diagnosis and economic constraints. Adolescents often seek the anonymous setting of the ED for treatment of problems related to pregnancy. The physician caring for these patients should be prepared to diagnose pregnancy, manage its complications, and arrange appropriate follow-up.

Clinical Manifestations

The adolescent may present with a concern of pregnancy or with a variety of chief complaints that often seem unrelated to the underlying pregnancy. Adolescents presenting to the ED are less likely to complain of amenorrhea, breast tenderness or enlargement, urinary frequency, or morning sickness. The information that they offer concerning menstrual cycle, sexual activity, and birth control is often inaccurate. Thus, the evaluating physician should have a low threshold for performing pregnancy tests for postmenarchal females, especially if diagnostic or therapeutic procedures are performed or medications administered. Making an early diagnosis and establishing appropriate referrals for care is in the best interests of the mother and the fetus.

During pregnancy, b-human chorionic gonadotropin hormone (b-hCG) is secreted by the trophoblast 9 to 11 days after ovulation. Concentration of this hormone doubles approximately every 1 to 3 days, reaching about 100 mIU/mL at the time of the first missed menses. An enzyme-linked immunoassay specific for the b subunit of hCG is available and offers virtually 100% sensitivity and specificity. This test is inexpensive, easy to perform, and detects hCG as low as 20 mIU/mL in the urine. The serum b-hCG is slightly more sensitive and should be obtained to confirm equivocal urinary pregnancy test results or when quantitation is necessary.

Evaluation and Management

A physical examination and a pelvic examination should be performed in patients with positive test results. The date of the last menstrual period and uterine size are used to estimate gestational age. Notable findings include enlarged breasts, galactorrhea, palpation of fetal movement and heart tones, palpable fundus on abdominal examination, palpable softening of the corpus (Hegar's sign), softening of the cervix (Goodell's sign), congested, bluish hue to the vaginal mucosa and cervix (Chadwick's sign), and palpable enlargement of the fundus on pelvic examination. The nongravid uterus approximates the size of a lemon. The 8-week gravid uterus approximates the size of an orange, and a 12-week gravid uterus is the size of a grapefruit and is just palpable at the pubic symphysis. At 16 weeks, the uterus is palpable midway between the pubic symphysis and the umbilicus, and at 20 weeks is at the level of the umbilicus. A gestational sac can be detected at 5 to 6 weeks by abdominal ultrasound and by radiography at 16 weeks. Routine pelvic cultures should be sent and hemoglobin and rapid plasma reagin (RPR) should be obtained at the time of the initial diagnosis.

Informing the adolescent of results of pregnancy testing should be done privately, without the parent. During this interview, the clinician should identify a support person for the adolescent, elicit feelings regarding the pregnancy, and attempt to disclose incest or rape. Most often, the adolescent chooses to involve an adult to help her through the crisis. If she refuses, it then becomes an individual decision to break confidentiality. The adolescent should then be introduced to the options regarding the management of her pregnancy, which depend on the estimated gestational dates. These options include keeping the baby, putting the baby up for adoption, or terminating the pregnancy through first (less than 13 weeks) and second (less than 18 weeks) trimester abortion. When possible, the father should be involved in the discussion if the mother so chooses. Above all, the clinician should emphasize that the ultimate decision regarding the pregnancy belongs to the adolescent mother alone.

Appropriate referral and follow-up of this high-risk group of patients is essential in providing the best possible patient care. Ideally, a follow-up within a few days to answer questions and to reach and act on a decision may help keep the adolescent within the health care system. The younger the pregnant adolescent is, the less likely she is to have prenatal care beginning in the first trimester. Therefore, to increase compliance and decrease the decisions that the adolescent has to make, an appointment should be scheduled for the adolescent when possible. This follow-up appointment does not necessarily have to occur in the ED, but ideally it should happen. An experienced, knowledgeable social worker is

invaluable and each ED should establish a reliable follow-up mechanism for these patients. Figure 130.5 provides an example of patient diagnosis and referral.

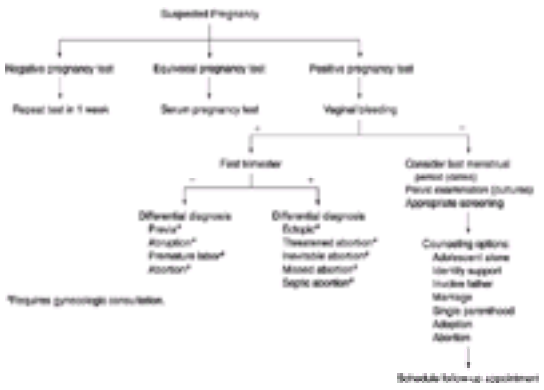


FIGURE 130.5. The pregnant adolescent.

Complications of pregnancy include hyperemesis, premature labor, placenta previa and abruptio, abortion (threatened, inevitable, incomplete, or complete), infection, and ectopic pregnancy. Patients presenting with signs and symptoms of these complications should be thoroughly evaluated by the emergency physician. When necessary, emergency gynecologic evaluation should be performed in the pediatric ED or the patient should be transferred to an appropriate facility in a timely fashion.

Concomitant with the sexual revolution, there has been an epidemic of sexually transmitted diseases, resulting in an increase in ectopic pregnancy. The frequency of this diagnosis has tripled over the past two decades. This increase is presumed to be caused by an increased incidence of tubal infection, a change in microbiology of infection (with the emergence of *Chlamydia*), iatrogenic causes secondary to fertility control (intrauterine device, tubal ligation, minipill), and an increase in recognition. Of patients with ectopic pregnancies, 50% have evidence of chronic salpingitis.

Ectopic pregnancy remains the third leading cause of maternal death, largely because of missed diagnosis. The classic triad of abdominal pain, abnormal vaginal bleeding, and adnexal mass are pathognomonic for this entity but are rarely present, especially during early pregnancy. However, 90% of patients complain of abdominal or pelvic pain and vaginal bleeding.

The earlier these patients present for evaluation, the more subtle their symptoms. The patient presenting with a ruptured ectopic pregnancy usually exhibits signs of intravascular volume depletion or shock, along with signs of intraperitoneal hemorrhage. These patients require acute resuscitation with attention to the ABCs (airway, breathing, and circulation), volume resuscitation, and immediate surgical intervention.

Patients with vaginal bleeding and pregnancy need a thorough evaluation so that the diagnoses of normal versus ectopic pregnancy; threatened, missed, or complete abortion; and placenta previa or abruption can be distinguished from each other (Fig. 130.5). The patient presenting with vaginal bleeding in the third trimester has placental abruption or previa until proven otherwise. No pelvic examination should be done in these patients. Oxygen and intravenous fluids should be administered and immediate gynecologic evaluation should be obtained. Occasionally, a patient in active labor may arrive in the ED and no obstetrician will be available immediately. In most instances, the mother delivers the infant without problems. For abnormal presentations, a textbook of gynecology/obstetrics should be available for reference.

Rape/Sexual Abuse

Background

Rape is defined as genital contact without consent, through use or threat of use of force or fraud, or when the victim is unable to give consent because of physical or mental disability. Statutory rape is intercourse with a female below the age of consent, which is considered to be 16 years in most states. The term *incest* applies to the situation in which the assailant and victim are related and therefore could not legally marry or have a functional situation simulating this relationship. *Sexual abuse* or *molestation,* a broader term, is involvement of the adolescent in activities that he or she does not fully comprehend. These include exhibitionism, fondling, oral–genital contact, and rectal or vaginal penetration. Incest is probably the most common form of adolescent abuse and is the most underreported and difficult to prove.

An estimated one of every four adolescents will be victims of sexual abuse before they reach adulthood. Most reported crimes are committed against females; however, it is estimated that for every two female victims of sexual abuse, there is one male. These figures represent only the tip of the iceberg because less than 50% of these crimes are reported. More than 50% of all rape victims are younger than 19 years, with a peak age from 14 to 17 years. Of all rape/homicides, 25% occur in adolescents younger than 18 years old. In the National Adolescent Student Health Survey (NASHS), 12% of eighth graders and tenth graders reported that someone had raped them or tried to rape them outside of school, and 18% of them said someone tried to force them to have sex. Thus, because of the magnitude of this problem in the pediatric age group, the pediatrician as well as the emergency physician should develop skill in recognition and appropriate workup, and have an organized system for patient follow-up. Most cities have special programs and designated rape and child abuse centers that can assist victims of assault and can offer advice to physicians regarding acute management. Physicians practicing in a particular area should investigate this topic and be knowledgeable of the state laws regarding the care of adolescents.

Clinical Manifestations

Adolescent victims present in one of two ways, either after an acute event with an unknown perpetrator or after an acute stress when an incestual relationship is revealed. All patients who have been assaulted within the previous 72 hours or those with symptoms should be evaluated on an emergency basis. Asymptomatic patients with ongoing chronic abuse (not occurring in the preceding 72 hours) can be scheduled in special outpatient clinics designed to care for this particular group. These patients require a multidisciplinary approach, including physicians, social workers, nurses, and psychologists, to provide optimal care. The aim of the acute intervention is to obtain the details of the incident, to perform a complete medical evaluation, to collect medicolegal evidence, and to provide appropriate medical and psychological follow-up. The acute intervention is not intended to ascertain whether a crime was committed. All suspected cases of abuse/rape must be reported to the police (see Chapter 128).

Evaluation and Management

Consent for interview, examination, and collection of evidence should be obtained from the victim. Accurate and thorough records are of the utmost importance. The victim should be given the control of the situation and has the right to terminate the process at any point. A supportive female or male, or ideally, an experienced rape counselor/nurse, should be present throughout the interview and examination. When possible, this process should take place in a secluded, quiet area of the ED.

Most facilities use a detailed information sheet and protocol for the evaluation of these patients. Figure 130.6 provides a sample from the state of California as an example. The history should include the details of the event, including time and place, the details of the sexual acts (including whether oral, rectal, or vaginal penetration occurred), whether or not ejaculation occurred, the force or threat that was used by the assailant, and the associated use of alcohol or drugs. Hygiene, including bathing, douche, or change of clothes after the event, should be recorded. Medical history, including menstrual history, sexual activity, previous history of sexually transmitted diseases, birth control use, last intercourse, previous obstetric and gynecologic history, and history of health problems, should be documented.

FIGURE 130.6. Example of medical report form for suspected sexual assault. (Reprinted with permission from State of California, Office of Criminal Justice Planning.)

As many as 46% of victims have non-genital injuries, with as many as 15% of them requiring therapy and follow-up. Up to 80% of victims have minor genital injuries, most of which are external and involve the posterior fourchette. These observations emphasize the need for a complete, careful examination. Photographs should be taken with the victim's consent, when possible. The taking of photographs does not preclude documentation of existing injuries on the patient's chart. A description of the patient's general appearance and emotional status, and description of clothing condition begins the physical examination. The victim's clothing should be placed in a paper bag for use as evidence. The physician should explain the parts of the examination before performing them to allow the patient to assume control and to alleviate as much anxiety as possible. A complete physical examination to assess for bruises, scratches, and sexual maturity rating should be performed. Debris under the fingernails should be removed with a wooden curette and placed in a labeled envelope. Dried semen should be removed with saline-moistened swabs and stored in dry test tubes. The use of a Wood's lamp may aid in identifying these areas. Matted pubic hair should be removed and the remaining pubic hair gently combed into a labeled envelope. A sample of the patient's pubic hair should be included in the evidence. A careful external examination is paramount, and the hymen and the posterior forchette should be carefully inspected for areas of laceration.

A speculum examination follows to assess for the presence of vaginal and cervical trauma. Lubricants should be avoided because they affect sperm motility and culture results. If secretions are present in the posterior fornix, they should be aspirated and placed in a sterile container for sperm and acid phosphatase detection. Cotton swabbings taken from the posterior fornix should be used to make slides for detection of motile sperm, acid phosphatase, and blood group antigen. Cultures for gonorrhea and *Chlamydia* and wet mount should also be obtained and the remainder of the pelvic examination be completed in the usual manner (see Chapter 94). The rectum and oral cavity should be carefully examined. If there is history or evidence of trauma, a swab from the gum line and buccal mucosa can also be evaluated for the presence of sperm. Next, the victim should be asked to chew on a piece of filter paper or a cotton ball so a sample of saliva may be obtained. Eighty percent of people secrete blood group antigens in their saliva, sweat, and other body fluids. Finally, serum for syphilis testing should be obtained. An additional serum sample may be obtained and stored and may be of help in the event of future diagnosis of venereal disease.

The risk of venereal disease ranges from 1 to 27%. Studies have shown that 2 to 12% of adolescents at the initial visit

have gonorrhea and 1.5 to 10% have *Chlamydia.* On follow-up visit, 1 to 3% have positive cultures. The risk of trichomonas and bacterial vaginosis ranges from 5 to 25%. Thus, most physicians treat their patients prophylactically. Options include a single-dose ceftriaxone, cefixime, or ciprofloxacin followed by 1 g of azithromax or by a course of doxycycline for 7 to 10 days. Alternatively, a single dose of 2 g of azithromax may be given. The risk of human papilloma-virus (HPV) is unknown; however, the proportion of patients having abnormal Papanicolaou smears ranges from 3 to 27%. The risk of herpes simplex virus (HSV), syphilis, and human immunodeficiency virus (HIV) is low. Follow-up of the patient 7 days after the initial examination is recommended by the Centers for Disease Control and Prevention for repeat vaginal specimens for gonorrhea, *Chlamydia,* and *Trichomonas.* A test for syphilis should be repeated at 6 to 8 weeks. Testing for HIV should occur only after counseling, at 3 to 6 months after the incident, and if negative, again at 1 year. The risk of transmission is low but may increase along with the increasing prevalence of the disease. Azidothymidine prophylaxis may be recommended for high-risk patients, but no standard guidelines currently exist.

All patients should have a sensitive pregnancy test performed. Pregnancy occurs as a result of rape in 1% of victims. If the patient is not at risk for early pregnancy, a protocol for pregnancy prevention may be followed. The most accepted regimen is the use of Ovral, two tablets initially followed by two tablets 12 hours later. This treatment should be given within 72 hours of the event. Finally, all patients should have scheduled medical and psychological follow-up before discharge from the ED.

Teenage Suicide

Background

Every year, 2000 children younger than 19 years of age commit suicide. This statistic represents an underestimation of the true occurrence because of underreporting and lack of recognition. Although suicide rates for adolescents are among the lowest compared with other age groups, the rate of suicide in the age group from 10 to 24 years has tripled in the last three decades and now ranks as the third leading cause of adolescent death. The rate of attempted suicides far exceeds this number; reports range from 50 to 200 attempts per one successful suicide. Males are three times more likely to successfully commit suicide and females are three times more likely to attempt suicide. White males are in the highest risk group. Firearms and explosives are used by 60% of successful male and 40% of female adolescent suicides, poisoning is used in 15 to 20% of male and 25 to 35% of female suicides, and suffocation by hanging, drowning, or strangulation is used in 15% of males and 10% of females. Drug overdose accounts for most suicide attempts presenting to the ED. Although an estimated 1 to 12% of all ED visits are secondary to suicide attempts, the adolescent proportion is closer to the higher estimation. As many as 9% of adolescents surveyed have made a suicide attempt, but less than half of these attempts reach the attention of the psychiatric professional. Thus, many of the existing studies report results in biased population samples; namely, those seeking care.

Many patients seek general medical care shortly before attempting suicide. Hawton reported that 50% of youths saw physicians 1 month prior and 25% within 1 week of attempting suicide. Slap and Vorters recently reported that suicidal adolescents had poorer mental health, impulse control, family relationships, and school performance than their ill counterparts, and they were also most likely to depend on the ED for their care. They identified five risk factors: 1) previous suicide attempts, 2) previous mental health care, 3) poor school performance, 4) marijuana use, and 5) dependence on the ED for primary care in 88% of the suicidal teenagers compared with 55% of other ill adolescents. Perhaps these factors, when prospectively studied, will help identify the adolescents who are at risk.

Much has been written regarding the risk factors having high association with adolescent suicide. The severity of the injury and the likelihood of rescue directly parallel the seriousness of the attempt. Other risk factors include the presence of a chaotic, disorganized family environment, poor support systems, a family history of suicidal behavior, psychiatric disorders or chronic substance abuse, and history of physical or sexual abuse. Patients with an underlying mental disorder have a substantially higher risk of both attempting and committing suicide. Disorders with highest risk include major affective disorders and schizophrenia. Patients who have had a previous hospitalization for their illness or who practice substance abuse also seem to have a higher risk. Male homosexuals as well as lesbians have a higher rate of suicide than their heterosexual counterparts. The attempted suicide rate among male homosexuals has been reported as high as 30%. Previous suicide attempts and continued suicidal ideation are worrisome. Patients who are hopeless and have low self-esteem are at higher risk (see Chapter 129).

Evaluation and Management

Many adolescents arriving in the ED after a suicide attempt require acute stabilization and treatment following purposeful ingestions or self-inflicted violence (see Chapter 88 and Section IV). The primary goals of the emergency physician are assessment, stabilization, recognition, and appropriate disposition. The physician is responsible for preventing the patient from leaving the medical facility before a full evaluation has been completed. In rare instances, patients might require physical restraint. However, most do well with one-on-one observation by a responsible individual. Regardless of the means, patient safety is of utmost importance and requires continued reassessment.

After initial assessment and stabilization, management should focus on 1) establishing whether suicidal ideation persists; 2) the intent of the patient and assessment of lethality of the means, degree of access, and risk:rescue ratio; 3) the patient's current mental status and existing signs of an underlying mental health disorder; and 4) the crisis that precipitated the event and the social situation and support system. Hospitalization may be required for medical treatment before this evaluation. Ideally, all patients should have an evaluation by a psychiatrist and a social worker. High-risk cases may benefit from a brief inpatient hospitalization, whereas others may do well with outpatient treatment. If a psychiatrist is not available to the patient, the emergency physician must rely on the social worker, the primary care physician, and the available mental health services in the area. Before discharge, a safety contract should be discussed with the patient and family. In addition, education directed toward the caretakers to limit access to means of suicide by removing firearms, medications, and so forth from the home environment is crucial. A follow-up system to ensure that the

patient and family have established access to mental health care is also important.

Substance Abuse

Background

Drug abuse is defined as the pathologic use of a substance that results in impairment in social, psychological, physical, or occupational functioning. The adolescent population is a polysubstance abusing group, with the highest users between ages 18 and 25 years. Long-term studies have revealed that the risk for abuse of drugs other than marijuana and alcohol decreases if the use is postponed to the later adolescent years. The National Institute on Drug Abuse (NIDA) has provided cross-sectional surveys from high school seniors since 1975 and has continually documented the magnitude of the problem. Use of illicit drugs increased dramatically in the 1970s and, fortunately, has decreased some recently. However, the use of drugs has been incorporated into our society; new substances continue to appear and overall use remains unacceptably high.

The most common substances abused by adolescents include alcohol, cigarettes, marijuana, stimulants, cocaine, inhalants, hallucinogens, tranquilizers, and sedatives. Adolescents abuse drugs for many reasons, including experimentation, low self-esteem, peer or family use, relief of stress or anxiety, and escape from parental constraints.

Clinical Manifestations

The most common reasons for these patients to come to the ED include acute intoxication, associated trauma, a frightening reaction to the ingested drug, drug-seeking behavior disguised under another complaint, and parental request for drug screening. If the adolescent does not present with symptoms of acute intoxication, only direct questioning regarding abuse may reveal the underlying problem. Again, beginning the discussion by inquiring about the use of drugs at parties, the attitude toward drugs, and the use of drugs by family members and close peers is often helpful. Determining the quantity and frequency of drug use and the degree of life disruption that has occurred is also helpful. Questions regarding physical symptoms of withdrawal, history of blackouts or accidents associated with intoxication, a fall in school performance and in extracurricular activities, arrests or juvenile court records, and conflict with family and peers define the severity of the problem (Table 130.9). Identifying significant depression in this group is also important because this diagnosis changes the management plan for the patient.

Medical	*Legal*
Blackouts	Arrests
Withdrawal symptoms	Friends with criminal background
Adverse reactions	Violence
Injury while intoxicated	*Family/Peers*
School	Social isolation
Fall in performance	Conflict with parents over drug use
Fall in extracurricular activities	Substance abuse in family, peers
Use of drugs in school	
Behavior problems	

From Farrow JA. Adolescent chemical dependency. Med Clin North Am 1990; 74:1265–1274.

Table 130.9. Substance Abuse History

Evaluation and Management

The principles of managing the acutely intoxicated patient are covered in depth in Chapter 88. The patient experiencing a "bad trip" may experience hallucinations or exhibit paranoia. These patients should be cared for in the quietest section of the ED, and the team should approach them in a calm and reassuring fashion. The potentially harmful or "out of control" patient presents another challenge. If the patient is armed, only a trained security guard should assume the task of removing the weapon. If reassuring the patient fails, physical restraint may be necessary. Safety is best achieved in numbers, and the general approach is to assign security guards or other personnel to each limb. The show of numbers is often enough to control the patient's behavior. Four-point leather restraints are used to secure the patient to a stretcher, taking care to avoid cardiorespiratory compromise and undue trauma. Some physicians prefer to restrain a patient on his or her side to avoid airway complications in case of vomiting. If the patient requires restraint, the clinician must remember to perform a thorough physical examination so that other problems that could cause such altered mental status are not overlooked. Occasionally, the patient may require sedation; the medication chosen depends on the drug intoxication (see Chapter 88).

Urine screening at the parent's request should be avoided because this procedure creates an adversarial situation between the medical staff and the adolescent. The possibility of counseling should be offered instead. Unfortunately, many adverse reactions resulting from drug abuse never come to medical attention. For those that do, treatment of the acute intoxication does not constitute definitive treatment. In general, confidentiality is the rule, and information given to the physician during the interview is kept confidential, unless the adolescent allows the physician to disclose the information or the degree of substance abuse poses a significant threat to the child's health.

Counseling begins in the ED. The patient with symptoms of acute intoxication as well as the adolescent presenting with only a minor manifestation of a drug reaction (i.e., a dystonic reaction) undoubtedly need further treatment, with definitive referral to an established program. A skilled social worker, drug counselor, or psychologist can be indispensable in beginning the counseling process in the ED. Before discharge, the patient should be evaluated for symptoms of major

depression or suicidal ideation because these may go hand in hand with substance abuse. The responsibility of the emergency physician and pediatrician includes a knowledge of the trends of adolescent drug abuse, the ability to impart knowledge and identify problem behavior, and a knowledge of the available community resources for drug treatment programs so that a proper referral can be made.

Psychosomatic Complaints

Background

Patients go to see doctors for many reasons. Some seek diagnosis and treatment of physiologic disease and informational needs. Other visits result from psychosocial illness secondary to life stresses, psychiatric disorders, and social isolation. A relationship between stress and recurrent pain has been identified clearly in the pediatric and adolescent population. Adolescents cope with life stresses in many ways. Adapting a sick role provides an acceptable means of receiving attention. Therefore, adolescents often present with chronic complaints that are not attributable to an underlying organic disorder but rather are related to psychosocial factors. Studies conducted in ambulatory care settings have repeatedly shown that up to 68% of these patients have no underlying physical disorder. Because malingering is rare in this age group, the physician's task is often one of diagnosing underlying affective disorders or eliciting current stresses in the patient's life.

Clinical Manifestations

The most common complaints include vague abdominal pain, chest pain, chronic fatigue, and headache.

Evaluation and Treatment

The evaluation of psychosomatic complaints is part of daily medical practice and does not exclude the practice of emergency medicine. The goal of treatment of these patients is screening through thorough medical and psychosocial history and physical examination. The possibility of significant disease is eliminated with a minimum of laboratory tests. A discussion with the adolescent regarding the role of stress in somatic symptoms follows along with gentle reassurance and appropriate referral, allowing the patient to reliably enter the health care system. The initial diagnosis is made with caution, and repeated observation is important to avoid missing other diagnoses.

Screening for known stressors may help in making the diagnosis of psychosomatic illness. These stressors include the onset of symptoms and associated events, the pattern of past visits, including multiple ED visits, a history of many somatic complaints, a strong family history for somatization, and the developmental stage of the adolescent. Unfortunately, these patients often undergo many tests that serve only to eliminate nonpsychosomatic possibilities and reinforce symptoms. The discussion between the physician and adolescent after the initial evaluation should include a summary of the physical examination and laboratory results and the reassurance that nothing serious seems to be wrong. An attempt should be made to link the presence of certain physiologic responses to stresses related to a current situation, along with attempts to recognize and remove the stress or to deal with it in another way. Regular scheduled appointments alleviate the patient's need to develop symptoms to see the doctor. Frequent physical examination and discussion can reduce the amount of costly and/or risky diagnostic tests or procedures.

People cope with life stresses in many ways, and adopting a sick role allows the individual to relinquish responsibility and provides an acceptable means for gaining attention and sympathy. Most patients with diagnosable psychiatric disorders still receive their care from medical physicians in this country. Socially isolated patients visit the doctor for interpersonal exchange to gain a sense of belonging. Patients distressed by physical symptoms often seek information as a method of coping with their symptoms and reducing the associated anxiety.

Chest Pain

Although chest pain is a common complaint in adolescents, it is rarely caused by serious disease. However, a recent prospective study of adolescents with chest pain, evaluated in an ambulatory setting by Pantell and Goodman, revealed that two-thirds of these patients restricted their activities and 40% had absences from school. Causes were found in 57% of the patients and included musculoskeletal pain (31%), hyperventilation (20%), breast-related problems (5%), respiratory disease (2%), gastrointestinal disease (2%), and cardiac disease (1%). No definite cause was found in the remaining 43% of patients. The typical teen complained of intermittent, frequent, sharp, substernal pain that had occurred over several months, and physical examination was normal except for occasional tenderness on chest wall palpation. More than half of the patients experienced significant anxiety concerning their illness, fearing a serious medical disorder. Approximately one-third of the patients had experienced a stressful life event in the preceding months. Multiple other existing reviews of children and adolescents report similar findings.

Most patients with chest pain with an identifiable cause have well-localized, well-defined, sharp pain consistent with anterior chest wall syndrome. This pain is not associated with exertion but rather with movement. This syndrome may be thought of to include costochondritis, Tietze's syndrome, slipping rib syndrome, and muscular strain. Pulmonary-related causes include pneumonia, asthma, pleurodynia, pulmonary hypertension, pulmonary embolus, and pneumothorax. Pain that is exertional or that is associated with palpitations, shortness of breath, dizziness, or syncope suggests a cardiac cause. This event is rare. Conditions to consider include myocarditis/pericarditis, aortic outlet obstruction, mitral valve prolapse, and anomalous coronary artery. Gastrointestinal causes include gastroesophageal reflux, ulcer disease, pancreatitis, and gall bladder or liver disease. Patients without an identifiable cause often have a history of recent stress.

Evaluation of patients presenting to the ED complaining of chest pain includes a history and physical examination and treatment of medical emergencies. The extent of diagnostic workup should be tailored to the individual patient (see Chapter 52 and Chapter 82). The goal of management with the remaining patients is to provide symptomatic relief,

reassurance, and appropriate long-term referral.

Hyperventilation Syndrome

In response to a stress, b-adrenergic stimulation results in hyperventilation and hypocapnic alkalosis. Underlying anxiety and stress are presumed to be the culprit. Some evidence suggests that this disease is biochemical; in susceptible patients, symptoms can be reproduced by infusions of sodium lactate and can be alleviated by b-blockers. The anxiety and fear created by the symptoms of hyperventilation that remain unrecognized by physicians and family are enough of a stress to perpetuate the chronic syndrome.

Clinical manifestations include breathlessness, fatigue, sleep disturbance, poor concentration, paresthesia, syncope, tunnel vision, chest pain, palpitations, tachycardia, bloating, belching, muscle stiffness, cramps, and carpopedal spasms. Observation reveals excessive thoracic muscle use, frequent yawning, coughing, clearing of the throat, and moistening of the lips. The presence of these symptoms should alert the physician to underlying family problems or other stresses leading to undue anxiety in the adolescent. These patients may present with a complaint of syncope or chest pain, and other causes must be considered (see Chapter 52 and Chapter 73).

Symptoms can sometimes be reproduced by using the hyperventilation provocative test or by asking the patient to hold his or her breath. The patient is asked to stand and take deep breaths at a rate of 30 to 40 breaths/minute for 4 to 5 minutes. As the symptoms are reproduced, the patient is asked to describe them. Then the patient is instructed to breathe slowly into a paper bag to demonstrate a method by which he or she can rapidly control the frightening symptoms. The patient is instructed to use this technique to control symptoms in the future. Referral for counseling and/or psychiatric evaluation with focus on the adolescent's underlying anxieties and fears may prevent the patient from becoming an adult with hyperventilation syndrome.

Chronic Fatigue Syndrome

The complaint of fatigue by an adolescent should be taken seriously because this age group typically has an endless supply of energy. The causes of fatigue include demanding, unrealistic activity; poor health habits, stress, anxiety, and depression; or an underlying medical disease. Most cases of fatigue in the adolescent age group are caused by stress and resolve with improved health habits and maintaining realistic scheduling of activities.

A complete history and review of systems, and a thorough physical examination are necessary to define life stresses and eliminate underlying organic disease. The patient who complains of fatigue that is present upon awakening and that is not relieved by rest or sleep most likely has these symptoms because of intercurrent stress and anxiety. Conversely, the patient who experiences increasing fatigue during the day that is relieved by rest often has an underlying medical cause for the fatigue. The presence of other symptoms, such as fever or weight loss, suggests an organic cause. Initial screening laboratory studies may include a complete blood count, sedimentation rate, and urinalysis. Further evaluation should be tailored to the patient's complaints, severity of illness, and physical examination findings. After initial evaluation, if no underlying disease is suspected, the patient should be reassured that his or her symptoms are caused by overactivity and stress and not to any medical disorder. Suggestions regarding health habits, including regular sleep patterns, healthy diet, and regular exercise, may be helpful to some of these patients. If underlying organic disease is suspected, appropriate evaluation and referral should be done. In the instance of underlying emotional problems, social work or psychiatric evaluation with referral is necessary.

