The deep peroneal, superficial peroneal, and saphenous nerves can be blocked through a single needle entry site (Fig. 43-18 and Plate 14). A line is drawn across the dorsum of the foot connecting the malleoli. The extensor hallucis longus tendon is identified by having the patient dorsiflex the big toe. The anterior tibial artery lies between this structure and the tendon of the extensor digitorum longus muscle and is palpable at this level. A skin wheal is raised just lateral to the pulsation between the two tendons on the intermalleolar line. A 25-gauge, 3-cm needle is advanced perpendicular to skin entry site, and 3 to 5 mL of local anesthetic injected deep to the extensor retinaculum to block the deep peroneal nerve. This technique anesthetizes the skin between the first and second toes and the short extensors of the toes.

The needle can now be directed laterally through the same skin wheal while injecting 3 to 5 mL of solution subcutaneously, thus blocking the superficial peroneal nerve and resulting in anesthesia of the dorsum of the foot, excluding the first interdigital cleft. The same maneuver can now be performed in the medial direction, thereby anesthetizing the saphenous nerve, a terminal branch of the femoral nerve that supplies a strip along the medial aspect of the foot.

BLOCKS OF THE HEAD AND NECK

Regional anesthesia of the head and neck has become less popular as safer methods of general anesthesia have developed. However, applications for these techniques still exist, especially in the postoperative and chronic pain settings. Furthermore, airway anesthesia is often needed to facilitate endotracheal intubation.

The cutaneous innervation of the head and neck is provided by sensory fibers from the trigeminal nerve and the cervical plexus. Innervation of the airway comes from the vagus and glossopharyngeal nerves. Sympathetic blockade of the face and upper extremity is achieved by anesthetizing the stellate ganglion.

Trigeminal Nerve Blocks

The trigeminal nerve divides into three main branches in the middle cranial fossa. These divisions, the ophthalmic, maxillary, and mandibular nerves, provide sensation to the eye and forehead, midface and upper jaw, and lower jaw, respectively (Fig. 43-19 A). With the exception of the motor fibers to the muscles of mastication, carried by the mandibular nerve, these nerves are wholly sensory.

The gasserian ganglion block, approached classically through the foramen ovale, is infrequently used for producing surgical anesthesia. In the past, it was primarily applied to the diagnosis and treatment of trigeminal neuralgia; however, the increasing popularity and safety of thermocoagulation

---

for ablation of the ganglion have rendered neurolytic blocks obsolete.

Clinical Applications

Blockade of the second and third divisions of the trigeminal nerve, as well as blockade of the peripheral branches, is still occasionally useful in the diagnosis and management of pain syndromes and for discrete surgical procedures in selected patients (Fig. 43-19 B).

Side Effects/Complications

The block of the maxillary nerve can be associated with hematoma formation, as well as with the spread of the local anesthetic solution to the optic nerve, causing temporary blindness. Mandibular nerve block is not associated with major complications. If the needle is advanced past the pterygoid plate more than the recommended 0.5 cm, the pharynx may be entered, thus increasing the theoretic risk of contaminating the infratemporal fossa. Rarely, subarachnoid spread of local anesthetic, resulting in brain-stem anesthesia, may occur. [43]

Technique: Mandibular and Maxillary Nerves

The mandibular and maxillary nerves, two divisions of the trigeminal nerve, can be blocked through the same needle entry site (see Fig. 43-19 B). The maxillary nerve (second division) is blocked as it exits the skull via the foramen rotundum and crosses the pterygopalatine or infratemporal fossa between the skull and the upper jaw. The nerve terminates as the infraorbital nerve as it exits via the infraorbital foramen, where it can also be anesthetized.

The coronoid notch of the mandible is located, and with the patient's mouth closed, a 22-gauge, 8-cm needle is inserted at the inferior edge of the coronoid notch perpendicular to the skin entry site. The needle contacts the lateral pterygoid plate at a depth of about 5 cm. It is then withdrawn and redirected anteriorly and superiorly to "walk off" the plate and is advanced approximately 0.5 cm into the pterygopalatine fossa (Fig. 43-19 C). From 3 to 5 mL of local anesthetic solution will produce anesthesia to the upper jaw and skin of the lower eyelid, cheek, and upper lip.

The mandibular nerve (third division) leaves the cranium via the foramen ovale and innervates the skin of the lower jaw and the skin anterior and superior to the ear via its posterior division. Peripheral sensory branches of V3 include the buccal, auriculotemporal, lingual, and inferior alveolar (terminating in the mental nerve) nerves. The anterior division supplies motor innervation to the muscles of mastication.

The mandibular nerve is blocked via the same entry site as the maxillary nerve. The needle is again advanced along the inferior margin of the coronoid notch until the bone of the lateral pterygoid plate is contacted (
5 cm). The needle is withdrawn and is redirected to walk off the posterior border of the pterygoid plate, and it is advanced in an attempt to elicit a paresthesia. The needle should not be inserted farther than 0.5 cm past the plate (Fig. 43-19 D). Injection of 3 to 5 mL of solution at this site is adequate.

Terminal Sensory Branches of the Trigeminal Nerve

Clinical Applications

Blockade of the terminal branches of the three divisions of the trigeminal nerve is primarily used for diagnosis of trigeminal neuralgia. Individual nerve blocks can also be used for minor surgical procedures.

Side Effects/Complication

Direct injection of the peripheral nerves within the bony foramina may result in nerve damage.

Technique: Supraorbital and Supratrochlear Nerves

The supraorbital and supratrochlear nerves, branches of the ophthalmic nerve (V1), are derived from the frontal nerve, which supplies the skin of the medial upper eyelid and forehead. The supraorbital notch can be easily palpated. This landmark lies on a vertical line with the pupil (when the eye is looking directly forward), the infraorbital foramen, and the mental foramen (Fig. 43-20 . and Plates 1 and 2)

Figure 43-20 Blockade of the terminal sensory branches of the trigeminal nerve. A vertical line connects the supraorbital notch, infraorbital foramen, and mental foramen.

A 25-gauge, 2-cm needle is inserted immediately superior to the supraorbital notch, and 2 to 4 mL of local anesthetic solution is injected. A paresthesia is sometimes elicited, but it is not essential. The supratrochlear nerve can be blocked by extending the supraorbital injection site medially with an additional 2 to 4 mL of solution.

Technique: Infraorbital Nerve

This nerve can be blocked to provide anesthesia of the upper lip and skin of the cheek. The infraorbital notch lies on the line connecting the supraorbital and mental foramina and the pupil of the eye. The nerve can be blocked by advancing a 25-gauge, 3-cm needle laterally and cephalad toward the foramen from a point 1 cm inferior to it. A paresthesia is frequently elicited. When the needle tip is in the region of the foramen, 3 to 4 mL of solution is injected. It is not essential that the needle enter the foramen (see Fig. 43-20) .

Technique: Mental Nerve

Blockade of the mental nerve as it exits the mental foramen provides anesthesia of the lower lip and chin. The mental foramen lies on the vertical line connecting the pupil of the eye with the foramina of the peripheral nerves of V1, V2, and V3. The foramen is palpated in the mandible, and a 25-gauge, 3-cm needle is inserted inferomedially. Infiltration of 2 to 4 mL of solution, either after elicitation of a paresthesia or in the region of the foramen, results in anesthesia of the mental nerve (see Fig. 43-20) .

Cervical Plexus Blockade

The cervical plexus is derived from the C1, C2, C3, and C4 spinal nerves and supplies branches to the prevertebral muscles, strap muscles of the neck, and phrenic nerve. The

Figure 43-21 Anatomic landmarks and method of needle placement for superficial cervical plexus block.

deep cervical plexus supplies the musculature of the neck segmentally, as well as the cutaneous sensation of the skin between the trigeminally innervated face and the T2 dermatome of the trunk. Blockade of the superficial cervical plexus results in anesthesia of only the cutaneous nerves.

Clinical Applications

Blocks of the cervical plexus are easy to perform and provide anesthesia for surgical procedures in the distribution of C2 to C4, including lymph node dissections, plastic repairs, and carotid endarterectomy. The ability to monitor the awake patient's neurologic status continuously is an advantage of this anesthetic technique for the latter procedure and has resulted in an upsurge in the popularity of this technique. [44] [45] Bilateral blocks can be used for tracheostomy and thyroidectomy.

Side Effects/Complications

Although these blocks are technically straightforward, needle placement for the deep cervical block allows local anesthetic injection in close proximity to a variety of neural and vascular structures. Reported complications and side effects include intravascular injection, blockade of the phrenic and superior laryngeal nerve, and spread of local anesthetic solution into the epidural and subarachnoid spaces.

Technique: Superficial Cervical Plexus

The superficial cervical plexus is blocked at the midpoint of the posterior border of the sternocleidomastoid muscle. A skin wheal is made at this point, and a 22-gauge, 4-cm needle is advanced, injecting 5 mL of solution along the posterior border and medial surface of the sternocleidomastoid muscle (Fig. 43-21) . It is possible to block the accessory nerve with this injection, resulting in temporary ipsilateral trapezius muscle paralysis.

Technique: Deep Cervical Plexus

The deep cervical plexus block is a paravertebral block of the C2 to C4 spinal nerves as they emerge from their foramina in the cervical vertebrae (Fig. 43-22 and Plate 4). The traditional approach utilizes three separate injections at C2, C3, and C4. The patient lies supine with the neck slightly extended and the head turned away from the side to be blocked. A line is drawn connecting the tip of the mastoid process and the Chassaignac tubercle (transverse process of C6); a second line is drawn 1 cm posterior to this first line. The C2 transverse process lies 1 to 2 cm caudad to the mastoid process, where it can usually be palpated. The C3 and C4 transverse processes lie at 1.5-cm intervals along the second line. After skin wheals are raised over the transverse processes of C2, C3, and C4, three 22-gauge, 5-cm needles are advanced perpendicular to the skin entry site with a slight caudad angulation. The transverse process is contacted at a depth of 1.5 to 3 cm. If a paresthesia is obtained,

Figure 43-22 Anatomic landmarks and method of needle placement for deep cervical plexus blocks at C2, C3, and C4.

3 to 4 mL of solution is injected after careful aspiration for blood and cerebrospinal fluid. If no paresthesia is elicited initially, the needle is walked along the transverse process in the anteroposterior plane until a paresthesia is obtained.

This block can also be performed with a single injection of 10 to 12 mL at the C4 transverse process. [46] Cephalad spread of the local anesthetic usually anesthetizes the C2 and C3 nerves. Cervical plexus anesthesia can also be observed after injection at the interscalene level for brachial plexus blockade. Maintenance of distal pressure and a horizontal or slightly head-down position may facilitate the onset of cervical plexus blockade using the interscalene technique.

Accessory Nerve Block

The accessory (11th cranial) nerve is occasionally blocked to supplement the interscalene brachial plexus approach for shoulder procedures. Blockade of the accessory nerve results in motor paralysis of the trapezius muscle, ensuring lack of patient movement during the surgical procedure. The nerve traverses the posterior triangle of the neck (bordered by the posterior border of the sternocleidomastoid muscle, middle third of the clavicle, and anterior border of the trapezius muscle) in a very superficial position, after emerging from the substance of the sternocleidomastoid muscle at the junction of the superior and middle thirds of that muscle's posterior border. It can easily be blocked at that site by an injection of 6 to 10 mL of local anesthetic. This nerve is often unintentionally anesthetized when a superficial cervical plexus block is performed.

Local Anesthesia of the Airway

Clinical Applications

Anesthesia of the airway can be used to facilitate diagnostic laryngoscopy and bronchoscopy, as well as to allow the comfortable placement of a tracheal tube in those patients whose anatomy dictates an awake endotracheal intubation. Blocks of the superior laryngeal nerves bilaterally, along with translaryngeal injection of local anesthetic, provide anesthesia of the airway from the infraglottic area to the epiglottis. Additional topical application of local anesthetic to the oral and nasal mucosa, along with appropriate sedation, provides satisfactory analgesia for endoscopic procedures.

Side Effects/Complications

The mucosa of the upper airway is well perfused, resulting in rapid uptake of local anesthetics injected or topically applied in this area. Careful attention to total drug dosages, close observation of the patient, and compulsive aspiration prior to injection diminish the risk of local anesthetic toxicity. Other problems and complications are rare; however,

Figure 43-23 (A) Anatomic landmarks and method of needle placement for superior laryngeal nerve block. (B) The needle is walked off the greater cornu of the hyoid bone inferiorly.

caution should be employed in the patient with a full stomach, because these blocks abolish the airway reflexes.

Technique: Superior Laryngeal Nerve

The patient is placed supine with the neck extended. The hyoid bone is displaced laterally toward the side to be blocked, and a 25-gauge, 2.5-cm needle is walked off the greater cornu of the hyoid bone inferiorly and is advanced 2 to 3 mm (Fig. 43-23) . As the needle passes through the thyrohyoid membrane, a slight loss of resistance is felt, and 3 mL of local anesthetic solution is injected superficial and deep to this structure. The block is then repeated on the opposite side. This technique produces anesthesia from the inferior aspect of the epiglottis to the vocal cords.

Technique: Translaryngeal Block

The translaryngeal block is simple to perform and results in anesthesia of the trachea below the vocal cords. However, the injection of local anesthetic usually stimulates the cough reflex, and this block should be avoided in patients in whom coughing is undesirable.

With the patient in the supine position, the cricothyroid membrane is located, and a 20-gauge or smaller 3- to 5-cm plastic catheter over a needle is introduced in the midline (Fig. 43-24) . The inner steel cannula is withdrawn with the plastic catheter held firmly in place; aspiration of air confirms correct catheter placement. From 3 to 5 mL of 4 percent lidocaine solution is injected rapidly, usually resulting in a vigorous cough, which aids in the spread of the solution within the trachea.

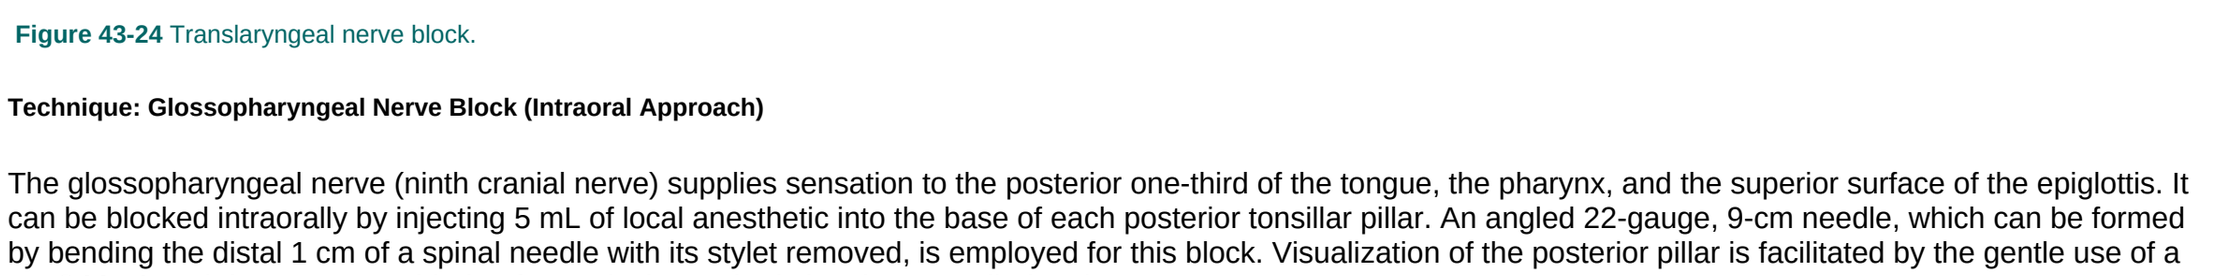

Figure 43-24 Translaryngeal nerve block.

Technique: Glossopharyngeal Nerve Block (Intraoral Approach)

The glossopharyngeal nerve (ninth cranial nerve) supplies sensation to the posterior one-third of the tongue, the pharynx, and the superior surface of the epiglottis. It can be blocked intraorally by injecting 5 mL of local anesthetic into the base of each posterior tonsillar pillar. An angled 22-gauge, 9-cm needle, which can be formed by bending the distal 1 cm of a spinal needle with its stylet removed, is employed for this block. Visualization of the posterior pillar is facilitated by the gentle use of a no. 3 MacIntosh laryngoscope blade after topical anesthetic has been applied to the

tongue. Careful aspiration prior to injection is mandatory because of the close proximity of the carotid artery.

Miscellaneous Head and Neck Blocks

Retrobulbar Block

Clinical Applications

The retrobulbar block (Ch. 63) provides anesthesia for corneal, anterior chamber, and lens procedures when combined with a block of the orbicularis oculi muscle. These blocks are often performed by the surgeon rather than the anesthesiologist, and they have gained increasing popularity for cataract surgery in the elderly outpatient population. The safety of this regional anesthetic technique was documented by Backer and coworkers, [47] who demonstrated a zero incidence of reinfarction or death in 288 patients with a history of myocardial infarction undergoing local anesthesia and/or retrobulbar block for ophthalmologic procedures.

Side Effects/Complications

Retrobulbar blocks are associated with several possible complications, including hematoma formation, local anesthetic toxicity, development of the oculocardiac reflex, and possible spinal anesthesia via the optic nerve sheath. [48] Retrobulbar block is uncomfortable for the patient. A small dose of a short-acting sedative, such as propofol, just prior to the injection prevents pain and patient movement.

Technique

The retrobulbar block is performed with the patient supine and looking straight ahead. A 23-gauge, 3-cm blunted needle is inserted at the inferolateral border of the bony orbit and is directed toward the apex of the orbit. A pop is often felt as the needle tip enters the orbital muscle cone, and 2 to 4 mL of solution is injected. Blockade of the facial nerve fibers that innervate the orbicularis oculi muscle is also performed to complete the anesthesia.

Stellate Ganglion Block

Clinical Applications

Blockade of the stellate ganglion is used primarily in the treatment of upper extremity sympathetic dystrophy and for increase of blood flow to this area (Ch. 70) .

Side Effects/Complications

Because of the close proximity of several major neural and vascular structures to the site of needle insertion, side effects and complications can occur. These include block of the brachial plexus and recurrent laryngeal nerves, hematoma formation, intravascular injection resulting in convulsions, and epidural and subarachnoid injections. [49]

Technique

The patient lies supine with the neck slightly extended. The most prominent cervical transverse process--the Chassaignac tubercle, C6--is palpated between the sternocleidomastoid muscle and the trachea. The anesthesiologist then palpates the C6 tubercle between the index and middle fingers, pushing the carotid artery laterally. A skin wheal is raised between the fingers, over the tubercle, and a 22-gauge, 4-cm short-bevel needle with a 12-mL syringe attached is inserted in a perpendicular direction until the tip contacts the C6 transverse process (Fig. 43-25) . The needle is then withdrawn 3 mm and is fixed. After careful aspiration, 8 to 12 mL of local anesthetic solution is injected. Signs of a successful stellate ganglion block include Horner syndrome, anhidrosis, injection of the conjunctiva, nasal stuffiness, vasodilation, and increased skin temperature.

BLOCKS OF THE THORAX AND ABDOMEN

Intercostal Nerve Block/Interpleural Catheter

Clinical Applications

Few surgical procedures can be performed with intercostal block alone, and the application of these blocks in

Figure 43-25 (A) Anatomic landmarks and method of needle placement for stellate ganglion block. (B) Stellate ganglion block: cross-sectional view.

Figure 43-26 (A) Intercostal nerve block: patient positioning. (B) The index finger displaces the skin up over the rib. The needle is inserted at the tip of the finger and rests on the rib. The needle is walked off the lower rib edge and inserted 3 to 5 mm. (C) An intercostal nerve and its branches.

combination with other techniques has largely been supplanted by epidural blockade. However, there are still special instances, for example, in the presence of anticoagulation or other contraindications to central neuraxial blockade, when these techniques can be used alone or combined with celiac plexus blocks and light general anesthesia to provide excellent surgical conditions for intra-abdominal procedures. In a similar fashion, intrathoracic surgery can be accomplished using intercostal and stellate ganglion blocks with endotracheal sedation.

Interpleural catheter placement for management of postoperative pain was first described by Reiestad and Stromskag in 1986. [50] Enthusiasm for this technique has waxed and waned. The mechanism of action is poorly understood, and reports of efficacy vary. Overall, the results with cholecystectomy have been most favorable. [51] [52] The advantages of interpleural analgesia are more difficult to prove in patients undergoing thoracotomy, perhaps because of technical problems relating to blood in the pleural space, chest tube drainage, and pleural disease. [53] [54] [55]

Side Effects/Complications

The major complication feared with intercostal blockade is pneumothorax. The actual incidence, however, was as low as 0.07 percent in a large series performed by anesthesiologists at all levels of training. Routine postoperative chest radiographs showed an incidence of nonsymptomatic pneumothorax of 0.42 percent. [56] Should this unusual complication occur, treatment is usually limited to observation, administration of oxygen, or needle aspiration. Rarely, chest tube drainage is required when these treatments are unsuccessful.

The risk of systemic local anesthetic toxicity is present with multiple intercostal blocks because of the large volumes and rapid absorption of the solutions. Use of epinephrine has been shown to decrease blood levels. Patients should be monitored and observed carefully during the block and for at least 20 to 30 minutes afterward. Interpleural block should not be performed in patients with pleural fibrosis or inflammation, pleural effusion, lung parenchymal disease associated with pleural disease, or bleeding diathesis. Pleural disease can result in poor spread of local anesthetic solutions or rapid uptake in the case of inflammation. Patients with severe pulmonary disease who rely on their intercostal muscles may evidence respiratory decompensation after bilateral intercostal blockade. [57]

Anatomy and Technique

The intercostal nerves are the primary rami of T1 through T11. T12 is technically a subcostal nerve and supplies branches to the ilioinguinal and iliohypogastric nerves. Fibers from T1 contribute to the brachial plexus; T2 and T3 provide a few fibers to the formation of the intercostobrachial nerve, which supplies the skin to the medial aspect of the upper arm. Each intercostal nerve has four branches: the gray ramus communicans, which passes anteriorly to the sympathetic ganglion; the posterior cutaneous branch, supplying skin and muscle in the paravertebral area; the lateral cutaneous branch, arising just anterior to the midaxillary line and sending subcutaneous branches both anteriorly and posteriorly; and the anterior cutaneous branch, which is the termination of the nerve (Fig. 43-26 C).

Medial to the posterior angles of the ribs, the intercostal nerves lie between the pleura and the internal intercostal

fascia. At the posterior angle of the rib, the nerve lies in the costal groove accompanied by the intercostal vein and artery.

The intercostal nerve can be readily blocked at the angle of the rib just lateral to the sacrospinalis muscle group. The patient is placed in the prone position with a pillow placed under the abdomen to reduce the lumbar curve (Fig. 43-26 A). A line is drawn along the posterior vertebral spines. Nearly parallel lines are drawn along the posterior angles of the rib, which can be palpated 6 to 8 cm from the midline. These lines angle medially at the upper levels in order to prevent overlying of the scapula. The inferior edge of each rib is palpated and is marked on the line intersecting the posterior angle of the rib. After appropriate skin preparation, skin wheals are injected at each of these points. A 22-gauge, short-bevel 4-cm needle is attached to a 10-mL syringe. Beginning at the lowest rib, the index finger of the left hand displaces the skin up over the patient's rib. The needle is inserted at the tip of the finger until it rests on the rib. The fingers of the left hand are shifted to grasp the needle hub firmly. The left hand then walks the needle 3 to 5 mm off the lower rib edge, where 3 to 5 mL of local anesthetic is injected (Fig. 43-26 B). This process is repeated at each rib. Appropriate intravenous sedation providing analgesia and some degree of amnesia is desirable for patient comfort.

Alternatively, intercostal block can be performed in the supine patient at the midaxillary line. Although, theoretically, the lateral cutaneous branch of the nerve can be missed, in reality, computed tomography studies show that injected solutions spread several centimeters along the costal groove. [58] Further injection of 1 to 2 mL of solution as the needle is withdrawn blocks the subcutaneous branches.

The technique for interpleural catheter placement is quite simple and can be performed with the patient in a lateral (and slightly oblique) or sitting position. The sixth or seventh intercostal space is identified. Needle insertion is performed about 10 cm lateral from the posterior midline, and an epidural needle tip is advanced until it

rests on the cephalad edge of the rib below the intercostal space to be entered. A glass syringe filled with saline or air is then attached to the needle, and the unit is advanced slowly over the superior edge of the rib. When the tip of the needle enters the parietal pleura, the solution in the syringe is drawn into the chest cavity because of the negative intrathoracic pressure. This effect can be observed in both mechanically and spontaneously ventilating patients, but it is accentuated in the latter group.

The catheter is then inserted approximately 5 to 8 cm into the interpleural space and is secured on the chest wall. During needle positioning and catheter placement, care must be taken to minimize entrainment of air through the needle. Lung parenchymal damage can occur with loss of resistance techniques or insertion of excessive lengths of catheter.

Celiac Plexus Block

Clinical Applications

The celiac plexus block can be combined with intercostal block to provide anesthesia for intra-abdominal surgery (Ch. 70) . Because it results in blockade of the autonomic nervous system, this block may help to reduce stress and endocrine responses to surgery.

Side Effects/Complications

Side effects associated with celiac plexus block include the following: hypotension; spinal, epidural, or intravascular injection; pneumothorax; puncture of viscera (kidney, ureter, gut); and retroperitoneal hematoma.

Anatomy and Technique

The celiac plexus contains visceral afferent and efferent fibers derived from T5 to T12 via the greater, lesser, and least splanchnic nerves. The plexus has no somatic fibers and is composed of a number of ganglia and nerve fibers. It innervates most of the abdominal viscera. A knowledge of the surrounding structures is important for correct needle placement. The plexus lies in close relation to the L1 vertebrae. The vena cava lies anteriorly to the right, and on the left anteriorly is the aorta. The kidneys lie laterally, with the pancreas anterior. The number of ganglia varies from one to five, and the size is 0.5 to 4.5 cm in diameter. Left-sided ganglia are usually lower than those on the right.

Bony surface landmarks can be reliably utilized for needle placement. With the patient in the prone position with a pillow beneath the abdomen, lines are drawn connecting the spine of T12 with points 7 to 8 cm lateral at the lower edges of the 12th ribs. These lines form a flattened isosceles triangle, the equal sides of which serve as directional guides for the needles (Fig. 43-27 B). A 20-gauge, 10- to 15-cm needle is inserted on the left side through a skin wheal at a 45-degree angle toward the body of T12 or L1. Bony contact should be made at an average depth of 7 to 9 cm. The needle is then withdrawn and is reinserted to allow the tip to slide off the vertebral body anterolaterally. The needle is advanced 1.5 to 2 cm past this point; aortic pulsations can be felt as they are transmitted along the needle when it is correctly placed (see Fig. 43-27). Once this depth is ascertained, the right-sided needle is inserted in a similar fashion to a depth of 1.0 to 1.5 cm farther (Fig. 43-27 A)

When the needles are in position, observation for leakage of blood, urine, or cerebrospinal fluid is made prior to careful aspiration. A 3- to 5-mL test dose of local anesthetic is given prior to injection of 20 to 25 mL of solution through each needle.

Paravertebral Block

Clinical Applications

This block can be added to multiple intercostal and/or bilateral celiac plexus blocks to provide anesthesia for abdominal, pelvic, and upper leg surgery. Application for paravertebral block alone is limited, although it is useful in the diagnosis and treatment of certain pain disorders.

Figure 43-27 (A) Celiac plexus block: the needle is inserted at a 45-degree angle toward the body of L1. The tip slides off the vertebral body anterolaterally and is advanced 1.5 to 2 cm. A, aorta; IVC, inferior vena cava. (B) Celiac plexus block: patient position and surface landmarks.

Side Effects/Complications

Because of the close proximity of the centroneuraxis, epidural or subarachnoid injection of local anesthetic is a risk. Intravascular injection via the lumbar vessels, vena cava, or aorta is possible.

Technique

Lumbar nerves exit the vertebral foramina inferior to the caudad edge of the transverse process. Each nerve divides into anterior and posterior branches; the anterior branches of L1 through L4 (with a contribution from T12) form the lumbar plexus.

The patient is placed in the prone position as described for intercostal blockade. Lines are drawn across the cephalad edges of the lumbar vertebral spinous processes. These lines lie opposite the caudad edges of the homologous transverse processes (Fig. 43-28 A). A skin wheal is raised 3 cm lateral to the midline, and a 20-gauge, 8-cm needle is advanced perpendicularly until it contacts the transverse process at a depth of 3 to 5 cm. The needle is then redirected to walk off the caudad edge of the transverse process. At 1 to 2 cm (the thickness of the transverse process) beyond this point, 6 to 10 mL of local anesthetic is injected (Fig. 43-28 B and Plate 10A and B). Elicitation of a paresthesia or use of a nerve stimulator is helpful in confirming correct needle placement.

CHOICE OF LOCAL ANESTHETIC

The choice of local anesthetic for a peripheral nerve block obviously depends to some degree on the duration of the surgical procedure; however, other factors are also important (Ch. 13) . Prolonged blockade for up to 24 hours is often seen with the long-acting agents such as bupivacaine. Although this feature results in superb postoperative pain relief for the inpatient, it may be undesirable for the ambulatory patient because of the possible risk of nerve or tissue injury in a partially blocked limb. A short- or medium-acting agent may be more appropriate in the outpatient setting. Whatever drug is chosen, the total dosage should be calculated for each patient and should be kept within acceptable safe limits (Table 43-1) (Ch. 13) .

The highest concentrations of local anesthetic drugs are not appropriate for peripheral neural blockade. Therefore, 0.75 percent bupivacaine, 2 percent lidocaine, 2 percent mepivacaine, and 3 percent 2-chloroprocaine are not recommended.

TABLE 43-1 -- Local Anesthetics for Peripheral Nerve Block[a]

DRUG	MAXIMUM DOSE (MG) (WITH EPINEPHRINE)	CONCENTRATION (%)	DURATION (H)
2-Chloroprocaine	1,000	1-2	0.5-1
Lidocaine	500	0.5-1.5	1-3
Mepivacaine	500	0.5-1.5	2-3
Bupivacaine	250	0.25-0.5	4-24
Etidocaine	400	0.5-0.75	3-12

[a] See Ch. 13 for more details.

Figure 43-28 (A) Paravertebral nerve block: patient position and surface landmarks. (B) Paravertebral nerve block: the needle is advanced perpendicularly until it contacts the transverse process. It is redirected to walk off the caudad edge of the transverse process and advanced 1 to 2 cm.

The lowest concentrations of the same agents (e.g., 0.25 percent bupivacaine and 0.5 percent mepivacaine or lidocaine) may not provide complete motor blockade.

Vasoconstrictors, usually epinephrine, can be added to the chosen local anesthetic to improve onset of action, to decrease drug uptake, and to prolong action. A concentration of 1:200,000 epinephrine is usually recommended. Ideally, the epinephrine should be added to the local anesthetic at the time the block is to be performed. Commercially prepared solutions with epinephrine have a lower pH than those in which it is freshly added, resulting in a higher percentage of ionized drug molecules. These ionized molecules do not readily cross the neural membrane, thus delaying the onset of drug action after injection. Epinephrine should not be added to the local anesthetic for blocks of the digits or penis because tissue ischemia may result. Various other additives including clonidine, opioids, and ketamine have been reported to enhance or to prolong local anesthetic peripheral nerve blockade.

SUMMARY

It is possible to perform all surgical procedures while the patient is under general anesthesia; however, the addition of peripheral nerve block techniques to the anesthesiologist's armamentarium adds flexibility and skills that benefit the patient intraoperatively as well as postoperatively. Successfully mastering these techniques and applying them to the appropriate clinical situations add valuable options to the anesthetic care. Finally, for the anesthesiologist, knowledge of regional anesthesia is essential for the diagnosis and treatment of acute and chronic pain syndromes (Chs. 69 and 70) .

Chapter 44 - Regional Anesthesia in Children *

Bernard J. Dalens

INTRODUCTION

Regional anesthetic techniques have regained an established place in pediatric anesthesia, and their field of application is rapidly expanding. The pharmacologic properties of available local anesthetics are fully evaluated, even in neonates, and the fear of nerve lesions and neurologic sequelae has proved unfounded as confirmed by a recent prospective study involving 24,409 children given a regional block. [1] Most of the technical difficulties have been overcome with the general use of physical means of nerve/space location independent of the (young) patient's cooperation such as loss-of-resistance techniques or use of nerve stimulators aimed at eliciting muscle twitches in relevant muscles. Devices specifically designed for use in pediatric patients are now commonly available, and safer approaches have been extensively studied. Most outpatient surgery can be managed successfully with regional anesthetic techniques, either as the sole anesthetic or, as usual in pediatric practice (in approximately 90% of cases), in combination with light general anesthesia. [1] Central blocks are partic-ularly well tolerated by infants and young children, which make them mandatory in many operations of the lower limbs and infraumbilical part of the abdomen. Additionally, the use of regional anesthesia reduces the cost of patient care.

SPECIFICITY OF THE PEDIATRIC PERIOD

Embryologic Development of the Vertebral Column and Spinal Cord

Many organs and their functions are not fully developed at birth. During the embryonic period, the spinal cord occupies the entire spinal canal, but from the fetal period onward, the growth of the spinal canal exceeds that of neural structures. Thus the termination of the spinal cord and that of the dural sac project at progressively higher levels, L4 and S3/S4 respectively, up to the end of the 1st year of life. During the 2nd year, it approaches adult levels (i.e., L1 and S2, respectively). As a consequence, lumbar epidural approach above L4 should be avoided in infants as the spinal cord can be directly damaged by the needle.

Myelinization begins during the fetal period in cervical neuromeres and extends progressively but is not fully completed until the end of the 12th year of life. [2] [3] This lack of myelin in young patients favors the penetration of local anesthetics within the nerve fibers, which are thinner, with reduced distance between successive nodes of Ranvier. Thus, diluted local anesthetics can produce consistent nerve blockade. Ossification of the vertebral column is not

** See Appendix 1, Practice Guidelines for Chronic Pain Management*

achieved at birth. The vertebral arches fuse posteriorly during the 1st year of life, and their junction with the vertebral body becomes ossified from the 3rd to the 6th year. [4] The sacrum is made up of distinct vertebral pieces, the fusion and ossification of which are not fully achieved before the 25th year of life. Posterior approach to the epidural space is possible, at sacral levels in the same way as at lumbar levels. On the other hand, because the sacrum is cartilaginous, it can be traversed easily by sharp needles.

At birth, the spine has a single regular flexure. Whatever the intervertebral space, any epidural needle is inserted with the same orientation. With the development of the cervical flexure (head sustained) and then the lumbar lordosis (sitting position), the orientation of the epidural needle has to be modified accordingly. Another important feature is the loose attachment of fasciae and sheaths to nerve trunks in young patients, allowing extended spread of local anesthetics, thus resulting in high-quality nerve blockade whatever the technique, but also, occasionally, in unwanted or undesirable distant nerve blocks.

Perception of Pain

Somatic pain is a subjective sensory experience resulting from the intermixing of three main components: [5] [6] (1) motivational-directive, conveyed by unmyelinated C fibers ("slow" pain or "true" pain), which leads to protective reflexes such as autonomic reactions, muscle contraction, and rigidity; (2) sensory-discriminatory, propagated by myelinated A delta fibers (fast pain), which allows accurate identification and location of the nociceptive stimuli and elicits withdrawal reactions; and (3) cognitive-evaluative, a multifactorial but typically cerebral process not involving any peripheral receptors. C fibers are functional from early fetal life onward; thus, the motivational-directive component ("true" pain) is perceived by the neonate and the fetus. As A delta fibers are thinly myelinated, the velocity of nerve impulses depends on the progression of myelinization. The main difference in pain perception between children and adults is related to the cognitive-evaluative component that develops throughout childhood and adolescence. This is influenced by environmental, educational, social, cultural, and individual factors, including previous experiences of pain. A major difficulty is the assessment, and at times even the identification, of pain in children, especially in infants. The younger the patient, the greater the difficulty to communicate because the ability to express distress and discomfort is limited. During the last decade, pediatric pain has received considerable attention, and reliable age-related pain scales have been developed to evaluate both the severity of pain and the efficacy of its treatment.

Pharmacology of Local Anesthetics, Narcotics, and Other Additives

Local Anesthetics

The pharmacology of local anesthetics in children is similar to that in adults (Chs. 13 and 59) . However, certain differences have to be taken into account before a regional block is performed, especially in neonates and infants. The effects of local anesthetics depend on (1) their spread from the site of injection, which is often considerable in infants, both in the epidural space and along the nerve sheaths; (2) their fixation at the local binding sites such as surface proteins and lipids, especially myelin [3] [7] and (3) the permeability of nerve fibers. In young patients, the endoneurium is loose and easily traversed in both directions. As the child grows up, the endoneurium becomes enriched in connective fibers and is less permeable. Both the latency and the duration of nerve blockade increase with age.

In their nonionized form, local anesthetics can cross almost freely the endothelium of the capillaries surrounding the site of injection. As the cardiac output and the local blood flow of infants are two to three times greater than in adults, the systemic absorption of local anesthetics is increased accordingly, and vasoactive agents such as epinephrine are effective in slowing down this systemic uptake. Within the blood stream, the local anesthetic binds to (1) albumin (and can compete with molecules previously bound to albumin, including bilirubin and various drugs), and (2) alpha $_1$ -acid glycoprotein (or orosomucoid), the plasma concentration of which is low in infants less than 9 months old. Because of this low concentration of plasma proteins, there is a significant increase in the unbound free form of all aminoamides with subsequent danger of systemic toxicity. [8] [9] [10]

Toxic levels of local anesthetics are not clearly established. The administration of common doses of local anesthetics (i.e., 6-8 mg/kg of lidocaine or mepivacaine and 1.5-2 mg/kg of bupivacaine) leads to peak plasma concentration ranging from 3 to 5 mug/mL for lidocaine or mepivacaine, and 0.5 to 1 mug/kg for bupivacaine. [9] Clinical signs of toxicity have been reported with plasma concentration ranging from 7 to 10 mug/mL for lidocaine or mepivacaine and from 1.5 to 2 mug/mL (intraoperatively) to 2 to 2.5 mug/mL (postoperatively) with bupivacaine. However, plasma concentrations of bupivacaine exceeding 4 mug/mL have been commonly detected without any clinical sign of toxicity. The toxic form of all local anesthetics is the free unbound form, which is difficult to measure and correlates poorly with measured concentrations. For bupivacaine, the toxic level of the free unbound form is believed to be around 0.2 mug/mL. [11] Thus, agents with a high protein affinity such as bupivacaine must be used cautiously in the very young, and etidocaine should be avoided in children less than 1 year old, even though there is an increase in the plasma concentration of alpha$_1$ -acid glycoprotein postoperatively. [12] [13] [14] [15] Greater attention will probably be paid, in the very near future, to enantiomers, especially for bupivacaine and mepivacaine, as considerable differences exist in their plasma-protein binding properties, cardiac toxicity, half-life, and pharmacodynamic effects. [16]

In the blood stream, the local anesthetic is also distributed in the red blood cells. In neonates, as erythrocytes are greater in number (polycythemia) and larger in size (macrocythemia), the amount of drug entrapped in red blood cells is relatively higher, and this significantly contributes to the neonatal increase in their half-life.

After systemic absorption and protein binding, the local anesthetic is redistributed to different body fluid compartments and tissues. The degree of tissue hydration

decreases with age. Water accounts for 80 percent of body weight in premature, 75 percent in full-term neonates, 65 percent in

Figure 44-1 Changes in body fluid compartments according to patient's age.

infants, and 60 percent in older children and adults (Fig. 44-1) At the same time, the relative importance of body fluid compartments changes considerably. Intracellular fluids increase from 20 percent of body weight in premature infants to 30 percent in adolescents, whereas extracellular fluids are reduced by 50 percent from birth to adulthood (see Fig. 44-1) The pharmacokinetics of local anesthetics is considerably affected by these major changes (Table 44-1) . The distribution volume of all agents is markedly increased in the very young. Therefore, the peak plasma concentration following injection of a single given dose is less in infants than in adults, thus reducing toxicity, and counteracts the increased systemic absorption due to greater local blood flow. At the same time, during the first 2 years of life, the clearance of all aminoamides is low, [9] [13] and their half-life is considerably increased. This can result in drug accumulation in case of repeated injections. [17] [18] [19] By the 2nd year of life, clearance of these agents increases progressively, becoming higher than that in adults. For this reason young children tolerate doses of local anesthetics that would be toxic in adults (however, this peculiarity should not encourage the administration of excessive doses of local anesthetics).

After systemic distribution, the local anesthetic is progressively eliminated by plasma or hepatic metabolism, and a small amount is excreted in the unchanged form in the urine and in gastric secretions, especially in neonates. Aminoesters are mainly hydrolyzed by plasma cholinesterases, the activity of which gradually increases throughout the first year of life. [20] Aminoamides are principally metabolized in the liver by microsomal enzymes (P_{450} cytochrome), the activity of which is reduced during the first months after birth, [21] but does not really impede the metabolism of clinically used local anesthetics after the first 2 or 3 weeks of life. The danger of systemic toxicity cannot be correlated to the patient's age. However, the rate of hydroxylation of lidocaine and moreover that of mepivacaine is significantly lowered in infants (see Table 44-1) in pathologic circumstances (respiratory distress, cardiac failure). Prilocaine must be avoided in infants as its biotransformation yields 6-hydroxytoluidine, which can cause severe methemoglobinemia following administration of even subtherapeutic doses. Repeated injections of high concentrations of local anesthetics may also result in local myotoxicity. [22]

Narcotics

The pharmacology of narcotics (Chs. 10 and 59) has no special features in infants and children and has been recently reviewed. [23] [24] After intrathecal administration, morphine reaches high concentration levels in the cerebrospinal fluid (CSF), whereas the plasma concentration remains very

TABLE 44-1 -- Influence of Age on Pharmacokinetic Parameters of Aminoamides

AGENTS	V_{DSS} (L/kg)	PROTEIN BINDING (%)	CLEARANCE L/kg/(h)	ELIMINATION HALF-LIFE (h)	ELIMINATION IN UNCHANGED FORM (%)
Lidocaine					
Neonate	1.4-4.9	25	0.30-1.14	2.9-3.3	0.16
Adult	0.2-1.0	55-65	0.30-1.09	1.0-2.2	0.-0.2
Mepivacaine					
Neonate	1.2-2.8	36	0.10-0.18	5.3-11.3	0.36
Adult	0.6-1.5	75-80	0.17-1.10	1.7-6.9	0.04
Bupivacaine					
Neonate	--	50-70	--	6.0-22.0	--
Adult	0.8-1.6	85-95	0.30-0.50	1.2-2.9	0.03
Etidocaine					
Neonate	--	--	--	6.0-22.0	--
Adult	1.5-1.8	90-95	0.75-1.15	2.0-5.6	0.03

low, making it difficult to estimate the half-life. After lumbar epidural injection, systemic uptake of morphine is comparable to that after intramuscular injection. [25] [26] Peak plasma concentration is reached within 10 minutes but does not account for the pharmacodynamic effects, which depend on the drug crossing the dura mater. From the 15th to 20th hour after epidural injection, the CSF concentration of morphine is 50 to 250 times higher than that of plasma. The elimination half-life from CSF is similar to that from plasma, following the same monoexponential elimination curve, but as original concentrations are very high, it takes 12 to 24 hours before the spinal concentration falls below the minimal effective concentration of approximately 10 ng/mL. As morphine is hydrosoluble, its distribution volume, when administered epidurally, equals that of the CSF volume. Addition of epinephrine to the narcotic solution decreases systemic uptake and increases CSF concentration of morphine, [27] which results in a slight but significant increase in duration of pharmacodynamic effects.

Morphine injection along the neuraxis is indicated for long-lasting pain relief. It improves the outcome of many major operations on both healthy and high-risk pediatric patients. [28] However, adverse effects occur in about 50 percent of patients. These include pruritus, nausea, vomiting, urinary retention, and respiratory depression, [29] which can be delayed several hours after the injection, thus making postoperative monitoring of respiratory parameters mandatory for the first 24 hours. The use of apnea monitors and/or pulse oximeters can be helpful but can never replace hourly clinical evaluation. Respiratory depression is almost always preceded by generalized pruritus and sedation, which must be carefully identified, before the respiratory rate progressively decreases over a period of 2 to 3 hours (a sudden apneic spell does not occur with either epidural or intrathecal administration of morphine). Thus, the practitioner has several hours to cure the problem before it becomes dangerous. Currently recommended doses via the lumbar route are 30 mug/kg for epidural morphine and only 10 mug/kg for intrathecal morphine. Higher dosages were commonly administered formerly with a concomitant increase in the adverse effects that could be prevented, without restoring pain, by the administration postoperatively of a continuous intravenous infusion of small doses (2 mug/kg/h) of naloxone. [30] [31] [32] The administration of nalbuphine instead of naloxone has been recommended to counteract adverse effects of epidural morphine. [33] Patients given epidural morphine are not eligible for day surgery. [34] [35]

Short-acting narcotics such as fentanyl (1 to 2 mug/kg) and sufentanil (0.5 mug/kg) can be administered epidurally instead of morphine. They improve intraoperative analgesia, especially when diluted solutions of local anesthetics are used, but have little effect on the prolongation of postoperative pain relief unless a continuous infusion or reinjections are made. Part of their action is due to systemic effects following vascular absorption, which can result in early respiratory depression (but delayed respiratory depression is unlikely). Owing to contradictory clinical effects and debatable pharmacologic basis, their administration for peripheral nerve blocks is not recommended in children. Buprenorphine has been used as an additive to local anesthetics, even in children [36] and can provide long-lasting postoperative analgesia (up to 24 hours). However, as buprenorphine adheres strongly to mu receptors, making reversal with naloxone inconstant and leading to the possibility of respiratory depression on the ward, its use as an adjuvant to centrally administered local anesthetics should be restricted to patients managed in intensive care units.

Other Additives

Epinephrine is the most commonly added alpha-agonist to a local anesthetic. Using solutions with epinephrine (1:200,000, or 1:400,000 before 1 year of age) has several advantages, as it reduces the vascular absorption of the local anesthetics, thus increasing their safety margin. Addition of epinephrine prolongs the duration of effects of short-acting agents (especially lidocaine and mepivacaine) and allows detection of an inadvertent intravascular injection by producing early (within 20 seconds) ST-segment elevation, T-wave change, [37] and hypertension [38] [39] provided the injected dose of epinephrine is at least 0.5 mug/kg. [40]

Clonidine, an $alpha_2$ -adrenergic agonist that can be safely administered along the neuraxis, [41] is being used increasingly as an adjuvant to local anesthetics

administered either centrally [42] [43] [44] [45] [46] or peripherally. [47] [48] At a dose of 1 to 3 mug/kg, clonidine significantly increases (by a factor of 2 approximately) the effects of the local anesthetic with no hemodynamic effects and decreases the peak plasma concentration of the local anesthetic (at least lidocaine). [49] Light to moderate sedation is commonly observed postoperatively for 1 to 3 hours, but it is more beneficial than detrimental, especially in the very young; and, unless the highest doses (i.e.,
2 mug/kg) are given, this sedation does not preclude discharge in cases planned for day surgery. Adding clonidine to the solution makes the insertion of a reinjection catheter unnecessary in many cases (thus reducing the overall morbidity of the procedure, the time required to perform the block, and the overall cost of the procedure). No respiratory depression has been reported, and its occurrence is very unlikely as suggested by adult studies. [50]

Ketamine is currently undergoing a renewed interest as an additive to local anesthetics because of its effects on *N*-methyl- D-aspartate receptors. The administration of a local solution containing 0.5 to 1 mg/kg provides a long-lasting analgesic effect. [51] [52] Behavioral side effects may be observed following the higher dosage but are virtually absent with the low dosage (i.e., 0.5 mg/kg). [53]

In two studies evaluating injectable biodegradable bupivacaine/polyester microspheres, [54] [55] dexamethasone has proved effective in prolonging sciatic nerve blocks in rats, up to 5.5 days after the injection; other data show that methylprednisolone shortens the effects of bupivacaine on C fibers (not A fibers) in rats. [56] The mechanism underlying dexamethasone-prolonged block effect is not understood; a recent study suggested this action could be mediated by suppression of ectopic neural discharges from injured nerve fibers. [57] Although corticosteroids are commonly injected along the neuraxis or spinal roots in rheumatologic diseases, corticosteroids should not be used as additives to local anesthetics for analgesic purpose in children, as severe complications may result from such injections. [58]

Neostigmine also seems to have analgesic properties when administered along the neuraxis, with a protective

effect against hypotension during spinal anesthesia. [59] However, these experimental data have not been established in humans, and the safety of spinal administration of neostigmine is not established.

Warning.

Most of these additives (with the exception of epinephrine, morphine, and, recently in the United States, clonidine) have no legal approval for use as adjuvants of local anesthetics. This does not necessarily mean that their use is forbidden, [60] but precautions should be taken and, in case of a medicolegal claim, the anesthesiologist will have the burden of proving that adding any particular additive was a sound decision. Any other additive (deliberately not mentioned in this chapter) would probably be considered irrelevant or even detrimental according to the current state of the art, particularly so as the stability of mixtures of local anesthetics with additives has not been properly evaluated, with little data being available. [61]

Physiologic and Psychologic Considerations

Surgery generates a neuroendocrine stress response in neonates, infants and children [62] [63] resulting in undesirable alterations of the metabolic state and immune function. [64] Epidural anesthesia diminishes or even suppresses this stress response [65] [66] and is well tolerated in children. Central blocks do not affect left ventricular function [67] and are virtually free of measurable hemodynamic effects, at least up to the age of 8 years. In older patients, the sympathetic block results in a slight but constant decrease in blood pressure, rarely exceeding 20 to 25 percent of systolic preinduction values. [68] [69] [70] [71] Preloading with saline is not recommended in children and, even in adolescents, fluids or vasoactive agents are rarely required to treat the hemodynamic effects of central blocks.

Children are frightened by new environmental conditions in the operating room, and most of them cannot cope with their anxiety (Ch. 59) . They feel abandoned by their parents and threatened by the strangers who intend to use needles, which they fear. Furthermore, even if they wanted to cooperate, they do not have their complete body image until the age of 10 years, which does not let them clearly distinguish between adjacent parts of their body such as forearm and arm. Additionally, they usually cannot understand the concept of paresthesia and that of differential block ("touch" is not "pain"). Thus, localization of nerve trunks and anatomic spaces has to be achieved by physical means such as electric stimulation or loss-of-resistance techniques that do not depend on the patient's cooperation; and sedation or, preferably, light general anesthesia before any block is desirable, as most of these patients are healthy and express the desire to be unconscious during the surgery.

Regional anesthesia has important psychologic effects on the patient, parents, and medical team. A pain-free postoperative course improves the morale of the patient, parents, and nurses. Also, the surgeon is happy to examine a calm, alert, and manageable patient in the postoperative period. Occasionally, regional anesthesia can result in negative psychologic effects. Persistence of motor (and even sensory) block during the postoperative course may be frightening to some children, especially those from 3 to 5 years of age, and sometimes to their parents. This anxiety can be reduced by friendly environmental conditions and precise preoperative explanations as to the expected course of events during the postoperative period. In any case, a motor block must be avoided when not absolutely required for surgery.

SAFETY CONDITIONS FOR PERFORMING REGIONAL BLOCKS IN CHILDREN

Indications and Contraindications

Indications [5] [6] [72] [73]

Regional anesthesia, especially peripheral nerve blocks, are indicated in patients with a full stomach and who require emergency surgery or pain relief. Pain-free clinical and radiologic examinations, wound dressings, and reduction of limb fractures can be safely achieved without compromising vital functions or affecting the evaluation of the status of the central nervous system. In elective surgery, regional techniques are recommended for intraoperative and postoperative pain relief for a number of procedures on the abdomen, pelvis, and extremities, and are applicable even to preterm neonates [74] provided adequate postoperative management is guaranteed. They are particularly suitable for outpatient surgery [75] either as the sole anesthetic or combined with light general anesthesia, which allows rapid and complete awakening at the end of surgery (Table 44-2) . Also, in some clinical conditions such as diabetes mellitus, cardiac failure, and respiratory abnormalities, general anesthesia is better avoided, and regional techniques may be the only alternative allowing a safe and efficient management of the patient. Other indications include relief of nonsurgical pain, physiotherapy of tallipus equinus deformity in children recovering from severe brain damage, and some nonanalgesic applications such as vasodilation in ischemic disorders or maintenance of motor block throughout the recovery period in patients with an unstable fracture, nerve, or tendon repair. The concept of preemptive analgesia, although controversial, [76] has brought new insights on the indications of all antinociceptive treatments, including regional block procedures. Performing a block before rather than at the end of the surgery seems to provide better and more long-lasting postoperative analgesia.

Contraindications

Absolute contraindications to regional anesthesia are similar to those in adults. These include [34] (1) infection at the puncture site, septicemia, and meningitis; (2) bleeding disorders or a patient on anticoagulant therapy; (3) true allergy to local anesthetics, which is rare even with aminoesters; [77] and (4) uncorrected hypovolemia (central blocks). Major vertebral anomalies are contraindications to central block procedures, at least at the level of the anomalies. Minor to moderate lumbosacral spinal anomalies, including tethered cord syndrome for some authors, a functioning ventriculoperitoneal shunt, or patients with mild seizure disorders are not contraindications per se for performing a central

TABLE 44-2 -- Recommended Indications of Regional Techniques for Outpatient Surgery

TYPE OF SURGERY	REGIONAL ANESTHESIA RECOMMENDED	REGIONAL ANESTHESIA NOT RECOMMENDED
Orthopedics	Usual fractures of the limbs, change of plaster, removal of wires and most implants, joint testing/mobilization, arthroscopy, arthrography, tenotomy, aponeurotomy, distal surgery (fingers, toes)	Other procedures
Plastic surgery	Correction of prominent ears, removal of superficial lesions and sutures, revision of scars, dressing changes, ingrowing toe nails	Cleft palate surgery, endonasal surgery
Odontology and stomatology [a]	Dental: conservation, extraction, orthodontics, drainage of sinuses	Multiple extractions, surgery of the mandible or maxilla
General surgery	Inguinal and crural hernia repairs, anal dilation, rectoscopy, epigastric or umbilical hernia repair [b]	Gastric or colonic fiberoscopies
Urology	Excision of hydrocele, cystoscopy, orchidopexy, circumcision, change of urethral catheter, urethral dilatation, submucosal teflon injection, glans plasty, meatotomy	Surgery of the kidney and upper urinary tract, hypospadias repair.
ENT	Myringotomy/grommets, nasal/aural foreign body removal, short-lasting endoscopic examination, antral lavage, nasal cautery	Adenoidectomy, tonsillectomy [c] , antrotomy, surgery of deep structures.
Ophthalmology	Simple skin lesions of eyelids, probing of tear ducts	Strabismus surgery, intraocular surgery, measurement of intraocular pressure.
Miscellaneous	Bone marrow sampling, skin/node biopsy, lumbar puncture, intrathecal injection, radiotherapy, venesection, arteriovenous fistula, blood tests, metabolic/endocrine tests	Computed tomography, magnetic resonance imaging, radiotherapy, interventional cardiology, electromyograms

[a] Regional techniques for odontology and stomatology are usually not performed by anesthesiologists.
[b] Epigastric and umbilical hernia repair is best managed as outpatient surgery with rectus sheath block (not caudal or lumbar epidural anesthesia).
[c] These procedures are not carried out as outpatient surgery in some countries.

block. [78] Degenerative axonal diseases have long been considered as contraindications, but no data support the hypothesis that regional anesthesia could worsen their course (equally, no data support the hypothesis that regional anesthesia could not worsen their course). Regional techniques must be avoided when there is a danger of compressive disorders in closed fascial compartments. In the presence of a plaster cast, the hemodynamic condition of the limb must be closely monitored. If local conditions do not permit reliable monitoring by trained nurses, regional anesthesia must not be provided. Parental refusal and severe psychoneurotic disorders should be considered as contraindications. Specific contraindications are mentioned with the description of the relevant technique.

Selection of Materials, Techniques, and Agents

General Considerations

Usual indications for regional anesthesia in children are pain relief and patient comfort. Therefore, regional techniques should be considered as methods of analgesia and not anesthesia. Their advantages and disadvantages must be compared with other techniques of analgesia (e.g., intraoperative and postoperative parenteral narcotics). Also, in chil-dren, general anesthesia and regional anesthesia are usually complementary. In selecting a regional technique, the anesthesiologist must carefully check the potential complications of this technique and restrict the choice to a technique virtually free of complications, even if less effective, and the

reliability and safety of which have been evaluated in a large series of pediatric patients.

Selection of a Suitable Block Procedure

Selecting the most appropriate technique is a matter of experience and common sense. Several factors must be considered: (1) the ability of the technique to abolish pain not only in the operative field, but also in all the areas involved in the surgery (e.g., site of tourniquet placement, sites where skin or bone grafts are to be taken); (2) the adequacy of the duration of the sensory block with the expected duration of postoperative pain; (3) the physical condition of the patient; (4) the local conditions at the site of puncture; (5) the suitability of the position required for performing the block according to the lesions and/or the physical condition of the child; (6) the similar importance of anesthetic and surgical techniques--under normal conditions, central blocks should be avoided for minor surgery; and (7) the experience of the anesthesiologist. The possibility that technical difficulties may be encountered in attempting to locate a nerve trunk or a spinal space must be envisaged preoperatively with the patient's family, and alternate procedures that would be used in such an event should be clearly detailed.

TABLE 44-3 -- Pediatric Doses and Clinical Characteristics of Usual Local Anesthetics

LOCAL ANESTHETIC	USUAL CONCENTRATION (%)	USUAL DOSES (mg/kg)	MAXIMUM[a] DOSE (PLAIN) (mg/kg)	MAXIMUM[a] DOSE WITH EPINEPHRINE (mg/kg)	LATENCY (min)	DURATION OF EFFECTS (h)
AMINOESTERS						
Procaine	1-2	7	10	10	10-15	0.3-1
Chloroprocaine	2-3	7	10	10	7-15	0.5-1
AMINOAMIDE[b]						
Lidocaine	0.5-2	5	7.5	10	5-15	0.75-2
Prilocaine [c]	0.5-1.5	5	7	10	15-25	0.75-2
Mepivacaine	0.5-1.5	5-7	8	10	5-15	1-1.25
Bupivacaine	0.25-0.5	2	2.5	3	15-30	2.5-6
Etidocaine [d]	1	3-5	5	7	5-10	2-5

These data are not applicable to spinal anesthesia, intravenous regional anesthesia or local anesthesia. Ropivacaine has no legal approval for use in children younger than age 12 years.

[a] Maximum doses are controversial and, in fact, irrelevant because toxicity is due to the free unbound form and neither to the total dose given nor the plasma peak concentration. The doses mentioned above are safe when given as single injections, but they may or may not be safe following multiple previous injections (or continuous infusion), especially during the postoperative course. This holds particularly true for long-lasting local anesthetics (bupivacaine and etidocaine, and, probably ropivacaine).
[b] Ropivacaine has not been included because of lack of information and approval for use in children younger than 12 years old.
[c] Danger of severe methemoglobinemia in infants (even with low therapeutic doses).
[d] Etidocaine should not be administered alone because sensory blockade can be insufficient.

Also, when confronted with a technical failure, the anesthesiologist should not make a second attempt without verifying both the position of the patient and the landmarks used. In any case, it is unreasonable to attempt to perform the same procedure more than three times in the same patient.

Selection of the Anesthetic Solution

Sound selection of local anesthetics [79] depends on the planned surgery, the expected duration of postoperative pain, and the pharmacologic characteristics of the drugs. The most suitable local anesthetics and their recommended doses are detailed in Table 44-3 . As previously mentioned, prilocaine should not be used in infants, and mepivacaine should be avoided during the first 2 or 3 weeks of life. Ropivacaine [80] has recently become available and will probably play a consistent role in pediatric regional anesthesia; but, currently, little information is available in children, and there is no approval for use in patients younger than 12 years old. The use of mixtures of local anesthetics has gained acceptance in recent years but remains controversial. [81] Expected advantages of such combinations include compensation against relative limitations of each agent (especially in regard to latency until completion of sensory block) and reduction of the hazards of systemic toxicity by producing low and separated peak blood concentrations of each agent. It should be kept in mind, however, that the toxicity of mixtures of local anesthetics is additive. [82] I regularly use mixtures of lidocaine with bupivacaine or, rarely, bupivacaine with etidocaine. Warming the anesthetic solution before injection reduces pain on infiltration. [83]

With regard to adjuvants, the addition of epinephrine is mandatory for the reasons mentioned (reduction of vascular uptake, increased duration of effects, early detection of an intravascular injection). However, epinephrine can produce ischemic disorders and gangrene when injected in areas supplied by terminal arteries; therefore, it is contraindicated for penile, peribulbar, pudendal, and digital nerve blocks. Narcotics, and especially morphine, have many indications when given epidurally or, although not accepted by some authors, [24] intrathecally, provided appropriate monitoring of respiratory parameters can be ensured for the first 24 postoperative hours.

Selection of Material

The (sterile) material necessary for performing a regional block is rather simple: a (nonreusable) block needle, a syringe, a local anesthetic, skin preparation solutions, and drapes. Different types of needles are available, and the anesthesiologist has to make a selection so that any regional block can be performed safely and sufficient experience gained with all the selected needles, especially with regard to the sensation felt during insertion.

Local infiltrations and field blocks can be performed with a single standard needle, (e.g., a 21- to 23-gauge and 30-50 mm long). Intradermal wheals are made with a short (no more than 30 mm long) and thin (25- to 27-gauge) needle. Compartment blocks (e.g., fascia iliaca compartment block, penile block via the subpubic space, rectus sheath block, peribulbar anesthesia) depend on the precise localization of a fascial plane. When the relevant fascia is unique and does not cover any vital structure, a large number of needles can be safely used; in any other case, especially when there are several successive fascial planes, the use of a short beveled needle (or a pinpoint needle) of adequate length is required. [84] [85]

Plexus and mixed nerve blocks should not be performed by seeking paresthesias with standard intramuscular needles because of a danger of direct nerve damage [86] [87] ; unsheathed short-beveled needles connected to a nerve stimulator proved to be suitable, [88] but the safest way to proceed is by using an insulated and short-beveled needle. Needles 35 mm long are appropriate for more than 80 percent of all peripheral blocks. Sciatic nerve blocks require longer needles,

especially when the lateral or the anterior route is selected and depending on patient size, 50-, 100-, 150-, and, occasionally, 180-mm needles should be available. Caudal blocks have been performed using virtually any type of needle available. This is no longer acceptable, and only a suitable needle must be used (i.e., 25-30 mm long, short-beveled, and using an obturator needle to avoid tissue coring [89]). Needles suitable for lumbar taps in the neonate are suitable for caudal blocks.

Tuohy needles are best suited for intervertebral epidural blocks (sacral, lumbar, and thoracic). At least two sizes of needles must be available: 20 gauge and 50 mm long for children younger than 8 years old and 18 to 19 gauge and 90 to 100 mm long for older patients. In infants, especially during the 1st year of life, a shorter needle is desirable (30 mm long and 22-21 gauge). Crawford needles can be safely used. Appropriately sized catheters should be available for each of these epidural

needles. Spinal blocks can be performed using lumbar tap (22 gauge) needles (especially in premature or ex-premature infants who are not to be given general anesthesia) or a standard spinal needle (24 or 25 gauge). Thinner spinal needles and Whitacre spinal needles are suitable, but they are not as advantageous in children as they are in adults [90] because children are less prone than adults to develop postspinal puncture headache. Furthermore, CSF reflux is delayed owing to the small size of the lumen, and the overall failure rate is significantly increased (10% with 29-gauge needles versus 0% with 25-gauge needles in the study by Kokki and Hendolin [91]). Of course, all spinal needles must be styletted, [89] but even with such needles, tissue coring can occur, [92] thus potentially leading to epidermoid tumors that become symptomatic 10 or 15 years later.

Techniques of Location of Nerves and Anatomic Spaces

Location of nerve trunks and anatomic spaces must be ascertained by physical means, as most children cannot reliably cooperate or are under general anesthesia. Plexus and mixed nerves are best localized by using electric stimulation to elicit muscle twitches. This requires a nerve stimulator delivering squared electric impulses lasting 50 to 100 musec at the rate of 1 to 5 impulses per second. The anode is connected to a skin electrode preferably fixed distal to the site of puncture, and the cathode to the block needle. [93] [94] To avoid traumatic nerve lesions, depolarization of motor fibers must occur before the needle contacts the nerve trunk and, at the same time, when it is close enough to it to allow a successful block. Thus, the key factor is intensity of the stimulus, which should range from 0.5 to 1.5 mA. With such intensities, motor fibers are depolarized, and muscle twitches are elicited, when the tip of the needle is approximately 1 mm away. At this distance, the injection site is within the perineural fascial sheath and the bevel far enough away to avoid damaging the nerve fibers.

The epidural space can occasionally be located by the hanging-drop method or the MacIntosh balloon technique, especially at thoracic levels. When the tip of the block needle enters the epidural space, the negative pressure thus created aspirates the hanging drop or deflates the balloon. However, the most common technique of identification is by seeking a loss of resistance while exerting a continuous (with fluid) or intermittent (with gas) pressure on the plunger of an airtight (glass or, preferably, plastic) syringe that offers no resistance to movement while the needle is advanced, until a sudden loss of resistance is felt as the ligamentum flavum is pierced. The medium used to fill in the syringe has generated much controversy. Air has been used for decades because of its availability, simplicity of use, and suitability for precisely identifying the ligamentum flavum. [95] [96] [97] For approximately 10 years, several complications have been reported, some minor such as transient headache [98] or patchy anesthesia due to air bubbles, [99] but others extremely severe such as spinal cord compression, [100] [101] multiradicular syndrome, [102] subcutaneous cervical emphysema, [103] or air embolism [104] [105] [106] [107] even following the hanging drop technique. [108] These complications led some authors to recommend abandoning this technique and use saline instead of air. [109] [110] In a well-conducted study using transesophageal echocardiography, Jaffe et al [111] detected a few air microbubbles in the blood stream (easily cleared by the pulmonary circulation in the absence of intracardiac shunt) but established that no significant air embolism occurred after quick injection of 5 mL of air into the epidural space. They also established that intravascular penetration constantly occurred, within 15 seconds, of consistent amounts of any solution (saline as well as local anesthetics) introduced into the epidural space, so that greater attention should be paid to the speed (and pressure) of injection and the injected volume [111] [112] rather than to the medium used. On the other hand, whereas the loss-of-resistance technique (LORT) using saline seems to be as suitable in grown-up children as in adults, this is not true in infants and young children whose ligaments are less densely packed and thus less easily detectable. Reports of adverse effects following fluid-LORT are still scarce. [113] The morbidity of this technique, however, is probably not negligible, as it implies several changes of syringes; results in diluting the local anesthetic (up to one fourth the volume administered to an infant), which could lead to insufficient blockade; increases the final volume given (with hazards of respiratory depression due to an excessive upper limit of anesthesia); and generates new problems in case of reflux of clear liquid on disconnection of the syringe (inadvertent dural tap or reflux of saline?). Because of the limitations of this technique in the very young, some authors developed LORT combining air and saline [114] [115] [116] [117] [118] or even more complicated techniques. All these techniques are more time-consuming and require several [106] changes of syringes (which implies hazards of syringe mismatches and bacterial contamination), and their safety and suitability in large series of patients are not established. In conclusion, air-LORT should be avoided in grown-up children where the saline-LORT is as reliable as in adults. Conversely, in younger patients, saline-LORT is not as dependable as air-LORT, and its use will probably introduce new dangers that could not compare favorably with air-LORT. [119] [120] Furthermore, using CO_2 , instead of air, as reported several years ago and still in general use in our department, without a single adverse effect, [29] would probably represent the best and safest compromise whatever the age and size of the patient.

The subarachnoid space is located by seeking CSF reflux. The diameter of the lumen of the needle and the position of the patient during the approach (which affects the hydrostatic pressure of the CSF) must be considered. It is recommended to approach the subarachnoid space while a negative pressure

is continuously exerted on the plunger of a syringe connected to the spinal needle (preferably with an extension line in between to ensure free movements of the needle).

Technique of Injection

The technique of injection is an essential factor of safety. Whatever the block procedure, five basic safety rules must be systematically followed: (1) aspiration test before any injection; in case of unexpected reflux of biologic fluid, especially blood, the procedure must be stopped and the needle withdrawn; (2) cardiac monitoring after the injection of a test dose (0.5 to 1 mL) containing 0.5 to 1 mug/kg of epinephrine (when not contraindicated) for 30 to 60 seconds; inadvertent intravascular injection is suspected in case of early (within 15 seconds) elevation of ST segment and T-wave amplitude changes, [121] [122] [123] then constantly followed by an increase in blood pressure [123] [124] [125] [126] and only occasionally by tachycardia that is often preceded by bradycardia; any of these symptoms require immediate cessation of the technique; in patients not eligible for administration of epinephrine (and this will probably be the case in the future with the use of ropivacaine) isoproterenol (0.1 mug/kg) has been used successfully as an alternative for the test dose [127] ; (3) injection at a slow rate (no more than 10 mL/min) (i.e., from 60 to 120 seconds depending on the volume [128]); (4) immediate cessation of injection if any unusual resistance is felt (to avoid potential danger of intraneural injection); (5) repeated aspiration tests during injection (every 5 mL) and before reinjection through a catheter (to verify that the tip of needle or catheter has not moved and pierced a vessel).

Environmental Conditions for Safe Regional Procedures

Monitoring Procedures

Regional anesthesia is not without consequences. Therefore, it must be performed by anesthesiologists in the operating room with the same monitoring equipment as used for general anesthesia. An intravenous line must be established before any injection of local anesthetic. As stated by Eyres, [79] "it may be deemed negligent not to have access to a reliable open vein during administration of significant doses of local anaesthetics." Placement of a precordial stethoscope and monitoring of electrocardiographic tracings, blood pressure, temperature, and respiratory rate are the minimal monitoring necessary. Evaluation of tidal volume, end-tidal CO_2 and peripheral oxygen saturation by pulse oximetry is desirable, especially in infants. All the data should be noted on a complete anesthesia chart.