Although less common, adolescents may present with a complaint of chronic persistent fatigue. Chronic fatigue syndrome is characterized by acute onset of overwhelming fatigue, malaise, painful lymphadenopathy, sore throat, low-grade or subjective fever, myalgia, arthralgia, headache, and mental exhaustion (Table 130.10). The symptoms are disabling and impact significantly on school attendance and participation in extracurricular activities. Currently, the cause of this syndrome is unknown; most likely, its origin is multifactorial, including viral infection in combination with psychologic predisposition.

1. Persistent fatigue ≥6 months that is new in origin, not the result of ongoing exertion and substantially alleviated by rest, resulting in substantial reduction in previous level of activity

AND

The concurrent occurrence of ≥4 of the following persists/recurring during 6 months:

2. Problems with memory or concentration
   Sore throat
   Tender cervical or axillary nodes
   Muscle pain
   Multi-joint pain with arthritis
   Headaches
   Unrefreshing sleep
   Postexertional malaise

Exclusion:
   Active medical condition that explains fatigue
   Past/current diagnosis of a major depressive disorder, bipolar affective disorder, schizophrenia, delusional disorder, anorexia nervosa, or bulimia nervosa.
   Substance abuse within 2 years of onset

From Fukuda K, Straus SE, Hickie I, et al. The chronic fatigue syndrome: a comprehensive approach to its definition and study. Ann Intern Med 1994; 121:953–959.

Table 130.10. Case Definition for Chronic Fatigue Syndrome

Chronic fatigue syndrome is a diagnosis of exclusion because no reliable physical examination or laboratory markers can indicate its presence. Thus, history and physical examination should focus on eliminating other organic causes, such as collagen vascular disease, malignancy, or chronic infection. Suggested laboratory tests, in addition to those already mentioned, include albumin, globulin, liver function tests, calcium, phosphate electrolytes, blood urea nitrogen, creatinine, glucose, and thyroid function tests. Management includes acknowledging the patient's complaints, explaining that evaluation and tests aid in ruling out other illnesses, and ensuring that long-term outcome for patients with this

disease is excellent. Patients should be referred back to their primary care physician for continued care. Psychological evaluation may prove to be beneficial.

Violence and Abuse

Violent encounters account for many ED visits by adolescents. In a recent report, half of all injuries seen in this age group resulted from violence. Rates of adolescent maltreatment (including physical, sexual, and emotional abuse and neglect) are also high. In 1990, 25% of all cases reported to Child Protective Services were teens between the ages of 12 and 17. Adolescents are less likely to have serious injury or death resulting from these incidents; however, long-term consequences include increased high-risk behaviors, including runaway behavior, violence, and substance abuse. In the ED, violent behavior and maltreatment can be screened for and recognized.

Non-threatening, open-ended interviewing yields maximum information. Barriers in adolescent disclosure include incomplete recall of abusive events as well as their perception that their behavior precipitated the punishment and therefore was deserved. Important information includes the circumstances of the injury, the relationship of the assailant, substance abuse, use of weapons, previous history of violent behavior, and whether the teen plans to seek revenge.

Cases of teen maltreatment should be evaluated by a social worker and reported to Child Protective Services and/or the police. All cases of sexual abuse should be reported to the police. Teens involved in violent behaviors resulting in an ED visit should also be evaluated by a social worker and decisions should be made regarding needs for mental health evaluation and treatment.

Currently, existing child protective and mental health services are sparse. However, this lack should not effect the decision to report.

CONCLUSION

The care of adolescents is both challenging and rewarding. They present to the ED with a wide spectrum of diseases and often require gynecologic evaluation and referral, crisis intervention, and medical or psychological follow-up. Thus, the ED should design an organized approach to the care of the adolescent patient.

CHAPTER 131

Behavioral Emergencies

MIRNA M. FARAH, MD and JOSEPH J. ZORC, MD

Department of Pediatrics, Division of Emergency Medicine, The University of Pennsylvania School of Medicine, and Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

This chapter reviews a number of conditions with prominent behavioral and somatic symptoms that may cause an infant or child 131to be brought to the emergency department (ED) (see Table 131.1). Although these conditions rarely require emergency intervention, the associated symptoms, such as stereotyped movements or cyanosis, may mimic other disorders with important physiologic consequences. The conditions reviewed in this chapter are heterogeneous: age of onset, symptoms, and prognosis vary widely. Some are part of normal childhood development, and others likely have an organic or genetic basis. All of these conditions, however, have prominent behavioral features as part of the history that are the key to diagnosis. Familiarity with these disorders aids the emergency practitioner in an appropriate evaluation followed by reassurance of the family and referral, when necessary, to a source for ongoing care that is the basis of treatment.

Cyanosis
Cyanotic breath-holding spells
Syncope
Cyanotic or pallid breath-holding spells
Motor Activity
Tic disorders and Tourette's syndrome
Paroxysmal choreoathetosis
Benign paroxysmal torticollis
Opsoclonus and myoclonus
Spasmus nutans
Hyperventilation Syndrome
Sleep-Related Disorders (see Table 131.2)

Table 131.1. Behavior-Related Problems Presenting with Somatic Symptoms

GENERAL APPROACH

Diagnosis of these disorders depends on obtaining a history of symptoms associated with the child's other activity at the time. Organic conditions such as seizures (see Chapter 70) or syncope (see Chapter 73) are involuntary and usually unrelated to other behaviors. Gathering the necessary information requires a careful history because the child's caretaker may not recognize the behavioral nature of the event, and emotional response may cloud recall. The clinician should review the episode chronologically in detail; key data include any precipitating events (e.g., breath-holding attacks, hyperventilation); the child's level of consciousness before, during, and after the episode (sleep disturbances); and any history of similar symptoms in the child or family members (tics). Having the caretaker act out the episode to demonstrate it and allow for measurement of duration may be useful. Social history and assessment of family dynamics (see Chapter 129) may further strengthen the diagnosis of some of these disorders.

Further evaluation beyond a careful history and physical examination is generally unnecessary for these conditions. The clinical picture may be specific enough to lead to the correct diagnosis. Laboratory values are generally normal or merely document the degree of symptoms (e.g., cyanosis) that has occurred. If the history is unclear or ambiguous, further investigation or referral may be warranted to rule out an important diagnosis as discussed in the appropriate chapter of this text. As in all uncertain clinical scenarios, the degree of evaluation should reflect the seriousness of potential diagnoses, in accordance with the maxim *primum non nocere* (above all, do no harm).

Management of these disorders generally requires referral to a physician with an ongoing relationship with the patient. For some of the conditions that are part of normal development (e.g., night terrors), reassurance may be all that is necessary. Nevertheless, the emergency practitioner may play an important role in this process because he or she may have the best opportunity to obtain important historical information that may be forgotten by the time of a later evaluation. The effect that a correct initial diagnosis may have on preventing unnecessary tests and reducing further anxiety should not be underestimated.

BREATH-HOLDING SPELLS

Background

Breath-holding spells in young children have been described since antiquity; accounts of this condition can be found in the works of Hippocrates, Rousseau, and Dickens, among others. In the modern medical literature, Lombroso and Lerman characterized the clinical syndrome in a group of 225 children with breath-holding spells. These patients were identified in a prospective study of almost 5,000 children, suggesting an incidence of 4.6%. The physicians described episodes of apnea and color change followed by loss of consciousness and postural tone that appeared to be triggered by an inciting event such as pain, fright, or agitation. Breath-holding children were categorized as cyanotic (62%), pallid (19%), or indeterminate (19%) based on the type of color change. These subgroups appeared to have distinctly different clinical features. Cyanotic breath-holding spells were usually preceded by vigorous crying; pallid spells were sudden and more likely to be followed by convulsive activity.

Pathophysiology

Although the cause of breath-holding spells remains unclear, research has refined the understanding of this condition. The diagnostic term itself is a misnomer. *"Breath-holding"* would suggest voluntarily "waiting to exhale," although most episodes appear to be involuntary and to occur at the end of expiration. Studies of breath-holding children have reported associations with autonomic dysfunction and anemia as well as an apparent familial predisposition. The clinical difference observed between pallid and cyanotic spells may have a basis in pathophysiology; pallid breath-holding spells can be reproduced by a vagal stimulus and are associated with significant bradycardia progressing to asystole. This finding suggests a similarity to vasovagal syncope or neurally mediated hypotension as described in adults. Cyanotic breath-holding spells have been attributed to cerebral hypoperfusion caused by hyperventilation followed by an increase in intrathoracic pressure. Further research is needed to validate these hypotheses.

Diagnosis

The diagnosis of breath-holding spells is based on the clinical history. Initial presentation usually occurs within the first 2 years of life and is not associated with other physical, developmental, or behavioral disorders. The typical episode begins with an inciting stimulus such as anger, frustration, fear, or pain. The child begins to cry, either briefly or for a prolonged period, and then suddenly stops in full expiration with mouth wide open. The spell may resolve at this point or proceed to color change followed by loss of consciousness. The child then becomes limp but soon may progress to an opisthotonic posture. Return to consciousness usually occurs within 1 minute. Severe breath-holding episodes may be associated with body jerks or incontinence and a transient recovery period of several minutes.

When a child is evaluated after a breath-holding spell, the clinician should expect to find a normal physical examination. Laboratory tests are also usually normal and add little to the evaluation. Some physicians suggest measuring hemoglobin because anemia has been associated with breath-holding spells. Electroencephalogram (EEG) performed during a spell reflects hypoxemia, but returns to normal afterward.

The differential diagnosis of breath-holding spells includes seizure disorders (see Chapter 70), structural cardiac disease (e.g., Tetralogy of Fallot), arrhythmia (e.g., long QT syndrome, see Chapter 82), syncope (see Chapter 73), and apnea (see Chapter 10) secondary to infection, brain tumor, injury, or congenital causes. A characteristic history in a healthy child with a normal physical examination should be sufficient to make the diagnosis. The key elements of the history are identifying the precipitating event and determining that the color change preceded any motor activity (unlike most seizures). In uncertain cases involving syncope, an electrocardiogram (ECG) is advisable to measure the QT interval corrected for heart rate. Although unlikely to be necessary in the usual clinical setting, serum prolactin measurement has been suggested as an adjunctive test because it is elevated after a seizure but normal in breath-holding spells and syncope.

Management

Once the diagnosis has been made, parents should be reassured that there is no evidence of long-term sequelae from typical childhood breath-holding spells. The relationship between the inciting event and the spell should be explained, as well as the possibility of recurrence. Frequency of recurrence varies from daily to yearly, but most breath-holding children stop having spells by school age. Inciting events such as pain and frustration are to be expected in healthy children, and overzealous attempts at prevention may impair the exploratory behavior and appropriate limit-setting that is part of normal development. If a spell recurs, parents should be instructed to clear the airway and place the child in a lateral, supine position away from other objects. In severe cases, referral to a specialist is indicated because treatment with atropine, theophylline, or other medications has been helpful in selected cases. A recent trial found a reduced frequency of spells in children treated with iron, although the efficacy of this treatment in non-anemic children remains unclear.

TICS AND MOVEMENT DISORDERS

Tics are involuntary, rapid, repetitive movements or vocalizations that may present throughout childhood and be confused with seizures or other disorders. Tic disorders affect 1 to 10 per 10,000 individuals and range from mild, self-limited symptoms to the chronic Giles de la Tourette syndrome, which can be severe and debilitating. Males are affected with tics three times as commonly as females, and familial predisposition has been well documented. Attention deficit hyperactivity disorder and obsessive–compulsive disorder are more common in children with tics.

Diagnosis of tic disorders relies on obtaining a history of stereotypical, involuntary motor activity that most often involves the muscles of the head and neck. Eye movements, head twitches, and shoulder shrugs are common, although complex movements and vocalizations may also occur. Unlike partial seizures, tics are non-rhythmic and partially suppressible,

which may result in their being absent at the time of an evaluation. Tics tend to increase at times of anxiety, stress, and fatigue and to decrease during sleep or relaxation. The differential diagnosis of tic disorders includes chronic diseases affecting the central nervous system, such as Wilson's disease, Sydenham's chorea, and metabolic disorders. A toxic cause should be considered because adverse reactions to many medications, including neuroleptics, metoclopramide, and antihistamines, can present with dystonic symptoms simulating tics.

ED evaluation and management of tics should be limited to establishing the diagnosis by history and ruling out other conditions. Physical examination is usually normal. Laboratory tests, imaging studies, and EEG are also usually normal and generally unnecessary. The emergency practitioner should reassure the family that the tics are not harmful and should encourage further discussion with a continuing care provider. Mild tics in young children often resolve spontaneously; more severe tics may require referral to a neurologist or psychiatrist for consideration of pharmacologic treatment.

Other movement disorders of childhood are listed in Table 131.1. Disorders of paroxysmal choreoathetosis are usually chronic and familial. Opsoclonus–myoclonus is a syndrome of chaotic, irregular eye movements that is associated with neuroblastoma in more than 50% of affected patients. Spasmus nutans is a condition involving head tilt, nodding, and nystagmus that presents in infancy and is associated with optic glioma in some cases. Benign paroxysmal torticollis presents in infancy with recurring episodes lasting minutes to days and must be differentiated from posterior fossa tumors and other conditions.

HYPERVENTILATION SYNDROME

Background

Hyperventilation is defined as ventilation in excess of that required to maintain normal arterial blood partial pressure of oxygen (PaO_2) and partial pressure of carbon dioxide ($Pa\,CO_2$). It may be produced either by an increase in frequency or in depth of respiration. This syndrome is common in adults but has received little attention in the pediatric literature. It can nonetheless be a disabling clinical pediatric problem that is often misdiagnosed and improperly treated.

Pathophysiology and Dynamics

The pathophysiology of the hyperventilation syndrome contains two components: 1) physiologic derangement produced by hyperventilation (Fig. 131.1) and 2) underlying psychiatric disturbance most often including anxiety.

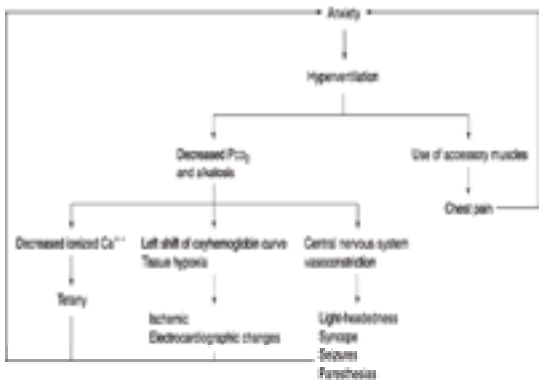

FIGURE 131.1. The pathophysiology of hyperventilation syndrome.

A single deep breath can reduce $PaCO_2$ by 7 to 16 mm Hg, and the $PaCO_2$ can drop to half of normal after only 30 seconds of hyperventilation. Thereafter, only an occasional deep breath superimposed on normal breathing is required to maintain low $PaCO_2$.

When normal subjects voluntarily hyperventilate, they experience relatively few and mild symptoms compared with the exaggerated complaints observed in patients with hyperventilation syndrome. This condition emphasizes the presence of an underlying psychiatric disturbance. Hyperventilation can be a signal of severe anxiety, which may persist into adulthood.

Clinical Manifestations

The age of onset is between 6 and 18 years, with more than half presenting during puberty. The incidence is equal in males and females. Patients almost always report that their symptoms occur in “spells” or “attacks.” In the ED, patients can present with various combinations of symptoms, including: tachypnea, anxiety, breathlessness, light-headedness, paresthesias, coldness of the extremities, tetany, trembling, chest pain, palpitations, blurred vision, feeling of impending doom, syncope, or seizure.

Physical examination may reveal obvious hyperventilation, or, more commonly, the patient may be observed to take periodic deep sighing respirations.

ECG changes, such as ST-segment depression and flattening and inversion of T waves both in the resting and exercise ECG, have been reported in adults who hyperventilate. However, unlike ischemic ECG changes, these changes occur

during early exercise and disappear as exercise continues.

Differential Diagnosis

The manifestations of hyperventilation syndrome are variable and can initially seem worrisome. Organic disorders that require serious consideration in the differential diagnosis include metabolic acidosis, hyperammonemia, hypocalcemia, drug intoxication (including salicylism), hypercapnia, cirrhosis, organic central nervous system disorders, fever, and the response to severe pain. A few paroxysmal disorders, such as hypotensive syncope, Stokes-Adams attacks, epilepsy, migraine, and asthma, must also be ruled out.

Many of these diagnoses can be excluded on the basis of careful history and physical examination. Elements of history that suggest the diagnosis of hyperventilation syndrome include chronicity of the complaint, unrelatedness of symptoms, references to breathlessness, and expressions of anxiety. Assessing whether voluntary hyperventilation reproduces the patient's symptoms is also helpful. This provocation test is currently the best diagnostic method, and is accomplished by asking the patient to hyperventilate for at least 3 minutes, enough to bring the $PaCO_2$, below 50% of baseline. Termination of symptoms on rebreathing into a paper bag is another suggestive finding. When the syndrome is recognized, extensive laboratory evaluation is rarely required in the pediatric population and may add to the child's overwhelming anxiety. However, as in many clinical situations that result in a diagnosis with psychological or psychiatric implications, the emergency physician may elect to order laboratory data to support the diagnosis. The specific tests obtained should be determined by the patient's symptoms, but will usually be selected from among chest radiograph, ECG, serum calcium and electrolytes, and blood gas determinations.

Treatment

The classic remedy for hyperventilation is breathing into a paper bag. The patient rebreathes his or her own expired air and thus inhales air enriched with CO_2.

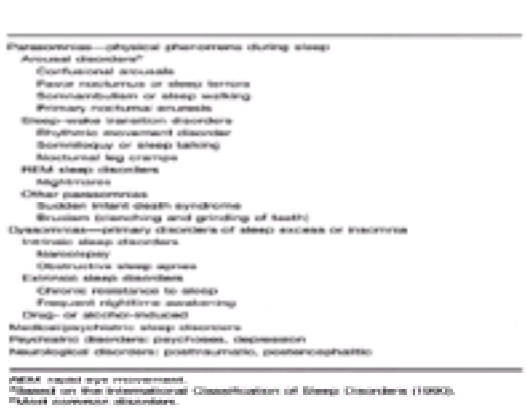
Most experts recommend that the patient understand the mechanism by which the symptoms are produced. Patients need to be reassured in specific terms relevant to their fears. For adolescents in particular, emphasizing that the patient has control over the production of symptoms is important. This understanding is often accomplished by voluntary overbreathing, attribution of cause of symptoms to hyperventilation, and breathing training with emphasis on diaphragmatic breathing and slowing of expiration. Counseling and supportive therapy are necessary to discover the sources of the psychological disturbance experienced by the child. These efforts should start in the ED, but psychiatric consultation and/or referral is often required. Propranolol has been used successfully in children with chronic refractory hyperventilation; however, its use should be limited to patients who fail to respond to educational and counseling therapy.

SLEEP DISTURBANCES

Background

Childhood sleep disturbances are common, and most reflect the particular stresses of certain developmental stages in infants and toddlers. These stresses include resistance to being put down for the night, frequent nighttime awakenings in infancy, and nightmares in the toddler. Anticipatory guidance on the part of the primary care physician can minimize the degree of such disturbances. Such problems are chronic and are rarely seen in the ED.

Some sleep disorders are based on disturbed sleep processes and may appear with dramatic, often paroxysmal clinical features that are frightening to the family and are likely to be seen in the ED (Table 131.2). The differential diagnosis and management of these disorders is discussed more fully in this chapter. Before such discussion, however, briefly reviewing current knowledge of sleep processes may be helpful.



Parasomnias—physical phenomena during sleep
Arousal disorders[a]
Confusional arousals
Pavor nocturnus or sleep terrors
Somnambulism or sleep walking
Primary nocturnal enuresis
Sleep–wake transition disorders
Rhythmic movement disorder
Somniloquy or sleep talking
Nocturnal leg cramps
REM sleep disorders
Nightmares
Other parasomnias
Sudden infant death syndrome
Bruxism (teeth grinding and grinding of teeth)
Dyssomnias—primary disorders of sleep excess or insomnia
Intrinsic sleep disorders
Narcolepsy
Obstructive sleep apnea
Extrinsic sleep disorders
Chronic resistance to sleep
Frequent nighttime awakening
Drug- or alcohol-induced
Medical/psychiatric sleep disorders
Psychiatric disorders: psychoses, depression
Neurological disorders: posttraumatic, postencephalitic
REM, rapid eye movement.
[a]Based on the International Classification of Sleep Disorders (1990).
[b]Most common disorders.

Table 131.2. Sleep-Related Disorders [a]

Sleep Processes

Sleep consists of two non-wakeful states that are best distinguished by the presence or absence of rapid eye movements (REMs). REM and non-REM states have vastly different process characteristics alternating in an orderly cycle of 90 minutes, with progressive increases in the REM sleep across the night. Non-REM sleep is what is commonly thought of as sleep and, after 6 months of age, is typically the first type of sleep entered from the awake state. Non-REM sleep is divided into stages, ranging from stage 1, drowsiness, to stage 4, deep sleep. During non-REM sleep, the pulse and

respiratory rates are slow and regular and some baseline muscle tone with minimal body movements is present. Mentation is light, and imagery is not vivid or easily recalled by a subject awakened from this stage.

REM sleep, conversely, is characterized by facial and body movements and the occurrence of bilateral, synchronous, rapid eye movements. REM sleep represents a period of heightened central nervous system activity, although arousal threshold (the level of stimulus necessary to awaken the subject) is comparable with the deeper non-REM stages. Dreaming occurs during REM sleep. Heart and respiratory rates are faster and more irregular than in non-REM sleep, whereas resting muscle tone is suppressed.

Clinical Manifestations and Management

Parasomnias

Arousal Disorders. All arousal disorders share common features. They tend to occur in the transition from deep non-REM to light non-REM sleep. The various disorders may occur at different times in the same child. A positive family history is often present. Males outnumber females in incidence. The disorders are paroxysmal, associated with activation of the autonomic nervous system and skeletal muscles, unresponsiveness to the environment, and amnesia for the episodes. Fever, physical or mental fatigue, sleep deprivation, and emotional distress can trigger these parasomnias in susceptible individuals.

Confusional arousals consist of disorientation in time and space, slow speech and mentation, and bizarre behavior, such as placing a piece of cloth in the refrigerator. These episodes may last from minutes to hours. They gradually decrease in frequency with age.

Pavor nocturnus (night terrors) is usually seen in preschool-age children. The child abruptly awakens 15 to 90 minutes after sleep onset, with a piercing scream or cry, sits up in bed with wide-open eyes, extreme anxiety, and many autonomic phenomena (sweating, flushing, racing heart-beat, and rapid breathing). The child may be inconsolable for 10 to 15 minutes, but then relaxes suddenly and falls back to quiet sleep. Night terrors usually occur so rarely that treatment is not necessary. Their frequency decreases with age.

Somnambulism appears in school-age children. The child sits up suddenly with eyes glassy and staring, and may then arise and walk around clumsily for 15 seconds to 30 minutes. The child often walks toward a light or a noise, and, after returning to bed, falls asleep uneventfully. Temporal lobe epilepsy may be difficult to distinguish from somnambulism but can be differentiated by adequate sleep EEG studies. Management consists of “sleep-proofing” the home because sleepwalkers can hurt themselves. As opposed to the incidence in adult sleepwalkers, significant psychopathology is not present in school-age children. Parents can be reassured that most children outgrow sleep-walking over several years.

Primary nocturnal enuresis is defined as enuresis occurring in a child older than 3 years of age, who is otherwise well, and has never been dry at night, although he or she can stay dry all day. This condition is the most common non-REM disorder, with an incidence ranging from 5 to 17% of all children between 3 and 15 years of age. The enuretic episode typically occurs during the first cycle of the night. It is characterized by tachycardia, tachypnea, penile erection in males, increased intravesical pressure, and spontaneous bladder contraction. The differential diagnosis includes organic problems such as diabetes mellitus, diabetes insipidus, and urinary tract infection, although these symptoms would be rare if the definition just given is adhered to. Treatment starts with conditioning modalities. Medications such as imipramine that have both anticholinergic effects on the bladder and stimulant effects on sleep stage patterns, or anti-diuretic hormones (DDAVP) are considered a last resort to be prescribed only in severe cases under the supervision of the primary care physician.

Sleep–Wake Transition Disorders. *Rhythmic movement disorder* starts around 8 months of age, and generally stops by age 4. Boys outnumber girls 3:1. The usual pattern is body rocking followed by head rolling or banging against the crib sides, immediately before sleep onset and throughout light sleep, lasting several minutes to an hour. Head banging is typically not associated with crying. No significant injuries are incurred, although callus formation and contusions may be observed. Management consists of reassurance and advice to pad the crib.

Somniloquy appears in school-age children. The speech can be spontaneous or induced by conversation from another person. Sleeptalking may be vivid and revealing, but is also usually outgrown with time.

REM Sleep Disorders *Nightmares* are unpleasant dreams from which the child is usually awake and responsive by the time the parents arrive, and for which substantial recall can occur. Nightmares usually occur in the last third of the night when REM sleep predominates. The child who just had a nightmare should be reassured with embraces and soothing words, and the parent should stay until the child is calm. Parents of children with occasional nightmares should be reassured about the benign nature of these episodes. Frequent nightmares may be a sign of distress that merits a psychological evaluation.

Dyssomnias

Narcolepsy is a rare syndrome of abnormality of REM sleep and excessive sleepiness. Although narcolepsy can begin before the age of 10, gradual onset between 15 and 35 years of age is usual. The two most important symptoms of narcolepsy are daytime sleepiness (that cannot be fully relieved by any amount of sleep) and cataplexy (sudden loss of muscle tone with preservation of consciousness). Other complaints include attacks of daytime sleep, sleep paralysis (inability to move during the onset of sleep or on awakening), hypnagogic hallucinations (vivid imagery at the onset of sleep or awakening), and disturbed nighttime sleep. The occurrence of REM sleep at the onset of sleep is the most characteristic and striking abnormality observed in narcolepsy. Management includes a regular schedule of naps and stimulant drugs, such as a low dosage of dextroamphetamine or methylphenidate for daytime sleepiness, and tricyclic antidepressants for cataplexy, sleep paralysis, and hypnagogic hallucinations. The degree of sleepiness rarely lessens

but cataplexy, sleep paralysis, and hypnagogic hallucinations improve or disappear with age in one third of patients.

Obstructive sleep apnea syndrome refers to upper airway obstruction, frequent apneic spells during sleep, and disordered sleep stages with increased stages 1 and 2 and decreased stages 3 and 4 of non-REM sleep. Children may present with loud snoring, excess daytime somnolence, morning headaches, hypertension, cardiac arrhythmias, cor pulmonale, enuresis, anoxic seizures, and poor school performance. Management involves otolaryngologic consultation for thorough airway evaluation and appropriate measures to relieve obstruction, maintenance of continuous positive airway pressure (CPAP), and initiation of weight loss in obese children (see Chapter 95).

Miscellaneous

A few additional sleep-related disorders are noted in Table 131.2, including nocturnal leg cramps, bruxism, sleep disorders related to substance abuse, neuropsychiatric conditions, and sudden infant death syndrome. The latter is discussed in detail in Chapter 10.

BACKGROUND—THE THREAT OF BIOLOGICAL AND CHEMICAL TERRORISM

Emerging Patterns of Terrorism

At 8:00 AM on March 20, 1995, at the height of a Monday morning rush hour, members of the Japanese Aum Shinrikyo religious cult placed 11 containers of the deadly nerve agent sarin in various downtown locations of the Tokyo subway system and unleashed on their fellow citizens, and the world, a new era in terrorism. An earlier sarin attack (targeting several judges involved in trials of Aum cult members) on a residential neighborhood of Matsumoto in June 1994 had caused hundreds of exposures, seven deaths and grim notice by experts in counter-terrorism. This same group also possessed, and attempted to deploy, anthrax and botulinum toxin weapons on several occasions.

However, the chemical warfare attack on downtown Tokyo, one of the world's largest and most cosmopolitan capitals, resulting in more than 5000 victims and 12 deaths, brought the potential of terrorist use of weapons of mass destruction on large civilian populations to international attention. Of course, the prior several decades had already witnessed enormous tragedy caused by terrorists of various ethno-nationalist and separatist groups, with attacks in most cases targeted at military installations, government officials or representatives, or on occasion at relatively small groups of ordinary civilians in highly visible circumstances.

Still, the 1990s has brought us across a new threshold, as detailed by Hoffman in his thoughtful analysis, *Inside Terrorism.* The rise of religious terrorism has allowed violence to become a seemingly justifiable means to accomplish a sacred theological imperative. This rationalization of violence by placing it in subservience to unquestioned religious ends has the effect of removing normal moral and political constraints to violence in the minds of many religious fundamentalists. Their deeply held convictions serve to legitimize in their own eyes the indiscriminate and large-scale killing of often broadly defined infidel enemies, who may include most of a population. Several terrorist attacks in the 1990s have highlighted this new willingness to kill large numbers of innocent people indiscriminately: witness the Oklahoma City bombing, and the bombing of the World Trade Center in New York City where the perpetrators were attempting to topple one of the twin towers into the other with hopes of killing up to 250,000 people. The threshold to attempt killing mass numbers of persons has already been crossed.