Sedation of the Patient

Regional blocks can be performed on cooperative and unpremedicated patients. During emergency procedures, especially in the presence of a full stomach, general anesthetics and sedatives should be avoided. It is surprising how well children accept these techniques when they are in pain. During elective surgery, many children fear needles, and general anesthesia is usually requested by the patient. If not contraindicated for medical reasons, light general anesthesia can be safely used and is widely accepted in pediatrics. [109] [129] [130] In the prospective study undertaken by ADARPEF involving 24,409 regional procedures, almost 90 percent of all the blocks were performed under general anesthesia, with only 5 percent without any sedation. [1] New halogenated agents have been little evaluated in association with regional anesthetic techniques but, based on experimental data, sevoflurane seems to be able to attenuate the cardiac and neurologic toxicity of bupivacaine, in the same way as isoflurane. [131] However, they are not able to prevent adverse effects in case of inadvertent intravascular injection or overdose of local anesthetics. [132] Potentially dangerous procedures such as interscalene blocks or thoracic epidurals must not be attempted on unanesthetized patients, even if they are apparently cooperative, as it cannot be guaranteed that the patient will not panic during the procedure; but injection of muscle relaxants must be delayed until the block procedure is fully achieved. [133] Occasionally, general anesthesia can be detrimental to the patient as symptoms of complications can be unrecognized.

Assessment of the Block

The efficacy and extent of any block have to be evaluated systematically whatever the patient's age. This evaluation is not easy in children, even when conscious, in the absence of a motor block. It cannot be achieved properly in alert patients unless the anesthesiologist (1) has gained the confidence of the child, (2) disguises what is being done (especially handling of needles), and (3) makes comparative tests in nonblocked areas. Gentle skin pinching is the most dependable technique of

sensory testing, especially in lightly anesthetized patients, whereas answers by very anxious alert patients can be misleading. Eliciting muscle twitches and using concentrated local anesthetics aimed at providing a motor block can be helpful in reassuring awake patients. Additionally, when the patient is awake, it is important that the anesthesiologist provides psychologic support during the first minutes following skin incision to avoid panic until the patient is convinced of the success of the block procedure.

Medicolegal Implication

In pediatric practice, the patient and parents must be convinced that no malpractice has occurred. Therefore, the recommendations appearing in Table 44-4 should be followed whenever possible so as to avoid irrelevant medicolegal problems.

Complications: Early Diagnosis and Management

Regional anesthetic procedures can infrequently lead to local, regional, or general complications, some of which can be lethal. From 1985 to 1992, the Committee on Professional Liability of the American Society of Anesthesiologists

TABLE 44-4 -- Basic Safety Rules for Any Type of Regional or Local Anesthesia

1. Select the least hazardous technique for a given block.

* * *

2. Even in emergency situations, provide full details concerning the scheduled anesthetic management, including beneficial and potentially detrimental effects.

* * *

3. Envisage the possibility of a block failure and explain what replacement procedure(s) will then be used.

* * *

4. Obtain written consent for anesthesia care.

* * *

5. Evaluate carefully the physical status of the patient and ask for complementary laboratory, radiographic, or any other examinations when useful.

* * *

6. Manage the patient in the same way and with the same monitoring procedures as for general anesthesia; a full anesthesia chart must be completed.

* * *

7. Treat all complications (if any).

* * *

8. Complete a postanesthetic chart to evaluate precise recovery of the block and to avoid irrelevant claims.

* * *

9. Hospitalize all patients given epidural or intrathecal morphine in postanesthetic care units where respiratory parameters will be recorded hourly for the first 24 hours postoperatively.

collected 238 pediatric closed malpractice claims, which included only seven records of children who had received a regional anesthesia. [134] This very low morbidity rate is more apparent than real because the overall proportion of children given conduction anesthesia in the United States was extremely low during the evaluation period. With the increasing use of regional anesthetic techniques, an increasing number of complications is to be expected; however, as established by the ADARPEF's prospective study, the overall morbidity rate in a large number of patients (24,409) is still low. [1] Similarly, the number of regional anesthesia-related maternal deaths have decreased considerably throughout the United States since 1984 (at the same time, the number of regional anesthesias have dramatically increased), whereas the number of deaths involving general anesthesia has remained stable. [135]

Complications can be assessed in four groups: (1) complications resulting from the block procedure itself (i.e., true complications); (2) complications resulting from poor selection of patients, inappropriate environmental conditions, and inadequate safety precautions--these complications are entirely avoidable; (3) effects that were not anticipated because of a lack of knowledge of all the consequences of the technique used (these are not complications but malpractice); and (4) complications, usually resulting in severe damage to the patient, attributed to a concomitant regional block procedure but with no established, sometimes even improbable, causal link with the regional technique. [136] [137] Only the first group ("true complications") are considered here.

Local adverse effects usually result from nerve damage due to incorrect needle placement [86] [87] [138] [139] rather than from toxicity of the injected solution. However, inappropriate formulations (hypotonic solutions, antioxidants, preservatives, wrong solutions) and, especially, the use of epinephrine in areas supplied by terminal arteries may result in tissue ischemia and gangrene. Some local complications such as needle trauma or intraneural injection can potentially be undetected, and thus worsened, by simultaneous general anesthesia. The importance of using appropriate devices, especially short-beveled needles, which are less traumatic, and of locating the position of the needle tip by physical means cannot be overemphasized.

Placement of catheters for reinjection is also a potential source of complications. Leakage around the puncture point occurs in approximately 10 percent of cases, [140] and inadvertent removal is not infrequent. [141] The danger of bacterial contamination is difficult to evaluate. It seems rather low in some studies [142] [143] and unexpectedly high in others [144] ; several pediatric cases have been reported. [15] Even though the luminal content of the epidural catheter can remain sterile for 8 hours if the fluid in the catheter remains static, [145] after accidental disconnection, the epidural catheter should be removed, especially in infants.

Several complications become apparent on removal of the catheter such as cutting and knotting. These complications are often directly related to the length of catheter introduced into the epidural space, which should usually not exceed 2 to 4 cm. [146] The overall number of catheter-related complications has been measured as high as 19 percent in a series of 1,014 continuous epidurals in adults [142] and 11 percent in a pediatric series. [140] Malfunctioning of infusion pumps is not unusual. [1] [140] All these complications must be identified as early as possible so as to avoid any delay in abandoning the technique.

Regional complications are usually due to the interruption of nerve conduction. They occur mainly during epidural and spinal blocks, including (1) hypoventilation secondary to respiratory muscle paralysis (spread of the local anesthetic to cervical spinal segments), [147] (2) urinary retention following caudal epidurals, and (3) complications, such as Horner syndrome, hypoglycemia, hypotension (in patients older than 8 years old), and other hemodynamic abnormalities due to paralysis of sympathetic nerve fibers. Undiagnosed conditions and tumor compression can suddenly be worsened by the block technique, which can possibly lead to intracranial hypertension, paraplegia, or activation of latent viral diseases. Inadvertent dural penetration with subsequent subarachnoid injection of an epidural dose of local anesthetic results in total spinal anesthesia, which requires respiratory assistance with tracheal intubation until complete spontaneous breathing is restored, and, occasionally, hemodynamic support. The potential morbidity of this complication could be reduced by aspirating CSF, as a significant amount of local anesthetic can thus be removed. [148]

Systemic toxicity results from inadvertent intravascular injection of local anesthetics, which is often due to neglect of basic safety rules, such as the use of an aspiration test, evaluation of a test dose, and slow speed of injection. In awake patients, the first symptoms are neurologic, with complaints of drowsiness, tinnitus, visual disturbances, dysarthria, and muscular twitches, followed by convulsions, coma, respiratory and circulatory depression. [149] Seizures must be treated immediately with inhaled oxygen; and, if they persist, intravenous injection of an anticonvulsant such as diazepam (0.1 mg/kg), midazolam (0.05 mg/kg), or thiopental (4 mg/kg) (thiopental is preferable as it is faster

acting) is required. Persistent convulsions require succinylcholine injection (1.5-2 mg/kg), intubation, and assisted ventilation to prevent acidosis (Table 44-5) .

Even though local anesthetics are antiarrhythmic agents, they slow down intraventricular conduction and can produce ventricular arrhythmias and fibrillation. The most cardiotoxic agents are bupivacaine and etidocaine. The cardiotoxicity of bupivacaine is mainly due to its blocking effect on sodium channels, but also on calcium and, even more, potassium channels. [150] [151] [152] Stimulation of the parasympathetic nervous system (due to nerve toxicity) and hypothermia can aggravate this toxicity. Cardiotoxicity is minimized by prevention of hypoxia and acidosis. Cardiac arrest is managed by external cardiac massage, assisted ventilation with oxygen, IV sodium bicarbonate and inotropic support (Table 44-6) . Ventricular tachycardia or fibrillation requires electric defibrillation (3-6 J/kg); bretylium tosilate (5 mg/kg) may also be used. Immediate single injection of clonidine (10 mug/kg) followed by continuous infusion of dobutamine (5 mug/kg/min) can suppress intraventricular conduction disorders and restore normal cardiac output within 2 minutes in experiments on dogs, [153] but no confirmation of this efficacy has been demonstrated in humans, and especially in children. Atropine may be helpful, as it decreases the refractory period of the auriculoventricular node [154] and, in patients experiencing toxic reactions during continuous epidurals, phenytoin infusions (5 mg/kg over 10 minutes), [155] but efficacy of either or both treatments has not been proven. Also, based on experimental data, [156] amrinone might be helpful, but its efficacy in clinical situations in humans has to be established. Systemic toxicity (both neurologic and cardiac) is increased in patients with right-left cardiac shunts.

Toxicity can also result from interactions with drugs or biologic products (e.g., bilirubin in the neonate) by competition at plasma protein binding sites. Other mechanisms may also be involved. Cimetidine and propanolol reduce hepatic blood flow, thus increasing the toxicity of agents (lidocaine), the metabolism of which depends on blood extraction by the liver. Agents such as verapamil potentiate cardiac toxicity by their action on myocardial fibers. Benzodiazepines have complex interactions. Whereas diazepam results in increasing plasma concentration of bupivacaine after caudal injection (probably due to their action on hepatic blood flow and liver metabolism), midazolam decreases both plasma peak and plateau concentrations of the same agent given by the same route. Therefore, premedication with midazolam appears to be advantageous.

TABLE 44-5 -- Emergency Treatment of Seizures During a Regional Block Procedure

1. Treat immediately with oxygenation (sufficient in most cases)
2. If convulsions persist:
a. IV thiopental 4 mg/kg
b. short-acting muscle relaxant: either
-succinylcholine (1.5-2 mg/kg)
-atracurium (0.5 mg/kg)
-(mivacurium 0.2-0.3 mg/kg) [a]
c. tracheal intubation and mechanical ventilation
d. IV diazepam (0.1 mg/kg) or IV midazolam (0.05 mg/kg)

[a] Mivacurium has not yet been evaluated in this situation.

TABLE 44-6 -- Emergency Treatment of Cardiac Complications During a Regional Block Procedure

COMMON TREATMENT FOR ALL CARDIAC COMPLICATIONS
1. Face mask oxygenation followed by tracheal intubation and assisted ventilation with oxygen
2. Restore hemodynamics (external cardiac massage if required)
3. Prevention of metabolic acidosis with sodium bicarbonate
-semimolar (4.2%) into a central vein: 2 mg/kg/10 min
-isotonic (1.4%) into a peripheral vein: 6 mg/kg/min
IF HEMODYNAMICS NOT RESTORED: INOTROPIC SUPPORT
1. IV atropine: 0.02 mg/kg (not exceeding 0.6 mg)
2. IV vasoactive agents: either
-epinephrine: 0.1 mL/kg of a 1/10,000 solution
-dopamine or dobutamine: 2 to 10 mug/kg/min
-occasionally: isoprenaline 0.1 mug/kg
3. Calcium chloride: 10 to 30 mg/kg
ADDITIONAL TREATMENT IN CASE OF VENTRICULAR TACHYCARDIA OR FIBRILLATION
1. Defibrillation: 3 J/kg (up to a maximum of 6 J/kg)
2. Antiarrhythmic agents:
-IV bretylium tosilate (5 mg/kg) (injection can be repeated up to a maximum dose of 30 mg/kg)
-clonidine [a] : 0.01 mg/kg (should not be repeated), then IV dobutamine: 5 mug/kg/min
3. Anticonvulsants [b] : either
-IV diazepam (0.1 to 0.2 mg/kg)
-IV midazolam (0.05 to 0.1 mg/kg)
-or IV phenytoin (5 mg/kg over a period of 10 minutes)
4. Inotropic support [a] : either or both
-IV atropine: 0.02 mg/kg (not exceeding 0.6 mg)
-IV dobutamine: 5 mug/kg/min (immediately after clonidine injection)
5. Amrinone [a] ?

[a] Indication based on experimental data only.
[b] Thiopental should preferably not be administered in this situation.

Allergic reactions to local anesthetics are extremely unusual. They may occur more frequently with aminoesters than with aminoamides or when adjuvants have been added to the commercial solution (such as metabisufite in solutions containing epinephrine or methylparaben). In fact, investigations with prick and intracutaneous

tests in a patient with a history of an event after application of local anesthetics show that true allergic reactions are extremely rare. [77]

BLOCKS ALONG THE NEURAXIS

Caudal Anesthesia

Anatomic Considerations

The two halves of the vertebral arches of the fifth and usually the fourth sacral vertebrae are not fused posteriorly, thus creating the sacral hiatus. This V-shaped orifice located just above the sacrococcygeal joint is limited by two easily palpable bony crests, the sacral cornua, and is covered by the sacrococcygeal membrane, which is the sacral continuation of the ligamentum flavum. The sacral hiatus allows access to the sacral epidural space below the termination of the dural sac, at a level where most roots of the cauda equina are no longer inside the sacral canal. In infants, the sacral canal is filled with fluid fat and loose areolar connective tissue, which allows easy spread of anesthetic solutions. In children older than 6 or 7 years, the epidural fat becomes more densely packed, thus reducing this spread. The epidural fat is traversed by many veins that are valveless; thus, any injection in such veins will result in immediate systemic distribution with possible toxic effects. The sacral epidural space communicates freely with the perineural space surrounding the sacral and the lumbar roots (especially the lumbar-sacral trunk). Because of considerable leakage, a large volume of local anesthetic is necessary to achieve an appropriate upper limit of sensory block.

Indications and Contraindications

Most surgical procedures of the lower part of the body (mainly below the umbilicus) can be performed under caudal anesthesia. The most common indications include herniorrhaphies; operations on the urinary tract, anus, and rectum; and orthopedic procedures on the pelvic girdle and lower extremities. [71] [72] [76] Specific contraindications include major malformations of the sacrum, myelomeningocele, and meningitis.

Block Procedure

The patient is placed in the lateral position with the side to be operated lying lowermost, but also can be placed in the prone position with a pillow slipped under the pelvis. The landmarks are the two sacral cornua, located by palpation at the caudal extremity of the vertebral spinous process line. These delineate a triangular zone at the center of which the block needle is inserted. Several insertion routes have been reported, but the most reliable is to insert the needle at right angles to the skin until it pierces the sacrococcygeal membrane (Fig. 44-2) . The needle is then redirected rostrally, at a 20- to 30-degree angle to the skin and advanced for 2 to 3 mm into the sacral canal. The distance from skin to the sacral epidural space is hardly influenced by the age and weight of the patient (Fig. 44-3) ; in virtually all cases, it is less than 20 mm from the skin.

With appropriately sized needles, it is extremely easy to insert a catheter within the sacral canal. This procedure can occasionally be used for providing high epidural block [157] [158] [159] (i.e., at lumbar or even thoracic levels) when a direct posterior approach appears too hazardous. Before the catheter is introduced within the epidural space, the distance from the sacral hiatus to the desired vertebral level is measured, and the final position of the catheter tip must be verified radiologically before any injection, as erratic placement is common. [159] [160] There are several drawbacks to this technique. In addition to exposure of the patient to x-rays and, often, iodine contrast material, it may be impossible to withdraw the catheter. Because of the proximity of the anus, there is a danger of bacterial contamination, especially in children who have not acquired sphincter control, if a catheter is kept in place postoperatively. Despite several publications suggesting that inserting a caudal catheter could be safe, caudal anesthesia is basically a single shot procedure, and if a catheter has been inserted for (rare) intraoperative purposes, it must be withdrawn at the end of the operation.

The upper limit of sensory block does not depend on the speed of injection [161] but on the total volume injected into the epidural space according to patient's age and weight. The optimal volume of local anesthetic to be administered is controversial, and several mathematical models and equations have been presented, the most dependable of which is that of Busoni and Andreucetti. [162] From a practical point of view, the prescription scheme of Armitage is valuable and easy to use. [163] Injecting 0.5, 1.0, or 1.25 mL/kg of a local anesthetic results in a high sacral, high lumbar, or a midthoracic upper limit of the sensory block, respectively. Occasionally, the larger volume (1.25 mL/kg) can lead to excessive rostral spread (above T4). [29] [71] Thus, if more than 1 mL/kg (to a maximum of 20 mL) of local anesthetic needs to be administered, it is preferable to avoid the caudal route and use a higher epidural approach.

Complications

Complications are unusual, about 1 per 1,000 procedures, [1] and usually minor. They result from misplacement of the needle into superficial soft tissues resulting in failure of the block, intravascular or intraosseous injections leading to systemic toxicity, and intrathecal penetrations with subsequent spinal anesthesia. [164] Penetration into pelvic viscera and vessels have been reported. These complications are easily avoided by using appropriate devices with a proper technique and following the basic safety rules of injection. Hypotension may occur in patients older than 8 years. [70] Postoperative voiding can be somewhat delayed, but true urinary retention is rare. Vomiting has been reported in up to 30 percent of patients, but is usually much less. Bacterial contamination of the epidural space has been reported only when an epidural catheter had been inserted caudally. In

Figure 44-2 Caudal block. (A) Insertion of the needle at right angles to the skin: (1) Right sacral cornua, (2) Sacrococcygeal membrane. (B) Cephalad redirection of the needle after piercing the sacrococcygeal membrane.

Figure 44-3 Distance from skin to epidural/subarachnoid space at different intervertebral levels.

fact, the most common adverse effect is the development of an inappropriate level of sensory block, either excessive, lateralized, or too low. Complete failure of the block is not unusual (3-5%). They occur mainly in children older than 7 years of age, but even in younger patients the failure rate can be rather high. [124]

Intervertebral Epidural Anesthesia

Anatomic Considerations of the Epidural Space

The epidural space surrounds the spinal cord and the meninges. It extends from the foramen magnum to the sacral hiatus. It is limited posteriorly by the vertebral laminae and the ligamentum flavum, and communicates with both the paravertebral spaces and the perineural space surrounding the spinal nerves. In the "dural cuff" region, near the spinal ganglia, it has intimate relations with the subarachnoid space due to the protrusion of arachnoid granulations, which are easily traversed by local anesthetics. It contains blood vessels and lymphatics and is filled with fat in infants and more densely packed and less permeable to local anesthetics in children older than 7 to 8 years of age. The epidural veins are numerous and plexiform. They are connected with both the azygous system and the inferior vena cava. They have no valves; thus, an inadvertent intravascular injection results in immediate systemic distribution. In the cadaver, the epidural space is shown to be triangular in shape in transverse sections, with its widest part lying poste-riorly in the median sagittal plane. Thus, midline approaches are usually considered safer than paramedian approaches.

Figure 44-4 Epidural blocks. (1) Thoracic approach (paramedian route). (2) Thoracic approach (midline route). (3) Lumbar approach (paramedian route). (4) Lumbar approach (midline route). (5) Sacral intervertebral approach.

Classically, the dorsal part of the epidural space is considered to have no restrictions, but several investigations [165] [166] [167] have shown that it is frequently divided in the midline by a median epidural band, the plica mediana dorsalis, which is areolar and easily traversed by epidural solutions but can occasionally account for unilateral blockade or difficulty in the insertion of an epidural catheter. Hogan [168] did not observe such a median band in his study very close to physiologic conditions, but he found that the epidural space was not as homogeneous and continuous as commonly believed. In fact, the epidural space consists of a succession of small pyramidal spaces (near the ligamentum flavum) separated by strictures at the level of the laminae. This segmentation of the posterior compartment is incomplete during early childhood. [169] By the age of 10 years, the adult pattern is evident, with posterior compartments separated from dural contact with the bony lamina.

Under physiologic conditions, the epidural space has probably only a potential volume. [168] Epidural anesthesia cannot be considered as a passive filling of a rather large and rigid tubing but as a dynamic process because any epidural injection produces changes in pressure and a variation in the normal anatomy. The compliance of the epidural space was found to be equal to 0.39 ± 0.13 mL/mm Hg and correlated with patient's age. [170] The subatmospheric pressure used for detecting epidural penetration is, in fact, due to the displacement of the dura mater by the block needle. As subcutaneous tissues and vertebral ligaments are less densely packed in infants and young children, the loss of resistance felt as the needle penetrates the ligamentum flavum is less significant than in adults and influences the choice of the LORT technique to be used. Also, previous extradural anesthesia may result in proliferation of connective tissue, adhesions between the dura mater and the ligamentum flavum, and granulation and changes in the ligamentum flavum due to inflammation, which may reduce the spread of local anesthetics during further epidural anesthesia. [171]

Indications and Contraindications

Epidural anesthesia can be used for operations of the lower extremities and almost any part of the trunk, including the chest. [163] [172] [173] [174] [175] However, its main indications are the same as those of caudal anesthesia (i.e., low abdominal and retroperitoneal surgery). The selection between either the caudal, sacral intervertebral, or lumbar routes may be difficult. Most operations on the pelvis and lower limbs in infants and young children are performed under caudal anesthesia, provided that a single shot technique is adequate. In patients older than 6 years of age or when a reinjection catheter is mandatory, intervertebral epidural approaches are preferred. Specific contraindications include severe malformations of the vertebral column and the spinal cord such as complete spina bifida or meningocele. Also, patients with a history of hydrocephalus or severe convulsive disorders, and those with vertebral implants, reduced intracranial compliance, or elevated intracranial pressure should preferably not be given epidural anesthesia (however, these are not absolute contraindications). [78]

Block Procedures

Lumbar Epidural Anesthesia

The midline lumbar intervertebral approach is the most common technique of epidural block in children. Although the patient can be in the sitting position if awake, or, rarely, in the prone position, the most usual position is the lateral position with the side to be operated lying lowermost and the hips and knees flexed by 90 degrees (Fig. 44-4) . The spine is bent so as to open the interspinous spaces and enlarge the interlaminar space. As the spinal cord ends at a lower level in children, it is safer to select the L4-L5 or the L5-S1 interspace ("Taylor" approach). [174] The line joining

the two iliac crests passes over the skin projection of the fifth lumbar vertebral body, and the relevant spinous process is located by palpation. The site of puncture is in the midline at an equal distance from the spinous processes of the two vertebrae limiting the selected interspace.

The epidural needle is inserted at right angles to the skin until it contacts the interspinous ligament. The introducer needle is then removed, and the syringe used for detecting the epidural space is connected. The epidural needle is then slowly advanced toward the laminae while constant pressure (with fluid), or intermittent pressure (with gas) is exerted on the barrel of the syringe. An increased resistance is detected when the needle touches the ligamentum flavum, followed by a sudden loss of resistance as the tip of the needle enters the epidural space. The epidural space is detected at a distance from the skin depending on both the age and weight of the patient (see Fig. 44-3) ; 1 mm/kg of body weight can be taken as a useful guideline for children between 6 months and 10 years of age as recently confirmed. [88] Once the needle is in the epidural space, the syringe is disconnected and the absence of any blood or CSF reflux is verified. Aspiration tests are made before insertion of an epidural catheter. A test dose of the local anesthetic with epinephrine is administered before every injection.

Difficulties may be encountered during the procedure due to an inappropriate insertion route, insufficient flexion of the spine, or deformities of the vertebral column. In these cases, the oblique paramedian route can be attempted; the technique is basically the same as in adults and does not require more experience to perform it successfully in children. [29] A lumbar plexus block (see later) following the Chayen technique [176] can occasionally be used as an alternative procedure to a failed or impossible lumbar epidural approach, as the anesthetic solution can spread medially along the lumbosacral trunk and reach the epidural space in about 80 percent of patients. The recommended volume of anesthetic solution depends on the upper level of analgesia necessary for completion of the surgery. In children older than 10 years of age, this volume is best evaluated by the formula reported by Schulte-Steinberg: [177]

V (in mL) = 1/10 × (age in years)

where V is the volume necessary to block one spinal segment. In younger children, it is preferable to take into account the weight of the patient. With the administration of 1 mL/kg (up to a maximum of 20 mL), the final height of sensory block ranges from T9 to T6 in more than 80 percent of cases.

A single shot epidural anesthesia is appropriate for many pediatric cases, especially when adjuvants such as clonidine (1-2 mug/kg) and, in appropriate indications only, morphine (30 mug/kg) are added to the local anesthetic. In other cases, placement of an epidural catheter will permit (intraoperative) reinjections (same volume but half the initial concentration of bupivacaine), then continuous infusion of plain bupivacaine (0.3 to 0.5 mg/kg/h of a 1.25% or 1.0% solution). Infants less than 12 months old are more prone to accumulation with prolonged continuous infusions. [14] [17] It is mandatory to avoid administering doses exceeding 0.375 mg/kg/h for the first 24 hours and then to decrease the infusion rate (if still necessary) to half this dose for up to 5 or 6 days (assays of plasma concentration of bupivacaine are recommended every other day).

Occasionally, as for caudals, a catheter can be introduced at low lumbar interspaces and inserted over a long distance with the aim of reaching high thoracic neuromeres; however, this procedure is unreliable and in almost 80 percent of cases the tip of the catheter is in the wrong place. [178] Combined spinal and epidural anesthesia, which is now commonly practiced in obstetrics, is not frequently used in children, although there are no theoretical contraindications to using this

technique, especially as children tolerate extended sympathetic blockade very well.

Sacral Epidural Anesthesia

Because of incomplete ossification of the sacrum, there are true posterior sacral interspaces suitable for epidural approach at virtually any sacral level. The easiest approach is via the S2-S3 interspace with the patient in the lateral position [179] (see Fig. 44-4) . This interspace is located by palpation 0.5 to 1 cm below the line joining the two posterosuperior iliac spines. The puncture site is at a midpoint between the second and third sacral spinous processes. The Tuohy needle is usually inserted at right angles to the skin but, as the sacral spinous processes are atrophic, the orientation of the needle can vary considerably. It is advisable to direct the needle at an angle of 45 degrees or more, with the bevel facing the coccyx so as to decrease the hazards of damaging the dural sac, which ends approximately at this level. The distance from skin to epidural space is significantly less than at lumbar levels (i.e., two interspaces above) due to the absence of lordosis (see Fig. 44-3) Intervertebral sacral epidurals are alternative procedures to both caudal anesthesia and lumbar epidurals when inapplicable or failed, especially for surgical procedures on the pelvic girdle and lower extremities.

Thoracic Epidural Anesthesia

Thoracic epidurals are rarely performed in pediatric patients. They accounted for 6 percent of all epidurals in the ADARPEF's prospective study, which included 15,013 central blocks. [1] The main indications are for operations on the chest and the upper part of the abdomen. The techniques are similar to those used in adults. For the midline approach, the needle is inserted at the midpoint between adjacent spinous processes and, due to their steep angulation, at a 45- to 60-degree angle to the skin, pointing rostrally, but in a strict median plane (see Fig. 44-4) . Alternatively, the paramedian route can be used. [6] [29] Whatever the route used, thoracic approaches to the epidural space are more hazardous than lumbar approaches, as there is a danger of direct needle trauma to the spinal cord. Thus, they should be performed only by experienced pediatric anesthesiologists on anesthetized children. A reinjection catheter can be safely maintained in place for postoperative pain relief. [175]

Cervical Epidural Anesthesia

Cervical epidural anesthesia has no place in pediatric anesthesia.

Adverse Effects and Complications

Basically, complications of epidural anesthesia in children are the same as in adults. Inadvertent vascular injection can result in ischemic disorders and systemic toxicity. Direct trauma of the spinal cord can occur during thoracic and upper lumbar approaches and may result in the same neurologic sequelae as reported in adults. Fortunately, they are extremely unusual in children. In the ADARPEF's prospective study, [1] no complication was reported following thoracic epidurals (nor was a complication observed after spinal anesthesia), whereas the overall morbidity rate was 0.37 percent and 0.68 percent for lumbar and sacral epidurals respectively. The morbidity rate was probably so low in these two high-risk groups because only experienced anesthesiologists performed such blocks with maximum precautions. By implication this suggests that complications could be virtually avoided if all the safety precautions are taken. Interestingly, a recent paper evaluated the morbidity of thoracic epidurals with catheter placement in 4,185 patients (including 2,059 cases evaluated prospectively) and also found a low morbidity rate in adults (0.7%). [180]

Epidural catheters may be inappropriately placed or ruptured. [181] [182] Complete failure of the block usually results from misplacement of the needle (or catheter). It is not unusual to observe an inadequate upper limit of block, either too low, excessive, unilateral or with persistence of unblocked segments. Unilateral blockade in patients having an epidural catheter is often due to migration of the catheter into the anterior epidural space. [183] Secondary displacement of the catheter, especially inward migration, can be reduced by using a subcutaneous tunnel. [184] The administration of epidural narcotics may lead to several complications, especially delayed respiratory depression. [185] [186] [187] [188] Therefore, children given epidural or intrathecal morphine must be monitored carefully during the first 24 hours postoperatively.

Spinal Anesthesia

Anatomic Considerations

The subarachnoid space is incompletely divided by the denticulate ligament laterally, and the subarachnoid septum medially. The main difference related to patient's age is due to the volume of CSF, which is doubled in infants (4 mL/kg) as compared with adults (2 mL/kg). Additionally, half the total volume of CSF is located within the spinal subarachnoid space in infants, whereas in adults this volume accounts for only 25 percent. These differences considerably influence the pharmacokinetics of intrathecally administered local anesthetics. The spinal fluid hydrostatic pressure ranges from 30 to 40 mm H_2O in the horizontal position, which is significantly less than in adults. This pressure is further decreased in patients under general anesthesia and when the patient is placed in the Trendelenburg position. It must also be remembered that, as in adults, the vascularization of the lumbar part of the spinal cord often depends on one small artery (Adamkiewicz artery) entering the spinal canal between T8 and L3. Any lesion of this artery can result in spinal ischemia leading to paraplegia.

Indications and Contraindications

Spinal anesthesia is used mainly for surgery of the lower part of the body, especially irreducible inguinal hernia repair, [189] but also for operations on the lower limbs and spine. [190] It is of major interest in premature infants whose conceptional age is less than 60 weeks, [191] especially those who experienced neonatal respiratory distress syndromes or presenting with anemia (hematocrit level below 30%). [192] [193] [194] [195] However, only 15 percent of such patients were operated on under spinal anesthesia according to the Hernia Survey of the Section on Surgery of the American Academy of Pediatrics. [196] These patients are at risk of postoperative apnea if they are operated on under general anesthesia, whereas this complication is virtually (but not always [197]) unknown following spinal anesthesia without any concomitant sedation. [198] [199] [200] In older children, despite occasional papers recommending its use for minor procedures due to its efficacy and apparent simplicity, [201] spinal anesthesia has to be restricted to conditions in which general anesthesia is contraindicated such as a congenital muscle disease. [202] In some developing countries, the technique is commonly used because it is the only available and safe technique of anesthesia. Children undergoing major operations (open heart surgery, spinal fusions) may benefit from the administration of intrathecal narcotics [37] [203] [204] for postoperative pain relief. However, this is a serious decision that requires careful postoperative monitoring due to risks of delayed respiratory depression (see epidural morphine). Spinal blocks have the same contraindications and complications as epidural blocks. Additionally, the limitations of the technique in regard to the extension and duration of the block can be regarded as contraindications. The younger the patient, the shorter the duration of the blocks. In premature infants, spinal anesthesia does not last longer than 45 minutes with lidocaine and 60 to 75 minutes with bupivacaine.

Block Procedure

Basically, the technique is a lumbar puncture that can be performed in the same positions as for lumbar epidural approaches. It is easier when the infant is in the sitting position, but it is safer, especially in high-risk infants, when performed in the lateral decubitus position. In any case, considerable attention must be paid to the position of the head, which must be maintained extended throughout the duration of the procedure. [205] [206] In experimental models, the distribution of local anesthetics within the subarachnoid space depends on the orientation angle of the flow on injection (at high injection rates). [207] This has been found to be clinically relevant with the use of Whitacre needles (in adults), the directional flow of which exerts a major influence on sensory level, as well as the duration of isobaric lidocaine spinal anesthesia. [208] Several local anesthetics are suitable in children, including 0.5 percent dibucaine, 5 percent lidocaine, 1 percent tetracaine, 0.75 percent, and 0.5 percent bupivacaine, either in hyperbaric solutions or in standard solutions. Use of a bupivacaine solution with epinephrine does not have any pharmacologic advantage. [209] The safety of hyperbaric lidocaine has recently been questioned in adults, [210] [211] [212] and the U.S. Food and Drug Administration (FDA) now recommends that

---

TABLE 44-7 -- Usual Doses of Hyperbaric Local Anesthetics for Spinal Anesthesia in Infants and Children

LOCAL ANESTHETIC[a]	0 - 5 kg	5 - 15 kg	> 15 kg
0.5% hyperbaric bupivacaine	0.5 mg/kg (0.1 mL/kg)	0.4 mg/kg (0.08 mL/kg)	0.3 mg/kg (0.06 mL/kg)
1% hyperbaric tetracaine	0.5 mg/kg (0.05 mL/kg)	0.4 mg/kg (0.04 mL/kg)	0.3 mg/kg (0.03 mL/kg)
5% hyperbaric lidocaine [b]	2.5 mg/kg (0.05 mL/kg)	2 mg/kg (0.04 mL/kg)	1.5 mg/kg (0.03 mL/kg)

[a] Hyperbaric solutions have legal approval for intrathecal injection. Nonhyperbaric and conservative-free solutions are being used increasingly but have no legal approval (which does not necessarily preclude their use). [60]

[b] The FDA recommends diluting 5% lidocaine with an equal volume of cerebrospinal fluid before injecting the total dose.

5 percent hyperbaric lidocaine should be diluted with CSF (1:1) before subarachnoid injection. To reach an upper limit of block between T10 and T7, the recommended doses of hyperbaric bupivacaine are 0.5 mg/kg in infants weighing less than 5 kg (Table 44-7) . In larger patients, 5 to 15 kg, the dose has to be reduced to 0.4 mg/kg, and in patients weighing more than 15 kg to 0.03 mg/kg. The same doses are recommended for tetracaine. For 5 percent hyperbaric lidocaine similar heights of block are obtained with doses ranging from 1.5 to 2.5 mg/kg.

EXTREMITY CONDUCTION NERVE BLOCKS

Block of Nerves Supplying the Upper Extremity

Anatomic Considerations of the Brachial Plexus and its Sheaths

The brachial plexus supplies sensory and motor innervation to the upper extremity. It is formed by the union of the ventral rami of the fifth cervical to the first thoracic spinal nerves. It is located in the interscalene space, being enveloped by a continuous sheath derived from the deep cervical fascia. Thus, a single injection within this envelope produces complete plexus block. The interscalene space does not communicate with the axillary region due to the presence of a transverse barrier at the level of the coracoid process of the scapula. [213] Supraclavicular and axillary blocks are not equiv-alent, and the nerves leaving the brachial plexus above this limit (suprascapular, axillary, and, in half the patients, musculocutaneous nerve) are not anesthetized by axillary blocks. In addition, both the interscalene and the axillary spaces are longitudinally subdivided, at least partially, with a fascial compartment for each nerve, [214] [215] which can occasionally limit the circumferential spread of injected local anesthetics.

Indications and Contraindications [5] [6]

Brachial plexus blocks are recommended for emergency surgery on the upper extremities. [216] [217] [218] [219] [220] In elective surgery, they have many indications as they provide adequate intra- and postoperative analgesia for many operations [221] [222] depending on the local anesthetic used. Use of mepivacaine seems to improve significantly the success rate and quality of blockade. [223] They are of particular interest in outpatient surgery, with high degree of patient satisfaction, [218] [224] whether they are used as the sole anesthetic technique or in combination with light general anesthesia. [220] Axillary blocks are considered first, especially when the lesions involve the forearm and the hand, as they are virtually free of complications. Supraclavicular blocks are recommended when the lesion (or a tourniquet) is located on the proximal part of the arm. They are often preferred in boisterous children, especially in case of an unstable fracture or a weak tendon or nerve repair. Specific contraindications of axillary blocks include axillary lymph adenopathies (infection, malignancies), unstable fractures, or lesions in which the movement of the upper extremity is prohibited, and proximal lesions or placement of a tourniquet. Contraindications to supraclavicular blocks depend on the insertion route (see later). Basically, they must be avoided in case of respiratory insufficiency or when a bilateral block is necessary. The parascalene approach is virtually free of complications.

Supraclavicular Blocks of the Brachial Plexus

Interscalene Approach[225]

The technique aims at entering the interscalene space at its upper end, near the transverse process of C6. The patient is placed in the supine position with the head turned opposite to the side to be blocked. The landmarks are (1) the interscalene groove between the anterior and middle scalene muscles, and (2) the anterior ramus of the transverse process of the sixth cervical vertebra (the Chassaignac tubercle), which projects at the intersection of the interscalene groove, with the circular line passing over the cricoid cartilage. This intersection corresponds to the site of puncture. The block needle is inserted medially at an 80-degree angle (not perpendicularly) to the skin, (i.e., slightly dorsal and caudad until muscle twitches (or paresthesias) are elicited in the upper limb (Fig. 44-5 A). The local anesthetic is then injected following the basic safety rules. The interscalene block provides a very effective block of the lower

Figure 44-5 Supraclavicular brachial plexus blocks. (A) Interscalene (1) and perisubclavian (2) artery approaches. (B) Parascalene approach. (1) Skin projection of Chassaignac tubercle. (2) Midpoint of the clavicle.

branches of the cervical plexus and upper branches of the brachial plexus, whereas the caudal branches of the brachial plexus may be poorly anesthetized. [226] [227] In pediatric anesthesia, its indications must be evaluated carefully, as it can lead to severe adverse effects: vascular lesions (especially vertebral artery injury), undesirable nerve blocks (phrenic nerve, recurrent laryngeal nerve, stellate ganglion), and accidental epidural or intrathecal penetration (especially when the needle is inserted at a 90- instead of an 80-degree angle to the skin). Still more worrying is the extremely high frequency of diaphragmatic paresis produced by the block procedure, [228] which precludes its use in patients with respiratory impairment (including healthy young infants) and for bilateral procedures, as this paresis results in significant Pa O_2 decrease even in healthy adult volunteers. [229]

Perisubclavian Artery Approaches

The brachial plexus trunks gather at the lower part of the interscalene space where they surround the subclavian artery. They can be approached by several insertion routes derived from the original technique by Kulenkampff and Persky, [230] which basically consists of penetrating the interscalene space slightly above the first rib (see Fig. 44-5 A). All these techniques are very effective on virtually all branches of the brachial plexus, but they require considerable experience on the part of the anesthesiologist, particularly when performing these blocks in young children, as they can result in severe complications, especially pneumothorax, undesirable nerve blocks, and subclavian vessel puncture. They cannot be considered safe techniques and, thus, have no place in routine pediatric practice.

The Parascalene Approach[231]

This technique aims at penetrating the interscalene space at a distance from the apical pleura [232] and avoids damaging the great vessels, the vagus and phrenic nerves, the stellate ganglion, and the spinal canal. The patient is placed supine with the arm extended along the chest wall and the head turned to the contralateral side. A pillow is slipped under the shoulders to extend the neck, thereby stretching and bringing the components of the brachial plexus more superficial. The landmarks are the clavicle, the posterior edge of the sternocleidomastoid muscle, and the Chassaignac tubercle. The site of puncture is at the junction of the upper two thirds, with the lower third of the line joining the Chassaignac tubercle and the midpoint of the clavicle (Fig. 44-5 B). The needle is inserted posteriorly at right angles to the skin until twitches are elicited in the upper limb. The depth at which the plexus is found is correlated with the patient's age and weight. It ranges from 7 mm (±3 mm) in

Figure 44-6 Distance from skin to plexus/nerve following the most commonly used techniques of peripheral nerve blocks.

neonates to 25 mm (±6 mm) in adolescents weighing more than 80 kg (Fig. 44-6) . Volumes of anesthetic solution usually administered are shown in Table 44-8 . The success rate of this block is high. [231] [233] The anesthetized area is that supplied by the brachial plexus and, in more than 50 percent of cases, that supplied by the lower branches of the cervical plexus. Proximal branches of the brachial plexus (i.e., those supplying the shoulder and the arm) are blocked earlier and sometimes more profoundly than the distal branches. Complications, including Horner syndrome, are unlikely with this procedure and only a very faulty technique ("... as suggested by the marked resistance to injection, by the agonizing pain experienced by the patient .... ") can result in adverse effects. [234]

Axillary Blocks of the Brachial Plexus

Axillary blocks are performed with the patient placed in the supine position. The relevant arm is both supinated and abducted to a 90-degree angle to the body. The landmarks are the pectoralis major muscle, the coracobrachialis muscle, and the axillary/brachial arteries. Several sites of puncture have been described due to loose attachment of fasciae; they do not influence the distribution of anesthesia in children, even in regard to the musculocutaneous nerve, the block of which depends on the site of emergence from the perineural space and not on the site or the technique of puncture (see previously). The most usual puncture site is at the upper border of the axillary artery, "as high as possible" in the axilla. The needle is inserted at a 45-degree angle to the skin, pointing toward the midpoint of the clavicle, until it crosses the perineurovascular sheath with a characteristic "click." At this stage, muscle twitches (or paresthesias) are elicited.

Several technical variants have been recommended occasionally, but they are of little interest, and are probably detrimental, in children. The use of a tourniquet does not allow upward spread of the local anesthetic toward the interscalene space and may lead to vascular and nerve compression. Also, exerting a digital pressure on the axillary sheath does not change either the proximal flow of the local anesthetic or the distribution of anesthesia. [235] Transaxillary artery approaches should not be used in children, as they can result in compressive hematomas. Two-injection techniques (i.e., with one injection at the upper edge and the other at the lower edge of the axillary artery) are not usual in children and may result in overdose of local anesthetics. I regularly use a more distal site of puncture, lying at the crossing of the coracobrachialis muscle with the lower edge of the pectoralis major muscle (Fig. 44-7) . The needle is introduced perpendicularly to the skin and advanced in the direction of the humerus, just above the axillary artery, which is firmly held by finger compression, until a "click" is perceived and twitches are elicited. Recommended volumes of anesthetic solution are shown in Table 44-8 . Irrespective of the technique used, axillary blocks are virtually free of complications. Accidental arterial puncture is the most undesirable occurrence, which may occasionally result in transient vascular insufficiency or a compressive hematoma. [236] Pneumothorax has been observed after the use of inappropriate insertion routes, but is unusual.

Distal Conduction Blocks

Distal conduction blocks at the shoulder, elbow, or wrist are only complementary blocks in pediatrics; and their indications result from the failure of a proximal brachial plexus block procedure (especially via the axillary route). These blocks are not usual in children and require fairly extensive experience. [5] [6]

Block of the Nerves Supplying the Lower Extremity

Anatomic Considerations of the Lumbar and Sacral Plexus

Nerve supply of the lower extremity is more complex than that of the upper limb, as it depends on two plexus, the lumbar (L1 to L4 spinal nerves) and the sacral (L5 to S4). The lumbar plexus supplies the anterior aspect of the limb and lies within the substance of the psoas muscle, in a fascial plane termed the *psoas compartment,* [237] where it can be approached percutaneously posteriorly through the quadratus lumborum muscle. The sacral plexus supplies the posterior

Figure 44-7 Axillary blocks. (1) Standard approach, (2) The author's technique.

aspect of the limb; it lies on the anterior aspect of the piriformis muscle, behind the posterior wall of the pelvic cavity, and cannot be directly approached by a block needle. Considerable attention must be paid to the fascial compartments of the thigh and the gluteal area, as injected solution cannot traverse fasciae but instead spread along their surface and then reach distant areas, which may be either favorable or detrimental. Schematically, the thigh is enclosed in a cylindrical envelope formed by the fascia lata and divided by two medial septa extending laterally and medially from this fascia to the posterior border of the femur. The posterior compartment is further divided by a reinforcement of the posterior fascia of the adductor magnus into a posterolateral compartment where the femoral vessels and saphenous nerve run, and a posteromedial compartment where the sciatic nerve runs. Injection of sufficient amounts of a local anesthetic in a compartment would ensure its diffusion to all the nerves traversing this compartment, whereas its penetration into adjacent compartments is prevented by the aponeurotic limits.

Indications and Contraindications

Lumbar Plexus Nerve Blocks

Femoral nerve blocks are the lower limb blocks most often used in pediatrics. Multieffective techniques are especially recommended in children with a fractured shaft of the femur and should be performed as early as possible after the accident to improve the conditions during transport, the ease of physical and radiologic examinations, wound dressings, and orthopedic procedures. These blocks are also suitable for providing intra- and postoperative pain relief during and after elective surgery of the soft tissues of the thigh (especially outpatient surgery) and operations on the femur. They are particularly useful in the latter case when epidural anesthesia is contraindicated. Conscious and slightly sedated pediatric patients tolerate quite well the performance of a muscle biopsy under femoral and lateral cutaneous nerve block. [238] Placement of a reinjection catheter allows long-lasting pain relief following femoral fractures. [239] [240] These block procedures have no specific contraindications.

Sacral Plexus Nerve Blocks

Sciatic nerve blocks are recommended for operations on the foot and leg (a femoral nerve block or a local infiltration is often necessary in the latter case). They have no specific contraindications. Damage to the sciatic nerve has been reported following intragluteal injections, [241] [242] [243] especially in infants, but both experimental

data and clinical experience with the use of local anesthetics have confirmed the safety of the procedure. [244] [245]

Lumbar Plexus and Lumbar Plexus Nerve Blocks

Direct Lumbar Plexus Block (Psoas Compartment Block)

The psoas compartment [237] enclosing the lumbar plexus can be approached percutaneously with the patient in the semiprone position, the side to be blocked lying uppermost. The landmarks are the ipsilateral posterior superior iliac spine, the line joining both iliac crests, and the spinous process of L5. Two puncture sites are suitable: (1) the midpoint between the posterior iliac spine and the spinous process of L5 [246] and (2) the line joining the iliac crests with a perpendicular line passing over the posterior iliac spine [247] (Fig. 44-8) . Whatever the puncture site, the needle is inserted perpendicularly to the skin until twitches are elicited,

Figure 44-8 Direct lumbar plexus block: (1) Winnie technique, (2) Chayen technique (slightly modified).

Figure 44-9 Lumbar plexus nerve blocks: (1) Fascia iliaca compartment block, (2) Femoral nerve block.

in the foot with the first puncture site or in the thigh with the latter puncture site. The distribution of anesthesia depends on the insertion route. When injected via the more medial puncture site, the anesthetic solution frequently reaches the epidural space in infants and young children, thus providing anesthesia to both sides of the lower part of the body, whereas the other technique results in an unilateral block of areas supplied by ipsilateral lumbar and, in about 75 percent of patients, sacral plexus nerves. [246]

Femoral Nerve Block

Femoral nerve blocks [247] [248] [249] [250] are performed with the patient in the supine position. Preferably, the ipsilateral limb should be slightly abducted, but any position is suitable. The landmarks are the inguinal ligament and the femoral artery. The needle is inserted perpendicularly to the skin 0.5 to 1 cm below the inguinal ligament and lateral to the femoral artery (Fig. 44-9) . It is moved dorsally until twitches are elicited in the quadriceps muscle. Alternately, a successful block can be obtained by injecting the local anesthetic blindly in a fan-like manner without attempting to elicit twitches. Both techniques anesthetize the upper aspect of the thigh, the medial aspect of the leg, and the periosteum of the femur.

Multieffective Blocks

"3-in-1" Block [251]

The technique consists of injecting an anesthetic solution within the femoral nerve sheath and forcing it cephalad with the aim of reaching the lumbar plexus within its psoas compartment. The technique is basically the same as that of the classic femoral nerve block, but, instead of being inserted vertically, the needle is advanced rostrally at a 30-degree (or less) angle to the skin until paresthesias or muscle twitches are elicited in the thigh. Firm finger pressure is then applied distally to the site of injection on the femoral artery before injecting the local anesthetic. This compression is maintained for several minutes while the swollen area is massaged to favor upward diffusion of the local anesthetic. Although constant femoral nerve block is obtained, the lateral cutaneous nerve and furthermore the obturator are

unblocked in many patients. This failure rate is consistent with the results of a recent anatomic study showing no femoral nerve sheath capable of conveying local anesthetic to the lumbar plexus and the obturator nerve. [252]

Fascia Iliaca Compartment Block [253] [254] [255]

The technique aims at injecting local anesthetics just below the fascia iliaca under which run all the nerves emerging from the lumbar plexus. The patient is placed in the supine position as for classic femoral nerve block. The line joining the pubic spine to the anterior superior iliac spine (skin projection of the inguinal ligament) is divided in three equal parts. The site of puncture lies 0.5 to 1 cm below the union of the lateral one third with the medial two thirds, (i.e., at least 2-3 cm lateral to the femoral artery) (see Fig. 44-9) . The (noninsulated) needle is connected via an extension line to the syringe filled with the anesthetic solution. It is then inserted at right angles to the skin while gentle pressure is exerted on the barrel. Two resistances followed by a loss of resistance are sought. The first one occurs as the tip of the needle crosses the fascia lata, and the second one occurs as the fascia iliaca is pierced. The injection is made at this level. Injecting a sufficient volume and massaging the swollen area favor spread of the solution to the inner surface of the fascia iliaca, thus improving the chances to block distant lumbar plexus nerves such as the obturator nerve. With this technique, the femoral and lateral cutaneous nerves are almost always blocked, whereas the obturator nerve is reached in more than 75 percent of patients. The anesthetized area also includes areas supplied by upper branches of the lumbar plexus in more than 70 percent of procedures, such as the genitofemoral nerve. Doyle et al [256] measured plasma bupivacaine levels after injection of 2 mg/kg of bupivacaine with or without epinephrine and found that plasma concentrations were acceptable with both solutions even though higher concentrations were observed after injection of plain bupivacaine (mean values: 1.1 versus 0.35 mug/mL); conversely, the median time to C_{max} was shorter with plain bupivacaine (20 versus 45 minutes in patients given bupivacaine with epinephrine).

Saphenous Nerve Block

The block of the saphenous nerve is a complementary block; its main indication is for extending the anesthetized area provided by a sciatic nerve block. The classic approach is performed at knee level, with the patient placed in either the semiprone or supine position with the knees flexed by 90 degrees. The landmarks are the anterior edge of the medial head of the gastrocnemius muscle and the tibial tuberosity. A line is drawn at a 45-degree angle with the intercondylar line, from the tibial tuberosity to the anterior edge of the gastrocnemius muscle. The technique consists of subcutaneously injecting a ring of local anesthetic along this line. This very simple technique is virtually free of complications, but its failure rate is rather high. Two alternate techniques, the transsartorial and the vastus medialis nerve approach, are promising because of their high success rate and low morbidity.

Transsartorial Approach [257]

The patient is placed supine with the leg extended. The landmarks are the patella and the sartorius muscle, on the medial aspect of the thigh. The puncture site lies 1 to 2 cm above the transverse plane tangential to the upper border of the patella, right on the body of the sartorius muscle. A 22-gauge (or 20-gauge) Tuohy needle, first blunt, then connected to a syringe filled with medium (local anesthetic) after the skin had been pierced, is introduced slightly posteriorly and caudad through the substance of the muscle until a loss of resistance is felt as the needle enters the fat pad beneath the sartorius muscle where the saphenous nerve runs. The injection of 15 mL was originally claimed to provide complete blockade of the saphenous nerve in virtually all patients [257] [258] then the success rate was reported to be close to 75 percent by the same team. [259] In children, the injection of 0.2 mL/kg (up to 10 mL) of local anesthetic results in consistent blockade of the saphenous in up to 90 percent of patients (personal data).

Saphenous/Vastus Medialis Nerve Block [260]

Whereas the saphenous nerve is a purely sensory nerve, the division branch of the femoral nerve supplying the vastus medialis that runs just medial to the saphenous nerve can be located easily by nerve stimulation. With the patient in the supine position, the landmarks are the femoral artery and the inguinal ligament

(see Fig. 44-9) . The insulated needle is inserted at right angles to the skin 0.5 cm lateral to the femoral artery and 3 to 6 cm (depending on patient's age and size) below the inguinal ligament until twitches are elicited in the vastus medialis, which occurs rather superficially (from less than 1 cm to no more than 3 cm from the skin). Then 0.1 to 0.2 mL of local anesthetic is injected and a saphenous nerve block is obtained in virtually 100 percent of cases.

Even though these two techniques have not been extensively evaluated, they appear promising and are particularly interesting in that they provide effective saphenous nerve block without requiring the high doses necessary to perform a complete femoral nerve block. Thus they are safe and (in regard to local anesthetic toxicity) suitable to complement a sciatic nerve block and provide complete anesthesia of the leg, ankle, and foot.

Other Lumbar Plexus Nerve Blocks

Obturator nerve block has virtually no indications in children for anesthetic purposes. The block of the lateral cutaneous nerve is usually performed for extending the area anesthetized by a femoral nerve block for performing a muscle biopsy. With the patient lying supine, the needle is inserted perpendicularly to the skin 1 cm below the union of the lateral one fourth with the medial three fourths of the inguinal ligament. [261] As the needle penetrates the fascia lata with a characteristic give, two thirds of the local anesthetic is injected in a fan-shaped manner almost parallel to the skin. The needle is then withdrawn, and the remaining solution is injected superficial to the fascia lata. Brown and Dickens [262]

Figure 44-10 Proximal sciatic nerve block: posterior approach: (1) Greater trochanter of the femur, (2) Coccyx.

recommended inserting the needle above the inguinal ligament at a point immediately medial to the anterosuperior iliac spine until a loss of resistance is felt as the needle enters the canal through which the nerve passes.

Sacral Plexus and Sacral Plexus Nerve Blocks

Proximal Sciatic Nerve Blocks[263]

Three proximal approaches to the sciatic nerve are suitable. The most classic is via the posterior route with the child in the lateral position, the side to be blocked lying uppermost. The landmarks are the greater trochanter of the femur and the end of the coccyx (Fig. 44-10) . The site of puncture lies at the midpoint of these landmarks, and the needle is inserted at right angles to the skin (i.e., both medially and ventrally), toward the ischial tuberosity until twitches are elicited in the foot. An anterior approach has been described for use in patients who should remain in the dorsal position. [264] [265] The landmarks are the inguinal ligament and the greater trochanter of the femur. The site of puncture lies at the crossing of (1) a line parallel to the inguinal ligament passing over the greater trochanter with (2) the parallel to the major axis of the body passing over the union of the medial one third with the lateral two thirds of the inguinal ligament (Fig. 44-11) . The needle is inserted almost perpendicularly to the skin toward the medial edge of the femur until twitches are elicited in the foot (a loss-of-resistance technique can also be used). This technique is more difficult than the posterior approach and can result in inadvertent puncture of the femoral vessel. A lateral approach has been described for use in patients lying supine, [266] [267] with the leg slightly rotated medially. The main landmark is the greater trochanter. The needle is inserted horizontally 1 to 3 cm below its lateral skin projection, until it contacts the lower edge of the femur (see Fig. 44-11) . Then, it is withdrawn and reinserted slightly more posteriorly until twitches are elicited in the foot (a loss-of-resistance technique can also be used). The depth at which the sciatic nerve is found depends on the insertion route

Figure 44-11 Proximal sciatic nerve block: anterior and lateral approaches: (1) anterior approach, (2) lateral approach.

(see Fig. 44-7) . Recommended volumes of anesthetic solution are shown in Table 44-8 The anesthetized area is that supplied by the sciatic nerve and, in virtually all patients, that supplied by the posterior femoral nerve block (i.e., the dorsal part of the thigh).

Sacral Nerve Blocks in the Popliteal Fossa[5] [6] [268]

The sciatic nerve and its two main branches can be approached in the popliteal fossa using virtually the same procedure. Two positions are suitable: (1) semiprone with the limb to be blocked lying uppermost and, preferably, (2) prone with the legs flexed 30 degrees from the table to make the limits of the popliteal fossa more apparent. The bisecting line of the upper angle of the popliteal fossa is marked down to its crossing with the skin crease behind the knee joint. The puncture site for each of the three nerve blocks lies on this line: (1) at the union of the upper two thirds with the lower one third, for the sciatic nerve; (2) slightly more

Figure 44-12 Intercostal nerve block: (1) Insertion of the needle at an 80-degree angle to the skin, (2) Caudal and dorsal redirection of the needle.

lateral, closer to the lateral border of the popliteal artery, for the tibial nerve; and (3) still more medial, close to the medial border of the tendon of the biceps femoris muscle, for the common peroneal nerve. The needle is inserted at a 45- to 60-degree angle with the skin, pointing to the thigh (sciatic nerve) or perpendicularly to the posterior aspect of the popliteal fossa (tibial and common peroneal nerves) until twitches are elicited in supplied areas. The last two nerves lie 2 to 5 mm below the popliteal membrane, which is easily identified by the characteristic "crack" felt as it is pierced by the block needle. This technique is safe and reliable. [269] A lateral approach [270] [271] with the patient in the supine position has been described in adults, but no data are available in children. A new approach to the tibial and peroneal nerve block has been described in adults [272] ; however, in my experience, its application to pediatric patients was not as easy or reliable as reported.

OTHER REGIONAL AND LOCAL PROCEDURES

Block of Nerves Supplying the Trunk

Intercostal Nerve Blocks

The thorax is supplied by the two main division branches of the spinal nerves, dorsal and ventral, which maintain a metameric disposition of sensory supply. The intercostal nerves are the continuation of the ventral branches. They run within the intercostal spaces along the lower border of the rib, accompanied by an intercostal vein (draining to the azygous venous system) and an intercostal artery. The intercostal space is triangular in section with (1) a medial border formed by the posterior intercostal muscle, and the innermost intercostal muscle, and (2) a lateral border formed by the external intercostal muscles. Intercostal nerve block is obtained by injecting a local anesthetic within the intercostal space; and, provided several adjacent intercostal spaces are infiltrated, adequate intra- and postoperative pain relief is obtained for thoracotomy, liver transplantation, pleural drainage, and management of rib fractures. This block must be avoided in the presence of impaired blood/gas exchange, and all patients must be kept under intensive medical observation because of the danger of clinically delayed pneumothorax; it is thus being contraindicated for outpatient surgery.

The safest approach to the intercostal space is in the midaxillary line with the child lying semiprone, using a short (30 mm or less), short-beveled, and not too thin (24-gauge or more) needle. Intradermal needles (25-gauge) are not appropriate, whereas 20-gauge or, preferably, 22-gauge Tuohy needles are almost ideal. The needle, connected to a syringe with interposition of an extension line, is inserted just below the lower border of the upper rib at an 80-degree angle to the chest, pointing cephalad, until it contacts the rib (Fig. 44-12) . It is then slightly withdrawn and, while continuous pressure is exerted on the barrel of the syringe, redirected both more caudad (so as to pass immediately below the rib) and dorsally (to avoid pleural damage). [273] A loss of resistance is felt at entry into the intercostal space where 1 mL of 0.125 to 0.25 percent bupivacaine with 1:400,000 epinephrine is injected. This provides 8 to 18 hours of analgesia (0.25-1% of either lidocaine or mepivacaine is also suitable, but pain relief lasts no longer than 3-4 hours).

Several adjacent intercostal spaces have to be blocked to produce adequate sensory block (thus multiplying the dangers of complications). As systemic uptake is considerable, almost equivalent to intravenous injection, [274] [275] only diluted solutions are suitable and the overall dose of bupivacaine should not exceed 2 mg/kg. Great attention must also be paid to the total dose of epinephrine, which must not exceed 4 mug/kg. A catheter can be introduced in the intercostal space located at the center of the area to be anesthetized to allow reinjections. Spread of large volume anesthetic solution can reach distant intercostal spaces (even contralateral ones), thus providing in a number of patients adequate prolongation of pain relief with a single injection. Spread to adjacent paravertebral spaces and to the epidural space can also occur. Thus, the patient should be admitted to the intensive care unit for careful monitoring of respiratory function and for delayed pneumothorax.

Iliohypogastric and Ilioinguinal Nerve Blocks [276] [277]

The iliohypogastric and ilioinguinal nerves are branches of the lumbar plexus, both originating from the first lumbar spinal nerve. The iliohypogastric nerve emerges from the lateral border of the psoas, perforates the transversus abdominis muscle, and runs obliquely, adjacent to the posterior aspect of the internal oblique muscle. Near the iliac crest, the nerve divides into two terminal cutaneous branches, lateral supplying the buttock, and medial supplying the abdominal wall, above the pubis. The ilioinguinal nerve has a similar course, below the iliohypogastric nerve. It crosses the quadratus lumborum and the iliacus muscle obliquely, pierces the transversus abdominis (at the level of the iliac crest) and the oblique muscles, then reaches the lower border of either the spermatic cord (in the male) or the round ligament of the uterus (in the female), within the inguinal canal. It provides sensory innervation to the upper medial part of the thigh and either the upper part of the scrotum and penis (male) or the labium major and the mons pubis (female).

Iliohypogastric and ilioinguinal nerve blocks usually provide adequate pain relief for operations on the inguinal region (herniorrhaphy, orchidopexy, hydrocele), including emergency procedures (strangulated hernia with intestinal obstruction). The patient is placed in the dorsal recumbent position and, according to the classic technique, two sites of puncture are identified--one at the union of the lateral one fourth, with the medial three fourths of the line joining the anterior superior iliac spine to the umbilicus, the other immediately lateral to the pubic tubercle (Fig. 44-13) . At both puncture sites, the needle is inserted subcutaneously and one fourth (one per site) of the total dose is injected in a fan-shaped manner. It then is inserted under the aponeurosis of the external oblique muscle (i.e., within the substance of the muscle) where a second quarter (one per site) is similarly injected. Any anesthetic agent can be used, but long-acting local anesthetics are usually preferred, especially 0.5 percent prilocaine or 0.25 to 0.5 percent bupivacaine, both with 1/200,000 epinephrine. The recommended total volume of injection ranges from 0.5 to 1 mL per year of age. Intraoperative infiltration of the hernia sac (which, in fact, is the same technique) effectively relieves postoperative pain [278] [279] but does not protect against intraoperative pain.

Ilioinguinal and iliohypogastric nerve blocks are easy to perform and virtually free of "true" complications, but their failure rate (>10%) is not negligible with the classic technique. Undesired nerve blocks (especially femoral nerve blocks) are occasionally observed [280] [281] [282] [283] because of the spread of the local anesthetic caudad to the inguinal ligament. The only problem with this undesired effect is that it can delay the discharge of the patient by a few hours. More worrying is a recent study on a small pediatric series (30 patients divided in two groups) showing unexpectedly high plasma bupivacaine concentrations (without clinical symptoms) in patients weighing 10 to 15 kg, thus inciting the authors to recommend injecting not more than 1.25 mg/kg when performing this block in infants. [284] These goals can be easily achieved by simplifying the technique. [285] With the patient in the same dorsal recumbent position, only the puncture site close to the anterosuperior iliac spine is used. Instead of being introduced perpendicularly to the skin at this point, the short-beveled needle is inserted at a 45- to 60-degree angle, pointing to the midpoint of the inguinal ligament, until the superficial layer of the external oblique muscle is pierced with a clearly identifiable "crack" (the piercing is sometimes rather difficult). Then a single injection of 0.3 to 0.4 mL/kg of 0.25 percent bupivacaine is made in a fan-shaped manner. With this insertion route, the tip of the needle pierces the fascia at a level where both the ilioinguinal and iliohypogastric nerves have crossed the fascia covering the internal oblique muscle. Additionally, because of the spread of the local anesthetic at the inner surface of the fascia of the external oblique muscle, which contributes to the constitution of the inguinal ring, the genital branch of the genitofemoral nerve, which enters the inguinal ring at close proximity, will usually be reached and anesthetized, thus making unnecessary any injection at the level of the pubic tubercle.

Figure 44-13 Iliohypogastric and ilioinguinal nerve blocks: (1) Umbilicus, (2) Anterior iliac crest, (3) Pubic spine.

Penile Blocks [286]

Except for its proximal part, which receives sensory fibers from the ilioinguinal and genitofemoral nerves, the penis is supplied by the two dorsal nerves of the penis, which are terminal branches of the pudendal nerves (sacral plexus nerves). Each dorsal nerve passes under the pubic bone, runs within the subpubic space and then through the substance of the suspensory ligament, accompanies the dorsal artery of the penis at the inner aspect of the Buck fascia close to the corpora cavernosa, and ends in the glans penis. During its course, the dorsal nerve gives off numerous branches to the corpora cavernosa, the skin of the penis, the glans, and the frenulum. The only safe approach to the dorsal nerves of the penis is within the subpubic space, a pyram- idal space limited by the perineal membrane and symphysis pubis (above), the pelvic part of the corpora cavernosa (laterally and below), the suspensory ligament, and the superficial fascia of the abdomen. At this level, the fascia superficialis divides into two layers. The superficial layer is

Figure 44-14 Penile block via the subpubic space: landmarks.

loose, fatty, and areolar in texture. The deep layer is membranous, thin but resistant, and aponeurotic in structure. It is also termed the *Scarpa fascia* and is continuous with the fascia penis (the Buck fascia).

Penile blocks are recommended for surface operations on the penis (i.e., foreskin [circumcision] and glans). They are suitable for providing long-lasting pain relief when performed at the end of surgery for hypospadias repair but are not usually sufficient for the surgery itself, which is best completed under caudal anesthesia. As the penis is supplied by terminal arteries, *epinephrine must not be added to the anesthetic solution.* With the patient in the supine position and the penis pulled down, either by manual traction or by taping, two sites of punctures are marked 0.5 to 1 cm both below the symphysis pubis and lateral to the midline (Fig. 44-14) . A 30-mm long needle, the bevel of which is not too short as Scarpa's fascia is not easily traversed due to its elasticity (a caudal or a neonatal lumbar tap needle is ideal), is inserted almost perpendicularly to the skin (see Fig. 44-14) , with a slight slope medially and caudally until it pierces the Scarpa fascia with a characteristic "give," at a distance ranging from 10 to 25 mm irrespective of the age and weight of the patient. As the subpubic space is frequently divided into two separate compartments by a medial division, a twoinjection technique is preferable. The volume of 0.5 percent bupivacaine *without epinephrine* to be injected is 0.1 mL/kg per side up to a maximum of 5 mL per side.

Several other techniques of penile blocks have been reported. Most of them aim at approaching the dorsal nerves at the proximal part of the penis where they run between the Buck fascia and the outer surface of the corpora cavernosa. These techniques are dangerous and should not be used in children. A safer alternative [287] [288] consists of performing a subcutaneous ring of local anesthetic at the base of the penis; however, this technique requires relatively large amounts of local anesthetic (2 mg/kg bupivacaine) and fails to provide adequate analgesia in less than 20 percent of patients. Topical anesthesia can occasionally be used as an alternative to penile blocks for urethral meatotomy [289] or even neonatal circumcision. [290] [291]

Other Techniques

Paravertebral Blocks

Spinal nerves can be directly blocked at their emergence from the spinal canal when they run in the paravertebral space. At thoracic levels, paravertebral blocks can be an alternative to intercostal nerve blocks. [292] At lumbar levels, they can be helpful for postoperative pain relief after surgery on the kidney. The technique for approaching the thoracic paravertebral space has recently been reevaluated in children. [293] [294] [295] The paravertebral space is poorly described in textbooks of anatomy. In the transverse plane, [296] the paravertebral space is limited medially by the vertebral bodies and intervertebral discs; posteriorly by the transverse processes, the ribs, and costotransverse ligaments; anterolaterally by the parietal pleura. Caudally, this space is closed by the psoas muscle at the level of T12, whereas its cranial extremity is not well defined but might communicate with the fascial planes of the neck. It is crossed by the intercostal pedicles, azygos and hemiazygos veins, the sympathetic chains and lymphatic ducts. The anesthetized patient is placed in the lateral decubitus position with the side to be blocked uppermost. The landmarks are the spinous and transverse processes of T7 to T9 (in case of thoracotomy, the block will be performed at T4-T6 levels), and the puncture site is marked 1 to 2 cm lateral to the spinous process (Fig. 44-15) . The same Tuohy needle that would be used for performing an epidural on the patient is inserted at right angles to the skin, while continuous pressure is exerted on the barrel of a loss-of-resistance syringe connected to the block

Figure 44-15 Paravertebral space block.

needle and filled with saline, until it contacts the transverse process. The needle is then "walked" along the surface of the process so as to pass over its cranial border and enter the paravertebral space after piercing the costotransverse ligament with a clearly identifiable loss of resistance. An epidural catheter is then inserted for 2 to 3 cm and, after a negative aspiration test and test dose, is securely taped on the skin, as for a continuous epidural. A starting dose of 0.5 mL/kg of 0.25 percent bupivacaine is then injected followed either by reinjection or continuous infusion of the same local anesthetic (0.25 mL/kg/h). The distance (mm) from skin to paravertebral space can be calculated by the following equation: [297]

Distance (mm) = 21.2 + [0.53 × (weight in kg)]

The injected local anesthetic can spread longitudinally (lateral to the spine, from T12 to T6 or above), or in a cloud-like, ill-defined manner (at least five dermatomes are blocked, even in this latter case). Continuous infusion provides better quality postoperative pain relief than intermittent bolus, and plasma concentrations remain rather low, both for lidocaine [298] and bupivacaine, at least in adults. [299] The technique compares favorably with continuous interpleural anesthesia [292] ; its failure rate is low and complications are rare. [300]

Interpleural (or Intrapleural) Block[301] [302] [303]

The pleura is formed by two sheets, the visceral pleura, which is in contact with the lungs, and the parietal pleura which is tightly adherent to the thoracic wall. These sheets enclose a potential space, the pleural cavity (one per lung), with a subatmospheric pressure. Intrapleural blocks (also termed *interpleural blocks*) consist of injecting a local anesthetic within this cavity without creating a pneumothorax. Indications for the technique are not well established in children, and, contradictory results concerning spread of analgesia have been reported. Biliary duct surgery and parietal pain due to thoracotomy are the most commonly accepted indications. The technique requires using a block needle, preferably a Tuohy needle (20 or 22 gauge, depending on patient's size), a syringe similar to that used for identifying the epidural space, and an appropriately sized "epidural" catheter. The best anesthetic solution is 0.5 percent bupivacaine with 1/200,000 epinephrine and recommended volumes to be injected range from 0.2 to 0.4 mL/kg up to a maximum of 20 mL.