The 1980s and 1990s saw several additional examples of religious and political terrorism in the United States. In 1984, the Rajneeshee cult poisoned 750 citizens of The Dalles, Oregon by intentionally contaminating restaurant salad bars

with *Salmonella typhimurium.* Recently, additional persons linked to white-supremacist militias have obtained anthrax, stockpiled the highly toxic substance ricin, a biotoxin extracted from castor beans, and have been arrested for transporting the bacterium *Yersinia pestis,* the causative agent of bubonic plague. Such incidents further illustrate the potential for biological or chemical terrorist attacks.

Finally, the Aum Shinrikyo sarin attack in Tokyo has opened Pandora's box not only by demonstrating the willingness to use chemical or biological warfare agents but also by proving that it can be done successfully. The stakes have been raised for other terrorists to outdo the Aum, and the coming of the millennium, with its mystical, apocalyptic interpretations to so many such cults, may portend even worse disasters. Thus, health care workers, particularly first-responders and emergency department (ED) personnel, must be familiar with the expedient diagnosis and management of chemical and biological terrorist events.

Weapons of Mass Destruction

The term *weapons of mass destruction* (WMD) has been used to denote weapons using *nuclear* (radiologic), *biological* or *chemical* (NBC) agents in devices intended to intentionally kill and injure large numbers of victims. Biological and chemical weapons are currently believed by U.S. military and counterterrorism experts to constitute a plausible and favored mode of WMD attack on civilian populations by terrorist groups. These agents are relatively inexpensive and technically far less difficult to produce and deploy than nuclear weapons, and the raw materials for their production are less highly regulated (radiologic exposure is discussed in Chapter 90). In recent years, state sponsorship of terrorism has risen, and access to biological and chemical agent information has increased via the Internet.

Chemical and biological weapons could be deployed in several ways readily accessible to terrorist groups. Relatively simple explosive devices can be combined with these agents, and additional simple mechanical devices such as garden sprayers, aerial crop dusting equipment, insect control vehicles, or aerosol spray devices, might all be used. In addition, a conventional attack on factories, chemical production facilities, or tank cars might result in the release of large quantities of toxic industrial chemicals, with resulting effects similar to an attack by military chemical warfare agents. Biological agents would likely involve aerosol dispersal.

Medical Consequences and Epidemiology

Estimating the real probability of a chemical or biological terrorist attack is difficult. According to Tucker's recent overview, extreme scenarios, such as a massive state-sponsored attack, can be conceptualized as a “low-probability, high-consequence event” that could potentially kill thousands and result in unparalleled demands on health care facilities for treatment of casualties. On the other hand, events such as The Dalles, Oregon, salad bars incident, and/or numerous hoaxes, are much more likely but have a lower potential for severe consequences. Chemical events, in particular, would likely combine elements of traditional mass disasters (e.g., secondary to earthquake), in which large numbers of casualties occur almost immediately, and elements of traditional hazardous materials (HAZMAT) incidents. However, chemical events differ from HAZMAT incidents in several important ways: 1) the intent is to inflict mass casualties; 2) the “hazardous materials” in these cases are of particularly high lethality; 3) the “HAZMAT” environment created would be extremely toxic to rescue workers; 4) considerable ambiguity might initially occur regarding the exact nature of the agent(s) involved; 5) the numbers of patients requiring relatively urgent treatment might be overwhelming to existing emergency medical services (EMS); 6) an even larger number of patients who were minimally affected, if at all, might self-transport to receiving EDs and place yet additional demands on the health care system; and 7) mass hysteria and panic would almost certainly ensue, further compromising the health care system's ability to respond optimally.

Okumura et al. reported many of these features in the Tokyo sarin attack. At about 8:00 AM, five subway cars were attacked simultaneously. By 8:28 AM, an ambulatory victim arrived to one area ED a short distance from the affected subway stations. At 8:43 AM, the first ambulance arrived, and the next hour brought an additional 500 patients, including 3 in cardiopulmonary arrest. City wide, 5510 persons sought emergency medical treatment at more than 200 facilities within a few hours of the attack, and of these, about 25% required hospitalization. Of note, most of the victims went to hospitals by taxi, bus, or private vehicles of good Samaritans, rather than by formal EMS transport, further compounding the understandable initial chaos. Until the identity of the agent was known, significant efforts at patient decontamination were lacking, resulting in several occurrences of illness among hospital staff, although most were of a mild degree. The morbidity of the attack was actually thought to have been substantially mitigated by several fortuitous factors. The sarin was dispersed via evaporation from plastic bags left open on the subway cars. Although considered a “nonpersistent” agent, the volatility of sarin at room temperature is only about the same as water, and thus the sarin had not disseminated widely throughout the cars when the incident was discovered. In addition, the Tokyo subways are considered to have an excellent ventilation system. The fact that the exposure to patients was via vapor, and that consequently their skin and clothing were minimally contaminated, also lessened secondary exposure to hospital personnel.

In a biological attack, it is important to emphasize that, because of their incubation periods, biological agent releases must be thought of in a different context than conventional and chemical terrorist attacks. Biological agent attack should be thought of as a public health emergency, when patients present remote in time and space from the point of exposure. Without an announcement by a terrorist group, an unusually large number of persons presenting with clinical findings of the disseminated disease would likely be the first indicator of a biological agent attack. The situation is further complicated because early symptoms resulting from biological agents are non-specific. Thus, patients may present to various clinics and EDs in piecemeal fashion, complaining, for example, of flu-like symptoms. The clinician in such settings must maintain a high index of suspicion if a biological attack is to be diagnosed in time for useful measures to be undertaken.

Moreover, as stressed by Franz et al., all such personnel must have a grasp of the fundamental principles of epidemiology and be able to apply these principles in working up an unexpected outbreak of unusual illness. These principles include 1) careful documentation of who is affected, 2) possible routes of exposure, 3) clinical findings of the

disease, 4) efforts at rapid identification of the causative organisms, 5) formulation of a case definition, 6) quantifying the number of cases, and 7) calculating the attack rate. The epidemic can then be described in terms of timing, place, routes of exposure, and other clinical characteristics of ill patients. The disease pattern that evolves is critical to recognizing a biological agent attack. Most natural epidemics evolve with a gradual rise in disease incidence because persons are progressively exposed to increased numbers of infectious patients, fomites, or vectors that spread the organism.

In contrast, after a biological agent attack, most persons would initially be exposed at the same time, and thus become ill and present in a relatively compressed time frame. Variations in the incubation period may occur, however, even with a point source exposure, possibly because of differences in dose of the agent received, immunologic status, and other factors. Diseases that are rare, not endemic in the area of exposure, or that are normally spread by vectors that are not indigenous to the relevant geographic area would of course also be suspect, especially if numerous cases developed simultaneously. Additional clues to a biological agent attack might include especially high infection rates among exposed persons, more respiratory forms of disease than usual, particularly high morbidity or mortality, several epidemics at once, attack rates lower in persons sheltered from the suspected route of exposure, infected or dying animals, and the discovery of suspicious actions or potential delivery systems. The earliest suspicion of such an outbreak should be reported at once to appropriate public health authorities.

DECONTAMINATION AND HEALTH CARE WORKER PROTECTION

The approach to patient decontamination after a WMD attack, similar to any significant hazardous materials incident, poses complex logistical challenges, involving both pre-hospital and ED-based operations. The on-scene and pre-hospital aspects of this process are of critical importance, but are beyond the scope of this discussion. From the hospital perspective, prioritization is to 1) protect current patients, staff, and facility; 2) provide optimal care to the patients presenting as victims of the incident; and 3) consider protection to the environment external to the hospital. In many communities, decontamination activity for most HAZMAT incidents is expected to be carried out on the scene by specially trained HAZMAT teams within the EMS system.

As previously noted, this scenario may be overly optimistic for a WMD event. Thus, although decontamination of the most severely affected patients would likely occur in the field, EDs should have a plan in place to enable decontamination of patients who arrive unexpectedly or on their own without prior decontamination. Although some distinctions can be made between necessary and sufficient health care worker protection from radiologic, chemical, and biological exposures, the predicted rarity of need for such a response suggests the utility of devising a single, universal ED decontamination protocol, and keeping this protocol as simple, practical, and inexpensive as possible. The following paradigm, adapted from the recent review by Barbera et al. in 1999, offers overall guidelines to such an approach.

Decontamination capability must be available on a short set-up time basis. Many models have been proposed, but most authorities recommend an outdoor facility with multiple patient stations, arranged so that parallel lines of ambulatory and non-ambulatory patients may be processed simultaneously. An outdoor facility is more capable of handling multiple patients and may make the use of copious water irrigation easier; however, it may end up exchanging a direct indoor airborne-dissemination hazard for the problem of defining and containing areas of outdoor vapor or aerosol hazard.

Optimally, an elevated platform would allow drainage, minimizing risk of patients slipping and falling, and of further exposure of victims to contaminated rinse water. Medical personnel in personal protective equipment (PPE) should staff an initial triage station at the entrance to the decontamination structure. Triage at this point facilitates rapid identification of patients requiring immediate antidotal or other life-saving intervention, as well as diversion of non-ambulatory patients to the appropriate area with medical assistance. Ambulatory patients are instructed in self-decontamination. Obviously, young children require assistance, or may be accompanied by parents if present. The outdoor facility must provide adequate water, temperature control during environmental extremes, and measures to maintain personal modesty, such as curtains or other barriers separating shower lines for males from lines for females.

A universal decontamination process has been proposed that simplifies staff education and uses easily accessible, inexpensive components. The sequential approach begins with complete disrobement and containment of contaminated clothes in impervious plastic bags. This step is followed by a dilute bleach wipe-down with 0.5% sodium hypochlorite solution made from a 1:10 dilution of standard household bleach (1 part bleach added to 9 parts water). This step is expected to disinfect almost all biological agents and may inactivate many chemical agents, including mustard and organophosphates. Little field testing has occurred under actual WMD circumstances, however, and even less discussion has taken place regarding applicability to infants and young children. The bleach solution is not recommended for open thoracic or intra-abdominal wounds, exposed nerve tissue, or in the eyes. Because as much as 15 to 20 minutes of contact time may be necessary to optimal inactivation of some chemical agents by bleach solutions alone, decontamination efforts should stress physical and mechanical removal over chemical decontamination for chemical warfare agents. In fact, the evolving consensus on biological agent decontamination is that clothing removal combined with soap and water washing/showering will be adequate in most cases of biological agent exposure.

Far more important than choice of dilute bleach or water for casualties exposed to these agents is gentle but thorough rinsing of affected skin, eyes, and wounds. Following the dilute bleach wipe-down, or in lieu of it, patients undergo a copious warm water rinse, and then thorough washing with a hypoallergenic soap and soft-bristle brushes or sponges (stiff brushes or abrasives should be avoided), followed by another rinse, and then a final rinse once they have moved past other in-use patient decontamination stations. A few hazardous materials, such as reactive metals (sodium, potassium, lithium) and strong corrosives in powder or particulate form are rare exceptions to the “universal” approach in that application of water is best avoided until all visible particles are removed with forceps, gentle brushing or vacuuming.

Riot-control agents are better not treated with dilute bleach because the reaction of bleach with these compounds creates equally irritating byproducts that could worsen skin burns. Persistent or thickened agents may require more prolonged soap and water washing. After passing through the decontamination process, patients are triaged again, with treatment categories assigned as appropriate. The matter of wash/rinse water run-off, and its containment, has been the

subject of some controversy. The potential for significant environmental damage in the context of ED-based patient decontamination after a WMD attack is likely limited, and notification of appropriate water-department authorities is probably sufficient.

Appropriate PPE for ED staff is an important consideration. The amount of chemical or biological agent believed to contaminate patients who would arrive alive at the ED after a WMD attack would consist essentially of that on their skin and clothing, and would thus be of far lower concentration than rescue workers would face at the scene of exposure. Most authorities believe adequate protection in this context would be afforded to ED staff garbed in level C PPE, which consists of a non-encapsulated chemically resistant body suit, gloves, and boots, with a full-face air purifier mask containing a cartridge with both an organic-vapor filter for chemical gases and vapors and a HEPA filter to trap aerosols of biological and chemical agents. Such PPE is much less cumbersome to work in than level A or B outfits (which use self-contained breathing apparatus) and is much less expensive.

Choices regarding specific materials used in level C PPE options are difficult because few such barrier materials have been tested against WMD agents. At least one such material, DuPont's Tyvek F, has been found effective against mustard and organophosphate agents, but again, given the predicted low concentration and short contact times relevant to the ED decontamination process, less expensive fabrics may be adequate. Biological agents require a considerable degree of energy to re-aerosolize from contaminated skin or clothing, and they are not (in contrast to chemical agents), either volatile or (with the exception of trichothecene mycotoxins) dermally active (i.e., they neither cause skin lesions nor penetrate intact skin to cause disease). Thus, surface decontamination of biological agents, although still necessary, is nevertheless considered less critical than decontamination of chemical agents.

BIOLOGICAL AGENTS

For biological threats in particular, considering the aims of the potential perpetrator is useful. Organized nation states may envision biological agents as either strategic or tactical weapons. When the strategic threat is considered, few agents possess the necessary stability to serve as large-scale weapons; the list of potential threats in this regard might include anthrax, plague, and smallpox. From a tactical perspective, toxin agents such as botulinum toxin and staphylococcal enterotoxins might be added to this list, although in reality, biological agents would seldom make good tactical weapons because these agents possess an important characteristic not shared by conventional or nuclear weapons; namely, an incubation period (of note, several chemical agents also exhibit a delay between exposure and the onset of clinical signs and symptoms; for chemical agents, this interval, analogous to the incubation period for biological agents, is called the latent period). Typically, these incubation periods are in excess of 24 hours. Many belligerents would not want to deploy a weapon on the battlefield and then wait several days for its effects to be realized.

When the terrorist threat is considered, however, the problem becomes immense. The aim of a potential terrorist often may simply involve publicity for a cause. In this sense, anthrax, plague, botulism, and smallpox still make excellent vehicles for terrorism. In addition, diseases not considered viable military weapons, such as those caused by human immunodeficiency virus (HIV), *Ebola, Shigella, Escherichia-coli* O157:H7, and the like, may be employed by terrorists for their “headline-grabbing” potential. This chapter limits discussion to a short list of the most viable agents typically considered in a weapons context (Table 132.1). A concise but comprehensive overview of biological warfare agents and their management is available in the U.S. Army Medical Research Institute of Infectious Diseases' (USAMRIID) monograph *Medical Management of Biological Casualties—Handbook.* An encyclopedic treatment of these agents, edited by Sidell, *Medical Aspects of Chemical and Biological Warfare* in Part 1 (Warfare, Weaponry and the Casualty) of the series *Textbook of Military Medicine,* has also been recently published.

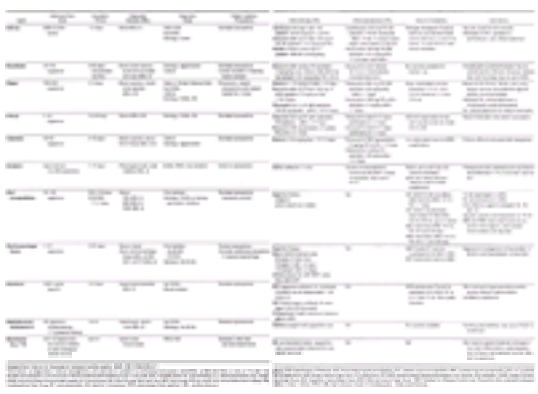

Table 132.1. Summary of Biological Warfare Agents

Anthrax

Background

Most planners agree that anthrax clearly represents the single greatest military and terrorist threat from biological warfare agents. Moreover, a World Health Organization (WHO) report estimated that 3 days after the release of 50 kg of anthrax spores along a 2-km line upwind of a city of 500,000 people, 125,000 infections would occur, producing 95,000 fatalities. This statistic represents far more fatalities than were predicted with any other agent considered. Furthermore, anthrax was made into a weapon by the United States in the 1950s (stockpiles were subsequently destroyed in 1969 when President Nixon renounced the use of biological weapons), by the Soviet Union, and by Iraq, attesting to its utility as a strategic weapon. In fact, an accident at a Soviet military compound in Sverdlovsk in 1979 resulted in at least 66 deaths caused by inhalational anthrax, an inadvertent demonstration of the viability of this weapon. None of these 66 known

victims were children. Whether this outcome is because of differences in susceptibility between pediatric and adult patients is unclear. A recent report by Elkin et al. from Canada noted a similar phenomenon in bison calves as compared to mature animals.

Pathophysiology

Anthrax is caused by infection with the Gram-positive sporulating rod-shaped bacterium *Bacillus anthracis.* The spore form of this organism is extraordinarily hardy and can survive long periods without nutrients or moisture. It lends itself well to aerosolization, drifts readily on air currents, and resists environmental degradation. Moreover, an anthrax biological weapon can be manufactured to contain particles of the ideal size (2 to 6 microns in diameter) for impinging on human lower respiratory mucosa, optimizing the chance for infection.

Most cases of endemic anthrax are cutaneous in nature and are contracted by close contact with the hides, wool, bone, and other byproducts of infected herbivores, principally cattle, sheep, and goats. Cutaneous anthrax is amenable to therapy with any number of antibiotics and is thus rarely fatal. Although common in parts of Asia and sub-Saharan Africa, anthrax is rare in the United States, the last case having been reported in 1991. Gastrointestinal (GI) anthrax is contracted via the consumption of contaminated meat and is also rare. Inhalational anthrax, also called woolsorter's disease, has been an occupational hazard of abattoir and textile workers; immunization has all but eliminated the hazard for these workers in western nations. However, this inhalational form of the disease poses a significant threat when anthrax is used as an aerosol weapon.

Upon inhalation of the necessary inoculum (estimated to be 8,000 to 10,000 spores), infection begins with the uptake of spores by pulmonary macrophages that carry the spores to lymph nodes located in the mediastinum. Here, *B. anthracis* finds a favorable milieu for growth, vegetates, and begins to produce proteins known as edema factor (EF) and lethal factor (LF). A third protein, termed protective antigen (PA), serves as a necessary carrier molecule for EF and LF and permits penetration into cells. Edema toxin results from the combination of EF and PA, whereas LF and PA together constitute lethal toxin. These toxins result in necrosis of lymph nodes and adjacent tissues, releasing more anthrax organisms. The organisms gain access to the circulation, and an overwhelming fatal septicemia rapidly ensues. At autopsy, widespread hemorrhage and necrosis, involving multiple organs, is seen.

Clinical Manifestations

Inhalational anthrax has an incubation period of 1 to 6 days. The ensuing flu-like illness is characterized by fever, myalgia, headache, cough, and chest “tightness.” A brief intervening period of improvement sometimes follows 1 to 2 days of these prodromal symptoms, and a rapid deterioration then occurs. This second phase is indicated by high fever, dyspnea, cyanosis, and shock. In some cases, chest wall edema (thought to be caused by the effect of EF) may be seen. Terminal hemorrhagic meningitis is present in up to 50% of cases. Chest radiographs obtained late in the course of illness may demonstrate a widened mediastinum and peripheral blood smears at this stage may reveal the characteristic Gram-positive spore-forming bacilli. Death is universal in untreated cases and may occur in as many as 95% of treated cases if therapy is begun more than 48 hours after the onset of symptoms.

A diagnosis of anthrax should be suspected upon finding Gram-positive bacilli with terminal spores in skin biopsy material (in the case of cutaneous disease) or in blood smears. Chest radiographs exhibiting a widened mediastinum in the proper setting of fever and constitutional signs and, in the absence of another obvious explanation (e.g., penetrating trauma), should also lead the clinician to consider a diagnosis of anthrax. Confirmation is obtained by culturing *B. anthracis* from blood.

Management

Ingelsby et al have recently published consensus-based recommendations for the management of anthrax used as a bioweapon. Endemic strains of *B. anthracis* are typically sensitive to a wide variety of antibiotics, including penicillin G, which remains the preferred drug for endemic anthrax. Because antibiotic-resistant strains of *B. anthracis* can be readily produced in laboratories, however, many experts consider ciprofloxacin (adult dosage: 400 mg intravenously every 12 hours; pediatric dosage: 20 to 30 mg/kg per day intravenously divided in two daily doses) the preferred drug for treating victims of intentional anthrax exposure. Doxycycline (adult dosage: 100 mg intravenously every 12 hours; pediatric dosage: 2.5 mg/kg intravenously every 12 hours) is considered an acceptable alternative, although doxycycline-resistant strains of *B. anthracis* are known. In cases of endemic inhalational anthrax or in which organisms are known to be susceptible, penicillin G (adult dosage: 4 million units intravenously every 4 hours; pediatric dosage: 200,000 units/kg per day intravenously in divided doses every 6 hours) is recommended.

Post-exposure prophylaxis against anthrax is achieved with oral ciprofloxacin (adult dosage: 500 mg orally every 12 hours; pediatric dosage: 20 to 30 mg/kg per day orally divided in two daily doses) or doxycycline (adult dosage: 100 mg orally every 12 hours; pediatric dosage: 2.5 mg/kg orally every 12 hours). All potentially exposed persons should be administered one of these regimens at the earliest possible opportunity. In addition to such chemoprophylaxis, victims must be immunized; based on animal data, chemoprophylaxis should be continued until a victim has received at least three doses of vaccine (thus, for a minimum of 4 weeks). The available vaccine is fully licensed, and consists of a purified preparation of protective antigen. It is given in a pre-exposure regimen at 0, 2, and 4 weeks, and at 6, 12, and 18 months. Persons at continuing risk of exposure receive yearly boosters. Exposed victims of bioterrorism would receive at least three doses, assuming no further exposure is likely, before discontinuing chemoprophylaxis. Postexposure chemoprophylaxis with antibiotics should be administered for up to 60 days if no vaccine is available for exposed individuals.

Several unique problems confront those managing the pediatric patient. First, anthrax vaccine is approved only for those 18 to 65 years of age. Second, both the quinolones and tetracyclines have relative contraindications to their use in children, although the dental staining seen with tetracyclines usually requires multiple courses and the risk of cartilage

problems associated with quinolones is theoretical. The extreme danger posed by anthrax exposure seems to warrant use of any or all of these modalities in the exposed child.

Anthrax has little potential for person-to-person transmission; standard precautions are thus adequate for health care workers managing anthrax victims. Moreover, given the 1- to 6-day incubation period, decontamination of victims presenting days after exposure would rarely be necessary.

Plague

Background

Plague, caused by infection with the Gram-negative bipolar-staining bacillus, *Yersinia pestis,* is usually transmitted in nature via the bite of fleas. This era is the plague's third global pandemic, and disease is still seen in areas of South and Southeast Asia, as well as in South America and Africa. Plague has long appeared attractive to bioweaponeers. Testimony to its extreme lethality and infectivity can be obtained by considering that the “Black Death” eliminated one-third of the population of Europe during the Middle Ages. Even then, its potential as a weapon was noted when Tatar invaders, in 1346, catapulted infected corpses over the walls of Kaffa (now Fyodosia) in the Crimea in an attempt to infect defenders within the city. Plague was extensively studied by the Japanese Unit 731 in occupied Manchuria in the 1930s and was suspected to have occupied a prominent place in the Soviet bioweapons arsenal.

Pathophysiology

Y. *pestis* is a facultative intracellular pathogen that is able to survive temporarily within the macrophage, thus aiding its dissemination to distant sites following inoculation or inhalation. It is lymphotrophic, and significantly tender regional lymphadenopathy (e.g., in the distribution of a flea bite) is often a prominent feature of bubonic plague. A plasminogen activator and coagulase produced by the organism contribute to the spread of the organism throughout the body. Pneumonic plague (along with smallpox) is one of the few bioterrorist threats readily transmissible from person-to-person via the respiratory route, and coughing patients are often highly contagious.

Clinical Manifestations

Bubonic plague is characterized by the classic bubo, a tender, enlarged, fluctuant lymph node in the distribution of the infected flea bite. Fever and malaise are usually present. Bubonic plague may progress to septicemia as bacteria gain access to the circulation; 80% of bubonic plague victims have positive blood cultures. Petechiae, purpura, and overwhelming disseminated intravascular coagulation (DIC) may develop.

Pneumonic plague may arise secondarily after seeding of the lungs or may be seen primarily after aerosol exposure. Symptoms include high fever, chills, malaise, fatigue, headache, and cough. Chest radiographs may reveal a patchy or consolidated bronchopneumonia, and the classic clinical finding is one of blood-streaked sputum; DIC and an overwhelming sepsis may develop as the disease progresses. Meningitis develops in 6% of cases. Untreated pneumonic plague has a mortality rate approaching 100%.

A presumptive diagnosis of plague can be made by observing the classic bipolar-staining “safety-pin”–like bacilli in Gram or Wayson stains of sputum, aspirated lymph node material, or cerebrospinal fluid. Confirmation is obtained via blood, sputum, or aspirate culture; the organism grows on standard blood or MacConkey's agars but is often misidentified by automated systems.

Management

Traditionally, streptomycin (15 mg/kg intramuscularly every 12 hours) has been the preferred drug for treating all forms of plague. Because of difficulties in obtaining this drug, however, clinicians have turned to alternatives, such as gentamicin (1.75 mg/kg intravenously every 8 hours) or doxycycline. Chloramphenicol (75 to 100 mg/kg per day in four divided doses) should be used in cases of plague meningitis. To be effective, therapy for pneumonic plague must be initiated within 24 hours after the onset of symptoms.

Post-exposure prophylaxis should be administered to asymptomatic victims of a bioterrorist attack, as well as to close contacts (including medical personnel) of pneumonic plague victims. Prophylaxis consists of tetracycline (25 to 50 mg/kg per day orally in four divided doses for 7 days) or doxycycline (2 to 4 mg/kg per day orally in two divided doses for 7 days). Again, although tetracyclines are relatively contraindicated in children, the potential severity of plague would seem to warrant their pediatric usage in this context. Trimethoprim—sulfamethoxazole may be used in tetracycline-intolerant patients. Droplet precautions should be employed in cases of suspected pneumonic plague. Such precautions should be continued in confirmed cases until sputum cultures are negative. Standard precautions are adequate in managing bubonic plague victims. Given the incubation period, decontamination would rarely be necessary in a clinical setting. A licensed plague vaccine exists, but production difficulties have made it problematic to obtain. This vaccine was developed to prevent bubonic plague in endemic regions, and animal data suggest that it is unlikely to protect against the pneumonic form of the disease.

Smallpox

Background

The global eradication of smallpox represents one of the great success stories of public health, with the last endemic case occurring in Somalia in 1977. Since then, research stockpiles of variola virus have been consolidated into two WHO-approved stores: at Centers for Disease Control and Prevention (CDC) in Atlanta, and at a Russian institute in

Koltsovo, near Novosibirsk. This achievement would seem to make terrorist use of this virus impossible; however, several factors give cause for concern. First is the fear that other stockpiles already exist in the hands of belligerent nations unbeknownst to WHO. Second, the entire viral genomic sequence is known and published; therefore, it is likely only a matter of time before technology permits reconstruction of the virus. Finally, although the virulence factors of variola virus are poorly understood, it may be possible for someone to manipulate related orthopoxviruses such as monkeypox to enhance their virulence in humans and create a disease like smallpox, as noted recently by Bremen and Henderson.

Smallpox, like plague, has a history of use in warfare. In 1763, during the French and Indian War, Sir Jeffery Amherst of the British Army was assigned to capture Fort Carillon from its Indian defenders. He obtained the scabs from smallpox victims, laced blankets with material from these scabs, and passed the blankets as “gifts” to the Indians. These Indians did, in fact, succumb to smallpox and Fort Carillon fell to the British.

Several factors might make smallpox an attractive weapon to potential belligerents. First, immunity after vaccination lasts only 3 to 5 years. Vaccine is no longer in production, stockpiles are dwindling and losing potency, and susceptibility to the disease is becoming nearly universal. Second, effective therapy is lacking. Third, modern health care providers are unfamiliar with the disease. Finally, the potential for rapid spread potentially permits a terrorist to cause widespread disease and panic with a minimum of infectious material.

Pathophysiology

Smallpox has an incubation period of 7 to 17 days, permitting wide dispersal of disease by exposed persons before clinical symptoms appear. During this time, the virus replicates in upper respiratory tract mucosa, giving rise to a primary viremia. The liver and spleen are then seeded, further amplification of the virus occurs, and a secondary viremia ultimately develops. The skin is seeded with this secondary viremia, and the classic exanthem of smallpox develops.

Clinical Manifestations

Clinical illness begins rather abruptly during the phase of secondary viremia, and is characterized by fever, malaise, rigors, vomiting, headache, and backache. The classic exanthem typically begins 2 to 4 days later as macules on the face and extremities. These lesions progress in synchronous fashion to papules, then to pustules, finally forming scabs. As scabs separate, survivors are left with disfiguring depigmented scars. The rash spreads centrally to the trunk but remains more abundant at the periphery. This centrifugal distribution and synchrony distinguish smallpox from the principal differential diagnostic consideration, chickenpox, which has a centripetal distribution of lesions in varying stages of development. An enanthem usually accompanies the characteristic exanthem, and internal organs become viral targets as well. Death occurs in 30% of variola major (the predominant form of smallpox in the past) patients and typically results from visceral organ involvement. Eye involvement leads to blindness in a small number of victims. Uncommon variants with lesser (variola minor) or greater (hemorrhagic, flat-type smallpox) mortality also existed.