With the patient in the semiprone (or ventral) position, usually at the end of the surgery, the eighth intercostal space is identified. The needle is connected to the syringe filled with 1 to 3 mL of either gas (preferably medical CO_2) or fluid (preferably local anesthetics). It is then introduced perpendicularly to the skin, in the midaxillary line (but any other point is suitable) immediately below the eighth rib with the bevel turned cephalad. A first loss of resistance is felt as the needle pierces the intercostal membrane, followed by a second one when the parietal pleura is traversed (with a characteristic "click"). The solution is then injected at this time while paying considerable attention to avoiding air penetration if the syringe has to be disconnected. Although the technique is not free of complications, [304] it has proved suitable for providing post-thoracotomy pain relief with continuous infusion of local anesthetics through the catheter that had been maintained in place. Several regimens have been evaluated, without or with a starting dose (0.625 mg/kg of 0.25% bupivacaine), followed by a continuous infusion of either 1.25 mg/kg/h, then 0.75 ± 0.32 mg/kg/h, [305] or 0.5 to 1 mL/kg/h of 0.1 percent bupiv-acaine. [306] However, at least one case of central nervous system toxicity has been reported (in an adult) with this technique. [307]

Pudendal/Perineal Nerve Block

Because of its better benefit/risk ratio, ilioinguinal/iliohypogastric nerve block is being increasingly used instead of caudal anesthesia for minor perineal surgery. Thus, the pudendal/perineal nerve block, which was ruled out from use in obstetrics by the emergence of the epidural era, is regaining interest, mainly in the male when a scrotal incision is necessary. The pudendal nerve is a terminal branch of the sacral plexus that runs along the lateral wall of the ischiorectal fossa within a sheath derived from the obturator fascia (Alcock canal). It gives off the inferior hemorrhoidal nerve, the perineal nerve, and the dorsal nerve of the penis (or clitoris). It can be easily blocked at the level of the ischial tuberosity. The patient is placed in the supine position, with the knee flexed and the plantar aspects of the feet conjoined (as for female bladder catheterization). The landmark is the skin projection of the ipsilateral ischial tuberosity in the frontal plane. A short and short-beveled needle is inserted in the same frontal plane in the direction of the ischial tuberosity, aiming at passing just medially to it until a give is felt as the obturator fascia is pierced. Then 0.1 mL/kg up to 5 mL of plain solution of local anesthetic is injected (the pudendal artery, which is close to the nerve is a terminal artery; therefore, epinephrine must be avoided). If no give is felt before contacting the medial aspect of the ischial tuberosity, the needle is removed a little, and local anesthetics are injected. An excellent block will be obtained in virtually all patients (unpublished data). An alternative to this technique consists of infiltrating the incisional line directly on the scrotum, [308] but the reliability of the technique is not as good as that of the pudendal/perineal nerve block and requires several changes in needle orientation, which could threaten the scrotal content.

Rectus Sheath Block/Paraumbilical Block

The rectus sheath block [309] also know as paraumbilical block [310] has gained renewed interest in pediatric anesthesia for providing both intra- and postoperative analgesia in patients undergoing umbilical and paraumbilical hernia repairs. The periumbilical area receives its sensory supply from the tenth right and left intercostal nerves after they have pierced and penetrated the rectus sheath (fascia covering the rectus abdominis muscle). The block procedure consists of introducing a rather short-beveled needle through the rectus sheath, on either side of the abdomen, at the crossing of the outer border of the muscle with the line

drawn downward from the umbilicus at a 45-degree angle to the horizontal line. The block needle is inserted obliquely toward the umbilicus at a 60-degree angle to the skin until it pierces the rectus sheath (with a characteristic "pop"). The local anesthetic (0.2 mL/kg of 0.5% bupivacaine with or without epinephrine) is then injected in a fan-shaped manner and excellent analgesia of the ipsilateral periumbilical region is provided almost instantly. This block is virtually free of complications provided a sharp needle is not used with the wrong insertion route (i.e., perpendicularly to the skin and through the parietal peritoneum). The technique is quite simple and the success rate extremely high. When it is used the surgeons may complain of some degree of "edema" at the site of incision, which they consider advantageous later on as dissection of fascial planes is then made easier.

Other Blocks of Nerves of the Trunk

Other blocks of nerves of the trunk, including paravertebral ganglion, genitofemoral, paracervical (uterosacral), and transsacral nerve blocks are not used in pediatric patients.

Block of Nerves Supplying the Head and Neck

Cervical Plexus Blocks

The cervical plexus is formed by the union of the ventral rami of the first four cervical spinal nerves. It lies just lateral to the relevant vertebrae and provides sensory supply to the shoulders, neck, and posterior aspect of the head. Specific cervical plexus blocks are unusual in children because "high" supraclavicular brachial plexus blocks (interscalene and parascalene blocks) provide adequate analgesia for most of the operations performed on the neck. The cutaneous branches can be anesthetized by a series of subcutaneous injections along the posterior border of the sternocleidomastoid muscle from C2 to C5. The various (and unusual) techniques for blocking this plexus are fully detailed elsewhere. [5] [6]

Laryngeal Nerve Block

The laryngeal nerve is a branch of the vagus nerve supplying the pharynx and larynx. The block of the laryngeal nerve allows laryngeal endoscopic examinations lasting no more than 30 minutes in an awake patient. It can be particularly helpful when tracheal intubation is difficult, as it allows awake intubation (or an attempt at intubation). A variant of the lateral approach is especially easy and safe in children. It consists of a subcutaneous injection of local anesthetics just lateral to the extremity of the hyoid horn. [311] The intradermal needle is inserted perpendicularly to the skin until it contacts the cartilage (Fig. 44-16) . After a negative aspiration test, 0.1 to 0.2 mL/kg (i.e., rather large volumes in this narrow area) up to a maximum of 8 mL of 1 percent lidocaine is injected subcutaneously.

Cervicothoracic (Stellate) Ganglion Block

The cervicothoracic (or stellate) ganglion belongs to the (ortho)sympathetic system. It extends from the transverse process of C7 to the neck of the first rib, between the longus colli muscle posteriorly, and the carotid and vertebral arteries anteriorly. It is in close contact with the subclavian artery, the recurrent laryngeal nerve, the inferior thyroid artery, and the cupola of the lung (right side mainly). Therefore, blocking the cervicothoracic ganglion is hazardous. The technique has two main pediatric indications: [312] (1) severe circulatory disturbances of one of the upper limbs (as it produces considerable vasodilation) and (2) severe ventricular tachyarrhythmias due to familial syndromes with prolonged QT interval on electrocardiographic tracings. [313] [314] [315] [316]

The patient is placed in the dorsal recumbent position, the hands extended along the chest. A pillow is slipped under the neck to extend the esophagus, and the head is strictly maintained in a median plane. The puncture site corresponds to the skin projection of the transverse process of C6, at the crossing of the circular line passing over the cricoid cartilage with the medial border of the sternocleidomastoid muscle. With his or her fingers, the anesthesiologist moves the carotid artery and trachea laterally before inserting the needle vertically until it contacts the transverse process. The needle is then slightly withdrawn (1 to 2 mm) before 0.3 mL/kg (up to a maximum of 15 mL) of lidocaine or bupivacaine is injected. The solution can spread a considerable distance along the sympathetic chain. [317] The sympathetic block produced covers the thorax, the axillary region, and the upper limb. It constantly results in Horner syndrome.

Figure 44-16 Laryngeal nerve block.

Blocks of Nerves Supplying Facial Sensory Innervation

Sensory Innervation of the Face

The face is supplied by the voluminous sensory branch of the fifth cranial or trigeminal nerve, which expands to form the trigeminal ganglion from which arise three divisions:

1. The ophthalmic nerve (V1), which supplies sensory innervation to the orbit and the upper third of the face (including the scalp) via its three division branches: the nasociliary, frontal, and lacrimal nerves.
2. The maxillary nerve (V2), which crosses the pterygopalatine fossa, reaches the infraorbital groove and canal in the orbital floor and then becomes the infraorbital nerve. Via its division branches, the meningeal nerve, a ganglionic branch to the sphenopalatine ganglion, and the anterior superior alveolar nerve, it

supplies sensory innervation to the dura mater, the maxillary bone, the nose, and the skin of the middle third of the face, including the upper lip.

3. The mandibular nerve (V3), which is the largest division of the trigeminal nerve, divides into (1) a small anterior trunk that gives off the (sensory) buccal nerve, and the (motor) masseteric, deep temporal, and lateral pterygoid nerves; and (2) a large posterior trunk, mainly sensory, which divides into the auriculotemporal, lingual, and inferior alveolar (dental) nerves. The inferior alveolar nerve reaches the mental foramen, becoming the mental nerve, which supplies sensory innervation to the soft tissues of the chin, lower lip, and its underlying mucosa and gingiva.

Most of these nerves are purely sensory nerves (precluding the use of a nerve stimulator), and although they are commonly blocked in adults, there are few indications for block in children, particularly in infants. However, three infiltration techniques as described later are easy to perform, safe, reliable, and recommended for analgesia for surgery involving facial skin, either in emergency (skin lacerations) or for superficial elective procedures.

Block of the Supraorbital and Supratrochlear Nerves

The supraorbital and the supratrochlear nerves are the two terminal branches of the frontal nerve that supply sensory innervation to the forehead and scalp. These two nerves can be easily blocked by a single injection technique (on each side). The landmark is the supraorbital foramen, easily palpable at the junction of the lateral two thirds and the medial one third of the superior orbital rim, in line with the centered pupils and both the infraorbital and mental foramina (Fig. 44-17) . An intradermal needle (25-gauge and 25 mm long) is inserted 0.5 to 1.5 cm below the foramen, on the vertical line uniting the three foramina. As the tip of the needle reaches the lower border of the foramen, 0.1 mL/kg (up to 3 mL) of local anesthetic (plain 1% lidocaine or mepivacaine, or 0 .25% bupivacaine) is slowly injected to block the supraorbital nerve. The needle is then withdrawn a little and redirected medially toward the angle formed by the union of the orbital rim with the nasal bone, and the same

Figure 44-17 Block of nerves supplying the face (supraorbital, infraorbital, and mental nerve blocks). (A) Supraorbital foramen. (B) Infraorbital foramen. (C) Mental foramen: (1) Block of the supratrochlear nerve, (2) Block of the mental nerve, (3) Block of the supraorbital nerve, (4) Block of the infraorbital nerve.

volume of local anesthetic is then injected while slowly withdrawing the needle (infiltration along the medial upper border of the orbit). If necessary, the same procedure is repeated on the other side to obtain complete anesthesia of the upper eyelids, forehead, and scalp.

Block of the Infraorbital Nerve

The landmark is the infraorbital foramen, easily palpable on the line joining the centered pupil and both the supraorbital and mental foramina, below the junction of the medial and the middle thirds of the lower border of the orbit. The puncture site lies on this line, at the crossing of the perpendicular line passing just below the nostrils (see Fig. 44-17) . The intradermal needle is directed cephalad toward the lower border of the infraorbital foramen (that must not be entered) and 0.1 mL/kg (up to 3 mL) of local anesthetic is injected. Alternatively, the block can be performed using an endobuccal route. The needle is inserted just above the upper canine tooth, then directed upward and laterally in the direction of the infraorbital foramen while palpating the canal orifice to avoid needle penetration into the foramen.

Block of the Mental Nerve

The landmark is the mental foramen, in line with the centered pupil and both the supraorbital and infraorbital foramina, at the level of the second premolars (adolescent) or the second deciduous molar teeth in a younger child. The mental foramen is directed backwards and upwards. The puncture

site lies 0.5 cm above the mental foramen (see Fig. 44-17) . The simplest procedure consists of inserting the needle pointing caudally, in the direction of the mental foramen and injecting 0.1 mL/kg (up to 3 mL) of local anesthetic. The endobuccal route is more reliable. The needle is inserted at first perpendicularly to the mucosa and then redirected at a 45-degree angle in the direction of the mental foramen until bony contact (or paresthesia) is felt. The local anesthetic is then injected slowly. The main indication of mental nerve block is surgery involving lower incisor and canine teeth. Bilateral blocks allow procedures on the lower lip.

Blocks of the Scalp

The scalp is supplied by branches of the trigeminal nerve (ventral portion) and the cervical plexus, both of which can be blocked by a subcutaneous injection of local anesthetics. Scalp blocks are performed using short 25-gauge intradermal needles. After cleaning the scalp with a bactericidal solution, a circular line is drawn from the glabella to the occiput and divided into four parts at the intersections of the sagittal and frontal planes. A ring of anesthesia is provided along the selected quarter depending on the site of the lesions by injecting a solution of 0.5 to 1 percent lidocaine with 1/200,000 epinephrine, subcutaneously and intraperiosteally (and intramuscularly in the temporal fossa). Great attention must be paid to the total dose given, which must not exceed 10 mg/kg of lidocaine. These blocks are not very common in pediatrics, and they are usually restricted to surgical repair of large wounds of the scalp in adolescents with a full stomach. (In most patients, local anesthesia by infiltrating the edges of the wound is preferable.)

Other Blocks

Several other conduction blocks of nerves supplying the head are commonly used in adults but only occasionally in children for ophthalmic surgery, operations involving the facial bones, or dental procedures. These blocks are not performed by anesthesiologists, and most of them require considerable expertise. Dental blocks especially may lead to severe complications, some of them being lethal. In dentistry, articaine is commonly used and appears to be both effective and safe. [318] A complete description of these techniques can be found elsewhere. [6]

Intravenous Regional Anesthesia

Intravenous regional anesthesia, also termed *Bier block,* has been used in children for upper limb operations distal to an inflated tourniquet. [319] [320] Occasionally, some authors still recommend its application in pediatric patients. [321] [322] Bupivacaine must not be used, whatever the concentration; chloroprocaine (thrombophlebitis), procaine (methemoglobinemia), and mepivacaine (acidosis and hyperkalemia) should also be avoided. Lidocaine (0.25-0.5%) without epinephrine is the safest agent and is administered on the basis of 1 mL/kg up to a maximum volume of 40 mL and a maximum dose of 3 mg/kg. The technique is the same as for adults. After placement of an intravenous plastic cannula, as close as possible to the site of surgery, the limb is exsanguinated, preferably by compression with an Esmarch bandage. A tourniquet is placed proximally and inflated (two to three times the systolic pressure) before the Esmarch bandage is removed and the anesthetic solution injected. Ten minutes later a second tourniquet is placed immediately below the first one (i.e., in an anesthetized area) and inflated to the same pressure values. The upper tourniquet is then removed and the surgeon can proceed. In no case should the tourniquet be deflated before the 20th or later than the 90th minute.

The tourniquets are not well tolerated by children, and the technique has many contraindications such as extensive wounds, ischemic disorders, unstable fractures, convulsive disorders, septicemia, cardiac dysrhythmias, hypovolemia, and sickle cell disease. Furthermore, Bier blocks cannot be considered safe procedures, as they depend on the inflation of a tourniquet. There is danger of systemic toxicity, and fatalities have been reported in children. [323] In children, the technique should not be used routinely for upper limb operations, and it is definitely contraindicated for lower limb procedures.

Local Infiltrations and Topical Anesthesia

Surface Anesthesia

Surface anesthesia of the larynx by local anesthetic sprays is commonly used in adults before tracheal intubation. This method of anesthesia has long been contraindicated in children, but the efficacy and safety of its use have been established [324] provided low doses of 5 percent lidocaine are administered (i.e., 8 mg in infants weighing less than 10 kg, and 16 mg in infants weighing more than 10 kg). Topical anesthesia, by spraying lidocaine on operative wounds such as the tonsillar

bed after tonsillectomy, or by applying anesthetic ointments on the incision site before or after circumcision, [290] [291] can provide adequate postoperative pain relief. The interest in topical anesthesia has been renewed in pediatrics by the availability of several new ointments containing a mixture of local anesthetics such as Emla cream, TAC cream, lidocaine-adrenaline-tetracaine gel, or Bupiv-anor. [325] [326] [327] [328] When Emla is applied on the skin and maintained in place with a sterile dressing for at least 1 hour, shorter periods with other formulations, complete analgesia of the skin and subcutaneous structures is provided. Thus venous cannulation and most techniques requiring needle puncture such as lumbar taps and repair of oral or scalp lacerations can now be made without pain, [325] [327] [328] which makes this technique highly recommendable.

Intradermal Wheals

Intradermal wheals are performed routinely to anesthetize the skin covering deeper structures. The technique consists of inserting a 25-gauge short needle almost tangentially to the skin, with the bevel facing downwards, without penetrating the subcutaneous layers. A small amount (less

than 0.5 mL) of local anesthetic (0.5-1% lidocaine or prilocaine, with or without epinephrine) is then injected. The skin covering the wheal looks like an orange peel, and almost immediate anesthesia of the relevant area is obtained.

Local Infiltrations and Field Blocks

Infiltration of local anesthetics (lidocaine or prilocaine, with or without epinephrine) in a fan-shaped manner in subcutaneous tissues and muscles surrounding the operative site (or the edges of a wound) provide adequate analgesia for soft tissue operations and wound repair. Great attention must be paid to avoid bacterial contamination and overdosage, especially in case of extensive wounds or reinjections, as serum concentration of lidocaine after subcutaneous administration is related linearly to the dose per kilogram of body weight. [329]

Intracapsular Injections

Intra-articular injection of local anesthetics provides consistent analgesia of joint capsules. The technique can be used for diagnostic or therapeutic procedures (injection of painful joints), but it is not widely used, as its efficacy is variable.

Transtracheal Injections

Instillation of local anesthetics into the trachea by cricothyroid membrane puncture is commonly used in adults for awake intubation and prevention of laryngospasm. This procedure is not usual in children because of dangers of systemic toxicity and producing lesions of both the cricoid cartilage and vocal cords.

Intraperitoneal Injections

The increasing use of laparoscopic surgery in children has generated new types of abdominal pain. Injections of rather large amounts of bupivacaine have occasionally been made at the end of the operation, but this procedure has not been evaluated in children, both with regard to efficacy and safety. According to data available from adult series, therefore, this type of intraperitoneal injections should be avoided. [330]

CONCLUSION

Regional block procedures have gained an established place in pediatric anesthesia, especially for outpatient surgery and postoperative pain relief. This increasing interest results from technical improvements, including the use of nerve stimulators for precise location of nerve trunks and the availability of equipment designed specifically for children. This greater acceptance and use of regional procedures in pediatrics are also a consequence of better understanding of the basic anatomic, physiologic, and pharmacologically relevant differences between children and adults, as well as a broader definition of anesthesia in which general and regional procedures are considered complementary to one another rather than being exclusive. The selection of an anesthetic procedure, either general, regional, or a combination of both, is made on a case-by-case evaluation of what is best for a given patient and reflects the ability of the anesthesiologist to make sound judgments about the technique that will provide the greatest comfort and safety to the patient.

INTRODUCTION

Water is the major component of all fluid compartments within the body. Total body water represents approximately 60 percent of total body weight in an average adult. In a 70 kg man, total body water is about 600 mL/kg or 40 L. The relative percentage of water varies significantly with age, gender, and adiposity. For example, muscle contains 75 percent water, whereas adipose tissue contains only 10 percent water. Water content of the fetus is high initially but decreases progressively during late gestation and the first 3 to 5 years of life.

The intracellular and extracellular compartments are separated by water-permeable cell membranes. The intracellular fluid volume averages 400 to 450 mL/kg (e.g., about 30 L), which includes 2 L of red blood cells. The extracellular

TABLE 45-1 -- Electrolyte Composition in Body Fluids

(Not Available)

From Rhoades RA, Tanner GA: Medical Physiology. Little, Brown & Co., Boston, 1995.

fluid volume averages 150 to 200 mL/kg, (e.g., about 14 L), which includes the plasma volume 30 to 35 mL/kg, interstitial fluid volume 120 to 165 mL/kg, and transcellular fluids including pleural, peritoneal, aqueous humor, sweat, urine, lymph, and cerebrospinal fluid. Extracellular fluid volume is greater in the young and in the male than in the elderly or the female (Table 45-1) (Table Not Available) . The blood volume is 60 to 65 mL/kg and is distributed 15 percent in the arterial and 85 percent in the venous system. The main metabolic reactions of the blood occur inside the red blood cells and thus within the intracellular fluid compartment.

The extracellular fluid compartment contains high concentrations of sodium, chloride, and bicarbonate. Plasma and interstitial fluid are rich in proteins, which determine plasma colloid osmotic pressure. Permeability to ions and proteins varies in each organ, with the brain having the least and the liver the most permeability.

Control of body water and its composition is multifactorial and involves (1) atrial natriuretic peptide, (2) vasopressin, (3) aldosterone (renin, angiotensin), (4) parathyroid hormone, (5) calcitonin, (6) prostaglandins, (7) dopaminergic receptors, (8) alpha-adrenergic receptors, (9) the thirst mechanism, and (10) intrinsic renal properties.

Water balance represents the difference between water intake and water loss. The kidneys are the major regulators of water output. Approximately 60 percent of the daily water loss is excreted in the urine. At high ambient temperatures or with significant exercise, the amount of water lost by sweating increases and may reflect the majority of total daily loss of water.

Heavy exercise can increase the loss of water via sweating up to 50 times the normal rate. In addition the increase in the ventilation increases the insensible loss of water through the respiratory tract (Table 45-2) (Table Not Available) . Under these conditions, renal water loss decreases to compensate for the increased sweating and insensible water losses. [1]

SODIUM PHYSIOLOGY

Sodium is the most abundant positive ion of the extracellular fluid compartment and is critical in determining the extracellular and intracellular osmolality. The distribution of sodium between plasma and interstitial fluid is roughly 5 or 6 to 1 at equilibrium, with the distribution equilibrium time being 15 to 20 minutes. Extracellular sodium balance is determined by sodium intake relative to sodium excretion. Most humans consume far more salt than they need. In certain states such as Addison disease, there is an inadequate aldosterone secretion resulting in a salt-craving behavior.

Sodium requirements vary with age. For infants born before 32 weeks' gestation, requirements are 3 mEq/kg/d; and at full term, 2 to 3 mEq/kg/d. [2] Neonatal stool losses are about 1 mEq/kg/d, and the growth process utilizes 0.5 mEq/kg/d. Adult requirements decrease to about 1.5 mEq/kg/d. Urinary sodium excretion represents the majority of sodium loss and approximately equals the daily intake of sodium. Under certain conditions, however, extrarenal sodium loss via profuse sweating, burns, severe vomiting, or diarrhea can be significant.

Normally, as much as 10 mL of urine can be formed for each milliosmole of solute excreted by the kidney. Normal kidneys respond to a volume challenge with diuresis and to a sodium load with natriuresis; if there is a decreased sodium intake or volume depletion, the kidney responds with antinatriuresis and antidiuresis (e.g., a patient undergoing surgery may excrete only 1.2 to 1.6 mOsm/mL of solute [3]). Under various pathophysiologic processes, abnormally high

---

TABLE 45-3 -- Major Causes of Natriuresis and Antinatriuresis

	NATRIURESIS
Volume-expanded states	High sodium intake; inappropriate antidiuretic hormone secretion
Volume-depleted states	Addison disease; renal salt wasting; Diuretic abuse
	ANTINATRIURESIS
Edematous states	Heart failure; chronic liver disease; nephrotic syndrome; acute glomerulonephritis; idiopathic edema
Nonedematous states	Hemorrhage; low sodium intake; diuretic withdrawal; acute mineralocorticoid administration; nonrenal sodium loss by sweating and/or vomiting

or low urinary sodium excretion can occur and are outlined below.

Many of the factors that control tubular sodium reabsorption are affected during the perioperative period including hemodynamic and physical factors, hormonal factors, and renal sympathetic nerve activity. The balance of Starling forces is responsible for sodium and water transport across peritubular capillary walls. The net pressure in the peritubular capillaries is about 10 mm Hg in favor of uptake of reabsorbed fluid. Volume expansion with isotonic saline decreases plasma protein concentration and, therefore, lowers colloid osmotic pressure in peritubular capillaries.

The renin-angiotensin system (RAS) is involved in control of blood pressure and blood volume along with the sympathetic nervous system, the kinin-kallikrein system, and arginine-vasopressin. The RAS plays a role in sodium homeo-stasis and renal function, particularly under stress conditions. The RAS may be initiated by decreases in blood pressure in the renal artery, by decreases in sodium delivery to the macula densa, or by sympathetic nervous system activation. In response, renin is synthesized from its precursor prorenin and secreted by the juxtaglomerular cells of the kidney. Renin, an aspartyl-protease (similar to pepsin and cathepsin), cleaves its substrate, angiotensinogen, an alpha$_2$-globulin, to generate the decapeptide angiotensin I. Although renin is mostly produced by the kidney, renin isoenzymes have been found in many tissues including brain, adrenal gland, vascular beds, uterus, and placenta. [4] [5] [6] [7] The gene for human renin has recently been cloned. Angiotensinogen levels are increased after nephrectomy, by estrogens, thyroid hormones, glucocorticoids, and during angiotensin I-converting enzyme inhibition. [8] [9] [10] [11]

Angiotensin I is rapidly converted to the octapeptide angiotensin II by angiotensin I-converting enzyme or by an endopeptidase. The pulmonary circulation appears to be the major site of angiotensin-converting enzyme activity, although angiotensin converting enzyme is also found in the vascular endothelium of the heart, kidney, adrenal cortex, testes, and brain, in addition to the lung. [12]

Angiotensin II is a potent vasopressor that stimulates aldosterone secretion via the adrenal cortex. Angiotensin II has a vagal inhibitory effect and causes ganglionic stimulation. [13] [14] [15] Angiotensin II partially suppresses renin secretion by a direct effect on the juxtaglomerular cells. [16] [17] Studies suggest that angiotensin II may stimulate a local increase of adenosine, a known inhibitor of renin release, and could therefore participate in a negative feedback loop whereby angiotensin II could limit its own biosynthesis. [18] Angiotensin II is degraded in the plasma to the carboxyterminal heptapeptide angiotensin III or the amino-terminal heptapeptide angiotensin (1-7), both of which appear to be biologically active. [19] [20] Thus, a fall in blood pressure, a decrease in sodium delivery to the macula densa, or sympathetic stimulation, may activate the RAS, generating angiotensin II. This results in an increase in blood pressure as well as sodium retention caused by enhanced aldosterone secretion. The renin-angiotensin system does not have an active role in maintaining blood pressure in the normal, sodium-replete, intact individual. In short, hydrostatic forces act to maintain a stable glomerular filling pressure. This, in turn, affects venous return, cardiac output, and blood pressure. Superimposed on this mechanism, under stress conditions, are a variety of neurohumoral control systems that include the sympathetic nervous system, antidiuretic hormone, atrial natriuretic hormone, and prostaglandins (Table 45-3) .

The anesthesiologist should understand that nitroprusside-induced hypotension is associated with increases in renin activity and marked elevations in the plasma concentrations of antidiuretic hormone, which are not seen with trimethaphan-induced blood pressure reductions. [21] [22] Propranolol administration during nitroprusside-induced hypotension prevents rises in plasma renin activity. [23]

Hyponatremia

Hyponatremia, typically defined as a plasma sodium less than 135 mEq/L, can result from excessive loss of sodium from excessive sweating, vomiting, diarrhea, burns, and the administration of diuretics. The most common cause of hyponatremia, however, is not a deficiency of total body sodium, but an excess of total body water.

Factitious hyponatremia can be seen in hyperlipidemia (chylomicronemia) or hyperproteinemia. Hyperosmolality resulting from nonsodium molecules (hyperglycemia,

mannitol overdose) draws water from the intracellular space to dilute the extracellular sodium concentration. Significant decreases in total body sodium most commonly occur from diuretic administration.

Transurethral prostate (TURP) syndrome is a recognized cause of hyponatremia and caused by intravascular absorption of irrigation solution, which typically contains glycine [24] ; hyponatremia, hyperglycemia, and hyperammonemia can result.

TABLE 45-4 -- Major Causes of Hyponatremia

(Not Available)

Modified from Oh M, Carrol H: Disorders of sodium metabolism: Hypernatremia and hyponatremia. Crit Care Med 20:94, 1992; Andreoli TE: Disorders of fluid volume, electrolyte, and acid-base balance. In Wyngaarden JB, Smith LH Jr (eds): Cecil Textbook of Medicine. 17th ed. Philadelphia, WB Saunders Co, 1985, p 525.

The syndrome of inappropriate antidiuretic hormone secretion (SIADH) is seen in association with a number of processes including pulmonary and cranial disorders and in a number of neoplasms, particularly bronchogenic carcinoma. High levels of vasopressin are secreted intermittently at an abnormally low threshold or continuously despite low osmolality. The presence of hyponatremia plus a urine osmolality higher than maximal dilution confirms the diagnosis. Diagnosis of SIADH rather than SIADH due to extrarenal causes is made when the urinary sodium concentration is less than 10 to 15 mEq/L and the fractional excretion of sodium is below 1 percent. In patients with SIADH, the urinary sodium concentration usually exceeds 30 mEq/L, the fractional excretion of sodium is greater than 1 percent, and the serum uric acid is reduced. Patients with SIADH exhibit a characteristic response to water restriction; a 2- to 3-kg weight loss is accompanied by correction of hyponatremia and cessation of salt wasting over 2 to 3 days. [25]

Hyponatremia also occurs in mixed disorders, in which nonosmotic antidiuretic hormone release and reductions in the rate of urinary sodium excretion blunt urinary diluting capacity. This can occur in advanced volume contraction, in intractable heart failure, and in advanced hepatic cirrhosis with ascites.

The signs and symptoms associated with hyponatremia are critical for the anesthesiologist particularly during TURP managed with regional anesthesia. Nausea, vomiting, visual disturbances, depressed level of consciousness, agitation, confusion, coma, seizures, muscle cramps, weakness, or myoclonus can be seen depending on the level of hyponatremia. Cerebral edema occurs at or below a serum level of 123 mEq/L, and cardiac symptoms occur at 100 mEq/L. Hyponatremia in association with increased intravascular volume can result in pulmonary edema, hypertension, and heart failure. [26]

The dose of sodium required to correct a deficit may be calculated using the following formula:

The optimal rate of correction appears to be 0.6 to 1 mmol/L/h until the sodium concentration is 125 mEq/L, then at a slower rate. Half the deficit can be administered over the first 8 hours and the next half over 1 to 3 days if symptoms remit. Sodium concentration should be monitored every 1 to 2 hours during rapid correction. When slow correction of hyponatremia in a volume-expanded patient is indicated, water restriction is preferred. If this is unsuccessful, diuresis with a loop diuretic such as furosemide is indicated. A number of different agents that interfere with urine concentration at the collecting duct have been used to manage chronic hyponatremia including lithium and demeclocycline. Antidiuretic hormone antagonists and the administration of urea as an osmotic diuretic are currently under investigation, although further studies are needed.

It is important to remember that rapid treatment of hyponatremia can lead to central pontine myelinolysis. Management of hyponatremia involves elimination of the underlying condition when possible (e.g., stop the TURP as soon as possible). The use of normal saline (308 mOsm/L) alone may make the hyponatremia worse depending on the patient's serum and urine osmolality. [27] Severe coma or seizures can be managed with a combination of hypertonic saline 3 percent (513 mEq/L), fluid restriction, and/or furosemide. [28] The most likely cause of postoperative hyponatremia is the syndrome of inappropriate antidiuretic hormone secretion (Table 45-4) (Table Not Available) .

Hypernatremia

Hypernatremia is defined as an increase in extracellular sodium concentration and may be accompanied by the presence of low, normal, or high total body sodium content. The major causes of hypernatremia are excessive loss of water, inadequate intake of water, a lack of antidiuretic hormone (vasopressin), or excessive intake of sodium (e.g., with solutions containing a high sodium concentration such as sodium bicarbonate). Diabetes insipidus may result from deficiency of vasopressin or inability of the kidney to produce a hypertonic medullary interstitium. Vasopressin deficiency is seen following pituitary surgery, basal skull fracture, and severe head injury. Nephrogenic causes include any systemic or kidney disease that impairs tubular function.

In the presence of an intact thirst mechanism, a slight increase in serum sodium concentration (e.g., 3 to 4 mmol/L) above baseline values elicits intense thirst. The lack of thirst in the presence of hypernatremia in a mentally alert patient indicates a defect either in the osmoreceptor or in the cortical thirst center. The most common objective sign of hypernatremia is lethargy or mental status changes, which can proceed to coma and convulsions. Additional signs and symptoms of hypernatremia include thirst, shock, peripheral edema, myoclonus, ascites, muscular tremor, muscular rigidity, hyperactive reflexes, pleural effusion, and expanded intravascular fluid volume. With acute and severe hypernatremia, the osmotic shift of water from the cells can lead to shrinkage of the brain with tearing of the meningeal vessels and intracranial hemorrhage. Slowly developing hypernatremia is usually well tolerated because of the brain's ability to regulate its volume. Treatment involves restoring normal osmolality and volume and includes removal of excess sodium through the administration of diuretics, hypotonic crystalloid solutions, and/or identification and removal of solutes. The speed of correction depends on the rate of development of hypernatremia and associated symptoms. Because chronic hypernatremia is well tolerated, rapid correction offers no advantage and may be extremely harmful or lethal because it may result in brain edema. [29] [30] Typically, a maximum of 10 percent of the serum sodium concentration or about 0.7 mmol/L/h should be the goal rate of correction. Hypernatremia increases the minimum alveolar concentration of inhalational anesthetic agents possibly because of enhanced sodium conductance during depolarization of excitatory membranes. [31] (Table 45-5) (Table Not Available) .

POTASSIUM PHYSIOLOGY

Potassium is the most abundant positive ion in the intracellular fluid. In the short term (minutes), potassium balance is influenced by insulin, pH, beta-adrenergic agonists, and bicarbonate concentration. Long-term regulation of potassium excretion and balance primarily involves the kidney and aldosterone. Several factors cause potassium concentration to average 0.4 to 0.5 mEq/L lower when measured on heparinized arterial samples, as compared with clotted venous samples.

Elevations in potassium intake increase renal excretion of potassium via a variety of cellular mechanisms. In response to increases in extracellular potassium levels, aldosterone is secreted from the zona glomerulosa of the adrenal gland

TABLE 45-5 -- Major Causes of Hypernatremia

(Not Available)

Modified from Andreoli TE: Disorders of fluid volume, electrolyte, and acid-base balance. In Wyngaarden JB, Smith LH Jr (eds): Cecil Textbook of Medicine. 17th ed. Philadelphia. WB Saunders CO, 1985, p 528.

and acts on cortical collecting ducts to increase potassium secretion into the tubular fluid and therefore increase potassium excretion.

Potassium requirements vary with age and growth. The typical full-term baby requires 2 to 3 mEq/kg/d, [32] whereas the adult uses 1.0 to 1.5 mEq/kg/d. Potassium demands are related to metabolic rate (2.0 mEq/100 kcal). In this regard, requirement increases dramatically during cell growth following establishment of nutrition in previously starved individuals. Extremely high or low levels of potassium can be life threatening.

Hypokalemia

Hypokalemia (<3.5 mEq/L) may occur owing to an absolute deficiency or redistribution into the intracellular space. A reduction in serum potassium of 1 mEq/L indicates a net loss of 100 to 200 mEq of potassium in a normal adult. Hypokalemia in the range of 2 to 2.5 mEq/L is likely to cause muscular weakness, arryhythmias, and electrocardiographic abnormalities including sagging of the ST segment, depression of the T wave, and U-wave elevation. These morphologic changes do not correlate with the severity of potassium depletion. However, cardiac dysrhythmias are more predictable and most frequently involve atrial fibrillation and premature ventricular systoles.

The four most common causes of hypokalemia include reduced intake, gastrointestinal losses, excessive renal losses of potassium (e.g., with excess of mineralocorticoids or diuretics), and potassium shifts from the extracellular to the intracellular fluid. These shifts can occur with acute alkalosis, insulin therapy, stress-related catecholamine activity, and hypokalemic periodic paralysis. Surgical stress may reduce the serum potassium concentration by 0.5 mEq/L and the administration of exogenous catecholamines such as isoproterenol, terbutaline, epinephrine, and ritodrine also decreases potassium levels. [33] [34] [35] [36] Clinically, this includes pregnant patients on tocolytic therapy or respiratory treatment with beta $_2$ -agonists and critically ill patients requiring pharmacologic cardiovascular support.

No studies demonstrate an increased morbidity or mortality for patients undergoing an anesthetic with a potassium level of at least 2.6 mEq/L. Even though administration of supplemental potassium chloride is a common practice for the anesthesiologist, studies demonstrate that in many instances therapy is ineffective, with most of the supplemental potassium being excreted in the urine despite continued hypokalemia. [37] [38] If therapy is indicated, the anesthesiologist uses intravenous potassium chloride. Because the rate of administration of potassium must be adjusted for the rate of distribution through the extracellular space before entry into the intracellular space, the rate of potassium administration is limited to 0.5 to 1.0 mEq/kg/h, with a typical replacement rate of 10 to 20 mEq/h for a normal adult with constant monitoring of the electrocardiogram [39] [40] (Table 45-6) (Table Not Available) .

Hyperkalemia

Hyperkalemia (>5.5 mEq/L) may occur in various disease states, in response to drugs that diminish renal potassium

TABLE 45-6 -- Major Causes of Hypokalemia

(Not Available)

Modified from Andreoli TE: Disorders of fluid volume, electrolyte, and acid-base balance. In Wyngaarden JB, Smith LH Jr (eds): Cecil Textbook of Medicine. 17th ed. Philadelphia, WB Saunders Co, 1985, p 532.

TABLE 45-7 -- Major Causes of Hyperkalemia

(Not Available)

Modified from Solomon RJ, Katz JD: Disorders of potassium homeostasis. In Stoelting RK (ed): Advances in Anesthesia, Chicago, Year Book Medical Publishers, 1986

excretion, or after sudden transcellular shifts of potassium from the intracellular to the extracellular fluid. Any condition or drug resulting in adrenal inhibition or decreasing aldosterone levels can cause potassium retention. Factitious hyperkalemia should also be considered in the differential diagnosis and occurs in response to lysis of the cellular components of blood.

Clinically, hyperkalemia can cause muscle weakness and even paralysis. Alterations in initiation and conduction of cardiac conduction increase automaticity and enhance repolarization. Mild elevations in potassium levels (6-7 mEq/L) may present with peaked T waves and can progress to a prolonged P-R interval, widening of the QRS complex, ventricular fibrillation, or even asystole as levels approach 10 to 12 mEq/L. [41]

Clinical treatment of hyperkalemia is determined by the setting and presence of electrocardiographic changes; it involves stabilization of the heart from effects of the potassium with intravenous calcium and redistribution of potassium from the plasma into cells. Intravenous glucose, insulin, bicarbonate, and hyperventilation are the major therapies used in the operating room setting. However, resin exchange, dialysis, diuretics, aldosterone agonists, and beta-adrenergic agonists are

well-established additional therapies (Table 45-7) (Table Not Available) .

/das/book/view/29494766/875/511.html

CALCIUM PHYSIOLOGY

Calcium is the key component that mediates muscle contraction, exocrine, endocrine and neurocrine secretion, cell growth, and the transport and secretion of fluids and electrolytes. There are approximately 1,300 g of calcium in a 70 kg adult, 99 percent of which is in the bones and teeth. The kidneys are the major organ responsible for regulating calcium between 4.5 and 5 mEq/L. Calcium is abundant in milk and milk products, is poorly absorbed by the intestine, and is excreted primarily in the feces and urine. Circulating calcium exists in three forms: (1) bound to plasma proteins

(primarily albumin) and not filtered by glomerular capillaries (40%); (2) ionized, physiologically active, filtered at the glomerular membrane, and maintained at a concentration of 2.0 to 2.5 mEq/L (50%); and (3) nonionized and chelated with phosphate, sulfate, and citrate (10%). Changes in pH alter the fraction of calcium that is bound to albumin, so the level of ionized calcium can change without alteration of total calcium. The majority of filtered calcium is reabsorbed in the proximal tubule, the thick ascending limb of the loop of Henle, and the distal tubule.

The concentration of serum proteins is an important determinant of calcium ion concentration. Ionized calcium can be measured directly with the use of calcium-specific electrodes. When ionized calcium cannot be measured, the approximate amount of calcium bound to protein is:

Plasma calcium levels must also be evaluated with careful consideration of plasma albumin concentration. To estimate ionized calcium in patients with subnormal serum proteins, a correction of 1 mg/dL is added to the serum calcium for every g/dL that serum albumin is below 4.0 g/dL. [42] For example, if the serum calcium is 7.8 mg/dL (a subnormal value) and the serum albumin is only 3.0 mg/dL; the stated serum calcium is then corrected by adding 1 mg/dL; the corrected value of 8.8 mg/dL is within the normal range.

Within minutes of a slight decrease in extracellular calcium concentration, the parathyroid glands release parathyroid hormone, which increases calcium reabsorption in the thick ascending limb and distal tubule, thus decreasing calcium excretion. Excision of the parathyroid glands eliminates parathyroid hormone secretion, which can significantly disrupt calcium homeostasis.

Calcitonin, produced in the thyroid gland, decreases renal reabsorption of calcium acutely but has little effect on chronic calcium homeostasis. Surgical removal of the thyroid gland eliminates calcitonin without changing extracellular calcium ion concentration.

Hypercalcemia

Hypercalcemia is associated with many disease processes and has many signs and symptoms. Hypercalcemia produces changes primarily in the central nervous system (mental status changes), the gastrointestinal tract (vomiting), the kidneys (polyuria, renal calculi, oliguric renal failure), and the heart (cardiac conduction disturbances). Today, hypercalcemia is most commonly diagnosed in asymptomatic patients, whereas, previously, clinical features were the earliest manifestation. Treatment essentially involves diuresis and administration of normal saline to dilute plasma calcium. These primary treatments are also useful because sodium inhibits the renal reabsorption of calcium. Additional therapies include bisphosphonates, calcitonin, ambulation, and treatment of the underlying condition. Certain conditions, including numerous cancer-related hypercalcemias, can be treated with calcium-lowering agents such as mithramycin and glucocorticoids. Thus, the anesthetic management of a patient with hypercalcemia should involve maintenance of hydration and urine output with sodium-containing fluids. Monitoring of the electrocardiogram is useful to detect cardiac conduction defects with prolonged P-R or Q-T intervals and/or widening of the QRS complex. Patients who have muscle weakness should receive decreased doses of nondepolarizing muscle relaxants (Table 45-8) (Table Not Available) .

Hypocalcemia

In the operating room, hypocalcemia is most commonly caused by acute hyperventilation or the infusion of citrated blood in excess of 1.5 mL/kg/min. The most common cause of hypocalcemia (plasma concentration less than 4.5 mEq/L) is a low albumin (e.g., in critically ill patients with severe sepsis, burns, acute renal failure, and extensive transfusions). Many critically ill patients will have low plasma albumin and low plasma calcium with normal ionized calcium levels. [43] The major signs and symptoms of hypocalcemia include mental status changes, tetany, Chvostek and Trousseau signs, laryngospasm, hypotension, and dysrhythmias.

Modified from Poitts JT: Diseases of the parathyroid gland and other hyper- and hypoclcemic disorders. In Isselbacher KJ, Braunwald E, Wilson JD et al: Harrison's Principles of Internal Medicine. 13th ed. New York, McGraw-Hill, Inc., 1995, p 2165.

Treatment involves intravenous infusion of 10 percent calcium chloride (1.36 mEq/mL) or calcium gluconate (0.45 mEq/mL). When equivalent calcium doses are administered, both preparations are equally efficacious in restoring the calcium level to normal (Table 45-9) (Table Not Available) .

/das/book/view/29494766/875/512.html

MAGNESIUM PHYSIOLOGY

Magnesium sulfate has been used for many years on an empirical basis to control convulsions in patients with preeclamptic toxemia. Magnesium ions are essential for many biochemical reactions, and a deficiency may produce clinically important consequences. Many of the pharmacologic properties have only recently been appreciated. Magnesium is excreted via the gastrointestinal tract and kidneys.

Total body magnesium is approximately 2,000 mEq. Magnesium is the fourth most important cation in the body and the second most important intracellular cation. Magnesium activates approximately 300 enzyme systems, including many involved in energy metabolism. It is essential for the production and functioning of adenosine triphosphate, which is fully functional only when chelated to magnesium. Other processes dependent on magnesium include the production of DNA, RNA, and protein synthesis. Magnesium is an essential regulator of calcium access into the cell and of the actions of calcium within the cell. Magnesium plays an essential role in the regulation of most cellular functions and may be regarded as a natural physiologic calcium antagonist.

Hypomagnesemia

With an absence of magnesium in the diet, the kidneys are able to significantly decrease excretion; however, hypomagnesemia is common in hospitalized patients, especially those in critical care areas, and presents with findings similar to hypocalcemia. Slight hypomagnesemia occurs in athletes, in hypermetabolic states such as pregnancy, and cold acclimatization. Magnesium deficiency alone and/or in combination with diuretic-induced hypokalemia and digitalisinduced arrhythmia can respond to magnesium therapy. [44] Furthermore, it is likely that anesthetizing patients with magnesium deficiency increases the risk of perioperative arrhythmias. Respiratory muscle power is impaired by hypomagnesemia, which may have important clinical consequences for anesthesia and critical care. Additional manifestations include central nervous system irritability with seizures and hyperreflexia, and skeletal muscle spasm (i.e., positive Trousseau and Chvostek signs). Treatment includes magnesium sulfate (1 g IV) with careful measurement and assessment of electrolyte levels. For acute arrhythmias, magnesium can be administrated in a dose of 8 to 12 mmol/L (200-300 mg) intravenously over 1 to 5 minutes with close monitoring of blood pressure and heart rate. Arterial pressure, deep tendon reflexes, and magnesium concentration should be monitored during either asymptomatic or life-threatening replacement. Beyond the theoretical risks of magnesium deficiency and neuromuscular blockade, the critical clinical importance of hypomagnesemia relates to the associated conditions and pathophysiologic processes associated with management of these conditions (Table 45-10) (Table Not Available) .

Hypermagnesemia

Hypermagnesemia (>2.5 mEq/L) occurs most commonly from iatrogenic causes and excessive use of antacids or laxatives. It is rare in clinical medicine, as magnesium is relatively

TABLE 45-10 -- Major Causes of Hypomagnesemia

(Not Available)

Modified from Potts JT: Diseases of the parathyroid gland and other hyper- and hypocalcemic disorders. In Isselbacher KJ. Braunwald E, Wilson JD et al: Harrison's Principles of Internal Medicine. 13th ed. New York. McGraw-Hill, Inc., 1995, p 2188.

poorly absorbed from the gastrointestinal tract, and renal elimination of excess magnesium is extremely rapid (within 4-8 hours of a magnesium load). Because elimination is directly related to glomerular filtration rate, patients with kidney failure are at increased risk of developing hypermagnesemia. Signs and symptoms are directly related to the blood level and include alterations in the nervous, cardiovascular, respiratory, and genitourinary systems.

Magnesium depresses the central nervous system and, in the early 1900s, was used effectively as a general anesthetic. Magnesium penetrates the blood-brain barrier poorly, however, and its level in the cerebrospinal fluid is well controlled by an active transport mechanism. Thus, magnesium probably does not have major anticonvulsant properties unless the convulsions result from magnesium deficiency. It is believed that the anticonvulsant activity of magnesium is related to its powerful cerebral vasodilator action, which reverses cerebral vasospasm, thought to be an important cause of convulsions. [45]

In the peripheral nervous system, magnesium interferes with the release of neurotransmitter substances at all synaptic junctions and potentiates the action of local anesthetics. At the neuromuscular junction, magnesium concentrations of 5 mmol/L cause significant presynaptic neuromuscular blockade and enhance the action of the nondepolarizing muscle relaxants. It may precipitate severe muscle weakness in patients with Eaton-Lambert syndrome or myasthenia gravis. Magnesium prolongs the action of depolarizing relaxants (succhinycholine); administration before the use of succinylcholine prevents the release of potassium provoked by the relaxant.

In the cardiovascular system, magnesium produces vasodilation by direct action on blood vessels and by interfering with a wide range of vasoconstrictor substances. It also reduces peripheral vascular tone by sympathetic blockade and inhibition of catecholamine release. In the isolated heart, increased concentrations of extracellular magnesium ion markedly depress contractile force. Decreased myocardial performance has been demonstrated after a bolus of 2.5 g of magnesium sulfate. Reports have been published of severe myocardial depression with combinations of magnesium and diltiazem. Also in the isolated heart, magnesium produces bradycardia. However, in the intact subject, the inhibition of vagal acetylcholine release produced by magnesium overrides the intrinsic slowing, and a mild tachycardia occurs. Magnesium is effective in treating a variety of arrhythmias, including ventricular arrhythmias, arrhythmias associated with epinephrine administration, and digitalis-associated arrhythmias. It is also efficacious in certain arrhythmias induced by hypokalemia, alcoholism, and myocardial infarction and may protect against bupivacaine-induced arrhythmias.

In the respiratory system, magnesium has no effect on central respiratory drive, and its only respiratory depressant effect is due to the neuromuscular block that it produces. It is an effective bronchodilator and has been successfully used in severe asthma. As magnesium inhibits catecholamineinduced arrhythmias, the possibility that magnesium may increase the effectiveness of beta-agonists in the management of asthma is currently being evaluated in clinical trials.

In the genitourinary system, magnesium is a powerful tocolytic and has been used for many years in the management of premature labor. In the kidney, magnesium is a renal vasodilator and a diuretic.

Symptoms and electrocardiographic changes of hypermagnesemia correspond to serum levels; depressed cardiac conduction, widened QRS complexes, prolonged P-Q intervals, and nausea appear between 5 and 10 mg/dL. Sedation, hypoventilation, decreased deep tendon reflexes, and muscle weakness appear at levels between 20 and 34 mg/dL, with hypotension, bradycardia, and diffuse vasodilation occurring at levels of 24 to 48 mg/dL. Areflexia, coma, and respiratory paralysis

occur at 48 to 72 mg/dL. For these reasons, all patients being treated with magnesium therapy are clinically observed for magnesium intoxication.

Elimination of magnesium involves fluid loading followed by or with concomitant diuresis. Definitive therapy involves dialysis. Temporary reversal of the effects of magnesium can be managed with calcium therapy. Because hypermagnesemia potentiates the effects of depolarizing and nondepolarizing muscle relaxants, these agents must be carefully titrated in conjunction with appropriate assessment of neuromuscular blockade. [46]

The deleterious effects of magnesium deficiency are now well recognized, and most critical care units now monitor magnesium levels. In coronary care units, several studies have shown that the infusion of magnesium sulfate can reduce the incidence and severity of cardiac arrhythmias associated with myocardial infarction. Numerous reports in the literature describe the bronchodilator effect of magnesium and of its successful use in the management of asthma. Magnesium may decrease the incidence of adrenergically mediated arrythmias without interfering with the bronchodilating action of beta-stimulants and contribute to smooth muscle relaxation of bronchioles.

In summary, magnesium has several important pharmacologic actions. Its only major toxic effect is neuromuscular paralysis. Its route of elimination is renal. Magnesium should be regarded as a cardiovascular drug, first and foremost, with calcium antagonistic and antiadrenergic properties, that may be accompanied by minimal myocardial depression.

PHOSPHATE PHYSIOLOGY

About 1 g of phosphorus is ingested daily. Approximately 70 percent (700 mg) is absorbed primarily from the small intestine, with the rest (300 mg) eliminated in the feces. The gut secretes phosphate into the lumen and then reabsorbs it, unless it is bound there by calcium or antacids or it is lost by diarrhea or drainage via ostomies or fistulas. The kidneys normally excrete 700 mg/d by filtering 6 g and reabsorbing 5.3 g. Thus, urine phosphate elimination approximately equals intestinal absorption.

Phosphate functions to store and release energy via high energy phosphates and is integral to the structure of proteins, lipids, and bone. Factors favoring cellular uptake include glucose, fructose, alkalosis, insulin, beta-adrenergic stimulation, and anabolism. Phosphate occurs in either organic or inorganic forms. Most of the intracellular phosphate is organic. Plasma contains lipid phosphates, organic ester phosphates, and inorganic phosphates, including divalent (HPO_4^{2-}) and monovalent ($H_2PO_4^-$) phosphate. At physiologic pH, 80 percent of the inorganic phosphate is divalent.

TABLE 45-11 -- Major Causes of Hyperphosphatemia

(Not Available)

Modified from Potts JT: Diseases of the parathyroid gland and other hyper- and hkypocalcemic disorders. In Isselbacher KJ, Braunwald E, Wilson JD et al: Harrison's Principles of Internal Medicine. 13th ed. New York, McGraw-Hill, Inc., 1995, p 2186.

Normally, plasma inorganic phosphate is maintained between 3.0 and 4.5 mg/100 mL in adults and 4.0 to 5.0 mg/100 mL in children. Parathyroid hormone inhibits proximal tubular inorganic phosphate reabsorption and increases inorganic phosphate excretion. In animals that are thyroparathyroidectomized, parathyroid hormone is absent, and reabsorption of inorganic phosphate increases significantly and ultimately increases plasma inorganic phosphate levels. In patients with primary hyperparathyroidism, parathyroid hormone secretion is elevated and plasma levels of inorganic phosphate are low; however, steady-state urinary inorganic phosphate excretion is not markedly increased, because it depends largely on intestinal inorganic phosphate absorption. Dietary restriction of inorganic phosphate leads to almost 100 percent reabsorption of filtered inorganic phosphate and to reduction of urinary phosphate to zero. [47]

Hyperphosphatemia

Severe hyperphosphatemia occurs following tissue damage or cell death. A moderate to severe hyperphosphatemia may be caused by an impaired ability to excrete phosphorus secondary to renal failure. Other causes include iatrogenic, hypothermia, massive liver failure, and certain hematologic malignancies associated with high cell turnover. The increased cell turnover can be part of the malignancy or may be because of cell destruction when chemotherapy is instituted. Treatment involves administration of phosphate-binding antacids such as aluminum antacids and sucralfate, calcium citrate, calcium carbonate, and/or dialysis, especially in association with renal failure. [48] (Table 45-11) (Table Not Available) .

Hypophosphatemia

Hypophosphatemia has many causes and is severe when serum phosphorous levels fall below 1.0 mg/dL. Conditions causing such low phosphate levels include prolonged respiratory alkalosis or rapid cellular uptake. Severe hypophosphatemia with total-body deficiency usually reflects poor dietary intake and/or consumption of phosphate-binding antacids.

Hypophosphatemia occurs in alcoholism (50% of hospitalized alcoholics), ketoacidosis, osmotic diuresis, acidosis, and catabolic states. Depressed intake or absorption and increased urinary losses are common causes. In chronic alcoholics, reduction of the phosphorus content of skeletal muscle occurs as a result of renal phosphate loss. The hypophosphatemic syndrome includes phosphate trapping, rhabdomyolysis, cardiomyopathy, respiratory insufficiency secondary to profound muscle weakness, erythrocyte and leukocyte dysfunction, skeletal demineralization, metabolic acidosis, and nervous system dysfunction (Table 45-12) (Table Not Available) .

Before initiating treatment, the cause should be clearly identified with measurement of arterial blood gases, ionized calcium, magnesium, potassium, and serum and urinary phosphorus. Phosphate salts such as sodium or potassium phosphate are available enterally or intravenously. Multiplying the volume of distribution (400 mL/kg) by the desired change in inorganic phosphate provides the total amount to be administered. The rate of administration should not exceed 0.25 mmol/kg IV over 4 to 6 hours to avoid hypocalcemia and tissue damage. Oral supplementation is often limited to 30 mmol/d (1 g/d) due to induction of diarrhea. Hyperphosphatemia should be avoided because it can cause hypocalcemia and crystal deposition in the eyes, heart, lung, blood vessels, and kidneys. Most hypophosphatemic patients, for example with diabetic ketoacidosis or recovering

TABLE 45-12 -- Major Causes of Hypophosphatemia

from exercise, are not severely phosphorus depleted unless they have been sick for an extended time. They may typically be treated with a glass of milk (100 mg/dL or 33 mmol/L of phosphorus). After achieving normal serum phosphate levels, serum inorganic phosphate, ionized calcium, and a 24-hour urine sample should be followed to ensure that balance has been achieved.

/das/book/view/29494766/875/514.html

CHLORIDE PHYSIOLOGY

Chloride is the predominant anion in the extracellular fluid volume. Hyperchloremic, metabolic acidosis results from excess intake, and/or inadequate excretion due to renal dysfunction. When administering infusions to such patients, bicarbonate, acetate, citrate, or phosphate salts should be substituted for chloride salts.

Excess loss of chloride in gastric secretions or urine causes hypochloremic alkalosis. Chloride depletion tends to limit bicarbonate excretion, and this may be due to reduced delivery of chloride to the collecting tubules where chloride is needed for bicarbonate secretion via bicarbonate-chloride exchange. Additionally, sodium reabsorption is enhanced in chloride-depleted states, as it is generally associated with extracellular fluid volume depletion. When less chloride is available for reabsorption, a greater fraction of the sodium must be reabsorbed with bicarbonate via increased proton secretion. [49] Sodium or potassium chloride should be administered if intravascular volume depletion or hypokalemia is present. If these are not a problem, 0.1 N HCl should be administered via a central catheter. The dose of chloride is

GLUCOSE PHYSIOLOGY

Glucose is a crucial fuel source, and insulin facilitates glucose movement into cells in a process that also requires potassium and phosphate. Red blood cells, healing wounds, the brain, and the adrenal medulla require glucose for fuel, totaling approximately 2 mg/kg/min. When controlling blood glucose, close monitoring is crucial. Reagent strips containing glucose oxidase, used in conjunction with glucometers, provide rapid and reliable results. It is imperative to know the insulin regimen or oral hypoglycemic agent of each patient and then measure the blood glucose preoperatively, intraoperatively, and postoperatively. In addition the degree of end-organ damage, coronary artery disease, and autonomic neuropathy can contribute to the risk of aspiration, myocardial infarction, and peripheral neuropathy.

Hyperglycemia

Hyperglycemia (>180 to 200 mg/dL) is most often due to insulin deficiency, insulin receptor resistance, or glucose overadministration. Hyperglycemia produces osmotic diuresis, exacerbation of brain, spinal cord, [50] and renal damage by ischemia, [51] delayed gastric emptying, [52] hypophosphatemia, [52] delayed wound healing, [52] [53] and impaired white blood cell function. [53] [54] Maternal hyperglycemia increases

TABLE 45-13 -- Classification of Diabetes

(Not Available)

Modified from Foster DW: Diabetes mellitus. In Isselbacher KJ, Braunwald E, Wilson JD et al: Harrison's Principles of Internal Medicine. 13th ed. New York, McGraw-Hill, Inc., 1995, p 1980.

the risk of neonatal jaundice, the risk of neonatal brain damage, and fetal acidosis if the fetus becomes hypoxic.

Even with supramaximal levels of insulin, adults can only use glucose at a rate of 3 to 5 mg/kg/min at rest (approximately 240 mL/h of 5 percent solutions). The maximal rate of metabolism is less in stress states and more with increased metabolic rates. In general the rate of administration should be limited to 2 to 3 mg/kg/min (120 to 180 mg/kg/h), that is, 100 g/h for a 70 kg person (200 mL of a 5 percent dextrose solution/h). Healthy infants and children become hyperglycemic if 5 percent dextrose is included in maintenance fluids. [55] The maximal rate of glucose disposition in young children is 4 to 8 mg/kg/min, and the optimal rate is less than 5 mg/kg/min. [56] It is not clear that glucose administration is necessary for intraoperative management of most patients. [57]

DIABETES MELLITUS

Diabetes mellitus (Ch. 25) is the most common endocrine disease and is characterized by long-term complications involving the eyes, kidneys, nerves, and blood vessels. Diabetes is a major risk factor for heart disease, stroke, kidney disease, blindness, and nontraumatic amputations. The cause of diabetic complications is multifactorial including glycosylation of proteins and glucose reduction to sorbital, which functions as a tissue toxin. This pathophysiologic process is associated with a decrease in myoinositol content and metabolism, and with a decrease in sodium-potassium-adenosine triphosphatase activity. Hyperglycemia has been recognized as a major factor in the development of complications associated with diabetes. The patient population is not homogeneous, and several diabetic syndromes have been delineated. There are nearly 8 million diagnosed diabetics in the United States and another 8 million who are unaware of their diabetes. These numbers approach 10 percent of the overall population in this country. [58] (Table 45-13) (Table Not Available)

Management and Evaluation of Diabetes Mellitus

Treatment and evaluation of diabetes (Ch. 25) includes diet, oral hypoglycemic drugs, exercise, exogenous insulin,

TABLE 45-14 -- Classification of Insulin Preparations

(Not Available)

Modified from Stoelting RK, Dierdorf SF: Endocrine disease. In Anesthesia and Co-Existing Disease: 3rd ed. New York, Churchill Livingstone, 1993, p 340.

and weight reduction if warranted. There are a number of different insulin preparations including pork, beef, and human or recombinant. Most diabetics are prescribed a combination of a rapid-acting and intermediate-acting insulin before breakfast and before bedtime. Rebound hyperglycemia may follow a hypoglycemic reaction (the Somogyi effect). In the last decade, new therapies for new-onset insulin-dependent diabetes mellitus (IDDM) have been introduced including transplantation of pancreatic tissue as well as immunosuppression. It is important to realize that 15 percent of patients with IDDM have other autoimmune processes and that the IDDM probably is secondary to destruction of pancreatic beta cells in these instances (Table 45-14) (Table Not Available) .

Insulin therapy can result in anaphylactic and anaphylactoid reactions, especially in protamine-containing insulin preparations. Protamine-derived insulin is made from fish sperm and can cause immunologic sensitization when protamine reversal is administered after cardiopulmonary bypass or heparin reversal. [59] This protamine reaction can be devastating and includes profound hypotension, pulmonary vasoconstriction, and noncardiogenic pulmonary edema.

Successful perioperative glucose management depends on careful monitoring. Perioperative management of blood glucose during a brief surgical procedure in the diet-controlled diabetic will generally involve only monitoring of blood glucose immediately perioperatively and every 3 hours until oral intake is resumed. [60] [61] The preoperative physical examination and history may reveal extensive diabetic neuropathy, which may be seen as orthostatic hypotension, syncopal episodes, mono- or polyneuropathies, erectile or bladder dysfunction, and an electrocardiogram showing a loss of R to R variability. Patients may present with a number of additional findings including nonfamilial short stature, cerebrovascular disease, renal dysfunction, microalbuminemia, and tight waxy skin. In an estimated 30 to 40 percent of diabetic patients, glycosylation of the atlantooccipital joint may limit joint mobility and cause difficulty with airway management ("stiff-neck syndrome"). [62] [63] Laboratory evaluation of glycosylated hemoglobin (HbA_{1c}) is an accurate measure of the severity of hyperglycemia and has been shown to correlate directly with increasing rates of complications. Conversely, lower HbA_{1c} values are associated with decreased risk and can be considered a measure of the quality of the diabetic care. HbA_{1c} provides the best evidence of overall blood glucose control over the last 1 to 2 months and should replace the oral glucose tolerance test as the "gold standard" for diagnosing diabetes. [64] Basic electrolyte and renal function tests should be evaluated, especially if the patient has frequent urinary tract infections or renal impairment. [65]

The regimen selected to manage diabetics undergoing surgery depends on the severity of the diabetes and the magnitude of the surgery. Frequent glucose monitoring and preparation for insulin administration are essential for the diabetic patient requiring less than 50 units of insulin per day or oral hypoglycemic agents for control, and who requires brief surgery; and the diet-controlled diabetic having major surgery. Recommendations include discontinuation of long-acting insulin or oral hypoglycemic agents 1 to 2 days preoperatively, six evenly spaced meals per day, and short-acting insulin every 4 to 6 hours subcutaneously, with the dose adjusted according to glucose levels just before administration. Urine glucose and ketone bodies should be measured periodically.

The typical "sliding scale" is destined to fail because it involves the administration of a fixed dose after documentation of hyperglycemia. A small modification improves control. The selected dose should be administered every 4 to 6 hours, based on response. If the glucose is below 60 mg/dL, the dose should be held for at least an hour, and 50 percent dextrose IV, 0.01 to 0.02 ml/kg/min administered, with blood glucose monitored hourly. When the blood glucose is above 125 mg/dL without supplemental dextrose infusion, the next insulin dose should be 20 to 40 percent lower. If the glucose is less than 100 or is less than 125 mg/dL and falling, the scheduled dose should be maintained until the hourly measured glucose is above 125, followed by resumption with a 10 to 20 percent lower dose. If the glucose level is 100 to 200 mg/dL and stable, the current dose and interval are continued. If the glucose level is 200 to 350 mg/dL, the scheduled dose is increased by 10 to 20 percent. If the glucose level is over 350 mg/dL, the dose is increased by 20 to 40 percent.

On the day of surgery, a dextrose infusion (2 mg/kg/min) is started at the time a meal would have been ingested and glucose measured preoperatively. For patients currently receiving insulin, an insulin infusion (0.25 units/mL) is started at a rate of 0.5 to 1.25 units/h, depending on the amount of insulin normally administered and the current glucose level. Blood glucose is monitored hourly and the infusion rate adjusted to maintain glucose 100 to 200 mg/dL. After the blood glucose is stable, urine glucose and ketone bodies are checked to ensure that glycosuria due to a low threshold will not confuse interpretation of urine output.

A more intense monitoring and treatment regimen is recommended for (1) patients requiring more than 50 units/d for control, (2) diabetics in poor control, or (3) the insulin-treated

diabetic undergoing major surgery. Long- and intermediate-acting insulin is discontinued, and the patient is managed with an intravenous insulin infusion or scheduled subcutaneous insulin perioperatively. Oral intake must be stopped 12 hours before anesthesia because some element of gastroparesis will exist in these patients. Typically, patients are administered a histamine $_2$ -blocker along with a gastric-emptying drug such as metoclopramide the night before and the morning of surgery.

The gastrointestinal tract is a prime target for autonomic neuropathy, and there may be esophageal dysfunction with difficulty swallowing, constipation, or diarrhea. When oral intake stops, maintenance fluids containing dextrose at 2 mg/kg/min are started and should be continued throughout the procedure. Glucose is measured before induction and hourly until stable postoperatively. Urinary ketones are measured every 6 hours. An insulin infusion is started with an initial rate of 1 to 2 units/h, or to match the amount administered hourly the previous day if good control was achieved. Patients with obesity, liver disease, steroid therapy, or severe infection require higher doses. Glucose levels should be maintained at 100 to 200 mg/dL and urinary ketones negative. Extremely high rates (up to 80 units/h) may be required during stressful procedures (e.g., cardiopulmonary bypass). [66] When the glucose level has remained stable and within the desired range for 3 hours, the frequency of glucose measurement can be decreased.

Provided a patient has reasonable glucose control (<250 mg/dL), an alternative to an infusion would be to hold all short-acting insulin and give half the intermediate or long-acting insulin the morning of the surgery. It is imperative to provide close preoperative, intraoperative, and postoperative glucose and electrolyte monitoring. Additionally, careful titration of a D_5W drip with an initial intravenous rate of 75 mL/h will prevent hypoglycemia or hyperglycemia. Diabetic ketoacidosis, dehydration, impaired wound healing, and electrolyte imbalance are minimized with the proper use of exogenous insulin. There is no clear consensus either to the method of insulin therapy or the exact range of blood glucose that will affect morbidity or mortality. [67] If a general anesthetic is used, clinical consideration would include a rapid-sequence induction owing to the high rate of gastroparesis. Cerebrovascular accidents, peripheral vascular disease, and cardiovascular infarction are 2- to 10-fold more common in diabetics. Strategies designed to reduce the risk of labile blood pressures and myocardial ischemia related to autonomic or vascular disease might include beta-blockade to blunt the stress of induction, a narcotic based anesthetic to minimize cardiopulmonary depression, and prophylactic nitroglycerin in these patients with their significant risk of coronary artery disease. Commonly associated conditions include obesity and stiff cervical joints, which may make airway management challenging. Associated cardiovascular conditions often result in the need for additional invasive monitoring.

Diabetic Ketoacidosis

Diabetic ketoacidosis is an emergent condition that often presents in the diabetic patient with leukocytosis and an acute surgical abdominal emergency and/or with nausea, vomiting, lethargy and signs of hypovolemia. The priorities are to restore intravascular volume (usually 1 L of saline IV rapidly), administer regular insulin (0.2 units/kg) followed by an infusion at a rate of 0.1 units/kg/h, eliminate the ketonemia, control blood glucose, and correct the underlying problem (e.g., antibiotics for urosepsis or pneumonia). Patients with ketoacidosis are dehydrated as a result of glucosuria; because the dehydration is due to water and electrolyte loss, colloids are not indicated. If the patient's osmolality is elevated, 0.45 percent sodium chloride can be administered, and the volume administered should be guided by the hemodynamic response and urinary output. When the blood glucose falls below 300 mg/dL, dextrose should be added to the fluids. Urine ketones are monitored every 2 hours after the blood glucose is within 100 to 200 mg/dL. If ketones are still present, the rate of glucose and insulin infusions should both be increased. The osmotic diuresis promotes loss of sodium, potassium, magnesium, and phosphate. Despite total body deficiencies, however, their concentrations may be elevated at the time of presentation owing to severe water loss. Alternatively, severe hyperglycemia may extract water from the intracellular space and may dilute the electrolyte concentrations. If the initial potassium is elevated or the patient is anuric, potassium should not be administered. As hydration improves and urinary output increases, potassium, magnesium, and phosphorous should be administered and monitored frequently. In general, the acidosis per se should not be treated with buffers. The ketoacidosis will correct as insulin and glucose levels improve, and the lactic acidosis resulting from poor perfusion will respond to intravascular fluid replacement. If the pH approaches 7.15, the bicarbonate ion concentration is less than 10 mEq/L and hypotension fails to respond to intravascular fluid administration, sodium bicarbonate therapy may be required.

Hypoglycemia

Hypoglycemia (<50 mg/dL) is dangerous, as glucose is the sole fuel source for much of the brain. Threshold levels depend on age range. Signs of hypoglycemia include irritability, seizures, bradycardia, hypotension, and respiratory failure. Symptoms commonly occur in adults at blood glucose concentrations below 57 mg/dL or 30 to 50 mg/dL in infants. Symptoms are seen at higher levels in diabetics than in nondiabetics and are obscured by general anesthesia. A biochemical stress response occurs at about 70 mg/dL, including sympathetic nervous system stimulation and elevated growth hormone and/or cortisol levels. Neurologic and electroencephalographic depression appears at 50 to 55 mg/dL in nondiabetics and 70 to 85 mg/dL in diabetics. [68] Selective neuronal necrosis, not infarction, occurs in the caudate, putamen, and cortex. There is a compensatory increase in cerebral blood flow. During labor, maternal starvationinduced ketosis has adverse fetal effects, including fetal ketonemia, hypoxia, and fetal lactic acidosis. [69] Neonates are at an increased risk for hypoglycemia because of limited glycogen stores and from large amounts of fetal insulin production in response to gestational hyperglycemic states. Adults are also at risk of hypoglycemia from either inadequate gluconeogenesis coupled with inadequate nutritional intake, or from excess insulin (e.g., due to an insulinoma, pancreatic islet cell adenoma or carcinoma, or iatrogenic overadministration).

Hypoglycemia can also follow too abrupt cessation of dextrose infusion during total parenteral nutrition (reactive hyperinsulinemic states). Inadequate gluconeogenesis occurs in liver failure, cortisol deficiency (primary or secondary), inadequate glucagon response, growth hormone deficiency, and during beta-adrenergic blockade. Fasting in women is likely to produce hypoglycemia in 24 hours, whereas men tolerate about 72 hours of fasting. [52] The incidence of hypoglycemia in healthy infants and children is low (2 of 446) with 4 to 8 hours of fasting. [56] Fetal hypoglycemia occurs if maternal glucose is greater than 150 mg/dL, because glucose crosses the placenta, inducing fetal insulin secretion. Treatment consists of an intravenous bolus of 5 g of dextrose followed by increasing the rate of dextrose infusion by 1 to 2 mg/kg/min.

ACID-BASE FACTORS

The necessity for treating a metabolic acidosis is judged largely on clinical grounds, with the metabolic acid level base excess (BE) used to determine the correct dose of bicarbonate (Ch. 38) . This prediction is based on the size of the treatable space and the magnitude of the problem:

The dose calculated will be sufficient to return the metabolic disturbance to about zero. However, bicarbonate therapy is reserved for emergencies and situations in which indications for therapy are compelling. It is usual to give a reduced dose, about half, because:

1. The bicarbonate is injected initially into the plasma volume, about 3 L, instead of into the calculated treatable space, 21 L.
2. When bicarbonate is added to acid it "fizzes." Fortunately, this does not occur literally in the blood. Nevertheless, the majority of the bicarbonate is converted to carbon dioxide and has to be eliminated. For each 100 mEq that is converted, about 2.24 L of carbon dioxide has to be exhaled, equivalent to 10 minutes of normal production.
3. The carbon dioxide that is produced enters the cells freely, unlike the bicarbonate ions that have been administered. Therefore, the inside of the cell might initially become even more acid. However, direct studies with nuclear magnetic resonance have not confirmed this (Severinghaus, personal communication 1986).
4. The bicarbonate is accompanied by sodium ions that will be responsible for a residual increase in the osmolality of the extracellular fluid. In combination with other therapy, such as intravenous glucose, the hyperosmolality may be critical and cause coma. In neonates, rapid infusion of bicarbonate may cause intracranial hemorrhage.
5. If the body deals with its metabolic acidosis there is a residual metabolic alkalosis.

Anion Gap

Some causes of metabolic acidosis release anions into the extracellular fluid that are not normally measured. When this occurs, there is an unexpected discrepancy between the sums of the principal cations and anions. The usual sum is the following:

When there are any additional, unmeasured anions, they become part of the "gap," which is then correspondingly larger. A gap greater than 30 suggests that there is an increase in the concentration of the unmeasured anions. Unfortunately, this method relies on the accuracy of the other measurements. Small errors in these large numbers cause a proportionately greater error in the result. If information is required about these anions, it is more appropriate to measure their concentration. In practice it suffices to analyze lactate in tissue hypoxia, 3-hydroxybutyrate in diabetic ketosis, and phosphate or sulfate in renal failure.

The common causes of perioperative metabolic alkalosis include antacid therapy, incidental administration of citrate with blood products, $NaHCO_3$ administration, gastric drainage, or renal bicarbonate retention owing to diuresis, or in compensation for respiratory acidosis. NaCl or KCl can be administered orally or via a peripheral intravenous catheter, or 0.1 normal HCl may be administered slowly through a central venous catheter. The required dose is calculated as follows:

CLINICAL ACID-BASE BALANCE DISTURBANCES

This section provides practical clinical cases and examples which can be reviewed to assist in understanding acid-base balance.

Metabolic Acidosis Resulting From Low Cardiac Output

A patient with coronary artery disease and an ejection fraction of 15 percent suffers myocardial perforation while undergoing balloon angioplasty in the cardiac catheterization laboratory. After resuscitation, intubation, insertion of an arterial line, and initiation of dopamine by infusion, the patient is transferred to the operating room for emergency thoracotomy. Blood pressure is 80/50 mm Hg, and the heart rate is 120 beats/min. During preparation for central venous cannulation, the blood pressure falls, followed by cardiac arrest. The patient undergoes immediate thoracotomy; blood gases obtained at the time reveal: pHa = 7.15, Pa $_{CO_2}$ = 35 mm Hg, BE = -15 mEq/L, bic = 12, Pa $_{O_2}$ = 90 mm Hg--a severe metabolic acidosis with mild respiratory alkalosis. After the administration of four units of packed red cells and the administration of 88 mEq of sodium bicarbonate, repeat blood gases reveal: pHa = 7.14, Pa $_{CO_2}$ = 39 mm Hg, BE = -14 mEq/L, bic = 13, Pa $_{O_2}$ = 95 mm Hg--still a severe metabolic acidosis but now with no respiratory alkalosis.

Clinical Pearl.

The first blood gas reveals a metabolic acidosis attributable to the low cardiac output with tissue ischemia, with slight hyperventilation. The second blood gas shows almost no benefit from the bicarbonate probably due to the continuing low cardiac output. Bicarbonate is converted to CO_2, which could explain the slightly higher Pa $_{CO_2}$.

Metabolic Acidosis During Anhepatic Phase

A patient with end-stage liver disease secondary to viral hepatitis is undergoing orthotopic liver transplantation. Blood gas analysis performed late in the anhepatic phase (Ch. 55) , after earlier administration of bicarbonate, reveals: pHa = 7.10, Pa $_{CO_2}$ = 28 mm Hg, BE = -18 mEq/L, bic = 8.6, Pa $_{O_2}$ = 260 mm Hg, Na^+ = 153 mEq/L--a severe metabolic acidosis with a moderate respiratory alkalosis. The patient is treated with 500 mL (150 mEq, 18 g) of 0.3 molar solution of tris(hydroxymethyl)-aminomethane (THAM) by infusion over 20 minutes. Repeat blood gas analysis shows: pHa = 7.09, Pa $_{CO_2}$ = 30 mm Hg, BE = -18 mEq/L, bic = 9.0, Pa $_{O_2}$ = 251 mm Hg, Na^+ = 154 mEq/L. A second dose of THAM is administered by infusion. After the transplantation is completed, blood gas analysis shows: pHa = 7.30, Pa $_{CO_2}$ = 33 mm Hg, BE = -9 mEq/L, bic = 16, Pa $_{O_2}$ = 283 mm Hg, Na^+ = 149 mEq/L--a marked metabolic acidosis with a mild respiratory alkalosis typical of a partially compensated metabolic disturbance.

Clinical Pearl.

The metabolic acidosis during the anhepatic phase demonstrates the importance of the liver in metabolizing lactate to bicarbonate. The high sodium mitigated against repeat administration of sodium bicarbonate. In this case, THAM was used to minimize sodium administration while controlling the metabolic acidosis. On reperfusion (phase 3), the new liver started to function, and there was improvement in the metabolic acidosis.

Metabolic Alkalosis Following Diuretics

A 4-kg male infant aged 3 months presents for repair of an atrioventricular canal (Ch. 50) . The patient's congenital heart failure has been controlled with digitalis and furosemide. Before induction of anesthesia, the blood gases were: Pa $_{O_2}$ = 110 mm Hg, pHa = 7.53, Pa $_{CO_2}$ = 44 mm Hg, bic = 35.9, BE = 14 mEq/L--a severe metabolic alkalosis with a minimal respiratory acidosis typical of a partially compensated metabolic disturbance. Following induction of anesthesia, blood gas analysis showed: pHa = 7.61, Pa $_{CO_2}$ = 35 mm Hg, BE = 14Eq/L, bic = 34, Pa $_{O_2}$ = 60 mm Hg. Following completion of the procedure and cessation of cardiopulmonary bypass, the blood gases showed: pHa = 7.40, Pa $_{CO_2}$ = 33 mm Hg, BE = -4 mEq/L, bic = 20.

Clinical Pearl.

The hypochloremic alkalosis that accompanies prolonged administration of furosemide explains the first set of results. After induction the hyperventilation decreased the Pa $_{CO_2}$ but had no effect on the base excess. Two major factors explain the change during the procedure: (1) hemodilution tends to return the pHa toward neutral (6.8 at body temperature) and (2) low perfusion during bypass frequently produces a metabolic acidosis which, in this case, also helped to overcome the initial metabolic alkalosis.

Chronic Respiratory Failure in a Neonate

A 3.5 kg male infant aged 2½ months with bronchopulmonary dysplasia is intubated and receiving oxygen (F $_{IO_2}$ = 0.3). He presents for cryoablation for proliferative retinopathy (Chs. 58 and 59). After the patient was transported to the operating room, blood gas analysis showed: pHa = 7.27, Pa $_{CO_2}$ = 65 mm Hg, BE = 3 mEq/L, bic = 29, Pa $_{O_2}$ = 35 mm Hg. Anesthesia is induced, and ventilation is controlled with a V_T of 60 mL, peak inspiratory pressure = 25 cm H_2O, positive end-expiratory pressure = 4 cm H_2O, respiratory rate = 40 breaths/min, no inspiratory pause, F $_{IO_2}$ = 0.3. Repeat blood gases show: pHa = 7.36, Pa $_{CO_2}$ = 50 mm Hg, BE = 3 mEq/L, bic = 28, Pa $_{O_2}$ = 48 mEq/L.

Clinical Pearl.

The mild metabolic alkalosis of the first analysis is compatible with compensation for chronic respiratory failure. The high Pa $_{CO_2}$ represented hypoventilation during transport. Appropriate selection of the ventilator settings returned the Pa $_{CO_2}$ to a value more typical for a neonate with bronchopulmonary dysplasia with a pHa about half way between no compensation and complete compensation.

Preparation for Chronic Hyperventilation

The author (AK) was a member of a team providing plastic surgery at high altitude. For two days preceding the trip, he was advised to take a carbonic anhydrase

inhibitor, acetazolamide, which would effectively slow the normal reversible reaction between carbonic acid and its dissociation products, carbonic acid and water. The effect of this drug is to alkalinize the urine and produce a moderate metabolic acidosis, the typical response to hypoxic hyperventilation at altitude. A typical blood gas after acclimatization to altitude might be: pHa = 7.42, Pa CO_2 = 31 mm Hg, BE = 4 mEq/L, bic = 19, Pa O_2 = 80 mm Hg.

Clinical Pearl.

The benefit of taking acetazolamide is debated by climbers, and the drug is not without side effects. During the initial experience of taking acetazolamide at sea level, a striking, if minor, side effect is the metallic taste associated with drinking any carbonated beverage, presumably attributable to the inability to convert the high CO_2 content in the beverages to carbonic acid.

Acute Hyperventilation and Hypotension

An elderly female, height 5 ft, weight 48 kg, blood pressure 115/75 mm Hg, heart rate 70 bpm, receiving no medications and in otherwise normal health, was scheduled for laparotomy and hysterectomy. After induction and orotracheal intubation, controlled ventilation was initiated with a tidal volume of 900 mL and a respiratory rate of 12 breaths/min. Shortly before incision, arterial blood pressure was 58/35 mm Hg and the end-tidal P CO_2 was 22 mm Hg. (Blood gases were not drawn, but typical values for a patient experiencing such acute hyperventilation would be: pHa = 7.53, Pa CO_2 = 26 mm Hg, bic = 21 mg/L, BE = 0 mg/L). The ventilator was immediately reset to provide 4 breaths per minute at a tidal volume of 500 mL. Arterial blood pressure about 2 minutes later was 85/55 mm Hg, and the next reading about 2 minutes later still was 95/65 mm Hg. The patient's end-tidal P CO_2 increased more slowly, and after about 8 minutes had returned to 36 mm Hg when the ventilatory rate was increased to 8 breaths/min. (Typically her blood gases would now be near normal, e.g., pHa = 7.44, Pa CO_2 = 38 mm Hg, bic = 23.3 mEq/L, BE = 0 mg/L).

Clinical Pearl.

Hyperventilation following induction is common and frequently contributes to hypotension by various methods including raised intrathoracic pressure, diminished venous return, and depressed cardiac output.

Acute Hypoventilation

An obese middle-aged female was undergoing laparoscopic cholecystectomy. After a routine induction and orotracheal intubation, low flow anesthesia was initiated and the ventilator was set to provide a tidal volume of 700 mL at a rate of 10 breaths/min (measured exhaled tidal volume was 560 mL). Ten minutes after induction of anesthesia, the P CO_2 was 35 mm Hg, the peak airway pressure was 28 mm Hg. Arterial blood gases drawn then showed: pHa = 7.43, Pa CO_2 = 35 mm Hg, bic = 22.4, BE = -1 mEq/L. Thirty minutes into the procedure, the peak airway pressure was 48 mm Hg, the end-expired P CO_2 was 49 mm Hg, and the measured exhaled tidal volume was 380 mL. Repeat blood gases showed: pHa = 7.27, Pa CO_2 = 55 mm Hg, bic = 24.9, BE = -1 mEq/L. The principal abnormality is a marked respiratory acidosis with no metabolic acidosis. It is characteristic of an acute respiratory disturbance.

Clinical Pearl.

The rise in Pa CO_2 can be attributed to two factors: (1) uptake of the inflating gas, CO_2, in the abdomen and (2) reduction of effective ventilation due to raised airway pressure required to overcome abdominal distention. The discrepancy between end-tidal P CO_2 and arterial blood gas Pa CO_2 is typical and results from the patient's temperature being slightly less than that of the analyzer, lack of time between breaths to reach true end-tidal equilibration, normal pulmonary maldistribution, and the slight loss occurring on the length of the tubing.

FLUID BALANCE AND FLUID REPLACEMENT SOLUTIONS

More than 22 million blood components are transfused each year in the United States, [70] many to surgical and obstetric patients. The transfusions of red blood cells, platelets, fresh frozen plasma, and cryoprecipitate have the potential for improving clinical outcomes in perioperative and peripartum settings. Benefits include improved tissue oxygenation and decreased bleeding; however, transfusions are not without risks or costs. Transmission of infectious diseases (e.g., hepatitis, human immunodeficiency virus infection), hemolytic and nonhemolytic transfusion reactions, immunosuppression, alloimmunization, and other complications are potential sequelae of blood component therapy. Although red blood cells and coagulation products have excellent volume-expanding capacity, they are not considered in this chapter (Ch. 46) .

In 1994, the American Society of Anesthesiologists convened the Task Force on Blood Component Therapy to develop evidence-based guidelines on the proper indications for perioperative and peripartum administration of red blood cells (RBCs), platelets, fresh frozen plasma, and cryoprecipitate. This section details only basic crystalloid, colloid, and hypertonic solution recommendations applicable to typical surgical and obstetric patients. Infants, children, and special clinical settings are found elsewhere in this book (Ch. 59) (Table 45-15) .

SURGICAL FLUID BALANCE

Physiologic changes during surgery and anesthesia lead to shifts in fluid balance. For example, epidural, spinal, or caudal anesthesia may all cause variable amounts of sympathetic blockade. Although younger and healthier patients may tolerate sympathectomy, patients who are severely dehydrated, or on antihypertensive drugs or diuretics, may not be able to respond to the effects of sympathectomy. It is common to administer up to 1 L of fluid before placement of a spinal or to concurrently administer fluid when epidural anesthesia is being induced. Vasopressors, typically ephedrine or phenylephrine, are needed to overcome the hemodynamic effects of sympathetic block.

Although inhaled anesthetics do not directly alter fluid losses, all anesthetics may blunt the normal physiologic responses to hypovolemia and the stress response. The stress response to surgery involves an increase in antidiuretic hormone production, which can be blocked with anesthetics. Superimposed are the variable effects of intravenous and inhalational agents on the myocardium, venous return, blood pressure, and the vasculature. Mechanical ventilation can decrease the release of atrial natriuretic hormone and increase the release of antidiuretic hormone resulting in retention of sodium and fluids.

In addition to blood loss, significant third space loss may occur, which essentially involves fluid that is still in the body but not contributing to intravascular volume, oxygen delivery, or waste removal; this is difficult to measure. Simple restoration of blood volume can be inadequate to ensure survival. [71] Patients undergoing major surgical procedures

require fluid replacement beyond simple blood loss, and the anesthesiologist plays a vital role in assessing and ultimately administering appropriate fluid therapy in intraoperative and postoperative clinical settings.

Crystalloids

Crystalloids are fluids that contain water and electrolytes. They are grouped as balanced, hypertonic, and hypotonic salt solutions. Crystalloid solutions are used to both provide maintenance water and electrolytes and expand intravascular fluid. The replacement requirement is 3- or 4-fold the volume of blood lost because administered crystalloid is distributed in a ratio 1:4 like extracellular fluid, which is composed of about 3 L intravascularly (plasma) and about 12 L extravascularly (i.e., about 20% should remain in the intravascular space).

Balanced Salt Solutions

Balanced salt solutions have an electrolyte composition similar to extracellular fluid (ECF), (e.g., lactated Ringer solution, Plasma-Lyte, and Normosol). With respect to sodium, they are hypotonic. A buffer is included in place of bicarbonate, which hydrates to carbonic acid, with production of carbon dioxide, which diffuses from the solution. Compared with 0.9 percent NaCl, these solutions provide small quantities of other electrolytes, which are inadequate to meet daily maintenance requirements.

Normal Saline

Normal saline, 0.9 percent NaCl, is isotonic and isoosmotic but contains more chloride than ECF. When used in large volumes, mild hyperchloremia (non-anion gap metabolic acidosis) results. It contains no buffer or other electrolytes. It is preferred to lactated Ringer solution (which contains a hypotonic concentration of sodium) when brain injury, hypochloremic metabolic alkalosis, or hyponatremia is present. Many patients with hyperkalemia, including patients with renal failure who are frequently in the operating room for vascular access bypass procedures, routinely receive normal saline, as it contains no potassium.

Hypertonic Salt Solutions

These solutions are less commonly used, and their sodium concentrations range from 250 to 1,200 mEq/L. The greater the sodium concentration, the less the total volume required for satisfactory resuscitation. This difference reflects the movement due to osmotic forces of water from the intracellular space into the extracellular space. In addition the reduced volume of water injected may reduce edema formation. This could be crucial in patients predisposed to tissue edema (e.g., prolonged bowel surgery, burns, brain injuries). Clinical studies have confirmed that a moderately hypertonic solution (Na = 250 mEq/L) can be associated with lower muscle interstitial pressure than lactated Ringer solution. Additionally, bowel function returned earlier, although pulmonary shunt fraction was no different. [72] Experimental

studies have demonstrated lower intracranial pressures in animals receiving hypertonic solutions. However, the intravascular half-life of hypertonic solutions is no longer than isotonic solutions of an equivalent sodium load. In most studies, sustained plasma volume expansion was achieved only when colloid was present in the resuscitation solution. Moreover, the osmolality of these solutions can cause hemolysis at the point of injection. [73] Hypertonic solutions have not gained widespread acceptance as resuscitation or intraoperative maintenance solutions, and these solutions are used primarily in the correction of hyponatremia.

Five Percent Dextrose

Five percent dextrose functions as free water, because the dextrose is metabolized. It is iso-osmotic and thus does not cause the hemolysis that would occur if pure water were injected intravenously. It may be used to correct hypernatremia, but is most often used in the prevention of hypoglycemia in diabetic patients who have had insulin administered.

Crystalloids Versus Colloids

Much controversy exists about the role of crystalloids and colloids (Ch. 45) in fluid therapy. Proponents of colloid fluid point out that resuscitation with crystalloid solution dilutes the plasma proteins, with a subsequent reduction of plasma oncotic pressure resulting in fluid filtration from the intravascular to the interstitial compartment and the development of interstitial pulmonary edema. Proponents of crystalloid solutions have argued that albumin molecules normally enter the pulmonary interstitial compartment freely and then are cleared via the lymphatic system returning to the systemic circulation. Thus, additional albumin should merely increase the albumin pool cleared by the lymphatics. A review of the literature by Moss and Gould [74] confirmed that all unflawed clinical and experimental studies showed that isotonic solutions are effective plasma volume expanders for resuscitation without the addition of a variety of colloid fluids. The additional cost and potential risks of colloids compared with crystalloids is another argument against colloid administration.

Colloids used in the United States include albumin, hydroxyethyl starch (hetastarch), and dextran. Because the molecules are large, colloids usually do not cross capillary membranes and remain intravascular. Distribution of fluid throughout the body is represented by the Starling-Landis equation:

where J_v represents the net volume of fluid moving across the capillary wall per unit of time (cubic microns per minute); K_h is the hydraulic conductivity for water, which is the fluid permeability of the capillary wall, expressed as cubic microns per minute per square micron of capillary surface area per mm Hg pressure difference. The value of K_h increases up to 4-fold from the arterial to the venous end of a typical capillary. P_{MV} is the capillary hydrostatic pressure; P_T is the tissue hydrostatic pressure; A is the capillary surface area; delta is the reflection coefficient for plasma proteins. This coefficient is necessary because the plasma proteins are slightly permeable to the microvascular wall, preventing full expression of the two colloid osmotic pressures. When delta is 0, molecules freely cross the membrane; when delta is 1, molecules cannot cross the membrane. Typical delta values for plasma proteins in the microvasculature exceed 0.9 in most organs, and these values remain constant but can be decreased significantly by pathophysiologic processes including hypoxia, inflammatory processes, and tissue injury. COP_{MV} is the colloid oncotic pressure; and COP_T is the colloid oncotic pressure in the tissue.

The hydrostatic and colloid pressure differences across capillary walls (Starling forces) cause movement of water and dissolved solutes into the interstitial spaces. These movements play a minor role with regard to tissue nutrition relative to simple diffusion. The reflection coefficient that expresses the ability of the semipermeable membrane to prevent movement of a solute varies greatly among tissues. The lungs are moderately permeable relative to other organs and during pathophysiologic processes such as surgical trauma, the reflection coefficient may further change to alter capillary permeability, resulting in increased capillary permeability or leak. In this setting, colloids move more easily into the interstitium and increase interstitial edema.

With leakage of colloid molecules into the interstitial space, further swelling of tissues occurs due to the unfavorable oncotic pressure gradient, and these molecules are removed by the lymphatic system. Removal of colloids requires longer periods than for crystalloids and is a significant problem in burn and major surgical patients. A well-known meta-analysis is by Velanovich [74A] of mortality from eight studies concluded that trauma patients should be resuscitated with crystalloid solutions, whereas colloids were more effective in nonseptic, nontraumatic elective surgical patients.

COLLOID SOLUTIONS AND BLOOD SUBSTITUTES

Colloid solutions are generally administered in a volume equivalent to the volume of blood lost (Ch. 46) . The initial volume of distribution is equivalent to the plasma volume. The half-life in circulation of albumin is normally 16 hours, but it can be as short as 2 to 3 hours in pathophysiologic conditions. [75] The synthetic colloids, processed albumin, and protein fractions have minimal if any risk of infection. Blood substitutes are useful to restore intravascular fluid volume temporarily until definitive treatment can be established. They are inexpensive, have a long storage life, and lack the risk of transmitting viral diseases.

Five Percent Albumin

Five percent albumin or plasma protein fractions (e.g., Plasmanate) have a colloid osmotic pressure of about 20 mm Hg (i.e., near-normal colloid osmotic pressure). Preparation methods eliminate infectious agents. These solutions are chosen when crystalloids fail to sustain plasma volume for

more than a few minutes owing to low colloid osmotic pressure. These solutions are most appropriate when there is an abnormal loss of protein from the vascular space, for example, in peritonitis or in extensive burns.

Twenty-Five Percent Albumin

A colloid solution of 25 percent, or "salt-poor," albumin contains purified albumin at five times the normal concentration. When administered, it has the potential to expand the plasma volume by up to five times the volume provided. It is selected when the current plasma volume is diminished, but blood pressure is acceptable, and the total extracellular fluid volume is expanded.

Six Percent Dextran 70

Dextran is available as either dextran 40 or dextran 70. The numbers 40 and 70 refer to the average molecular weight of the molecules in the solution. The mean molecular weight of dextran 40 is about 40,000, and the mean molecular weight of dextran 70 is about 70,000. The dextran solutions are water-soluble glucose polymers synthesized by certain bacteria from sucrose. Both dextran solutions are ultimately degraded enzymatically to glucose. A colloid solution of 6 percent Dextran 70 is administered for the same indications as 5 percent albumin. Dextran 40 is used in vascular surgery to prevent thrombosis and is rarely used as a volume expander.

Side effects include anaphylactic or anaphylactoid reactions in about 1 in every 3,300 administrations, increased bleeding time caused by decreased platelet adhesiveness (at doses of 20 mL/kg/24 h), rouleaux formation (interfering with cross-matching of blood), and rare cases of noncardiogenic pulmonary edema thought to be a direct toxic effect on pulmonary capillaries following intravascular absorption. [76] [77]

Hydroxyethyl Starch

Hydroxyethyl starch (hetastarch) is a synthetic colloid solution in which the molecular weight of at least 80 percent of the polymers ranges from 10,000 to 2,000,000. It is available in the United States as a 6 percent solution in 0.9 percent sodium chloride (Hespan). The pH of hetastarch is about 5.5 and the osmolarity is near 310 mOsm/L. The larger molecules are degraded enzymatically by amylase. It is stored in the reticuloendothelial system for several hours and is believed to be ultimately renally excreted. It produces dilutional effects similar to other volume expanders and also reduces factor VIII:C levels by 50 percent in a dose of 1 L with prolongation of the partial thromboplastin time. [78] Hetastarch can also interfere with clot formation by direct movement into the fibrin clot by the hetastarch molecules. In clinically recommended volumes, (i.e., 20 mL/kg), there is minimal interference with subsequent crossmatching. Repeated doses can result in accumulation and side effects, which include allergic reactions and bleeding as described with higher doses (20 to 25 mL/kg.)

Pentastarch

Pentastarch is a lower molecular weight hetastarch with less hydroxyethyl groups per molecule. It is currently undergoing clinical trials in the United States and has similar anticoagulant effects as hetastarch.

Perfluorochemical Emulsions and Stroma-Free Hemoglobin

Perfluorochemical emulsions have linear oxygen-carrying capacity but are insufficient to sustain human cellular function and therefore are not clinically useful at this time. [79] Stroma-free hemoglobin solutions are produced by processing human or animal red blood cells. Initial studies of stroma-free hemoglobin have shown potential harm in renal function and are not approved for clinical use, although these compounds have similar oxygen-carrying capacity as normal hemoglobin.

FLUID MANAGEMENT OF SPECIFIC CLINICAL CONDITIONS

The following guidelines are intended to facilitate initiating therapy, but the choice of fluid and rate of administration must be adjusted to achieve physiologic goals (i.e., the guidelines below are *a* starting point (not *the* starting point) for patients without other major comorbidity of vital organs. Careful observation of the patient's response forms the basis for ongoing modification in a continuous feedback loop.

Routine Maintenance Fluids

Routine maintenance fluids for a 70-kg postoperative patient include the following. The patient requires 110 mL H_2O and 110 kcal/h, or 2,640 mL and 2,640 kcal/d. This example is based on the 4-2-1 rule (Table 45-16) , which provides a close approximation of water requirements. The sodium requirement (1.5 mEq/kg/d) is dissolved in the daily fluid requirement of 2.64 L; 100 mEq/kg/d requirement for potassium is placed in the 2.64 L/d water requirement: 100 mEq K/2.64 L = 42 mEq/L. However, the potassium concentration needs to be limited if the fluid is to be infused into a peripheral vein because of the chemical irritation induced

TABLE 45-16 -- Example of Calculations of Fluid Requirements by the 4-2-1 Rule [a]

BODY WT (kg)	FLUID RATE (mL/kg)	WEIGHT CATEGORY (kg)	FLUID (mL/h)
0-10	4	10	40
11-20	2	10	20
21+	1	5	5
Total	--	25	65

[a] Assumes a patient weighing 25 kg, resulting in an estimated fluid requirement of 65 mL/h

TABLE 45-17 -- Volume and Composition of Gastrointestinal Fluids

	24-HR VOLUME mL	NA^+ mEq/L	K^+ mEq/L	CL^- mEq/L	HCO_3^- mEq/L
Saliva	500-2,000	2-10	20-30	8-18	30
Stomach	1,000-2,000	60-100	10-20	100-130	0
Pancreas	300-800	135-145	5-10	70-90	95-120
Bile	300-600	135-145	5-10	90-130	30-40

by high concentrations of potassium. The obligatory glucose needs of the brain and RBCs consume roughly 2 mg/kg/min glucose. Dextrose contains 3.41 kcal/g instead of 4 kcal/g of glucose, so about 17 percent more dextrose than glucose is required. If carbohydrate is not provided, glycogenolysis and gluconeogenesis from amino acid pools will provide the necessary glucose, but will accelerate protein catabolism.

Thus, carbohydrate is said to prevent catabolism (i.e., protein sparing); however, the benefit of this dose of dextrose is not clear. Total starvation may be preferable because insulin concentrations decrease to very low levels, facilitating lipolysis as a caloric source. The osmolarity of 7.5 percent dextrose is 417 mOsm/L, to which one adds 156 mOsm/kg H_2O, resulting in a highly hyperosmolar solution. A compromise between the need for glucose and hyperosmolality has been 5 percent dextrose.

If there are other losses (e.g., gastric drainage), additional sodium and water are required. Gastric drainage of 0.5 L/d will lose 30 to 50 mEq of sodium and 50 to 65 mEq of chloride (Table 45-17) . When these are added to the maintenance fluid, the concentration approximates 0.45 percent NaCl. This solution is commonly used as a maintenance intravenous fluid postoperatively in patients with nasogastric drainage.

Routine Intraoperative Administration

The goals of intraoperative fluid administration are to maintain adequate oxygen delivery, normal electrolyte concentrations, and normoglycemia. The total fluid requirement is composed of compensatory intravascular volume expansion (CVE), deficit replacement, maintenance fluids, restoration of losses and substitution for fluid redistribution (third space fluids):

Rate = CVE + deficit + maintenance + loss + third space

Compensatory Intravascular Volume Expansion

Intravascular volume must generally be supplemented to compensate for the venodilation and cardiac depression caused by anesthesia. Sustaining adequate oxygen delivery in relation to oxygen consumption is an important goal of fluid therapy. Tissue oxygen delivery depends on hemoglobin concentration, oxygen tension, organ perfusion pressures, and organ vascular resistance. Organ perfusion pressures depend on systemic arterial pressure and the higher of organ venous pressure or tissue pressure. Arterial pressure depends on cardiac output and systemic vascular resistance. Cardiac output (CO) is related to stroke volume and heart rate; and stroke volume is dependent on preload, contractility, and afterload. Most general and regional anesthetics cause arteriolar and venous dilation, expanding the vascular capacity. The latter reduces peripheral venous pressure and, therefore, venous return and CO. Therefore, fluid must be administered to expand the blood volume to compensate for venodilation. Additionally, general anesthestics produce myocardial depression (Ch. 5) . Increasing cardiac preload, by infusing fluid intravascularly to take advantage of the Starling mechanism, often returns stroke volume to an acceptable range. Postoperatively, venodilation and myocardial

depression rapidly subside when administration of the anesthetic is stopped. Patients with impaired cardiac or renal responses may then become acutely hypervolemic. CVE with 5 to 7 mL/kg of balanced salt solution must occur before, or simultaneous with, the onset of anesthesia.

DEFICITS

The fluid deficit equals the maintenance fluid requirement multiplied by the hours since last intake plus unreplaced preoperative external and third space losses. When hypovolemia is present, sufficient fluid should be infused to restore mean arterial pressure, heart rate, and filling pressures to near normal values before induction. If sufficient time is available, restoration of normal urine flow rate is also desirable. If clinical signs of hypovolemia are present (neck vein distention, elevated central venous pressure (CVP) or pulmonary artery occlusion pressure, hemodynamics should be closely monitored without infusing a bolus of fluid intravascularly. The fluid infusion rate for normal patients should then be set to deliver three to four times the maintenance rate until the calculated deficit has been corrected.

Electrolyte abnormalities are common among hospitalized patients. Surgical urgency often forces us to evaluate and correct preexisting abnormalities that may be directly related to the surgical problem, or to comorbid diseases or their therapy. The principles of management of these are outlined in other sections of this chapter. The induction of anesthesia and the onset of mechanical ventilation, fluid

---

shifts, and stress responses induced by surgical trauma all lead to redistribution of water, protein, and electrolytes. The common and most studied of these are abnormalities of potassium, calcium, and magnesium.

Maintenance Fluid

The maintenance fluid meets ongoing basal needs for water and electrolytes as described earlier. The onset of surgical stimulation and to a smaller extent onset of anesthesia elicits changes in catecholamines, cortisol, and growth hormone. These tend to reduce insulin secretion or impede its glucose-lowering effect, leading to hyperglycemia. If dextrose-containing solutions are infused at the usual 5 percent concentration at the rates often required during surgery, severe hyperglycemia will result. Thus, the fluid used for volume maintenance should not contain dextrose.

LOSSES

External losses (e.g., blood, ascites) should be replaced to maintain normal blood volume and normal composition of the ECF volume. Blood loss is replaced initially with either 3 mL of balanced salt solution or 0.9 percent NaCl for each milliliter of blood loss. For each milliliter of blood lost, 1 mL of colloid solution should be administered to provide improvement of filling pressures, arterial blood pressure and heart rate. Packed RBC infusions are used at roughly 1 mL for each 2 mL of blood lost plus either crystalloid or colloid as described. Although the effect on volume is 1:1, the hematocrit of packed RBCs (PRBC) (60-70%) is about twice the necessary hematocrit of the patient. In patients with reasonable cardiac reserve and without compromised regional circulations (e.g., coronary, cerebral, renal, intestinal), hemoglobin levels of 7.5 g/dL and above are usually well tolerated. [80] If blood volume is normal and cardiac failure is not a problem, then signs of sympathetic activation, mixed venous oxygen desaturation, or electrocardiogram signs of myocardial ischemia suggest the need for RBC administration. The following equation is used to calculate the necessary volume of RBCs to be infused. Because packed RBCs have a hematocrit of 60 percent, the volume to be infused is found by dividing the volume of RBCs desired by the hematocrit of the unit of PRBCs.

Ascites and pleural effusions drained during surgery reform at extremely variable rates. The electrolyte composition is the same as that at the ECF volume, but it also contains protein at concentrations 30 to 100 percent of the plasma value. Balanced salt solutions are most appropriate for replacement, but colloid should be added when dilution of the patient's colloidal osmotic pressure (COP) becomes severe (<15-17 mm Hg) and the apparent volume of redistribution of crystalloid begins to increase.

The electrolyte composition of gastrointestinal tract losses is site dependent (see Table 45-17) . Most gastrointestinal losses removed at the time of surgery entered the bowel lumen preoperatively and should be considered to be part of the deficit. Evaporation from exposed viscera is entirely water, but the electrolyte is left behind, leading to a need for free water. The amount evaporated is directly proportional to temperature and exposed surface area and inversely proportional to relative humidity. Excess urine due to diuretics, glycosuria, or diabetes insipidus should be replaced with a solution based on urinary electrolyte measurements. In general, sodium concentration ranges between 50 and 100 mEq/L; potassium concentration ranges between 20 and 60 mEq/L.

Redistribution

Redistribution, or so-called third-space losses, are due primarily to tissue edema and transcellular fluid displacement. Functionally, this fluid is not available to the vascular space. [81] [82] The volume of edema formed is governed by the principles discussed earlier. Colloid enters the injured tissue at a more rapid rate than normal, but at a slower rate than electrolyte. For example, bowel wall edema is lessened by utilizing colloid containing fluids compared with crystalloid. [83] The composition of third-space losses is equivalent to the ECF volume electrolyte concentration plus a smaller amount of protein. Therefore, balanced salt solution is the most appropriate replacement fluid. The volume redistributed correlates roughly with the degree of tissue manipulation. Intra-abdominal procedures with small incisions (e.g., hysterectomy) may require an additional 2 mL/kg/h, whereas a major bowel resection requires an additional 4 to 6 mL/kg/h.

Table 45-18 describes the fluid management for a 70-kg patient undergoing gastrectomy, starting with a hemoglobin of 15 g/dL, who has been fasting for 10 hours. The maintenance rate is 110 mL/h, producing a deficit of 1,100 mL.

During the first and second hours of intra-abdominal activity, 100 mL of blood was lost and replaced at 3:1 with a balanced salt solution. By the fourth hour, the deficit had been replaced, and because the abdomen was being closed during part of that hour, the third-space (redistribution) losses estimate was likewise reduced and no further blood loss was noted. The assumption is made that urine flow was 50 to 80 mL/h and that heart rate and arterial blood pressure were in an acceptable range and the CVP remained 6 to 9 mm Hg. Had the CVP or urine output begun to increase, the rate of fluid administration would have been slowed. If oliguria and tachycardia had occurred, a fluid bolus would have been administered.

The Pediatric Patient

There are few special considerations relevant to pediatric fluid management in addition to those for the adult (Ch. 59) . The neonate has limited ability to dilute or concentrate urine and has a high fluid requirement. Thus, neonates should not be without fluid for more than 3 to 4 hours; otherwise, significant dehydration may result. Food should be offered until 6 to 8 hours before induction, and glucose-containing clear liquids should be given about 4 hours before induction. Clear liquids are defined as transparent liquids

TABLE 45-18 -- Example of Fluid Calculations [a]

TIME	COMPENSATORY	DEFICIT	MAINTENANCE	BLOOD LOSS [b] (mL) [e]	THIRD SPACE (mL)	THIS HOUR [c] (mL)	CUMULATIVE [d]
P-I [e]	350	220	110	0	0	680	680
I-S [f]	--	220	110	0	0	330	1,010
1st hour [g]		220	110	300	350	980	1,990
2nd hour [g]		220	110	300	350	980	2,970
3rd hour [g]		220	110	150	350	830	3,800
4th hour [g]		0	110	0	200	330	4,130

[a] Simulated case. See text for details.

[g] Operative time

and do not contain particulate material or protein, which coagulate in the acid medium of the stomach. Using the same principles as outlined for adults, the neonate requires maintenance fluids of 0.3 percent NaCl with potassium. Dextrose administration should not exceed 5 mg/kg/min. This can generally be met by using 2.5 percent dextrose-containing fluids. During extensive prolonged procedures, blood glucose should be monitored and the rate of dextrose administration modified accordingly. Otherwise, the choice and volumes of fluid are as described for an adult.

The Postoperative Patient With Bowel Obstruction

Patients with bowel obstruction are often older, with limited reserves in several organ systems. Estimating the degree of loss of fluids is difficult because fluid is retained in the bowel lumen where it cannot be measured. The slowly developing volume depletion allows time for full expression of compensatory mechanisms that mask the degree of the deficit. Patients have often ingested no fluids for many hours before entering the hospital and are often vomiting. The patient may have ischemic bowel injury with severe bowel wall edema and continued sequestration of luminal fluid and formation of ascites. Perioperative fluid intake will be much greater than measured output, leading consultants to suggest diuresis for *fluid overload.* Nutrition is impaired preoperatively and protein losses into the bowel are increased, leading to hypoalbuminemia and exacerbating the loss of fluid from the vascular space. The clinical picture is one of ongoing fluid requirement in the absence of external fluid loss, commonly referred to as *third spacing.*

The goals of fluid management in this group are similar to those of other patients and include restoration of the vascular volume and interstitial volume, correction of electrolyte depletion, correction of acidosis, reduction of systemic vascular resistance into the normal range, and optimization of oxygen delivery and utilization. Initial fluid infusion can restore intravascular volume sufficiently for blood pressure and heart rate to improve. Yet intravascular volume may still be depleted with a low cardiac output and severe arterial and venous vasoconstriction. The ECF volume (except for the bowel) remains dehydrated and will continue to accept fluids from the vascular space. The vasoconstricted patient will fail to perfuse all tissue, limiting the rate at which the ECF volume can be replenished. If fluids are infused more rapidly than the rate at which they can enter the ECF volume, increased filling pressures may result in pulmonary edema. It is crucial to estimate filling pressures, cardiac, output and systemic vascular resistance, while aggressive intravascular fluid with balanced salt solution and colloid is pursued. It may be necessary to administer arterial vasodilators such as nitroprusside to facilitate correction.

Management of a typical patient includes frequent monitoring of arterial blood pressure, heart rate, CVP, pulse pressure and respiratory variation, urine output, and electrolytes. If these are stable, hemoglobin and COP should be monitored every 2 to 4 hours until stable. A rising hemoglobin level indicates ongoing loss of plasma water, with or without protein loss. An increasing COP indicates continued loss of plasma water in excess of protein loss. Because maintenance fluid requirements persist, dextrose 5 percent is infused in 0.45 percent NaCl with 20 to 40 mEq of KCl/L at maintenance rate.

The fluid lost to the bowel and ECF volume is similar to plasma water in electrolyte composition, so a balanced salt solution is a reasonable first choice for the fluid boluses required to sustain plasma volume. The fluid lost will also contain protein, so either albumin or colloid osmotic pressure should be monitored and colloid infused. If a low COP (<15-18 mm Hg) coexists with hemodynamic instability, replacement should be started at 3 mL/kg/h if the CVP (and PAOP if pulmonary artery catheter has been placed) is within the patient's usual range. If it is high, replacement should start at 1 to 2 mL/kg/h. If the urine output rises above 1.5 mL/kg/h, one should check for glucos-uria. If glucosuria is absent, the fluid infusion rate is reduced by 0.5 mL/kg/h. If the CVP or pulmonary artery occlusion pressure (PAOP) rises above the patient's usual values and urine output is 0.5 to 1.5 mL/kg/h, the fluid infusion rate is reduced by 0.5 mL/kg/h. If the CVP (and/or PAOP) decreases below the patient's baseline and urine flow rate is low, balanced salt or colloid solution is administered rapidly (0.5 to 2 mL/kg/min) with close monitoring of filling pressures.

The Patient With Liver Failure

Fluid management of the patient with liver failure (Chs. 54 and 55) is complicated by several interacting problems. These patients appear to be simultaneously hyper- and hypovolemic. Most infused fluid is retained, yet renal function deteriorates, with avid sodium retention and arterial underfilling. Neither explains all the clinical findings or leads to consistently successful therapy.

According to the arterial underfilling (primary vasodilation) [84] hypothesis, some factor produced by, or not catabolized by, the failing liver causes inappropriate arterial dilation. The relative hypotension leads to activation of the systematic nervous system, the RAS, and vasopressin release. These lead to subsequent sodium and water retention, resulting in ascites and tissue edema.

In fact, cirrhotic patients have a low systemic vascular resistance, high cardiac output, and relative hypotension. Persistent endotoxemia (shunting via portosystemic anastomoses and enhanced endotoxin absorption from the intestine due to bile salt deficiency) may contribute to the vasodilation via activation of a cascade of secondary mediators beginning with tumor necrosis factor and interleukins. In addition, other vasodilator neurotransmitters may be produced or may not be cleared by the damaged liver.

The primary sodium retention hypothesis explains the avid sodium retention on the basis of hormonal (aldosterone) hyperactivity due to failure of the liver to metabolize aldosterone. Given the ECF volume expansion, the distribution into ascites and tissue edema is explained by the abnormally high portal venous pressures and hypoalbuminemia. More recently, abnormalities of atrial natriuretic peptide (ANP) have been investigated. ANP levels are normal or low in cirrhotic patients; this contrasts with the increase usually found in volume expanded patients. [85] ANP increased with water immersion or fluid administration, but natriuresis was not closely correlated with ANP levels. (Water immersion of the lower body compresses the venous capacitance system, resulting in centralization of blood volume. This simulates a volume infusion without adding any sodium or water to the body and should cause ANP release.) Water immersion did not increase ANP levels in patients with ascites who, therefore, apparently have blunted responses. Thus, impaired ANP release failed to explain sodium retention. [85] Patients with tense ascites had increased ANP, renin, and aldosterone concentrations. After paracentesis, ANP increased, but renin and aldosterone decreased. [86] The reasons for these findings were not clarified, but a reduction in intra-abdominal pressure would have decreased inferior caval pressure, facilitated venous return, and increased ANP levels. Decreased intra-abdominal pressures would also improve renal perfusion pressure, causing a reduction in renin release and subsequent aldosterone generation.

The role of increased intra-abdominal pressure may be important in sustaining sodium retention after ascites develops. Increased intra-abdominal pressure raises caval pressure. This decreases renal blood flow and glomerular filtration rate (GFR) because the renal perfusion pressure gradient (MAP minus renal venous pressure) is decreased both by systemic hypotension and increased caval pressure. The hypotension and reduction in renal blood flow can lead to renin activation, with aldosterone production. Hypotension, increased aldosterone, and decrease in GFR lead to enhanced sodium reabsorption, and low fractional excretion of sodium.

Hypoalbuminemia results from impaired synthesis by the liver, transudation into ascitic fluid due to portral hypertension, and malnutrition. Low COP favors loss of fluid from the vascular space into the interstitial space, producing intravascular hypovolemia. Ascites results from high portal venous pressure and hypoalbuminemia, markedly increasing the volume of transcellular fluid, which is functionally excluded from rapid exchange in the ECF volume.

Splanchnic blood pooling resulting from increased portal venous resistance plus lower body pooling resulting from elevated caval pressures from ascites tend to decrease net systemic venous return. Patients are thus functionally hypovolemic despite normal or elevated total blood volume. Heart failure owing to alcoholic cardiomyopathy may further complicate the clinical picture.

The goals in these patients are to avoid increasing interstitial fluid overload, maintain normal potassium concentration, and maintain intravascular volume. If cardiac failure is present, treatment must include administration of inotropic drugs and diuretics when filling pressures are increased. Restore intravascular COP by infusion of 25 percent albumin when possible. If the patient is acutely hypovolemic, 5 percent albumin solutions should be preferred to crystalloid, which will tend to further expand the already overexpanded ECF volume (i.e., produce more edema and ascites). In addition, intra-abdominal pressure should be estimated from urinary bladder pressure and paracentesis performed whenever it increases above 20 to 25 mm Hg. Finally, trials of dopamine, norepinephrine, phenylephrine, or vasopressin may be performed in hypotensive patients with low vascular resistance and hypotension in attempts to increase renal perfusion pressure and renal blood flow.

The Patient With Heart Failure

Fluid management of heart failure is directed to optimize cardiac preload, avoid overadministration of sodium, diminish edema, and correct common electrolyte abnormalities. Maintaining ideal cardiac preload during rapid fluid shifts that occur perioperatively is facilitated with direct or indirect measures of both preload and cardiac contractile function. Measures of preload include CVP, thermodilution cardiac output, end-diastolic volume, echocardiography, pulmonary artery occlusion pressure, and left atrial pressure. Measures of cardiac contractile function include stroke volume, ejection fraction, and stroke work. Patients with a history of cardiac failure scheduled for major or prolonged surgery should have monitoring instituted preoperatively and an intravascular fluid challenge (i.e., 500-1,000 mL/70 kg of crystalloid) performed to identify the optimal preload. Tissue edema is avoided by frequent monitoring of preload and arterial blood pressure coupled with support of contractility and control of vascular resistance. These patients have impaired ability to excrete fluids during the fluid mobilization, which occurs postoperatively. Because the ECF volume

is usually already expanded in these patients, the initial rates of fluid infusion intraoperatively should be at the lower ranges of estimates. Similarly, maintainance of intravascular volume without expansion of the interstitial space favors the use of colloid during the immediate perioperative period. Postoperatively, hemodynamic monitoring is continued until fluid mobilization is complete. The goal postoperatively is to give as little crystalloid as required to maintain adequate overall cardiovascular performance. Perioperative patients commonly receive more than 200 mEq of sodium per day including maintenance fluids, saline used to measure cardiac output, sodium from antibiotics administration, and sodium infused with vasoactive medications and inotropic agents. Thus, fluid should be maintained at a low maintenance, and flush fluids and sodium dosage should be measured. As soon as either urine output begins to increase or filling pressures or diastolic volume begin to rise, maintenance fluids should be stopped completely. If preload becomes excessive, diuretics should be administered.

Patients with heart failure have primary electrolyte problems owing to compensatory physiologic mechanisms activated by the impaired cardiac performance. These are then complicated by therapy with diuretics, digitalis, vasodilators, and angiotensin-converting enzyme inhibitors. Hyponatremia is common because of excess activation of the vasopressin system despite sodium retention. Treatment is directed at excreting the excess water load with diuretics, which should increase free water excretion more than sodium excretion. Sodium administration is not indicated unless volume depletion is documented. Aldosterone activation and diuretics lead to loss of potassium and magnesium. These ions are crucial for maintaining the stability of cardiac electrophysiology, as well as the effectiveness of digitalis and catecholamine. Ionized calcium is crucial for cardiac contractility, and hypocalcemia is extremely common during the perioperative period. Ionized calcium must be measured and corrected routinely. Severe hypophosphatemia often coexists with abnormalities of calcium, potassium, and magnesium and leads to depressed contractility.

The Patient With Cerebral Edema

Fluid management of patients with cerebral edema (Ch. 52) is directed at maintaining cerebral perfusion pressure, avoiding elevations of cerebral venous pressure and hypertension, preventing large changes in plasma osmolality (particularly depression of plasma osmolality), and avoiding hyperglycemia. Cerebral perfusion pressure (CPP) should be maintained in the normal range, 80 to 90 mm Hg, because autoregulation is impaired in the damaged brain, with a baseline increase in cerebrovascular resistance. Avoidance of intracranial hypertension, the other determinant of CPP, is crucial to preserve blood flow to compromised but viable brain. Cerebral edema formation is related to capillary pressure, COP, and permeability. The capillary pressure is between the arterial and venous pressures. Thus, systemic arterial or venous hypertension needs to be prevented. The normal brain capillary bed is essentially impermeable to sodium, mannitol, and protein, although water crosses freely. The damaged capillary bed becomes excessively permeable, with conductivity being greatest for the smallest molecules, but less for colloids. A degree of water dehydration without hypovolemia is desired to maintain the plasma sodium between 142 and 148 mEq/L. Thus, it is common to provide 75 to 90 percent of maintenance fluids with 0.9 percent NaCl or lactated Ringer solution and to minimize water volume required for other medications. Isotonic crystalloids or colloids do not cause edema in normal brain and can be used to sustain intravascular volume. [87] In fact, hyponatremia is often due to hypovolemia with inappropriate sodium loss [88] and subsequent water retention. This should be treated with intravascular volume expansion with isotonic or hypertonic sodium chloride. Parenteral nutrition can be prepared with 15 percent amino acid solutions, 20 percent lipid, and 70 percent dextrose to give full protein and caloric support in a minimal volume. Similarly, tube feeding formulations with 2 cal/mL should be prescribed. Hypovolemia must be carefully avoided. Colloid infusion to sustain intravascular volume, guided by hemodynamic monitoring, tends to provide better long-term control of the intravascular volume than crystalloid. If diuretics or diabetes insipidus cause loss of more than 2 mL/kg/h for more than 2 to 4 hours, a pulmonary artery catheter may be indicated for closer monitoring. Blood glucose should be maintained at 80 to 175 mg/dL by close monitoring, initially hourly, with decreasing frequency as stability is demonstrated. During acute resuscitation, dextrose administration is limited to no more than 2 mg/kg/min. Fortunately, indications for steroid use have become fewer in recent years, lessening the problems of hyperglycemia.

The Patient With Anuric Renal Failure Undergoing Nontransplant Surgery

Fluid management of the patient with anuric renal failure for nontransplant surgery (Ch. 53) should avoid excessive intravascular fluid administration and ECF volume expansion and maintain, or correct, electrolyte and acid-base status. The clinical anesthesiologist should also attempt to prevent precipitating conditions that would require dialysis during the immediate postoperative period (hyperkalemia, pulmonary edema, metabolic acidosis). Dialysis is difficult or impossible in the hemodynamically unstable patient and anticoagulation may be strongly contraindicated for several hours postoperatively. Patients with chronic renal failure often present with hypertension, diabetes, and vascular disease. Thus, avoidance of hypotension may be indicated to maintain coronary or cerebral perfusion pressure. In patients with acute renal failure, hypotension may worsen ischemic renal injury. This contrasts with the lack of concern for an adverse effect on renal function in the patient with chronic renal failure. Furthermore, recent dialysis often induces acute electrolyte shifts and hypovolemia and acidosis. The best compromise appears to be dialysis 12 to 24 hours preoperatively. If dialysis is performed close to the time of surgery, volume removal should be minimal. Patients with renal failure are often malnourished, have hypoproteinemia, are anemic, and have poor glucose tolerance. Hemodynamics should be closely monitored. If hypovolemia develops, colloid should be used early, but one should avoid producing vascular overexpansion. Likewise,

one must avoid interstitial fluid overload, which would require acute postoperative dialysis. Crystalloid replacement of third-space losses should be limited to 1 to 2 mL/kg/h, whereas blood loss should be replaced with colloid or RBCs. Correction of sodium, potassium, and acidosis can be achieved by the use of isotonic fluid without potassium, with reduced amounts of chloride, and increased amount of buffer. Initially, an infusion of 30 percent of calculated maintenance fluid rate is important because approximately 70 percent of normal fluid requirements are used in excreting solute via the kidney, a route no longer available. Na^{+}, K^{+}, pH, HCO_3^{-}, and glucose should be monitored at regular intervals.

The Patient With Adult Respiratory Distress Syndrome

Fluid management of the patient with adult respiratory distress syndrome (ARDS) (Ch. 72) involves maintaining colloid osmotic pressure and requires a CVP and PAOP as low as possible consistent with good ventricular function. Oxygen delivery should be sustained, ideally above 600 mL/min/m^2, by increasing cardiac index and hemoglobin concentration. Compensation for hemodynamic effects of increased airway pressure is achieved by maintaining adequate right and left ventricular filling volumes. When airway pressure increases, the lung expands in proportion to its compliance. The intrapleural pressure increases in direct proportion to lung expansion, and inversely with chestdiaphragm compliance. The increased intrapleural pressure increases CVP, which reduces the gradient between the periphery and the CVP. This reduces venous return unless peripheral venous tone increases or fluids are administered. The increased venous pressure increases fluid filtration out of the capillary bed, tending to produce hypovolemia. The increased pleural pressure is transmitted via the pericardium to reduce the filling pressure gradient for all cardiac chambers. The consequent reduction in end-diastolic volume diminishes preload to all chambers. The elevation of intrapulmonary pressure increases pulmonary artery pressure, which leads to augmented right ventricular afterload. The reduced venous return, decreased right ventricular preload, and increased afterload may severely compromise right ventricular stroke volume, cause stiffening of the interventricular septum and reduce preload for the left ventricle.

All these consequences can be improved by intravascular volume expansion, except for the increased afterload on the right ventricle. Thus, CVP and right ventricular enddiastolic volume are monitored to aid in the decision to institute inotropic therapy. An increase in CVP also compromises lymphatic return from the lung and periphery. Additionally, sepsis, the most common coexisting condition with ARDS, causes increased vascular capacity and vasodilation, decreases COP, and results

in tissue edema. The net clinical outcome of these factors is that fluid intake usually exceeds output until the ARDS (and sepsis) begins to subside. Additionally, studies comparing crystalloid and colloid management over the entire time course of ARDS are currently being evaluated. However, after 48 hours, pulmonary function may be somewhat better in patients managed with colloid, in part, than with crystalloids alone.

The Acutely Burned Patient

Fluid management of the acutely burned patient focuses on restoration of plasma volume and a shift of the ECF volume into the burned but viable tissue, accompanied by increased losses caused by loss of the normal barrier function of the skin. The tissue injury produced by the burn leads to an abrupt disruption of the capillary bed, manifested by local vasodilation, increased permeability, and, presumably, decreased reflection coefficient to proteins. Vasodilation increases the surface area for filtration and tends to increase capillary pressure. The lowered reflection coefficient diminishes the ability of colloids to retain fluid in the capillaries. Thus, water, electrolytes, and protein enter the burned tissue at the expense of the intravascular volume. Fluid is mobilized from uninjured tissues by a variety of processes, with a net result of transfer of fluid from normal tissue into the injured tissue and intravascular hypovolemia. Capillary permeability was formerly thought to increase in all tissues after a serious burn injury, but this is not the currently held view. [89] In addition to the tissue edema, there is a marked increase in loss of water by evaporation from the wound surface, and the metabolic rate increases dramatically, leading to proportionate increases in fluid requirements. Several formulas have been developed to aid in writing the initial fluid prescription. The key to success is close hemodynamic monitoring with titration of therapy to the individual patient's physiology. For example, if urine output increases progressively, or if filling pressures increase, fluid administration must be decreased. The Parkland formula [90] prescribes fluids based on the percentage of the body surface area (BSA) burned (percent BSA-burned): 2 mL/kg/percent BSA-burned during the first 8 hours and 2 mL/kg/percent BSA-burned during the next 16 hours.

The formula prescribes ([0.25 mL/kg]/[percent BSA-burned])/h for 8 hours, then ([0.125 mL/kg]/[percent BSA-burned])/h for 16 hours, then 5 percent dextrose in water, ([0.8 mL/kg]/[percent BSA-burned])/h, plus 5 percent albumin, ([0.015 mL/kg]/[percent BSA-burned])/h for 24 hours. For example, a 50-kg person with 50 percent BSA burn should receive (50 kg) × (0.25 mL/kg) × (50 percent BSA-burned), which equals 625 mL/h for 8 hours, followed by (50 kg) × (0.125 mL/kg) × (50 percent BSA-burned), which equals 310 mL/h for 16 hours. During the second 24 hours, one should administer (50 kg) × (0.08 mL/kg) × (50 percent BSA-burned), which equals 200 mL/h of 5 percent dextrose in water, plus (50 kg) × (0.015 mL/kg) × (50 percent BSA-burned), which equals 37.5 mL/h of 5 percent albumin. Colloids are not contraindicated, even during the acute phase of fluid resuscitation. Although they will pass into the injured tissue at an accelerated rate, they have a more sustained effect on plasma volume than does crystalloid alone.

The Pregnant Patient With Preeclampsia

Goals of fluid management of the pregnant patient with preeclampsia (Ch. 57) are to (1) restore the contracted intravascular volume, [91] (2) avoid excessive intravascular fluid administration because of normal postpartum fluid mobilization,

(3) replace increased sensible (sweat) and insensible (respiratory) losses due to labor, (4) be prepared to replace rapid blood loss, (5) avoid hypotension due to anesthetic induced vasodilation to preserve uteroplacental flow, (6) maintain normoglycemia, (7) avoid decreasing the COP further, and (8) prevent pulmonary and cerebral edema.

Restoration of depleted plasma volume to normal is crucial for control of hypertension and for administration of anesthesia. Plasma volume is decreased in preeclamptic patients secondary to elevated lower body venous pressure due to uterine compression, pressure-induced natriuresis as seen in hypertension, severe vasoconstriction, and hypoproteinemia secondary to proteinuria. After parturition, fluid retained during pregnancy is usually quickly mobilized and excreted. The preeclamptic patient, however, may have compromised hepatic, renal, or cardiac function, impeding the timely excretion of this fluid. These patients are at risk of pulmonary edema due to cardiac failure secondary to severe hypertension and lowered COP. Cardiac filling pressures should be monitored and a PAOP of less than 12 to 15 mm Hg maintained. Plasma tonicity must be maintained by administration of isotonic fluid because these patients are at risk of developing cerebral edema.

Chapter 46 - Transfusion Therapy *

Ronald D. Miller

BLOOD THERAPY

According to a survey conducted by the Committee on Blood and Blood Products of the American Society of Anesthesiologists, [1] anesthesiologists administer more than half of all blood given to patients. Obviously, the anesthesiologist should be an expert on the implications and the complications associated with blood transfusions.

Indications for Transfusion

Allogeneic (Homologous) Blood

Blood transfusions are given to increase oxygen-carrying capacity and intravascular volume. Theoretically, increasing vascular volume is not an indication for blood transfusions, because volume can be augmented with administration of fluids that do not transmit infections (e.g., crystalloids or some colloids). On the practical side, when a patient is hemorrhaging, blood is given to increase both oxygen-carrying capacity and intravascular volume. However, increasing oxygen-carrying capacity is the only real indication for blood transfusions.

The critical question is "What is/are the specific indications for blood transfusions?" With a specific indication (i.e., increase oxygen-carrying capacity), this question should be easy to answer. Unfortunately, there is little or no way, except in severe life-and-death situations, to determine whether oxygen-carrying capacity is inadequate. The controversy revolves around how much emphasis should be placed on hemoglobin or hematocrit values. The limitation of such values is based on a potential extreme variability from one patient to another regarding their need for increased oxygen-carrying capacity. For example, young healthy patients with normal cardiorespiratory function may easily compensate for anemia (either chronic or acutely induced by hemorrhage), whereas at an identical hematocrit value, elderly patients with cardiac disease may have serious problems with surgery and anesthesia. This concern has led many medical organizations to place emphasis on overall medical judgment rather than a specific laboratory value, [2] [3] with some debate. [4] Conversely, other organizations have chosen to make far more complex directions, such as those in Table 46-1 from the American College of Surgeons. Despite the intellectual appeal of the latter approach, most of the American College of Surgeons' criteria cannot distinguish inadequate intravascular volume from diminished oxygen-carrying capacity. *Therefore, in this author' s opinion, the hemoglobin concentration should be the basis around which clinical judgment revolves in order to define transfusion requirements for an individual patient.*

The foundation for using the hemoglobin or hematocrit value as the initial consideration for defining transfusion requirements follows. A National Institutes of Health Consensus Conference [5] concluded that otherwise healthy patients with a hematocrit value greater than 30 percent rarely require perioperative blood transfusions, whereas patients with acute anemia (as in intraoperative blood loss) of less

*See Practice Guidelines for Blood Component Therapy

TABLE 46-1 -- American College of Surgeons Classes of Acute Hemorrhage

FACTORS	I	II	III	IV
Blood loss, *mL*	750	750-1,500	1,500-2,000	2,000 or more
Blood loss, % BV	15	15-30	30-40	40 or more
Pulse, *bpm*	>100	>100	>120	140 or higher
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure (mm Hg)	Normal/increased	Decreased	Decreased	Decreased
Capillary refill test	Normal	Positive	Positive	Positive
Respirations *per minute*	14-20	20-30	30-40	>35
Urine output, *mL/h*	30	20-30	5-10	Negligible
CNS (mental status)	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic
Fluid replacement (3:1 rule)	Crystalloid	Crystalloid	Crystalloid + blood	Crystalloid + blood

than 21 percent frequently require blood transfusions. They also recognized that patients with chronic anemia (as in renal failure) may tolerate a hemoglobin concentration of less than 7 g/dL. The ultimate determination of that hematocrit or hemoglobin value at which blood should be given will have to be a clinical judgment based on many factors, such as cardiovascular status, age, anticipated additional blood loss, arterial oxygenation, mixed venous oxygen tension, cardiac output, and blood volume. To further complicate this issue, indications for blood transfusions also probably depend on the source of the blood. For example, indications for autologous blood may be more liberal because it is unlikely to transmit diseases (e.g., hepatitis and acquired immunodeficiency syndrome [AIDS]) than is allogeneic blood. However, autologous blood should not be viewed as completely safe because of the possibility of laboratory error or a hemolytic transfusion reaction.

More recently, usually in intensive care patients, several groups have attempted to define the point at which blood transfusions should be given by measures of tissue oxygenation and hemodynamics (e.g., increase in oxygen consumption in response to added oxygen content). [6] [7] [8] [9] [10] [11] [12] [13] [14] No specific measure could consistently predict when a patient would benefit from a blood transfusion. Yet, there is suggestive evidence that the quality (e.g., age) of the blood and its increased oxygen capacity (e.g., hemoglobin value >10 g/dL) may benefit very sick patients. In fact, one study found that when blood stored for more than 15 days was given, evidence of splanchnic ischemia occurred. [9] More recently, this concept was confirmed by Purdy et al, [15] who found that patients who received 17-day-old blood (range, 5-35 days) versus 25-day-old blood (range, 9-36 days) had a higher survival rate. The influence of the age of blood infused is discussed later in this chapter. Perhaps the development of more sensitive indicators of tissue oxygenation (e.g., intramucosal pH) will provide indicators for transfusion. [9] [15] By use of outcome data in an orthopedic surgery population, variations in hemoglobin levels were unrelated to duration of hospitalization, [16] yet trained athletes and postoperative cardiac patients showed improved physical capabilities when hemoglobin levels were increased. [17] Conversely, Weiskopf et al [18] found that in healthy patients, decreases in hemoglobin concentration to 5.0 g/dL did not produce any evidence of inadequate oxygenation. However, these patients were not subjected to the stresses of

recovery from surgery and anesthesia. However, Weiskopf et al [19] found that these patients compensated for their low hemoglobin levels by increasing heart rate and stroke volume. One might then argue that patients who have a higher than expected heart rate or who cannot increase their cardiac output should receive a transfusion to a higher hemoglobin level than 10 g/dL. Unfortunately, precise conclusions cannot be derived from these helpful and suggestive data.

In the absence of physiologic indicators, arbitrary guidelines are recommended. In fact, in the July 1989 Food and Drug Administration (FDA) Drug Bulletin, even more stringent guidelines were proposed for red blood cell (RBC) administration. That bulletin states, "adequate oxygencarrying capacity can be met by a hemoglobin of 7 g/dL or even less when the intravascular volume is adequate for perfusion." There are medical conditions (e.g., coronary artery disease) that justify giving blood to achieve a higher hemoglobin level. Nevertheless, the general concern of many individuals in regulatory positions that blood is often given inappropriately will inevitably lead to more scrutinizing of our transfusion practice. For example, many hospital transfusion committees are conducting audits in which patients who have postoperative hematocrit values higher than a certain percentage (e.g., 33-36%) [19] and who have received blood will have the original indications for blood transfusion reevaluated to determine whether blood was given inappropriately. This increased scrutiny dictates that anesthesiologists clearly state in the hospital record the reasons for giving blood transfusions. [3]

To arrive at some conclusions in the presence of incomplete data, two complementary recommendations are given. First, the recommendations of the American Society of Anesthesiologists Practice Guidelines: [2]

1. Transfusion is rarely indicated when the hemoglobin concentration is greater than 10 g/dL and is almost always indicated when it is less than 6 g/dL, especially when the anemia is acute.
2. The determination of whether intermediate hemoglobin concentrations (6 to 10 g/dL) justify or require red blood cell (RBC) transfusion should be based on the patient's risk for complications of inadequate oxygenation.
3. The use of a single hemoglobin "trigger" for all patients and other approaches that fail to consider all important physiologic and surgical factors affecting oxygenation are not recommended.
4. When appropriate, preoperative autologous blood donation, intraoperative and postoperative blood recovery,

acute normovolemic hemodilution, and measures to decrease blood loss (deliberate hypotension and pharmacologic agents) may be beneficial.
5. The indications for transfusion of autologous RBCs may be more liberal than those for allogeneic RBCs because of lower (but still significant) risks associated with the former.

With the help of Habibi et al, [20] the following guidelines are recommended with the rule of thumb that administration of one unit of packed RBCs will increase hematocrit value by 3 to 5 percent. Indications are

1. Blood loss >20 percent of blood volume when more than 100 mL
2. Hemoglobin <8 g/dL
3. Hemoglobin <10 g/dL with major disease (e.g., emphysema, ischemic heart disease)
4. Hemoglobin 10 g/dL with autologous blood
5. Hemoglobin <12 g/dL and ventilator dependent

Although the recommendations of Habibi et al [20] are current, the elusive "transfusion trigger" remains in a prominent part of the debates in not only anesthesia specifically, but in medicine in general. In 1999, Herbert et al [20A] found that in critically ill patients, a restrictive transfusion strategy (hemoglobin <10 gm/dL) was as effective as a more liberal transfusion (hemoglobin 10-12 gm/dL) except in patients with acute myocardial infarction and unstable angina. Despite the problem with identifying a specific transfusion trigger, Ely and Bernard [20B] have generally confirmed the conclusions of Habibi et al. As concluded by Weiskopf [20C] , "we merely await advances in technology that will enable us to measure directly the value of concern and thereby free us from arguments over which surrogate (e.g., hemoglobin) to measure and what value indicates the need for augmented oxygen delivery."