Management

Even a single case of smallpox would represent a grave public health emergency, as detailed recently by Henderson et al. Strict quarantine (with both airborne and contact precautions) should be instituted immediately (preferably at dedicated sites away from hospitals) for victims (until all scabs separate) as well as for close contacts (for 17 days from last exposure). Based on past experience, vaccination of victims within the first several days after exposure should be efficacious in preventing disease; vaccine may be obtained through the CDC.

Although successful at eradicating smallpox, vaccination with live vaccinia virus is fraught with complications. Formation of a “pock” at the vaccine site is believed to be necessary for development of adequate immunity. This pock contains infectious material, and scratching the lesion can lead to autoinoculation of the skin or eye. Generalized vaccinia, a self-limited, immune-mediated phenomenon, occurs in a significant minority of vaccine recipients, and more serious complications may arise if vaccine is given to immunocompromised patients, patients with atopic dermatitis (eczema), or pregnant women. To manage these complications, vaccinia immunoglobulin (VIG) must be kept on hand when contemplating a vaccination effort. VIG (0.6 mg/kg intramuscularly) may be given to vaccine recipients who experience severe complications or to significantly immunocompromised individuals exposed to smallpox. An additional concern is that current stocks of VIG are no longer FDA-approved at this time. In the case of a bona fide exposure to smallpox, however, pregnancy and atopic dermatitis would not constitute absolute contraindications to vaccination.

No licensed antiviral drugs are currently available to treat smallpox. Cidofovir has shown promise in treating other orthopoxvirus infections in animal models.

Botulism

Background

Botulism's potential as a weapon has long been recognized. Pancho Villa developed recipes for the manufacture of botulinum toxins using decaying meat and beans; he may have used these preparations as crude biological weapons against Mexican federal troops during the period from 1910 to 1912. Botulinum toxin was included in the U.S. biological arsenal in the 1950s and 1960s, and was weaponized by the Soviet Union and by Iraq. The Aum Shinrikyo cult in Japan tried unsuccessfully to disseminate botulinum toxin before deciding to release sarin in the Tokyo subway system.

Botulism occurs as a result of exposure to one of seven botulinum neurotoxins (A through G). Only types A, B, E, and rarely, F appear to cause human botulism in nature. Therefore, a licensed antitoxin having activity only against types A, B, and E is produced. This fact has potential implications to the terrorist attempting to weaponize this agent.

Pathophysiology

Botulinum toxins are produced by certain strains of *Clostridium botulinum,* a strictly anaerobic spore-forming Gram-positive bacillus commonly found in soil. Recently, a few cases of type F neonatal botulism have been described; in these cases, *Clostridium baratii* was believed to be the source of toxin. Botulism has additional unique epidemiologic considerations in infants and neonates; more extensive discussion of infant botulism, and of botulism in general, may be found elsewhere in this text (see Chapter 83 and Chapter 88). The botulinum toxins are the most toxic substances known to man, with an LD50 of 0.001 µg/kg. These toxins function at the presynaptic nerve terminal, preventing the release of acetylcholine, thereby leading to a generalized flaccid paralysis and autonomic symptoms.

Clinical Manifestations

Following a latent period ranging from 24 hours to several days, victims begin to experience cranial nerve dysfunction, manifesting as bulbar palsy, ptosis, photophobia, and blurred vision owing to difficulty in accommodation. Symptoms progress to include dysarthria, dysphonia, and dysphagia. Ultimately, a descending, symmetric, flaccid paralysis ensues. The mucous membranes are dry; this fact, along with mydriasis, the nature of the paralysis (lack of initial fasciculations), and the latent period, all differentiate botulism from nerve agent intoxication. A solitary case of botulism must also be differentiated from myasthenia gravis, Guillain-Barré syndrome, tick paralysis, and a few other uncommon neurologic disorders. The presence of multiple casualties with similar symptoms makes the diagnosis of botulism rather straightforward. Botulism deaths result finally from paralysis of respiratory muscles.

Management

Supportive care, with meticulous attention to ventilatory support, remains the mainstay of botulism management. Patients may require such support for several months, making the management of a large-scale botulism outbreak especially problematic in terms of medical resources.

A trivalent (types A, B, and E) botulinum antitoxin is licensed and available through the CDC. Although administration of antitoxin is unlikely to reverse disease, it may be useful in preventing progression when administered to exposed persons. The antitoxin is prepared from horse serum and requires that a test dose be administered before therapy; patients reacting to this test dose require desensitization prior to treatment. An investigational heptavalent despeciated (Fab2) antitoxin, also produced in horses, is available through USAMRIID on a compassionate use protocol, and has been used on rare occasion to treat type F botulism in neonates. Administration of a test dose is also required with this product because it still contains approximately 4% whole antibody. A human botulinum immunoglobulin is being used on an investigational basis by the California State Health Department to treat infant botulism cases in California (see Chapter 83 and Chapter 88).

Other Agents

Numerous other agents may present bioterrorist threats of varying degrees. In addition to previously discussed incidents, terrorists and belligerents have attempted to use *Salmonella, Shigella,* Glanders, ricin, Cholera, Typhus, and probably many other organisms or toxins to induce disease. Many of these agents are discussed adequately elsewhere in this and other texts; several others warrant additional comment (see Table 132.1).

Venezuelan equine encephalitis makes an attractive weapon because of its high infectivity; virtually all non-immunes contracting the virus become symptomatic. In adults, this disease is usually self-limiting, with few patients developing encephalitis. In infants and young children, however, the disease can be severe, with as many as 4% developing overt encephalitis, often leading to permanent sequelae and death. In nature, the disease is transmitted via the bite of *Culex* mosquitoes. When delivered intentionally via aerosol, access to the olfactory bulbs may produce more rapid and/or more severe neurologic disease. Treatment is supportive.

Tularemia is another disease with high infectivity; as few as 10 organisms constitute an infectious dose in humans. Given this high infectivity, clinical laboratories should be alerted to the possibility of tularemia before attempting to culture the causative agent, *Francisella tularensis.* Several clinical forms of tularemia are known, but inhalational exposure in a terrorist attack would presumably lead to pneumonia or to the typhoidal form of the disease and would manifest as a variety of non-specific symptoms, including fever, prostration, weight loss, and abdominal pain. Treatment is accomplished with streptomycin or gentamicin at dosages similar to those recommended for plague. Post-exposure prophylaxis consists of doxycycline, tetracycline, or ciprofloxacin given for 2 weeks. Given the potential problems with these drugs in young children, prophylaxis should not be undertaken without adequate cause.

Staphylococcal enterotoxins are often mentioned as biological threat agents, and staphylococcal enterotoxin B (SEB) has been weaponized in the past. Although familiar to many clinicians as a common cause of food poisoning, SEB would also be a potent toxin if delivered by aerosol. Symptoms produced in this manner would begin 3 to 12 hours after exposure and consist of fever, headache, chills, myalgias, and non-productive cough. Dyspnea and chest pain accompanies high dosages of inhaled toxin. Nausea, vomiting, and diarrhea may occur as a result of inadvertently swallowed toxin. Treatment is supportive; meticulous attention should be paid to fluid management. Patients may be ill for as long as two weeks with aerosol exposure.

Various fungal toxins, such as the trichothecene mycotoxins, have been mentioned in a biowarfare or bioterrorism context. After the Vietnam War, the U.S. government accused the Soviets of using a trichothecene toxin, T-2 (otherwise known as “yellow rain”) against Hmong tribesmen. The Iraqis are known to have weaponized another fungal toxin, aflatoxin, which in addition to acute clinical effects is a potent hepatic carcinogen. Trichothecene toxins are of particular importance to those clinicians treating children because young infants may possess a unique susceptibility to the effects of these toxins. From 1993 to 1996, a cluster of acute pulmonary hemorrhage cases occurred among infants in

Cleveland, Ohio. In a case control study, homes of affected infants were found to have greater amounts of *Stachybotrys atra,* a fungus that appears to thrive on damp building materials, than did control homes. *S. atra* produces trichothecene toxins, which were implicated in these infants' illnesses. Symptoms produced by various mycotoxins are variable and depend on the route of exposure. The trichothecene mycotoxins are different from virtually all other bioterrorist agents in that they are dermally active. Treatment is supportive.

Chemical Agents

Background

The history, toxicology, and medical management of chemical warfare agents have recently been reviewed in an excellent monograph prepared by the U.S. Army Medical Research Institute of Chemical Defense (USAMRICD) at Aberdeen Proving Ground, Maryland. An encyclopedic discussion of these agents can be found in the Army's recently released volume, *Medical Aspects of Chemical and Biological Warfare,* in Part 1 (Warfare, Weaponry, and the Casualty) of its series *The Textbook of Military Medicine.* Chemical warfare dates back to antiquity, when the Chinese used arsenical smokes in about 1000 BC and Spartan allies used burning sulfur and coal smoke to attack the Athenian-held fort of Delium in 423 BC, during the Peloponnesian war. The 19th and early 20th centuries saw early but unsuccessful attempts to limit chemical warfare on ethical grounds via the Brussels Convention of 1874, and the Hague conventions of 1899 and 1907. World War I became the venue for the first large-scale use of such agents, particularly the gases chlorine and phosgene and the vesicating agent sulfur mustard. Thousands of casualties occurred because of pulmonary, cutaneous, and ocular effects.

The Geneva Protocol of 1925 proscribed the first use, although not the possession or retaliatory use, of biological and chemical weapons, and has since been signed by most nations. In the 1930s, the German chemical industry synthesized potent organophosphate compounds in the search for improved insecticides. These compounds were weaponized during World War II as tabun (GA) and sarin (GB), the first of the nerve agents. Neither side is believed to have used chemical agents in battle during World War II, with the possible exception of poorly documented attacks by Japan against China. However, both Allied and Axis powers produced and stored enormous amounts of both vesicants and (after the war) nerve agents, leaving a heritage of chemical-weapon stockpiles throughout the world today. Iraq is known to have used chemical agents against Iran and also its own Kurdish population during the Iraq–Iran war in the 1980s. During the Gulf War, the existence of the Iraqi chemical agent armamentarium was well known, and led to an increased determination to prepare and defend American military forces against such an attack. Finally, as previously noted, religious terrorists used sarin against civilians in Japan in 1994 and 1995.

Most chemical warfare agents are liquids at room temperature, but may exist as aerosols of tiny droplets after dispersal by munitions. Liquids are also volatile to varying degrees and thus may vaporize into a gaseous phase, particularly in conditions of high temperature, strong wind, and deposition onto relatively non-porous surfaces. A few agents, for example chlorine, phosgene, and hydrogen cyanide, exist primarily as gases in typical summertime conditions. Chemical agents may also be characterized by their environmental persistence, which is inversely related to volatility. Persistent agents, such as mustard and the nerve agent VX, pose a greater secondary contamination hazard from exposed terrain or material, or via contact by rescue and/or health care workers with a victim's clothing or skin than do the nonpersistent agents chlorine, phosgene, hydrogen cyanide, and the G nerve agents.

Toxic effects from chemical agents may occur via topical injury to the skin, the eyes, and the respiratory epithelium of the respiratory tract and via systemic absorption. Although chemical agents are volatile and dermally active, biological agents in general possess neither of these properties. Most of the modern medical literature on the clinical effects of chemical warfare agents centers on the nerve agents, which are emphasized in this chapter. Clinical syndromes related to vesicants, pulmonary agents, cyanide, and riot-control agents are also briefly summarized (Table 132.2). General principles of supportive care for poisoned patients are detailed in Chapter 88, and apply largely to the general support of chemical warfare agent victims as well.

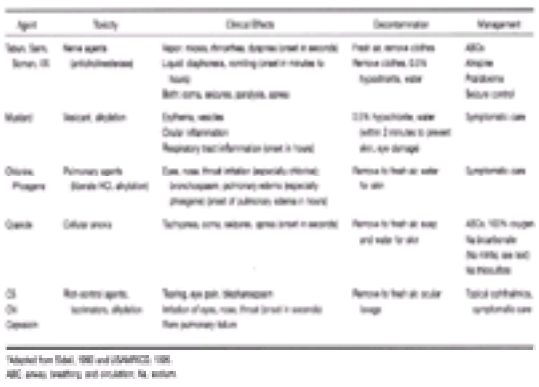

Table 132.2. Principal Chemical Warfare Agents*

Nerve Agents

Nerve agents are organophosphorus compounds, and, similar to organophosphate insecticides, are potent and essentially irreversible inhibitors of acetylcholinesterase (see Chapter 88). Certain oximes can dissociate bound nerve agents from acetylcholinesterase but only initially; after a variable period (depending on the structure of the nerve agent), a portion of the organophosphate is cleaved (in a process called aging) and the resulting nerve-agent–cholinesterase complex becomes refractory to oxime action. The “G” (for “German”) nerve agents, developed in Germany just before and

during World War II, include GA, or tabun; GB, or sarin; and GD, or soman (“GC” was allegedly not used to avoid confusion with the common designation for gonorrheal infection); VX (reportedly “Venom” X) was developed by Great Britain and the United States in the late 1940s and early 1950s. All four nerve agents are liquids at temperate conditions, but may be aerosolized by spraying or during an explosive detonation.

The G agents are moderately volatile, and relatively nonpersistent; the most volatile, sarin, evaporates at almost exactly the same rate as does water. Although VX is minimally volatile, potentially lasting weeks or longer on contaminated surfaces, at temperatures above 100°F (37.8°C) it can cause inhalational toxicity. The time required for these agents to undergo aging varies from a few minutes for soman to 48 hours for VX. The nerve agent vapors are all heavier than air, and would thus affect persons closer to the ground (e.g., those in trenches and basements, and perhaps young children) disproportionately. Although all these agents are hazardous by ingestion, inhalation, and cutaneous absorption, the primary danger from the G agents is inhalation of vapor, whereas VX is primarily a skin-contact hazard except when it is explosively aerosolized.

Toxicology

Nerve-agent–induced inhibition of acetylcholinesterase causes the neurotransmitter acetylcholine to accumulate in cholinergic synapses and in neuromuscular and neuroglandular junctions; this excess of acetylcholine initially causes end-organ stimulation which may then lead to end-organ failure. Cholinergic sites are found in the central nervous system (CNS), in the neuromuscular junctions of somatic nerves, and in several autonomic nervous system sites, including parasympathetic nerve endings, some sympathetic nerve endings (e.g., sweat glands), and both parasympathetic and sympathetic ganglia. The cholinergic syndrome thus produced is classically divided into CNS, nicotinic (neuromuscular junction and sympathetic ganglia), and muscarinic (smooth-muscle and exocrine-gland) effects. CNS effects include altered mental status progressing through lethargy to coma, ataxia, convulsions, and respiratory depression (central apnea). Although seizure initiation is probably a result of excess cholinergic stimulation, other mechanisms, including excitatory glutamate receptor stimulation and antagonism of inhibitory gamma-aminobutyric acid receptors, may also play important roles in seizure propagation. Neuropathologic changes observed in animal studies also suggest that prolonged seizure activity further disturbs excitatory amino acid and *N*-methyl-D-aspartate receptor function, ultimately leading to neuronal calcium influx and neuronal injury, as recently reviewed by McDonough and Shih.

Nicotinic effects include muscle fasciculations and twitching, and then weakness progressing to flaccid paralysis. Nicotinic effects on sympathetic activity may also result in tachycardia, hypertension, and metabolic aberrations (e.g., hyperglycemia, hypokalemia, metabolic acidosis). Muscarinic toxicity is manifested by 1) ocular findings (miosis, visual blurring, eye pain, and lacrimation); 2) respiratory findings (watery rhinorrhea, bronchospasm, and increased bronchial secretions causing cough, wheezing, dyspnea, and cyanosis); 3) dermal findings (flushing and sweating); 4) GI findings (salivation, nausea, vomiting, and diarrhea progressing to fecal incontinence and abdominal cramps); 5) genitourinary findings (frequency, urgency, and incontinence); and 6) cardiovascular findings (bradycardia, hypotension, atrioventricular block). Because muscarinic effects on the heart are opposed by the cardiovascular effects of nicotinic hyperstimulation at autonomic ganglia, heart rate and blood pressure in nerve-agent victims may be either elevated or depressed and are not reliable indicators of the severity of nerve-agent intoxication.

Clinical Presentation

The clinical presentation in a given patient depends on dose and route of exposure. For vapor exposures, mild toxicity would be suggested by miosis, rhinorrhea, mild dyspnea, and wheezing—all local effects caused by contact of vapor with epithelial surfaces. As the dose increases, and systemic distribution of the agent occurs, the victim might experience increased respiratory secretions and dyspnea, nausea, vomiting, and muscle weakness. In the Tokyo experience with sarin vapor exposure, miosis (99%), dyspnea (63%), nausea (60%), and headache (74%) were particularly common among moderately symptomatic patients at hospital admission. In severe cases with exposure to high vapor concentrations, rapid onset of paralysis and seizures leading to death from respiratory arrest may occur within minutes. In the Tokyo sarin incident, 3 patients of 640 presented to one ED in cardiopulmonary arrest. One patient was unresponsive to initial resuscitation, one patient experienced severe hypoxic damage and died on hospital day 28, and one patient was extubated after one day and recovered fully.

With vapor inhalation, affected patients do not typically deteriorate once they are removed from the exposure. In contrast, with dermal exposure, symptoms may progress even after the agent is removed from the skin surface. Initial findings after a small dose might include localized sweating, followed by localized fasciculations of underlying muscle. Systemic effects from larger doses of liquid usually begin with GI signs and symptoms but then progress to generalized fasciculations, muscle weakness, paralysis, convulsions, and death resulting from respiratory failure from CNS depression and respiratory muscle paralysis. Eye findings and obstructive respiratory effects tend to be less prominent in these patients. Because of the time (up to 18 hours for a small drop of VX) needed for liquid nerve agent to penetrate the skin, dermal exposures have a longer latency, and patients may not become symptomatic for several hours after exposure, even after decontamination. However, a pin-head-sized droplet (10 mg) of VX may cause sudden collapse with paralysis, apnea, and death after a latent interval of only 10 to 30 minutes.

Management

The diagnosis of nerve-agent poisoning is primarily by clinical recognition and response to antidotal therapy. Routine toxicologic studies do not identify organophosphate compounds or their metabolites in blood or urine. Measurements of acetylcholinesterase in plasma or in erythrocytes has traditionally been used to confirm organophosphate insecticide poisoning, and the activity of these enzymes is decreased after significant nerve agent toxicity as well. Erythrocyte acetylcholinesterase activity is a more accurate guide to acute toxicity, whereas measurements of plasma cholinesterase (pseudocholinesterase, or butylcholinesterase) are more useful for monitoring patient recovery during the weeks after exposure. However, correlation between cholinesterase levels and clinical effects is poor in mild to moderate exposures, and the test is rarely available on a stat basis. Treatment for symptomatic patients is indicated without awaiting

cholinesterase levels, but antidotal therapy is not needed for exposed asymptomatic patients, even if cholinesterase levels are depressed.

Treatment considerations begin with appropriate decontamination strategies and ED staff personal protection, as previously reviewed. Triage is based on patient prognosis and availability of resources. In cases of exposure to nerve agent vapor, in particular, maximum toxicity is manifested rapidly, and patients presenting with severe symptoms obviously require emergent therapy. Patients similarly exposed with milder effects will not worsen after arrival to the ED (unless they have continuing exposure from vapor trapped in and then released from clothing) and pose little threat of secondary contamination. The primary decontamination necessary for these individuals is clothing removal and perhaps hairwashing to remove agent vapor absorbed to scalp or facial hair. In contrast, patients with liquid dermal exposure require meticulous decontamination. Their skin and clothing pose a serious risk to ED personnel, and these patients may develop late-onset effects, or worsen, even after decontamination. Patients with ocular exposure should have copious eye irrigation with saline or water.

The overall approach to specific interventions for these agents focuses on airway and ventilatory support, and aggressive use of antidotes, particularly atropine. If a rapid sequence intubation is necessary, most authors discourage the use of succinylcholine because its effect is significantly prolonged (as a result of depressed cholinesterase activity). After intubation, positive-pressure ventilation may prove difficult because of bronchospasm and copious airway secretions. Because prompt administration of atropine may be life-saving in a patient with otherwise intractable bronchospasm, atropine should be administered in such a patient even before intubation and ventilation are attempted. If the patient presents with seizures, and in any patient with signs of severe intoxication, immediate administration of benzodiazepines beginning in usual anticonvulsant doses is indicated as well (e.g., diazepam, 0.1 to 0.3 mg/kg intravenously in children, 5 to 10 mg intravenously in adolescents or adults). Additional doses of diazepam may be required in such patients. Ongoing seizure activity may be missed if the patient is paralyzed by prolonged iatrogenic neuromuscular blockade or by the paralytic effects of the nerve agent toxicity, and subsequent bedside electroencephalographic monitoring may be necessary. Rapid, aggressive treatment of seizure activity is considered vital to prevent nerve agent–induced neuropathology, and prophylactic administration of benzodiazepines in severely poisoned patients at high risk for seizures is also crucial.

Antidotal therapy includes atropine for its anti-muscarinic effects and pralidoxime chloride to reactivate acetylcholinesterase. By acting as a competitive inhibitor of acetylcholine at postsynaptic and postjunctional cholinergic receptors, atropine antagonizes the effects of excess acetylcholine on smooth muscle, the heart, secretory glands, and the CNS, thus alleviating bronchospasm and increased bronchial secretions, bradycardia, and the GI effects of nausea, vomiting, diarrhea, and cramps. However, atropine does not reverse skeletal muscle paralysis. The dose is 0.02 mg/kg in children with mild to moderate exposure (minimum dose 0.1 mg), but may be increased to 0.05 mg/kg in more severely affected patients. Comparable doses in adolescents or adults are 2 and 5 mg, respectively. This treatment may be repeated every 2 to 5 minutes as needed to reverse muscarinic effects.

Miosis is not a good clinical sign for gauging atropinization, and although atropine may elevate an already increased heart rate, tachycardia by itself is definitely not a contraindication to continued use of atropine. Conversely, bradycardia by itself is not an indication for additional atropine, and an underlying cause such as hypoxia should be sought. The two major clinical endpoints for atropine administration are 1) decrease in secretions, and 2) decrease in airway resistance, manifested by decreasing resistance to ventilation in an apneic patient or decreasing dyspnea in a conscious patient. In nerve-agent poisoning, the total dose of atropine (usually no more than 20 mg during the first 24 hours in adults) needed has been observed to be considerably less than the massive quantities (sometimes more than 1000 mg) necessary in severe intentional pesticide overdoses.

Pralidoxime (2-PAM) is an oxime that cleaves the bound nerve agent from the acetylcholinesterase, and regenerates the intact enzyme if aging has not yet occurred. Although the action of this antidote is on the bound enzyme/nerve-agent complex, the observed clinical effects are predominantly nicotinic, with improved muscle strength. Pralidoxime thus complements the actions of atropine and should be given with atropine in all serious cases of nerve-agent poisoning. The dosage is 25 to 50 mg/kg intravenously over 30 minutes in children (1 to 2 g for adolescents or adults). Side effects of pralidoxime include nausea, vomiting, transient diplopia, headache, and most important, hypertension, all of which are minimized by the recommended slow infusion rate. Too rapid intravenous delivery of 2-PAM has also been reported to temporarily worsen cholinergic findings.

For severe cases without initial improvement, a repeat dose may be given immediately after the first. If some improvement is noted, a second dose 60 to 90 minutes later is warranted. Patients with nerve agent poisoning who have undergone adequate decontamination are not expected to require either numerous repeated doses or continuous infusion of pralidoxime, as has been advocated with severe insecticide overdose. Both atropine and pralidoxime may be administered intramuscularly at similar dosages if intravenous access is not readily available. In fact, the U.S. military has issued intramuscular autoinjector kits of atropine and 2-PAM to soldiers for in-the-field buddy and self-administration and is developing a combination atropine–2-PAM autoinjector. Intramuscular injection of 2-PAM in normotensive patients results in therapeutic blood levels within 10 minutes, and may hasten the action of concomitantly administered atropine.

Many authorities, including military medical specialists, have recommended routine use of anticonvulsant doses of benzodiazepines in significant cases even without observed convulsive activity, because animal studies have indicated some amelioration of subsequent seizures and morphologic brain damage with such use. However, ED personnel administering benzodiazepines prophylactically should anticipate the need for airway support because benzodiazepine-induced respiratory depression may exacerbate that caused by nerve-agent toxicity. Last, recent work by Lallement et al. suggests that a glutamate antagonist, GK-11 (gacyclidine), has synergistic anti-convulsive and neuroprotective effects with atropine and pralidoxime in a primate-soman model.

Pediatric Considerations

Little experience is available to comment on differences between pediatric and adult patients in the dose–response curve or the toxic-effect spectrum with exposure to nerve agents, or in response to therapy. The thinner skin of children might make them more susceptible to dermal absorption on a mg/kg basis in comparison to adults. Likewise, the immature blood–brain barrier in infants might increase the relative risk of CNS toxicity. One case series of anticholinesterase pesticide poisoning in children found that depressed sensorium and muscle weakness/flaccidity were more prominent than muscarinic findings. Nevertheless, more than half of these patients did demonstrate miosis (80%), tearing and excess salivation (60%), and GI findings (52%).

Also, severe organophosphate pesticide poisoning in children may certainly manifest by dramatic muscarinic findings, including respiratory compromise, in many cases (see Henretig, 1994, Chapter 88). It seems doubtful that the nerve agent toxidrome, and hence the appropriate management approach, would differ significantly in children from that in adults. During the Gulf War, 240 Israeli children were evaluated for accidental autoinjection of atropine, most commonly in the hand. None of these patients had been exposed to nerve agent. Administered doses were up to 17 times the recommended dose for age. Systemic effects occurred in 48% of victims, but no seizures, severe arrhythmias, or deaths were observed. Thus, atropine, even at high dosages, and without organophosphate nerve agent toxicity, seemed to be fairly well tolerated in this pediatric cohort.

Disposition and Prognosis

The disposition of exposed patients depends on severity of symptoms and route of exposure. Most patients presenting after vapor exposure manifest peak toxicity by the time of hospital arrival, and when their symptoms have either resolved, or abated to only mild eye findings (miosis from exposure to nerve-agent vapor may persist for up to 6 weeks), they may be discharged. After dermal exposure, symptom onset may lag up to 18 hours, and most experts recommend a 24-hour observation period even in initially asymptomatic victims.

The prognosis for apparently full recovery from even severe nerve agent poisoning appears to be good with timely life support interventions and adequate antidotal therapy. Apneic patients have recovered ventilatory function within 3 hours, and once consciousness was regained, muscle weakness and obtundation have resolved over a few days, whereas miosis and subtle mental status effects have persisted for several weeks. Nerve agents, unlike some pesticides, have not been implicated in delayed peripheral neuropathy.

Vesicants

The major vesicants, or blistering agents, are cellular poisons and include the mustards (sulfur mustard and nitrogen mustards) and Lewisite. The mustards are believed to act primarily as alkylating agents, whereas Lewisite is an organic arsenical thought to affect the thiol groups in critical cellular enzymes. Both nitrogen mustards and sulfur mustard were used as chemical-warfare agents in World War I, but only sulfur mustard is regarded as a significant concern today (one of the nitrogen mustards, HN_2 or mechlorethamine, was introduced in the 1940s as the first cancer chemotherapy drug). Sulfur mustard was used extensively in World War I, by several countries after that war, and recently by Iraq in the Iraq–Iran war of the 1980s. Lewisite is not known to have been used in battle, but concern about the potential of Lewisite as a chemical-warfare agent led British scientists to develop an antidote, British Anti-Lewisite (BAL), at the end of World War II. This compound is recognized today as an important chelating medication, finding use in the treatment of poisoning by lead and mercury, as well as by its original target metal, arsenic. However, because little clinical experience with Lewisite exposure exists, this discussion focuses on mustard.

Mustard exists as an oily, yellow to dark brown liquid with a garlic or mustard odor. It has relatively low volatility and is considered persistent, although at high temperatures vapor hazard is considerable. An estimated 80% of mustard casualties during World War I were caused by mustard vapor exposure (although 80% of World War I *fatalities* from chemical warfare agents were caused by pulmonary agents). The lethality of mustard to well-protected troops on the battlefield in World War I was less than 5%, but this agent would be far more deadly against unsuspecting and unprotected civilians, as mustard use against Abyssinia (now Ethiopia) in the 1930s and in the Iraq–Iran War of the 1980s amply demonstrated. An amount as little as one teaspoon may kill a 70-kg adult.

Mustard causes injury to rapidly reproducing cells (i.e., is “radiomimetic”), and its clinical effects are most evident on the skin, in the eyes, and in the respiratory tract. With severe exposures, the bone marrow, GI mucosa, and the CNS may also be damaged. Although mustard-induced cell injury begins within the first few minutes after exposure, clinical effects of mustard usually follow a latent period that is inversely related to dose but that is often 4 to 6 hours. Skin lesions after liquid contact begin with erythema, followed by blister formation, or if the dose is large enough, skin sloughing without blister formation. The burns are usually partial-thickness (second-degree). Blister fluid does not contain active mustard and is not hazardous. Vapor exposure results in later, and usually milder, skin injury.

Ocular lesions from vapor include conjunctival inflammation, corneal damage, and often severe lid edema. Permanent blindness is a rare complication, but many patients presenting for treatment may be functionally blind because the pain and blepharospasm induced by mustard renders them unwilling to open their eyes. Vapor-induced pulmonary effects begin with upper respiratory tract irritation, and may progress through dyspnea and a productive cough to a severe necrotizing tracheobronchitis with pseudomembrane formation. Patients may succumb to secondary bacterial bronchopneumonia. Bone marrow damage may occur in severe cases on about the third to fifth days after exposure, and manifest as progressive pancytopenia. Low leukocyte counts (less than $500/mm^3$) or a precipitous decrease in leukocyte count portend a serious risk of sepsis and death. An accident involving the explosion of a mustard-containing shell caused a heavy exposure to three children. These patients presented acutely with altered mental status and muscle activity, and two of them died 3 to 4 hours after exposure. A case series of Iranian children and adolescents exposed to mustard during the Iraq–Iran War found that compared with adults, the younger victims exhibited a shorter onset and more severe dermal lesions, attributable to the more delicate skin in this age group.