Autologous Blood

Autologous blood is assumed to be (and probably is) much safer than allogeneic blood, mainly because of the decreased risk of infection. Because of a marked decrease in infectivity from allogeneic blood (see Infectivity of Blood), the difference in safety compared with autologous blood is much less. [21] [22] For example, Kanter et al [23] found that 25 of 140 patients undergoing hysterectomy who donated blood received blood transfusions, whereas 1 of 123 patients who did not donate autologous blood was transfused. Therefore, they concluded that elimination of preoperative autologous blood donation does not increase the risk of allogeneic blood transfusion. They further argued that autologous blood does have risks. One of every 16,000 autologous blood donations results in a reaction severe enough to require hospitalization. [24] Complications associated with autologous blood transfusions include the following:

1. Anemia
2. Preoperative myocardial ischemia from anemia
3. Administration of the wrong unit (1:100,000)
4. Need for more frequent blood transfusions

However, the relative value of autologous blood is based on the assumption that the risks of allogeneic blood have been properly assessed. The advocates for the elimination of autologous blood transfusion have not included immunosuppression or outbreaks of other infections in allogeneic blood. For example, from 1986 to 1991, 182 transfusionassociated fatalities were reported to the FDA, 29 (16%) of which were caused by bacterial contamination. [25] Since then, 10 cases of *Yersinia enterocolitica* have been reported. These cases all involved allogeneic blood, although two patients also received autologous blood. Furthermore, autologous blood can affect the immune system (see Transfusion-Induced Immunodepression). In addition, the testing and screening of blood donors is by no means perfect. [26] Ask yourself the question: If given a choice, would you want your own blood or allogeneic blood?

Nevertheless, the conclusion still is that autologous blood is preferred over allogeneic (homologous) blood with a more generous hemoglobin level (<10 g/dL) than that at which autologous blood can be given. [2] [27]

Compatibility Testing

The ABO-Rh type, crossmatch, and antibody screen are frequently referred to as *compatibility tests.* These tests were designed to demonstrate harmful antigen-antibody interactions *in vitro* so that harmful *in vivo* antigen-antibody interactions could be prevented. Donor blood used for emergency transfusion of group-specific blood must be screened for hemolytic anti-A and/or anti-B antibodies. Also, all donor blood must be tested for the correct ABO and Rh type and screened for unexpected antibodies. Similarly, recipient blood must also undergo ABO-Rh typing, as well as testing for unexpected antibodies. Once this has been completed, proper selection of donor blood requires a test for compatibility between recipient blood and donor blood; this test is known as a crossmatch (Fig. 46-1) .

ABO-Rh Typing

Determination of the patient's correct blood type is exceedingly important because the most serious and tragic reactions are usually caused by accidental transfusion of ABO-incompatible blood. These reactions are due to naturally occurring antibodies (anti-A and anti-B), which activate, complement, and lead to rapid intravenous hemolysis. Anti-A and/or anti-B antibodies are formed whenever the individual lacks either or both of the A and B antigens. In essence, antibodies are directed against those antigens that are lacking in the individual's own cells. ABO typing is performed by testing RBCs for the A and B antigens and the serum for the A and B antibodies before transfusion (Table 46-2) .

The only additional required testing is that for the Rh(D) antigen. Antigen D is a very common one and, except for the A and B antigens, the one most likely to produce immunization. Approximately 60 to 70 percent of Rh(D)-negative recipients are immunized (produce anti-D) if they are given blood transfusions with Rh(D)-positive blood. About 85 percent of individuals possess the D antigen and are termed Rh(D)-positive; the remaining 15 percent, who lack the D antigen, are termed

Rh(D)-negative. Because anesthesiologists and surgeons often have difficulty understanding the

Figure 46-1 Outline of the tests used for a crossmatch. The X over the word *crossmatch* means that the crossmatch is not included in the type and screen.

blood grouping system, Table 46-3 is included to facilitate identification of donor blood groups whose blood patients can receive.

Crossmatching

A crossmatch is essentially a trial transfusion within a test tube in which donor RBCs are mixed with recipient serum to detect a potential for serious transfusion reaction. The crossmatch can be completed in approximately 45 to 60 minutes and is carried out in three phrases: an immediate phase, an incubation phase, and an antiglobulin phase.

The first phase is conducted at room temperature and is a check against errors in ABO typing. It detects ABO incompatibilities and those caused by naturally occurring antibodies in the MN, P, and Lewis systems. This takes approximately 1 to 5 minutes to complete.

The second phase involves incubation of the first-phase reactions at 37°C in albumin or low-ionic strength salt solution. The addition of albumin and low-ionic-strength salt solution aids in the detection of incomplete antibodies or those antibodies that are able to attach to a specific antigen (sensitization) but are unable to cause agglutination in a saline suspension of RBCs. This phase primarily detects antibodies in the Rh system. The incubation of 30 to 45 minutes in albumin and of 10 to 20 minutes in lowionic-strength salt solution in this phase is of sufficient duration to allow antibody uptake sensitization by cells so that incomplete

TABLE 46-2 -- ABO Compatibility Testing

A	A, AB
B	B, AB
AB	AB

antibodies missed in this phase can be detected in the subsequent antiglobulin phase.

The last, and third, phase of the crossmatch, the indirect antiglobulin test, involves the addition of antiglobulin sera to the incubated test tubes. With this addition, antihuman antibodies present in the sera become attached to the antibody globulin on the RBCs, thus causing agglutination. This antiglobulin phase detects most incomplete antibodies in the blood group systems, including the Rh, Kell, Kidd, and Duffy blood group systems.

Although all three phases of the crossmatch are important, the first two stages are of prime importance in preventing serious hemolytic transfusion reactions (see Type and Screen). The incubation and antiglobulin phases are especially important because the antibodies appearing in these phases are capable of causing serious hemolytic reactions. Except for hemolytic reactions involving anti-A and anti-B, reactions caused by antibodies appearing in the immediate phase (RT) are frequently less severe. This is because many of the antibodies appearing in this phase are naturally occurring antibodies present in a low titer and are not reactive at physiologic temperatures.

Antibody Screening

The antibody screen is also carried out in three phases and is similar in length to the crossmatch. The screen, however, is a trial transfusion between the recipient serum and commercially supplied RBCs that are specifically selected to contain optimal numbers of RBC antigens, or those antigens that will react with antibodies that are commonly implicated in hemolytic transfusion reactions.

The screen for unexpected antibodies is also used on donor serum and is performed shortly after withdrawal of blood from the donor. It is necessary to screen donor serum for unexpected antibodies in order to prevent their introduction into the recipient serum. This screen is performed primarily to prevent reactions between transfused donor units.

Approaches Requiring Less Than a Complete Crossmatch

Type and Screen

The term *type and screen* refers to elimination of the crossmatch in which blood is set aside with only the ABO-Rh type having been determined and antibody screening having been performed. The type and screen without crossmatch determines both the ABO-Rh of the patient and the presence of the most commonly found unexpected antibodies. Specifically, the patient's serum is screened for the presence of unexpected antibiotics by incubating it with selected reagent RBCs (screen cells). [28] These cells contain all antigens capable of inducing clinically significant RBC antibody reactions.

Complete transfusion testing for compatibility between donor and recipient blood ensures optimal safety and therapeutic effect of transfused blood. In some cases, however, the crossmatch is eliminated, and blood can be set aside in which only the ABO-Rh type and antibody screen are performed (type and screen). For those few patients in whom the antibody screen reveals the presence of unexpected antibody, the antibody is subsequently identified in the blood bank, and units of blood lacking the corresponding antigen are set aside for surgery. If an emergency transfusion is required after type and screen alone, an immediate-phase crossmatch is performed before transfusion to eliminate reactions that may result from human errors in ABO-Rh typing. Blood given in this manner is more than 99 percent effective in preventing incompatible transfusion reactions due to unexpected antibodies. [29] The type and screen without the complete crossmatch does not protect against reactions due to antibodies reactive against lower-incidence antigens, those not represented on the screening cells but present on the donor RBCs. Generally, antibodies that are not detected in the type and screen are weakly reactive antibodies that do not result in serious hemolytic transfusion reactions. In a study of 13,950 patients, Oberman et al [30] discovered only 8 "clinically significant" antibodies after complete crossmatch that were not detected during the antibody screening.

The antibodies were all in lower titer and were believed by Oberman and coworkers to be unlikely to cause serious hemolytic reactions.

The type and screen should not be confused with the term *type and hold.* The latter term refers to a sample of blood from a potential blood recipient received by the blood bank in which the blood type but no crossmatch has been ordered. This term is misleading because it does not denote how long the blood should be held, nor does it indicate that an antibody screen has been performed on the sample. However, in most cases in which a type and hold has been ordered, an antibody screen is performed on that sample. Because of the confusion that has arisen with type and screen, the type and hold terminology and method of ordering blood have been abandoned by most blood banks.

Maximal Surgical Blood Order Schedule

Routine preoperative crossmatching of blood for surgical cases means that crossmatched blood is unavailable for others for 24 to 48 hours. During this time, 1 to 2 days is lost, and the chance for outdating increases. A second aspect relates to the growing realization that, for certain elective surgical procedures, the number of crossmatched units that are ordered frequently far exceeds the number actually transfused. To quantify this problem better, the crossmatch-to-transfusion (C/T) ratio has been used. If the C/T ratio is high, the blood bank is burdened with keeping a large blood inventory, using excessive personnel time, and having a high incidence of outdated units. Sarma [31] recommended that for surgical procedures in which the average number of units transfused per case is less than 0.5, determination of the ABO-Rh type and a screen of the patient serum for unexpected antibodies (type and screen) should be used. This would be in lieu of a complete type and crossmatch for patients with negative antibody screens. For those with a positive antibody screen, the blood bank must provide compatible units that lack the corresponding antigen. Blood banks attempt to maintain C/T ratios of 2.1 to 2.7. [31] To increase utilization rate and lower the C/T ratio, blood banks attempt to decrease the emphasis on crossmatching of blood through such means as the type and screen and such programs as the maximal surgical blood order schedule. [32] This schedule consists of a list of surgical procedures and the maximum number of units of blood that the blood bank will crossmatch for each procedure. This schedule is based on the blood transfusion experience for surgical cases in hospitals in which the schedule is employed. Each hospital's maximal surgical blood order schedule is developed by both the suppliers and the users of blood in that hospital, such as blood bankers, anesthesiologists, and surgeons.

Is the Crossmatch Really Needed?

In previously transfused or pregnant patients, only about 1 patient in 100 may have an irregular antibody other than the anti-A and/or anti-B antibodies. However, some of these irregular antibodies are reactive only at temperatures below 30°C and therefore are insignificant in most transfusions. Others that are reactive at about 30°C can produce serious reactions if the transfused cells contain appropriate antigen. In order of probable significance, anti-Rh(D), Kell, C, E, and Kidd are the most common of clinically significant antibodies. After anti-A and anti-B, anti-Rh(D) is the most common significant antibody. If the correct ABO and Rh blood type is given, the possibility of transfusing incompatible blood is less than 1 chance in 1,000. Put in other terms, ABO-Rh typing alone results in a 99.8 percent chance of a compatible transfusion, the addition of an antibody screen increases the safety to 99.94 percent, and a crossmatch increases this to 99.95 percent. [33]

The blood bank can reduce the chance of incompatibility by performing an antibody screen. The chances of this screening test's missing an antibody that is potentially dangerous has been estimated to be no more than 1 in 10,000.

Emergency Transfusion

In many situations, there is urgent need for blood before completion of compatibility testing (ABO-Rh, antibody

screen, and crossmatch) (Ch. 62) . For those situations that do not allow time for complete testing, an abbreviated format for testing can be used. The preferred order for the selection of partially crossmatched blood is as follows.

Type-Specific Partially Crossmatched Blood

When using uncrossmatched blood, it is best to obtain at least an ABO-Rh typing and an immediate-phase crossmatch. This incomplete crossmatch is accomplished by adding the patient's serum to donor RBCs at room temperature, centrifuging it, and then reading it for macroscopic agglutination. This takes 1 to 5 minutes and eliminates serious hemolytic reactions resulting from errors that may occur in ABO typing. Only a few unexpected antibodies outside the ABO systems are detected, such as those directed against antigens in the MN, P, and Lewis systems, most of which are not clinically significant.

Type-Specific, Uncrossmatched Blood

For proper use of type-specific blood, the ABO-Rh type must be determined during the patient's hospitalization. Blood types from historical records, relatives, ambulance drivers, and other hospitals are frequently inaccurate. For those who have never been exposed to foreign RBCs, most ABO type-specific transfusions are successful. Caution should be used for those patients who have previously received transfusions or have had pregnancies. In the author's experience in the military, type-specific uncrossmatched blood was frequently used in emergencies with no serious consequence. In the civilian setting, using 1 year's experience with 56 patients, uncrossmatched, type-specific blood for emergency transfusion produced no adverse effects, even though complete serologic testing had not been performed. [34] These authors concluded that although the use of uncrossmatched blood is usually safe, the potential for serious reaction still exists, and they thus cautioned against its indiscriminate use. Specifically, about 1 in 1,000 patients has an unexpected antibody detected in crossmatch. For those who have previously been exposed to RBC antigens, transfusion of the ABO-Rh type-specific uncrossmatched blood may be more hazardous. For every 100 of these individuals, one has an antibody detected in the crossmatch.

Type O Rh-Negative (Universal Donor), Uncrossmatched Blood

Type O blood lacks both the A and B antigens and consequently cannot be hemolyzed by anti-A or anti-B antibodies in the recipient's blood (see Tables 46-2 and 46-3) . Because of this, type O blood has been termed the *universal donor* and can be used in emergency transfusion when typing or crossmatching is not available. However, some type O donors produce high titers of hemolytic IgG, IgM, anti-A, and anti-B antibodies. High titers of these hemolysins in donor units are capable of causing destruction of A or B red blood cells of a non-type O recipient. Thus, type O Rhnegative uncrossmatched packed RBCs should be used in preference to type O Rh-negative whole blood because packed erythrocytes have smaller volumes of plasma and are almost free of hemolytic anti-A and anti-B antibodies. If type O Rh-negative whole blood is to be used, the blood bank must supply type O blood that is free of hemolytic anti-A and anti-B antibodies.

During emergency transfusion of more than two units of type O Rh-negative uncrossmatched whole blood, the patient probably cannot be switched to his or her blood type (A, B, or AB) once the blood bank determines the correct blood type. Switching could cause major intravascular hemolysis of donor RBCs by increasing titers of transfused anti-A and anti-B. Continued use of O Rh-negative whole blood results only in minor hemolysis of recipient RBCs, with hyperbilirubinemia as the only complication. The patient must not be transfused with his or her correct blood type until the blood bank determines that the transfused anti-A and anti-B has fallen to levels that permit safe transfusion of type-specific blood.

Specific Recommended Protocol

In view of the aforementioned considerations, the following steps are recommended in patients who are hypovolemic and require blood transfusion:

1. Infuse crystalloids or colloids
2. Draw a blood sample for typing and cross-matching
3. If crossmatched blood is not ready to give: typespecific or type O Rh-negative cells, or type O Rh-positive cells for males or postmenopausal females without a history of transfusions; type-specific, partially crossmatched blood; type-specific, crossmatched blood

Storage of Blood

Citrate phosphate dextrose adenine (CPDA-1) is an anticoagulant preservative in which blood is stored at 1 to 6°C. Citrate is an anticoagulant, phosphate serves as a buffer, and dextrose is a red cell energy source. The addition of adenine to CPD solution allows RBCs to resynthesize adenosine triphosphate (ATP), which extends the storage time from 21 to 35 days. As a result, RBCs or whole blood can be stored for 35 days when stored in CPDA-1. [35] The shelf life can be extended to 42 days when AS-1 (Adsol) or AS-3 (Nutricel) is used. [36] [37] Adsol contains adenine, glucose, mannitol, and sodium chloride; Nutricel contains glucose, adenine, citrate, phosphate, and sodium chloride. This duration of storage has been set by U.S. federal regulation and is determined by the requirement that at least 70 percent of the transfused RBCs remain in circulation for 24 hours after infusion. RBCs that survive 24 hours after transfusion disappear from the circulation at a normal rate. Those that do not survive are subsequently removed from the circulation by the blood recipient.

The citrate ion prevents clotting by binding calcium; dextrose allows the RBCs to continue glycolysis and thus maintain sufficient concentrations of high-energy nucleotides (ATP) to ensure continued RBC metabolism and subsequent viability during storage. The storage at 1 to 6°C assists

TABLE 46-4 -- Properties of Whole Blood and Packed Red Cell Concentrates Stored in CPDA-1

PARAMETER	DAYS OF STORAGE		
	0	***35 (WHOLE BLOOD)***	***35 (PACKED CELLS)***
pH	7.55	6.73	6.71
Plasma hemoglobin (mg/dL)	0.5	46	246.0
Plasma potassium (mEq/L)	4.2	17.2	76.0
Plasma sodium (mEq/L)	169	153	122

preservation by slowing the rate of glycolysis approximately 40 times the rate at body temperature. The addition of adenine prolongs storage time by increasing RBC survival by allowing RBCs to resynthesize the ATP needed to fuel metabolic reactions. Without adenine, RBCs gradually lose their ATP and their ability to survive after transfusion.

During storage of whole blood and packed RBCs, a series of biochemical reactions occur that alter the biochemical makeup of blood and account for some of the complications that are discussed later. During storage, RBCs metabolize glucose to lactate, hydrogen ions accumulate, and plasma pH decreases. The storage temperatures of 1 to 6°C stimulate the sodium-potassium pump, and RBCs lose potassium and gain sodium. The osmotic fragility of RBCs increases during storage, and some cells undergo lysis, resulting in elevated plasma hemoglobin levels. Also, storage is associated with progressive decreases in RBC concentrations of ATP and 2,3-diphosphoglycerate (2,3-DPG).

Interestingly packed RBCs have a slightly lower survival than whole blood (Table 46-4) , although values for hemoglobin and potassium concentrations may appear somewhat high in 35-day stored RBC concentrates. However, it should be remembered that the total plasma volume in the concentrates is only 70 mL.

Frozen Storage

Satisfactory storage of RBCs in the frozen state became possible when these cells, mixed with glycerol, could be frozen and thawed without damage. RBCs previously frozen to 79°C in glycerol survive well in humans. RBCs must be free from glycerol before being transfused; unfortunately, a simple and inexpensive method of removing the glycerol has been difficult to develop. Valeri [38] studied the efficacy of using frozen RBCs and has attempted to simplify the method of freezing and thawing RBCs to make it a more viable process. The advantages of frozen and thawed RBCs are the following: (1) blood of rare types can be stored for long periods, increasing viability and eliminating outdating; (2) frozen, reconstituted blood is believed to be safer in patients who are especially susceptible to allergic reactions, because the freezing and washing process reduces sites with histocompatible antigens; (3) frozen washed blood may reduce risk of transfusion hepatitis; (4) frozen blood, low in fibrin and leukocytic aggregates, would be safer in patients requiring massive blood transfusion; and (5) frozen RBCs may be desirable in clinical conditions requiring prompt tissue oxygenation because normal levels of 2,3-DPG are retained in frozen erythrocytes. The efficacy of using frozen, thawed RBCs on a large-scale basis was proved possible at Cook County Hospital in Chicago, during a 28-month period. [39] In my opinion, there can be no doubt that blood can be stored for years, and this certainly would help alleviate the problem of having uncommon blood types not readily available. The incidence of transfusion reactions can clearly be reduced. Furthermore, the use of frozen RBCs can minimize alloimmunization to human leukocyte antigen and to membrane-specific antigens present on transfused white blood cells. However, these advantages can be more readily achieved by use of currently available washing devices. However, the original claim that the use of frozen RBCs would decrease the incidence of hepatitis seems to be unfounded. [40] As a result, frozen storage will continue to be used only on a limited basis.

Heparin

Whole blood stored in heparin is used in some situations for priming the pump during cardiopulmonary bypass. Heparinized whole blood is used by some clinicians in open-heart surgery to prevent cardiac abnormalities that might result from depression of ionized calcium levels by the citrate in other storage solutions. Furthermore, factor VIII complex is more stable than when other storage solutions are used for storage. Heparin anticoagulant is not a RBC preservative because it lacks glucose. Its anticoagulant effect is also neutralized during storage by the thromboplastic substances liberated by the cellular elements of blood during storage. Consequently, blood stored in heparin must be used within 24 to 48 hours of collection.

Complications

Changes in Oxygen Transport

RBCs are transfused primarily to increase transport of oxygen to tissues. An increase in the circulating red cell mass produces an increase in oxygen uptake in the lungs and a corresponding probable increase in oxygen delivery to tissues. The respiratory function of red cells may be impaired during preservation, making it difficult for them to release oxygen to the tissues immediately after transfusion.

In 1954, Valtis and Kennedy [41] first described a leftward shift of the oxygen dissociation curve *in vitro,* the magnitude of which was directly related to the length of time the acid citrate dextrose (ACD) blood had been stored. After transfusion of 7-day or older ACD blood, the oxygen dissociation curves of all patients also shifted to the left. The magnitude of the left shift was related to the volume and storage time of the infused ACD blood. In some cases, the curve remained shifted to the left for as long as 24 hours after transfusion.

Figure 46-2 Factors that shift the oxygen dissociation curve. *(From Miller [176])*

Review of the Oxygen Dissociation Curve

The oxygen dissociation curve is determined by plotting the partial pressure of oxygen (P_{O_2}) in blood against the percentage of hemoglobin saturated with oxygen (Fig. 46-2) . As hemoglobin becomes more saturated, the affinity of hemoglobin for oxygen also increases. This is reflected in the sigmoid shape of the curve, which indicates that a decrease in Pa_{O_2} makes considerably more oxygen available to the tissues. Thus, the sigmoid shape of the curve implies greater efficiency of blood transportation of oxygen from the lungs to tissues.

Shifts in the oxygen dissociation curve are quantitated by the P_{50}, which, by convention, is the partial pressure of oxygen at which hemoglobin is half saturated with oxy-gen at 37°C and pH 7.4. A low P_{50} indicates a left shift in the oxygen-dissociation curve and an increased affinity of hemoglobin for oxygen; in other words, the left shift of the curve indicates that a lower-than-normal oxygen ten-sion saturates hemoglobin in the lung and the subsequent release of oxygen to the tissues occurs at a lower than normal capillary oxygen tension. An increased affinity may be enough to ensure that oxygen is released to the tissues unless the tissue P_{O_2} is in the hypoxic range. The theoretical and clinical evidence supporting the accuracy of this hypothesis during infusion is discussed in the following sections.

Theoretical Evidence

A close relationship between the oxygen affinity of stored blood and intraerythrocytic 2,3-DPG has been established. [42] The intraerythrocytic 2,3-DPG levels decrease stored bank blood. Alkalosis and hypothermia shift the curve to the left even more (Fig. 46-2) . Support for the importance of these shifts in the curve base can be derived from studies that manipulate the Fick equation, that is, that cardiac output (CO) equals oxygen consumption (O_2) divided by the arteriovenous oxygen difference (Ca_{O_2} - Cv_{O_2}, or $C(a\text{-}v)O_2$). Rearranged, the equation reads

$$Cv_{O_2} = Ca_{O_2} - VO_2/CO$$

Therefore, mixed venous oxygen content or tension reflects the relationship between oxygen consumption and cardiac output. A low mixed-venous oxygen tension suggests that cardiac output cannot meet the tissue oxygen demands.

Clinical Evidence

The clinical evidence is not consistent, reflecting the difficulty of conducting a systematic study of seriously ill patients in varied clinical settings. Kopriva et al [43] found that 2,3-DPG levels decreased in 31 seriously injured battle

casualties, each of whom received 12 or more units of ACD-stored blood. Furthermore, transfusion of fresh or stored blood did not influence the 2,3-DPG levels. The more common finding is that the P_{50} and 2,3-DPG levels do decrease after infusion of stored blood. [44] Although Sheldon [45] did find low P_{50} and 2,3-DPG values after infusion of CPD-stored blood (at 90% of the blood volume), no correlation between these values and cardiac index was found. On a theoretical basis, however, the left shift in the oxygen dissociation curve and the increased affinity for oxygen may increase cardiac output and work of the heart. [44] If a patient has marginal cardiac reserve and cannot increase cardiac output, tissue hypoxia may occur.

Although this evidence is suggestive, specific organ hypoxia has not been shown to result from infusion of blood with a low P_{50} or from increased affinity for oxygen. Valeri and Collins [46] performed a study in a group of patients who especially depended on adequate levels of 2,3-DPG for oxygen transport. Patients who had anemic hypoxia were transfused with three to five units of washed, liquid-stored RBCs that were depleted of 2,3-DPG and experienced an increased affinity for oxygen. No change in cardiac index or oxygen consumption resulted. Therefore, even in patients in whom 2,3-DPG is especially important for oxygen transport, no changes occurred. In fact, Bowen and Fleming [47] showed that although oxyhemoglobin affinity increases after transfusion of stored blood, arteriovenous oxygen extraction by organs or tissue may not be altered by changes in oxyhemoglobin affinity, particularly if a compensatory flow mechanism takes place at the capillary level. Such mechanisms may open capillaries, permitting increased blood flow to tissue, thereby increasing cardiac output and reducing the capillary tissue oxygen gradient to maintain the rate of tissue oxygen extraction. Because of the low P_{50} and the increased oxyhemoglobin affinity of stored blood, assessment of specific organ function is necessary to substantiate the possible injurious effect of stored blood. Marik and Sibbard [9] found that the administration of blood that had been stored for more than 15 days actually decreased intramucosal pH, suggesting that splanchnic ischemia had occurred. Was this effect due to low 2,3-DPG levels in the stored blood and to an increased affinity of hemoglobin for oxygen? Despite these data, the evidence that possible changes in oxygen affinity from blood transfusions are important is not available. Therefore, it is difficult to come to definitive conclusions.

Coagulation

A bleeding tendency is often present in massively transfused patients. This coagulopathy is caused by a combination of factors of which the most important are the volume of blood given and the duration of hypotension or hypoperfusion. [48] Patients who are well perfused and are not hypotensive for a long period of time (e.g., 1 hour) can tolerate multiple units of blood without developing a coagulopathy. Clearly, the patient who is hypotensive and has received many units of blood probably has a coagulopathy from both disseminated intravascular coagulation (DIC) and dilution of coagulation factors from stored bank blood. When such bleeding occurs, the differential diagnosis for a patient who did not have a pretransfusion coagulopathy (e.g., hemophilia) is dilutional thrombocytopenia, low factors V and VIII, DIC, or hemolytic transfusion reaction. Clinical manifestations include oozing into the surgical field, hematuria, gingival bleeding, petechial bleeding from venipuncture sites, and ecchymoses.

Dilutional Thrombocytopenia

Dilutional thrombocytopenia is a cause of a hemorrhagic diathesis in a patient who has received multiple units of bank blood. At a storage temperature of 4°C, platelets in stored blood are damaged sufficiently to be readily trapped and absorbed by the reticuloendothelial system soon after infusion. Even those platelets that are not immediately stored have a reduced survival time. Considering survival time and viability, total platelet activity is only 50 to 70 percent of the original *in vivo* activity after 6 hours of storage in bank blood at 4°C. After 24 or 48 hours of storage, platelet activity is only about 10 or 5 percent of normal, respectively. Thus, infusion of bank blood stored for longer than 24 hours dilutes the available platelet pool. In one study during the Vietnam conflict, platelet counts were found to decrease to below 100,000/mm^3 when 10 to 15 units of blood had been given to acutely wounded, previously healthy soldiers. [49] Obviously, the platelet count in smaller, older patients may decrease to 100,000/mm^3 after fewer units of blood because these patients have a smaller blood volume and possibly a lower preoperative platelet count than soldiers. I strongly emphasize the importance of the platelet count because when it is approximately 75,000/mm^3 or lower, a hemorrhagic diathesis is likely to occur (Table 46-5) .

Although major emphasis had been placed on monitoring the platelet count, several authors [48] [50] [51] have questioned the role of dilutional thrombocytopenia in the coagulopathy of massively transfused patients. They correctly point out that the platelet count rarely decreases as low as what would be predicted from dilution alone (Fig. 46-3) (Figure Not Available) . This is probably because platelets are released into the circulation from the spleen and bone marrow and because of the presence of nonfunctional platelets. Furthermore, Reed et al [51] found no benefit to prophylactic platelet administration during massive transfusion. Platelets should not be given to treat laboratory evidence of thrombocytopenia unless clinical coagulopathy is also present. Treating laboratory numbers without correlation with the clinical status is fundamentally contrary to good medical practice; transfusion medicine is no exception. Clearly, when the platelet count is below 50,000 to

TABLE 46-5 -- Correlation Between Platelet Count and Incidence of Bleeding

PLATELET COUNT (cells/mm^3)	TOTAL NO. OF PATIENTS	NO. OF PATIENTS WITH BLEEDING

>100,000	21	0
75,000-100,000	14	3
50,000-75,000	11	7
<50,000	5	5

Data from MIller et al [49]

Figure 46-3 (Figure Not Available) Mean platelet counts after massive transfusions in relation to number of units of blood transfused. Observed versus predicted values calculated on the basis of blood exchange model. *(From Myllyla* [179] *)*

75,000/mm^3 , a bleeding problem is likely and is probably a combination of dilutional thrombocytopenia and DIC. Platelet therapy would be appropriate in this situation (see Platelet Concentrates).

To place such emphasis on the platelet count as a guide is appropriate, as defended previously, with some exceptions. For example, patients with chronic thrombocytopenia or leukemia are commonly known to survive and not have a hemorrhagic diathesis with a platelet count lower than 15,000 cells/mm ^{3} . However, this does not negate the general guideline that patients with a platelet count of less than 75,000 cells/mm ^{3} are likely to bleed. For unexplained reasons, patients with an acutely induced thrombocytopenia (e.g., from blood transfusions) develop a hemorrhagic diathesis at a much higher platelet count than do patients with a chronically induced thrombocytopenia (e.g., idiopathic thrombocytopenia purpura). Furthermore, a higher platelet count is required to maintain adequate hemostasis with a surgical incision or trauma, because damaged capillaries require platelets to plug the holes. Thus, the platelet count is a reasonably accurate guide as to when patients will develop a bleeding problem from dilutional thrombocytopenia (see Table 46-5) .

Low Factors V and VIII

Most of the factors are stable in stored blood, with two exceptions: factors V and VIII. [52] These factors gradually decrease to 15 and 50 percent of normal, respectively, after 21 days of storage. Furthermore, packed RBCs even have fewer coagulation factors. Consequently, administration of fresh frozen plasma (FFP), which contains all the factors except platelets, has been recommended on either a therapeutic or a prophylactic basis. However, this practice is of questionable benefit because only 5 to 20 percent of factor V and 30 percent of factor VIII are needed for adequate hemostasis during surgery. In other words, in spite of a patient's receiving massive blood transfusion, factors V and VIII rarely decrease below those levels required for hemostasis. Miller et al [49] examined this problem by giving 500 to 1,000 mL of FFP to five patients who had received more than 15 units of bank blood and who had a clinically significant hemorrhagic diathesis. Despite the partial thromboplastin times (which measure all factors except VII and XIII) and platelets' having returned to normal, bleeding persisted in every patient. Only when platelets in the form of fresh blood were administered did bleeding cease. [49] Thus, although low factors V and VIII appear to be an unlikely primary cause of bleeding during massive blood transfusion, such deficiencies may intensify bleeding from other causes, usually dilutional thrombocytopenia in the case of blood transfusion.

Despite evidence to the contrary, FFP continues to be commonly given for treatment of transfusion-induced coagulopathies. The overall increased use of FFP in the 1970s led the National Institutes of Health to conduct a consensus conference on this issue in 1985. [53] The conference concluded that there was little or no scientific evidence for the administration of FFP as part of the therapy for coagulopathy induced by multiple blood transfusion. Despite the National Institutes of Health statement, component blood therapy, especially FFP, continues to be given. [54] If the clinician insists on seriously considering giving FFP, the following criteria should be established:

1. Generalized bleeding that cannot be controlled with surgical sutures or cautery
2. Partial thromboplastin time at least 1.5 times normal
3. Platelet count greater than 70,000/mm^3 (to ensure that thrombocytopenia is not the cause of bleeding)

Disseminated Intravascular Coagulation

The coagulation system consists of clotting and fibrinolytic mechanisms. The function of the former is to prevent excessive blood loss, and that of the latter is to ensure circulation within the vasculature. With DIC, the clotting system is deranged, and this leads to disseminated fibrin deposition, which renders the fluid blood unclottable. The deposited fibrin may severely alter the microcirculation and lead to ischemic necrosis in various organs, particularly the kidney. The unclottable blood or circulating serum may induce a severe hemorrhagic diathesis.

The specific reasons for the development of DIC are usually not apparent. However, hypoxic acidotic tissues with stagnant blood flow probably release tissue thromboplastin either directly or through liberation of some toxin. In sepsis and eventual organ failure, the pathogenesis of DIC is more apparent. Apparently the extrinsic route of coagulation is activated by tumor necrosis factor and endotoxins. Presumably, tumor necrosis factor induces tissue factor expression on the surface of activated monocytes and possibly by exposure to subendothelially localized tissue factor in blood. [55] Although the intrinsic system does not induce DIC, it may contribute to hypotension. This triggers the coagulation

Figure 46-4 (Figure Not Available) Schematic representation of primary fibrinolysis and fibrinol-ysis secondary to disseminated intravascular coagulation (DIC). Although epsilon-aminocaproic acid (EACA) inhibits primary fibrinolysis, it also inhibits secondary fibrinolysis, one of the main defenses against DIC. *(From Miller* [52] *)*

process (Fig. 46-4) (Figure Not Available) , resulting in consumption of factors I, II, V, and VIII and platelets. Supposedly, thrombi and fibrin are deposited in the microcirculation of vital organs, interrupting their blood flow.

In an attempt to counteract the hypercoagulable state, the fibrinolytic system is activated to lyse the excessive fibrin almost simultaneously; this is termed *secondary fibrinolysis.* Primary fibrinolysis is very rare and refers to activation of the fibrinolytic system without concomitant DIC (Fig. 46-4) (Figure Not Available) . With secondary fibrinolysis, activation of plasminogen to plasmin (fibrinolysis; see Fig. 46-4) is a protective mechanism that tends to prevent further DIC. With fulminate DIC and subsequent rapid depletion of coagulation factors, plasmin is formed from plasminogen at a rapid rate. The resultant fibrinolysis caused by plasmin creates a paradoxical state. Fibrinolysis does protect against further DIC but may also contribute to the severity of the bleeding diathesis. Plasmin digests fibrinogen, further reducing the fibrinogen level. The digestion of fibrinogen results in the formation of fibrin-split products in the serum; the presence of these products indicates fibrinolysis. While the fibrinolytic system is actively trying to counteract DIC in early stages, plasminogen activator activity and plasmin generation rapidly decline, leaving DIC to progress unopposed. [55] It is at this stage that severe morbidity and eventually mortality are likely to occur.

Disseminated intravascular coagulation should not be considered a distinct disease entity but rather a sign of another disease. Accordingly, DIC has been associated with nearly all life-threatening diseases. Any condition in which tissue damage is sufficient to release tissue products or toxins into the circulation can be associated with DIC. Should enough thromboplastin lodge in the circulating blood, the result is massive focal necrosis or more generalized activation of the coagulation system.

That DIC is a primary cause of organ failure, as suggested earlier, is an attractive hypothesis but has been challenged. Attar et al [56] observed probable DIC in 294 patients with shock but found no fibrin deposits in 52 of them examined at autopsy. Furthermore, survival rates of patients who have DIC associated with hypovolemia or septic shock are not increased by the administration of heparin. [57] [58] Mant and King [59] provided an excellent evaluation of 47 patients with severe acute DIC mostly resulting from shock, infections, trauma, hepatic disease, and malignancy. Routine treatment included aggressive therapy of the underlying diseases and administration of blood products and vitamin K when indicated. Of the 47 patients, 12 were treated with heparin; bleeding worsened in seven (58%) and DIC diminished in five (42%). A total of 35 patients did not receive heparin; the DIC diminished in 13 (37%), but overall, 30 patients (86%) died. The investigators felt death could not have been prevented by heparin therapy. Also, microvascular thrombi were not found in 25 patients examined at autopsy. On the basis of these

findings, Mant and King [59] provided the following conclusions, which we feel accurately summarize the current knowledge of DIC:

1. DIC is a relatively uncommon entity.
2. Accompanying microvascular thrombosis is uncommon.
3. DIC rarely causes significant organ damage and infarction.
4. Accompanying large vessel thrombosis is relatively common but is probably not primarily caused by DIC.
5. Although bleeding is common, severe bleeding usually originates from sites of local disorder (e.g., lacerated liver).
6. Heparin is seldom useful and often causes hemorrhage.
7. DIC is associated with high mortality primarily because of the severity of the patient's underlying disorder.
8. DIC is perhaps best regarded as an incidental preterminal event in most patients.

More recently, Fourrier et al [60] confirmed the aforementioned statements and concluded that DIC is a strong predictor of death. These investigators found that measurements of antithrombin III, protein C, and protein S levels were consistent with sustained DIC and inhibition of fibrinolysis. In fact, they stated that initial antithrombin III levels were the best predictor of death in septic patients.

Hemolytic Transfusion Reaction

The appearance of a hemorrhagic diathesis after blood transfusion should signal the possibility of a hemolytic transfusion; this entity is discussed later in this chapter.

Figure 46-5 (Figure Not Available) Correlation between units of blood administered and percent of patients who had a hemorrhagic diathesis. The numbers in parentheses represent the number of patients at each data point. *(From Miller [180])*

Diagnosis and Treatment of a Hemorrhagic Diathesis After Whole Blood Transfusions

Although treatment is more likely to be successful when the cause of the bleeding problem has been identified, precise diagnosis is often difficult. The more common, readily available laboratory tests seldom yield information precise enough to establish an accurate diagnosis. [52] For example, thrombocytopenia is most likely on a dilutional basis but could be secondary to DIC alone or DIC associated with a hemolytic transfusion reaction. Laboratory tests offering more precise information, such as euglobulin lysis time, often are not readily available or take too long to perform to be practical in an emergency situation.

When the problem of a clinical hemorrhagic diathesis associated with blood transfusions occurs, one approach is to obtain a blood specimen on which the following tests can be performed: platelet count, partial thromboplastin time, plasma fibrinogen level, and observation of a clot for size, stability, and lysis and of the plasma for evidence of hemolysis. For many years, thromboelastography and assessment of the viscoelastic properties of plasma (Sonoclot) [61] have occasionally been recommended for monitoring the influence of blood loss and transfusions on coagulation. However, these techniques have not been widely accepted.

Although many other diagnostic approaches probably are equally valid, the preceding approach works well for me. Provided that the partial thromboplastin time is 1.5 times normal or more increased and other tests are normal, the bleeding is probably a result of very low levels of factors V and VIII. This can be treated with FFP, which contains all the coagulation factors except platelets. Although the preceding situation is a nice textbook description, I have never observed clinical situation involving blood transfusions in which the partial thromboplastin time was increased without the presence of thrombocytopenia.

As indicated, dilutional thrombocytopenia in association with DIC is the most likely cause of bleeding from blood transfusion. [49] [52] When the platelet count is less than 100,000/mm^3 , a bleeding problem is likely to develop (see Table 46-4) ; therefore, platelets are ordered. Unfortunately, the common delay between ordering and receiving the platelets dictates that they be ordered before the appearance of a hemorrhagic diathesis. Our rule of thumb is based on the fact that a bleeding diathesis probably will develop after infusion of 20 units of stored blood in healthy patients and after lesser amounts in debilitated or small patients (Fig. 46-5) (Figure Not Available) . Therefore, platelets should be ordered after infusion of 9 or 10 units of blood when several more will probably be required. Ideally, the platelets are available when 20 to 25 units of blood has been administered. The timing of ordering platelets in relation to when they will actually be required depends on the capabilities and the limitations of the local blood bank, which differ widely throughout the United States. Thus, the anesthesiologist and the surgeon must consult the blood bank before the need for platelets or any other blood component emerges.

Whether platelets are administered in the form of fresh blood, platelet-rich plasma, or platelet concentrates depends on volume replacement requirements, personal preference, and availability of laboratory personnel. Fresh blood (<6 hours old) supplies the greatest number of platelets per donation. More than 80 percent of the platelets can be given by platelet-rich plasma, which has half the volume of a unit of blood. However, because most blood banks advocate giving patients only those components that are necessary, platelet concentrates are frequently recommended. The remainder of the unit of blood, such as RBCs, plasma, and albumin, can be saved for other patients. Platelet concentrates are contained in a 50-mL unit and provide about 70 percent of the platelets in a unit of blood. In a 70-kg person, about 10 units of platelet concentrates is required to increase the platelet count by 100,000/mm ^{3} Although platelet concentrates are usually recommended, when a hypovolemic patient also needs replacement of RBCs, albumin, and other plasma coagulation factors, the infusion of fresh whole blood, if available, may be more practical than trying to infuse each of the components individually.

Although logistically difficult to obtain, fresh blood has been found to be extremely effective in treating transfusion-induced coagulopathies. My personal and subjective observations in Vietnam indicated that fresh blood (i.e., 6 hours or less and unrefrigerated blood) had a dramatic effect in patients with extensive hemorrhage. [49] About 20 years later, Lavee et al [62] found that 1 unit of fresh whole blood was as effective as, if not superior to, 8 to 10 platelet units. In 1996, Erber et al, [63] used fresh unrefrigerated whole blood in surgical patients with ongoing extensive bleeding despite adequate component replacement therapy and adequate surgical hemostasis. An accompanying editorial expressed caution and described the unfortunate problems with conducting a larger trial with fresh blood. [64] I believe that fresh blood also contains unidentified factors that make it far more effective than blood components.

Determining the plasma fibrinogen level is useful because this coagulation factor does not decrease in bank blood. Therefore, if the *in vivo* plasma fibrinogen level is low (<150 mg/100 mL), this is not a result of a dilutional coagulopathy and strongly suggests DIC. DIC is likely with thrombocytopenia, hypofibrinogenemia, and lysis of a clot within 2 hours. [52] Unfortunately, fibrinogen levels in packed

---

RBCs decrease with increasing storage time. As a result, hy-pofibrinogenemia occurs on a dilutional basis when multiple units of packed RBCs are given. [65] Thus, the separation of thrombocytopenia on a dilutional basis versus DIC cannot be accomplished by the use of fibrinogen level when packed RBCs have been given. Perhaps more specific readily available tests will be available in the future, [60] which will be especially important with potential therapies that are currently unavailable (e.g., monoclonal antibodies, anti-tumor necrosis factor antibodies, recombinant interleukin/receptor antagonists). [55] As indicated previously, the most effective treatment of DIC is removal or treatment of the basic disease process causing the DIC; these diseases usually cause DIC by release of damaged tissue products into the circulation. For example, the DIC associated with abruptio placentae usually ceases after emptying of the uterus and restoration of blood volume.

epsilon-Aminocaproic acid (EACA) inhibits the formation of plasmin and attenuates fibrinolysis (see Fig. 46-4) (Figure Not Available) . Obviously, EACA should not be used in the treatment of DIC. Blocking the fibrinolytic system and having the coagulation system activated have resulted in disseminated thrombosis. Because primary fibrinolysis is extremely rare other than in prostatectomy and liver transplantation [66] (Ch. 55) , EACA probably should not be given unless the preceding diagnosis is clearly established after expert consultation. As indicated, administration of EACA (for what was thought to be primary fibrinolysis but was really fibrinolysis secondary to DIC) can result in severe thrombotic episodes. Because the tests to distinguish primary from secondary fibrinolysis are not usually available, the risks of thrombotic episodes from EACA can be minimized by concomitant administration of heparin. Obviously, this becomes a complicated coagulation problem that exceeds the expertise of most surgeons and anesthesiologists.

Drugs Used to Improve Hemostasis

In addition to EACA, three other drugs have been recommended for perioperative coagulation problems. Two of those drugs have received special attention. The first is desmopressin (DDAVP), which is a synthetic analogue of the antidiuretic hormone vasopressin. It increases factor VIII and von Willebrand factor. It is, therefore, wellestablished therapy for hemophilia and von Willebrand disease. It has also been shown to reduce blood loss and transfusion requirement in patients with normal preoperative coagulation status who are undergoing spinal or cardiac surgery. However, the ultimate role of DDAVP remains to be determined. [66] [67] [68] DDAVP can cause hypotension, hyponatremia, and increased platelet adhesion.

Another drug is aprotinin, a serine protease inhibitor that inhibits fibrinolysis and improves platelet function. [69] It has been used to decrease blood loss in multiple surgical procedures, including cardiopulmonary bypass. However, its ultimate place in the treatment of coagulopathies has not been established.

The third drug is tranexamic acid, which is also an antifibrinolytic drug. Two studies found a decreased blood loss from total knee arthroplasty. [70] [71] Presumably, release of the pneumatic tourniquet releases fibrinolytic material, which is inhibited by tranexamic acid.

A large meta-analysis using perioperative blood transfusion as the outcome in cardiac surgery concluded that aprotinin and tranexamic acid, but not DDAVP, decreased the exposure of patients to allogeneic blood transfusion perioperatively. [72]

Clearly, the ultimate use of these drugs is evolving.

Diagnosis and Treatment of Hemorrhagic Diathesis After Packed RBC Transfusions

Most studies have examined the influence of massive transfusion of whole blood on coagulation because many trauma centers use whole blood. However, packed RBCs (see Packed Red Blood Cells) are often given because whole blood may not be available. With much less plasma, dilution of certain coagulation values may be more profound with the use of packed RBCs rather than whole blood.

Murray et al [65] specifically examined the question of using packed RBCs for major blood loss. In general, the direction of coagulation changes was similar to that seen with whole blood, with one major exception. With use of packed RBCs, fibrinogen levels decreased significantly in contrast to use of whole blood, in which fibrinogen levels remained unchanged unless DIC was present (Fig. 46-6) (Figure Not Available) . Although all the coagulation factors decreased, the decrease was less than expected from dilution. The researchers felt that factors such as VIII are probably stored in endothelial cells and released from the endothelium during surgical stress. When packed RBCs are used to replace major blood loss, the cli-nician may be tempted to give FFP prophylactically. However, Murray et al [65] specifically recommended not following the policy; they stated that FFP was needed only when prothrombin time and partial thromboplastin time were at least 1.5 times normal and fibrinogen levels were less than 75 mg/dL. These recommendations are similar to those stated in the section Fresh Frozen Plasma. More recently, Leslie and Toy [73] provided more specific guidelines when packed red cells are used for massive transfusions. They believed that when 12 or more units of packed red cells or cell-saver blood had been given, coagulation factors (i.e., FFP) were

Figure 46-6 (Figure Not Available) Decreases in fibrinogen level as blood volume is replaced with Adsol-packed red blood cells and crystalloid solutions. Each patient is represented by a solid line. *(From Murray et al [65])*

Figure 46-7 (Figure Not Available) Algorithm of the evaluation and initial therapy of the patient with suspected perioperative coagulopathy. Evaluation is based on the clinical scenario and is readily affected by type and location of injury, the amount of fluid administered, and the age and body temperature of the patient. necessary. Those patients who received 20 or more units often required platelet therapy, a finding identical to that of patients given whole blood.

An algorithm for the evaluation and initial therapy of a patient with a suspected coagulopathy is given in Figure 46-7 (Figure Not Available) .

Citrate Intoxication and Hyperkalemia

Citrate intoxication is not caused by the citrate ion per se, but because citrate binds calcium. Thus, the signs of citrate intoxication are those of hypocalcemia, that is, hypotension, narrow pulse pressure, and elevated intraventricular enddiastolic pressure and central venous pressure. However, if circulatory volume is reasonably well maintained, these cardiovascular changes do not occur unless ACD blood is given at a rate greater than 150 mL/70 kg/min, or about 1 unit of blood per 5 minutes in an average-sized adult. With newer preservatives with less citrate, intoxication is even less likely.

Decreased levels of serum ionized calcium do occur in low flow states, especially in out-of-hospital cardiac arrests. [74] These decreases have no predictable relationship to total plasma concentration. A possible conclusion is that if blood is given to such a critically ill patient, the serum ionized calcium levels may decrease even more. However, Drop and Laver [75] found that these abnormally low concentrations of ionized calcium were not readily corrected by intravenous administration of calcium salts in doses generally recommended (i.e., 1.0 g of calcium chloride). However, ionized calcium levels returned toward normal when hemodynamic status was improved by increasing the isoproterenol infusion rate. The beneficial effect of isoproterenol probably indicates that mobilization ionized calcium from body stores may be inadequate because of abnormal distribution of blood flow. Thus, improvement of a patient's circulatory status (blood transfusion) may ultimately increase ionized calcium levels without calcium administration. If calcium is given to patients with low-output states, calcium chloride may have to be administered at rates as high as 1.5 mg/kg/min. Drop and Laver [75] recommended that this amount of calcium chloride not be given without close monitoring of serum ionized calcium levels, because a constant relationship with total serum calcium level is not established.

With the absence of ionized calcium electrodes, the well-known inotropic stimulation may lead the clinician to administer calcium any time evidence of inadequate cardiac output is present, especially when multiple blood transfusions have been given.

Thus, even in patients with low-output states, I believe that emphasis should be placed on correcting the underlying disorder (i.e., hypovolemia) and that calcium administration is rarely necessary. [76] The reason that serum ionized calcium levels rapidly return to normal immediately after cessation of the blood transfusion (Fig. 46-8) (Figure Not Available) probably is rapid citrate metabolism by the liver and rapid calcium mobilization from available endogenous stores. Hypothermia, liver disease, liver transplantation, and hyperventilation increase the possibility of citrate intoxication. In fact, the appearance of severe hypocalcemia during liver transplantation is well documented (Ch. 55) . Obviously, the combination of infusion of large amounts of citrate (i.e., via blood transfusions) and of reduced metabolism from absent or reduced liver blood flow (i.e., in the anhepatic phases of liver transplantation) leads to citrate intoxication. As a result, calcium infusions are common during liver transplantation (Kelley S, personal communication, 1999). The rate of citrate metabolism is decreased by 50 percent when body temperature is decreased from 37° to 31°C. Excluding these conditions, infusion of more than 1 unit of blood every 10 minutes is necessary for ionized calcium levels to begin to decrease. Even at these rates of infusion, ionized calcium levels do not decrease enough to cause bleeding. As indicated previously, if a hemorrhagic diathesis starts after administration of blood, low calcium levels are not part of the differential diagnosis.

As evidenced from the preceding discussion, citrate intoxication is obviously rare. Serum potassium levels may be as high as 19 to 30 mEq/L in blood stored for 21 days. Although hyperkalemia is occasionally reported, [77] large amounts of blood must be given. For significant hyperkalemia to occur clinically, bank blood must be given at a rate of 120 mL/min or more. The fact that such rapid infusion rates of blood are required for the production of hyperkalemia suggests that the potassium ion must leave the intravascular spaces by diffusion into extravascular spaces, by reuptake into red cells, or via the kidneys. As with citrate intoxication, hyperkalemia is rare, and this again rules against the routine administration of calcium. In fact, calcium may cause cardiac arrhythmias, particularly in patients anesthetized with

halothane. Calcium administration should be based on diagnostic signs of hyperkalemia (peak T wave).

Even though it is reported to be irritating to veins, 10 percent calcium chloride provides three times more calcium than an equal volume of 10 percent calcium gluconate because chloride has a molecular weight of 147 and gluconate a molecular weight of 448.

Temperature

Administration of unwarmed blood that has been stored at 4°C can decrease the recipient's temperature. If the temperature decreases to less than 30°C, ventricular irritability and even cardiac arrest may occur. This can be prevented by warming the blood to body temperature before transfusion. I believe that there are more subtle reasons for warming all

Figure 46-8 (Figure Not Available) Correlation between the time during and after citrated whole blood infusion and serum-ionized calcium (mM/L.). *(From Denlinger et al [181])*

blood, even in patients receiving only 1 to 2 units intraoperatively. Because of the cool temperature of the operating room, body temperature often decreases, particularly in patients undergoing extensive abdominal surgery [79] (Ch. 37) ; administration of cold blood further decreases temperature. A decrease in body temperature as small as 0.5 to 1.0°C may induce shivering postoperatively; this in turn may increase oxygen consumption by as much as 400 percent. To meet the demands of elevated oxygen consumption, cardiac output must be increased. Is this too much stress for the patient with marginal cardiac reserve? More studies are required to confirm this fear.

Perhaps the safest and most common method of warming blood is to pass it through plastic coils immersed in warm water (37° to 38°C) bath. With increased use of packed RBCs (e.g., in contrast to whole blood), other methods of warming blood have been suggested. For example, Zorko and Polsky [79] added normal saline warmed to 45°C to packed RBCs. Clearly, maximal flow rates are achieved with diluted cells not passed through a warmer, but delivery temperature is higher when passed through a warmer (Table 46-6) (Table Not Available) . Despite the aforementioned well-documented information, five cases of overheated hemolyzed blood have been reported to the FDA during the past 10 years. [80] A variety of warming techniques have been reviewed by Iserson and Heustis. [81]

TABLE 46-6 -- Four Methods of Warming Packed Red Blood Cells

(Not Available)

Acid-Base Abnormalities

The pH of most storage media is very acidotic (CPD, 5.5). When this solution is added to a unit of freshly drawn blood, the pH of the blood immediately decreases to approximately 7.0 to 7.1. As a result of accumulation of lactic and pyruvic acids by RBC metabolism and glycolysis, the pH of bank blood continues to decrease to about 6.9 after 21 days of storage. A large portion of the acidosis can be accounted for by the P_{CO_2} of 150 to 220 mm Hg. The P_{CO_2} is high mainly because the plastic container of blood does not provide an escape mechanism for carbon dioxide. With adequate ventilation in the recipient, the high P_{CO_2} should be of little consequence. Even when the P_{CO_2} is returned to 40 mm Hg, metabolic acidosis is still present in blood (see Table 46-4) , and some clinicians empirically recommend giving alkalizing agents. Also, other reasonably well-controlled clinical studies have indicated that not only is empirical administration of sodium bicarbonate not indicated but it may also actually be unwise without concomitant analysis of arterial blood for P_{CO_2} and pH. [82] Miller et al [83] found that the metabolic acid-base response to blood transfusion was variable (Fig. 46-9) (Figure Not Available) . Actually, blood transfusions provide a substrate, namely citrate, in large quantities for the endogenous generation of bicarbonate, and this accounts for the significant incidence of metabolic alkalosis after blood transfusions. [82] Therefore, there is little logic in the empirical administration of bicarbonate for prophylactic treatment of an unpredictable acid-base abnormality. Bicarbonate therapy should be initiated when metabolic acidosis is diagnosed. This can be accomplished by analysis of arterial blood for P_{CO_2} and pH. When a suitable artery cannot be palpated because an

Figure 46-9 (Figure Not Available) Correlation between the amount of blood administered (mL) and corrected base excess intraoperatively. *(From Miller et al [83])*

extremity is inaccessible during a particular operative procedure, peripheral venous blood can be used for P_{CO_2} and pH determinations. During anesthesia, peripheral venous blood usually has a P_{O_2} of more than 60 mm Hg. Therefore, because this blood is arterialized, P_{CO_2} and pH can be determined, and the amount of bicarbonate required can be calculated. [84]

Although treatment of metabolic acidosis with bicarbonate has been viewed as being important, can any harm result from excessive bicarbonate administration or from metabolic alkalosis (Chs. 38 and 75) ? Actually, large doses of bicarbo-nate (e.g., 1-10 mEq/kg) can interfere with coagulation, as evidenced by prolonged prothrombin and thrombin clotting times. [85] Also, alkalosis augments a left shift of the oxygen dissociation curve. Because of citrate metabolism, exogenous bicarbonate, and administration of lactated Ringer solution, metabolic alkalosis commonly occurs after infusion of several units of blood. Thus, bicarbonate administration should be reserved for patients in whom severe metabolic acidosis (base excess >7 mEq/L) has been diagnosed.

Infusion of Microaggregates

In 1970, Moseley and Doty [86] demonstrated that amounts of clot and debris in bank blood increased with duration of storage. Some of this particulate matter is not filtered by the standard 170-m filter during routine transfusion and enters the recipient's blood stream. [86] These authors suggest, therefore, that respiratory insufficiency in patients with severe trauma and hemorrhage (so-called shock lung) or adult respiratory distress syndrome may be a result of the accumulation of this particulate material in the lungs, resulting in vascular obstruction. Several filters with pore sizes less than 40 m (micropore filters) are now available to remove microaggregates from bank blood. When massive transfusions of stored blood are involved, the use of micropore filters, in theory, should eliminate this important contributor to the development of adult respiratory distress syndrome. However, the evidence supporting the preceding concept and the need for micropore filters during massive transfusions of stored blood is unproved.

More recent information suggests that the thrombocytopenia associated with transfusions can be attenuated by the use of micropore filters. [87] [88] Also, the removal of white blood cells may reduce the infectivity of blood. [89] In fact, it is likely that prefiltered blood designed to remove most of the white blood cells will be routinely provided by blood banks in the future. Lastly, newer preservative solutions will probably eliminate microaggregates. Clearly, the use of micropore filters is evolving and is not resolved. [90]

Transfusion Reactions

Hemolytic Transfusion Reaction

Since 1975, the FDA has required that all fatal reactions occurring in blood recipients or donors be reported within 24 hours by telephone, or within 7 days in writing, by all FDA-registered transfusion services. In the 10-year period from 1976 to 1985, 328 deaths have been reported and ana-lyzed. [91]

Of these deaths, 159 were acute from hemolytic reactions and 23 from delayed reactions. Of the 159 deaths due to acute hemolytic reaction, 137 were caused by errors involving ABO incompatibility. More than half of these mistakes occurred after the blood had been issued by the blood bank and were committed by nurses and physicians in the operating room, emergency room, or ward. The incidence of hemolytic transfusion reaction is in the range of 1/300,000 to 1/700,000 RBC transfusions. [92] [92] However, when delayed hemolytic reactions (discussed in a later section) are included, the incidence of ABO-incompatible RBC transfusion is much more frequent. [94] Even though the incidence is low, the anesthesiologist must know the principles of recognizing and treating hemolytic transfusion reactions

because of the high morbidity and mortality rate. One of the most catastrophic transfusion reactions is that arising from intravascular hemolysis. Intravascular hemolysis occurs when there is a direct attack on transfused donor cells by recipient antibody and complement. Such a reaction can occur from infusion of as little as 10 mL of blood. [95] Mortality may occur in 20 to 60 percent of those patients with severe symptomatic hemolytic reactions, and these deaths usually result from ABO blood group incompatibility between the donor and the patient. Hemolytic transfusion reactions involving extravascular RBC destruction are generally less serious than those of the intravascular variety. In these cases, recipient antibody coats but does not immediately hemolyze the transfused RBCs. Destruction occurs primarily in the reticuloendothelial system.

Signs and Symptoms

The clinical consequences of incompatible blood transfusions are very serious and yet quite variable. Factors include volume of transfused blood, number of antigenic sites on the red cell membrane, and activity of the reticuloendothelial system. The properties of the antibody, including concentration and ability to activate complement, are also important.

The classic signs and symptoms (Table 46-7) of a hemolytic transfusion reaction--chills, fever, chest and flank pain, and nausea--are masked by anesthesia. Under general anesthesia, the only signs may be hemoglobinuria, bleeding diathesis, or hypotension. In my and Huh and Lichtiger's experience [96] with six and four hemolytic transfusion reactions, respectively, the presenting sign was hemoglobinuria in nine

TABLE 46-7 -- Frequency and Signs and Symptoms From Hemolytic Transfusion Reactions in 40 Patients

SIGN OR SYMPTOM	NO. OF PATIENTS
Fever	19
Fever and chills	16
Chest pain	6
Hypotension	6
Nausea	2
Flushing	2
Dyspnea	2
Hemoglobinuria	1

Figure 46-10 Schematic representation of what happens to hemolyzed erythrocytes as a result of the administration of incompatible blood.

of the ten cases. As little as 50 mL of incompatible blood may exceed the binding capacity of haptoglobin, which is a protein that can bind about 100 mg of hemoglobin per 100 mL of plasma. When hemoglobin not exceeding this amount is injected or liberated into the blood stream, the hemoglobin circulates as a complex with haptoglobin, which is cleared by the reticuloendothelial system (Fig. 46-10) . A sample of plasma that contains 2 mg/dL of hemoglobin is faintly pink or light brown. When the level of hemoglobin reaches 100 mg/dL, then the plasma is red. When the level of plasma hemoglobin reaches 150 mg/dL, hemoglobinuria occurs. In general, the quantity of the free hemoglobin in the plasma is correlated with the volume of incompatible blood transfused. Thus, the symptomatology can be so alarming that cessation of blood is indicated, even if hemoglobin is not seen in plasma. Laboratory tests that should be performed if hemolytic transfusion reaction is suspected include serum haptoglobin, plasma and urine hemoglobin, bilirubin, and direct antiglobulin determinations. The direct antiglobulin test can confirm the presence of hemolytic transfusion reaction because it shows that there is antibody attached to transfused donor red blood cells. [97]

Treatment

If a hemolytic reaction is suspected, blood and urine samples should be sent to the laboratory for examination. The blood bank should check all paperwork to ensure that the correct blood component was transfused to the patient. Laboratory tests should be performed to determine the presence of hemoglobinemia: a direct antiglobulin test, repeat compatibility testing, repeat other serologic tests (i.e., ABO and Rh) and analysis of urine for hemoglobinuria.

Although there are several consequences of intravascular hemolysis, mainly the renal and coagulation systems are affected. The exact cause of acute renal failure from intravascular hemolysis is controversial, but the most common hypothesis is that hemoglobin in the form of acid hematin precipitates in the distal tubule and causes mechanical tubular blockage. The magnitude of the precipitation probably is inversely related to the volume of urine flow and its pH. The primary emphasis of therapy should be directed toward maintaining urinary output in excess of 75 mL/h by generous administration of intravenous fluids and diuretics. My

approach is summarized in Table 46-8 and includes the administration of lactated Ringer solution to maintain the central venous pressure between 10 and 15 cm H_2O while initially administering 12.5 to 50 g of mannitol. If ineffective, then the dose of mannitol may be increased and/or the use of more potent diuretics, such as furosemide, which increases blood flow to the renal cortex, may be required to maintain adequate urinary output. Alkalinization of the urine to prevent precipitation of acid hematin in the distal tubules is of questionable value but is easy and therefore recommended. DIC commonly occurs with hemolytic transfusion reactions, probably because RBC stroma is severed, releasing erythrocytin, which activates the intrinsic system of coagulation. This activated coagulation leads to fibrin formation. Subsequently, platelets and factors I, II, V, and VII are consumed. As soon as a hemolytic transfusion reaction is recognized, platelet count, prothrombin time, and partial thromboplastin time should be determined to provide baseline values with which subsequent laboratory values can be compared. Hypotension during a hemolytic transfusion reaction may be due to activation of the kallikrein system. [98] After a series of reactions, plasma kininogen is converted to bradykinin, a potent vasodilator that can cause hypotension.

Another approach to treatment of a severe hemolytic transfusion reaction has been proposed by Seager et al, [99] who postulated that the kidneys might be spared from exposure to massive amounts of hemolyzed red cells by removing all blood from a patient and replacing it with compatible blood. This was accomplished in a patient who had received 3,000 mL of incompatible blood by hemodilution by use of an extracorporeal circuit. Because the patient had rapid recovery of urinary function, this method shows much promise.

In summary, hemoglobinuria or hemolysis should be assumed to be a hemolytic transfusion reaction until proved otherwise. The steps outlined in Table 46-8 should be taken when the diagnosis is suspected or confirmed.

Delayed Hemolytic Transfusion Reaction (Immune Extravascular Reaction)

As described earlier, an immediate hemolytic transfusion reaction often is a dramatic event because the concentration of the antibody is high enough to cause immediate and appreciable RBC destruction. However, in many cases of hemolytic transfusion reaction, the transfused donor cells may survive well initially but after a variable delay (2-21 days) is hemolyzed. [100] [101] This type of reaction occurs mainly in recipients sensitized to RBC antigens by previous blood transfusions or pregnancy. As a result, this type of delayed reaction is more common in females who have a known disposition of alloimmunization. These reactions are delayed hemolytic transfusion reactions and are those in which the level of antibody at the time of transfusion is too low to be detected or too low to cause RBC destruction. RBC destruction occurs only when the level of antibody is increased after a secondary stimulus (anamnestic response). These delayed reactions are often manifested only by a decrease in the posttransfusion hematocrit value. However, jaundice and/or hemoglobinuria can occur in these patients and can

TABLE 46-8 -- Steps for the Treatment of a Hemolytic Transfusion Reaction

1. STOP THE TRANSFUSION.

2. Maintain the urine output at a minimum of 75 to 100 mL/h by the following methods:

a. Generously administer fluids intravenously and possibly mannitol, 12.5 to 50 g, given over a 5- to 15-minute period.

b. If intravenously administered fluids and mannitol are ineffective, then administer furosemide, 20 to 40 mg, IV.

3. Alkalinize the urine; because bicarbonate is preferentially excreted in the urine, only 40-70 mEq/70 kg of sodium bicarbonate is usually required to raise the urine pH to 8, whereupon repeat urine pH determinations indicate the need for additional bicarbonate.

4 Assay urine and plasma hemoglobin concentrations.

5. Determine platelet count, partial thromboplastin time, and serum fibrinogen level.

6. Return unused blood to blood bank for re-crossmatch.

7. Send patient blood and urine sample to blood bank for examination (see text for details).

8. Prevent hypotension to ensure adequate renal blood flow.

---

also cause some impairment in renal function, but only rarely do they lead to death. Unlike immediate reactions, antibodies most commonly involved in delayed hemolytic reactions are those in the Rh and Kidd systems rather than the ABO system. Although improved blood banking procedures have decreased the incidence of immediate hemolytic transfusion reactions, the delayed hemolytic reaction may not be preventable, because pretransfusion testing is unable to detect very low levels of antibody present in potential blood recipients.

Although impairment of renal function is uncommon, the surgical team should include in their differential diagnosis a delayed hemolytic transfusion reaction in any patient who has an unexplained decrease in hematocrit 2 to 21 days after a transfusion, even without obvious manifestation of hemolysis. This is especially important in a postoperative patient when the decrease in hematocrit value is thought to be from blood loss and may be an important criterion as to whether additional surgery is necessary.

Nonhemolytic Transfusion Reactions

These reactions to blood transfusions usually are not serious and are either febrile or allergic in nature. On occasion, fever could be the first sign of a hemolytic reaction or of bac-terial contamination. If the temperature increase is more than 1°C, a hemolytic reaction should be considered. [93] Bacterial contamination usually occurs with transfusion of platelets.

For less serious febrile reactions, the most common adverse reactions to blood transfusions are the febrile reactions. The symptoms consist of chills, fever, headache, myalgia, nausea, and nonproductive cough occurring shortly after blood transfusion. Less frequently, the patient may have hypotension, chest pain, vomiting, and dyspnea. Even pulmonary infiltrations with x-ray evidence of prehilar nodule formation and lower lung infiltrates along with overt pulmonary edema have been reported. [102] Because febrile reactions obviously involve fever, they can be easily confused with a hemolytic transfusion reaction. A direct antiglobulin

---

test readily differentiates a hemolytic reaction from a febrile reaction because this test rules out the attachment of an RBC antibody to transfused donor RBCs.

There is no clear consensus on whether the transfusion should be terminated when a febrile reaction occurs. [93] [103] [104]

Most allergic transfusion reactions are mild and are considered to be caused by the presence of foreign protein in the transfused blood. The most common symptom is urticaria associated with itching. Occasionally, the patient has facial swelling. Allergic reactions occur in about 3 percent of all transfusions. When these reactions are accompanied by fever or any other symptoms suggestive of a serious hemolytic reaction, it is not necessary to discontinue the transfusion. Antihistamines are used to relieve the symptoms of the allergic reaction. Infrequently, a more severe form of allergic reaction involving anaphylaxis occurs in which the patient has dyspnea, hypotension, laryngeal edema, chest pain, and shock. These are anaphylactic reactions caused by the transfusion of IgA to patients who are IgA deficient and have formed anti-IgA. This type of reaction does not involve red cell destruction and occurs very rapidly, usually after the transfusion of only a few milliliters of blood or plasma. The patients who experience these anaphylactic reactions must be given transfusions with washed red blood cells from which all traces of donor IgA have been removed, or with blood lacking the IgA protein. [105]

There are many other rare transfusions reactions, which have been reviewed by several authors. [91] [95] [96]

Infectivity of Blood

With the introduction of transfusion-induced AIDS, the infectivity by homologous blood transfusion has received renewed attention. In fact, for many years, blood banks use one or two tests (i.e., syphilis and hepatitis B surface antigen) to screen blood. In recent years, many more tests have been added (Table 46-9) (Table Not Available) . Overall, blood is probably safer than it has been for years.

Hepatitis

When blood transfusions became a reality in the 1940s, viral hepatitis was recognized as a major complication. Now, in the past 10 years, the incidence of viral hepatitis has dramatically

TABLE 46-9 -- Infectious Disease Testing for Blood Transfusions

(Not Available)

From JAMA 1995:274:1374

decreased. Nevertheless, when it occurs, it is very serious. Classically, icteric hepatitis develops 50 to 180 days after a blood transfusion and has a variable clinical course, ranging from asymptomatic to fatal. However, two to five anicteric cases occur for every case of overt icteric hep-atitis. Generally, the diagnosis of acute anicteric posttransfusion hepatitis is made with the observation, between 14 and 180 days after transfusion, of two consecutive elevations (at least 14 days apart) of the recipient's alanine aminotransferase level. Other possible causative factors, such as congestive heart failure, alcohol, and certain drugs that can mimic or simulate viral hepatitis, obviously must be considered. Both transaminase elevations must be at least 2 standard deviations above the geometric mean value for healthy persons.

Serologic requirements for the diagnosis of hepatitis B include the *de novo* appearance of hepatitis B surface antigen or hepatitis B surface or core antibody. Hepatitis A antibody seroconversion is considered evidence for hepatitis A infection. However, 90 percent of posttransfusion hepatitis is caused by the hepatitis C virus. Less than one-third of these patients develop jaundice. [106] To determine their ultimate fate, Tong et al [106] monitored 131 patients with chronic posttransfusion hepatitis C for several years and found the following incidence of signs, symptoms, and conditions:

1. Fatigue (67%)
2. Hepatomegaly (67%)
3. Chronic hepatitis (23%)
4. Chronic active hepatitis (51%)
5. Hepatocellular carcinoma (11%)

On follow-up, it was found that 20 patients had died, from

1. Complications of cirrhosis (eight patients)

2. Hepatocellular carcinoma (11 patients)
3. Chronic active hepatitis-pneumonia (one patient)

Before 1983 to 1985, the overall incidence of posttransfusion hepatitis ranged from a low of 3 percent to a high of 19 percent, depending on the institution and the location (e.g., donors from large cities have a higher incidence of the hepatitis virus). In most areas, the incidence of hepatitis has ranged from 3 to 10 percent. Since 1985, the incidence of posttransfusion hepatitis has decreased, probably for three reasons. First is improved donor screening. In 1984, donors who were in a high-risk category for AIDS were requested not to donate blood on a volunteer basis. Second, in 1985 all donor blood was tested for antibodies to the AIDS virus (see Acquired Immunodeficiency Syndrome). Third, a specific test for hepatitis C was developed. Specifically, molecular techniques were used to derive clones from the genome of hepatitis C. The derived proteins from these clones were used to develop an enzyme-linked immunosorbent assay to detect antibodies to hepatitis C. As a result, the incidence of posttransfusion hepatitis is lower by far than it has been for more than 20 years (Table 46-10) . [107] Despite the effectiveness of this test, donor infectivity is important as a screening device. Demographics of infectivity among donors is variable and is especially frequent in intravenous drug users. [108] Finally, it should be remembered that many blood components, such as packed red cells, FFP, and platelet concentrates, also transmit hepatitis at an incidence equal to that of whole blood.

There has been a concern about the relationship between transfusions and hepatitis delta virus. This virus is a defective RNA virus that cannot survive on its own and requires the helper function of a DNA virus, hepatitis B, to support its replication and expression. Therefore, the hepatitis delta virus can infect only persons with hepatitis B, either one in whom infections occur simultaneously or one who is a hepatitis B carrier. [109] This is a very virulent form of hepatitis, which can transform a mild chronic hepatitis B infection to severe progressive chronic active hepatitis and cirrhosis. Delta hepatitis can be prevented by vaccinating susceptible or high-risk individuals, such as anesthesiologists (Ch. 84) , with hepatitis B vaccine. However, the delta virus can be transmitted by blood transfusions. Rosina et al [110] concluded that screening donors for hepatitis B provides a high degree of safety in preventing infection with hepatitis delta virus but that the risk is greater in patients who are already carriers of hepatitis B. They concluded that hepatitis B carriers should be given only blood derivatives from a single donor or minipool donors.

Acquired Immunodeficiency Syndrome

Acquired immunodeficiency syndrome is characterized by severe depression of cellular immunity. Clinically, opportunistic infections and/or Kaposi sarcoma appears, progressing to debility and death. Pattern of transmission is similar to that of hepatitis B. Although AIDS is most frequently transmitted by intimate homosexual contact and intravenous drug abuse, nevertheless, whole blood, plasma, blood cellular products, or clotting factors can transmit AIDS. [111] Several measures have been recommended to decrease the chances that donor blood will be infected with AIDS. Blood banks have instituted procedures to discourage members of high-risk groups from donating blood. Designated donors and surrogate testing have been recommended. [112] [113] Despite these measures, there were hundreds of cases of transfusion-transmitted AIDS. In March 1985, all donor blood was tested for the presence of antibodies to the AIDS virus (human immunodeficiency virus type 1 [HIV-1]). This testing has dramatically reduced the incidence of transfusion-transmitted AIDS (Table 46-10) . [107]

TABLE 46-10 -- Percentage Risk of Transfusion-Transmitted Infection With a Unit of Screened Blood in the United States

	RISK	WINDOW PERIOD (DAYS)
HIV	1/493,000	22
HTLV	1/641,000	51
Cytomegalovirus	<1.0%	rapidly
HCV	1/103,000	82
HBV	1/63,000	59
Aggregate infection risk	1/34,000	--

[a] 88% of which is HBV and HCV

HIV, human immunodeficiency virus type 1; HTLV, human T-cell lymphotropic virus; HCV, hepatitis C virus; HBV, hepatitis B virus

Human T-Cell Lymphotropic Virus Type I

Human T-cell lymphotropic virus type I (HTLV-I) can be transmitted by blood transfusions and has been causally associated with adult T-cell leukemia and progressive myelopathy. Cohen et al [114] found that there is a very small risk of HTLV-I infection from transfused blood and blood products that have been screened for antibodies to HIV, but that risk is nearly 10-fold higher than risk of HIV infections. Specifically, they found the risk to be 0.003 percent/U for HIV infection and 0.024 percent/U for HTLV-I infection. Even though there is no firm association between transfusion and leukemia or myelopathy, the decision was made to test all donor blood for antibodies to the HTLV-I virus.

Cytomegalovirus

Asymptomatic chronic infection with cytomegalovirus (CMV) is so common in healthy adults that this agent can almost be viewed as normal flora. CMV survives best within cells and is thought to exist in latent form in the leukocytes of many people with antibodies indicative of earlier infection. CMV causes a heterophil antibody-negative response that closely resembles infectious mononucleosis in many respects. An infectious mononucleosis-like syndrome that can occur 1 to 2 months after open heart surgery is known as the postperfusion syndrome or posttransfusion mononucleosis. The evidence for transmission of CMV is most convincing when the recipient changes from a seronegative state before transfusion to a seropositive state accompanied by the mononucleosis-like illness several weeks after transfusion.

Transfusion-transmitted CMV can cause significant clinical problems in certain patient populations, such as premature neonates, allograph recipients, and patients who have had their spleens removed. [115] To prevent infection in high-risk populations, use of leukocyte-depleted blood, use of frozen deglycerolized RBCs, and screening of donors for the absence of antibody to CMV have been sometimes recommended. The risk of seroconversion is about 0.14 percent overall or 0.38 percent per unit of seropositive donor blood. [116] Wilhelm et al [117] concluded that it is not necessary to provide blood products from CMV-seronegative donors for most patients who receive blood transfusions. They con-tinue to use CMV-seronegative blood to prevent CMV infection in preterm and newborn babies. Whether CMVneg-ative blood should be used for other immunocompromised patients and pregnant women has not yet been resolved.

Other Transfusion-Associated Infectious Diseases

Although many other infectious diseases can theoretically be transmitted by blood transfusion, only a few are of real concern. They include *Y. enterocolitica* infection, syphilis, and malaria.

During the late 1980s, Tripple et al [118] described seven cases of fatal transfusion-associated *Yersinia enterocolitica* sepsis. These investigators also reviewed the literature and

found 26 cases of gram-negative bacterial sepsis with whole blood or packed RBCs. *Y. enterocolitica* is a bacterium that can cause mostly mild gastrointestinal problems. However, in severe cases, sepsis and death can occur. Unfortunately, storage of blood at 4°C in phosphate buffer enhances its growth. Aber [119] suggested that the donor screening process include assessment as to whether gastrointestinal problems occurred within 4 weeks of donation and that the storage time be minimized. More specific recommendations were not provided, although some were suggested by Grossman et al. [120]

Posttransfusion syphilis is unlikely because the infective agent cannot survive during storage at 1° to 6°C. The only blood products that have the potential to transmit syphilis are those stored at room temperature. Platelet concentrates are the blood component most likely to be implicated because they commonly are stored at room temperature.

Posttransfusion malaria has never been a significant cause of blood recipient morbidity. Nevertheless, malaria can occur, especially if blood donors at risk of harboring parasites are not excluded. Consequently, blood banks thoroughly question donors for history of travel or migration from areas where malaria is endemic.

Several other diseases have also been reported to be transmitted by blood transfusion, including herpes virus infections, infectious mononucleosis (Epstein-Barr virus), toxoplasmosis, trypanosomiasis, leishmaniasis, brucellosis, typhus, filariasis, measles, salmonellosis, and Colorado tick fever.

The Future of the Infectivity and Testing of Blood

Although the data in Table 46-10 are correct as of 1999, they will change fairly soon. With new tests that identify the nucleic acid of the virus, the "window period" will be reduced to as short as 1 day. This could decrease the incidence of HIV and hepatitis C to 1:1,000,000, making allogeneic blood incredibly safe from an infectivity point of view.

Other Adverse Effects of Blood Transfusion

Transfusion-Associated Graft-Versus-Host Disease

This disease occurs when donor lymphocytes from transfused blood products engraft in the recipient, initiating an immune reaction against host tissue. A generalized rash, leukopenia, and thrombocytopenia occur. Sepsis and death usually result. Irradiation of blood can prevent transfusion-associated graft-versus-host disease from occurring, although there is a report of one case occurring despite leukocyte filtering. [121]

Transfusion-Related Acute Lung Injury

This injury manifests as noncardiogenic pulmonary edema resulting from immune reactivity of certain leukocyte antibodies a few hours after transfusion. Specifically, it involves an antigen-antibody mechanism involving human leukocyte antigen and granulocyte antigens. Transfusionrelated acute lung injury is associated with a mortality rate (<10%) much lower than that from the adult respiratory distress syndrome.

Adverse Ocular Reaction

In 1997, 112 cases of bilateral conjunctival erythema were reported to have occurred within 24 hours of transfusion. The Centers for Disease Control and Prevention studied 49 other cases in 1997 and 1998 and concluded that they were toxic reactions to a chemical or material used in the blood collection filtration system, most likely a leukocyte-reducing filter system. [123]

Transfusion-Induced Immunodepression

Homologous (allogeneic) blood transfusion exerts a nonspecific immunosuppressive action on the recipient. This effect is therapeutic for kidney transplant recipients. However, many authors have presented data to indicate that blood transfusions increase susceptibility to infection and enhance progression of malignant tumors. Although many factors may be involved with seriously ill patients (e.g., patients who receive blood transfusions probably have more extensive and invasive disease), convincing evidence indicates that there is a relationship between perioperative transfusion and tumor recurrence or survival in patients with many types of cancer.

The mechanism of this effect on cancer is unknown but has been related to increased synthesis of prostaglandin E, decreased interleukin 2 generation, and fibrinogen degradation products in FFP. [124] This later finding has led to some concern about giving FFP to immunodepressed patients. Blumberg [125A] found that patients transfused with packed RBCs had a better survival rate than those patients receiving whole blood. As a result, it has been recommended that packed RBCs be given instead of whole blood when transfusions are indicated in patients with cancer. If this observation can be applied to the broad practice of transfusion medicine, the fewer problems with packed RBCs may be related to the presence of fewer white blood cells. This and other problems stimulated the Blood Products Advisory Committee of the FDA to recommend universal leukocyte reduction of cellular blood components. [125B] As with all aspects of transfusion medicine, careful evaluation of the indications for blood transfusions and emphasis on autologous blood transfusions (Ch. 47) are especially helpful in these patients.

Although much emphasis has been placed on the importance of transfusion-induced immunodepression, more recent evidence suggests the contrary, at least as far as cancer is concerned. For example, Younes et al [125] examined 116 patients who underwent resection of colorectal liver metastasis and concluded that number of hypotensive episodes, site of primary tumor, number of metastases, and preoperative carcinoembryonic antigen levels (and not blood transfusions) were the primary factors that could predict freedom

---

from disease 1 to 2 years postoperatively. One might conclude that autologous blood may be better than allogeneic blood because of the former's lack of effect on the immune system. As a result, allogeneic blood depresses cytokine production because of immunodepression. Anders et al [126] found that administration of autologous blood increases cytokine production. Cytokines play a central role in hemolytic reactions, and anaphylatoxins (C3a, C4a, and C5a) can cause release of vasoactive amines, smooth muscle contraction, increased vascular permeability, and release of lysosomal enzymes. Could it be that autologous blood actually has a disadvantage when compared to allogeneic blood (Ch. 47) ? Busch et al [127] compared the use of autologous versus allogeneic (i.e., homologous) blood with regard to prognosis. They concluded that regardless of the type of transfusion, transfusions are associated with a poor prognosis, probably because of the reasons that necessitated the use of blood. These observations emphasize the problems with attempting to assess the impact of one factor (i.e., transfusions) in complicated seriously ill patients. Because immunologic effects and "reactivation" of latent viral activity (e.g., HIV) are likely to be influenced by white blood cells, it is likely that increasing amounts of blood released for clinical use by the blood bank will be prefiltered to remove most of the white blood cells before transfusion.

Immunodepression is a complicated and controversial topic that ultimately could be very important. The mechanisms (Table 46-11) (Table Not Available) and downregulated immune functions (Table 46-12) (Table Not Available) have been reviewed by Landers et al. [128] Be-cause

hundreds of studies have been published, review articles in various anesthesia journals may be the best source of overall information. [128] [129] [130]

Overall Safety of Blood

This chapter is directed toward blood transfusion therapy as it relates to the practice of anesthesia. Reviews by authorities regarding the overall safety of blood

transfusion provide helpful information regarding the practice of medicine in general. [130] [131]

/das/book/view/29494766/875/528.html

BLOOD COMPONENT THERAPY

A major advance in the field of blood banking has been the development of blood component therapy. It is beyond the scope of this chapter to describe the various separation steps in detail, but a superficial outline of the scheme by which various blood components are derived is shown later in Figure 46-11 . The basic philosophy is based on the concept that patients are best treated by administration of the specific fraction of blood that they lack. This concept has presented problems to the surgical team, who often desire whole blood.

Packed Red Blood Cells

In essence, packed RBCs contain the same amount of hemoglobin as whole blood, but much of the plasma has been removed. Thus, the hematocrit value is 40 percent in whole blood and 70 percent in packed erythrocytes (Table 46-13) . The position of the American Association of Blood Banks has been that transfusion of whole blood is required primarily for blood loss acute enough to cause hypovolemic shock. More specifically, they state that the primary indication for whole blood is for patients who are actively bleeding and have sustained a loss of greater than 25 percent of their total blood volume. In other words, whole blood provides both oxygen-carrying capacity and blood volume expansion. Less severe degrees of hemorrhage may be effectively treated with packed RBCs, thus retaining the plasma and the components

TABLE 46-13 -- Comparison of Whole Blood and Packed Red Blood Cells

VALUE	WHOLE BLOOD	PACKED RED BLOOD CELLS
Volume (mL)	517	300
Erythrocyte mass (mL)	200	200
Hematocrit (%)	40	70
Albumin (g)	12.5	4
Globulin (g)	6.25	2
Total protein (g)	48.8	36
Plasma sodium (mEq)	45	15
Plasma potassium (mEq)	15	4
Plasma acid (citric-lactic) (mEq)	80	25
Donor/recipient ratio	1 unit per patient	1 unit every 4-6 patients

Figure 46-11 Diagrammatic scheme of separation of whole blood for component therapy.

thereof for other patients (see Fig. 46-11) . Many blood banks have religiously followed this principle, so that whole blood cannot be obtained in the operating rooms except by special request. In essence, blood bankers are saying that except for a rare situation (i.e., hypovolemic shock), whole blood is not necessary.

For the patient who has lost blood and needs both erythrocytes and intravascular volume, what advantage is there in receiving packed erythrocytes instead of whole blood? There are no prospective data that document reduced risk of posttransfusion hepatitis. Furthermore, the incidence of transfusion reactions is not reduced unless "buffy-poor" or previously washed cells are used. It is doubtful whether small plasma and white blood antigenic load are of any benefit. For those patients in whom anaphylactic reactions to IgA develop, the erythrocytes must be completely free of plasma. Finally, the use of packed RBCs does not reduce potassium load unless the erythrocytes are packed immediately before infusion. If the RBCs are packed when the blood is freshly drawn, as is the usual case, the amount of potassium removed is minimal.

Despite all the preceding evidence to the contrary, I believe packed RBCs should still be used instead of whole blood, except in cases of severe hemorrhage. My rule is to use packed RBCs for losses of blood of less than 1,500 to 2,500 mL/70 kg. With greater losses, whole blood probably should be used. The concept that whole blood should be used for losses of blood greater than 2,500 mL/70 kg is now widely accepted, even in blood banking circles. In our hospital, patients undergoing operative procedures known to require more than 3 to 4 units of blood (e.g., aortoiliac reconstruction) are automatically crossmatched for whole blood instead of packed RBCs. The greater use of packed RBCs will allow blood banks to use the plasma to make other components of blood readily available. Depending on the type of surgery, anywhere from 50 to 80 percent of the RBCs given should be in the form of packed RBCs.

Because of this trend, some hospitals do not have whole blood readily available. This may force the surgical team to use packed RBCs for losses of blood greater than 1,000 to 1,500 mL/70 kg. One fear has been that if large volumes of packed RBCs reconstituted with a crystalloid are given, serum albumin deficiencies may result. On the basis of limited clinical data, Howland et al [132] proposed that infusion of saline-reconstituted RBCs would lead to low serum levels of fibrinogen and albumin, which could be an etiologic factor in postoperative pulmonary edema. This fear has not been substantiated. Despite this controversy, administration of saline-reconstituted RBCs for losses of blood less than 2,500 mL/70 kg usually does not induce low serum levels of albumin, although fibrinogen concentration can be decreased in the recipient. [133]

The administration of packed RBCs is facilitated by reconstituting them with a crystalloid or colloid; however, not all crystalloids are suitable. If the solution contains calcium, clotting occurs. Therefore, lactated Ringer solution is usually not recommended for use as a diluent for packed RBCs (Table 46-14) . Conversely, using flow rates and clot formation, Cull et al [134] found both lactated Ringer's solution and normal saline to be equally acceptable. A more important

TABLE 46-14 -- Compatibility of Blood With Intravenous Solutions

BLOOD TO INTRAVENOUS SOLUTION: 1 : 1 RATIO	HEMOLYSIS AT 30 MIN	
	ROOM TEMPERATURE	37 ° C
5% dextrose in water	1+	4+

Plasmanate [a]	1+	3+
5% dextrose in 0.2% saline	0	3+
5% dextrose in 0.4% saline	0	0
5% dextrose in 0.9% saline	0	0
0.9% saline	0	0
Normosol-R, pH.4 [b]	0	0
Lactated Ringer solution	0 (clotted)	0 (clotted)

[a] Cutter Laboratories, Berkeley, California
[b] Abbott Laboratories, Chicago, Illinois

factor may be whether the diluent is hypotonic with respect to plasma. If so, then the RBCs will swell and eventually lyse. Those solutions that cause hemolysis are listed in Table 46-14 . Clinicians who fear that the crystalloid-reconstituted RBCs may cause low serum concentrations may be tempted to use a plasma derivative, such as Plasmanate. [135] However, these solutions can cause hemolysis also. In the case of Plasmanate, its osmolality is only 180 mOsm/kg. Thus, those solutions recommended for reconstituted packed erythrocytes are 5 percent dextrose in 0.4 percent saline, 5 percent dextrose in 0.9 percent saline, 0.9 percent saline, and Normosol-R with a pH of 7.4.

Blood banks have made available packed RBCs that have been diluted with the addition of 100 mL of an adenine-saline-dextrose solution (Adsol) as described earlier. This addition allows the blood to flow readily without the addition of saline. If improved flow is desired, however, the clinician should not use 5 percent dextrose in water or lactated Ringer solution. [136] Also some centers have used modified whole blood (i.e., the platelets are removed but much more plasma remains than that with packed RBCs) in which the flow characteristics are similar to those of whole blood. [137]

Leukocyte-Reduced Blood

The number of leukocytes in packed RBCs can be markedly reduced by three approaches. First, one can use an in-line filter that is integral to the collection system used to obtain blood from donors. Second, after collection, blood can be filtered through a filter attached to the collection bag. Third, the blood can be filtered immediately before or at transfusion.

Usually, leukocyte-reduced blood is used to minimize the likelihood of febrile, nonhemolytic transfusion reactions. However, it can be used to reduce alloimmunization and transfusion-transmitted infection. Leukocyte-reduced blood will probably be used more frequently in the future. As indicated earlier, the Blood Products Advisory Committee of the FDA has recently recommended universal leukocyte reduction of cellular blood components. [125A] This approach showed reduced infectivity, transfusion reactions, and immunosuppression.

Platelet Concentrates

Platelet concentrates are prepared by differential centrifugation, either from freshly drawn units of blood or from donors who specifically donate large amounts of platelets by recently developed plateletpheresis techniques. If platelets are stored at room temperature, they are satisfactory to use 5 days after collection with constant and gentle agitation. However, in the report of 10 septic platelet transfusions between 1982 and 1985, half were platelets stored for 5 days or more. A prospective analysis from 1987 to 1990 resulted in seven cases of sepsis in patients receiving platelets for thrombocytopenia secondary to bone marrow failure. [138] Because use of multidonor platelet products stored for 5 days results in an incidence of sepsis five times higher than use of those stored for 4 days, shorter storage times are being emphasized. In fact, platelet-related sepsis is about 1/12,000. [125A] The increased risk of bacterial overgrowth is related to the storage temperature of 20 to 24°C. Because there is no test to identify bacterially contaminated blood products, any patient who develops a fever within 6 hours after receiving platelets, sepsis from platelets should be considered. If blood products are stored at 4°C, then they should not be used longer than 24 or possibly 48 hours after collection. The allowable storage time is based on *in vivo* survival. The longer allowable storage time at room temperature adds flexibility to the blood bank.

Indications for the use of platelets are somewhat difficult to define. The July 1989 FDA Drug Bulletin stated that platelets should not be given (1) to patients with immune thrombocytopenia purpura (unless there is life-threatening bleeding), (2) prophylactically with massive blood transfusion, (3) prophylactically after cardiopulmonary bypass. However, the use of fresh blood rather than platelet concentrates as a source of platelets is still emphasized by some cardiac groups [139] and is advocated by some for treatment of hemorrhage in general. [70] [71] More recently, the ASA Task Force 2 recommended that

1. Prophylactic platelet transfusion is ineffective and rarely indicated when thrombocytopenia is due to increased platelet destruction (e.g., idiopathic thrombocytic purpura).
2. Prophylactic platelet transfusion is rarely indicated in surgical patients with thrombocytopenia due to decreased platelet production when the platelet count is greater than 100×10^9 /L and is usually indicated when the platelet count is below 50×10^9 /L. The determination of whether patients with intermediate platelet counts ($50\text{-}100 \times 10^{1C}$ /L) require therapy should be based on the patient's risk of bleeding.
3. Surgical and obstetric patients with microvascular bleeding usually require platelet transfusion if the platelet count is less than 50×10^9 /L and rarely require therapy if it is greater than 100×10^9 /L. With intermediate platelet counts ($50\text{-}100 \times 10^9$ /L), the determination should be based on the patient's risk for more significant bleeding.
4. Vaginal deliveries or operative procedures ordinarily associated with insignificant blood loss may be undertaken in patients with platelet counts less than 50×10^9 /L.
5. Platelet transfusion may be indicated despite an apparently adequate platelet count if there is known platelet dysfunction and microvascular bleeding.

Patients with severe thrombocytopenia (<20,000 cells/ m^3) and clinical signs of bleeding usually require platelet transfusion. However, patients may have very low platelet counts (much less than 20,000 cells/m^3) and not have any clinical bleeding. Patients such as these probably do not need platelet transfusion. Individuals who have undergone trauma or require surgery need higher platelet counts. As indicated previously, these patients probably need a platelet count of 100,000 cells/m^3 to maintain adequate hemostasis (see Table 46-5) . Thus, both laboratory determinations and clinical evaluations must be taken into account before a decision to transfuse platelets is made.

Whenever possible, ABO-compatible platelets should be used. The need to use them, however, is not well documented. Specific testing is difficult. Aggregation, the end point of RBC crossmatch, cannot be used because platelets cause clumping. The platelet membrane has immunoglobu-lins. Any additional deposit of recipient antibodies is diffi-cult

to detect. Despite the fact that platelets can be destroyed by antibodies directed against class I human leukocyte antigen proteins on their membranes and to a lesser extent by antibodies against ABO, platelets chosen for transfusion will continue to usually be chosen without regard to antigen systems. [140] ABO-incompatible platelets clearly produce very adequate hemostasis.

Platelets may be pooled into a single transfer bag or a syringe for administration or they may be administered as individual units. Several platelet administration sets are available for use. These all have filters with a pore size of about 170 m. Filters with smaller pore size (microaggregate filters) should not be used, because they tend to remove a significant number of platelets. Conversely, small filters are increasingly being used to hopefully decrease infectivity. Standard blood administration sets with 170-m filters are also acceptable. To decrease the loss of platelets, a 19-gauge needle, or greater, should be used. In order to ensure complete delivery of

all the platelets available, the containers should be rinsed with saline.

The effectiveness of platelet transfusions is difficult to monitor. Under ideal circumstances, one platelet concentrate usually produces an increase of about 7,000 to 10,000 platelets/m^3 1 hour after transfusion to the 70-kg adult. Thus, 10 units of platelet concentrates is required to increase the platelet count by 100,000 cells/m^3. However, many factors, including splenomegaly, previous sensitization, fever, sepsis, and active bleeding, may lead to decreased survivals and decreased recovery of transfused platelets.

In recent years, various different types of platelet concentrates have been proposed, including apheresis (i.e., collecting more platelets from one donor to avoid pooling of platelets from multiple donors), leukocyte-depleted platelets, and ultraviolet B-irradiated platelets. Whether these products will ultimately be used commonly is reviewed by Kruskall. [140]

Fresh Frozen Plasma

FFP is prepared at the time that blood is obtained from a donor. It contains all the plasma proteins, particularly factors V and VIII, which gradually decline during the storage of blood. The use of FFP carries with it certain inherent risks that are observed with the use of essentially any blood product. The major risk is transmission of infectious diseases, such as hepatitis B, C, and AIDS. Other risks include sensitization to foreign proteins.

Despite all the problems associated with FFP, its use has increased tenfold during 1974 to 1984 and had reached almost 2 million units annually. This alarming increase caused the National Institutes of Health to conduct a Consensus Development Conference on Fresh Frozen Plasma in September 1984, of which I was a member. [53] More recently, the American Society of Anesthesiologists Task Force 2 recommended the administration of FFP with the following guidelines:

1. For urgent reversal of warfarin therapy.
2. For correction of known coagulation factor deficiencies for which specific correlates are unavailable.
3. For correction of microvascular bleeding in the presence of increased (>1.5 times normal) prothrombin time or partial thromboplastin time.
4. For correction of microvascular bleeding secondary to coagulation factor deficiency in patients transfused with more than one blood volume and when prothrombin time and partial thromboplastin time cannot be obtained in a timely fashion.
5. FFP should be given in doses calculated to achieve a minimum of 30 percent of plasma factor concentration (usually achieved with administration of 10-15 mL/kg of FFP), except for urgent reversal of warfarin anticoagulation, for which 5 to 8 mL/kg of FFP usually suffice. Four to five platelet concentrates, one unit of single donor apheresis platelets, or one unit of whole blood provides a quantity of coagulation factors similar to that contained on one unit of FFP (except for decreased, but still hemostatic, concentrations of factors V and VIII in whole blood).
6. FFP is contraindicated for augmentation of plasma volume or albumin concentration.

> As indicated in the section on coagulation problems with massive transfusions, they concluded that there is little scientific evidence to support the increasing use of FFP in clinical medicine. While FFP is a reliable solution for intravascular volume replacement in acute blood loss, alternative therapies are equally satisfactory and considerably safer. There is no documentation that FFP has a beneficial effect when used as part of transfusion management of patients with massive hemorrhage.
>
> A further comment: The practice of administering both packed red cells and FFP to the same patient should be discouraged, as this adds to the cost and doubles the infection exposure. When conditions are appropriate, whole blood should be given.

The only indications for FFP administration they agreed on were the following:

1. Replacement of isolated factor deficiencies (as documented by laboratory evidence)
2. Reversal of warfarin effect
3. In antithrombin III deficiency
4. Treatment of immunodeficiencies
5. Treatment of thrombotic thrombocytopenia purpura
6. Massive blood transfusion (rarely, and only when factors V and VIII are <25% of normal)
7. Requirements for indications 1 and 6 would be a prothrombin and partial thromboplastin time at least 1.5 times longer than normal.

Cryoprecipitate

Cryoprecipitate is prepared in such a way that it contains significant levels of factor VIII and fibrinogen. It also contains von Willebrand factor and fibronectin. All other plasma proteins are present in only trace amounts in cryoprecipitate. The use of cryoprecipitate in the treatment of factor VIII deficiency or hemophilia A has been outlined by Brown et al. [141] Cryoprecipitate contains factor VIII:C (the procoagulant activity), factor VIII:vWF (von Willebrand factor), fibrinogen, factor XIII, and fibronectin, which is a glycoprotein that may play a role in reticuloendothelial clearance of

foreign particles and bacteria from the blood. Cryoprecipitate can also be used in the treatment of fibrinogen deficiencies and is preferable to commercially prepared fibrinogen preparations. This is because commercially prepared fibrinogen preparations have a very high incidence of hepatitis, whereas the risk of hepatitis in cryoprecipitate is no greater than that from a single unit of blood.

Cryoprecipitate is frequently administered as ABO compatible; however, this probably is not very important, because the concentration of antibodies in cryoprecipitate is extremely low. Cryoprecipitate may contain red cell fragments, and thus cryoprecipitate prepared from Rh-positive individuals can possibly sensitize Rh-negative individuals to the Rh 0 antigen.

"Paradoxical bleeding" has been described during infusion of cryoprecipitate. [142] This means that bleeding persists during infusion of cryoprecipitate despite factor VIII levels of 30 to 50 percent of normal, which should be adequate for hemostasis. Cryoprecipitate has a large amount of fibrinogen, so that if the hemophiliac is transfused with enough cryoprecipitate, serum fibrinogen levels may also rise, increasing the risk of bleeding, even in the presence of normal amounts of factor VIII. Conversely, hyperfibrinogenemia is not observed when commercial factor concentrates are used.

Cryoprecipitate should be administered through a filter and as rapidly as possible. The rate of administration should be at least 200 mL/h, and infusion should be completed within 6 hours of thawing.

Commercial concentrates of factor VIII have been the standard therapy for hemophilia. Although heat inactivation of factor VIII concentrate reduces infectivity, such a risk is still present. Recombinant DNA techniques have been used to develop factor VIII, which is free of disease transmission. [143] Mild cases of hemophilia may be treated without blood products by administration of DDAVP. Appropriate therapy is difficult to ascertain for patients who have inhibitors (alloantibodies) to factor VIII.

Fibrin glue is used occasionally by surgeons to create local hemostatis. It is prepared in a manner similar to that of cryoprecipitate. When FFP is thawed, the precipitate contains large amounts of fibrinogen. When centrifuged, about 4 mL of concentrated precipitate results. With added thrombin, it is applied locally, the efficacy of which is difficult to determine.

Prothrombin Complex

Factor IX can be recovered from plasma or plasma fractions by absorption with ion exchanges or inorganic chemicals. These products are all complexes of factors II, VII, IX, and X. Two commercial preparations available are Konyne (Cutter Laboratories, Berkeley, Calif) and Proplex (Hyland Division of Travenol Laboratories, Costa Mesa, Calif).

The main indication for this product is treatment of factor IX deficiency, or hemophilia B (Christmas disease). This is a hemorrhagic disorder that is distinguishable from hemophilia A only by laboratory tests. Factor IX or prothrombin complex has also been used for the treatment of acquired hypoprothrombinemic bleeding disorders, principally sodium warfarin overdose; however, its use is limited because of the risk of hepatitis.

Single-Donor Plasma

Single-donor plasma is plasma that has been removed from stored blood without any effort being made to preserve coagulation factors. Single-donor plasma is very effective as a volume expander. All the precautions outlined for the administration of FFP should be followed when single-donor plasma is administered. It obviously cannot be used to correct deficiencies in coagulation factors.

Other Options to Reduce Infectivity of FFP [143A]

Solvent-Detergent

Plasma from multiple donors is pooled and subjected to a lipid-destroying mixture of a solvent (tri- *n*-butyl phosphate) and a detergent (Triton X-100) to inactivate lipid-enveloped infectious agents, including HIV, HTLV, hepatitis C virus, and hepatitis B virus. It has several disadvantages, including the risk of contamination of nonenveloped agents. Recalls can occur after any fraction of a lot has been released. It could be much more expensive.

Single-Donor Plasma, Donor Retested

A donation is made, and FFP is prepared. The unit (the first donation) is kept if all history and infectious diseases markers are negative. That unit is not released for use until the same donor donates a second unit at least 3 months after the first donation and again passes all donor intake and serologic testing. At that time, the first unit is released. The second unit is not released until the donor returns more than 3 months later for a third donation and again passes all the testing. At that time, the second unit can be released for use. This approach has obvious advantages but would be administratively complex.

Frequent-Donor Plasma

An inverse relationship exists between the number of donations a person has given and the chance that he or she will become seropositive. The relationship is independent of the time over which the donations were given. One appears to reach a maximum reduction of the incidence of seropositivity at four or more donations. Predictions are that reduction in seropositivity (and therefore transmission) to one-third to one-half the current figures is possible.

These options were presented at the University of California, San Francisco, Transfusion Committee meeting, and indicate that clinicians will have many ways of ensuring safer plasma for patients.

Summary

With the new tests of infectivity, the above FFP approaches may not be necessary.

Albumin and Plasma Protein Preparations

Several commercial products containing albumin are available for use as clinical volume expanders. Albumin is available as either a 5 or a 25 percent solution in isotonic saline. Furthermore, plasma protein fractions containing albumin and alpha- and beta-globulins are available. These solutions are prepared commercially from albumin fractions from large pools of plasma reconstituted in isotonic electrolyte solutions. Such solutions can be given without regard to ABO blood type and without crossmatch and should be used primarily as volume expanders. They are very expensive and in short supply. In fact, bacterial sepsis has been associated with albumin administration. [144] For much of 1997, there was a shortage of 5 percent albumin because of the concern about contamination with Creutzfeldt-Jakob disease, or "mad-cow disease." If available, albumin should be administered within 4 hours of initiation of the infusion because of potential contamination after entering the bottle.

Administration of plasma protein fraction solutions can result in hypotension, primarily as a result of a decrease in systemic vascular resistance [145] probably caused by the generation of bradykinin in recipients. [146] This type of prekallikrein activator activity rarely occurs with albumin. That administration of 5 percent albumin solution does not cause hypotension suggests that one of the globulin fractions in the plasma protein fraction is the cause.

We believe that administration of plasma protein fraction of 5 percent serum albumin solutions should be restricted for the treatment of documented hypoproteinemia or those conditions, such as burns and peritonitis, in which hypoproteinemia is likely. These solutions expand the vascular space for a longer period of time than balanced electrolyte solutions. [147] However, albumin's osmotic ability draws fluid into the vascular space from other extracellular fluid compartments. In most states of hypovolemia and dehydration, the entire extracellular fluid space already is depleted. Fluids such as 0.9 percent saline or lactated Ringer solution, which expand the entire extracellular fluid space, should be given.

The crystalloid versus colloid conflict has been debated for many years. The University Hospital Consortium developed guidelines for the use of albumin, nonprotein colloid, and colloid solutions. [148] Unfortunately, no anesthesiologists were represented in the Consensus Exercise. Their conclusions were not different from those described earlier.

Granulocyte Concentrates

Granulocyte concentrates have been obtained either by continuous-flow or intermittent-flow leukopheresis or by filtration leukopheresis. Such concentrates are difficult to obtain, require great time commitment on the part of the donor, survive for only short periods of time in the recipient, and have yet to be definitely proved efficacious in the treatment of recipients. In spite of these cautions, granulocyte transfusions are frequently used in larger centers for the treatment of severely leukopenic (a leukocyte count of 500/mm^3) patients with evidence of septicemia and fever.

Granulocytes should be ABO- and Rh-compatible. Furthermore, many centers also check the recipient's serum for the presence of antibodies reacting against the donor white blood cells. Granulocytes should be administered through a filter and should be administered slowly over 2 to 4 hours because more rapid infusion may cause severe pulmonary reactions. Fever and chills are common after administration of granulocytes. Granulocyte concentrates should be administered daily for at least 4 to 5 days or until a satisfactory clinical response is observed.

/das/book/view/29494766/875/529.html

ARTIFICIAL COLLOID SOLUTION THERAPY

The most commonly used artificial colloids are the dextrans, which are polysaccharides built up from glucose molecules. Dextran 70, with a molecular weight of about 70,000 (Macrodex), is an effective volume expander. [149] However, after infusion of more than 20 mL/kg/24 h, dextran 70 may interfere with normal blood clotting, causing a deficiency with crossmatching procedures and possibly causing bleeding diathesis. These clotting defects are due to reduced platelet adhesiveness secondary to an antithrombin effect. Of prime importance is a significant incidence of severe anaphylactoid or anaphylactic reactions. [150] [151] These reactions are mediated by dextran-reactive antibodies that are IgG immunoglobulins. Dextran-reactive antibodies are formed in response to dextran polysaccharides. This process can be prevented if the potentially reactive sites on the dextranreactive antibody are blocked before the antibody is given. By prior administration of a hapten, a substance capable of combining with immunoglobulins but not producing a reaction, the reactive sites are occupied and unable to react to the antigen. Prior administration of dextran I (Promit, mo-lecular weight 1,000) has proved effective as a hapten, and decreases, but does not eliminate, the incidence of severe reactions. [152] [153] In addition, dextran 70 exerts a higher colloid osmotic pressure than blood. Thus, both dextran 70 and albumin may deplete the extracellular fluid space of water as does albumin. [154]

Dextran 40, molecular weight of 40,000 (Rheomacrodex), has been used primarily to reduce blood viscosity and cellular aggregation and to improve microcirculation during low-flow states. It is often given prophylactically to decrease the incidence of postoperative thromboembolism. Blood viscosity may be increased by trauma, blood loss, burns, and endotoxin shock. Although viscosity can be decreased by dextran 40, the presumed improvement in flow through the microcirculation has not been well documented.

Expansion of the intravascular space by dextran 40 is of less duration and consistency than that observed with dextran 70. Carey et al [147] suggested that the addition of dextran 40 to crystalloid solutions with blood is beneficial for treatment of hypovolemia. Renal failure has been reported in several patients after administration of dextran 40 in an amount greater than 20 mL/kg. Obviously, with loss of blood greater than 20 percent of the blood volume, therapy with dextran 40 must be augmented with balanced electrolyte solution and blood.

Gelatin and starch preparations also have been produced to be used as intravascular volume expanders. [154] Although gelatin is the least effective, all of these synthetic products are as effective in expanding the intravascular volume as 5

percent albumin. However, they all can produce anaphylactoid reactions. [154]

In addition to the dextrans, hydroxyethyl starch (Hespan) is frequently used in the United States. It is a synthetic starch molecule that resembles glycogen and is given as a 6 percent solution. Several studies have substantiated that Hespan is as effective as albumin as an intravascular volume expander. [155] [156] [157] The elimination of Hespan has not been completely resolved, although it is stored in the reticuloendothelial system of the liver for hours. Apart from its dilutional effect, it does decrease factor VIII when more than 1,000 mL/70 kg is given. [158] Although the precise dose required to cause a coagulopathy is not clear, a general recommendation is that no more than 20 mL/kg/day of 6 percent hetastarch be given. [159] Also, urinary specific gravity can be elevated when Hespan is given to patients with acute oliguric renal failure. [160] This emphasizes using urinary osmolality rather than specific gravity when Hespan is used. Finally, an additional problem was difficulty in interpretation of typing and antibody screening in samples that contained more than 30 percent of the hydroxyethyl starch solution. [161]

Hypertonic Saline Possibly With Dextran

The sodium concentration of hypertonic saline solutions is 250 to 1,200 mEq/L. The theoretical advantage is that the greater the sodium concentration, the less total volume required for adequate resuscitation. The lower infusion volume is probably related to osmotically related movement of intracellular water into the extracellular space. Other mechanisms include a direct inotropic effect on the myocardium and a direct peripheral vasodilator effect. The main problem is severe hypernatremia, which can cause brain dehydration and can be fatal. The reader is referred to an excellent review by Moss and Gould [162] for further information.

Various hyperosmotic-hyperoncotic solutions have been used for resuscitation in hypovolemic patients. The most common combination is with hypertonic saline and 6 percent dextran 70. In animals, these fluids restore gut and kidney microcirculation more effectively than does normal saline. [163] [164] [165] Clinical practice will be required to ascertain the ultimate role, if any, of these fluids.

Synthetic Oxygen-Carrying Substances

Various substances that carry or facilitate the transport of oxygen have been made. The most notable is the perfluorochemical emulsion called Fluosol-DA. However, it will probably have little use because it carries oxygen (i.e., a small amount) only when the Pa O_2 is greater than 300 mm Hg. [165] Fluosol-DA was given to patients who had extensive surgical blood loss but who refused blood transfusions on religious grounds. In essence, administration of Fluosol-DA was of no benefit even in severe anemia. [166] Furthermore, there are many adverse effects. [167] [168] A newer perfluoro compound, perfluorocytylbromide, has been developed that carries three to four times more oxygen and has a longer half-life and presumably fewer problems than are associated with Fluosol-DA. Clinical trials will be required to determine its ultimate usefulness.

Hemoglobin can now be prepared from outdated human blood by a crystallization procedure and then dissolved in an isotonic medium. This solution can then be used as an intravascular volume expander. Animal studies indicate that this lysophilized crystalline solution is very effective. [169] However, these solutions are not without complications, [170] the most concerning of which are kidney toxicity and an increase in affinity for oxygen (i.e., left shift in the oxygen dissociation curve). A variety of approaches are being used, including crosslinking, pyridoxylation and polymerization, and conjugation and encapsulation, to decrease oxygen affinity, to decrease deposition in the reticuloendothelial system, and to increase half-life. Genetic engineering has provided hope for blood products. Initially, recombinant erythropoietin was developed for treatment of anemias and facilitation of autologous blood donation (Ch. 47) . In 1992, a human recombinant hemoglobin was designed as a blood substitute. [171] By use of genetic engineering, it was made from *Es-cherichia coli.* It functions just like normal hemoglobin in terms of oxygen-carrying capacity, but it does not require crossmatching nor does it transmit disease or become rapidly outdated. How much recombinant material can be tolerated by humans remains to be determined.

As of 1998, several synthetic blood products are under investigation:

1. Stroma-free hemoglobin solutions containing some modifications of the hemoglobin molecule
2. Genetically engineered hemoglobin (e.g., having *E. coli* produce human red cells)
3. Liposome-encapsulated hemoglobin solutions containing hemoglobin with a synthetic membrane

4. Perfluorocarbons, organic solutions with high oxygen solubility

To prevent many of the complications seen with the use of synthetic blood products (e.g., renal damage, endotoxin release), various approaches have been used, such as cross-linking, polymerization, and conjugators with chemical or genetic engineering, as summarized earlier. With stroma-free hemoglobin, outdated human cells strip the oxygencar-rying substance out of the cell coating and then chemically modify it by one or more of the aforementioned approaches. By removing the cell lining, allergic reactions are prevented.

Originally, these products were viewed as blood substitutes. However, comparing safety is easy, but efficacy compared with that of bank blood is difficult to determine. FDA criteria of efficacy are difficult to establish. [172] Now, more emphasis is on their ability to transport oxygen. [173]

Dietz has provided an excellent review of this entire topic. [174] Goodnough et al [143A] have updated their status.

INFORMED CONSENT

Before any transfusion is given, an informed consent should be obtained (Ch. 85) . What constitutes such a consent varies across the United States and is under constant change. If a patient is damaged by a transfusion adminis-tered without a valid consent, damages may be recovered

even though the defendant did everything properly. [174] During the past decade, the public has demanded to know more about transfusions. A dramatic example was the passage of the Paul Gann Blood Safety Act in California. This law mandates that patients be informed of the risks of blood transfusions and of any alternatives (Ch. 47) . This law has appar-ently already had a restrictive impact on transfusion practice in California. [175] Clearly, the rapid changes in transfusion medicine probably dictate an intense ongoing educational process for those clinicians who administer blood products to patients. [176] [177]

Chapter 47 - Autologous Transfusion *

Linda Stehling

INTRODUCTION

Autologous transfusion is not a new concept. Reinfusion of shed blood was employed as early as 1818, [1] and preoperative donation of autologous blood was advocated in the 1930s, when the first blood banks were established. [2] Several factors are responsible for the current popularity of autologous transfusion. The introduction of complex operative procedures, such as cardiac surgery and organ transplantation, stimulated the search for alternatives to allogeneic (homologous) transfusion. Technologic advances made possible the development of safe, easy-to-use devices for recovery and reinfusion of shed blood, and fear of transfusion-transmitted disease stimulated growth of autologous programs.

There are three types of autologous transfusion: preoperative blood donation, acute normovolemic hemodilution (ANH), and intraoperative and postoperative blood recovery (blood salvage). The advantages and disadvantages, applications, and complications vary with the techniques being used. It is often appropriate to employ more than one technique for patients undergoing surgical procedures associated with significant blood loss.

ADVANTAGES OF AUTOLOGOUS TRANSFUSION

The two primary reasons for employing autologous transfusion are (1) avoidance of complications associated with allogeneic transfusion and (2) conservation of blood resources. The altruistic public has thus far donated sufficient blood to meet the needs of virtually all patients, but blood shortages do occur. Patients with rare blood phenotypes can benefit from autologous transfusion because compatible allogeneic blood may not always be available. Potential complications of allogeneic transfusion that can be eliminated or minimized when autologous blood is administered include acute and delayed hemolytic reactions, alloimmunization, allergic and febrile reactions, transfusion-transmitted infectious diseases, and immunosuppression. Intraoperative blood recovery may be the only option for providing a sufficient volume of compatible blood when severe, rapid blood loss occurs. ANH provides the only practical source of fresh whole blood.

HISTORY OF AUTOLOGOUS TRANSFUSION

The early history of autologous transfusion is confined to descriptions of recovery and reinfusion of blood shed by surgical and obstetric patients. Blood salvage was first reported in the American literature in 1917. [3] By 1936, 277 cases had been reported. [4] [5] [6] [7] Sporadic reports of use of the technique in patients with hemothorax appeared in the surgical literature from 1931 [8] through the early 1970s. However, the technique was used only as a life-saving measure, and little was known about the quality of the product reinfused. In 1966, Symbas [9] undertook a series of laboratory and clinical studies leading

* *See Practice Guidelines for Blood Component Therapy*

Figure 47-1 Bentley autotransfusion system.

to adoption of an autotransfusion protocol for managing patients with acute traumatic hemothorax that was employed in more than 400 patients between 1966 and 1978.

Reports of instrumentation developed specifically for intraoperative blood recovery and autologous transfusion began to appear in 1966. [10] In 1969, investigators reported on the use of a continuous-flow centrifuge bowl that was capable of separating and concentrating erythrocytes in the irrigating fluid returned during transurethral resection of the prostate. [11]

The first commercially available apparatus for intraoperative blood recovery and reinfusion was marketed by Bentley Laboratories. It employed a disposable cardiotomy reservoir and a DeBakey-type roller pump (Fig. 47-1) . Initial clinical trials were performed in Vietnam and reported in 1970. [12] The first article in the anesthesia literature appeared in 1975 and detailed experience with the device in 71 patients who received a mean volume of 4,000 mL of reinfused blood. [13] Systemic anticoagulation was not employed, but the reservoir was primed with crystalloid containing 3 units of heparin per mL of priming fluid. The unit was demonstrated to be safe and effective in patients sustaining blunt and penetrating trauma to the chest and abdomen and ruptured ectopic pregnancies, as well as in patients undergoing a variety of elective and emergency intra-abdominal operations. Although the apparatus was equipped with a device for detecting air and a safety alarm, air embolism did occur as a result of operator error, and the Bentley device was withdrawn from the market.

In 1974, the Haemonetics Corporation introduced the Cell Saver, a system that washes and concentrates recovered red blood cells (RBC) before reinfusion (Fig. 47-2) (Figure Not Available) . Two years later, experience with an inexpensive canister collection system was reported. [14] A variety of disposable blood collection and reinfusion devices for intraoperative and postoperative blood collection have been introduced since that time. Apheresis technology has also been adapted for the collection of platelet-rich plasma (PRP) in the operating room.

Figure 47-2 (Figure Not Available) Haemonetics Cell Saver 5. *(Courtesy of Haemonetics Corporation, Braintree, Mass.)*

The role of the anesthesiologist in autologous transfusion is still evolving. An anesthesiologist may be responsible for the perioperative autologous transfusion program. At a few institutions, members of the anesthesia care team monitor high-risk patients during predonation. The one technique that is the purview of the anesthesiologist--ANH--has received the least attention. A few papers appeared in the literature during the early 1970s, but it was several years before the technique became known to many anesthesiologists.

PREOPERATIVE BLOOD DONATION

Preoperative autologous blood donation (PABD) should be considered before elective surgical procedures during which significant blood loss may occur and for which blood would ordinarily be crossmatched. The technique is both underutilized [15] and overutilized. [16] Some patients who should donate do not; others are donating without indication. Although it has been suggested that the transfusion requirements of 50 percent of patients having elective surgical procedures could be met by predonation, [17] 10 percent is a more reasonable estimate. [18] In 1992, approximately 8 percent of whole blood collections in the United States were autologous. [19]

Patient Selection

The criteria for autologous donors are not as stringent as those for allogeneic donors. The Standards of the American Association of Blood Banks require that the donor-patient's hemoglobin (Hb) be no less than 11 g/dL or the hematocrit (HCT) 33 percent before each donation. [20] There are no age or weight limits. Patients weighing 50 kg or more may donate 450±50 mL, in addition to testing samples, whereas those weighing less than 50 kg can donate proportionately smaller volumes. Donations may be scheduled more than once a week, but the last should occur no less than 72 hours before surgery to allow time for restoration of intravascular volume and for transport and testing of the donated blood. Donation is contraindicated when the patient has, or is being treated for, bacteremia or has a significant bacterial infection that can be associated with bacteremia. [20]

Blood center and transfusion service policies differ regarding collection and use of autologous blood with positive viral markers. It is common practice to preclude use of blood reactive for hepatitis B surface antigen and the human immunodeficiency virus because of concerns for the safety of both patients and personnel. Some hospitals accept and transfuse autologous blood with any positive viral markers, and denying patients infected with human immunodeficiency virus the opportunity to receive their own blood could be a violation of the Americans with Disabilities Act. [21]

Adolescents requiring corrective surgery for scoliosis are often ideal candidates for PABD. [22] [23] Experience is limited in very young children, but blood has been donated at the time of cardiac catheterization by children younger than 1 year who have weighed as little as 5 kg and were scheduled to undergo cardiac surgery. [24] Avoidance of allogeneic transfusion was reported in over 90 percent of children as young as 3 years who donated an average of three times before cardiac surgery. [25] Predonation of approximately 20 mL/kg has also been reported in children scheduled for general surgical procedures who ranged in age from 9 months to 10 years and weighed as little as 7.3 kg. [26] Factors limiting PABD by pediatric patients are commitment of parents, surgeons, and blood center personnel; patient cooperation; and vascular access.

There is extensive experience with PABD by older patients, especially those undergoing total joint arthroplasty [27] [28] [29] [30] and cardiac surgery. [31] [32] [33] [34] [35] [36] [37] Patients with unstable angina, left anterior descending coronary artery disease, congestive heart failure, or myocardial infarction within the previous 3 months are usually excluded. Critical aortic stenosis may be a contraindication, but one publication supports the safety of donation before aortic valve surgery. [38]

Predonation by obstetric patients does not adversely affect the mother or the baby. [39] [40] [41] [42] [43] However, PABD can be justified only in patients with placenta previa. The need for peripartum transfusion cannot be predicted with sufficient accuracy to justify donation by other obstetric patients.

Patients scheduled for procedures during which transfusion is rarely necessary should be discouraged from donating. Approximately 50 percent of predonated units are not transfused to the donor-patient and are destroyed. [19] A survey of 600 hospitals in which 40 percent of predonated units were not transfused found that almost 25 percent were collected for procedures in which transfusion was only a remote possibility, and 40 percent of the patient-donors required no transfusions in the perioperative period. [16] Inappropriate donation by gynecologic surgery patients is especially common and can lead to inappropriate transfusion. A retrospective review of 263 patients having elective abdominal or vaginal hysterectomy demonstrated that PABD was the major risk factor for transfusion, independent of all other considered variables, including admission Hb level and estimated RBC loss. Twenty-five of 140 patients who predonated were transfused, whereas only one of 123 who did not was transfused. [44] It was concluded that the increased transfusion rate was most likely the result of iatrogenic anemia resulting from blood donation and a more liberal threshold for transfusing autologous blood.

Establishing a schedule of optimal preoperative collection of autologous blood, which is similar to a schedule for allogeneic maximum surgical blood ordering, can lead to more appropriate autologous blood collections. [45] The likelihood of a surgical patient requiring RBC transfusion can be predicted more accurately if, in addition to the type of surgical procedure, the patient's preoperative Hb value and weight are considered. [46] One group who calculated the predicted and tolerated blood loss for each surgical patient in order to determine the best transfusion strategy decreased wastage of autologous blood to less than 15 percent. [47]

Erythropoietic Response to Donation

RBC production in autologous donors is dependent on adequate iron stores and is influenced by the number of units donated and the frequency of donation. Ferrous sulfate is usually prescribed in order to prevent anemia, allowing some patients to donate up to six units if donation is begun early. Twice-weekly phlebotomy is associated with

greater erythropoiesis than is weekly donation. [37] Administration of recombinant human erythropoietin stimulates erythropoiesis and allows donation of more units. [48] [49] [50] [51] Patients with Hb levels of less than 13.5 g/dL appear to benefit most from administration of recombinant human erythropoietin. [51] Various dosage regimens have been reported, with the drug being administered subcutaneously or intravenously a few days to 3 weeks before surgery. The optimal dosage regimen for recombinant human erythropoietin has not been determined.

Processing of Autologous Units

If CPDA-1 preservative is employed and blood is stored as liquid whole blood, the shelf life is 35 days. Separation into plasma and RBCs allows addition of a preservative solution (e.g., Adsol, Nutricel) to the RBCs, thereby extending the shelf life to 42 days. The plasma can be frozen or retained in the liquid state, but it is often discarded. Although RBCs can be frozen, the procedure is time consuming, expensive, and usually unnecessary. If surgery is delayed, liquid preserved RBCs can be frozen any time before 42 days.

Predonated units are conspicuously labeled as autologous, and the patient-donor's name and identifying number are written on the attached tag. Blood intended for autologous transfusion is tested for ABO type and Rh as a confirmation of patient identification. At this time, testing for infectious disease is not mandatory if blood is drawn and transfused at the same facility. However, most donations occur at blood centers, and the units are tested in the same manner as allogeneic blood. Testing

of all units maximizes safety by allowing units with positive test results to be identified and tagged with biohazard labels or destroyed.

The issue of "crossover" of unused autologous units for allogeneic use is controversial. Although proponents argue that the blood supply could be increased, opponents point out that only about 30 percent of autologous units would be suitable for transfusion to other patients. [52] Units may be unsuitable on the basis of the donor's medical or risk behavior history and/or reactive test results. Blood centers may omit questions regarding risk behavior when obtaining autologous donor histories, precluding crossover of those units even if all test results are negative. When the questions are asked, there is a possibility that donors will not disclose disqualifying information because they assume the blood is only for their use. Thus, crossover of autologous units might result in transfusion of blood that is less safe than that from volunteer donors. Because many units are donated several days to weeks in advance of surgery and are reserved for the patient for a period of time after surgery, the potential shelf life for allogeneic use is short.

Complications of Donation and Transfusion

Autologous donors may sustain complications in association with the donation process or when the blood is transfused. Reaction rates among autologous donors of 1.5 to 5.5 percent [17] [53] [54] are similar to those in allogeneic donors. Most are transient vasovagal reactions requiring no treatment. As with allogeneic donors, younger donors experience more reactions than older donors. The reaction rate is highest among first-time donors and is greater in women than in men. In one series of approximately 187,000 allogeneic and 8,900 autologous donations, the reaction rate was 2.4 percent for allogeneic and 2.5 percent for autologous donors, whereas it was 13 percent in first-time donors. [55] AuBuchon and Popovsky [56] compared donors who did not meet allogeneic donor criteria (usually on the basis of cardiovascular disease) with those who met the criteria and found reaction rates of 4.3 percent and 2.7 percent, respectively. They were unable to identify any distinguishing features that were predictive of reactions. A review of approximately 4 million donor records found the prevalence of very severe outcomes (defined as events requiring hospitalization) to be 1 in 16,783 autologous donations and 1 in 198,119 allogeneic donations. [57]

Three groups have reported experience with cardiovascular monitoring of autologous donors. Eighty-six percent of patients scheduled for coronary artery bypass grafting (CABG) evaluated with continuous electrocardiographic monitoring for 24 hours before and 24 hours after donation demonstrated at least one episode of ST-segment depression, but the incidence was not greater after donation. [58] In a similar study, 37 percent of patients had ischemic episodes during or after donation, and all indices of ischemia were more common on the day following donation. [59] A significant percentage of high-risk patients monitored during 224 donations exhibited hypotension, arrhythmias, ST-T wave changes, syncope, and tachycardia. [60] Five were treated with ephedrine and/or atropine, but it is unknown whether any morbidity would have occurred in the absence of treatment.

Although controversy regarding the advisability of PABD by patients scheduled for cardiac surgery continues, [61] [62] [63] several investigators have demonstrated its safety. [31] [32] [33] [34] [35] [36] [37] [38] [57] [58] [59] Donation of up to eight units by patients awaiting heart and lung transplantation has also been reported. [64] [65] Although PABD was without apparent adverse effects, even in patients receiving small doses of vasopressors, the authors [64] [65] caution that such donations are best performed in a hospital-based donor facility where full medical support is readily available.

The greatest potential hazard associated with transfusion of predonated blood is administration of an autologous unit to an unintended recipient. In an editorial, Linden and Kruskall [66] reviewed results of two surveys related to autologous transfusion. A 1992 American College of Pathologists survey found that autologous blood had been issued to the wrong patient on at least one occasion in the previous year by 0.9 percent of facilities and that almost half of those facilities reported that autologous units had been transfused to the wrong patient on one or more occasions. In a 1994 American Association of Blood Banks survey, 1.2 percent of respondents indicated errors involving transfusion of autologous blood to other patients during the previous year. Half of the errors occurred in institutions that permitted transfusion of units with positive viral markers.

A study of autologous donation error rates in Canada indicated that errors were associated with one of 149 autologous units. [67] About half of the errors involved late receipt of units or delivery of blood to the wrong hospital, but no data were presented to indicate whether the errors resulted in allogeneic transfusions. One unit of autologous fresh frozen

plasma was transfused to the wrong patient. Errors were most frequent when components were produced and when shipment between hospitals or blood centers was involved.

An analysis of autologous donations by 175 pediatric orthopedic patients revealed 13 errors. [68] Three patients received allogeneic blood when autologous units were available. Several units expired, and some had to be destroyed because of difficulties related to storage, necessitating allogeneic transfusion. One patient received the wrong type of allogeneic blood. A prospective study by the Belgian SANGUIS group found that three of 55 patients with autologous blood available received allogeneic blood instead. [66]

The clinician's index of suspicion for a transfusion reaction may be low when the patient is receiving blood thought to be his or her own, reducing the probability of early diagnosis and intervention and increasing the likelihood of serious consequences. In addition to hemolytic reactions due to inadvertent administration of the wrong unit of blood, there is potential for administration of contaminated blood. Two of 10 cases of sepsis due to transfusion of blood contaminated with *Yersinia enterocolitica* reported in the United States between 1991 and 1996 were associated with administration of autologous RBCs. [69] Additional reported complications are acute intravascular hemolysis resulting from transfusion of inadequately deglycerolized previously frozen RBCs [70] and hypotension, possibly resulting from hypersensitivity to stabilizers or sterilizing agents used in plastic blood bags. [71]

Transfusion of Predonated Blood

The mere availability of autologous blood should not be an indication for transfusion. There is controversy regarding whether the indications for autologous and allogeneic transfusion should be the same. [72] [73] The "Practice Guidelines for Blood Component Therapy" of the American Society of Anesthesiologists [74] state that the indications for transfusion of autologous RBCs may be more liberal because of the lower (but still significant) risks associated with autologous blood. The "Guidelines for Red Blood Cell and Plasma Transfusion for Adults and Children" published by the Canadian Medical Association [75] state that the indications for transfusion of autologous and allogeneic blood should be the same.

Cost-Effectiveness of Predonation

The conventional measure of efficacy of PABD is the extent to which patients avoid allogeneic transfusion. Numerous studies have demonstrated attainment of that goal in about 70 percent of patients. [76] If avoidance of allogeneic transfusion is the only factor considered, PABD is efficacious. But is it cost-effective?

Charges for autologous units are usually more than those for allogeneic blood. The surcharge imposed by collecting facilities is based on personnel time required for scheduling and processing autologous donors and the complex logistics of handling and transporting the blood. One center estimated the direct costs of collecting, testing, and processing autologous and allogeneic blood to be $198.04 and $149.80, respectively. [77] Most units are drawn at blood centers and are subsequently shipped to, and purchased by, hospitals. Wastage rates of approximately 50 percent account for much of the expense of autologous blood because hospitals incur nonreimbursable costs for nontransfused units.

Decision analysis techniques have been applied to determinations of the cost-effectiveness of PABD. With this methodology, cost-effectiveness is expressed in dollars per quality-adjusted year of life saved (QALY). Most accepted medical and surgical interventions cost less than $50,000 per QALY, a benchmark commonly applied as a threshold of cost-effectiveness. [78] Predonation for CABG costs $508,000 to $909,000 per QALY. [79] Estimates for primary unilateral hip replacement and unilateral knee replacement are $373,000 to $740,000 and $1,147,000 to $1,467,000, respectively. [80] For abdominal hysterectomy and transurethral resection of the prostate, the costs per QALY are $1,358,000 and $23,643,000, respectively. [77] Critics of QALY analysis point out that it includes only known, quantifiable risks and costs and uses death and dollars as the primary end points. [81] The peace of mind provided by PABD and additional potential benefits from avoiding risks of allogeneic transfusion other than currently identified infectious diseases cannot be measured.

Predonation practices must periodically be reviewed in light of changing surgical techniques and transfusion practices. For example, PABD has become standard practice for radical retropubic prostatectomy in some institutions, but some reports document decreasing transfusion requirements and question the need for

predonation. [82] [83] [84] Not only was the recommendation for PABD eliminated at one institution, crossmatching was also discontinued and only a type-and-screen was routinely ordered. [83] After reviewing the records of 200 consecutive patients and the charges associated with PABD, another group concluded that PABD should be an option, but not a routine practice. [82]

ACUTE NORMOVOLEMIC HEMODILUTION

The term *acute normovolemic hemodilution* refers to the removal of blood from the surgical patient immediately before or just after induction of anesthesia, replacement with asanguinous fluid, and later reinfusion of the withdrawn blood. [85] [86] *Acute limited* or *moderate normovolemic hemodilution* is the term applied when the HCT is reduced to approximately 28 percent. [65] *Acute extreme normovolemic hemodilution* designates a reduction of the HCT to levels below 20 percent. [66] *Augmented acute normovolemic hemodilution* is the term coined by the author to refer to administration of an oxygen-carrying RBC substitute in addition to other asanguinous fluid.

Advantages

As with other autologous transfusion techniques, ANH is employed to reduce the need for allogeneic RBCs and to avoid the potential complications of transfusion. There are additional benefits of ANH that are not common to other autologous transfusion modalities. When the blood is kept in

---

the same operating room with the patient, the chances of clerical error are eliminated. Unlike stored predonated autologous units, blood withdrawn during ANH does not undergo biochemical alterations associated with the "storage lesion." Levels of 2,3-diphosphoglycerate are maintained, and there is no influence on the oxygen-Hb dissociation curve. [87] If the units are maintained at room temperature, platelet function is preserved, and hypothermia associated with transfusion of refrigerated blood is avoided. An additional potential advantage of ANH is improvement in tissue perfusion as a result of decreased viscosity.

There are also logistic advantages. [87] Scheduling difficulties may preclude the use of intraoperative blood recovery in urgent or emergent circumstances. The presence of malignancy or wound infection may contraindicate intraoperative blood recovery, but not ANH. It is simpler and less expensive to obtain autologous blood by ANH than by PABD. [88] [89] Patients with cardiovascular or neurologic disease may not be appropriate candidates for PABD but may safely undergo ANH while being intensively monitored in the operating room. When potential bacteremia (e.g., the presence of an indwelling urinary catheter or chronic osteomyelitis) precludes predonation, ANH may be the ideal solution. Because all of the blood is ordinarily reinfused in the operating room or shortly thereafter, the iatrogenic anemia and blood wastage often associated with PABD do not occur.

Efficacy

A decrease in allogeneic transfusion requirements of 20 to 90 percent has been reported for a wide variety of surgical procedures. [87] [90] [91] [92] [93] [94] However, early studies were flawed by the use of historic controls and did not consider the influence of increasing surgical experience or changing transfusion practices. Multiple blood conservation strategies were often employed, making the contribution of ANH difficult to evaluate. Transfusion criteria usually were not specified. The first prospective controlled study comparing ANH and PABD involved 50 patients undergoing radical retropubic prostatectomy performed by the same surgeon. The anesthetic technique was also standardized. The two autologous transfusion techniques were equally effective in decreasing the need for allogeneic transfusion. [95] In a larger nonrandomized study of 250 patients having radical retropubic prostatectomy, Monk et al [89] found the two techniques comparable in decreasing allogeneic transfusion and also demonstrated that ANH was more cost-effective than PABD.

Three small studies in which patients undergoing total hip or knee arthroplasty were randomized to a hemodilution or control group have been published. [96] [97] [98] Each study included only 30 to 40 patients, and the average volume of blood removed was about 1 L. One group reported that transfusion requirements were the same in both groups, [96] whereas a second group reported a decrease in the total number of allogeneic units transfused in the ANH patients. [98] The third group of investigators, who also utilized PABD and intraoperative blood recovery, considered the technique successful because fewer patients in the ANH group required transfusion of their predonated units. [97]

When employed during cardiac surgery, ANH is also referred to as *blood pooling*[99] or *intraoperative autologous donation.*[100] Most reported studies are retrospective. Schonberger et al [101] studied 100 patients undergoing CABG, 50 of whom had approximately 800 mL heparinized blood removed before cardiopulmonary bypass (CPB). They found that the net blood loss, amount of reinfused shed blood, and postoperative blood requirements were less in the ANH group. Sixty-five percent of ANH patients did not receive allogeneic blood, compared with 10 percent of control patients. Petry et al [99] retrospectively studied 90 patients having CABG, half of whom had heparinized blood (500-1000 mL) removed before CPB. Although 16 percent of control patients received no allogeneic blood, 44 percent of ANH patients did not require allogeneic transfusion. Canver et al [102] compared 140 patients who had a mean of 1,430 mL heparinized blood removed before CPB with 64 control patients in whom ANH was not performed. Although RBC transfusion requirements were no different, fewer units of platelets and fresh frozen plasma were administered to patients in whom ANH was performed.

In the first of two prospective studies, Helm et al [100] randomized 90 patients undergoing CABG or valvular operations to have ANH performed or to serve as controls. An average of 1,540±302 mL was removed before anticoagulation in the treatment group. Uniform transfusion criteria were applied. The investigators found a significant decrease in both the percentage of patients who received allogeneic RBCs (17 versus 52%) and the number of RBC units transfused per patient (0.28±0.66 versus 1.14±1.19 units) in the ANH group. There was no difference in chest tube output, incidence of excessive postoperative bleeding, or coagulation factor transfusion requirements. In a second prospective study, 100 patients undergoing CABG were randomized to have 10 mL/kg heparinized blood withdrawn before CPB or to serve as controls. [103] Transfusion indications were standardized. Patients in the ANH group had a 28 percent reduction in chest tube drainage at 8 hours and a 45 percent reduction in total allogeneic units transfused. Fifty-two percent of ANH patients received no transfusion, whereas 31 percent of control patients were not transfused.

Mathematic and computer modeling have been used to assess the efficacy of ANH. [104] [105] [106] Results are somewhat conflicting, but several of the conclusions are reasonable. First, the RBC "savings" depends on the patient's initial HCT value, the volume of blood removed, and the blood loss. [105] Second, the amount of RBCs saved is overestimated by the simple formula conventionally utilized for ANH. [104] Most importantly, efficacy is greatest when substantial hemodilution is followed by significant blood loss. For example, a savings of four units of allogeneic transfusion can be realized when a patient with an estimated blood volume of 5 L and HCT of 45 percent is hemodiluted to a HCT of 15 percent. If only two units are removed, resulting in a HCT of approximately 37 percent, only about 100 mL is saved. [106]

Hemodilution is efficacious in reducing RBC transfusion requirements in patients undergoing cardiac surgery, but the potential advantage of fresh whole autologous blood in decreasing postoperative bleeding remains to be proved. There are limited data from controlled studies to document the efficacy of ANH in other surgical populations.