Because mustard penetrates tissue rapidly, and binds to cellular components within the first 2 to 5 minutes, the most important early intervention is immediate (i.e., at the scene) decontamination as soon as possible after exposure. Skin and eye decontamination are accomplished similarly as discussed for nerve agents. Additional, or delayed, decontamination at the time of ED arrival may still be of value in preventing further skin damage, systemic absorption, and secondary contamination of the patient and health-care workers, although it must again be pointed out that blister fluid from mustard casualties does not pose a contamination threat. No specific antidotes to mustard poisoning are available. Supportive care for skin lesions is analogous to that provided for burn injury, although fluid requirements are usually far less than with comparable body-surface-area thermal burns. Additional treatment of respiratory tract inflammation, ocular injury, and immunosuppression associated with leukopenia may be required (see Chapter 114,Chapter 95,Chapter 111, and Chapter 87, respectively).

Pulmonary Agents

Toxic inhalant agents may cause injury in several ways, including simple asphyxia by displacing oxygen, topical damage to airways or alveoli, systemic absorption through the pulmonary capillary bed, and allergic hypersensitivity reactions. Both chlorine and phosgene were used in battle in World War I, are commonly used for industrial purposes today, and are reviewed briefly in this section.

Chlorine is considered a gas with relatively low to intermediate water solubility and chemical reactivity, whereas phosgene is considered to have low solubility and reactivity. Because the initial irritant symptoms of gas exposure tend to correlate with water solubility and chemical reactivity, low-dose exposures to chlorine, and even moderate exposures to phosgene, might cause either no symptoms at all or only mild irritation of eyes, nose, and upper airways during exposure. Victims could easily dismiss these effects, thus prolonging exposure and the severity of the ultimate lung injury. Chlorine lung injury is probably mediated by both hydrochloric acid generation in the upper airway and by free oxygen radical cascade at the alveolocapillary membranes in the lower airway.

Phosgene (carbonyl chloride) is also thought to generate hydrochloric acid, contributing particularly to upper airway, nasal, and conjunctival irritation, as well as a carbonyl group that participates in acylation reactions at the pulmonary alveolocapillary membranes; the resulting leaking of fluid across damaged membranes eventually leads, after an asymptomatic period, to pulmonary edema. Phosgene lung injury may also be mediated in part by an inflammatory reaction associated with leukotriene production.

Chlorine is a dense, acrid yellow–green gas of intermediate water solubility and tends to settle close to the ground. Initial effects after mild to moderate exposure include ocular and nasal irritation, followed by cough, and progressing to a choking sensation and substernal chest tightness. Bronchospasm often occurs, especially in patients with a history of reactive airway disease. Pulmonary edema may follow significant exposures within 2 to 4 hours. Severe exposures result in the rapid onset (within 30 to 60 minutes) of pulmonary edema, in addition to the initial irritation.

Mild to moderate exposures to phosgene may be initially asymptomatic, with only the perception of a pleasant odor of newly mown hay. Thus, lung exposure time may be significant before the victim removes himself or herself from the affected area. Pulmonary edema occurs after a considerable delay, typically 4 to 6 hours, but with lower exposures as late as 24 hours after exposure. In these cases, dyspnea precedes objective clinical or radiologic findings. With higher exposures, early lacrimation may be followed by cough and dyspnea, and pulmonary edema, although still delayed, supervenes earlier than with a low-dose exposure. The pulmonary edema may be so severe as to result in hypotension from hypovolemia. The onset of dyspnea within the first 4 hours after exposure to phosgene portends the eventual development of massive pulmonary edema and a grave prognosis.

Management of exposure to pulmonary agents is primarily supportive (see Chapter 95). Decontamination is primarily removal to fresh air. Careful attention to control of pulmonary secretions, bronchospasm, and pulmonary edema, as well as to aggressive treatment of secondary bacterial infection (often occurring 3 to 5 days after exposure) is required. Enforced bed rest may delay the onset and reduce the eventual severity of phosgene-induced pulmonary edema. Steroids have not been of significant benefit and may increase risk of secondary infection; however, they may be warranted in patients with severe bronchospasm and a history of asthma. In chlorine exposures, some symptomatic relief has been reported with nebulized 2% sodium bicarbonate therapy, but the impact of this regimen on pulmonary damage is unknown. Animal models have suggested a benefit of anti-inflammatory agents, including ibuprofen and *N*-acetylcysteine, to ameliorate phosgene-induced pulmonary edema, but these interventions have not yet been reported in clinical trials.

Cyanide

Compounds containing the cyanide ion (CN^-) have a long history as favored agents for homicide and suicide, but their efficacy as chemical warfare agents is somewhat limited by their volatility in open air and, on the battlefield, by their flammability. However, if released nonexplosively in a crowded, closed room, they could have devastating effects. Chemical agents containing cyanide include the liquids hydrocyanic acid (hydrogen cyanide, HCN) and cyanogen chloride (ClCN), both of which rapidly vaporize after release.

Cyanogen chloride may cause some initial eye, nose, and airway irritation from its chlorine moiety, but its systemic effects are the same as those of hydrocyanic acid and result from toxicity of its cyanide anion. Hydrogen cyanide dissociates only minimally to hydrogen ions and cyanide, but the intact molecule (HCN) appears to act by the same mechanism as the cyanide anion itself.

Toxicology

Some cyanide is normally present in human tissues and several pathways exist for its metabolism. Cyanide reacts

reversibly with metals such as ferric ion (Fe^{3+}) and cobalt; in the body, the reaction of hydroxocobalamin with cyanide yields cyanocobalamin, or vitamin B_{12}. Cyanide also reacts with sulfur-containing compounds. The enzyme rhodanese detoxifies cyanide by catalyzing its reaction with a sulfur donor to form the relatively nontoxic thiocyanate and sulfite ions, which are then renally excreted. The ability of the body to metabolize small quantities of cyanide given sufficient time accounts for the dependence of cyanide toxicity on conditions of concentration and exposure time. The same amount of cyanide that will kill when given over a few minutes may be successfully metabolized by the body if administered over several hours.

Doses of cyanide large enough to overwhelm normal metabolism inhibit electron transport at the cytochrome aa_3 complex (cytochrome oxidase) of the mitochondrial cytochrome chain. The inactivation of this enzyme site, critical to aerobic adenosine triphosphate (ATP) production, results in cellular anoxia and a decreased arteriovenous oxygen difference (from inability of cells to utilize delivered oxygen), as well as in lactic acidosis (from attempts to generate energy anaerobically).

Clinical Manifestations

Clinical manifestations of cyanide poisoning relate to cellular anoxia, and thus those organs that are metabolically most active, particularly the brain and heart, are most severely affected. The carotid body chemoreceptors, which receive the highest relative blood flow and oxygen delivery of any tissue in the body, are rapidly stimulated by the presence of high concentrations of cyanide, and mediate a pronounced gasping reflex, which increases rate and depth of respiration. They also indirectly stimulate the adrenal medulla to release epinephrine, with resulting initial tachycardia and hypertension. Thus, high concentrations of cyanide vapor initially produce tachypnea, hyperpnea, and hypertension within 10 to 15 seconds. Anoxic injury to the CNS and myocardium soon follow, with unconsciousness and seizures (30 seconds after exposure), opisthotonus, trismus, decerebrate posturing, bradycardia, arrhythmias, hypotension, and eventually cardiac arrest (as soon as 4 to 8 minutes after exposure).

Exposure to low concentrations of vapor produces nonspecific effects such as headache, light-headedness, nausea, and ataxia. “Classic” signs of cyanide poisoning are said to include severe dyspnea without cyanosis, or even with cherry-red skin (because of lack of peripheral oxygen use), and a bitter almond odor to breath and body fluids. However, some cyanide-poisoned patients develop cyanosis, and only about half the population is genetically capable of detecting the cyanide odor. Noteworthy laboratory abnormalities in cyanide poisoning include an abnormally high mixed venous oxygen saturation (because of decreased peripheral oxygen utilization), a decreased arteriovenous oxygen content difference, and a high anion gap metabolic acidosis (because of increased lactic acid production with the shift to anaerobic metabolism).

Sidell has emphasized that in a chemical attack, the observation that people are convulsing or dying within minutes of exposure implies the weapon is either cyanide or a nerve agent. With high concentrations of cyanide, seizures begin within seconds and death ensues within minutes, usually with little cyanosis or other findings. Exposure to lethal concentrations of a nerve-agent liquid or vapor may also lead to sudden collapse with pre-terminal apnea and convulsions. Cyanosis in such cases is more common than in cyanide casualties. Miosis and increased naso-ocular secretions indicates exposure to nerve-agent vapor rather than to cyanide but could be absent in a victim exposed only to nerve-agent liquid.

Management

Management of cyanide poisoning begins with removal to fresh air. Dermal decontamination is unnecessary if exposure has been only to vapor, but wet clothing should be removed, and the underlying skin should be washed with soap and water, or with water alone if liquid on the skin is a possibility. Attention to the basics of intensive supportive care is critical, and includes 1) provision of 100% oxygen to all significantly symptomatic patients (regardless of arterial P_{O_2}), 2) mechanical ventilation as needed, 3) circulatory support with crystalloid and vasopressors, 4) correction of metabolic acidosis with intravenous sodium bicarbonate, and 5) seizure control with benzodiazepine administration. The cyanide-induced inhibition of cellular oxygen use might lead to the expectation that supplemental oxygen would not be of use in cyanide poisoning, but in fact, administration of 100% oxygen has been found empirically to exert a beneficial effect, possibly by directly displacing cyanide from cytochrome oxidase binding sites.

Symptomatic patients, especially those with severe manifestations, may further benefit from specific antidotal therapy, which is provided in a two-step process. First, a methemoglobin-forming agent such as amyl nitrite (available as crushable ampoules for inhalation in the pre-hospital setting, or when intravenous access is not immediately available) or sodium nitrite (for intravenous use) is administered. The ferric ion (Fe^{3+}) in methemoglobin has an even higher affinity for cyanide than does cytochrome aa_3. The equilibrium of this reaction causes disassociation of bound cyanide from the cytochrome oxidase and restores aerobic energy production.

Nitrites may also have therapeutic efficacy independent of methemoglobin formation, possibly via conversion to nitric oxide with subsequent beneficial vasodilatory effects. However, nitrite administration is potentially hazardous because too rapid intravenous infusion may cause or exacerbate hypotension, and overproduction of methemoglobin may compromise oxygen-carrying capacity. Thus, nitrite is probably not indicated for conscious patients with minimal symptoms, and is relatively contraindicated in patients whose cyanide toxicity is complicated by existing impaired oxygen delivery (e.g., smoke inhalation victims from a house fire, with likely concomitant lung injury and carbon monoxide poisoning).

These potential adverse effects of nitrites would obviously be less compelling in the context of a severely intoxicated, prostrate casualty of a terrorist cyanide vapor attack, and careful attention to proper dosing and rate of administration should allow safe use of this antidote. Pediatric nitrite dosing depends on body weight and hemoglobin concentration. The recommended initial pediatric dosage, assuming hemoglobin concentration of 12 g/dL, is 0.33 mL/kg of the standard 3% sodium nitrite solution, given slowly intravenously over 5 to 10 minutes; the initial adult dosage is 10 mL, equivalent

to one of the two sodium nitrite vials in the standard Pasadena (formerly Lilly) Cyanide Antidote Kit. Dosing may be adjusted for patients with significant anemia, although this knowledge would rarely be available in the context of emergent treatment of a critically poisoned child.

The second step is provision of a sulfur donor, typically sodium thiosulfate, which is used as a substrate by rhodanese for its conversion of cyanide to thiocyanate. Thiosulfate itself is efficacious, relatively benign, and also synergistic with oxygen administration, and thus may be used without nitrites in situations such as smoke inhalation. The initial thiosulfate dose for children is 1.65 mL/kg of the standard 25% solution intravenously, and the initial adult dose is 50 mL, equivalent to one of the two large bottles in the Pasadena kit. Second treatments with each antidote may be given at up to half the original dose if needed. Several alternative therapies and experimental antidotes are used in Europe (DMAP, or 4-dimethylaminophenol, a methemoglobin former; and cobalt compounds such as dicobalt edetate or hydroxocobalamin, as cobalt itself binds cyanide) or undergoing clinical trials (other aminophenol derivatives, also methemoglobin formers; aldehydes, which are cyanohydrin formers).

Riot-Control Agents

Riot-control agents, also called lacrimators (“tear gas”), include several compounds, the most important of which are CS (*o*-chlorobenzylidene malononitrile), CN (1-chloroacetophenone, “Mace”), and pepper spray (containing capsaicin).

CS and CN are solids and are typically dispersed as an aerosol of fine particles. Although the United States does not consider riot-control agents to be official chemical-warfare weapons, these agents are widely available, cause significant incapacitating effects in closed spaces, and could conceivably be used in a terrorist attack; therefore, they are outlined briefly in this section. As a group, these agents are often used by law enforcement agencies to cause temporary incapacitation for riot control and related situations. Their mechanism of action after low-level exposure is unclear but, in the case of pepper spray, appears to be related to the release of the pain-modulating neurotransmitter substance P. All of these agents cause 1) transient ocular effects, including burning sensation, tearing, blepharospasm, and photophobia; 2) irritation of the nose, throat, and upper airway; and 3) skin burning, erythema, and vesication (at high concentrations and high ambient temperatures and humidity). A few riot-control agents, such as Adamsite (DM), cause pronounced vomiting in addition to irritating the eyes and the upper airway and are referred to as vomiting agents. Most victims, under usual circumstances of exposure, become symptomatic within seconds, but remain so for only 20 to 60 minutes. However, high concentrations in closed spaces or discharge of agent close to the victim's face have been associated with serious medical complications, including severe ocular toxicity, dermal burns, and pulmonary failure. A few lethal cases have been described in which death was caused by severe tracheobronchitis with pseudomembrane formation and pulmonary edema.

Management includes careful ocular and dermal decontamination. The skin should be washed with soap and water, although this may cause transient increased pain. Hypochlorite solution should not be used because it may exacerbate dermal burns via the creation of toxic byproducts. The eyes should be thoroughly lavaged after a single dose of topical anesthetic if necessary. Respiratory complications must be managed supportively, as previously described for mustard and pulmonary agent toxicity. Severe respiratory effects may not manifest for 12 to 24 hours; therefore, patients with dyspnea or any objective findings should probably be observed in the hospital. Severe respiratory complications from exposure to riot-control agents have been described in at least two young infants, one of whom was in a house into which CS was sprayed. A canister of pepper spray was accidentally discharged directly into the face of the other infant. Both survived with prolonged care, the latter requiring ventilatory support including 5 days of extracorporeal membrane oxygenation. A few cases of children ingesting CS powder are known, which resulted only in transient diarrhea and abdominal cramping.

EMERGENCY DEPARTMENT AND EMERGENCY MEDICAL SERVICES PREPAREDNESS

Overview

The appropriate ED and EMS preparation for a medical response to terrorist incidents involving WMD is currently the subject of intense activity by the U.S. government, including the military and numerous civilian federal agencies. In addition, preparation is being actively pursued at state and local levels by regional EMS and HAZMAT systems, police and fire departments, and individual hospitals, poison control centers, and physicians with various backgrounds, including public health, toxicology, infectious disease, and emergency medicine. The 1996 Centennial Olympic Games in Atlanta provided a recent opportunity to conduct a highly orchestrated “disaster drill” preparation for a possible terrorist incident involving chemical or biological weapons. A comprehensive review of this experience, highlighting the coordinated efforts by local, state, federal, and military resources, was reported by Sharp et al. The preparedness of various cities and localities to manage the medical consequences of a terrorist chemical or biological attack varies from well prepared to totally unprepared. The pre-hospital and community-wide responses to terrorist chemical or biological attacks are obviously of critical importance, but a detailed analysis is beyond the scope of this chapter.

In brief, local first-responders, typically police, fire department, and EMS personnel, would be first at the scene of a chemical attack, and would be responsible for on-scene extrication, decontamination, triage, emergent field treatment, and evacuation of patients to area hospitals. They would also be at greatest risk of personal injury. Local hospital and health care providers would provide care to the first wave of casualties on short notice, and, based on the Tokyo experience, would likely receive numerous unannounced patients transported by private vehicle or other non–EMS-based means. Many such health care workers would be exposed initially to chemical agents if patients arrive before an accurate understanding of the event has occurred. If the consequences of the attack overwhelm local resources, mechanisms are in place for regional and state authorities to activate the federal response system, although depending on the locality involved this response may take several hours to activate.

Emergency Department Issues

Hospital EDs will likely be involved in WMD incidents in one of two characteristic scenarios, as recently reviewed by Barbera et al. A “sudden” presentation would result from a chemical attack with resulting large numbers of symptomatic victims presenting almost immediately and with little advance warning. Similarly, an announced biological agent release, or discovery of such a release, might result in numerous patients seeking health care services, although in most cases victims would initially be asymptomatic. The second scenario involves an “insidious” presentation (not unlike a natural epidemic in some ways) with sub-acute onset of unusual clinical symptoms in a number of patients presenting to diverse health care facilities, most likely as a result of biological agent attack. In this latter scenario, health care providers must recognize the pattern as a potential WMD exposure, as detailed previously under the discussion regarding epidemiologic aspects. In both presentations, many persons who have sustained either minimal exposure, or no exposure at all, will experience stress-related symptoms (the “worried-well”), and likewise present for services, placing further demands on EDs already likely to be overwhelmed. In either scenario, initial suspicion of the WMD incident should trigger ED protocols for initiation of the previously noted community-wide response, notification of public health authorities, and rapid deployment of the already-established decontamination structure and process.

The ED response to WMD incidents needs to be integrated into the hospital's standing disaster plan. Appropriate protocols for calling in extra help, using hospital security for patient direction and diversion at the ED entrance and around the decontamination site, and handling the dissemination of information to the public and news media all should be anticipated. Hospital spaces that are not routinely used for patient care, such as cafeterias, may be used as holding areas for large numbers of exposed but minimally symptomatic patients. Routine hospital supplies such as gowns and towels may be depleted rapidly in the face of mass casualties. Demands for hospital beds, and particularly intensive care unit beds, are likely to be overwhelming. Alternative care facilities staffed by outside help may be needed in mass casualty situations (e.g., warehouses or other such buildings might need to be converted to temporary care sites). Pre-disaster planning for both “natural” disasters and WMD incidents must take into account such factors. As previously noted, a framework exists for activating medical assistance plans at the federal level through the Federal Response Plan, and the National Disaster Medical System, augmented if necessary by military medical assets from the Department of Defense.

The issue of stocking specific antidotes, medications, and vaccines in the context of planning for a WMD event involving the potential for mass casualties poses additional challenges. Many hospitals do not routinely stock adequate amounts of such pharmaceuticals for even one critical patient. WMD incident planning should establish some mechanism for local or regional stockpiling of these critical medications, and/or a means to rapidly acquire them. For some medications, such as atropine, lower-cost alternatives such as rapid bulk preparation from pharmaceutical-grade powder may be an attractive option. Table 132.3 offers an attempt to quantify the magnitude of antidotal medications that might be needed in one ED for the management of a nerve agent or cyanide attack involving both pediatric and adult victims, on a scale of the Tokyo sarin attack. A biological agent attack would place similar enormous demands on the hospital pharmacy for antibiotics, vaccines, antitoxins, and so on. Funds have been allocated for a federal stockpile of pharmaceuticals, but in some cases (such as with smallpox vaccine) no current production capability exists.

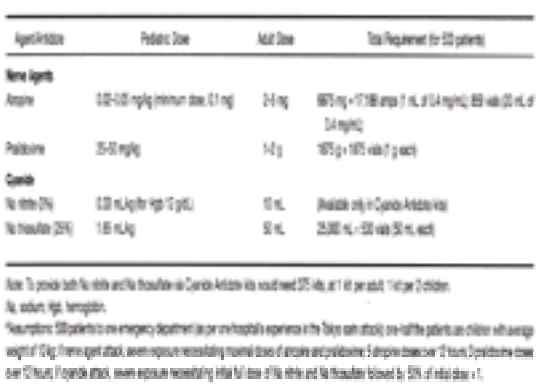

Table 132.3. Pharmaceutical Stocking Estimates for One Emergency Department in a Hypothetical Chemical Agent Attack[a]

In the context of a biological agent attack, concern arises regarding possible transmission of infection to health care workers and other ED patients. Most such biological agents pose minimal risk of person-to-person transmission to ED staff and other patients if standard barrier protection techniques are practiced. Nevertheless, patients with smallpox or pneumonic plague (both of which are easily transmissible by the respiratory route) and patients with viral hemorrhagic fevers should be placed into appropriate isolation as soon as possible after their identification. Further issues in such a context would include the need for isolation rooms with anterooms and special air-handling precautions (e.g., negative pressure and HEPA-filtered exhaust), large isolation wards, potential quarantine, and chemoprophylaxis. In the case of smallpox, pneumonic plague, and hemorrhagic fevers, health care worker respiratory and mucous membrane protection may have to be upgraded.

The earliest suspicion of these infections would obviously necessitate expert consultation with infectious disease and public health specialists. CDC, USAMRIID, and (through Domestic Preparedness resources) USAMRICD have 24-hour hot-line services available to aid physicians and local public health authorities in this context (CDC 770-488-7100; USAMRIID 1-888-USA-RIID; CB HelpLine [for non-emergency planning and information]: 1-800-368-6488; CB HotLine [for emergencies]: 1-800-424-8802).

Obviously, many unanswered questions exist regarding ED preparedness for a WMD attack, including 1) optimal decontamination techniques, especially for young children; 2) optimal PPE for ED staff; 3) issues regarding safety of

decontamination water run-off into public drainage systems; 4) the community-wide needs for education and training; and 5) financial considerations for individual hospital and regional planners. Continued activity on an expert consensus basis, as well as new research, should help to address many of these issues.

CONCLUSION

The prospect of a terrorist WMD incident with resulting mass casualties is unfortunately more likely now than ever before. Although the impact of such an event is almost unimaginable, at the same time, efforts must be made to prepare for the "unthinkable." Such preparedness requires highly coordinated responses involving local and regional EMS systems, HAZMAT teams, police and fire departments, hospital EDs, local and federal public health agencies, and military medical specialists. In particular, EDs must consider important issues, including 1) the early recognition, triage, decontamination, treatment, and disposition of multiple casualties of such an attack, 2) protection of health care workers and existing patients, and 3) the integrity of the ED itself to provide on-going care to later arriving casualties and to continue to meet normal patient demands.

EMERGENCY DEPARTMENT

1. **Airway**

    1.1 Tongue blades
    1.2 Suction catheters 6, 8, 10 Fr (2 of each)
    1.3 Yankauer suction tips (4)
    1.4 Magill forceps
    1.5 Oxygen catheters for suction 10, 14 Fr (2 of each)
    1.6 Oropharyngeal airways 0–5 (2 of each)
    1.7 Nasopharyngeal airways 12, 16, 20, 24, 28, 30 Fr. (2 of each)
    1.8 Humidivent
    1.9 Meconium aspirator
2. **Breathing**

    2.1 Oxygen supply
    2.2 Oxygen flow meter
    2.3 Oxygen tubing
    2.4 Cylinder key
    2.5 Oxygen masks
    2.6 Nasal cannula
    2.7 Non-rebreathing mask
    2.8 Nebulizer and administration equipment
    2.9 Self-inflating bags with oxygen reservoir (adult, infant)2.10 Mapleson D bags with reservoir (0.5, 1, 5 L)
    2.11 Laryngoscope handle with knurled finish
    2.12 Laryngoscope blades

        2.12.1 Miller 0, 1, 2, 3
        2.12.2 Wis-Hipple 1.5
        2.12.3 MacIntosh 2, 3

    2.13 Extra “C” batteries (2)
    2.14 Endotracheal tubes

        2.14.1 Uncuffed sizes 2.5–8.5 (2 of each)
        2.14.2 Cuffed sizes 7–9 (2 of each)

    2.15 Stylets (1 adult, 1 infant)
3. **Circulation**

    3.1 Stat IV tray
    3.2 Central venous pressure tray 5, 10, 11 (2 of each)
    3.3 Cutdown tray (2)
    3.4 Umbilical catheterization tray
    3.5 Intra-osseous needles—16, 18 (2 of each)
    3.6 Radial artery tray (2.5F 5 cm, 2.5F 2.5 cm)
    3.7 Drugs prepackaged

        3.7.1 Epinephrine 1:1000
        3.7.2 Dextrose (D 25%)
        3.7.3 Atropine
        3.7.4 Sodium bicarbonate
        3.7.5 Calcium chloride

3.7.6 Xylocaine 2%

3.8 Drugs

3.8.1 Adenosine
3.8.2 Afrin®Pr Nasal Spray
3.8.3 Benadryl
3.8.4 Bretylium
3.8.5 Calcium gluconate
3.8.6 Chloramphenicol
3.8.7 Cyanide kit
3.8.8 Diazepam
3.8.9 Diazoxide
3.8.10 Digoxin
3.8.11 Dilantin
3.8.12 Dobutamine
3.8.13 Gastrografin
3.8.14 Gentamicin
3.8.15 Glucagon
3.8.16 Heparin Vial
3.8.17 Hydralazine
3.8.18 Hydrocortisone
3.8.19 Isuprel
3.8.20 Ketamine
3.8.21 Furosemide
3.8.22 Lidocaine 1%
3.8.23 Lidocaine 2%
3.8.24 Mannitol
3.8.25 Flumazenil
3.8.26 Naloxone (1 mg/mL)
3.8.27 Neostigmine
3.8.28 Norepinephrine (Levophed)
3.8.29 Procainamide
3.8.30 Solu-Medrol
3.8.31 Thiopental
3.8.32 3% saline
3.8.33 Vasopressin
3.8.34 Vecuronium
3.8.35 Verapamil

3.9 IV fluids

3.9.1 Tubing
3.9.2 Stopcocks
3.9.3 Normal saline solution 1 L (10 bags)
3.9.4 Lactated Ringer's solution 1 L (10 bags)
3.9.5 Albumin 5%, 25%

3.10 Syringes
3.11 Alcohol pads
3.12 Needles
3.13 Broselow tape or wall chart
3.14 Infusion pumps (3)
3.15 Cardiac board
3.16 Arm boards
3.17 Tape
3.18 Tincture of benzoin

4. **Monitoring**

4.1 Sphygmomanometer Doppler and aneroid
4.2 Blood pressure cuffs (neonate, child, adult, large adult, thigh)
4.3 ECG/leads
4.4 Pulse oximeter
4.5 End-tidal CO_2 monitor
4.6 Doppler (hand-held)
4.7 Defibrillator/defibrillator paste
4.8 Temperature probe
4.9 Hypothermia thermometer
4.10 Blood pressure–monitoring lines
4.11 Intracranial pressure–monitoring lines

5. **Laboratory testing**

5.1 Syringes
5.2 Needles
5.3 Alcohol pads

5.4 Betadine
5.5 Tubes including culture media
5.6 Blood gas kit
5.7 Glucometer, test strips
5.8 Hemoccult cards
5.9 Sterile basins, bedpans, urinals
5.10 Evidence bags
5.11 Shroud, autopsy permits, related supplies

6. **Trauma care**

6.1 Cervical collars: Baby no-neck®Pr, Pediatric no-neck®Pr, Short, Regular
6.2 Nasogastric tubes, 10, 16 (2 of each)
6.3 Feeding tubes, 3½–8 Fr (2 of each)
6.4 Foley catheters, catheterization tray
6.5 Tracheostomy tray (2)
6.6 Thoracentesis tray
6.7 Chest tube insertion (2)
6.8 Chest tubes 12, 16, 20, 24, 28, 32, 34, 40 Fr (2 of each)
6.9 Pleurovac
6.10 Thoracotomy tray
6.11 Minor procedure tray (3)
6.12 Peritoneal tray (11Fr Dialysis set)
6.13 Obstetric pack
6.14 Blood administration sets
6.15 Blood warmer
6.16 Pressure bags
6.17 Garder-Walls tongs
6.18 Hare traction splint
6.19 Scalpels No. 10, 11, 15
6.20 Suture Material—1 box of each:

2.0 silk ties
3.0 silk
4.0 vicryl
Tevdek cardiovascular 2.0, 4.0, 5.0
TFE polymer pledgets (8677-01)
TFE polymer pledgets (8675-01)

7. **Other**

7.1 Protective supplies

7.1.1 Gloves
7.1.2 Gowns
7.1.3 Masks
7.1.4 Shoe covers
7.1.5 Protective eye shields
7.1.6 Needle receptacles

7.2 Stat worksheet on clipboard
7.3 Key phone numbers
7.4 Drug formulary
7.5 Drug labels
7.6 Scissors, heavy gauge
7.7 Flashlight
7.8 Ophthalmoscope
7.9 Otoscope
7.10 Overbed warmers
7.11 Blankets

8. **Transport equipment**

8.1 Portable suction
8.2 Portable monitors
8.3 Infusion pump
8.4 Airway box
8.5 Drug box

OFFICE OR CLINIC

1. **Airway equipment**

1.1 Oxygen tank with flow meter
1.2 Face masks
1.3 Oxygen reservoir masks
1.4 Nasal cannula

1.5 Oxygen tubing
1.6 Oropharyngeal airways—(all sizes)
1.7 Nasopharyngeal airways—(all sizes)
1.8 Suction machine, portable
1.9 Suction catheters
1.10 Yankauer suction tips (4)
1.11 Magill forceps

2. **Breathing equipment**

2.1 Bag-valve-mask with O_2 reservoir (adult, pediatric)
2.2 Masks—(infant to adult sizes)
2.3 Pulse oximeter

3. **Circulation equipment**

3.1 Cardiac board
3.2 Butterflies—25, 23, 21 (3 of each)
3.3 Medicuts—22, 20, 18 (3 of each)
3.4 Intraosseous needles (4)
3.5 Normal saline 5% dextrose, 500 mL (2)
3.6 Normal saline solution, 500 mL (2)
3.7 Solusets (2)
3.8 Sphygmomanometers—cuffs (4 sizes)
3.9 Drug box—prepackaged syringes
3.9.1 Epinephrine 1:10,000
3.9.2 Sodium bicarbonate, full strength
3.9.3 Sodium bicarbonate, half strength
3.9.4 Dextrose, 25%
3.9.5 Atropine, 0.4 mg/0.5 mL
3.9.6 Naloxone
3.9.7 Diazepam/lorazepam
3.9.8 Phenobarbital
3.9.9 Activated charcoal
3.9.10 Tourniquets
3.9.11 Betadine swabs
3.9.12 Alcohol swabs
3.9.13 Tape
3.9.14 Syringes
3.9.15 Armboards

4. **Other equipment**

4.1 Resuscitation cart checklist
4.2 Semirigid cervical collars—(adult, pediatric)
4.3 Sand-bags (3)
4.4 Splints, inflatable
4.5 Nasogastric tubes
4.6 Rubber gloves
4.7 Protective eyewear
4.8 Broselow tape or wall chart

APPENDIX B

Emergency Drug Compendium

***DEBORAH H. SCHAIBLE, PharmD and †MONICA H. DARBY, BS**

**Department of Pediatrics, †Department of Pharmacy, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania*

The purpose of Appendix B is to provide an easily accessible resource for dosages and side effects of medications included in the main text. The dosages included here are based on literature available at the time of preparation of the text. For medications that are relatively new to pediatrics (e.g., cisapride, sumatriptan, parenteral labetalol), further refinement in drug dosage recommendations may occur after publication. Other frequently updated drug information resources such as the American Hospital Formulary Service (updated quarterly) or Facts and Comparisons (updated monthly) may provide additional information. Finally, for added safety, prescribers should check the package insert and one or two additional resources for dosage information when prescribing an unfamiliar drug.