Physiologic Effects

The withdrawal of blood and its replacement with acellular fluid are accompanied by a decrease in arterial oxygen content, but oxygen delivery is usually unaffected. A number of mechanisms are invoked as physiologic compensation for the acute reduction in Hb. The most important is an increase in cardiac output. The primary factor responsible for the increased cardiac output seen with ANH is decreased viscosity. The decrease in viscosity is most pronounced between HCT values of 45 and 30 percent, and the effect is progressively less significant when the HCT is below 25 percent. [107] Decreased viscosity results in increased venous return, decreased peripheral resistance, and reduced afterload. The reduced peripheral resistance may also be due to reflex vasodilation or local regulatory factors, such as endogenous release of nitric oxide. [108] In the canine model, there is evidence of increased myocardial contractility, in addition to decreased afterload, as a contributing factor to the increased cardiac output. [109] Increased sympathetic stimulation of the heart may also contribute. [107]

The relative importance of an increase in heart rate or stroke volume to the increased cardiac output depends on the species studied, the subject's state of awareness (i.e., awake versus anesthetized), and the type of anesthesia administered. In the anesthetized adult, an increase in stroke volume is most important; heart rate does not ordinarily increase in the absence of hypovolemia. Anesthetized children tend to respond with tachycardia, as do awake dogs. An increase in heart rate occurs in awake baboons, whereas stroke volume increases during ANH in anesthetized baboons. [107]

Although increases in total and local blood flow are sufficient to maintain oxygenation in resting normovolemic, moderately hemodiluted subjects, other mechanisms are involved with more extreme degrees of ANH. These include redistribution of blood flow to the heart and brain and increased tissue oxygen extraction. A significant increase in coronary and myocardial blood flow occurs with ANH in subjects with normal coronary circulation. Coronary vasodilation and decreased viscous resistance are responsible for the increased coronary blood flow. Myocardial blood flow and arterial oxygen delivery are maintained at HCT values as low as 12 percent in dogs and 9 percent in pigs. The myocardial oxygen extraction ratio remains unchanged in baboons and pigs hemodiluted to HCT values of 4 percent and 9 percent, respectively. Redistribution of myocardial blood flow away from the subendocardium is observed at HCT levels of approximately 9 percent, signifying exhaustion of the subendocardial vasodilator capacity and thus the limit of tolerance to hemodilution. [107] The limits of ANH have been studied in a canine model of coronary artery disease. [110] The median lowest Hb level tolerated without contractile dysfunction in animals with surgically induced stenosis of the left anterior descending coronary artery was 7.5 g/dL. Marked contractile dysfunction was seen at a mean Hb level of 6.0 ± 0.4 g/dL. Increasing the Hb level by approximately 2 g/dL restored contractile function. The cardiovascular compensatory mechanisms remained intact for at least 4 hours. [111]

Patient Selection

Hemodilution should be considered for any patient with an adequate Hb who is expected to lose more than 25 percent of estimated blood volume. Because the Hb decreases approximately 1 g/dL for each unit of blood removed and because ANH is not efficacious if only a small volume of blood is withdrawn, it usually is inappropriate to employ the technique when the Hb is less than 11 g/dL, particularly if limited ANH is to be performed.

Although some anesthesiologists limit use of the technique to healthy adults, ANH has been employed in small children [112] [113] [114] [115] [116] [117] [118] [119] and the elderly. [120] [121] [122] [123] Two groups of investigators have studied the tolerance of patients with known coronary artery disease to acute limited hemodilution. Catoire et al [122] employed transesophageal echocardiography in patients undergoing abdominal aortic surgery who were hemodiluted to a target HCT of 30 percent and a comparable group who were not hemodiluted. Hemodynamic changes associated with aortic clamping were less marked in the ANH group. The authors concluded that ANH did not worsen myocardial ischemia and may actually improve hemodynamic tolerance to aortic clamping. Herregods et al [124] studied patients with left main coronary artery stenosis undergoing semiurgent CABG who were hemodiluted to HCT levels of 34 percent and patients with similar lesions in whom ANH was not performed. They found no increase in frequency, degree, or duration of ST-segment changes in the ANH group. Allogeneic transfusion requirements were decreased by ANH: 64 percent of treated patients did not require allogeneic blood, compared with 38 percent of control patients.

The patient's overall health status, rather than chronologic age should be considered. In a group of patients aged 66 to 88 years (mean, 76±2 years), Spahn et al [123] demonstrated that ANH to a mean Hb of 8.8±0.3 g/dL was well tolerated. In a separate study, the investigators hemodiluted patients receiving chronic beta-adrenergic blocker therapy to Hb levels of 9.9±0.2 g/dL before CABG was performed. The patients tolerated ANH well, and it was concluded that compensatory mechanisms during ANH are largely independent of age and left ventricular ejection fraction. [125]

Experience with extreme ANH in children and adolescents has been reported by several groups. Fontana et al [118] demonstrated that global oxygen consumption was maintained in healthy children hemodiluted to a mean Hb level of 3.0±0.8 g/dL. The oxygen extraction ratio increased from 17 to 44 percent, and mixed venous oxygen saturation decreased from 90.8±5.4 to 72.3±7.8 percent. In children of the Jehovah's Witness faith in whom the HCT was reduced to 16 percent, the oxygen extraction ratio increased from 22 to 33 percent, and mixed venous oxygen saturation declined from 80 to 70 percent. [115] Aly Hassan et al [117] also demonstrated that global tissue oxygenation was preserved at HCT levels of approximately 17 percent. The safety of extreme ANH to HCT values of 12 to 14 percent in combination with mild hypothermia and controlled hypotension to mean arterial pressures of 40 to 50 mm Hg has been shown in patients undergoing spinal fusions. [116]

Patients of the Jehovah's Witness usually agree to ANH if the blood is maintained in a closed-circuit continuous-flow

---

system. [112] Combining ANH with intraoperative blood recovery is also an option for such patients. [115]

Contraindications

Patients with decreased renal function are not suitable candidates for ANH because excretion of diluent fluids may be impaired. Significant restrictive or obstructive pulmonary disease is a contraindication because decreased arterial oxygen content is inherent with ANH and tissue oxygenation may be inadequate. Preexisting coagulopathy precludes the use of the technique. Caution is required in patients with hepatic disease or other disorders associated with a reduction in coagulation factors, thrombocytopenia, or impaired platelet function.

Technique

The amount of blood to be withdrawn depends on the patient's estimated blood volume (EBV), preoperative HCT, and the lowest HCT desired. [126] The volume (V) to be removed equals the EBV multiplied by the patient's initial HCT (H_o) minus the minimum allowable HCT (H_f), divided by the average HCT (H_{av}):

$$V = EBV \times [(H_o) - (H_f)]/H_{av}$$

For a patient with an EBV of 5 L, an HCT of 45 percent, and a desired lower HCT of 30 percent, the approximate amount of blood to withdraw is calculated as

$$V = 5\ L \times [45 - 30]/37.5 = 2{,}000\ mL$$

Serial HCT determinations should be performed during blood removal and at intervals throughout the surgical procedure.

Hemodilution is usually performed in the operating room following induction of anesthesia. If an induction room or holding area is adequately equipped with monitoring equipment, it may be advantageous in terms of efficiency of operating room utilization to perform ANH in such an area. The procedure can also be initiated before induction of anesthesia. Atallah et al [127] compared the stress response to ANH performed before and after induction. On the basis of hemodynamic, hematologic, biochemical, and hormonal indexes, the investigators concluded that ANH is not a stress-producing technique and can be performed in awake or anesthetized patients.

Crystalloid and/or colloid are infused as blood is withdrawn. When crystalloid is used, the amount must be approximately three times the volume of blood removed because much of the crystalloid moves out of the intravascular compartment. Colloids have the primary advantage of intravascular retention. Therefore, the amount infused can be approximately equal to the amount of blood removed. Some evidence suggests that when albumin is used as a diluent, the volume may need to be greater than the volume of blood removed to ensure normovolemia. [128] Hemodynamic studies comparing dextran, albumin, and hydroxyethyl starch have demonstrated no significant differences among diluents. [129] The advantage of crystalloid, in addition to cost, is that ex-cess fluid can easily be excreted if a diuretic such as furosemide is administered before reinfusion of the blood.

Blood is withdrawn from a central or large peripheral vein or radial artery. Use of veins distal to the antecubital area is not recommended, because poor blood flow often results in clotting. When an artery is used, blood pressure can be transduced intermittently by incorporation of a stopcock in the system. Blood is collected in standard blood bags containing anticoagulant, usually citrate-phosphate-dextrose. Hemodilution kits containing bags with an anticoagulant, a Y-type connection set with Luer-Lok adapter, and a blood recipient identification band are available (Autologous Blood Collection Kit 4R5012, Fenwal Division, Baxter Healthcare, Deerfield, Ill.). In cardiac surgery, heparinized blood can be collected from the venous line into transfer bags, or an autologous kit can be used (Autologous Blood Collection Kit 4R5010, Fenwal Division, Baxter Healthcare, Deerfield, Ill.). A scale should be used to weigh the bags to ensure that they contain the appropriate amount of blood relative to anticoagulant. Ideally, an automated blood collection and mixing device or blood "shaker" is used to monitor collection volumes and prevent clotting (Blood Shaker/Flow and Weight Monitor Model 1040, Sebra, Tucson, Ariz.).

Monitoring requirements depend on the patient's physical status, the operative procedure and anticipated blood loss, and the degree of hemodilution. Use of a pulmonary artery catheter during extreme ANH is advisable to permit determination of mixed venous oxygen saturation as a measure of global oxygenation. Preliminary data utilizing a synthetic perfluorochemical temporary oxygen carrier during ANH indicate that it increases mixed venous oxygen tension. [130] It may be possible to increase the number of units withdrawn by using a temporary oxygen carrier to provide an additional margin of safety.

Each unit is labeled with the patient's name, hospital number, and time of blood withdrawal and is numbered sequentially. The blood is kept in the same operating room as the patient and is maintained at room temperature to preserve platelet function. If it is anticipated that more than 8 hours will elapse before reinfusion, refrigeration of the blood is required. Refrigerated units must be reinfused within 24 hours or be discarded. [20] Blood is reinfused after major blood loss has ceased, or sooner if indicated. The units are reinfused in the reverse order of collection so that the first unit, which has the highest HCT and the most clotting factors, is administered last. Estimation of blood loss and serial HCT determinations are used to guide transfusion therapy.

Complications

The minimal safe HCT depends on the patient's ability to compensate for the decreased arterial oxygen content. Myocardial ischemia and cerebral hypoxia are the major potential complications. The augmented cardiac output increases myocardial oxygen consumption while the oxygen content of blood supplying the myocardium is reduced. Tachycardia and decreased cardiac output resulting from hypovolemia can further impair myocardial oxygen supply-demand relationships. In the adult, tachycardia should be

considered an indication of hypovolemia and should be corrected immediately.

Laboratory studies of the effects of extreme ANH on the intestine indicate that jejunal mucosal oxygen supply is well maintained at HCT values of 10 percent. [131] In the canine model, myocardium compromised by coronary stenosis is more sensitive to hemodilution-induced ischemia than is normally perfused gut mucosa. [132] These findings limit the potential usefulness of gastric tonometry as a guide to tolerable levels of hemodilution.

Animal studies indicate that cerebral function may not be affected until the HCT is less than 5 to 10 percent. [133] [134] In the canine model, hemodilution to a HCT of 19 percent impairs hypocapnia-induced vasoconstriction in the brain and spinal cord. [135] A potential clinical implication is that induced hypocapnia might be a less effective maneuver to reduce increased intracranial pressure during ANH. Conversely, the blunted vascular response to hypocapnia may confer brain protection by maintaining cerebral blood flow in the presence of decreased oxygen-carrying capacity. Experience with children hemodiluted to Hb levels of approximately 3 g/dL demonstrates the safety of extreme ANH in young patients without cerebrovascular disease. [118] Hemodilution to Hb levels of 7 to 9 g/dL in elderly patients, some of whom would be expected to have cerebrovascular disease, has not been reported to result in neurologic dysfunction. [122] [123] However, no studies have specifically addressed the issue, and caution is advised in patients with carotid or vertebral artery disease.

Coagulopathy related to dilution of clotting factors and increased bleeding resulting from enhanced capillary blood flow are potential complications. However, pediatric patients subjected to a 75 percent volume exchange during ANH still had a mean platelet count of 158±26 × 10^9 /L, which is ordinarily adequate for hemostasis. [119] Monitoring coagulation parameters is advisable with extreme ANH but is not required during moderate ANH.

Peripheral edema is common in hemodiluted patients, especially when crystalloid is administered as the sole diluent. However, pulmonary edema should not occur if ANH is properly performed.

INTRAOPERATIVE BLOOD RECOVERY

There are several techniques for recovery or salvage of shed blood. The most complex systems employ semicontinuous flow centrifugation to process the recovered blood. Blood collected in rigid canisters with sterile disposable liners can be washed before reinfusion or administered without processing. Shed blood can also be collected and filtered in sterile disposable single-use reservoirs for immediate reinfusion. The newest additions to the market are similar in concept to conventional cell processing devices but employ different technology for blood separation.

Semicontinuous Flow Centrifugation Devices

Several devices are available. The degree of automation, size, cost, and clinical applications vary. The disposable equipment consists of an anticoagulation and aspiration assembly, a reservoir with filter, a centrifuge bowl, a waste bag, and tubing (Fig. 47-3) (Figure Not Available) . The double-lumen aspiration set incorporates an anticoagulant line through which either a heparin or a citrate solution is administered at a controlled rate. Recovered blood, mixed with anticoagulant, is collected in the disposable reservoir containing a filter. The filtered blood is then pumped into a wash bowl with a centrifugation speed of approximately 5,000 repetitions per minute. Once the bowl is filled, the contents are washed with saline. The RBCs suspended in saline are pumped into a reinfusion bag. Most of the white blood cells, platelets, activated clotting factors, plasma Hb, cell fragments, and other debris are eliminated into the waste bag along with excess saline wash solution. The washing and concentrating process requires 3 to 10 minutes, depending on the device.

Characteristics of Processed Blood

The HCT of processed blood is 50 to 60 percent and can be varied by altering the processing parameters. The oxygen transport properties and survival of recovered RBCs are equal or superior to those of stored allogeneic RBCs. The 2,3-diphosphoglycerate content of recovered blood has been measured as a marker of RBC function. Processed blood consistently has higher 2,3-diphosphoglycerate levels than allogeneic blood. [136] [137] [138] The survival of RBCs has been studied by use of ^{51}Cr-tagged cells recovered during spine, [139] aortic, [137] [140] [141] and cardiac [142] surgery. The life span is comparable to that of transfused allogeneic RBCs. The pH of processed blood is alkaline, and potassium and sodium levels are normal. [138]

Plasma Hb levels may exceed 400 mg/dL in blood recovered during cardiac surgery and may be several times higher in orthopedic surgery. Adequate washing removes over 90 percent of the free Hb. [143] Residual leukocytes and platelets are present in washed blood, but their function and significance are uncertain. [144] Tumor necrosis factor-alpha, a cytokine produced by stimulated monocytes that has immunomodulatory activity, has been detected in unwashed, recovered blood. [145] Plasma elastase, an enzyme implicated in the pathogenesis of respiratory distress syndrome, has also been demonstrated in unprocessed blood. Washing removes these substances, thereby reducing the potential deleterious effects associated with reinfusion of unprocessed blood. [146]

When citrate is used as an anticoagulant, it is metabolized by the liver. Processed RBCs do not contain a clinically significant amount of residual heparin. [143] [147] [148] Instruments conventionally employed in cardiac surgery for determining activated clotting time and heparin assays (e.g., Hepcon, Medtronic Blood Management, Parker, Col.) cannot be used to measure residual heparin because coagulation proteins and antithrombin III, which are required for the test, are removed during the wash cycle. [143] [149]

Catecholamines are not removed during processing, and significant hypertension has been reported when blood recovered during surgery for pheochromocytoma was reinfused. [150] Washing does remove tissue factor in blood contaminated with amniotic fluid. [151] D-dimer levels have been measured in recovered blood as an indication of activation of the coagulation and fibrinolytic systems and the presence

Figure 47-3 (Figure Not Available) Diagram representing the recovery of blood from the surgical field, the processing cycle, and the return of washed red blood cells to the patient. *(Courtesy of COBE Cardiovascular Inc., Arvada, Col.)*

of fibrin degradation products. Although D-dimer levels may be increased 85 times in unwashed blood, normal levels are found in processed blood. [152]

Reports describing the quality of blood processed with newer devices employing technology different from semicontinuous flow centrifugation are beginning to appear. [153] [154] [155] [156] Unacceptable residual heparin levels were demonstrated with one ultrafiltration device. [153] Initial reports indicate that the continuous autologous transfusion system (CATS, Fresenius AG, Bad Homburg, Germany) produces a product with a mean HCT of 62 percent, greater than 99 percent heparin elimination, and removal of most plasma proteins. [154] An *in vitro* study using soya oil, which has a fatty acid composition similar to that of fat found in bone marrow, indicated complete removal of fat particles. [155]

Complications

Potential complications associated with use of cell processing devices include air and fat embolism, pulmonary dysfunction secondary to infusion of debris in recovered blood, coagulopathy, renal dysfunction, sepsis, and dissemination of malignant cells. The most serious complication--air embolism--is rare if the devices are used in accordance with the manufacturer's instructions. However, one report cited an incidence of fatal air embolism of 1:30,000 to 1:38,000 in approximately 127,000 blood recovery procedures. [157] All cases involved infusion of recovered blood under pressure. Contributing causes were deviations from accepted practice, lack of operator vigilance, and insufficient knowledge of the procedure. Suggested measures to prevent air embolism include transferring the blood to a reinfusion bag before transfusion (i.e., not reinfusing directly from the recovery container) and avoiding reinfusion under pressure.

Although processed blood, particularly that collected during orthopedic procedures, contains visible fat particles, there is no documented instance of fat embolism associated with the technique. There are also concerns about transfusing blood containing leukocytes, platelets, and other cellular debris that can lodge in the lungs, potentially causing pulmonary dysfunction. Despite reinfusion of shed blood in thousands of patients, no adverse effects on pulmonary function have been documented.

Lysis of RBCs can occur as a result of high vacuum suction levels or aspiration techniques that cause turbulence during blood collection. Two cases of renal dysfunction requiring dialysis have been reported. [158] In both cases, excessive vacuum levels and insufficient washing of recovered blood were implicated. Most operator's manuals recommend a maximum vacuum level of 100 to 150 mm Hg. A laboratory study demonstrated the absence of excessive hemolysis when levels of up to 300 mm Hg were employed, but the author stressed that the lowest level of vacuum compatible with a clear surgical field should be used. [159] Use of a suction regulator with a factory-set maximum vacuum level is recommended, and the accuracy of the suction regulator should periodically be verified. [158] Suctioning small amounts of blood mixed with air (skimming) may induce greater degrees of hemolysis than high suction vacuum levels. [159] This is most likely to occur during

orthopedic surgery. Greater wash volumes are usually recommended during orthopedic surgery. In any case, the blood should be washed until the effluent is clear.

Processed blood is depleted of coagulation proteins and functional platelets. It is not surprising that coagulopathy

has been reported in patients receiving more than 15 units of processed blood. [160] The same guidelines for platelet and fresh frozen plasma administration apply when shed blood and allogeneic RBCs are infused. [74] There is a report of two cases of disseminated intravascular coagulation in patients undergoing spine surgery during which recovered blood was reinfused. [161] By the authors' own admission, vacuum levels of 300 mm Hg were used throughout the procedure. Coagulopathy may have been the fault of the procedure, but it is more likely that a faulty procedure caused the coagulopathy.

As a general principle, blood contaminated with intestinal contents should not be reinfused. However, there are reports of intraoperative blood recovery and reinfusion in patients with blunt and penetrating abdominal injuries associated with disruption of bowel integrity. [162] [163] One report evaluated trauma patients who received potentially culturepositive blood. [164] Wound infection rates were identical to those in patients with similar injuries who were not autotransfused. *In vitro* studies demonstrate that cell washing reduces the bacterial count but does not remove all bacteria. [165] The risk-benefit ratio of employing the technique when the wound is contaminated (or potentially contaminated) with intestinal contents should be carefully evaluated.

Bacteriologic and endotoxin analysis of blood recovered during cardiac surgery has shown a significant incidence of bacterial contamination with gram-positive commensals of the skin, as well as low concentrations of endotoxin. No adverse clinical outcomes were noted. [166] [167] Similar results have been found with blood recovery during liver transplantation. [168] It is speculated that the sources of contamination are the skin and room air and that the quantity of bacteria is too small to be of clinical significance in patients receiving prophylactic antibiotics. This hypothesis is supported by a study in which blood recovered during hip arthroplasty in patients receiving antibiotic prophylaxis with cefuroxime was compared with blood from patients not receiving antibiotics. [169]

The presence of tumor cells in the operative field has traditionally been considered a relative contraindication to intraoperative blood recovery. Although experience with the technique in patients with genitourinary tumors undergoing radical cystectomy, nephrectomy, prostatectomy, and radical hysterectomy indicates that it may be acceptable, [170] [171] [172] laboratory studies using human tumor cell lines have demonstrated that tumor cells remain in the washed RBC suspension. [173] [174] Filtration of the RBC concentrate with a third-generation leukocyte-reduction filter removes the tumor cells. [175] [176] [177] [178]

An additional safety issue when blood is recovered during urologic procedures is contamination of the surgical field with urine. Biochemical analysis of concentrated RBCs mixed with an equal volume of urine has demonstrated complete removal of urine constituents. [176] Concentrated RBCs inoculated with bacteria demonstrated bacterial growth, indicating that bacteria were not removed by the washing process. The investigators suggested preoperative elimination of bacterial urinary tract infection when blood recovery is planned in patients undergoing urologic surgery. [176]

Blood should not be aspirated during application of topical hemostatic agents, such as thrombin and microfibrillar collagen hemostat (Avitene). *In vitro* studies indicate that it can pass through the filtering system and become lodged in tissues. [179] Laboratory investigations have demonstrated that either a leukocyte-reduction filter or a 20-mum microaggregate filter can remove approximately 97 percent of potentially thrombogenic particles of Avitene. [180] Blood also should not be aspirated when the wound is irrigated with antibiotics that are not licensed for parenteral use or during the application of methylmethacrylate. The wound should be copiously irrigated following use of these substances before blood recovery is resumed.

Clinical Applications

Intraoperative blood recovery should be considered when it is anticipated that blood will be shed into a clean wound from which it can be aspirated without undue hemolysis. Limiting use of the procedure to situations in which the following criteria are met can serve as a guideline: blood would normally be crossmatched, the anticipated blood loss is at least 20 percent of the patient's estimated blood volume, 10 percent or more of patients undergoing the procedure require transfusion, the mean transfusion for the procedure is more than one unit. The major applications are cardiac, [181] [182] [183] [184] vascular, [137] [140] [185] [186] orthopedic, [187] [188] [189] [190] [191] and trauma surgery [162] [163] [164] [165] [192] [193] and liver transplantation. [194] [195]

Utilization appears to be increasing in neurosurgery. Following the tradition of Harvey Cushing, [5] the Mayo Clinic group reported experience with blood recovery during resection of intracranial arteriovenous malformations. [196] More recently, Cataldi et al [197] infused recovered blood in patients undergoing intracranial surgery, and Jimenez and Barone [198] demonstrated a 46 percent decrease in allogeneic transfusion requirements with intraoperative blood recovery in children undergoing surgery for craniosynostosis.

Preliminary clinical data indicate that the technique can safely be utilized during cesarean delivery if a separate suction apparatus is used for removing the amniotic fluid. [199] Laboratory studies confirming removal of tissue factor in aspirated blood that contains amniotic fluid also suggest that the technique can be utilized after delivery of the baby when unexpected hemorrhage occurs. [151]

Cost-Effectiveness

The expenses associated with cell processing units include not only the apparatus and the software but also the time of a dedicated, trained operator. The institution's experience with allogeneic transfusion for comparable procedures should be periodically reviewed when the procedures for which the technique will be used are determined.

Three groups of investigators studied patients undergoing primary total hip replacements and concluded that intraoperative blood recovery was not cost-effective and was unnecessary in patients who donated two or three units before surgery. [189] [190] [200] Siller et al [201] compared the efficacy and the cost of PABD and intraoperative blood recovery in adolescents undergoing posterior spinal instrumentation and fusion. The cost of intraoperative blood recovery was approximately $240, and patients were billed approximately $640. The addition of intraoperative blood recovery had no

effect on blood exposure, and the investigators do not recommend it if sufficient predonated blood is available.

After reviewing their experience with blood recovery during emergency spine surgery, Cavallieri et al [192] suggested that cost-effectiveness could be improved if use of the technique was restricted to patients with thoracolumbar spine injury with preoperative HCT values of less than 35 percent and Injury Severity Scores of greater than 20. Smith et al [193] calculated the total cost of intraoperative blood recovery for patients sustaining abdominal trauma to be $63,252, whereas the cost of bank blood would have been $114,523. Use of the technique was considered cost-effective in 75 percent of the cases.

Two groups evaluated cost-effectiveness of intraoperative autologous transfusion during abdominal aortic surgery. Using $50,000/QALY as a threshold, Huber et al [185] concluded it was not cost-effective. The cost was $263.75 per case, or $120,794/QALY. They recommended the technique be restricted to select cases in which large volumes of blood loss are anticipated. Goodnough et al [186] calculated that the RBC volume recovered represented the equivalent of 1.6 allogeneic RBC units. The mean blood bank cost saved by use of the device was $248, or 79 percent of the $315 spent on use of the technique. There was no decrease in the percentage of patients transfused unless recovered volumes infused exceeded 750 mL.

Although intraoperative blood recovery is not cost-effective for most patients undergoing primary total joint replacements, it may be for those having hip arthroplasty revisions. For intra-abdominal aortic surgery, spine, and abdominal trauma procedures, it is often reasonable to use an anticoagulant-suction apparatus and blood collection reservoir but not to open a centrifuge bowl unless sufficient blood is collected to make processing worthwhile.

Unprocessed Blood

The primary stimulus for developing devices that do not require processing of recovered blood was the desire to eliminate the need for expensive equipment that required the constant attention of dedicated operators. Intraoperative use is usually restricted to vascular surgery. The devices are more commonly used in the postoperative period.

POSTOPERATIVE BLOOD RECOVERY

Cardiac surgeons have long advocated recovery and reinfusion of mediastinal drainage following cardiac surgery. Collection and reinfusion of blood shed following orthopedic surgery was introduced later.

Cardiac Surgery

Blood within the mediastinum undergoes coagulation and subsequent fibrinolysis. It contains virtually no fibrinogen, and no anticoagulation is required before reinfusion. The HCT value usually ranges from 20 to 25 percent, and free Hb levels are 300 to 400 mg/dL. [143] [202] [203] [204] [205] The transfused RBCs have normal survival [206] and oxygen delivery capacity. [207]

Fibrin degradation products are detected in most patients when unwashed shed mediastinal blood is reinfused. [208] [209] [210] The presence of fibrin degradation products should not be interpreted as indicative of disseminated intravascular coagulation in the absence of clinical bleeding. The greatest danger posed by the fibrin degradation products is misinterpretation of laboratory tests for disseminated intravascular coagulation and unnecessary blood component administration. [208] Serum creatine kinase, serum glutamic-oxaloacetic transaminase (SGOT), and lactate dehydrogenase levels are also elevated after reinfusion of unwashed mediastinal blood. [211] [212] [213] [214] [215] Conflicting results have been reported regarding elevation of the MB band of creatine kinase. Caution must be exercised when cardiac enzyme levels in patients who receive shed mediastinal blood are interpreted. The enzyme elevations caused by reinfused blood can mimic a myocardial infarction. Alternatively, falsely attributing enzyme abnormalities to the shed blood may result in a myocardial infarction going undiagnosed.

The cost-effectiveness of reinfusing shed mediastinal blood has been questioned by several investigators. [209] [216] [217] The volume of blood collected is often small and the amount reinfused insufficient to decrease allogeneic RBC transfusion requirements. Potential complications resulting from transfusion of the blood include difficulties in diagnosing perioperative myocardial infarction, activation of the fibrinolytic and kallikrein-kinin system, enhanced reperfusion injury related to administration of activated platelets, and infection from contaminated blood. [217] Proponents of routine collection and reinfusion of shed blood cite studies demonstrating decreased allogeneic transfusion requirements [218] [219] [220] and emphasize that it is impossible to know in advance who will bleed excessively (and benefit from the technique) and who will not. [221] Processing of recovered blood obviates most of the problems potentially associated with reinfusion, but it is expensive, and the volume is often insufficient to make it worthwhile.

Orthopedic Surgery

Postoperative blood recovery is employed most often for total hip and knee arthroplasties. [222] [223] [224] [225] [226] Experience with the technique following spine surgery is limited. [227] [228] [229] Two questions arise: (1) is it effective and (2) is it safe?

The volume of wound drainage recovered in most series is 400 to 500 mL, but unilateral and bilateral hip and knee procedures are often reported together, making evaluation of the data difficult. The HCT of the reinfused blood is variable, depending on the procedure and the collection period. Most investigators do not provide these data. One group measured the volume and the HCT of recovered blood and found the mean postoperative RBC loss following total hip and knee replacement to be 55±29 mL and 121±50 mL, respectively. [230] The 6-hour wound drainage represented 8.7 and 16.8 percent of overall RBC loss during hospitalization for hip and knee replacements, respectively. Only three of 51 patients lost the equivalent of one or more RBC units in recovered drainage. The volume of RBCs recovered after surgery bore no relationship to total perioperative RBC loss.

Although several groups have demonstrated decreased allogeneic transfusion requirements, [224] [225] [226] others have concluded

---

that routine postoperative blood recovery is not justified, particularly in patients who participate in PABD programs. [230] [231] [232] [233] Selective use of postoperative blood recovery in patients undergoing bilateral total knee replacements or hip revision surgery or those in whom other forms of autologous transfusion are not employed may be costeffective.

There is considerable controversy regarding the necessity for processing the blood before reinfusion. Complement activation has been demonstrated in recovered blood, but not in the recipients of amounts up to 15 percent of estimated blood volume. [234] Recovered blood has elevated levels of cytokines (tumor necrosis factor-alpha, interleukin-1alpha, interleukin-6, interleukin-8) [235] [236] [237] and fibrin degradation products. [238] [239] Bone fragments, fat, and other debris are often visible, and fat particles too small to be removed by microaggregate filters have been demonstrated. [240] Levels of methylmethacrylate monomer in shed blood peak within minutes of drain insertion following total joint arthroplasty but are not detectable after the blood remains at room temperature for 6 hours--the maximum recommended collection period before reinfusion. [240]

Despite the potential complications of reinfusing blood recovered after total joint arthroplasty, there are few reported complications. Faris et al [241] found a 22 percent incidence of febrile reactions associated with reinfusion of blood collected for 6 to 12 hours after operation, compared with a 2 percent incidence when the period of collection was 6 hours or less. Hypotension [242] and upper airway edema [243] have been reported with transfusion of unwashed blood. Despite laboratory evidence of activation of the coagulation and fibrinolytic systems, coagulation studies in recipients are no different than those in patients who receive liquid-preserved RBCs. [225] Reinfused RBCs have a normal life span. [244] [245] [246]

COLLECTION OF PLATELET-RICH PLASMA

Cardiopulmonary bypass is associated with hemostatic abnormalities, the most significant being impaired platelet function. In an attempt to decrease postoperative bleeding and allogeneic transfusion requirements, autologous PRP may be collected before CPB and then reinfused following bypass. Conventional apheresis apparatus can be employed, but plasma collection kits designed specifically for intraoperative use with cell processing devices are preferable.

Conflicting results have been reported regarding the efficacy of PRP in reducing allogeneic transfusion requirements. Some differences can be attributed to study design, volume of collected platelets, time of collection (before or after heparinization), types of surgical procedures included, and absence of defined transfusion criteria. Two blinded, randomized studies did not demonstrate a decrease in transfusion requirements. Ereth et al [247] collected 600 to 700 mL of PRP in patients undergoing repeat valvular surgery and performed a sham procedure in control patients. Tobe et al [248] collected 8 to 10 mL/kg of PRP and reinfused it immediately in control patients and after heparin reversal in treated patients undergoing primary CABG. Shore-Lesserson et al [249] included patients undergoing repeat CABG and/or valve replacement in a prospective randomized controlled study in which treated patients had 1,000 mL of PRP (mean platelet count, 1.2×10^{11}/L) removed. In addition to no effect on bleeding or transfusion requirements, there was a 60 percent incidence of hypotension requiring treatment when the PRP was reinfused. When the effect of fresh whole blood (mean volume 924±130 mL) obtained by intraoperative hemodilution was compared with that of PRP (mean volume, 650±124 mL; mean platelet count, $1.42\pm0.74\times10^{11}$/L), a comparable hemostatic effect that manifested as reduced postoperative bleeding was demonstrated, but neither technique influenced allogeneic transfusion requirements. [250] No differences in coagulation tests, platelet counts, chest tube drainage, or allogeneic transfusion requirements were demonstrated between control patients undergoing elective primary cardiac surgery and those who had PRP (mean volume, 892±150 mL; mean platelet count, 1.4×10^{11}/L) removed and reinfused. [251]

In contrast to the foregoing, two other studies have demonstrated decreased blood loss and transfusion requirements. Christenson et al [252] studied a small group of patients undergoing repeat CABG in whom approximately 20 percent of circulating platelets were harvested. Blood loss and transfusion requirements were significantly decreased in treated patients. In addition, postoperative ventilation time and intensive care unit stay were shorter, and postextubation gas exchange was better. In a larger study, Armellin et al [253] evaluated 293 consecutive patients undergoing cardiac surgery, 147 of whom had PRP (10 mL/kg) removed before heparinization. Mediastinal drainage was less in treated patients during the first 12 postoperative hours, but no difference in total postoperative blood loss was noted. The volume of RBCs and fresh frozen plasma administered was less in treated patients than in control subjects. Transfusion criteria were defined in both of these studies.

What can be concluded from the aforementioned studies? As pointed out by Boldt [254] in his review, collection of PRP is time consuming, requires additional staff, and adds to the cost of surgery. However, collection and reinfusion of PRP are less expensive than transfusion of an equal amount of allogeneic fresh frozen plasma and platelets. Routine use of the technique in cardiac surgery does not appear warranted, but selective use may be beneficial. For example, patients undergoing complicated procedures who are expected to have prolonged CPB and significant blood loss may benefit.

An aliquot of the PRP can also be used for preparation of fibrin sealant or glue. [255] The PRP (or autologous cryoprecipitate prepared from predonated whole blood) is applied to bleeding tissues simultaneously with bovine thrombin and calcium. Numerous reports have documented improved hemostasis with application of fibrin sealant. [256] It is anticipated that a product prepared from solvent-detergent inactivated plasma recently licensed in the United States will reduce the collection of autologous blood for this purpose.

SUMMARY

Autologous transfusion can significantly decrease allogeneic transfusion requirements in surgical patients, and it is often appropriate to employ several blood conservation

techniques. However, the time has come to refine the indications for, and the limitations of, each technique. Destroying approximately 50 percent of predonated autologous units is not acceptable. Patients who can reasonably be expected to profit from predonation should do so, but predonation should be discouraged when it is inappropriate. ANH can be beneficial when large volumes of blood are removed and significant blood loss occurs. Additional controlled studies are needed to define the role of this technique. Intraoperative and postoperative blood recovery should be utilized in cases in which adequate data substantiate efficacy. Routine use is not justified. Newer processing devices requiring less operator intervention may improve cost-effectiveness. The role of PRP in cardiac surgery (and some noncardiac procedures) has not been defined.

Section 4 - Subspecialty Management

Chapter 48 - Anesthesia for Thoracic Surgery *

Jonathan L. Benumof
David D. Alfery

INTRODUCTION

The techniques for administering anesthesia for thoracic surgery have undergone a dramatic, progressively refined, and scientifically based evolution. Initially, the general problem of gas exchange with an open thorax was defined and its physiology understood; the problem was solved with the use of controlled positive-pressure ventilation. The introduction of clinically useful muscle relaxants facilitated the use of controlled ventilation. The need for isolating one lung from another became apparent during surgery for lung abscess, bronchopleural fistula, and hemoptysis; a plethora of methods for providing separation of the lungs was developed. Considerable clinical experience subsequently defined and refined the indications and techniques for one-lung anesthesia. Concomitantly, the changes in the distribution of blood flow and ventilation, in the awake state and in the anesthetized and mechanically ventilated state in both the supine and the lateral decubitus positions, became understood. Methods have been developed to manage one-lung ventilation so that arterial oxygenation levels are close to those achieved during two-lung ventilation. The postoperative period can now be almost pain-free and without great risk with the use of epidural narcotics, patient-controlled analgesia, and/or cryoanalgesia (Ch. 69) .

This chapter is divided into two sections. The first part moves temporally through the perioperative period and provides the essentials for the management of a patient under-going thoracic surgery. Preoperative considerations include pulmonary evaluation and optimal pulmonary preparation. Intraoperative period considerations are monitoring requirements, choice of anesthesia, respiratory physiology of the lateral decubitus position and one-lung ventilation/anesthesia, and most importantly, the indications and techniques for providing one-lung ventilation/anesthesia. Finally, the postoperative problems of immediate lifethreatening complications, management of mechanical ventilation, therapeutic respiratory care maneuvers, and control of pain are discussed. The second part of this chapter deals with specific anesthetic techniques and problems encountered in a variety of special diagnostic, elective, and emergency thoracic procedures.

THE PREOPERATIVE PERIOD

Preoperative Evaluation

The vast majority of noncardiac, noncardiopulmonary bypass thoracic surgery procedures consist of resectional or repair procedures for cancer and other masses of the lung and bronchi. Consequently, this section emphasizes these lesions and gives special attention to the respiratory and cardiovascular systems. [1] [2] [3] [4] [5] Also see Chapter 23 .

Respiratory System

History

The history (Chs. 23 and 25) often raises suspicion of the diagnosis of lung cancer. The average patient with cancer of

* *See Appendix 1, Practice Guidelines for Management of the Difficult Airway*

the lung (carcinoma constitutes approximately 90 percent, adenomas 8 to 10 percent, and benign masses 1 percent of lung tumors) is in the sixth or seventh decade of life, has a history of heavy cigarette smoking and recent weight loss, and resides in an urban area. However, a small percentage of lung carcinomas occur in nonsmokers (<10%) (many of these can be traced to a history of passive or involuntary smoking), [6] [7] [8] and lung carcinoma has a higher incidence of occurrence in workers in some chemical industries (such as asbestos, arsenic, chromates, and nickel) than in the general population. Uranium miners have a greatly increased risk for the development of lung carcinoma, especially if they smoke. All age groups are affected, but the disease is rare in persons less than 30 years of age. Five percent of patients are asymptomatic, and in this group the tumor is discovered only by routine roentgenographic examination of the chest. The vast majority of patients, however, have one or more symptoms related to the presence of the tumor. The symptoms may be designated as bronchopulmonary, extrapulmonary intrathoracic, extrathoracic metastatic, extrathoracic nonmetastatic, and nonspecific. On the average, symptoms have been present for 6 to 7 months before the time the patient seeks medical advice; because the first chest roentgenographic findings frequently antedate the first symptoms by several months, lung carcinoma will be at least 1 year old (and perhaps 2-5 years old) by the time of clinical presentation.

Bronchopulmonary Symptoms.

Bronchopulmonary symptoms arising from involvement of the lung (cough, sputum, chest pain, dyspnea, wheeze) are due to bronchial irritation, ulceration, obstruction, infection distal to the obstruction, or a combination of these processes. In a large series of patients with carcinoma of the lung, 75 percent had cough as one of the major symptoms, and this symptom was severe in 40 percent of patients. However, cough is possibly the most common manifestation of respiratory disease in general. It is so common among cigarette smokers that many of them regard a morning cough as "normal." The most common stimulus to cough is the formation of sputum in the respiratory tract (see below), and the cough process is an essential element in keeping the tract clear.

The normal adult produces about 100 mL of mucus from the respiratory tract in a day. When excess mucus is formed, it may accumulate, stimulate the mucous membrane, and be coughed up as sputum. Sputum in patients with bronchogenic carcinoma may be formed in response to physical, chemical, or infective insult to the mucous membrane of the airways. Mucoid sputum is clear or white. Black sputum is due to the detritus of cigarette or atmospheric smoke. Purulent sputum can vary from small streaks to gross hemoptysis (see later) and always warrants investigation for carcinoma. Hemoptysis generally manifests itself as episodic blood streaking of the trophils. Failure to clear a recent change in the quality and quantity of sputum within a few days of initiating antibiotic therapy should raise suspicion of a neoplasm. Blood-stained sputum can vary from small streaks to gross hemoptysis (see below) and always warrants investigation for carcinoma. Hemoptysis, generally manifest as episodic blood streaking of the sputum, is present in 57 percent of patients with bronchogenic carcinoma and is the first symptom in many.

Chest pain is present in 40 percent of patients presenting with a new carcinoma. It is usually a mild, constant, dull ache on the side with the tumor. Another important form of chest pain with lung carcinoma is pleuritic pain. It is due to direct tumor extension to the pleura, is characteristically worse on breathing and coughing, and can usually be accurately localized by the patient. Mediastinal tumors can cause pain that is usually aching and retrosternal but poorly localized.

Dyspnea is a common complaint in patients with both chronic lung disease and lung carcinoma (30%). In chronic diseases, it is common to find that the patient begins to complain of dyspnea only after the respiratory reserve is quite severely impaired, whereas in patients with lung carcinoma dyspnea occurs more abruptly and with less objective functional impairment.

Wheezing is described by 10 percent of patients and is frequently localized to one side. It is due to airway obstruction, and, if the obstruction is located in the trachea, severe dyspnea and stridor may develop.

Extrapulmonary Intrathoracic Symptoms.

Other symptoms of chest disease occur as a result of growth of the tumor beyond the confines of the lung. These symptoms are due to involvement of the pleura (effusion), chest wall (pain), esophagus (dysphasia), superior vena cava (superior vena cava syndrome), pericardium (pericarditis), brachial plexus (arm pain, Horner syndrome), and right or left recurrent laryngeal nerve (hoarseness). Approximately 15 percent of patients with carcinoma of the lung have these kinds of extrapulmonary intrathoracic symptoms.

Extrathoracic Metastatic Symptoms.

Symptoms resulting from metastatic spread of the tumor outside the thorax account for a small percentage of the presenting or major complaints of patients with carcinoma of the lung. These extrathoracic metastatic symptoms can be referable, in order of general decreasing frequency, to brain, skeleton, liver, adrenals, gastrointestinal tract, kidneys, and pancreas. The history with regard to these other organs is extremely important because any positive history referable to these organs requires specific organ workup for metastatic disease (for staging, see the section *Pulmonary Function Testing*), and the finding of such metastases precludes surgery.

Extrathoracic Nonmetastatic Symptoms.

Extrathoracic nonmetastatic symptoms are usually due to a paraneoplastic syndrome caused by secretion of endocrine or endocrine-like substances by the tumor. The endocrine-like manifestations include Cushing syndrome, excessive antidiuretic hormone secretion, carcinoid syndrome, hypercalcemia, ectopic gonadotropin secretion, and hypoglycemia. The neuromuscular manifestations consist of carcinomatous myopathies (Eaton-Lambert Syndrome) and various myopathies related to brain dysfunction. Other manifestations can be skeletal (clubbing, pulmonary hypertrophic osteoarthropathy), dermatologic (scleroderma, acanthosis nigricans), vascular (thrombophlebitis), and hematologic.

Nonspecific Symptoms.

Weight loss, anemia, weakness, anorexia, lethargy, and malaise occur in a large number of patients. Vague febrile respiratory (cold-like) syndromes

Figure 48-1 (Figure Not Available) In patients with lung carcinoma the chest radiograph findings result from the presence of the tumor within the lung (parenchymal mass), changes in the pulmonary parenchyma distal to a bronchus obstructed by the tumor (atelectasis and infection), and spread of the tumor to extrapulmonary intrathoracic sites (hilar and mediastinal masses and other direct extension pathology). *(From Benumof [604])*

may be present in 22 percent of these patients. In 10 to 15 percent of patients, these symptoms are responsible for the initial visit to the physician.

Physical Examination

The basic tools of inspection, palpation, auscultation, and percussion should allow the physician to assess, in a gross way, the overall severity of chronic lung disease, regardless of whether major consolidation, atelectasis, or pleural effusion is present and whether there is any obvious extrathoracic complication of thoracic carcinoma. Because it is mandatory subsequently to use much more sensitive radiologic means of determining resectability, further discussion of physical examination methods for making these determinations is not included here. The detection of bronchospasm, however, is particularly important in that it requires further documentation, is usually reversible with treatment, and has important anesthetic management implications, which are discussed in the section *Preoperative Preparation.*

Common Laboratory Tests

Some of the routine laboratory tests (Ch. 23) that are performed on all patients are especially relevant to the preoperative evaluation of the patient with a lung or bronchial mass. The complete blood count may indicate polycythemia, which may reflect decreased arterial hemoglobin saturation; leukocytosis may be indicative of active pulmonary infection. Gram stain of the sputum provides a qualitative index of infection; cultures and sensitivity studies direct specific antibiotic therapy. Sputum cytology is useful in diagnosing neoplasms. Liver and bone enzymes, blood urea nitrogen and creatinine, and urinalysis can help establish the diagnosis of metastatic lung cancer. However, the chest roentgenogram is, by far, the most useful common laboratory test.

The Chest Radiograph

It has been estimated that when a tumor of the lung is first detected on a chest radiograph, it has completed three fourths of its natural history, [9] and this first radiographic abnormality frequently antedates the first symptoms or signs of the disease by 7 or more months. [10] By the time bronchial carcinoma becomes symptomatic, the chest radiograph is abnormal in 98 percent of all patients, and the abnormality is most suggestive of tumor in over four fifths of these.

The radiographic findings due to carcinoma of the lung (Fig. 48-1) (Figure Not Available) may be the result of the presence of the tumor within the lung [11] (Table 48-1) (Table Not Available) (70% are centrally located), of changes in the pulmonary parenchyma distal to a bronchus obstructed by the tumor (atelectasis, infection, and cavitation), and of spread of the tumor to extrapulmonary intrathoracic sites (hilar and mediastinal lymph nodes, pleura, chest wall, and diaphragm).

The usual radiographic manifestations of lung carcinoma frequently include the hilar and extrapulmonary intrathoracic manifestations in addition to the pulmonary parenchymal manifestations. In a review of the radiographs of the chest of 600 patients with carcinoma of the lung, [12] the average lung cancer mass at radiologic presentation was 3 to 4 cm in diameter. A large parenchymal mass was present in 22 percent of patients and a smaller mass in 20 percent; multiple masses were present in only 1 percent. Obstructive pneumonitis, collapse, or consolidation was present in 41 percent. A hilar abnormality, either alone or associated with other abnormalities, was present in 41 percent of the patients.

TABLE 48-1 -- Radiologic Criteria for Differentiating Malignant From Benign Pulmonary Opacities

(Not Available)

From Batra et al [11]

The various extrapulmonary intrathoracic manifestations, of which mediastinal widening, pleural effusion, and raised hemidiaphragm were the more common, were present in 11 percent.

Several radiographic findings can have specific anesthetic implications. These lesions consist of tracheal deviation or obstruction (difficulty with intubation or ventilation); mediastinal mass (difficulty with ventilation, superior vena cava syndrome, compression of pulmonary artery); pleural effusions (decreased vital capacity and functional residual capacity [FRC]); cardiac enlargement (susceptibility to anesthetic agents that depress the heart); bullous cyst (hazard of rupture, compression of adjacent lung); air-fluid levels (abscess with hazard of spread of infection); and parenchymal reticulation, consolidation, atelectasis, or edema (increased ventilation/perfusion [V/Q] inequality and transpulmonary shunt). It is important to note that as many as 10 percent of patients with chronic diffuse infiltrative lung disease may have normal chest radiographs. [13]

Pulmonary Function Testing

Preoperative pulmonary evaluation (Ch. 24) of patients with cancer of the lung should resolve questions concerning both resectability and operability. The question of resectability requires local tumor, regional node, and distant metastasis (T, N, and M, respectively) staging of the disease and is based on clinical examination, radiographic (including computed tomographic [CT]) studies (T staging), bronchoscopic and mediastinoscopic examination (N staging), and individual organ evaluation and scanning (M staging). Operability addresses the question of how much pulmonary tissue can be safely removed without rendering the patient a pulmonary cripple (the remaining lung may be diseased by a long history of smoking), and this question is best answered by pulmonary function tests. When making an evaluation of operability, the physician must remember that untreated carcinoma of the lung is associated with a mean survival of less than 1 year and that the only currently effective method for curing carcinoma of the lung is surgical excision.

There is a general consensus that in the performance of a pneumonectomy, pulmonary function testing should proceed in three phases [14] [15] (Table 48-2) . The first phase evaluates total lung function and consists of analysis of room air arterial blood gases as well as simple spirometry and determination of lung volumes. More recent reports indicate carbon monoxide diffusing capacity and exercise testing may be indicated as well (Table 48-3) . Increased risk is present when hypercapnia ($Pa_{CO_2} > 45$ mm Hg) is present on a room air blood gas sample, the forced expired volume in 1 second (FEV_1), and/or the maximum breathing capacity is less than 50 percent of predicted, and/or the residual volume is greater than 50 percent of total lung capacity. If any of these whole-lung pulmonary function values is worse than the stated limits, testing should proceed to the second phase, which evaluates the function of each lung separately; this phase consists of measurement of the ventilation [16] [17] [18] and, more recently, the perfusion [19] [20] of each individual lung (as a fraction of the total) by radioisotopic (^{133}Xe and ^{99}Tc) scanning. Combining right-left fractional lung function tests with conventional spirometry should yield a predicted postoperative FEV_1 greater than 0.85 L. [16] [17] [18] For example, if the

perfusion of the lung to be removed is 40 percent of the total perfusion and the preoperative FEV_1 is 1.4 L, the predicted postoperative FEV_1 is 0.84 L. That is, predicted postoperative FEV_1 equals preoperative FEV_1 multiplied by contralateral perfusion (expressed as a percentage).

If the second-level criterion of acceptable predicted postoperative FEV_1 cannot be met and surgery is still contemplated or desired, the postoperative condition of the patient can be simulated (the third phase of testing) by functionally resecting the vascular bed of the lung to be taken out by temporary balloon occlusion of the major pulmonary artery on that side, with and without exercise. [19] [21] [22] [23] [24] Under these conditions, the distensibility (compliance) of the remaining pulmonary vascular bed is tested, and an increase in mean pulmonary artery pressure to greater than 40 mm Hg, and/or an increase in Pa CO_2 above 60 mm Hg, and/or a decrease in Pa O_2 less than 45 mm Hg indicates an inability to tolerate the removal of this amount of lung.

Ventilatory function postpneumonectomy (or after any resection) can also be simulated preoperatively by passing, with the aid of a fiberoptic bronchoscope, a balloon occlusion catheter, which can occlude either lung (or any lobe), and then measuring spirometry of the remaining lung tissue (after careful withdrawal of the bronchoscope). Supplemental

TABLE 48-2 -- Preoperative Pulmonary Function Tests (PFTs) and Operative Risk of Pneumonectomy

TESTING PHASE	PFT*	INCREASED OPERATIVE RISK RESULT
1. Whole-lung tests	Arterial blood gases	Hypercapnia on room air
	Spirometry	FEV_1 < 50% of FVC
		FEV_1 < 2 L
		MBC < 50% predicted
	Lung volume	RV/TLC > 50%
2. Single-lung tests	Right-left (individual-lung) split-function tests	Predicted postoperative FEV_1 < 0.85 L or > 70% blood flow to diseased lung
3. Mimic postoperative condition	Temporary unilateral balloon occlusion of right or left main stem bronchus or right or left pulmonary artery (must provide supple- mental O_2)	Mean pulmonary artery pressure > 40 mm Hg, severe breathlessness, Pa CO_2 > 60 mm Hg, or Pa O_2 < 45 mm Hg

Abbreviations: RV, residual volume; TLC, total lung capacity; MBC, maximum breathing capacity; FEV_1, forced expired volume in first second; FVC, forced vital capacity.

*The testing phases and PFT are listed in order of proper temporal performance and increasing invasiveness. (Also see Chs. 24 and 25 for more details.)

TABLE 48-3 -- Minimal Pulmonary Function Test Criteria for Variously Sized Pulmonary Resections

TEST	UNIT	NORMAL	PNEUMONECTOMY	LOBECTOMY	SEGMENTECTOMY
MBC	L/min	>100	>70	40-70	40
	% predicted	100	>55	>40	>35
	L	>5.0	>2.1		
	Predicted postoperative, L		>1.3		
FVC	% predicted	100	>51-64	--	--
	Predicted postoperative % predicted		>41		
	L	>2	>1.7-2.1	>1-1.2	>0.6-0.9
	Predicted postoperative, L		>0.8-0.9	>1.0	
FEV_1	% predicted	100	>55-65	40-50	>40
	Predicted postoperative % predicted		>30-40		
FEV_{25-75}	L	2	>1.6	>0.6-1.6	>0.6
	% predicted	100	>60		
DL	Predicted postoperative % predicted		>40	--	--
	VO_2 max	2.8 L/min			
			>1.0 L/min		

	VO_2 max	40 mL/kg	
			>10-15 mL/kg
Exercise testing	DeltaSa O_2	No change	
			2%
	Stair climbing	5 flights	3 flights

Abbreviations: MBC, maximum breathing capacity; FVC, forced vital capacity; FEV_1 , forced expiratory volume in 1 second; FEV_{25-75} , forced expiratory volume between 25 and 75% of FVC; DL
, carbon dioxide diffusing capacity; VO_2 max, maximum C_2 consumption; SaO_2 , arterial O_2 saturation.

Data from refs. [25] [26] [27] [28] [29] [30] [31] [32] [33] [34] [35] [36] [37]

oxygen must be administered during bronchial blockade because the blocked segment would still be perfused, and all this perfusion would be right-to-left shunt flow, which would create a risk of hypoxemia.

This pulmonary function testing cascade is logical because it starts out with simple, relatively inexpensive, noninvasive tests and only increases the degree of difficulty, expense, and invasiveness as indicated.

Although less restrictive pulmonary function test criteria for operability for pulmonary resections less radical than pneumonectomy have been published [25] [26] [27] [28] [29] [30] [31] [32] [33] [34] [35] [36] [37] (see Table 48-3) , there are several reasons why, at least in some patients, it may be prudent to think of a lobectomy (and lesser procedures) as a functional pneumonectomy. [38] First, during the immediate postoperative period, the function of the lung tissue remaining on the operative side may be significantly impaired by atelectasis and perhaps infection; consequently, these patients may experience significant transient postoperative functional impairment. [39] Patients who are most likely to have a stormy postoperative course with minor resections are those who have had intraoperative exposure problems that required severe and prolonged lung manipulation. Intraoperative exposure problems are most likely to occur when the lung being operated on is large and moving (large tidal volume with positive-pressure ventilation). Second, at the time of thoracotomy more accurate staging of the disease is possible, and it may become apparent that it is necessary to perform a pneumonectomy. [15] Third, the function of the lung on the nonoperated side may be impaired preoperatively [39] and may acutely deteriorate intraoperatively as a result of spillage of blood and/or pus from the operated to nonoperated lung or by inability of the nonoperated lung to tolerate a prolonged period of dependency and compression in the lateral decubitus position. Finally, postlobectomy function studies have shown that although the ventilation and perfusion of the lung remaining on the operated side become significantly greater during the long-term interval (3-51 months), the volume of the remaining lung gradually increases and becomes significantly greater than the increase in either ventilation or perfusion to this lung. [40] The compensatory hyperinflation represents dilation of the preexisting respiratory units without disruption or fragmentation of the elastic tissue as seen in pathologic emphysema; however, the pulmonary hyperinflation decreases the compliance and therefore the ventilation per unit volume of the ipsilateral remaining pulmonary tissue. In addition, the hyperinflated lung stretches and thins out the capillaries in the alveolar walls, decreasing the perfusion per unit volume of the ipsilateral remaining pulmonary tissue.

Cardiovascular System

Pulmonary Vascular and Right Ventricular Function Testing

The vast majority of patients with pulmonary tumors have had a long history of smoking; consequently, they have varying degrees of chronic obstructive pulmonary disease (COPD). The cardiovascular response to the pathologic alveolar and airway changes in COPD consists of the development of pulmonary hypertension and increased pulmonary vascular resistance (PVR), followed by right ventricular (RV) hypertrophy and dilation.

Increased PVR has important implications for patients undergoing pulmonary resection. Whereas a normal pulmonary vasculature is distensible and capable of accommodating large increases in pulmonary blood flow (to approximately 2 to 2.5 times normal, as would occur through the remaining lung after a pneumonectomy) with only minor increases in pulmonary artery pressure (Fig. 48-2) (Figure Not Available) , the relatively

Figure 48-2 (Figure Not Available) Mean pulmonary artery pressure (y axis) does not increase until cardiac output (x axis) has been increased 2- to 2.5-fold when the pulmonary vascular bed is normal, whereas mean pulmonary artery pressure increases linearly with increasing cardiac output is increased when the pulmonary vascular bed is restricted. *(From Robin and Gaudio [41])*

rigid and restricted pulmonary vascular bed of chronic lung disease patients cannot accommodate even small increases in pulmonary blood flow without concomitant increases in pulmonary vascular pressure. [41] The inability to tolerate increases in blood flow occurs over the entire range of physiologic cardiac output and may be an important contributing factor to the development of postpneumonectomy pulmonary edema when it occurs. [42]

The preoperative pulmonary function testing cascade as outlined in pulmonary function testing phases 1 and 2 in Table 48-2 (which, in reality, is the extent to which the great majority of patients are studied preoperatively) does not allow diagnosis of increased PVR and RV disease. Increased PVR may be noninvasively suspected preoperatively by the presence of the auscultatory and radiographic signs of pulmonary hypertension and by electrocardiographic (ECG) evidence of right atrial and ventricular hypertrophy (Table 48-4) . The development of a positive hepatojugular reflex, ascites, and peripheral edema indicates the onset of cor pulmonale. In COPD patients without waking hypoxemia, cor pulmonale can be detected twice as sensitively and frequently by echocardiography (definition criteria are pulmonary hypertension and RV enlargement and/or hypertrophy) as by the preceding clinical methods. [43]

Measurements of PVR have been made directly by determining mean pulmonary artery and pulmonary artery wedge pressures at various levels of cardiac output produced by varying treadmill exercises. Thus, using the patient's own cardiac output, pulmonary vascular compliance can be determined. PVR measurements made in this way have been good indicators of risk for pneumonectomy. [44] [45] Operative risk was considered to be increased if PVR was greater than 190 dyne/s/cm. [5] However, if the risk, expense, and time to pass a pulmonary artery catheter have been accepted, it is logical to take one further step and measure pulmonary vascular pressures during temporary unilateral pulmonary artery balloon occlusion in states of rest and exercise (see pulmonary function testing, phase 3). This maneuver specifically tests the compliance of just the pulmonary vascular bed that will remain after pneumonectomy. Performing this procedure during exercise is the most realistic preoperative approximation of pulmonary vascular and right ventricular

TABLE 48-4 -- Noninvasive Diagnosis of Pulmonary Hypertension, Increased Pulmonary Vascular Resistance, Right Atrial and Ventricular Hypertrophy, and Cor Pulmonale

AUSCULTATORY SIGNS OF PAP AND PVR	RADIOGRAPHIC SIGNS OF PAP AND PVR	ELECTROCARDIOGRAPHIC SIGNS OF RA AND RV	ADDITIONAL SIGNS OF CP
		RV	
Pulmonary component of second heart sound	Dilation of main pulmonary artery	Clockwise vector rotation	All those of PAP, PVR, RA, RV
Loss of normally present split in second heart sound	Fullness of apical pulmonary vessels	Right axis deviation	Pulmonary diastolic murmur
Presence of fourth heart sound	Counterclockwise cardiac rotation: globular shape on P-A film (RV comprises left and right heart border, aortic knob)	R and ing S wave V_2 -V_6	Third heart sound
Appearance of high-pitched early systolic ejection click	Lateral film showing encroachment of retrosternal air space (RV dilation)	Inverted T wave V_1 -V_6	Prominent right sternal border pulsation plus retration over left chest rocking motion synchronous with heartbeat
		RA	
		ST segment V_2 -V_6	
		P wave II and III: diphasic P wave V_1	Chronic dependent edema, large tender liver, ascites, distension neck veins (large A waves)

RV, right ventricular hypertrophy; CP, cor pulmonale.

function to be expected in the ambulatory postpneumonectomy patient. [14] [21] [22] [23] [24] Also, echocardiography is increasingly being used to estimate right ventricular alterations and pulmonary hypertension [43] (see earlier).

In addition to the preoperative condition of the pulmonary vasculature, the intraoperative anesthetic and surgical experience can introduce numerous other causes for further acute increases in PVR, including episodes of hypoxia, [46] [47] acidosis, [48] increased airway resistance during spontaneous exhalation [49] (which causes air trapping, increased alveolar pressure, and compression of the small intra-alveolar vessels), positive end-expiratory pressure (PEEP), [50] [51] and sepsis. [52] In addition, resection of a significant amount of the pulmonary vascular bed further increases PVR, especially if the remaining pulmonary vascular bed is diseased to begin with and the cardiac output is increased. [41] [53] [54] Finally, the remaining (nonresected) lung may become further diseased either intraoperatively (surgically traumatized) or postoperatively. [38] [39] Thus, PVR in patients undergoing thoracic surgery may be additively and sequentially increased preoperatively, intraoperatively, and postoperatively.

Left Ventricular Function Testing

The possible independent causes that may contribute to left ventricular (LV) dysfunction in patients with lung disease consist of coronary artery or valvular disease, [55]

[56] systemic hypertension, [55] [56] presence of carboxyhemoglobin, [57] systemic hypoxemia and acidosis, [58] marked alterations in intrathoracic pressure, [59] [60] and RV dysfunction. [55] [61] [62] [63] [64] Considering the usual age, the long and heavy smoking history, and the frequently sedentary life-style of patients undergoing thoracic surgery, it is not surprising that coronary artery disease is by far the most likely independent cause of LV dysfunction. Myocardial ischemia leading to infarction may occur throughout the perioperative period, although peaks of incidence occur during operation and on the third day after operation. The first peak is caused by intraoperative changes in hemodynamics and the second peak is caused by episodes of hypoxia, uneven administration of pain medication, and withdrawal or alteration of drug therapy. [65]

There are only two proven preoperative clinical predictors of perioperative cardiac morbidity (defined as occurrence of myocardial infarction, unstable angina, congestive heart failure, serious dysrhythmia, or cardiac death during the intraoperative or in-hospital postoperative periods); these predictors are recent (<6 months) myocardial infarction and current congestive heart failure. [66] The classic historical intraoperative predictors of morbidity--emergency surgery, prolonged (>3 hours) operations, and thoracic or upper abdominal surgery--also appear to be independent predictors of perioperative morbidity, whereas choice of anesthetic is not. The dynamic intraoperative predictors of perioperative cardiac morbidity are intraoperative hypotension and tachycardia. Hypertension remains a controversial predictor.

If a history of angina or the ECG is suggestive, then further preoperative evaluation of coronary artery function is necessary (suggestive evidence includes Q waves [previous infarction], left bundle branch block, ST segment elevation [transmural ischemia], ST segment depression [subendocardial ischemia], T-wave inversions, and positive U-wave [left main coronary artery disease]). The first step should be noninvasive exercise testing. ECG and thallium scans (in that order) appear to be the best such exercise tests at this time. An exercise study provides information about the functional level of the patient. Unfortunately, the degree of exercise stress may be limited by low ventilatory reserve as well as by low cardiac reserve. If the exercise ECG is normal, surgery should proceed; if the exercise ECG indicates ischemia, a thallium exercise test is indicated. [67] If the thallium exercise test is negative, the planned pulmonary resection should proceed; if the thallium exercise scan is positive for ischemia, coronary angiography should be performed. [68] However, if for any reason there is a strong suspicion that the patient is indeed having significant angina, even though exercise testing is negative or equivocal, coronary angiography is indicated. Consideration should always be given to coronary angiography in the patient with proven previous myocardial infarction, especially if the patient currently has angina. Echocardiography is increasingly being used to estimate LV function.

If significant coronary artery disease is present, the patient needs coronary artery bypass grafting before or at the time of pulmonary resection. For lesser degrees of coronary artery disease, pulmonary resection for carcinoma of the lung should be performed after appropriate medical therapy for coronary insufficiency has been initiated. If the patient needs coronary artery bypass grafting and a limited resection can encompass the cancer, both procedures can be performed under the same anesthetic, but the coronary artery bypass grafting should be done before pulmonary resection. [69] [70] After bypass, if the patient is stable, has good myocardial function, and is not bleeding, a pulmonary wedge resection can be done. For patients who require coronary artery bypass grafting and have pulmonary lesions that require segmentectomy, lobectomy, or pneumonectomy, there is a good possibility that the prolonged nature of the pulmonary procedures will increase the operative mortality (and therefore should not be done), although a small number of successful combined procedures have been reported. [70] [71] In one series of 21 patients, the pulmonary mass was discovered on the preoperative chest x-ray film (for cardiac surgery) and therefore before the occurrence of any symptoms and by definition constituted a fortuitously early diagnosis. Not surprisingly, resection at the time of cardiac surgery (17 wedge resections, 4 lobectomies) resulted in a 95 percent 5-year survival. [72]

In cases that require large resections in compromised patients, coronary artery bypass grafting should be done first, and pulmonary resection should be delayed until the patient has gained weight and muscle mass (usually 4-6 weeks). The risk of general anesthesia for a noncardiac operation in the patient with previous coronary artery bypass grafting is similar to that in patients without proven coronary artery disease. [73] [74] Although it is not possible to estimate the true effects of delay in pulmonary resection in terms of tumor spread in a possibly immunocompromised patient (especially after general anesthesia), [75] it seems reasonable that in the latter group (those requiring bypass grafting and major pulmonary resection), the operative risk of combined procedures probably exceeds the risk of tumor spread.

Figure 48-3 (Figure Not Available) There are preoperative, intraoperative, and postoperative reasons why thoracic surgery impairs postoperative lung function (see text for details). *(From Benumof [604])*

Preoperative Preparation

Thoracic surgical patients are at high risk for the development of postoperative pulmonary complications. In most of the medical literature, "postoperative complications" refers to the development of atelectasis and/or pneumonia. [76] The incidence of pneumonia usually parallels that of atelectasis, and the onset of pneumonia lags behind the onset of atelectasis because atelectasis provides the ventilatory and mucociliary stasis conditions necessary for the development and growth of the organisms that cause pneumonia. [77] [78]

There are three major reasons why thoracic surgery promotes postoperative pulmonary complications; these reasons originate in the preoperative, intraoperative, and postoperative periods (Fig. 48-3) (Figure Not Available) . First, the incidence of postoperative respiratory complications after any surgery is positively correlated with the degree of preoperative respiratory dysfunction, and most thoracic surgical patients come to surgery with some degree of preoperative lung dysfunction. Compared with nonsmokers, smokers have a sixfold increase in the incidence of pulmonary complications after major operative procedures. [79] [80] In patients with chronic lung disease as compared with normal healthy patients, there is a 20-fold increase in the incidence of postoperative pulmonary complications. [81] Preoperative pulmonary function testing will identify the patients at high risk because of poor preoperative lung function. The impact of this first factor (presence of preoperative respiratory dysfunction) can be significantly reduced by preoperative prophylactic respiratory preparation measures (see later). [82] [83] [84] [85] [86]

The second reason thoracic surgery promotes postoperative pulmonary complications is that the performance of surgery can impair lung function in any patient. During actual surgery, nondependent lung function may be impaired by resection of functional lung and/or by trauma to the remaining nondependent lung (due to various nondependent lung manipulations), and dependent lung function may be impaired as a result of the development of atelectasis and edema formation. This second factor can be minimized by appropriate intraoperative management (such as one-lung ventilation, PEEP, or continuous positive airway pressure [CPAP]--see later).

The third cause of increased pulmonary complications in these patients is that thoracotomy and upper abdominal incisions are most painful and cause patients to resist deep breathing and coughing in the postoperative period, leading to retained secretions, atelectasis, and pneumonia. [82] [87] [88] [89] [90] [91] [92] [93] [94] It is painful for these patients to deep breathe and to stretch either the chest or the abdominal wall (i.e., the incision); consequently, they fail to cough (which requires a deep breath), and they retain secretions (promoting the development of atelectasis and infection). The third factor can be minimized by appropriate postoperative pain management (e.g., epidural narcotics) (Ch. 69) .

Preoperative Respiratory Preparation Maneuvers

The preceding data indicate that patients undergoing thoracic surgery are particularly susceptible to postoperative respiratory complications [79] [80] [81] [82] [83] [87] [88] [89] [90] [91] [92] [93] [94] and that prophylactic measures do decrease such complications. [82] [83] [84] [85] [86] [93] [94] Consequently, preoperative evaluation should be followed by preoperative preparation efforts (Ch. 23) directed toward optimally managing any preexisting pulmonary disease. [95] In general, a full preoperative respiratory preparation regimen involves a five-pronged attack on airway disease. The five elements of the preoperative regimen are stopping smoking, dilating airways, loosening and removing secretions, and taking measures to increase motivation and education and to facilitate postoperative care (Table 48-5 and Fig. 48-4) (Figure Not Available) .