A list of the abbreviations used and their definitions is presented at the end of this appendix.

APPENDIX C

Parental Instruction Sheets

NANETTE C. KUNKEL, MD

Department of Pediatrics, University of Utah School of Medicine, and Emergency Department Primary Children's Medical Center, Salt Lake City, Utah

ANIMAL BITES

Your child was bitten by an animal. This can be frightening to some children and your child may need some extra comfort to feel better.

The examining doctor cleaned the bite wound. The doctor may have given you instructions to clean the wound at home. They are:

[ ] Your child was given a **tetanus** shot in the emergency department (ED). Show this to your regular doctor to update your child's records. _____

[ ] Your doctor has decided that **anti-rabies** treatment is needed. Your child was given the first injection (shot) today. He or she will need to return to the ED for the rest of the shots.

3rd day __ 7th day __ 14th day __ 28th day__
If your child gets a fever or the needle site is red or swollen, call your doctor. All the shots must be given to protect your child.

[ ] Your doctor has given your child a prescription for **antibiotics.** Not all bites need antibiotic treatment. Your child must take all the medicine as directed. Your dose is: _____

Signs of Infection

Call your doctor or return to the ED if any of these signs develop after your visit:

1. Increased redness around the bite
2. Pain
3. Discharge or pus from the bite
4. Increased swelling
5. Bad smell
6. Fever

WOUND CARE

Your child hasan injury in which the skin was broken. These injuries can be fixed in different ways depending on the age of your child and the size and location of the injury. However, all wounds heal with a scar. This scar will remodel itself in the first 6 months.

[ ] *Stitches (Sutures) or Staples*

Your child had ___ stitches or staples placed for an injury to his or her _____.

___ These stitches must be removed in ___ days. Call your doctor for an appointment to remove the stitches. If you do not have a regular doctor_____

___ Your child's wound should be rechecked in ___ days. Call your doctor for an appointment or return to the ED.

___ The stitches do not need to be removed. They will come out by themselves. Follow up with your regular doctor in _____ days.

Washing with a washcloth at the sink is OK. Do not take a bath, soak the stitches/staples, or allow your child to swim with them. If the stitches should loosen or if the wound pops open, bring your child back to the ED. If the wound starts bleeding, apply direct pressure for 15 minutes. If it continues to bleed, call your doctor or return to the ED.

___ Apply an antibiotic ointment to the stitches ___ times per day.

___ Keep the area covered with a clean bandage.

___ No cover is necessary after the first 48 hours.

Apply sunscreen to wound area when outdoors to protect new skin.

[ ] *Steri-Strips*

Your child had paper tapes (Steristrips) used to fix the wound. Allow these to fall off by themselves (usually in 5 to 7 days). Do not soak in water or allow your child to swim with steristrips. Keep clean and dry.

___ Your child received a **tetanus** shot in the ED. Show this to your regular doctor to update your child's records.

___ Your doctor has given your child a prescription for **antibiotics.** Not all wounds need antibiotic treatment. Your child must take all the medicine as directed. Your dose is: _____

Signs of Infection

Call your doctor or return to the ED if any of these signs develop:

1. Increased redness around the wound
2. Pain
3. Discharge or pus from the wound
4. Increased swelling
5. Bad smell
6. Fever

ASTHMA

Children with asthma have a reactive airway. The tubes that carry air to the lungs and the small passages in the lungs are sensitive to many things. When triggered, the airways react by getting smaller, swelling, and forming mucous plugs. This reaction can happen with colds and viruses; with exposure to pets, dust, odors, or allergens; or with exercise and emotional stress. The treatment your child received in the ED helps open the airways and reduce the swelling.

Asthma is a condition that can affect your child for many years. Identifying something that triggers wheezing in your child may help avoid future episodes. **No smoking** should be allowed in the house because smoke irritates the airways of all asthmatics. Your child can return to school if he or she is feeling better. If medicine needs to be taken at school, talk with your doctor and the school nurse. If an older child uses an inhaler, get permission for him or her to carry it. Your child can participate in gym class but may need to be excused during a cold if coughing or mild wheezing is present. If your child has multiple episodes of asthma, he or she should wear a medical alert bracelet.

Home Treatment

1. If your child starts wheezing, keep him or her calm or playing quietly. Excitement and physical activity can make the wheezing worse.
2. Give the medicine as prescribed. Talk with your doctor about restarting medicine when your child gets a cold to prevent future episodes.
3. Do not run out of the medicine. Make sure you always have refills.

4. Over-the-counter medicines often do not work in asthma. Call your doctor before giving your child a nonprescription medicine.

Your doctor has prescribed the medicine below:

Nebulized Medicine (Aerosol)

[ ] Give _____ by aerosol ___ times per day at the following times_____.

[ ] Give _____ by aerosol mixed with _____times per day at the following times _____.

Inhaler

[ ] Use ___ puffs _____ inhaler ___ times per day at the following times _____.

Other Medicines

[ ]

Steroids (Used for a Few Days to Decrease Airway Swelling)

[ ]

Call Your Doctor or Return to the Emergency Department If:

1. Your child has increasing shortness of breath or trouble breathing.
2. Your child is breathing fast.
3. Your child looks blue or passes out **(call an ambulance immediately, do not drive yourself).**
4. Your child looks sick or anxious.
5. You have any questions or concerns.

BRONCHIOLITIS

Children with bronchiolitis have an infection with a virus that produces wheezing and trouble breathing. The tubes that carry air to the lungs and the small passages in the lungs themselves are infected by the virus. This condition causes the most problems in young babies (less than 2 months), children with heart or lung problems, and babies who were premature or have other medical problems. The most common virus causing bronchiolitis is the respiratory syncytial virus (RSV). No medicine or antibiotic can cure this infection. Because it is a virus, antibiotics do not help. We do try to make children more comfortable and help them breathe easier. Your doctor has decided that your child can be treated at home, but we know that this infection can sometimes worsen. If you think your child is getting worse you need to return to the ED.

Home Treatment

1. If your child starts wheezing, keep him or her calm or playing quietly. Excitement and physical activity can make the wheezing worse.
2. Run a vaporizer in your child's room. (We prefer a cool mist vaporizer to avoid the risk of burns.)
3. If your child's nose is stuffy you may use a bulb syringe and salt water drops to suction the mucus.
4. Encourage fluids.
5. Over-the-counter medicines often do not work in bronchiolitis. Call your doctor before giving your child a nonprescription medicine.

Sometimes breathing treatments that open the airways help children breathe easier. Sometimes these treatments do not help. If your doctor prescribes breathing treatments, he or she must think they will help. Use them as instructed. However, if you do not think they are helping and your child has trouble breathing, please return to the ED.

Your doctor has prescribed the medicine below:

Nebulized Medicine (Aerosol)

[ ] Give _____ by aerosol ___ times per day at the following times _____.

Other Medicines

[ ]

Call Your Doctor or Return to the Emergency Department If:

1. Your child has increasing shortness of breath or trouble breathing.
2. Your child is breathing fast (faster than 60 times per minute).
3. Your child stops breathing (even if he or she does not turn blue).
4. Your child is unable to drink (often a sign of trouble breathing).
5. Your child looks blue or passes out **(call an ambulance immediately, do not drive yourself).**
6. Your child looks sick or anxious.
7. You have any questions or concerns.

BURNS

Your child was treated for a burn. Burns occur when the skin is injured by contact with heat, fire, chemicals, or electricity. Your child has a clean dressing on the burn to protect it and prevent infection. We ask that you have the dressing changed for the first time by a doctor or nurse. Your doctor has arranged the following follow-up:

If the dressing falls off before this change, replace it with a clean, dry bandage. Your child may have received a tetanus booster in the ED. If so, notify your regular doctor to update your child's records.

How to Change the Dressing at Home

1. Wash your hands thoroughly with soap and water.
2. Remove the old bandage. If it sticks, you can soak it for a few minutes in warm (not hot) water.
3. Wash the burn with warm, soapy water.
4. Rinse and pat dry with a clean towel.
5. With a sterile tongue depressor, apply the antibiotic cream _____ to the burn area in a thin layer. Do not put a dirty tongue depressor back in the container of antibiotic cream.
6. Carefully rewrap the burn with a sterile bandage as directed by your doctor.

Signs of Infection

1. Increasing redness or red streaks around the burn
2. Swelling
3. Pain
4. Yellow pus or discharge
5. Fever

If you notice any signs of infection, call your doctor immediately or return to the ED.

Pain

Acetaminophen (e.g., Panadol, Tylenol) or ibuprofen (e.g., Advil, Motrin) can be used for pain. If your child was given a prescription for a different pain medication, you should use that medication as prescribed. Speak with your doctor about timing the dose with the dressing changes to relieve pain. Your medication is:

Exercise

Your doctor may have directed your child to perform certain exercises to help regain use of the burned area. Please ask your doctor if you have questions about the exercises or if you think your child is becoming stiff or tight around a burned area.

Long-Term Care

Once the skin has healed, apply a lubricating cream or lotion to the burned area. This treatment will keep it soft and decrease itching. Avoid extremes of heat or cold for 1 year after the burn. Avoid direct sunlight for 1 year after the burn. Apply a sunscreen to any burned areas to protect the new skin.

CAST OR SPLINT CARE

Your child has an arm or leg cast that will keep an extremity quiet and immobile after a serious injury.

What to Do in the First 48 Hours

1. Keep the cast elevated as much as possible to prevent swelling.
2. If your child has a splint and there is a lot of pain or the fingers or toes are cold and pale, unwrap the ace wrap to relieve the pressure from swelling. If this helps, rewrap it a little looser. If this does not help, rewrap the splint and return to the ED.
3. Give ibuprofen (Motrin, Advil) every 6 hours as needed for pain. Your child's dose is: ___

[ ] Your child may need additional pain medicine. Your doctor has written a prescription for:___

_____

General Cast or Splint Care

1. Do not allow your child to walk or put weight on the cast unless your doctor specifically tells you to do this.
2. Keep long arm casts in a sling at all times except when sleeping.
3. Do not get the cast wet unless you are told this is OK.
4. Do not allow your child to place objects inside the cast.
5. Do not use devices such as knitting needles, coat hangers, and so forth to scratch underneath the cast.
6. Your child can take a bath if the cast is covered with a plastic bag and kept above the water.
7. Keep the skin around the cast edges clean and dry. You can put rubbing alcohol on the skin near the cast edge to prevent irritation.
8. If the cast edge feels rough, you can put adhesive tape around it or “petal” around the edge with moleskin. Ask your doctor or nurse how to do this.
9. If your child is unable to go to school, have his or her teacher provide homework assignments and ask for a tutor if necessary.

Return to the Emergency Department or See Your Orthopedic Doctor If:

1. Your child's fingers or toes feel numb or cold, look blue or pale and unwrapping the splint does not help.
2. Your child complains of tingling, tightness, or pain in the injured arm or leg.
3. There is pain under the cast in one spot, or pain anywhere for no apparent reason.
4. It hurts your child to move the fingers or toes.
5. Your child has a fever.
6. You smell a bad odor coming from the cast.
7. The skin around the cast edge is red or irritated.
8. The cast gets soft or cracked.
9. The pain medication does not make your child feel better.

[ ] *Use of Crutches*

1. Help your child walk with crutches as demonstrated. Do not allow him or her to put weight on the cast unless told to do so.
2. Help your child go up and down stairs until you are comfortable he or she can do it well.
3. Do not have your child rest his or her underarms on the crutches. Putting weight on the underarms can cause nerve damage.
4. Always use crutches with rubber tips, and wipe the tips dry if they get wet so they are not slippery.

CHICKENPOX

Chickenpox (Varicella) is a viral infection. It causes fever, tiredness, loss of appetite, and a rash. The rash starts out as small red bumps that then develop into clear, fluid-filled blisters that break and crust over. New blisters keep forming for 3 to 4 days and a child is contagious from 2 days before the rash appears until all the blisters are crusted over. You should keep your child away from people who cannot fight infection well, including pregnant women, small babies, people taking steroid medication, and those with cancer, leukemia, or acquired immunodeficiency syndrome (AIDS). Your child cannot return to school or day care until all the blisters have crusted over.

Treatment

1. Give acetaminophen (e.g., Tylenol, Panadol) for fever. **DO NOT USE ASPIRIN.** Some doctors do not like to use ibuprofen with chickenpox. Ask your doctor's opinion.
2. Encourage your child to drink plenty of fluids. He or she may have blisters inside the mouth, and citrus drinks or sodas might be irritating. Other cool liquids (e.g., milk, apple juice, Kool-Aid) may help soothe the blisters.
3. Chickenpox is very itchy. Bathe your child in lukewarm water. Add ½ cup baking soda to the water and allow your child to bathe for 30 minutes. You can also tie oatmeal flakes in an old stocking and swirl this in the bath water or use a commercial oatmeal product (Aveeno).
4. Keep your child's fingernails cut short to prevent scratching.
5. Have your child wear socks on his or her hands at night to keep from scratching.
6. Calamine lotion can be applied to the chickenpox blisters.
7. Your doctor may prescribe a medicine for itching. This medicine can make your child sleepy. If you notice a change in your child's behavior or if you think he or she is too sleepy, stop the medicine and call your doctor. Your medication is: _____

_____

[ ] Sometimes acyclovir is used for chickenpox in those children who are at risk for a serious infection. This medicine may shorten your child's illness and decrease the number of chickenpox blisters your child develops. Your doctor has decided to use this medicine for your child. Your dose is: _____

_____

Call Your Doctor or Return to the Emergency Department If:

1. The blisters or surrounding skin look infected, are red and swollen, or have yellow pus.
2. Your child is sleeping too much or has a change in behavior.
3. Your child has blisters in his or her eyes.
4. Your child has trouble walking or severe headache.
5. Your child has trouble breathing.
6. The fever persists after the third day or if the fever was gone and then came back.
7. Your child looks sick or you have any questions or concerns.

COMMON COLD (UPPER RESPIRATORY INFECTION)

The common cold is an infection of the nose and throat that is usually caused by a virus. It can make your child have sneezing, coughing, fever, and not feel well. No medicine can cure a cold, and it can last as long as 7 to 10 days. Colds spread from person to person by coughing or breathing and when people do not wash their hands well after blowing their nose or sneezing. Your child can return to school or day care when he or she feels well and does not have a fever. Small amounts of coughing and sneezing should not keep your child out of school.

Home Treatment

1. Home treatment is aimed at keeping your child comfortable. If your child is uncomfortable or looks sick, he or she needs to see a doctor for a reexamination.
2. Encourage your child to drink plenty of fluids such as juice, soda, or Kool-Aid. Do not force him or her to eat because it may cause vomiting. Your child may not feel like eating, but it is important that he or she drinks to prevent dehydration.
3. Warm liquids sometimes ease a sore throat and help open a clogged nose. Grandmother's chicken soup may be the perfect meal for a child with a cold!
4. For nasal congestion (runny nose), you can use salt water drops to loosen the mucus. These drops should be used before feeding your child and at bedtime, but they can be used in between if you think your child's nose is clogged and he or she has trouble breathing.

   To make salt water drops:

   Mix ¼ teaspoon salt with ½ cup warm water. If you have a clean medicine bottle, you can store this solution for 24 hours (label it salt water). If you do not have a clean bottle, throw away the salt water after each use.

   Using a medicine dropper, put two drops of the salt water in one nostril. Have your child lying flat when you do this. You may want to support his or her neck or shoulders with a rolled-up towel. Wait 30 to 60 seconds before suctioning the mucus with a rubber bulb syringe. Squeeze the air out of the bulb, put the tip of the bulb into the nostril. Let the air come back into the bulb, and the suction will pull the mucus out of the nose. Squeeze the mucus out of the bulb onto a tissue.

   Repeat this process with the other nostril. Do not do this more often than six times a day. Wash the bulb syringe in warm soapy water after each use. Squeeze it in the water to clean the inside.
5. Do not use over-the-counter cold medicines without discussing this with your doctor first. Those medicines can have dangerous side effects and often do not help the cold symptoms.
6. Use a cool mist vaporizer in your child's room. This will moisten the air and help loosen your child's nasal secretions. Warm mist vaporizers can cause burns so we recommend cool mist. Do not add medicine to the vaporizer; use plain water. Wash the vaporizer as instructed after each use.
7. Give acetaminophen (Panadol, Tylenol) or ibuprofen (Advil, Motrin) if your child has a fever. Your dose is:

Call Your Doctor or Return to the Emergency Department If:

1. Your child has trouble breathing or starts wheezing.
2. Your child gets a new fever higher than 102°F (38.5°C) (or higher than 100.5°F [38.0°C] if your baby is less than 6 months old).
3. Your child has trouble swallowing.
4. Your child is not drinking well or you think he or she is dehydrated (dry).
5. Your child complains of ear pain or tugs at his or her ears.
6. Your child is sleepy or lethargic.
7. Your child looks sick.
8. You have any questions or concerns.

CONJUNCTIVITIS (PINK EYE)

Conjunctivitis is an infection or irritation of the outer part of the eye. It makes the “white” of the eye appear pink or red and is commonly called pink eye. It can be caused by allergies or infections from viruses or bacteria. Pink eye is very contagious. All members of your household should wash their hands carefully, and other children should not touch your child's eye. Your child should have his or her own washcloth and towel. Whenever you touch his or her eye, you must wash your hands.

Treatment

1. Clean any pus or drainage with a warm, wet washcloth or cotton ball.
2. Your doctor may have prescribed antibiotic drops or ointment. Place this medicine in your child's eyes as directed by the doctor. Do not use the same medicine for other people in the house. Have them examined by a doctor and given their own medicine. Your medicine is: _____
3. Try not to get the medicine in the other eye if it is not affected.
4. Do not use the medicine longer than directed. If the infection persists, see your doctor.

Call Your Doctor If:

1. The eyelids get red or swollen.
2. Your child has trouble seeing or blurry vision.
3. Your child gets a fever or looks sick.
4. The infection is not better in 2 to 3 days.
5. You have any other questions or concerns.

CORNEAL ABRASION

Your child has a scratch on the cornea, which is the outer surface of the eye. The doctor who examined your child put some drops in the eye. These drops ease the pain and prevent the scratch from getting infected. We placed a patch over your child's eye. This will help protect the eye from further injury and allow it to rest while it heals. If possible, please keep this patch in place. We understand that some children try to remove the patch; try to distract your child so this does not happen.

Your child must be seen **tomorrow** to see how the scratch is healing. An infected scratch or one that does not heal well can cause a permanent scar on the surface of the eye. Your doctor has arranged the following follow-up:

_____

Call us if you have any questions or concerns.

CONSTIPATION

Constipation is hard, dry stools that usually hurt or cause pain when they are passed. There are no rules about the number of stools a child needs to have in a day or week. As long as your child has soft stools, he or she probably is not constipated. It can be normal for babies or small children to grunt, strain, and even cry while they are having a bowel movement. It can also be normal for a baby to go a few days without a bowel movement. Each child develops a pattern of his or her own.

The doctor who examined your child decided that he or she is constipated. Most constipation can be treated by some **dietary changes.**

1. If your baby is less than 4 months old, add 1 to 2 ounces of apple or prune juice to your baby's diet each day until stools are soft and regular. Constipation is very rare in breast-fed babies; talk with your doctor if you breast-feed. Do not continue the juice for more than 1 week without asking your doctor. You can also move your baby's legs in gentle bicycle motions if you think he or she is having trouble passing a hard stool.
2. If your baby is more than 4 months old, give him or her one 4-ounce bottle of juice per day, and encourage fruits and vegetables if he or she has begun taking baby food.
3. If your child is eating table food:
   a. Increase the amount of fruits and vegetables he or she eats. Adding raw ones provides increased “roughage.”
   b. Increase the bran content of his or her foods. Feed your child bran cereal, bran muffins, oatmeal, and whole wheat bread if possible.
   c. Increase fluids such as juices and water.
4. Some children have severe constipation or a long-term problem that needs additional help with medication. Your doctor has written any additional instructions below.

_____

_____

Additional Tips

If your child complains of pain with a bowel movement, he or she may have a small tear or fissure in the rectal area. You can put vaseline or a protective diaper cream in this area to allow it to heal.

Give older children protected time at least twice each day for toilet sitting. Your child should be able to sit on the toilet for about 15 uninterrupted minutes two times per day. After meals works best.

Exercise also helps improve constipation, and you and your child may want to participate in activities together.

Call Your Doctor If:

1. The constipation does not improve in 2 weeks.
2. Your child has severe abdominal pain.

3. You see more than a few drops of blood in the stool.
4. Your child begins losing control of bowel movements or soiling his or her underwear.

Final Note: Although you may reward your child for a successful bowel movement, never punish your child for not having a bowel movement or for soiling his or her underwear.

CROUP

Croup is a swelling of the upper airway in the area commonly called the windpipe and voice box, or more technically, the trachea and larynx. Most children with croup have a virus, and some children are likely to get croup more than once. Croup is worse at night and better during the day. It usually lasts about 5 days.

Children with croup may have a fever and cold symptoms. The cough is harsh like a barking dog or seal. The noisy breathing is called stridor and is made by the narrowing of the airway from the swelling.

Treatment

[ ] Some doctors like to use a steroid medicine (Decadron), which can help with the airway swelling in croup. Your doctor has decided to use this medicine for your child. Your dose is: _____

Home Treatment

1. Stay calm and keep your child calm. It can be frightening when your child has trouble breathing, but if he or she is anxious or crying, it will make things worse.
2. Use a cool mist vaporizer in your child's room to humidify the air. Do not use a hot steam vaporizer because it could burn your child if he or she gets too close.
3. Prop your child's head up with a few pillows, or sit up with him or her. Your child may find his or her own position that makes breathing easier, but sitting up often helps.
4. Give acetaminophen (e.g., Tylenol, Panadol) for fever. Use a suppository if your child has trouble breathing or is throwing up.
5. Encourage your child to drink clear liquids. Do not force your child to eat if he or she does not want to eat or has difficulty breathing.
6. If your child's breathing sounds worse or the noisy stridor is louder, turn on the hot water in the bathroom shower or sink. Close the door and let the room steam up. Take your child in the bathroom with you and sit down for about 15 minutes. Keep your child occupied by reading to him or her or playing with toys. STAY CALM!
7. Sometimes cool air will also help your child. If the steamy bathroom does not help, you can dress your child for the outdoors and then take him or her outside for 10 minutes.

Return to the Emergency Department Immediately If:

1. Your child has trouble breathing, is using his neck or abdominal muscles to breathe, is pulling in his chest to breathe.
2. Your child looks pale or has blue areas around the mouth/lips, fingernails, or toenails.
3. Your child passes out.
4. Coughing is continuous, or there is no improvement after mist or cool air is tried.
5. Your child is uncomfortable or unable to sleep.
6. Your child is drooling or has trouble swallowing.
7. Your child has a high fever (greater than 102°F [38.5°C]).
8. Your child seems to be getting tired.
9. You have any concerns or the child is rapidly getting worse.

Transport your child yourself if you have your own car, the drive is less than 15 minutes, and your child seems comfortable and stable. When driving with a sick child, have two people in the car, one in the back with the child and one in front driving. Keep the child in his or her car seat. Open the windows and allow some cool air inside. **Call an ambulance if your child has trouble breathing, is passed out, looks blue, or is getting worse.**

DIAPER RASH

A diaper rash is usually caused by irritation of the baby's skin from contact with urine or bowel movements. Sometimes the skin can also be infected with yeast or bacteria, and your doctor will let you know if your baby has an infection.

Treatment of Diaper Rash

1. Keep the baby's bottom as clean and dry as possible. Change the diapers often. Wash the diaper area gently with soap and water at each change and pat dry. Avoid premoistened wipes while the rash is present because they may sting.
2. Leave the diaper off, if you can, to allow the air to dry and heal the rash. This can best be done at naptime with your baby lying on his or her back on an open diaper.
3. If your doctor ordered a protective ointment, you should apply this in a thin layer with each diaper change. Medicated ointments or creams should be used as prescribed.

4. Do not use talcum powder or baby powder because it can injure your baby's lungs if inhaled.
5. Avoid plastic pants or tight-fitting disposable diapers if possible. They trap in moisture and make the rash worse.

Call Your Doctor or Return to the Emergency Department If:

1. Your baby develops a fever.
2. The rash does not appear to be improving after 5 to 7 days.
3. The rash is getting worse or pimples or blisters develop in the diaper area.
4. You are concerned about your baby.

EAR INFECTIONS

Your child has an ear infection, which is an infection of the middle ear, the space behind the eardrum. Ear infections can be caused by viruses or bacteria and are more common in the winter. An ear infection is not contagious, but it can start as a cold. The germs in the throat or nose migrate into the middle ear. Fluid also can build up in the middle ear and swelling from a cold prevents it from draining into the throat. The combination of germs and fluid becomes an infection and pus is produced, putting pressure on the eardrum and causing pain. If your child has a drainage from the ear, this may mean the ear drum has torn. The small tear in the eardrum will heal itself if the infection is treated. However, if fluid stays behind the eardrum for long periods, your child may have hearing problems. Therefore, you should follow up with your doctor to make sure the infection has been treated and the fluid is cleared. Your child can return to school or day care as soon as he or she is feeling better.

Treatment

1. **Antibiotics:** Ear infections are treated with antibiotics. The fever and pain may continue for 1 to 2 days after starting the antibiotic. Some antibiotics cause diarrhea. If the diarrhea is severe or you think your child is getting dehydrated (not urinating well, not drinking well, no tears when crying), see your doctor. If your child gets a rash, he or she may be allergic to the antibiotic. See your doctor.
   Your dose of medicine is:

   Give your child all the antibiotic prescribed, even if your child feels better. The full course is needed to kill the infection. Keep all medicines out of reach of small children.
2. **Ear Drops:** Your doctor may give you ear drops to treat an infection in the ear canal or external ear. Have your child lie on your lap with the infected ear up. Put two drops in the ear canal and massage in front of the ear to help the drops fall into the canal. Do not put anything else in the ear canal. Use the drops _____ times a day for _____ days.
3. **Pain and Fever:** Your child may have a fever or some ear pain. Acetaminophen (e.g., Tylenol, Panadol) or ibuprofen (Motrin, Advil) will treat this pain. Your child's dose is:_____
4. **Follow-up:** Follow up with your regular doctor after 2 weeks to make sure the infection is gone.

Call Your Doctor or Return to the Emergency Department If:

1. Your child looks sick or fever continues more than 2 days after starting antibiotics.
2. Your child has a new drainage from the ear.
3. Your child gets a rash.
4. Diarrhea becomes severe or you think your child is dehydrated (dry).
5. Your child is sleepy or lethargic, or if you have any questions or concerns.

ECZEMA

Eczema is common. Children with eczema usually have a family history of allergies, hayfever, or asthma. Eczema cannot be cured, but it can be controlled with skin care and some changes in your child's surroundings. Eczema usually improves as your child gets older.

Changing Your Child's Environment

1. Avoid wool clothing because it can be irritating. Dress your child in cotton when possible, and try to keep his or her arms and legs covered (tights or long pants, long-sleeve shirts).
2. Keep your child's room free of dust, and keep the air moist with a cool mist vaporizer or humidifier.
3. Wash your child's clothes in a mild detergent and avoid fabric softeners that can be irritating.

Skin Care

1. Do not overdo bathing. Wash your child when he or she is obviously dirty, but cut down on routine bathing to two times per week. Use a mild soap with moisturizer. Avoid deodorant soaps. Do not use a washcloth, and bathe in warm, not hot, water. Do not use bubble baths.
2. Your doctor may have prescribed a steroid cream for specific areas. Apply this cream as directed to those areas.
   Apply _____
3. One hour after applying the steroid cream, apply a general moisturizing cream to your child's entire body. Apply this moisturizing cream two times per day, *every day.*

   ---

4. If itching is a problem, your doctor may prescribe a medicine to be used for a short period.

These medicines can make your child sleepy and teenagers should not drive a car while taking this medicine. Keep your child's fingernails cut short if scratching is a problem. Some children need to wear socks on their hands when they go to sleep to keep them from scratching.

Call Your Doctor If:

1. The eczema is red or irritated looking, your child develops sores or scabs, or your child gets a fever.
2. You think the eczema is not under good control.
3. You have any questions or concerns.

FEBRILE SEIZURE

A febrile seizure is a “fit” or “convulsion” that occurs with a fever. Most children who have febrile seizures outgrow them by 4 to 5 years of age. Having a febrile seizure does not mean that your child has brain damage or will be retarded. There is a chance, however, that your child may have another seizure when he or she has a fever.

When your child becomes sick, the suggestions below will help you control the fever and prevent a seizure.

1. Give acetaminophen (e.g., Tylenol, Panadol) or ibuprofen (Advil, Motrin) in the correct dose for your child's age. Acetaminophen can be given every 4 hours, ibuprofen every 6 hours while your child's temperature is 101°F (38.0°C) or higher.
2. Do not bundle or overdress your child. The body loses heat through the skin, and if you bundle him or her the excess heat cannot escape.
3. Sponge your child with lukewarm water or put him or her in a shallow tub containing 2 to 3 inches of water and drip water over his or her body. Do *not* use alcohol or cold water to bring your child's fever down. If your child begins shivering or shaking, stop sponging and remove him or her from the bath water.
4. While your child has a fever, give plenty of fluids to prevent dehydration.
5. Give any medications prescribed by your doctor.

Your child may have another febrile seizure because they can happen before you realize your child is ill.

If Your Child Has Another Seizure:

1. Stay calm!
2. Do not put anything in your child's mouth.
3. Place your child on his or her side to help drain secretions.
4. Loosen clothing.
5. Do not try to hold your child still. Move objects away from your child so he or she does not get hurt.
6. Support your child's head with a pillow or soft object.

Call an ambulance if the seizure is lasting longer than 5 minutes or if your child has difficulty breathing or looks blue. Otherwise, once the seizure stops, call your doctor or bring your child to the ED for further instructions and a physical examination. Your child may be sleepy after the seizure and needs to be checked by a doctor.

SEIZURE

Your child has had a seizure. A seizure happens when the brain cells send electrical discharges that cause the arms and legs to jerk or twitch, and the eyes to stare or blink. Usually a child is sleepy or confused after having a seizure.

What to Do If Your Child Has a Seizure

1. Stay calm!
2. Do not put anything in your child's mouth.
3. Place your child on his or her side to help drain secretions.
4. Loosen clothing.
5. Do not try to hold your child still. Move objects away from your child so he or she does not get hurt.
6. Support your child's head with a pillow or soft object.
7. Do not try to give your child any medicine during a seizure. It may cause him or her to choke.
8. Try to observe what happens during the seizure: which arm or leg twitches, how long the seizure lasts, and so on. This information may help your doctor decide how to treat the seizure.

Call for Help If:

1. Your child has trouble breathing or looks blue.
2. The seizure is lasting longer than 5 minutes.
3. You cannot wake your child 30 minutes after the seizure.

After the Seizure

Your child may be sleepy and should be allowed to rest. Continue to give any medications prescribed for the seizure disorder. Do not give extra medicine or change the dosage without calling your doctor. Make sure you do not run out of

the medication. Give all medicine as scheduled.

Follow up with your regular doctor when a seizure occurs. This can be a good time to review your child's medical care and make changes if necessary. Your child may want to participate in sports or activities such as bicycle riding, swimming, or driving a car or motorcycle. Discuss this with your doctor before you allow your child to participate.

FEVER

Your child has a fever. This means the body temperature is above normal. In the mouth, normal temperature is 98.6°F (37°C); under the arm, normal is 98°F (36.6°C); and by rectum, it is 100°F (37.7°C). A fever is the body's way of fighting an infection and is not always a bad thing. You only need to treat the fever if it is high (greater than 102°F [38.5°C]) or if your child is uncomfortable. How high the temperature is does not indicate how severe the illness is that causes the fever. Your child should see a doctor if you have any concerns.

What to Do to Keep Your Child Comfortable

1. Dress your child lightly to be comfortable in your home's temperature. Do not overbundle or use heavy blankets because this will raise your child's temperature further. A T-shirt and underwear or diaper with a light sheet or blanket is fine for sleeping.
2. Encourage plenty of liquids. Your child may not be hungry but it is important that he or she continues to drink and does not get dry.
3. Keep the room around 70°F if possible. In the winter, do not overheat, and in the summer, use a fan or air conditioner if available.
4. Acetaminophen (e.g., Panadol, Tylenol) lowers fever. Your pharmacy may sell a generic fever product with acetaminophen. These are just as effective and may cost less. Check your child's temperature before giving the medicine. The dose can be repeated every 4 hours.

   If your child is vomiting or does not like to take medicine, you can buy acetaminophen suppositories at your pharmacy without a prescription. Ask your doctor or nurse about how to use a suppository.
5. Ibuprofen (Advil, Motrin) is also used for fever control in children 6 months and older. The dose can be repeated every 6 hours.
6. Do not use aspirin for fever control in children.
7. Sponging your child with lukewarm water will also lower his or her temperature but is not as helpful as fever medicine. Do not use alcohol or add alcohol to a bath. Never leave your child alone in a bath. If your child starts shivering, take him or her out of the bath and dry off. Shivering can raise the body temperature.

Call Your Doctor or Return to the Emergency Department If:

1. Your child is less than 6 months of age and has a fever greater than 101°F (38.2°C).
2. The fever continues for more than 2 additional days without other symptoms.
3. Your child has other symptoms—rash, trouble breathing, ear pain, headache, stiff neck, vomiting, diarrhea, joint swelling, or pain.
4. Your child acts sick, is irritable, sleeps a lot, stops playing, or does not eat or drink.
5. You have any questions or concerns.

FEVER LESS THAN 2 MONTHS

Your baby has a fever. This means the body temperature is above normal. We worry about babies with fever because they can have more trouble fighting a serious infection, and it is harder for parents and doctors to tell when they are getting sick. Your baby was evaluated in the ED and the doctor decided he or she could be cared for at home. You should follow up as instructed.

What to Do to Keep Your Baby Comfortable

1. Dress your child lightly to be comfortable in your home's temperature. Do not overbundle or use heavy blankets because this will raise your child's temperature further. A T-shirt and diaper with a light sheet or blanket is fine for sleeping.
2. Encourage plenty of liquids. It is important that he or she continues to drink and does not get dry.
3. Keep the room around 70°F if possible. In the winter, do not overheat, and in the summer, use a fan or air conditioner if available.
4. Acetaminophen (e.g., Panadol, Tylenol) lowers fever. Your pharmacy may sell a generic fever product with acetaminophen. These are just as effective and may cost less. Check your baby's temperature before giving the medicine. The dose can be repeated every 4 hours.
   Your baby's dose is:_____

   Use the dropper that comes with the acetaminophen (e.g., Tylenol, Panadol) bottle. Other droppers may be a different size.
5. Follow-up is usually arranged with your physician or the ED within 24 hours of this visit. **Your follow-up is:**

Return to the Emergency Department If:

1. The fever continues for more than 2 additional days without other symptoms.
2. Your baby has other symptoms—rash, grunting or trouble breathing, stiff neck, vomiting, diarrhea, or pain.

3. Your child acts sick, is irritable, sleeps a lot, or does not drink.
4. You have any questions or concerns.

HEAD INJURY

The doctor who examined your child determined that he or she can safely be observed at home. You will need to watch your child for the next 24 to 72 hours and bring him or her back to the ED if necessary. Please tell your doctor before leaving the ED if you do not think you can do this.

Normal Behaviors in the First 8 Hours After a Head Injury

1. Your child may be **sleepy.** It is OK to let him or her sleep, but you need to wake your child every 1 to 2 hours initially. Your child should be able to wake up and behave normally, recognize people and things, and speak clearly.
2. **Vomiting,** or throwing up, is also normal in the first few hours following a head injury.
3. Your child may complain of a **headache.** You can give acetaminophen (e.g., Tylenol, Panadol).

What to Do

1. Have your child rest or play quietly for the first 24 to 72 hours.
2. Wake your child every 1 to 2 hours for the first 8 hours.
3. Feed your child a lighter than normal diet.
4. Give acetaminophen for a headache.

Return to the Emergency Department Immediately If:

1. **Vomiting** continues after the first 8 hours or begins later than the first few hours after the injury.
2. Your child is **difficult to wake up** or is **not acting normally** when awakened.
3. Your child's **headache worsens,** changes your child's behavior, or is not relieved by acetaminophen.
4. Your child has **trouble seeing** or **walking** or **acts clumsy** or uncoordinated.
5. Your child has **bleeding or clear drainage** from his or her **nose** or **ears.**
6. Your child has a **convulsion** or **seizure.**
7. Your child is unusually **sleepy** or has any **unusual behavior** or **change in behavior.**

HIVES

Urticaria, or hives, are red blotches on the skin. They can be many different sizes and are very itchy. Most hives are an allergic reaction to something your child touched, ate, or put on his or her skin. Hives can also be a reaction to cold, heat, emotional stress, or a viral infection. Some common substances that cause hives are peanuts, strawberries, shellfish, grass, bushes, perfumes, medicines, pets, insect bites, soaps, and detergents. Hives can last only a few hours or several weeks. Often, the cause is unknown, but if you think you know what caused the hives, you should try to avoid reexposing your child to this substance.

Treatment

1. Sometimes no treatment is necessary, and the hives go away on their own.
2. Warmth makes the itching worse, so use a cool washcloth or cool bath to make your child more comfortable.
3. Your doctor may prescribe a medicine for itching. These medicines can make your child sleepy. Teenagers should not drive while using this medicine.
   Your dose is:_____
4. The best treatment is to avoid whatever caused the hives, so try to play detective and figure out what caused them.

Call the Doctor If:

1. Your child has **trouble breathing** or feels a **tightness in his or her throat or chest.**

   Call an ambulance immediately and get to the nearest ED.
2. Your child has **lip or tongue swelling. You need to seek emergency treatment immediately.**
3. The itching is not relieved by the medicine prescribed.

IMPETIGO

Impetigo is a skin infection caused by bacteria. You can get impetigo by scratching and infecting insect bites and dry skin or by touching sores on other people. It is easily spread to other parts of the body and to other people, so your child should not return to day care or school until the crusts are gone.

Things to Do If Your Child Has Impetigo

1. Wash your hands before and after caring for your child.
2. Gently wash the crusty areas three times each day with soap and water. You may need to soak the area in warm water to remove all the crusts.
3. Blot the areas dry.
4. If your doctor prescribed an ointment, apply this to the sore and the area around it. Rub it in well.

5. If your doctor prescribed a medication by mouth, give it to your child as directed until it is all gone. Your dose is: _____
6. Carefully wash the bathtub or bathroom sink your child used with soap and water. Do not use the kitchen sink if possible. Wash your child's towel, washcloth, and bed linens after each use. Do not allow your child to share these.
7. Keep your child's fingernails cut short and try to keep him or her from scratching.

Call Your Doctor or Return to the Emergency Department If:

1. Your child gets a fever.
2. The infection is not improving in 4 to 5 days.
3. The sores appear to be spreading.
4. The sores are not cleared up after 10 days.

LICE

Head lice are small, gray insects that live on human beings. They can be spread by direct contact and by shared combs, hats, and clothes. They live in the hair and lay tiny white eggs called nits that stick to each hair shaft. Lice can cause itching.

Treatment

Your child was given a prescription for either cream rinse or shampoo to treat the lice. **To use the shampoo:**

1. Apply to dry hair until thoroughly coated (Wear rubber gloves when applying the shampoo).
2. Leave the shampoo on the hair for 10 minutes, but not longer.
3. Add a small amount of water to get a lather and shampoo the hair.
4. Do not get shampoo in the eyes or mouth. If you do, rinse immediately with water.
5. Rinse the hair with water and towel dry. Use a fine-tooth comb to remove all nits. They may stick to the hair shaft and be difficult to remove. If so, rinse hair with a dilute vinegar and water solution (dilute vinegar with an equal amount water). This will make nits easier to remove.

To Use the Cream Rinse:

1. Wash the hair with your regular shampoo and towel dry.
2. Apply the cream rinse to coat the hair thoroughly.
3. Leave the cream rinse on the hair for 10 minutes.
4. Rinse the hair with water and towel dry. Remove nits as previously described.

   Re-treat with the shampoo or cream rinse in 7 days if lice or nits are still present. Itching may continue for a few weeks even though the lice are gone.

To Eliminate Lice from Your Home:

1. Vacuum all surfaces thoroughly.
2. Clean combs and brushes in hot water with some antilice shampoo or cream rinse.
3. Wash all pieces of clothing worn in the last 3 days and any sheets, blankets, and pillow cases your child used in hot water (more than 130°F) and dry in a hot dryer for at least 20 minutes.
4. Any items not washable—stuffed toys, coats, hats—must be set aside in airtight plastic bags for 2 weeks.

NOSEBLEEDS

Nosebleeds are common in children. They are usually caused by dryness inside the nose plus some irritation from rubbing, picking, or cold symptoms. They can begin suddenly and sometimes happen during sleep.

How to Stop a Nosebleed

1. Have your child sit up and lean forward. You may need a container so that your child can spit out any blood that has drained into his or her throat.
2. Firmly pinch the soft part of the nostrils (not the tip) together for a **full** 5 minutes. Use a clock to time this and do not let go sooner. Tell your child to breathe through his or her mouth.
3. When you release the pressure, if the bleeding begins again, repeat Step 2 one time.
4. If the bleeding continues, call your doctor or take your child to the ED. If possible, have someone hold pressure on the nose while traveling to the ED.
5. Do not place anything inside the nose while it is bleeding (e.g., gauze, tissue).
6. Cold washcloths or ice to the face will not help stop the bleeding.
7. Swallowed blood can irritate the stomach, causing your child to vomit, and it can look bloody.

How to Prevent Nosebleeds

1. Using your finger, gently place a small amount of vaseline to the inside of the nose. This will help ease the dryness and irritation.
2. Use a cool mist vaporizer or humidifier in your child's room.
3. Discourage your child from picking his or her nose and keep fingernails cut short.

4. If your child has a stuffy nose, you can use saline nose drops to make the mucus easier to clear. Avoid vigorous nose blowing.
5. Do not give your child aspirin unless directed by your doctor. If your child has many nosebleeds and is on aspirin, tell your doctor.

Call Your Doctor If:

1. You cannot stop the bleeding or your child has many nose bleeds in one day.
2. You think a lot of blood was lost, or your child faints, or looks dizzy or pale.
3. You see blood elsewhere—in urine, stool—or your child has bruises or a rash.
4. Your child looks sick.

RINGWORM

Ringworm is a fungal infection that can cause a skin rash or infect the scalp and cause hair loss, scaling or pimples, and pus. Your doctor can usually diagnose this condition by looking at it. Sometimes he or she will scrape the rash and take a culture. Ringworm is spread from person to person, from animals, or from shared combs, towels, or hats.

Treatment

Skin Infection: Your doctor prescribed a cream. Put this cream on the rash as directed. The rash should improve in 7 to 10 days, but you should continue the cream for a full 2-week course. If it is not gone after 2 weeks, call your doctor.

Scalp Infection: Your doctor prescribed a medicine (griseofulvin) to be taken by mouth. Your child's dose is_____. This medicine should be taken for the full course and is best taken with milk or a fatty meal. If your child gets vomiting, diarrhea, abdominal pain, or a rash or if he or she looks ill while taking this medicine, call your doctor. Your doctor also prescribed a special shampoo (selenium sulfide 2.5%) to decrease the time that your child is contagious. This shampoo can be used twice a week or as directed by your doctor. If your child wears braids or ponytails, they should be undone so the shampoo can penetrate to the scalp. Your child's combs, brushes, and clothing should be cleaned with ordinary soap and water. Ask your doctor or school nurse about when your child can return to school.

Call Your Doctor If:

1. The rash is not gone after a full course of the medicine.
2. Your child gets ill while taking griseofulvin.
3. You have any questions or concerns.

SCABIES

Scabies are little bugs that burrow in the skin and cause severe itching and a rash. These bugs can only be seen with a microscope. They can spread easily from person to person by direct contact or by wearing clothes that have the scabies bug living in them.

Treatment

Your doctor has prescribed a special cream containing 5% permethrin (Elimite). Massage the cream into the skin from the head to the soles of the feet, including the scalp for an infant. Try to avoid the eyes because the cream can irritate them. If any of the cream gets in the eyes, wash them with cool water. Scabies like to live between the fingers and toes, under arms, and around the waist and genitals. Make sure to include all these areas. Leave the cream on for at least 8 hours, then give your child a bath to wash off the cream. The itching and rash may last for 2 to 4 weeks after treatment. Your doctor may be able to give your child some medicine that helps the itching. If it continues longer than this, return to your doctor. Everyone in your household should be treated at the same time because scabies spread easily from person to person. Even people without symptoms should be treated; ask your doctor about this.

Medication for itching:_____

Cleaning Your House

1. Scabies can live on clothing or bed linens for up to 1 week.
2. Using hot water (more than 120°F), wash all clothing, bed linens, towels, and washcloths used in the past week, and dry them with high heat for 20 minutes to kill the scabies.
3. Items that cannot be washed (e.g., toys, blankets) should be placed in a plastic bag and stored for 1 week.
4. Clean clothes and clean sheets should be used after applying the cream.

Your child can return to school after treatment with the cream. Remember to keep the cream stored out of reach of your child because it can be poisonous if swallowed.

Call Your Doctor If:

1. The itching persists longer than 4 weeks after using the cream.
2. You think the skin has become infected or looks red with blistering or crusting.

SORE THROAT

A sore throat happens when the tonsils or back of the mouth get infected by a virus or bacteria. The infection usually spreads from person to person by coughing or sneezing but can also spread by sharing drinking cups or eating utensils. Your doctor may have sent a swab of your child's throat for a culture. The culture will diagnose a strep throat caused by the streptococcus bacteria. The culture may take up to 2 days for a result, and sometimes a quicker test called a rapid strep is used.

[ ] **The rapid strep test was negative or not available at this time.** If the rapid test was negative, this does not absolutely mean your child does not have strep throat. Call _____ for the culture results on _____ from _____. Have your pharmacy phone number ready in case the doctor needs to phone in a prescription for your child.

[ ] **The rapid strep test was positive.** Your child has strep throat and needs antibiotic treatment. Your doctor may give you a prescription for an antibiotic, or your child can get a shot of long-acting penicillin in the ED. Both medicines will treat the infection. If you choose the antibiotic at home, you need to give your child all the medicine.
Your dose is:

Home Treatment:

1. The antibiotic will not make your child feel better right away. It may take 2 to 3 days to see improvement. Watch for a rash, trouble breathing, or swelling of the face, hands, or feet as signs of an allergic reaction to the antibiotic.
2. Encourage your child to drink plenty of fluids such as juice, soda, and fruit drinks. Soft foods like applesauce, pudding, and mashed potatoes may be less irritating to the throat.
3. Give acetaminophen (e.g., Tylenol, Panadol) or ibuprofen (Motrin, Advil) for fever. Your child's dose is:_____
4. Salt water gargles (½ tsp salt in 1 cup warm water) may make an older child's sore throat feel better. Do not let your child swallow the salt water. Have him or her spit it out.
5. Your child may go back to school 24 hours after starting the antibiotic as long as he or she feels well and does not have a fever.

Call Your Doctor or Return to the Emergency Department If:

1. Your child has drooling or difficulty swallowing.
2. Your child has a stiff neck.
3. Your child has trouble breathing.
4. Your child has a rash or swelling of the hands or feet.
5. Your child still has a fever 2 to 3 days after starting antibiotics.
6. You are unable to give your child the antibiotic.
7. Your child looks sick or you have any questions or concerns.

SPRAINS AND STRAINS

A *sprain* is an injury to the ligaments that hold your bones together. A *strain* is an injury to the muscle or muscle tendon from stretching or pulling.

Treatment

1. Keep the injured area quiet. If your doctor gave you a splint or crutches, have your child use these as instructed. Do not allow your child to put weight or stress on the area until your doctor tells you this is OK. Follow the doctor's instructions for exercise.
2. Keep the injured area elevated as much as possible. Prop up an arm or leg with pillows.
3. Use an ice pack for the first 24 hours. Do not put the ice directly against the skin; wrap it in a towel first.
4. After the first 24 hours, use a heating pad or hot water bottle (be careful not to burn the skin).
5. You may give your child ibuprofen (Motrin, Advil) for pain. Your dose is:_____
6. Follow up with your doctor or with an orthopedic surgeon in _____days. Do not let your child stop using the splint or crutches until you follow up with a doctor.

Call Your Doctor or Return to the Emergency Department If:

1. Your child has increased redness or swelling at the injury site.
2. Your child gets a fever.
3. Your child has no feeling in the injured arm or leg or it feels cold.
4. Your child is not feeling better in 3 to 5 days or is not making steady progress in 3 to 5 days.
5. You have any questions or concerns.

STOMATITIS

Stomatitis is a viral infection that can cause sores or blisters to develop on the gums, tongue, and other areas inside the

mouth. Your child may have a fever and the ulcers are painful. He or she may not want to eat or drink. Because this is a viral infection, it will usually clear up by itself within 5 days. However, some children may have sores in the mouth for 1 to 2 weeks.

To Keep Your Child Comfortable and Prevent Dehydration

1. Give acetaminophen (e.g., Tylenol, Panadol) or ibuprofen (Advil, Motrin) at the correct dosage for your child's age. This medicine will help with the pain and fever. Acetaminophen suppositories are available at your pharmacy without a prescription. Your dose is:_____
2. Encourage cold or cool liquids. These may be soothing to the mouth and help numb the pain. Avoid citrus and carbonated drinks (e.g., orange, grapefruit juices, lemonade, soda). Soft foods such as applesauce, yogurt, pudding, or mashed potatoes may be less irritating to the mouth.
3. Avoid salty or spicy foods.
4. If your doctor has given you a mouthwash or other medication, use as directed.

To Prevent Spread of this Infection

1. Wash your hands and your child's hands frequently and before eating.
2. Do not share your child's eating utensils or drinking cups while sick; wash after each use.
3. Wash any toys your child places in his or her mouth before and after your child plays with them.

Call Your Doctor or Return to the Emergency Department If:

1. Your child is refusing to drink or cannot swallow.
2. Your child appears dehydrated (no urine output in the last 8 hours, no tears when crying, lips are dry or cracked).
3. You think your child looks worse than when you were initially seen in the ED.
4. Your child is not getting better after 1 week.

URINARY TRACT INFECTION

Your child has been diagnosed with a urinary tract infection. This is an infection of the bladder or kidneys. It can cause symptoms of fever, abdominal or back pain, vomiting, or burning with urination, or it may have no symptoms in small babies. The diagnosis is made by looking at a clean sample of urine under a microscope and then growing bacteria with a urine culture.

Treatment

1. Antibiotics are used to treat the infection. Your child's dose is _____times per day. Make sure to give all doses for the full course to completely get rid of the infection. Diarrhea can be a side effect of antibiotics, so do not stop them if this happens. If your child does get a rash or severe diarrhea, call your doctor.
2. Encourage fluids to help clear the infection.
3. Allow your child to urinate as often as he or she desires, and encourage him or her not to “hold” the urine.
4. Follow-up is important to make sure the infection is cured. Your doctor should check another urine sample after the antibiotics are finished to confirm this.

Long-Term Follow-Up

Urinary tract infections can sometimes come back. Your doctor may want to follow your child more frequently and look at urine samples. Some children need to have their kidneys and bladder evaluated to make sure that there is not a problem that led to the infection. Your doctor may schedule tests to look for this.

Tips for Prevention

1. Teach your child to wipe from front to back and then throw away the toilet paper.
2. Have girls wear cotton underwear. Synthetics can irritate the genital area and lead to infection.
3. Avoid bubble baths, creams, or powders in the genital area.
4. Encourage your child to drink plenty of fluids each day.
5. Encourage him or her to empty the bladder completely every 3 to 4 hours during the day and to urinate before bedtime.

Call Your Doctor or Return to the Emergency Department If:

1. Fever lasts longer than 2 days with antibiotic treatment or your child develops a fever while taking the antibiotic.
2. Your child stops urinating or the urine becomes bloody.
3. Your child gets worse.
4. Your child refuses to take the antibiotic.
5. Your child gets a rash or has severe diarrhea while taking the antibiotic.

VOMITING AND/OR DIARRHEA

Vomiting or diarrhea happens when the lining of the stomach or intestines is irritated by an infection. Usually, the infection is a virus and needs to run its course, which may vary from 1 day to 1 week. The doctor who examined your child decided that you could treat this illness at home. To make your child feel better, he or she needs to rest the

stomach and intestines and help prevent more vomiting and diarrhea. This can be done by giving your child clear liquids and foods that are easily digested and by avoiding spicy or greasy foods that can further irritate the gastrointestinal tract. The goal is to keep your child from becoming dehydrated (dry). Your child can return to school or day care when the diarrhea or vomiting have resolved and he or she is feeling better.

Follow the Instructions Below:

For Babies 2 to 6 Months

1. Feed your baby an oral electrolyte solution (Pedialyte or Ricelyte). If severe vomiting or diarrhea is a problem, try a small amount at frequent intervals (example: 1 ounce every 1 hour). Babies who are breastfeeding may continue but still may need additional fluids such as Pedialyte or Ricelyte.
2. DO NOT GIVE PLAIN WATER.
3. If the vomiting and diarrhea improve in 24 hours, restart the baby's regular formula.
4. Some stooling may occur; keep feeding the formula unless your baby has very liquid stool, vomits more than five times, or has more than five stools in 1 day.
5. See your doctor or return to the ED if the vomiting and diarrhea continue. Do not give your baby Pedialyte or Ricelyte for more than 24 hours.

For Babies 6 Months to 1 Year

1. Feed your baby an oral electrolyte solution (Pedialyte or Ricelyte) for 24 hours. If your child does not like Pedialyte, you can also use Kool-Aid or flat soda (shake out the fizz), but only for 24 hours. DO NOT GIVE PLAIN WATER. Babies who are breast-feeding may continue but may still need additional fluids.
2. If the vomiting and diarrhea improve in 24 hours, restart formula. In addition, you can begin some soft foods such as rice cereal, bananas, or applesauce.
3. At 48 hours, you can add other fruits and vegetables that are in your child's diet.
4. At 72 hours, you can resume your child's regular diet.
5. If the vomiting and diarrhea return or continue at any stage, go back to the clear liquids and see your doctor. Do not give your baby clear liquids for more than 48 hours without talking to your doctor.

For Children Older than 1 Year

1. Give your child clear liquids only for 24 hours (clear liquids are ones you can see through), and allow the stomach to rest. Examples of clear liquids are flat soda (shake out the fizz), Kool-Aid, Gatorade diluted with an equal amount of water, Hawaiian Punch, juices (not apple, orange, grapefruit), tea with sugar, Jell-O, popsicles, water ice, sherbet, clear soups, or broth. DO NOT GIVE MILK.
2. At 24 hours, if the vomiting and diarrhea improve, add soft, bland foods. Examples include oatmeal, rice cereal, bananas, applesauce, dry toast, crackers, vanilla wafers, dry mashed potatoes, noodles, boiled chicken, and turkey. STAY AWAY FROM FRIED OR SPICY FOODS.
3. At 48 hours, add other fruits and vegetables and plain cooked meat.
4. At 72 hours, resume a regular diet and give milk as you would normally.
5. If the vomiting and diarrhea return or continue at any stage, go back to the clear liquids, and see your doctor. Do not give your child only clear liquids for more than 48 hours without calling your doctor.

Call Your Doctor or Return to the Emergency Department If:

1. The vomiting and diarrhea do not improve.
2. Your child is unable to take fluids or is weak, sleepy, or lethargic.
3. You think your child looks dry (eyes look sunken, soft spot is depressed, no tears when crying, mouth looks dry).
4. Your child has not urinated in 8 hours.
5. There is blood in the vomit or stool, or brown flecks like coffee grounds in the vomit.
6. Your child has abdominal pain.
7. Your child has a fever higher than 102°F.
8. You think your child looks sick or is getting worse.
9. You have any questions or concerns.

APPENDIX **D**

Practical Information

BENJAMIN K. SILVERMAN, MD

Emergency Services, Harbor/UCLA Medical Center, Children's Hospital of Orange County, Orange, California

VITAL SIGNS

Blood Pressure

Values:
Neonate Range: Systolic 40–80 mm Hg
Diastolic 20–55 mm Hg

	Percentile (Syst/Dias)	
Age (Yr)	50%	95%
2	96/60	112/78
6	98/64	116/80
9	106/68	126/84
12	114/74	136/88

Lower extremity pressures usually measure 10 to 40 mm Hg higher.

Pulsus Paradoxicus

Pulsus paradoxicus is defined as a drop in systolic blood pressure of greater than 10 mm Hg when taken during inspiration and then taken during expiration.

Respiratory Rate

Age	Per Minute
Neonate	30–50
1–6 mo	20–40
6 mo–2 yr	20–30
2–12 yr	16–24
Adolescent	12–20

Heart Rate

Age	Per Minute
Newborn	80–180
1 wk–1 mo	80–160
3 mo–2 yr	80–150
2–10 yr	75–110
10 yr–adult	50–100

Temperature

Conversion:
Fahrenheit vs. Centigrade:

$$°C = (°F - 32) \times 5/9$$

Example: $°C = (98.6 - 32)$ (or 66.6) $\times 5$ (= 333)/9 = 37

$$°F = (°C \times 9/5) + 32$$

Example: $°F = (39 \times 9 = 351)$ (/5 = 70.2) + 32 = 102.2
Extrapolating Points: 38°C = 100.4°F
39°C = 102.2°F
40°C = 104.0°F
41°C = 105.8°F

Weight

Conversion: Wt (lb)/2.2 = Wt (kg)
Wt (kg) × 2.2 = Wt (lb)

Weight

Conversion: Wt (lb)/2.2=Wt (kg)
Wt (kg)×2.2=Wt (lb)

	Percentiles (Using Kg)		
Age	5%	50%	95%
Neonate			
32 wk	1.3	1.8	2.8
40 wk	2.7	3.5	4.2
6 mo			
Female	5.9	7.2	8.6
Male	6.3	7.7	9.5
1 yr			
Female	7.8	9.5	11.4
Male	8.4	10.1	12.0
2 yr			
Female	9.8	11.8	14.0
Male	10.5	12.7	14.7
5 yr			
Female	14.1	17.9	22.2
Male	15.2	19.0	22.8
7 yr			
Female	15.5	19.5	29.0
Male	16.6	21.0	29.8
9 yr			
Female	21.7	28.0	40.6
Male	22.6	28.0	40.2

(See Fig. I.2 and Fig. I.3 in Chapter 1.)

Surface Area

Body surface area can be determined by connecting the height and weight numbers with a straight line. The point at which the line intersects the surface area abscissa is the reading for Surface Area in meters squared (Fig. D.1).

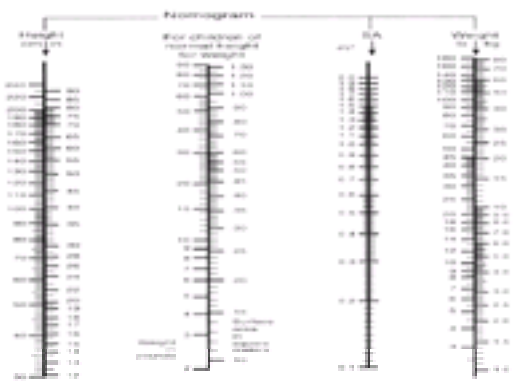

FIGURE D.1. Surface area. (Adapted from Harriet Lane Handbook. 14th ed., St Louis: Mosby, 1996.)

To determine the approximate body surface area for normally proportioned children, use either the second line from the left in the above nomogram or the following formula.

$$\text{Surface area } (m^2) = \text{Square root of:}$$
$$[\text{Ht (cm)} \times \text{Wt (kg)} \div 3600]$$

IMMUNIZATIONS

Recommended Schedule for Healthy Infants and Children

Age	Immunizations
Birth or 1 mo	Hep B-1
2 mo	DTaP or DTP, HIB, IPV, Hep B-2
4 mo	DTaP or DTP, HIB, IPV
6 mo	DTaP or DTP, HIB, HepB-3
(In the face of a measles epidemic, the first MMR can be given as young as this)	
12–15 mo	MMR, HIB
15–18 mo	DTaP or DTP, OPV, VAR
4–6 yr	DTaP or DTP, OPV
11–12 yr	MMR
14–16 yr	Td (repeat every 10 yr)
	VAR (if susceptible, 2 doses 1 month apart)

An oral rotavirus vaccine is to be added to the infant vaccine schedule at ages 2, 4, and 6 months.

Immunization Modifications for Children with HIV

1. Use only IPV; no OPV (same for household contacts).
2. Add PnV at age 2 years; booster 3 to 5 years later (a new conjugate PnV is in advanced stages of testing).
3. Varicella vaccine should not be used.
4. Severely immunocompromised patients should not receive MMR.

Children immunosuppressed for causes other than HIV should be immunized only in consultation with their primary or subspecialty physician.

Abbreviations:

OPV—oral polio vaccine.
IPV—inactivated polio vaccine.
DTaP—diphtheria, tetanus, acellular pertussis.
DTP—diphtheria, tetanus, pertussis.
Td—full tetanus toxoid dose; half diphtheria dose.
MMR—measles, mumps, rubella.
HIB—Haemophilus b conjugate vaccine.
PnV—pneumococcal vaccine.
Hep B— hepatitis B.
VAR—Varicella vaccine.

(Adapted from Report of the Committee on Infectious Diseases of the American Academy of Pediatrics. 24th ed. Georges P, ed. Elk Grove Village, IL. 1997.)

Recommendations for immunization upon exposure to tetanus, rabies, meingococcemia, hepatitis A and B, and varicella are defined in the Prophylaxis section of these Practical Information points (pp. 1946–1949).

BEDSIDE LABORATORY TESTING

Rapid Screening Test for Cold Agglutinins

Collect a few drops of blood in a purple-top tube (small test tube with about 0.2 mL of 3.8 NaEDTA). Place in ice water bath for about 60 seconds. Tilt tube and look for flocculation in the blood as it starts up the side of the tube. Warm the tube to room temperature and see if the flocculation disappears. Presence of flocculation when observed by the naked eye with subsequent disappearance on warming is a positive test for cold agglutinins and equates with about a 1:64 or greater cold agglutinin titer.

Apt-Downey Test for Fetal Blood

If a stool specimen passed by a neonate is grossly bloody, mix a small sample of the specimen in a test tube with an equal quantity of tap water. Centrifuge briefly or else filter out the solid material. The supernate should have a pink color due to the suspended blood. Add 1 part of 1.0% NaOH to 5 parts of the supernate. Read in 2 minutes. A persistent pink color indicates presence of fetal hemoglobin because fetal hemoglobin is resistant to alkali denaturation; if the supernate turns yellow, the hemoglobin is adult and therefore is probably swallowed maternal blood.

Stool Examination for Leukocytes

Place a small specimen of stool on a glass slide and smear a bit. Mix with a drop or two of methylene blue stain. Cover

with thin cover slip. Examine under microscope in about 3 minutes. Presence of a moderate to profuse number of polymorphonuclear leukocytes is suggestive of a specific bacterial cause of diarrhea.

Gram Stain

Make a thin smear of blood, spinal fluid, or vaginal or urethral secretion on a glass slide. Allow to air dry. Pour on gentian violet for 1 minute and wash with water. Then pour on iodine solution for 1 minute and wash. Decolorize by applying acetone/alcohol for a few seconds and wash. Stain with safranin for 15 seconds and wash. Examine under high-power microscope.

Tzanck Preparation

Denude a vesicular or bullous lesion; blot it and scrape the base with the scalpel edge. Spread the scraped material onto a glass slide and fix with methyl alcohol. Stain for 30 seconds with Wright stain. Wash. Look for multinucleated giant cells indicative of herpetic simplex or zoster lesions.

Pinworm Evaluation

1. Place a piece of cellophane over the end of a tongue stick with sticky side out. Press over the perianal mucosa with moderate pressure for about a minute. Spread the sticky side of the tape over a glass slide. Look through the microscope for ova.

or

2. Instruct the parents to turn over the child who has been asleep for about an hour and look carefully at the perianal area. Live, threadlike worms, about 1 cm in length can be seen wiggling out of the anus to lay their ova.

Methemoglobin Screening Test

To evaluate the apparently cyanotic patient who has no cardiac or respiratory impairment and does not respond to oxygen, place a drop of blood on filter paper. Wave it in the air for 60 seconds. Blood without methemoglobin will remain red or bluish, whereas blood with methemoglobin will turn chocolate-brown.

ELECTROCARDIOGRAPHIC CAVEATS

In young children, the right ventricle normally extends to the right of the sternum, as can be seen graphically on an anteroposterior chest radiograph. Because of this, an electrocardiogram in children less than 5 years of age must include a chest lead taken on the right side of the chest at a point analagous to the left-sided V4 lead. This lead is called V4R. Occasionally, if a heart is grossly enlarged and extends well to the right of the sternum, a V6R and even a V7R lead must be taken to make a complete tracing that properly displays right ventricular potentials.

The right ventricle is normally the dominant ventricle in young children. Right axis is normal, and aVR usually has a dominant R wave in its QRS complex. The QRS progression across the chest leads usually goes from dominant R wave in V4R through the transitional zone to dominant R wave again in the left-sided chest leads. This may be true until as late as 4 years of age.

On the right-sided chest leads and in extremity lead III, T waves are usually normally inverted in young children.

In determining whether a QT interval is prolonged, of particular importance in evaluating the patient with syncope and fainting, the formula to use is as follows:

$$\text{Corrected QT (QTc)} = \text{Measured QT (in fractions of a second)} \div \sqrt{\text{R-R interval (in fractions of a second)}}$$

QTc should not exceed:
- 0.45 in young infants
- 0.44 in older infants and children
- 0.43 in adolescents and adults

FLUID AND ELECTROLYTE AIDES:

A millimole is the atomic weight expressed in milli grams.
Equivalents are the number of electric charges per liter or the atomic weight divided by valence.
A milliequivalent is the equivalent weight expressed in milligrams.

Serum osmolality is calculated with the formula:

$$2(\text{Na}) + \text{Glucose (mg/dL)} \div 18 + \text{BUN (mg/dL)} \div 2.8$$

Normal range is about 285–295 mOsm/L.

Anion gap is the difference between measured cations and measured anions in the serum. Practically, it is:

$$(Na + K) - (Cl + bicarb)$$

Normal value is about 10–15 mEq/L.

Maintenance 24-hour fluid requirements for children:
For the first 10 kg, 100 mL/kg
For the second 10 kg, 1000 mL + 50 mL/kg
Beyond that, 1500 mL + 20 mL/kg

Maintenance electrolytes:
sodium, 2–3 mEq/kg/day
potassium, 1–2 mEq/kg/day
chloride, 2 mEq/kg/day

Total body water (as percentage of body weight):
80% at birth
70% at 6 mo
60% at 1 yr

Two-thirds is intracellular fluid and one-third extra cellular.

SENSORY NERVE DERMATOMES:

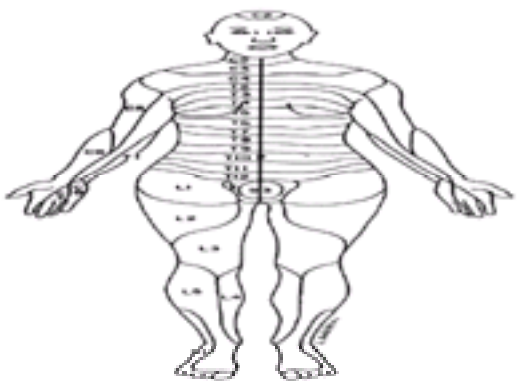

FIGURE D.2. Anterior aspect. (Adapted from Athreya BH, Silverman BK. Pediatric Physical Diagnosis. Norwalk, CT: Appleton-Century-Croft, 1985.)

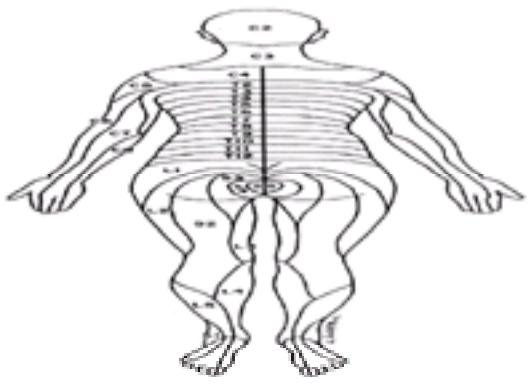

FIGURE D.3. Posterior aspect. (Adapted from Athreya BH, Silverman BK. Pediatric Physical Diagnosis. Norwalk, CT: Appleton-Century-Croft, 1985.)

PROPHYLAXIS AFTER DISEASE EXPOSURE

Tetanus Exposure

Exposure to *Clostridium tetani,* the causative organism for tetanus (lockjaw), occurs primarily through wounds incurred at a site contaminated by human or animal excreta. The first step in prophylaxis involves thorough cleaning and irrigation of potentially contaminated wounds. A decision about which, if any, immunization entity should be ordered is based on the nature and severity of the wound and on the prior tetanus immunization record of the patient. The following table serves as guide:

Prior Tetanus Toxoid Immunization (Doses)	Clean Minor Wound	All Other Wounds
Uncertain (or less than 3 doses)	DTaP or DTP or Td	DTP or Td & TIG or TAT
3 or more (most recent more than 10 yr ago)	Td	Td
3 or more (most recent within past 5 yr)	None	None

3 or more (most recent between 5–10 yr)	None	Td

DTP, diphtheria, tetanus, pertussis toxoid;*DTaP,* diphtheria, tetanus, acellular pertussis;*Td,* adult formulation of diphtheria, tetanus toxoid; *TIG,* tetanus immunoglobulin (dose: 250–500 units intramuscularly); *TAT,* tetanus antitoxin; should be used only if TIG is not available and only after testing (dose: 3000–5000 units intramuscularly).

Rabies Exposure:

Rabies exposure occurs on being bitten by an animal carrying the rabies virus in its saliva. The most common animal reservoirs include bats, skunks, raccoons, foxes, and woodchucks. Dogs and cats, when bitten by these animals, carry the virus in their saliva before becoming symptomatic and may transmit it to humans by biting or abrading. Rarely, small rodents and rabbits transmit the disease. In recent years, more than half the 36 cases of rabies diagnosed in the United States have been associated with bat variants of the rabies virus, in many cases with no clear history of a bite.

The decision about when to institute prophylaxis after an exposure must be guided by the location and severity of the wound, the status of the offending animal if known, and knowledge of the local epidemiology. In northeastern United States, for instance, rabies is prevalent in the raccoon population, with resultant fear of infection in the dog and cat population. If a patient has heavy exposure to bats in the home or workplace, even in the absence of a history of bite, prophylaxis with human diploid cell vaccine (HDCV), should probably be initiated.

Prophylaxis should begin with thorough cleaning and irrigation of the wound. HDVC, although expensive, is relatively free of side effects.

Active Immunization

Five doses of HDCV, 1 mL each, should be given intramuscularly on days 0, 3, 7, 14, and 28 after exposure. Persons who have been previously immunized can be given just two doses—one on day 0 and one on day 3.

Passive Immunization

In addition to HDCV, rabies immunoglobulin (human) should be given to patients who have had no prior immunization in a dose of 20 units/kg on day 0 of exposure. Half should be given IM and half infiltrated around the wound.

Pre-exposure prophylaxis for those traveling to or working in endemic areas consists of 3 injections of either HDCV or rabies vaccine absorbed (RVA) given on days 0, 7, and 28.

***Haemophilus influenzae* b Exposure**

Recommendations for use of rifampin on exposure to illness caused by *Haemophilus influenzae* b:

1. For all household contacts in which at least one of the contacts is less than 12 months of age and has not received the 12-month booster dose of Hib. For all household contacts in which those less than 48 months have not completed their Hib immunization series.
2. In day-care homes with children less than 2 years of age, in which contact is 25 hours a week or more, regardless of attendee's immunization status.
3. All attendees in day-care centers in which two or more cases have occurred within 60 days, regardless of the child's immunization status.
4. All household contacts in which an immunocompromised child lives, regardless of immunization status.
5. To ensure complete eradication of the organism from the pharynx, the index case should receive rifampin if the patient had been treated with ampicillin and chloromycetin.
6. Should not be given to pregnant women.
7. Provide a warning that urine may turn red and contact lenses may stain.

Dosage: rifampin, 20 mg/kg/day orally every day, to a maximum of 600 mg for 4 days.

Meningococcal Infection Exposure

All those who have had contact with the patient's oral secretions, including household, day-care center, and nursery school contacts and intimately exposed (intubaters, mouth-to-mouth) medical personnel, should receive antibiotic or chemical prophylaxis as soon as possible.

Drug Options and Dosage:

Rifampin—10 mg/kg/day to a maximum of 600 mg/day, divided in two doses for a total of 2 to 4 days (infants less than 1 month, 5 mg/kg/day); not for pregnant women; urine and contact lenses may turn red.

Ceftriaxone—has been evaluated for group A meningococcal strains only but is probably effective for all strains—single intramuscular dose of 125 mg for ages less than 12 years and 250 mg for ages 12 and older.

Ciproflaxin—for nonpregnant contacts 18 years and older. A single oral dose of 500 mg.

Sulfisoxazole—when the isolate is known to be sensitive to sulfa; 0.5 g/day for age less than 1 year; 0.5 g every 12 hours for ages 1 to 12 years; and 1 g every 12 hours for ages more than 12 years—total 2 days.

Meningococcal polysaccharide vaccine (groups A, C, Y, and W-135)—currently given to all military recruits, can be

considered in cases when ongoing exposure is likely. Has inconsistent effectiveness in infants but can be given to children 2 years and older in high-risk categories, including asplenia. Can be used as an adjunct to chemoprophylaxis. The vaccine does not include the B strain of meningococcus, which is the most common in the United States.

Measles (Rubeola) Exposure:

Within 72 hours of exposure: Live virus measles vaccine (to be repeated at appropriate age—15 months and again at 11 to 12 years for those between 6 months and 1 year; at 11 to 12 years for those older than 1 year). Children less than 6 months at the time of exposure should receive immunoglobulin (0.25 mL/kg intramuscularly).

More than 72 hours up to 7 days after exposure (or for those in whom time of exposure is unclear, as in some group home or shelter residents, when a shower of cases are appearing): Immunoglobulin (0.25 mL/kg) followed in 6 months by live virus measles vaccine.

Immunodeficient children: Immunoglobulin (0.5 mL/kg). Subsequent immunization with live virus vaccine will vary with the nature of the immunodeficiency and should be determined by the physician providing ongoing care.

Varicella Exposure

Varicella-zoster virus (VZV) is highly contagious. The vaccine is not currently recommended for preventing varicella in the exposed individual. Its use, however, is essentially free of risk and may or may not prevent clinical illness if given within 3 days of exposure.

The only guaranteed protection for the contact at this time is provided by varicella-zoster immunoglobulin (VZIG). Its use should be confined to those who have been exposed and who are at high risk of developing complications of varicella, particularly premature infants weighing less than 1000 g and others who are immunosuppressed or immunodeficient. Pregnant women with no history of varicella can be evaluated on exposure and considered for VZIG. Larger prematures and term neonates born to mothers who develop the disease within 5 days before or 2 days after delivery should also be given VZIG. Infants born to mothers given VZIG during the last few days of pregnancy should be given VZIG, even if the mother did not develop the disease.

With the advent of acyclovir as an effective treatment for varicella, it is not necessary to give VZIG to the healthy susceptible adolescent or adult who is exposed to the disease. Acyclovir therapy can be initiated shortly after the disease erupts. However, acyclovir has no role in prevention of varicella in an exposed individual.

The dosage of VZIG is 125 units (1.25 mL intramuscularly) per each 10 kg or less, up to a maximum of 625 units (6.25 mL).

Rubella Exposure

Rubella is a mostly benign disease except to the fetus of the pregnant woman. Antibody status should be determined before pregnancy and vaccine administered at that time to those women at risk. Immunoglobulin is of questionable value in rubella but should be administered to those who have serologic evidence of having developed the disease during pregnancy and who choose to continue the pregnancy. Congenital rubella may occur in the fetus despite administration of immunoglobulin to the mother. No other indication for prophylaxis against rubella exposure exists.

Mumps Exposure

Immunoglobulin is of no value. Live virus vaccine should be administered to susceptible adults when exposed to mumps.

Hepatitis A Exposure

Hepatitis A is foodborne and waterborne and is also transmitted by face-to-face personal contact. The hygienic measure of careful handwashing for all medical, day-care center, and restaurant personnel should be followed at all times. Potentially contaminated food and water should be avoided.

The hepatitis A vaccine is not recommended for postexposure prophylaxis. Household and sexual contacts, institutional residents, and day-care workers in contact with an index case can be protected with low-dose immunoglobulin (0.02 mL/kg intramuscularly) given within 14 days of exposure.

Individuals traveling to potentially endemic areas can be protected by immunoglobulin doses of 0.02 to 0.06 mL/kg, with the higher dosages recommended for longer stays.

Hepatitis B Exposure

Hepatitis B virus (HBV) is transmitted by exposure to contaminated blood through wounds, needle exposure, medical management, improperly prepared transfusion, and sexual activity and maternal–child transmission.

Universal administration of hepatitis B vaccine is begun in infancy. Medical and institutional personnel and others at high risk of exposure also should be vaccinated with hepatitis B vaccine. Four doses are given at intervals of 0, 1, 2, and 6 to 12 months. The dose is either 1.0 mL or 0.5 mL intramuscularly, depending on the patient's age and the vaccine used. The dose should be doubled for immunosuppressed patients.

Immunization can be started at the time of exposure, but previously nonimmunized individuals should receive

simultaneously with the first dose of vaccine a dose of hepatitis B immunoglobulin (HBIG) (0.06 mL/kg) (minimum dose: 0.5 mL). This treatment does not appear to interfere with the response to the vaccine.

Neonates born to hepatitis B surface antigen–positive mothers should receive HBIG (0.5 mL) and then begin a vaccination schedule by day 7.

Hepatitis C Exposure

Hepatitis C is parenterally transmitted. No vaccine is available. Immunoglobulin appears to be of equivocal value and is not recommended.

For additional information, refer to Report of the Committee on Infectious Diseases. American Academy of Pediatrics. Georges P, ed. Elk Grove Village, IL: American Academy of Pediatrics, 1997.

HIV Occupational Exposure:

Medical and dental personnel (MDP), particularly those working in emergency departments and in the various surgical and laboratory areas, are susceptible to inadvertent exposure to the human immunodeficiency virus (HIV). This may occur 1) percutaneously (needle stick or scalpel wound); 2) by contact of MDP skin or mucous membranes with potentially contaminated body fluid such as blood, semen, or vaginal secretions; or 3) by direct MDP skin or mucous membrane contact with laboratory specimens. If MDP skin is previously irritated or abraded, the risks under 2) and 3) are increased.

The first step in prophylaxis is always, when possible, prevention of exposure. This is best accomplished by MDP by carefully following the guidelines of appropriate handwashing, use of gloves and proper cleaning and draping for any procedure that may involve exposure, careful disposal of all needles and other disposable instruments and syringes, effective sterilization of all reusable equipment and devices, and careful monitoring of all the foregoing by trained infection control personnel in institutional and office settings.

When exposure does occur to MDP, careful cleaning of the wound area is essential. Relevant details of the exposure should be recorded in a confidential record, including date and time, job duty being performed, full details of the circumstances and nature of the exposure, and description of the source of the exposure material. Ongoing record should include details of counseling, postexposure management, and follow-up of the MDP and the individual who was the source of the exposure material.

Hepatitis B prophylaxis should be considered as described previously.

With permission, HIV testing should be performed on the source individual and, if possible, repeated periodically for 6 months. The exposed MDP should undergo HIV testing at the time of exposure. If the source individual for the exposure material is HIV positive, becomes HIV positive, or refuses to be tested, the MDP should be retested at periodic intervals up to 6 months. Seroconversion usually occurs within 3 months of exposure.

Consideration should be given to initiation of postexposure prophylaxis for the MDP when the source individual is known to be, or is at high risk for being, HIV positive. Two antiretroviral drugs, at least one of which should be zidovudine, should be included in the regimen. A protease inhibitor should also be added for the higher exposure risks. The potential toxicity of the drug regimens should be balanced against the degree of risk imposed by the exposure to the MDP. If prophylaxis is to be initiated, it should be done so within a few hours after exposure. A decision must be made by the MDP and personal physician after adequate and appropriate counseling and consideration of all the factors involved in weighing risk versus toxicity. (Adapted from the MMWR—Morbidity and Mortality Weekly Report—of the Centers for Disease Control and Prevention; 1996;45:468–472.)

SCORES

Glasgow Coma Scale

Eye Opening	
Spontaneous	4
To speech	3
To pain	2
None	1
Best Motor Response	
To verbal command	
Obeys	6
To painful stimulus	
Localizes	5
Flexion withdrawal	4
Flexion decorticate	3
Extension decerebrate	2
No response	1
Best Verbal Response[a]	
Oriented and converses	5
Disoriented; converses	4
Inappropriate words	3
Incomprehensible sounds	2
No response	1

[a]Children less than 2 years of age should receive full verbal score for crying after stimulation.

AVPU

A—alert

V—responds to vocal stimuli

P—responds to painful stimuli

U—unresponsive

Revised Trauma Score

Attribute	Coded Value
Respiratory Rate	
10–29	4
>29	3
6–9	2
1–5	1
0	0
Systolic Blood Pressure	
>89	4
76–89	3
50–75	2
1–49	1
0	0
Glasgow Coma Scale	
13–15	4
9–12	3
6–8	2
4–5	1
3	0
Unweighted Revised Trauma Score:	

Adapted from Champion HR, Sacco WJ, et al. A Revision of the trauma score. J Trauma 1989;29:623.
NOTE: Of value in determining whether to triage to a trauma center. Higher scores are generally associated with less urgency and better outcomes.

Pediatric Trauma Score

Component	+2	+1	-1
Size	>20 kg (40#)	10–20 kg	<10 kg
Airway	Normal	Maintainable	Unmaintainable
Systolic blood pressure	>90 mm Hg	50–90 mm Hg	<50 mm Hg
Central nervous system	Awake	Obtunded/loss of consciousness	Coma/decerebrate
Skeletal	None	Closed fracture	Open/multiple fractures
Cutaneous	None	Minor	Major/penetrating

Adapted from Tepas JJ, Mollitt DL, et al. The Pediatric Trauma Score as a predictor of injury severity. J Pediatr Sur 1987;22:14.

Assign a value to each of the six components. A score of 8 or less may suggest that care should be provided in a pediatric trauma center.

APGAR Score

Sign	0	1	2
Heart rate	Absent	Below 100	Over 100
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Limp	Some flexion of extremities	Active motion
Response to catheter in nostril (tested after oropharynx is clear)	No response	Grimace	Cough or sneeze
Color	Blue, pale	Body pink, extremities blue	Completely pink

To be checked on each newborn at 1 minute and again at 5 minutes after completion of birth.

Trauma Protocol

To be done simultaneously under direction of a leader and including a recorder if sufficient personnel are available.

Primary Survey and Resuscitation

“A” AIRWAY—positioning; stabilization of C-spine

“B” BREATHING—midline trachea; subcutaneous air; breath sounds; open pneumothorax; airway obstruction; tension pneumothorax; hemothorax; flail chest; gastric distension; oxygen; bag-valve-mask or intubation as indicated

“C” CIRCULATION—hemorrhage; peripheral pulses; heart sounds; capillary refill; jugular vein distension; vascular access (venous; intraosseous); bloods for lab, including type and crossmatch

“D” DISABILITY—pupils; level of consciousness; AVUP; Glasgow Coma Scale and/or Revised Trauma Score; other cranial nerves if possible

“E” EXPOSURE—open wounds, front and back

“F” FOLLOW—monitors; rhythm strip; catheter; G-tube

“G”—blood gases if indicated

“H” HISTORY—preliminary

Secondary Survey

- Complete physical examination, including cranial nerve check, fundal examination, careful neurologic screening, repeated check of vital signs, abdominal examination, check for blood from penis; rectal examination, and evaluation of all open wounds
- Complete history of the current episode and medical history if possible
- C-spine film, chest radiograph, abdominal and pelvic films; consideration of emergency ultrasound and/or computed tomography scan
- Careful splinting and wound dressing as indicated

SECTION II Signs and Symptoms

Fred M. Henretig, MD, Section Editor

Suggested Readings

In this section, the chapters focus on the problem-oriented approach to the rapid diagnosis and initial management of patients coming to the emergency department (ED) with specific signs or symptoms as chief complaints. The particular presenting complaints covered in the following chapters have been chosen because they may result from serious diseases, requiring urgent diagnosis and therapy, or because they are quite common.

In each chapter, the sign or symptom is defined, and in most cases, there is a brief review of underlying pathophysiology. The chapter then concentrates on a realistic diagnostic approach that is applicable in the ED. These chapters are supplemented in most cases by a table that lists the common causes of each sign or symptom and an algorithm that outlines the key steps in sorting out the differential diagnosis.

The chapters in this section mesh closely with those in the medical, surgical, and psychosocial sections that are organized around specific diseases. Thus, there will be many cross-references in Chapter 28, Fever, and to specific topics in Chapter 84, Infectious Disease Emergencies. These cross-references guide the reader to text that discusses details of the evaluation for the treatment of specific infectious diseases, once the likely diagnosis has been established. Brief comments on symptomatic therapy are included only if specific treatments are not discussed elsewhere in the text.

Entire textbooks have been devoted to the differential diagnosis of pediatric signs and symptoms; the spectrum of childhood disease demands such lengthy works. However, the few rapidly progressive, life-threatening causes of each complaint sometimes may become obscured in an all-inclusive detailed discussion by the information presented on less urgent conditions. Thus, the chapters in this section emphasize the serious conditions of greatest concern to the emergency physician or the pediatrician in an ED. Readers interested in pursuing broader coverage of particular pediatric signs and symptoms are referred to the invaluable works by Illingworth, Green, and Tunnessen.