TABLE 48-5 -- Preoperative Respiratory Care Regimen

1. Stop smoking
2. Dilate airways

a. beta$_2$ -Agonists

b. Theophylline

c. Steroids

d. Cromolyn sodium

3. Loosen secretions

a. Airway hydration (humidifier/nebulizer)

b. Systemic hydration

c. Mucolytic and expectorant drugs

d. Antibiotics

4. Remove secretions

a. Postural drainage

b. Coughing

c. Chest physiotherapy (percussion and vibration)

5. Increased education, motivation, and facilitation of postoperative care

a. Psychologic preparation

b. Incentive spirometry

c. Exposure to secretion removal maneuvers

d. Exercise

e. Weight loss/gain

f. Stabilize other medical problems

The five treatment modalities are instituted and proceed in parallel fashion. Before discussing each element separately, it is important to point out that the desirable results of these maneuvers should be, for the purpose of understanding their interaction, achieved in a sequential manner (see Fig. 48-4) (Figure Not Available) . The logic behind this concept is as follows. First, stopping smoking eliminates the stimulus for the production of airway secretions and bronchoconstriction. Next, the airways should be dilated to facilitate secretion removal. Similarly, thick, tenacious, and adherent secretions must be loosened in order to be removed. Once the airways are dilated and the secretions loosened, then it makes sense to use physical maneuvers to remove the secretions. Finally, patients should assist, as much as possible, in their preoperative preparation and postoperative respiratory care. The studies cited below indicate that using the maneuvers in this sequence (dilating the airways, loosening the secretions, removing the secretions) allows the maneuvers to complement one another in improving mucociliary transport function. Of course, it is recognized that patients who do not have bronchospasm will not benefit from bronchodilator treatment, and patients who do not have secretions will not benefit from measures to enhance secretion removal. [96]

Discontinuing Smoking

An improvement in mucociliary transport and small airway function and a decrease in airway secretions and reactivity occur over several weeks after cessation of smoking. [97] [98] Consequently, preoperative cessation of smoking for more than 4 to 8 weeks is associated with a decrease in the incidence of postoperative respiratory complications. [97] [98] Although stopping smoking for only 24 hours will do nothing to decrease the amount of secretions (at least 1-2 weeks is required), [96] [99] airway irritability, and incidence of postoperative respiratory complications, a number of important benefits accrue in the first 1 to 2 days of abstinence. [97] [98] [95] Cessation of smoking for as short a time as 12 to 48 hours has been shown to decrease carboxyhemoglobin levels significantly (increasing hemoglobin available for oxygen transport), to shift the oxyhemoglobin dissociation curve to the right (increasing the availability of oxygen to the tissues), [100] and to reduce nicotine-induced tachycardia [98] [99] in addition, cessation of smoking for a few days may greatly improve ciliary beating. [98] [99] All these acute effects may confer a critical benefit to the marginal patient. [84]

For a few select patients, the risks of stopping smoking for 1 or 2 days may outweigh the benefits. These risks include excessive anxiety, [101] causation of a hypersecretory and bronchospastic state, [100] and increased incidence of deep vein thrombosis [98] [99] nevertheless, a good argument can be made that these potential benefits of continuing smoking during the 1 or 2 days before surgery can just as easily be accomplished with anxiolytics, bronchodilators, and anticoagulants.

Dilating the Airways

The next preparatory step should be to dilate the airways (Ch. 14) . beta$_2$ -Sympathomimetic drugs, such as albuterol, terbutaline, and metaproterenol, are administered to patients

Figure 48-4 (Figure Not Available) A full, aggressive, preoperative respiratory preparation regimen consists of a five-pronged attack: *(1)* require the patient to stop smoking, *(2)* dilate the airways, *(3)* loosen secretions, *(4)* remove secretions, and *(5)* increase patient participation. Using these five maneuvers in the numbered sequence allows them to complement one another in improving secretion removal. *(From Benumof [604])*

TABLE 48-6 -- Two Basic Different Approaches to the Use of Bronchodilators in Asthma and COPD

STEP	APPROACH TO BRONCHODILATION IN ASTHMA AND COPD			
	BONE[120]		*LAM AND NEWHOUSE*[121] *AND NEWHOUSE*[122]	
	ASTHMA	*COPD*	*ASTHMA*	*COPD*
1	Inhaled beta$_2$ agonists	Inhaled anticholinergics	Inhaled steroids	Inhaled steroids/? inhaled cromolyn
2	Inhaled anticholinergics	Inhaled beta$_2$ -agonists	Inhaled beta$_2$ agonists	Inhaled beta$_2$ agonists (rarely anticholinergics)
3	Inhaled steroids + cromolyn	Theophylline and steroids	Inhaled anticholinergics	Oral or intravenous steroids and theophylline
4	Theophylline	Theophylline and steroids	Theophylline	Oral or intravenous steroids and theophylline
5	Oral or intravenous steroids	Theophylline and steroids	Oral or intravenous steroids	Oral or intravenous steroids and theophylline

Abbreviation: COPD, chronic obstructive pulmonary disease.

who have a demonstrable reversible bronchospastic airway component to their respiratory disease. Patients who have increased airway responsiveness and therefore are candidates for preoperative bronchodilation are smokers, [102] atopic individuals, [102] patients with airway symptoms of allergies, [102] patients with COPD, [103] [104] [105] [106] [107] [108] and asthmatics. [109] [110] The sympathomimetics (so-called first messengers) are believed to act on their target cells in the lungs by increasing the activity of adenyl cyclase, an enzyme in the cell membrane, which catalyzes the formation of cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP). cAMP functions as a "second messenger" in the cell, where it acts on smooth muscle to decrease tension and motility. In addition, adrenergic compounds (epinephrine, ephedrine, isoproterenol) can also increase ciliary activity; this may help in removing secretions. [111] [112]

cAMP is broken down by a cytoplasmic enzyme, phosphodiesterase, whose activity can be inhibited by methylxanthines such as theophylline and aminophylline.

Thus, the methylxanthines also increase cAMP but by a mechanism different from that of beta$_2$ -adrenergic receptor agonists. Because the methylxanthines and beta$_2$ -agonists act by different mechanisms, theophylline is often given to patients with bronchospasm already receiving beta-adrenergics, and thus they work in synergy to increase intracellular concentrations of cAMP [113] [114] (Table 48-6) . In addition, aminophylline improves the contractility of the diaphragm and renders it less susceptible to fatigue. [115] Recently, however, there has been considerable concern about the short-term toxicity of inhaled beta-adrenergic agents when used in the presence of methylxanthines; specifically, myocardial ischemia might occur as a result of the drugs' combined effect on the heart, with resultant (and possibly fatal) ventricular arrhythmias. [116] [117] Therefore, appropriate caution should be exercised when combining inhaled beta $_2$ -agonists with methylxanthines. [118]
Adrenocorticosteroids may also be given, by either oral, parenteral, or aerosol routes, to the subgroup of patients with COPD who have especially reactive airways. [119] Steroids are not considered to be bronchodilators but probably act by decreasing mucosal edema and preventing the release of bronchoconstricting substances.

At present there are two basic different approaches (plans) to the use of bronchodilators in asthma and COPD patients; the essential difference between the two approaches is whether the inhaled beta$_2$ -agonists and/or anticholinergics are considered the front-line drugs with inhaled steroids considered the second-line drugs or vice versa (i.e., inflammation is considered most important [120] [121] [122]) (see Table 48-6) . Although the patient's subjective feeling of relief is an important end point, the effect of bronchodilator drug treatment should be quantified by pulmonary function tests.

Loosening the Secretions

The next step in preparing patients for thoracic surgery should be to thin and loosen thick adherent secretions. The most important method of thinning and loosening secretions is by hydration. When tracheal mucus transport velocity is quantitatively measured by radioactive tracer methods, it can clearly be shown that dehydration decreases and rehydration increases velocity. [123] The most common method of hydrating secretions is by use of a jet humidifier or ultrasonic nebulizer to produce a heated, sterile water aerosol that is delivered by a close-fitting mask for 20 minutes to a patient breathing spontaneously with large tidal volumes. Concurrently, continuous systemic hydration must be ensured by adequate oral intake or intravenously.

Pulmonary infection, if present, is treated according to the results of culture and sensitivity tests; broad-spectrum antibiotics such as ampicillin or a cephalosporin frequently have the required specificity and potency. If the antibiotic treatment clears the infection to any extent, it may also decrease the tenacity, viscosity, and volume of secretions.

Removing the Secretions

The next preoperative respiratory preparation step is the actual removal of secretions, and this is accomplished by a combination of postural drainage (several different positions may be required), coughing, and chest percussion and vibration (common methods include tapping with cupped hands and use of electric vibrators) for 15 to 20 minutes several times a day. [101] [124] [125]

When removal of tracheobronchial secretions is quantitatively measured with radioactive tracer methods in patients with COPD, chest physiotherapy (chest percussion and vibration along with postural drainage) with cough is effective in increasing both central and peripheral airway clearance and sputum yield, whereas cough alone is effective in increasing

only central airway clearance and sputum yield. [126] Thus, chest physiotherapy moves peripheral bronchial secretions to more central airways for expectoration by coughing. The reason cough alone cannot clear peripheral airways is that an effective cough must attain a high enough airflow rate so as to shear secretions away from the airway wall. In patients with chronic lung disease, flow rates are low (especially peripherally), and the shearing of secretions by cough may well be limited to the trachea and perhaps just the first two airway generations. [127] Obviously, with either chest physiotherapy or cough it will be much easier to expel the secretions if the airways have already been dilated and the secretions loosened.

Chest physical therapy is relatively contraindicated in patients with lung abscesses, metastases to the ribs, a history of significant hemoptysis, and inability to tolerate the postural drainage positions. It is generally agreed that intermittent positive-pressure breathing regimens do not have sufficient efficacy to warrant the excessive cost of routine use. [128] [129] [130] [131]

The forced expiration technique (FET) is increasingly being regarded as more effective in removing secretions than a cough. [132] The FET comprises a forced expiration starting from midlung volume (50% of inspiratory reserve lung volume) to a low lung volume, usually the RV, followed by a period of relaxation and diaphragmatic breathing. This forceful expiration maneuver differs from a cough because it is performed without closure of the glottis and without the accompanying compressive phase that characterizes cough. The transpulmonary pressure is less during the FET than during cough, resulting in less airway compression and permitting improved proximal and distal clearance of bronchial secretions as compared with a conventional cough (documented by radioaerosol techniques). [132] The FET is now being increasingly used as an alternative to cough during chest physiotherapy. [132]

Measures to Increase Motivation and Postoperative Care

The last step of preoperative preparation consists of general measures designed to increase motivation and education and to facilitate postoperative respiratory care. These measures include stabilization of all other medical conditions, psychologic preparation, improvement of nutrition, exercise, weight loss in the obese, use of oxygen (where appropriate), antibiotics, instruction about realistic expectations of postoperative pain, and education in postoperative respiratory care procedures (including incentive spirometry, chest physiotherapy, postural drainage, and ambulation and exercise programs).

Preoperative Use of Digitalis

The preoperative use of digitalis in the thoracic surgical patient deserves special comment. Resection of pulmonary tissue reduces the available pulmonary vascular bed for perfusion and can cause postoperative RV and right atrial enlargement. Thus, it is not surprising that the incidence of postoperative arrhythmias (due to atrial stretching) increases progressively with age and amount of lung resected. In addition, there is a higher incidence of atrial arrhythmias after left than after right pneumonectomy because a greater degree of manipulation of the atrium occurs during the former operation. Although the postoperative incidence of arrhythmias has provided the basis for the prophylactic use of digitalis in thoracic surgical patients without evidence of congestive heart failure, this practice is still controversial. [133] [134] [135] [136] Widely accepted indications for preoperative digitalization in patients without cor pulmonale undergoing thoracic surgery include congestive (left-sided) heart failure and supraventricular arrhythmias with a rapid ventricular response. [137]

The indications for preoperative digitalization are more straightforward in patients with cor pulmonale. However, it is important to note that these patients have a propensity to develop hypoxemia, hypercarbia, and acidosis, and they are therefore at an increased risk of developing digitalis toxicity; thus the drug should be used with caution. [138] [139] If these patients do receive digitalis preoperatively, it is important to normalize the serum potassium in order to decrease the risk of arrhythmias. Digitalis should probably be withheld on the day of surgery to help prevent confusion with digitalis intoxication if arrhythmias occur postoperatively. [140]

THE INTRAOPERATIVE PERIOD

Monitoring Requirements

Monitoring requirements (Chs. 30 - 33) differ among individual patients for two reasons. First, patients undergoing thoracic operations have varying degrees of preexisting cardiorespiratory disease. Second, the very nature of thoracic procedures (e.g., one-lung ventilation) causes further derangements in respiratory and cardiovascular function in the perioperative period. On the basis of these two considerations and their interactions, individual patients can and should be categorized into a progressively sophisticated and complex tier system with regard to what monitoring is necessary to make possible accurate and rapid diagnosis and therapy during anesthesia. It should be apparent from this monitoring approach that an individual with severe pulmonary disease who is to undergo a minor surgical procedure may well require as extensive a monitoring system as a patient with normal lungs who is to have extensive thoracic surgery.

Table 48-7 presents three major categories for patients undergoing thoracic surgery and recommends the monitoring required for each category. The first category (tier I) includes healthy patients without special intraoperative conditions, such as a young patient undergoing pleurodesis. This tier contains the minimal, yet essential, monitoring required for any patient undergoing a thoracic procedure.

Because failure to check equipment properly before the induction of anesthesia is responsible for 22 percent of critical incidents that occur during anesthesia, [141] the function of the anesthesia machine and ventilator must be assessed preoperatively in an orderly and complete fashion. [142] * Failure of the oxygen delivery system to the patient must be signaled

* FDA Checkout Recommendations.

TABLE 48-7 -- Tiered Monitoring System Based on Amount of Pre-existing Lung Disease and Presence of Special Intraoperative Conditions

TIERED MONITORING SYSTEM	REQUIRED MONITORING RELATED TO RESPIRATORY FUNCTION								
	A ANESTHESIA MACHINE	B OXYGEN DELIVERY	C APNEA	D MINUTE VENTILATION	E GAS EXCHANGE	F AIRWAY MECHANICS	G CARDIOVASCULAR FUNCTIONS	H MUSCLE RELAXATION	I TEMP
Tier I [a] Essential (used in all patients)	Complete check plus ventilator	Inspired O_2 monitor; pulse oximetry	Stethoscope, alarm system, observa-tion, $ETCO_2$	Respiratory rate, bag and chest movements; $ETCO_2$	Color of shed blood, cya-nosis, capillary and venous blood gas ten-sions, pulse oximetry, $ETCO_2$	Stethoscope, feel of breathing bag $ETCO_2$, PIP	Heart rate, blood pressure, ECG, $ETCO_2$	Simple motor tests, blockade monitor	Probe
Tier II [b] Special intermittent and/or continuous monitoring	As above	As above	As above plus D, E, G, F	As above plus respirometer, spirometer	As above plus arterial blood gas tensions	Whole-lung and individual compliance, vital capacity, peak inspiratory force (postoperative)	As above plus accurate input vs. output, and frequent automated central venous and arterial pressures	As above	As above
Tier III [c] Advanced monitoring	As above	As above	As above	As above	As above plus Q_S/Q_T, [d] V_D/V_T, [d] Q_T, VO_2 , mass spectrometry	As above plus airway resistance [d]	As above plus pulmonary vascular pressures, mixed venous oxygen saturation, cardiac out-put, lung water measurements [d]	As above	As above

[a] Tier I: Routine healthy patients without special intraoperative conditions.
[b] Tier II: Routine healthy patients with special intraoperative conditions and/or patients with moderate preexisting lung disease without special intraoperative conditions.
[c] Tier III: Patients with severe preexisting respiratory disease with special intraoperative conditions.
[d] Mainly confined to research.

by audiovisual alarms from an inspired oxygen monitor. Pulse oximetry will also serve as a relatively late indicator of inappropriately decreased inspired oxygen fraction (F_{IO_2}) to the patient. Observation of the respiratory rate and movements of the rebreathing bag, ventilator bellows, and chest wall permits rough estimation of minute ventilation and, along with constant use of a stethoscope to hear breath sounds, provides for rapid diagnosis of a breathing circuit disconnect or apnea. However end-tidal carbon dioxide ($E_{T\ CO_2}$) monitoring allows precise breath-by-breath analysis and diagnosis of all of these respiratory functions (apnea, minute ventilation, gas exchange) and is therefore now an essential monitor. In addition, because the slope of the alveolar plateau correlates positively with airway resistance, $E_{T\ CO_2}$ can function as a rough continuous monitor of airway mechanics. The stethoscope is also used to assess airway mechanics (detection of bronchospasm), along with an "educated" hand on the rebreathing bag (manual detection of total lung compliance and resistance). Adequacy of gas exchange is further assessed by observing the color of shed blood, looking for cyanosis (nailbeds, lips, mucous membranes, skin), and listening to the character of the breath sounds. More importantly, pulse oximetry allows precise, on-line, beat-by-beat, continuous monitoring of arterial oxygenation and is therefore now an essential

monitor. Pulse oximetry also indicates desaturation when blood pressure or blood flow is very low and is therefore an on-line monitor of severe changes in cardiovascular function. Because pulse oximetry is a crude monitor in this regard, cardiovascular function must be monitored by frequent use of the blood pressure cuff or, increasingly commonly, an automated oscillometric blood pressure monitor and by continuous ECG. With constant minute ventilation, acute changes in $E_T CO_2$ are proportional to acute changes in cardiac output (i.e., pulmonary blood flow). Muscle relaxation is assessed by simple observation for motor activity and by a peripheral nerve stimulator. Body temperature is continuously measured by a probe. These recommendations for monitoring are routine for anesthesia for nearly all kinds of surgery.

It should be emphasized that if a serious question arises about the adequacy of arterial oxygenation and/or minute ventilation while the pulse oximeter and $E_T CO_2$ monitor, respectively, are being used, arterial blood gases should be drawn (see tier II); thus, pulse oximetry and $E_T CO_2$ monitoring should not be regarded as a total substitute for arterial blood gases. However, venous blood from the back of a warmed hand or large neck vein obtained with no tourniquet or a short-time low-pressure tourniquet has a P_{CO_2} near enough to that of arterial blood (usually 4-8 mm Hg) to be useful for most clinical purposes. [143] [144] In addition, under these sampling conditions a sufficiently high oxygen tension and saturation of venous blood (>40 mm Hg and 75%, respectively) provides a good indication that arterial hypoxemia is most probably absent. As an alternative sampling site, capillary earlobe blood (obtained by needle prick or cut) is usually acceptable for clinical management, because this blood has a Pa_{CO_2} ± 2.0 percent of simultaneous arterial samples. [145]

The second tier in Table 48-7 represents an increase in risk, caused by either special unfavorable intraoperative conditions for relatively healthy patients or significant preexisting cardiopulmonary disease in patients who will not experience special intraoperative conditions. An example of the former circumstance is a patient with mild lung disease having a lobectomy. An example of the latter circumstance is a patient with moderate to severe interstitial lung disease who requires an open lung biopsy. Anyone with some lung disease undergoing one-lung ventilation for a major thoracic procedure must be considered to be in a tier II category. For this second monitoring level, in addition to the preceding essential system (tier I), the following monitoring modalities are required: a respirometer to permit accurate measurement of tidal volume and minute ventilation (the ventilator bellows can be very inaccurate); arterial blood gas analysis to ensure adequate ventilation and oxygenation; an inspiratory pressure gauge to calculate and to follow changes in whole-lung and individual-lung dynamic and static compliance; accurate measurements of intake (intravenous fluids) and output (blood loss, urine output, irrigation fluids, estimation of third space loss); central venous pressure measurement to assess intravascular volume status (depending on expected fluid shifts, condition of the patient's heart); and an automated oscillotonometric blood pressure device or directly transduced arterial pressure for more continuous and accurate systemic blood pressure measurements.

Finally, a third tier of monitoring requirements is constructed for patients with significant preexisting cardiopulmonary disease who will experience further compromising intraoperative conditions. An example of such a patient is one with cor pulmonale undergoing lobectomy or pneumonectomy. For this high-risk group of patients, the anesthesiologist should consider the following additional monitoring: the adequacy of tissue oxygenation continuously assessed by in-line arterial or mixed venous P_{O_2} and P_{CO_2}; measurement of mixed venous oxygen saturation (Sv_{O_2}), which is especially helpful as an index of global well-being in that a major decrease is probably never a good event (Sv_{O_2} is decreased by either a decrease in cardiac output, an increase in oxygen consumption, or a decrease in arterial oxygen content [Ca_{O_2}]); an esophageal ECG obtained by modifying an esophageal stethoscope and used to differentiate atrial arrhythmias [146]; a V_5 ECG lead to detect myocardial ischemia by analysis of the ST segment of the ECG, which is especially important in patients with coronary artery disease; and a pulmonary artery catheter with a thermistor to permit continuous measurement of intravascular filling pressures and rapid determination of cardiac output (and therefore myocardial work indices and assessment of myocardial contractility). Advanced monitoring mainly confined to research at this time includes measurement of right-to-left transpulmonary shunt, ventilation dead space, airway resistance, and aortic pulse pressure contour for beat-to-beat estimation of cardiac output and myocardial contractility.

Two of the preceding monitoring recommendations deserve special discussion and emphasis: arterial cannulation and pulmonary artery catheterization. Direct arterial cannulation (usually of the radial artery) permits frequent arterial blood gas analysis (and perhaps continuous in-line measurement of arterial P_{O_2} and P_{CO_2}); this alone is sufficient justification for arterial line placement for patients with double-lumen endotracheal tubes and/or serious respiratory disease. In addition, an arterial line permits continuous measurement of systemic blood pressure; similarly, this alone is frequently sufficient justification for arterial line

placement in patients with serious cardiovascular compromise. When it is used with a paper readout, the "trend" in arterial pressure is demonstrated. An electrical mean pressure can be calculated, allowing a more precise measurement of perfusion pressure. Finally, an increase in positive-pressure-induced variation in systolic blood pressure may be an early indicator of hypovolemia. [147]

Normally, the central venous pressure is an adequate index of intravascular volume status. With progressive pulmonary disease and/or LV dysfunction, however, the left- and right-sided cardiac circulations must be assessed separately, because the central venous pressure may no longer reflect left-sided filling pressure (pulmonary artery wedge pressure [Ppaw]). In addition, with significant pulmonary disease and/or tachycardia, the pulmonary artery diastolic pressure will be elevated above the pulmonary artery wedge pressure, and a significant pulmonary artery diastolic-to-wedge pressure gradient will be present. In this situation only the wedge pressure can be used to reflect left-sided cardiac volume/ compliance status. Finally, cardiac output is easily determined by using pulmonary artery catheter thermodilution techniques. For these reasons, the use of a pulmonary artery rather than a central venous catheter should be considered if pulmonary hypertension and/or cor pulmonale and coronary artery disease are present, especially if extensive perioperative fluid shifts or blood loss is anticipated.

Special Pulmonary Vascular Monitoring Considerations Related to Thoracotomy in the Lateral Decubitus Position

Pulmonary artery catheters usually (in >90% of cases) float to and locate in the right lung. [148] Consequently, during a right thoracotomy (left lateral decubitus position), the pulmonary artery catheter will be in the nondependent lung and therefore either in a collapsed lung if one-lung ventilation is used or possibly in a zone 1 or 2 region of the lung if large tidal volume two-lung ventilation is used. Conversely, when a left thoracotomy is performed (patient in the right lateral decubitus position), the pulmonary artery catheter will be in the dependent lung and will probably be in a zone 3 region. Thus, it is theoretically possible that the pulmonary artery catheter might function differently or yield different pulmonary vascular pressure and cardiac output data during right versus left thoracotomies and during two-lung versus one-lung ventilation.

Indeed, with the pulmonary artery catheter tip located in the right lung, the cardiac output is lower during right thoracotomy with one-lung ventilation (right lung collapsed) than during left thoracotomy with one-lung ventilation (left lung collapsed) in patients who were otherwise similar [149] (Fig. 48-5 (Figure Not Available) A). Consequently, it is possible that when the pulmonary artery catheter is located in the collapsed lung, where blood flow patterns may be distorted or the function of the thermistor interfered with (so that it is not free in the lumen of the vessel), the measured output is indeed lower. This hypothesis is supported by the concurrent finding that continuously measured Sv_{O_2} is also decreased during right thoracotomies as compared with left thoracotomies when the pulmonary artery catheter is located in the collapsed nondependent lung. The decrease in Sv_{O_2} may have been caused by stagnant blood flow and therefore not truly representative of whole-patient Sv_{O_2}. [149] When the nondependent lung is ventilated with varying levels of PEEP (in contrast to nondependent lung collapse), there is no difference in the cardiac output measured simultaneously from thermistors located in the nondependent and dependent lungs. [150] This finding implies that when the pulmonary artery catheter tip is in the nondependent lung and the nondependent lung is ventilated, blood flow to the nondependent lung is undistorted and/or there is no interference with the function of the thermistor.

When the pulmonary artery catheter is in the nondependent lung and the nondependent lung is ventilated with large tidal volume, PEEP, or CPAP, the wedge pressure may not reflect left atrial pressure (Pla) [151] (Fig. 48-5 (Figure Not Available) B). When the pulmonary artery catheter is in the dependent lung and presumably in the zone 3 region, wedge pressure should accurately reflect Pla, even when PEEP is applied to the dependent lung. [151]

In summary, the lateral decubitus position is important with regard to pulmonary artery catheter monitoring in three situations. First, when the nondependent lung is collapsed and the catheter is in the nondependent lung, the measured cardiac output and mixed venous blood P_{O_2} (Pv_{O_2}) may be decreased compared with more normal conditions or the "real" value. Second, when the nondependent lung is ventilated with PEEP and the catheter is in the nondependent lung, Ppaw may not equal Pla. Third, when the catheter is in the dependent lung, Ppaw will be a faithful index of Pla, even if PEEP is used.

Finally, after pneumonectomy, inflation of the balloon of the pulmonary artery catheter to obtain Ppaw can result in considerable occlusion of the remaining cross-sectional area of the pulmonary circulation. This occlusion acutely decreases the preload on the left ventricle and increases the right ventricular afterload, resulting in reduced cardiac output and reduced Pla. Although the Ppaw under these circumstances still accurately reflects the Pla, both these values have been

artificially lowered by the blocked pulmonary circulation; hence, they result in a falsely low Ppaw reading. [152] This falsely low value for the left ventricular filling pressure is misleading and may result in fluid management that contributes to the development of pulmonary edema and to the excessively high mortality reported in postpneumonectomy patients. Advancing the catheter carefully without inflating the balloon and wedging it into a smaller peripheral vessel can minimize the reduction in the cross-sectional area of the pulmonary vasculature. Thus, a more accurate value for Ppaw, reflecting the true Pla, can be obtained.

Choice of Anesthesia and Arterial Oxygenation During One-Lung Ventilation

Effect of Anesthetics on Hypoxic Pulmonary Vasoconstriction

Thoracic surgery may be greatly facilitated by causing selective atelectasis of the lung being operated on (one-lung

Figure 48-5 (Figure Not Available) Conditions during thoracotomy in the lateral decubitus position when pulmonary artery catheter data may be inaccurate. (A) During right thoracotomy with a pulmonary artery (PA) catheter located in the collapsed right lung (one-lung ventilation [1 LV]), the cardiac output (CO) may be lower than when the right lung is ventilated. The thermistor in the collapsed lung may be exposed to abnormal flow patterns or vascular wall interference. (B) When the PA catheter is in the nondependent lung and the nondependent lung is exposed to CPAP or PEEP, the pulmonary artery wedge pressure (P_{paw}) may be inaccurate. Nondependent lung CPAP or PEEP may cause zone 1 conditions in the nondependent lung. The P_{paw} is probably always reasonably accurate when the PA catheter is in the dependent lung, even if the dependent lung is exposed to PEEP. *(From Benumof [604])*

ventilation/anesthesia conditions). The normal response of the pulmonary vasculature to atelectasis is an increase in PVR (in just the atelectatic lung). The mechanism of the increase in PVR is thought to be due almost entirely to hypoxic pulmonary vasoconstriction (HPV). [153] [154] [155] The selective increase in atelectatic lung PVR diverts blood flow from the atelectatic lung toward the remaining normoxic or hyperoxic ventilated lung. Figure 48-6 shows the theoretically expected effect of HPV on Pa_{O_2} as the amount of lung that is made hypoxic increases. When the percentage of lung that is hypoxic is between 30 and 70 percent, which encompasses the one-lung ventilation/anesthesia condition, there is a large difference between the Pa_{O_2} expected with a normal amount of HPV and that when there is no HPV. In fact, in this range of hypoxic lung, HPV increases the Pa_{O_2} from levels that might cause arrhythmias to much higher and safer values. Thus, HPV is an autoregulatory mechanism that protects the Pa_{O_2} by decreasing the amount of shunt flow that can occur through hypoxic lung.

General anesthesia with controlled ventilation is the safest method of anesthetizing patients for the vast majority of elective thoracic procedures. Inhibition of HPV in the

Figure 48-6 Effect of hypoxic pulmonary vesoconstriction (HPV) on PaO_2. As the amount of lung that is made hypoxic is increased (x axis), the arterial oxygen tension (Pa_{O_2}) decreases (y axis). In the range of 30 to 70 percent of hypoxic lung, the normal expected amount of HPV increases Pa_{O_2} from arrhythmogenic levels to much higher and safer levels. Normal cardiac output, hemoglobin concentration, and mixed venous oxygen tension (PvO_2) are assumed. *(Data from Marshall and Marshall [205])*

nonventilated nondependent lung by the anesthetic should be prevented. All the inhaled and many of the injectable anesthetics have been studied with regard to their effect on HPV; halothane has been studied most extensively (Table 48-8) . [156] [157] [158] [159] [160] [161] [162] [163] [164] [165] [166] [167] [168] [169] [170] [171] [172] [173] [174] [175] [176] [177] The experimental preparations may be divided into four basic categories: (1) *in vitro;* (2) *in vivo*-not intact (pumped perfused lungs, no systemic circulation or neural function); (3) *in vivo*-intact (normally perfused lungs, normal systemic circulation); and (4) humans (volunteers or patients). It appears from this breakdown of experimental preparations that inhibition of HPV by halothane is a universal finding in the *in vitro* and *in vivo*-not intact preparations. However, in the more normal or physiologic *in vivo*-intact and human studies, halothane has caused no or only a very slight decrease in HPV response. Thus, it appears that a fundamental property of halothane is its inhibition of HPV in experimental preparations that can be controlled for other physiologic influences (e.g., pulmonary vascular pressure, cardiac output, mixed venous oxygen tension, carbon dioxide level, temperature) that can have an effect on the HPV response. In the more biologically complex *in vivo*-intact models, other factors that greatly diminish the inhibitory effect of halothane on HPV seem to be involved. Important methodologic differences between the *in vitro* and *in vivo*-not intact preparations and the *in vivo*-intact and human models that could account for the observed differences in halothane effect on HPV are the presence (or absence) of perfusion pulsations; perfusion fluid composition; size of perfusion circuit [171] ; baroreceptor influences, absence of bronchial blood flow (which abolishes all central and autonomic nervous activity in the lung) [178] ; chemical influences (e.g., pH, P_{O_2}); humoral influences (e.g., histamine and prostaglandin release from body tissues); lymph flow influences; and, very importantly, unaccounted for or uncontrolled changes in physiologic variables (e.g., cardiac output, Pv_{O_2} , and pulmonary vascular pressures) that might have directionally opposite effects on HPV, and use of different species. [179] [180] [181]

Ether has been the next most studied drug, and it appears that the quantitative effect of ether on HPV is also dependent on the type of experimental preparation used. Thus, the *in vitro* and *in vivc*-not intact models show much more inhibition of HPV by ether than the *in vivo*-intact and human models [155] [157] [158] [161] [164] [182] [183] (Table 48-9) . Although the number of studies involving halogenated drugs other than halothane, namely isoflurane, [160] [172] [173] [177] [184] [185] [186] [187] [188] [189] [190] [191] enflurane, [155] [160] [192] [193] [194] methoxyflurane, [156] [157] [158] [195] [196] fluroxene, [172] [173] and trichloroethylene [161] has been too small to permit recognition of an experimental preparation result pattern, most of these anesthetics have demonstrated inhibition of HPV (at least in the *in vitro* models) (see Table 48-9) . Nitrous oxide seems to cause a small, somewhat consistent inhibition of HPV [158] [168] [172] [173] [197] [198] [199] (see Table 48-9) . None of the injectable anesthetics studied to date have an effect on HPV [157] [158] [169] [172] [194] [200] [201] [202] [203] [204] [205] (see Table 48-9) .

To summarize previous animal studies, it appears that a fundamental property of inhaled anesthetics is to decrease HPV. However, in intact animal preparations some biologic or physiologic property seems to remove or greatly lessen the inhibitory effect of anesthetic drugs on HPV. It may be

that the cause(s) of the difference in effect of anesthetic drugs on regional HPV from preparation to preparation, anesthetic to anesthetic, and species to species (see later) are closely related to the fundamental mechanism of HPV, which is still unknown.

Effect of Anesthetics on Arterial Oxygenation During One-Lung Ventilation

An often-made extrapolation of the much more numerous *in vitro* and *in vivo*-not intact HPV studies is that anesthetic drugs might impair arterial oxygenation during one-lung anesthesia by inhibiting HPV in the nonventilated lung. One of the previously cited studies on the effect of isoflurane on regional canine HPV was especially well controlled and showed that when all nonanesthetic drug variables that might change regional HPV are kept constant, isoflurane inhibits single-lung HPV in a dose-dependent manner. [186] Additionally, the study is valuable because the authors offer the reader an easily comprehensible quantitative summary of the relationship between dose of isoflurane administered and degree of inhibition of the single-lung canine HPV response. If the summary can be extrapolated or applied to the clinical one-lung ventilation situation (at least as an approximation), insights can be gained into what might be expected with regard to arterial oxygenation when such patients are anesthetized with isoflurane. To put this insight into clinical focus, it is necessary first to understand what should happen to blood flow, shunt flow, and arterial oxygenation as a function of a normal amount of HPV when two-lung ventilation is changed to one-lung ventilation in the lateral decubitus position (LDP). Once the stable one-lung ventilation condition has been described, it is possible, by using the data from the previously mentioned study, to see how isoflurane administration would affect the one-lung ventilation blood flow distribution, shunt flow, and arterial oxygen tension (Pa_{O_2}).

Two-Lung Ventilation: Blood Flow Distribution

Gravity causes a vertical gradient in the distribution of pulmonary blood flow in the LDP for the same reason that it does in the upright position. Consequently, blood flow to the dependent lung is significantly greater than blood flow tothe nondependent lung. When the right lung is nondependent, it should receive approximately 45 percent of total blood flow as opposed to the 55 percent that it received in the upright and supine positions. When the left lung is nondependent, it should receive approximately 35 percent of total blood flow as opposed to the 45 percent that it receivedin the upright and supine positions (closed-chest data with normal pulmonary

artery pressure). [206] [207] [208] If these blood flow distributions are combined (both the right and left lungs being nondependent an equal number of times), average two-lung ventilation blood flow distribution in the lateral decubitus position would consist of 40 percent of total blood flow perfusing the nondependent lung and 60 percent of total blood flow perfusing the dependent lung (Fig. 48-7 (Figure Not Available) , left-hand panel).

One-Lung Ventilation: Blood Flow Distribution, Shunt Flow, and Arterial Oxygen Tension

When the nondependent lung is nonventilated (made at-electatic), HPV in this lung will increase its PVR and de-crease its blood flow. In the absence of any confounding or inhibiting factors to the HPV response, a single-lung HPV response should decrease the blood flow to that lung by 50 percent. [209] Consequently, the nondependent lung should be able to reduce its blood flow from 40 to 20 percent of total blood flow, and the nondependent/dependent lung blood flow ratio during one-lung ventilation should be 20:80 (see Fig. 48-7 (Figure Not Available) , middle panel).

Figure 48-7 (Figure Not Available) Effect of 1 MAC isoflurane anesthesia on shunt during one-lung ventilation (1LV) of normal lungs. This diagram shows that for two-lung ventilation the ratio of the percentages of blood flow to the nondependent and dependent lungs is 40:60 (left-hand side). When two-lung ventilation is converted to one-lung ventilation (as indicated by atelectasis of the nondependent lung), the HPV response decreases the blood flow to the nondependent lung by 50 percent, so that the nondependent/dependent lung blood flow ratio is now 20:80 (middle). According to the data of Domino et al [186] administration of 1 MAC isoflurane anesthesia should cause a 21 percent decrease in the HPV response, which would decrease the blood flow reduction from 50 to 40 percent. Consequently, the nondependent/dependent lung blood flow ratio would now become 24:76, representing a 4 percent increase in the total shunt across the lungs (right-hand side). *(From Benumof [603])*

All the blood flow to the nonventilated nondependent lung is shunt flow, and therefore one-lung ventilation creates an obligatory right-to-left transpulmonary shunt flow that was not present during two-lung ventilation. If no shunt existed during two-lung ventilation (ignoring the normal 1-3% shunt flow due to the bronchial, pleural, and thebesian circulations), we would expect the ideal total shunt flow during one-lung ventilation (i.e., with intact HPV) to be 20 percent of total blood flow. With a normal hemodynamic and metabolic state, the Pa O_2 should be approximately 280 mm Hg. [210] Other much more complicated models have been constructed to describe what to expect in terms of shunt during one-lung ventilation when varying degrees of shunt exist during two-lung ventilation. [211]

Effect of Isoflurane on One-Lung Ventilation Blood Flow Distribution, Shunt Flow, and Arterial Oxygen Tension

Domino et al [186] found the percentage inhibition of regional HPV response to equal 22.8 (percentage alveolar isoflurane) minus 5.3 (see Fig. 48-7 (Figure Not Available) , top equation). [186] The top equation and right-hand panel of Fig. 52-7 (Figure Not Available) show that isoflurane anesthesia at one minimum alveolar concentration unit (1 MAC) would inhibit the nondependent lung HPV response by approximately 21 percent, which would decrease this response from a 50 to 40 percent blood flow reduction in this lung; this in turn would increase nondependent lung blood flow from 20 to 24 percent of total blood flow, causing shunt to increase by 4 percent of the cardiac output and Pa O_2 to decrease a moderate amount to 205 mm Hg (F_{IO_2} = 1.0). A decrease in Pa O_2 and an increase in shunt of this magnitude are small and may not be detectable given the usual accuracy of clinical methodology. In fact, in clinical one-lung ventilation studies involving intravenously anesthetized patients with this level of shunting, administration of 1 MAC isoflurane (and halothane) anesthesia during stable one-lung ventilation conditions causes no detectable decrease in Pa O_2 . [177] [212] In one of these clinical studies, [212] stable one-lung ventilation conditions in the lateral decubitus position were established in patients who were anesthetized with only intravenous drugs. While stable one-lung ventilation was maintained, inhaled anesthetics were administered (halothane and isoflurane end-tidal concentrations were greater than 1 MAC for at least 15 minutes) and then discontinued (halothane and isoflurane end-tidal concentrations decreased to near zero). In the other study, [177] steady-state one-lung ventilation conditions in the LDP were established in patients who were anesthetized with only inhaled drugs (halothane and isoflurane end-tidal concentrations were greater than 1 MAC for more than 40 minutes). While one-lung ventilation was continued, inhaled anesthesia was then discontinued and intravenous anesthesia administered (halothane and isoflurane end-tidal concentrations decreased to near 0). There was no significant difference in Pa O_2 during inhaled anesthesia with either halothane or isoflurane as compared with intravenous anesthesia during one-lung ventilation in either of the two experimental sequences. In addition, there were no significant changes in physiologic variables, such as cardiac output, PVR, and Pv O_2 , that might secondarily alter nondependent lung HPV. Thus, irrespective of whether inhaled anesthesia is administered before or after intravenous anesthesia during one-lung ventilation, inhaled anesthesia does not further impair arterial oxygenation. These findings are consistent with the interpretation that 1 MAC halothane or isoflurane in patients with a moderate level of shunting does not inhibit HPV enough to cause a significant decrease in Pa O_2 during one-lung ventilation in the LDP. Almost identical results have been obtained during one-lung ventilation with nitrogen (while the other lung was ventilated with 100 percent oxygen) of volunteers who were alternately anesthetized with isoflurane and intravenous drugs [191] and enflurane and intravenous drugs. [193]

Recommended Anesthesia Induction and Maintenance Drugs and Techniques

Summary of Advantages of Anesthetic Drugs

Inhaled Anesthetics.

General anesthesia with controlled ventilation (Chs. 3 - 7) is the safest method of anesthetizing patients for the vast majority of elective thoracic procedures. Although a variety of general anesthesia techniques can be used, the volatile halogenated anesthetic drugs are good choices for several reasons. First, the halogenated drugs have a salutary effect on airway irritability. The mechanism of this action is controversial, but as previously discussed, there is evidence that these drugs can block specific forms of bronchoconstriction, [213] [214] as well as having a nonspecific bronchodilating effect related to the depth of anesthesia. [215] Obtundation of airway reflexes in patients who have reactive airways (i.e., smokers) and who may have their airways directly manipulated by the surgeon is a highly desirable property of the general anesthesia produced by these drugs. Second, the use of volatile halogenated drugs allows delivery of a high inspired oxygen concentration without loss of anesthesia. Although a nitrous oxide-oxygen-narcotic-relaxant anesthesia technique can be used, nitrous oxide necessitates a significant decrease in F_{IO_2} and increases the chance of developing hypoxemia (especially if one-lung ventilation is used). [216] Unless very high doses of narcotics are used, airway reflexes and reactivity may remain at a high level. Third, because the volatile halogenated drugs can be rapidly eliminated, concern about postoperative hypoventilation in extubated patients may be diminished. Relatively high doses of intravenous anesthetics, such as narcotics, ketamine, and barbiturates, may cause the patient to require a period of postoperative ventilation. Fourth, in the usual clinical doses (near 1 MAC), the halogenated anesthetic drugs provide a reasonable degree of cardiovascular stability. This may be of particular importance in patients who have a history of smoking and therefore a high incidence of coronary artery disease and systemic hypertension. [217] [218] Fifth, the halogenated drugs do not appear to decrease Pa O_2 any more than intravenous anesthetics during one-lung ventilation (see the following section). [177] [212]

Intravenous Anesthetics.

The narcotics, especially fentanyl, have a number of desirable properties (Chs. 8 - 11) that could be used to advantage for patients undergoing thoracic surgery. First, fentanyl has no significant adverse hemodynamic

effects and therefore is a useful drug in patients who have coronary artery disease. Second, if significant blood levels exist at the end of surgery, the narcotics can allow an intubated patient to have a smooth transition from surgery into the postoperative period. Third, the narcotics, if used in moderate dosage, diminish the amount of volatile halogenated drug anesthesia required to achieve surgical levels of anesthesia. Fourth, high doses of narcotics or moderate doses in conjunction with halogenated drugs allow the use of a high F_{IO_2} without loss of anesthesia. Fifth, the narcotics are thought not to diminish regional HPV and, therefore, should permit optimal oxygenation during one-lung ventilation.

Ketamine, in combination with nitrous oxide and a muscle relaxant, has also been used for anesthesia for thoracic surgery. [219] Although we do not ordinarily use ketamine for elective thoracic procedures, the drug is useful for induction of general anesthesia in critically ill patients undergoing emergency thoracic surgery for several reasons. First, ketamine has sympathomimetic properties [220] that are highly desirable because many emergency thoracic procedures are associated with hypovolemia (gunshot and stab wounds of the chest, blunt trauma, and massive hemoptysis). However, it should be remembered that ketamine depresses cardiovascular function (systemic blood pressure, cardiac contractility) if the degree of hypovolemia is severe and the patient is sympathetically exhausted. Second, ketamine has a rapid onset of action and can be used safely, along with cricoid pressure, to induce anesthesia in patients with full stomachs. Third, ketamine may

reduce bronchospasm in asthmatic patients [221] ; the clinical extrapolation of this effect to thoracic surgical patients is uncertain but seemingly reasonable at this time. Fourth, ketamine does not impair arterial oxygenation during one-lung ventilation (perhaps because of its lack of effect on HPV). [204]

Recommended Anesthetic Drugs and Techniques

It should be obvious from the foregoing discussions that there are advantages and disadvantages to both inhaled and intravenous anesthetic drugs. One recent study made this point very well by examining the respiratory and cardiac differences between various anesthetic regimens (intravenous-based, inhalation-based, epidural-based) before and during one-lung ventilation. [222] The 36 patients were randomly allocated to one of the following groups: A--propofol 10 mg/kg/h, fentanyl; B--1 MAC enflurane, fentanyl; C--thoracic epidural anesthesia, 0.4 percent enflurane. Before induction of anesthesia significant differences were not found. During two-lung ventilation cardiac index was significantly decreased in the B in comparison with the C group (*P*
.01). During one-lung ventilation significant differences were not found except for an increased shunt fraction (Q_S/Q_T) in group B (A versus B, *P*
.05; B versus C, *P*
.05; A versus C, not significant). Since Q_S/Q_T was significantly increased and hypoxemia occurred with regimen B, regimen A or C might be preferred in patients at high risk for hypoxia or in situations where the application of CPAP to the nondependent lung is not possible. Cardiac index was best maintained in group C. Regimen C might be of value in patients at high risk for poor perfusion, taking into account both the possible complications of the epidural block and the reduced need for postoperative analgesic agents.

The following recommended anesthetic technique takes advantage of the desirable properties and minimizes the undesirable properties of these drugs. Thus, the halogenated drugs are used for their effect on bronchomotor tone, to allow administration of 100 percent oxygen, and to allow early extubation without decreasing hemodynamic function and arterial oxygenation; fentanyl is used to ensure hemodynamic stability without jeopardizing early extubation if desired. If it is thought that the patient will not be extubated early or if greater hemodynamic stability is desired, anesthesia consisting of more fentanyl and less halogenated drug can be used.

Induction of Anesthesia.

The patient is preoxygenated by spontaneously breathing 100 percent oxygen through an anesthesia mask that is connected to an anesthesia circle system. Fentanyl is administered intravenously until the respiratory rate is approximately 8 to 10 breaths/min. This usually corresponds to a dose of 3 to 6 mug/kg and is generally administered over several minutes. When the respiratory rate is relatively slow and deep and response to commands is becoming sluggish, a small dose of sodium thiopental (2-3 mg/kg) or ketamine (1.0-2.0 mg/kg) (if the patient is thought to have an especially reactive airway or to be minimally to moderately hypovolemic) is administered to render the patient unconscious and usually apneic. Control of the airway is then established and ventilation is begun with intermittent positive-pressure oxygen via the mask. While the patient is being ventilated with positive pressure, a concentration of 0.5 to 2.5 percent isoflurane is administered. The higher isoflurane concentration is used initially for a short period of time (overpressure, 1-2 minutes); as the patient demonstrates signs of deepening anesthesia, the inspired isoflurane concentration is decreased. In view of the fact that general anesthetics significantly decrease the ventilatory response to carbon dioxide (to a much greater degree in patients with mechanical ventilatory impairment than in normal patients), patients are not allowed to breathe spontaneously until the end of the procedure; alarming degrees of hypercapnia have been observed in similar circumstances when spontaneous ventilation was allowed. [223]

Early during the period of positive-pressure ventilation with isoflurane, paralysis is induced with a nondepolarizing muscle relaxant. The development of full paralysis is noted with a neuromuscular blockade monitor. During the period of deepening isoflurane anesthesia and paralysis, blood pressure is supported with an infusion of approximately 10 mL/kg crystalloid followed by small doses of vasopressors if needed. When the patient has been judged to have been adequately (surgical stage) anesthetized (as ascertained by changes in blood pressure, heart rate, and eye signs [the eyes should be central, conjugate, fixed, staring, without tears, and with nondilated pupils]) and paralyzed in this manner, 1 mg/kg lidocaine is administered intravenously, laryngoscopy is performed, the tracheobronchial tree is sprayed with a laryngotracheobronchial topical anesthesia spray system, and the trachea is intubated with a doublelumen

tube. The intravenous and intratracheal lidocaine should diminish both airway and cardiovascular response to endotracheal intubation. [224] The patient is then ventilated with maintenance doses of isoflurane and given maintenance doses of narcotics and relaxants. Use of maintenance paralysis decreases isoflurane requirements, possibly allowing for a more rapid emergence from anesthesia.

Maintenance of Anesthesia.

Anesthesia is maintained with both isoflurane (concentration approximately 0.5-1.0 MAC) and narcotics. Isoflurane is used primarily if the patient is thought to have a reasonable chance of being extubated within the first couple of hours postoperatively. Narcotics (fentanyl) are primarily used if the patient is thought not to have a reasonable chance of being extubated in the immediate postoperative period and to require a significant period of postoperative ventilation. Relaxants are administered in small doses to keep the level of neuromuscular blockade, as judged by a neuromuscular blockade monitor, near the 90 percent paralysis level. If there is a reasonable chance of extubating the trachea in the first postoperative hour, the patient is turned supine, the double-lumen tube changed to a single-lumen tube, paralysis reversed, and spontaneous ventilation allowed to recur. Fentanyl is administered in extremely small increments (0.3 mug/kg) while the patient is breathing spontaneously. The goal of the fentanyl administration is to have the patient breathing relatively slowly (approximately 10 to 12 breaths/min) and deeply when surgery is completed. The presence of a moderate narcotic base allows the patient to be returned to the recovery room for a short period of mechanical ventilatory support (if needed) and weaned and extubated in a relatively smooth manner.

THE INTRAOPERATIVE PERIOD - continued

Physiology of Spontaneous Ventilation with an Open Chest

Mediastinal Shift

An examination of the physiology of the open chest during spontaneous ventilation reveals why controlled positive-pressure ventilation is the only practical way to provide adequate gas exchange during thoracotomy. In the spontaneously breathing closed-chest patient in the LDP, gravity causes the pleural pressure in the dependent hemithorax to be less negative than in the nondependent hemithorax, but there is still negative pressure in each hemithorax on each side of the mediastinum. In addition, the weight of the mediastinum causes some compression of the lower lung, contributing to the pleural pressure gradient. With the nondependent hemithorax open, atmospheric pressure in that cavity exceeds the negative pleural pressure in the dependent hemithorax; this imbalance of pressure on the two sides of the mediastinum causes a further downward displacement of the mediastinum into the dependent thorax. During inspiration the caudad movement of the dependent-lung diaphragm increases the negative pressure in the dependent lung and causes a still further displacement of the mediastinum into the dependent hemithorax. During expiration, as the dependent-lung diaphragm moves cephalad, the pressure in the dependent hemithorax becomes relatively positive, and the mediastinum is pushed upward out of the dependent hemithorax (Fig. 48-8) (Figure Not Available) . Thus, the tidal volume in the dependent lung is decreased by an amount equal to the inspiratory displacement caused by mediastinal movement. This phenomenon is called *mediastinal shift* and is one mechanism that results in impaired ventilation in the open-chested,

Figure 48-8 (Figure Not Available) Schematic representation of mediastinal shift and paradoxical respiration in the spontaneously ventilating patient with an open chest who is placed in the lateral decubitus position. The open chest is always exposed to atmospheric pressure (+). During inspiration, negative pressure (-) in the intact hemithorax causes the mediastinum to move downward (mediastinal shift). In addition, during inspiration, movement of gas from the nondependent lung in the open hemithorax into the dependent lung in the closed hemithorax and movement of air from the environment into the open hemithorax causes the lung in the open hemithorax to collapse (paradoxic respiration). During expiration, relative positive (+) in the closed hemithorax causes the mediastinum to move upward (mediastinal shift). In addition, during expiration, the gas moves from the dependent lung to the nondependent lung and from the open hemithorax to the environment; consequently, the nondependent lung expands during expiration (paradoxic respiration). *(From Benumof [604])*

spontaneously breathing patient in the LDP. The mediastinal shift can also cause circulatory changes (decreased venous return) and reflexes (sympathetic activation) that result in a clinical picture similar to shock: the patient is hypotensive, pale, and cold, with dilated pupils. Local anesthetic infiltration of the pulmonary plexus at the hilum and the vagus nerve can diminish these reflexes. More practically, controlled positive-pressure ventilation abolishes these ventilatory and circulatory changes associated with mediastinal shift.

Paradoxic Respiration

When a pleural cavity is exposed to atmospheric pressure, the lung is no longer held open by negative intrapleural pressure, and it tends to collapse because of unopposed elastic recoil. [225] Thus, the lung in an open chest is at least partially collapsed. It has long been observed during spontaneous ventilation with an open hemithorax that lung collapse is accentuated during inspiration, and, conversely, the lung expands during expiration. This reversal of lung movement during respiration with an open chest has been termed *paradoxic respiration.* The mechanism of paradoxic respiration is similar to that of mediastinal shift. During inspiration, the descent of the diaphragm on the side of the open hemithorax causes air from the environment to enter the pleural cavity on that side through the thoracotomy opening and to fill the space around the exposed lung. The descent of the hemidiaphragm on the closed-chest side causes gas to enter the closed-chest lung in the normal manner. However, gas also enters the closed-chest lung (which has a relatively negative pressure) from the open-chest lung (which remains at atmospheric pressure); this results in further reduction in the size of the open-chest lung during inspiration. During expiration the reverse occurs, with the collapsed, open-chest lung filling from the intact lung and air moving back out of the exposed hemithorax through the thoracotomy incision. The phenomenon of paradoxic respiration is illustrated in Figure 48-8 (Figure Not Available) . Paradoxic breathing is increased by a large thoracotomy and by increased airway resistance in the intact lung. Paradoxic respiration may be prevented either by manual collapse of the open-chest lung or, more commonly, by controlled positive-pressure ventilation.

Physiology of the Lateral Decubitus Position and the Open Chest During Controlled Two-Lung Ventilation: Distribution of Perfusion and Ventilation

Awake, Closed-Chest, Lateral Decubitus Position

Gravity causes a vertical gradient in the distribution of pulmonary blood flow in the LDP for the same reason that it does in the upright position (Ch. 15) . Because the vertical hydrostatic gradient is less in the LDP than in the upright position, there is ordinarily less zone 1 blood flow (in the nondependent lung) in the former than in the latter position. Nevertheless, blood flow to the dependent lung is still significantly greater than that to the nondependent lung (Fig. 48-9) (Figure Not Available) . Thus, when the right lung is nondependent, it should receive approximately 45 percent of total blood flow as opposed to the 55 percent that it receives in the upright and supine positions. When the left lung is nondependent, it should receive approximately 35 percent of total blood flow, as opposed to the 45 percent that it receives in the upright and supine positions. [206] [207]

Because gravity also causes a vertical gradient in pleural pressure (Ppl) in the LDP, ventilation is relatively increased in the dependent as compared with the nondependent lung (Fig. 48-10) (Figure Not Available) . In addition, in the LDP the dome of the lower diaphragm is pushed higher into the chest than the dome of the upper diaphragm; therefore, the lower diaphragm is more sharply curved than the upper diaphragm. As a result, the lower diaphragm is able to contract more efficiently during spontaneous respiration. Thus, in the awake patient in

Figure 48-9 (Figure Not Available) Schematic representation of the effects of gravity on the distribution of pulmonary blood flow in the lateral decubitus position. The vertical gradient in the lateral decubitus position is less than in the upright position. Consequently, there is less zone 1 and more zone 2 and 3 blood flow in the lateral decubitus position than in the upright position. Nevertheless, pulmonary blood flow increases with lung dependency and is greater in the dependent lung than in the nondependent lung. $P_{A,}$ alveolar pressure; P_{pa} , pulmonary artery pressure; P_{pv} , pulmonary venous pressure. *(From Benumof [604])*

Figure 48-10 (Figure Not Available) Awake, closed chest distribution of ventilation. (A) Pleural pressure (Ppl) in the awake upright patient is most positive in the dependent portion of the lung, and alveoli in this region are therefore most compressed and have the least volume. Pleural pressure is least positive (most negative) at the apex of the lung, and alveoli in this region are therefore least compressed and have the largest volume. When these regional differences in alveolar volume are translated over to a regional transpulmonary pressure-alveolar volume curve, the small dependent alveoli are on a steep (large-slope) portion of the curve, and the large nondependent alveoli are on a flat (small-slope) portion of the curve. In this diagram regional slope equals regional compliance. Thus, for a given and equal change in transpulmonary pressure, the dependent part of the lung receives a much larger share of the tidal volume than the nondependent part of the lung. (B) In the

lateral decubitus position gravity also causes pleural pressure gradients and therefore similarly affects the distribution of ventilation. The dependent lung lies on a relatively steep portion and the nondependent lung lies on a relatively flat portion of the pressure-volume curve. Thus, in the lateral decubitus position the dependent lung receives the majority of the tidal ventilation. V, alveolar volume; P, transpulmonary pressure. *(From Benumof [604])*

the LDP, the lower lung is normally better ventilated than the upper lung, regardless of the side on which the patient is lying, although there remains a tendency toward greater ventilation of the larger right lung. [226] Because there is greater perfusion to the lower lung, the preferential ventilation to the lower lung is matched by its increased perfusion, so that the distribution of the V/Q ratios of the two lungs is not greatly altered when the awake subject assumes the LDP. Because perfusion increases to a greater extent than ventilation with lung dependency, the V/Q ratio decreases from the nondependent to the dependent lung (just as it does in upright and supine lungs).

Anesthetized, Closed-Chest, Lateral Decubitus Position

Comparison of the awake with the anesthetized patient in the LDP (Ch. 26) reveals no difference in the distribution of pulmonary blood flow between the dependent and nondependent lungs. Thus, in the anesthetized patient, the dependent lung continues to receive relatively more perfusion than the nondependent lung. The induction of general anesthesia, however, does cause significant changes in the distribution of ventilation between the two lungs.

In the LDP, more ventilation is switched from the dependent lung in the awake subject to the nondependent lung in the anesthetized patient [227] [228] (Fig. 48-11) (Figure Not Available) . There are several interrelated reasons for this change in the relative distribution of ventilation between the nondependent and dependent lungs. First, the induction of general anesthesia usually causes a decrease in FRC, and both lungs share in the loss of lung volume. Because each lung occupies a different initial position on the pulmonary pressure-volume curve while the subject is awake, a general anesthesia-induced reduction in the FRC of each lung causes each lung to move to a lower, but still different, portion of the pressure-volume curve (see Fig. 48-11) (Figure Not Available) . The dependent lung moves from an initially steep part of the curve (with the subject awake) to a lower and flatter part of the curve (after anesthesia is induced), while the nondependent lung moves from an initially flat portion of the pressure-volume curve

Figure 48-11 (Figure Not Available) The distribution of ventilation in the patient in the lateral decubitus position when awake (A) and when anesthetized (B). The induction of anesthesia has caused a loss of lung volume in both lungs, with the nondependent lung moving from a flat, noncompliant portion to a steep, compliant portion of the pressure-volume curve and the dependent lung moving from a steep, compliant part to a flat, noncompliant part of the pressure-volume curve. Thus, the anesthetized patient in a lateral decubitus position has more of the tidal ventilation in the nondependent lung (where there is the least perfusion) and less of the tidal ventilation in the dependent lung (where there is the most perfusion). V, alveolar volume; P, transpulmonary pressure. *(From Benumof [604])*

Figure 48-12 (Figure Not Available) Schematic depiction of a patient in the lateral decubitus position, comparing the closed-chested anesthetized condition with the open-chested anesthetized and paralyzed condition. Opening the chest increases nondependent lung compliance and reinforces or maintains the larger part of the tidal ventilation going to the nondependent lung. Paralysis also reinforces or maintains the larger part of tidal ventilation going to the nondependent lung because the pressure of the abdominal contents (P_{AB}) pressing against the upper diaphragm is minimal (smaller arrow), and it is therefore easier for positive-pressure ventilation to displace this lesser resisting dome of the diaphragm. V, alveolar volume; P, transpulmonary pressure. *(From Benumof [604])*

(with the subject awake) to a lower and steeper part of the curve (after anesthesia is induced). In fact, in the LDP the ratio of nondependent to dependent lung FRC is approximately 1.5 (average values are 1,400 and 900 mL, respectively) in the adult patient. [229] [230] [231] [232] Similar findings may be expected in children. [230] Furthermore, in the LDP the compliances of the nondependent and dependent lung are 30 and 23 cm H_2O, respectively. [229] Thus, with the induction of general anesthesia, the lower lung moves to a less favorable (flat, noncompliant) portion and the upper lung to a more favorable (steep, compliant) portion of the pressure-volume curve. Second, if the anesthetized patient in the LDP is also paralyzed and mechanically ventilated, the high, curved diaphragm of the lower lung no longer confers any advantage in ventilation (as it does in the awake state), as it is no longer actively contracting. [231] [232] Third, the mediastinum rests on the lower lung and physically impedes lower lung expansion, as well as selectively decreasing lower lung FRC. Fourth, the weight of the abdominal contents pushing cephalad against the diaphragm is greatest in the dependent lung, which physically impedes lower lung expansion the most and disproportionately decreases lower lung FRC. Finally, suboptimal positioning, which fails to provide room for lower lung expansion, may considerably compress the dependent lung. Opening the nondependent hemithorax further disproportionately increases ventilation to the nondependent lung (see below).

In summary, the anesthetized patient, with or without paralysis, in the LDP and with a closed chest has a nondependent lung that is well ventilated but poorly perfused and a dependent lung that is well perfused but poorly ventilated, which results in an increased degree of V/Q mismatching. The application of PEEP to both lungs restores more of the ventilation to the lower lung. [207] Presumably, the lower lung returns to a steeper, more favorable part of the pressure-volume curve, and the upper lung resumes its original position on a flat, unfavorable portion of the curve.

Anesthetized, Open-Chest, Lateral Decubitus Position

As compared with the condition of the anesthetized, closed-chested patient in the LDP, opening the chest wall and pleural space alone does not ordinarily cause any significant alteration in the partitioning of pulmonary blood flow between the dependent and nondependent lungs; thus, the dependent lung continues to receive relatively more perfusion than the nondependent lung. Opening the chest wall and pleural space, however, does have a significant impact on the distribution of ventilation (which must now be delivered by positive pressure). The change in the distribution of ventilation may result in further V/Q mismatching [233] (Fig. 48-12) (Figure Not Available) .

If the upper lung is no longer restricted by a chest wall and the total effective compliance of that lung is equal to that of the lung parenchyma alone, it will be relatively free to expand and will consequently be overventilated (and remain underperfused). Conversely, the dependent lung may continue to be relatively noncompliant and poorly ventilated and overperfused. [206] Surgical retraction and compression of the exposed upper lung can provide a partial, although nonphysiologic, solution to this problem in that if expansion of the exposed lung is mechanically or externally restricted ventilation will be diverted to the dependent, better-perfused lung. [208]

Anesthetized, Open-Chest, Paralyzed Lateral Decubitus Position

In the open-chested anesthetized patient in the LDP, induction of paralysis alone does not cause any significant alteration in the partitioning of pulmonary blood flow between the dependent and nondependent lungs. Thus, the dependent lung continues to receive relatively more perfusion than the nondependent lung. There are, however, strong theoretical and experimental considerations indicating that paralysis might cause significant changes in the distribution of ventilation between the two lungs under these conditions.

In the supine position and the LDP, the weight of the abdominal contents pressing against the diaphragm is greatest on the dependent part of the diaphragm (posterior lung and lower lung, respectively) and least on the nondependent part of the diaphragm (anterior lung and upper lung, respectively) (see Fig. 48-12) (Figure Not Available) . In the awake, spontaneously

breathing patient, the normally present active tension in the diaphragm overcomes the weight of the abdominal contents, and the diaphragm moves the most (largest excursion) in the dependent portion and least in the nondependent portion. This is a healthy circumstance because this is another factor that maintains the greatest amount of ventilation where there is the most perfusion (dependent lung) and the least amount of ventilation where there is the least perfusion (nondependent lung). During paralysis and positive-pressure breathing, the passive and flaccid diaphragm is displaced preferentially in the nondependent area, where the resistance to passive diaphragmatic movement by the abdominal contents is least; conversely, the diaphragm is displaced minimally in the dependent portion where the resistance to passive diaphragmatic movement by the abdominal contents is greatest. [234] This is an unhealthy circumstance because the greatest amount of ventilation may occur where there is the least perfusion (nondependent lung), and the least amount of ventilation may occur where there is the most perfusion (dependent lung). [234]

Summary of Physiology of the Lateral Decubitus Position and the Open Chest

In summary (Fig. 48-13) (Figure Not Available) , the preceding section has developed the concept that the anesthetized, paralyzed patient in the LDP with an open chest may have a considerable V/Q mismatch, consisting of greater ventilation but less perfusion to the nondependent lung and less ventilation but more perfusion to the dependent lung. The blood flow distribution is mainly and simply determined by gravitational effects. The relatively good ventilation of the upper lung is caused in part by the open-chest and paralyzed conditions. The relatively poor ventilation of the dependent lung is caused in part by the loss of dependent lung volume with general anesthesia and by compression of the dependent lung by the mediastinum, abdominal contents, and suboptimal positioning effects. In addition, poor mucociliary clearance and absorption atelectasis with an increased F_{IO_2} may cause further dependent-lung volume loss. Indeed, on rare occasion the dependent lung may be massively atelectatic and edematous. [235] Consequently, two-lung ventilation under these circumstances may result in an increased alveolar-arterial oxygen tension difference [$P(A\text{-}a)_{O_2}$] and less than optimal oxygenation.

A physiologic solution to the adverse effects of anesthesia and surgery in the LDP on the distribution of ventilation and perfusion during two-lung ventilation would be selective application of PEEP to the dependent lung (via a double-lumen endotracheal tube). [236] Selective PEEP to the lower lung should increase the ventilation to this lung by moving it up to a steeper, more favorable portion of the lung pressure-volume curve. Indeed, this has been done with reasonably good success. [236] [237] A series of 22 mechanically ventilated patients (both lungs) undergoing thoracotomy in the LDP was divided into two groups. [237] Group I patients had 10 cm H_2O of PEEP applied to the dependent

Figure 48-13 (Figure Not Available) Schematic summary of ventilation-perfusion relationships in the anesthetized patient in the lateral decubitus position who has an open chest and is paralyzed and suboptimally positioned. The nondependent lung is well ventilated (as indicated by the large dashed lines) but poorly perfused (small perfusion vessel); the dependent lung is poorly ventilated (small dashed lines) but well perfused (large perfusion vessel). In addition, the dependent lung may also develop an atelectatic shunt compartment (indicated on the left side of the lower lung) because of the circumferential compression of this lung. (See text for detailed explanation.) P_{AB} , pressure of the abdominal contents. *(Modified from Benumof [604])*

lung while zero end-expiratory pressure (ZEEP) was applied to the nondependent lung. Group II (control) patients were intubated with a standard endotracheal tube, and both lungs were ventilated with ZEEP. Selective PEEP to the dependent lung in group I patients resulted in an adequate Pa_{O_2} with a lower F_{IO_2} during surgery and a smaller $P(A\text{-}a)_{O_2}$ at the end of surgery than when both lungs were ventilated with ZEEP. Thus, even if the selec-tive PEEP to the dependent lung increased dependent lung PVR and diverted some blood flow to the nondependent lung, the diverted blood flow could still participate in gas exchange with the ZEEP-ventilated nondependent lung. [238] However, it should be noted that this technique requires that the nondependent (and operative) lung be ventilated, and this may impede the performance of surgery. The physiology of one-lung ventilation and distribution of perfusion is discussed in the chapter on respiratory physiology.

One-Lung Anesthesia/Ventilation

Indications for Separation of the Two Lungs

There are several absolute and relative indications for separation of the two lungs during thoracic operations or procedures (Table 48-10) .

TABLE 48-10 -- Indications for Separation of the Two Lungs (Double-Lumen Tube Intubation) and/or One-Lung Ventilation

ABSOLUTE

1. Isolation of one lung from the other to avoid spillage or contamination
   - A. Infection
   - B. Massive hemorrhage
2. Control of the distribution of ventilation
   - A. Bronchopleural fistula
   - B. Bronchopleural cutaneous fistula
   - C. Surgical opening of a major conducting airway
   - D. Giant unilateral lung cyst or bulla
   - E. Tracheobronchial tree disruption
   - F. Life-threatening hypoxemia due to unilateral lung disease

4. Severe hypoxemia due to unilateral lung disease

Absolute Indications

Separation of the two lungs for any of the absolute indications discussed here should be considered a lifesaving maneuver because failure to separate the lungs under any of these conditions could result in a life-threatening complication or situation. There are three general absolute indications for separating the lungs (see Table 48-10) . First, separation of one lung from the other is absolutely necessary to prevent spillage of pus or blood from an infected (abscessed) lung or bleeding lung, respectively, to a noninvolved lung. Acute contamination of a lung with either blood or pus from the other lung usually results in severe massive (bilateral) atelectasis, pneumonia, and sepsis. Second, there are a number of unilateral lung problems that can prevent adequate ventilation of the noninvolved side. A large bronchopleural or bronchopleural-cutaneous fistula or a surgically opened conducting airway has such a low resistance to gas flow that a tidal inspiration delivered by positive pressure will exit via the low-resistance pathway, and it may become impossible to ventilate the other, more normal, lung adequately. A giant unilateral bulla or cyst may rupture if exposed to positive-pressure ventilation and result in a tension pneumothorax or pneumomediastinum. Very severe or life-threatening hypoxemia due to unilateral lung disease may require differential lung ventilation and PEEP. [239] Finally, positive-pressure ventilation of a lung with a tracheobronchial tree disruption can result in dissection of gas into the pulmonary interstitial space or mediastinum, causing a tension pneumomediastinum. Third, separation of the

lungs is absolutely necessary to perform unilateral bronchopulmonary lavage in patients with pulmonary alveolar proteinosis (and rarely, asthma or cystic fibrosis).

Relative Indications

There are a large number of relative indications for separation of the lungs, and they are all for the purpose of facilitating surgical exposure by collapsing the lung in the operative hemithorax. These relative indications can be divided into high-priority and low-priority categories (see Table 48-10) . Of the relative indications, repair of a thoracic aortic aneurysm usually has the highest priority because it may require exposure of the thoracic aorta as it runs the entire length of the left hemithorax. A pneumonectomy, especially if performed through a median sternotomy, [240] is greatly aided by the wide exposure of the lung hilum that is afforded by collapse of the operative lung. Similarly, an upper lobectomy, which is technically the most difficult lobectomy, and many mediastinal exposures may be made much easier by eliminating ventilation to the lung on the side of the procedure. Examination of the pleural space (thoracoscopy) and pulmonary resections through a thoracoscope are considerably aided by collapse of the ipsilateral lung. The surgical items in the medium-priority category do not routinely require collapse of the lung on the operative side but still significantly aid surgical exposure and eliminate the need for the surgeon to handle (retract, compress, pack away) the operative lung. Severe intraoperative retraction of the lung on the operated side can traumatize the operative lung and impair gas exchange both intraoperatively [241] [242] and postoperatively. [243] [244] The lower-priority items consist of middle and lower lobectomies, less extensive pulmonary resections, thoracic spinal procedures that are approached anteriorly through the chest, and esophageal surgery. However, even relatively small operations such as wedge and segmental resections benefit by double-lumen tube insertion because of the ability to alternate easily and quickly between lung collapse and inflation, which is sometimes required to better visualize lung morphology and facilitate identification and separation of planes and fissures. Additionally, the separation of the lungs after removal of totally occluding and predominantly unilateral chronic pulmonary emboli (postcardiopulmonary bypass) can be very helpful because of the possibility of massive transudation of hemorrhagic fluid across the alveolar capillary membrane in the region of the lung supplied by the previously occluded vessel (reperfusion of a previously and chronically nonperfused vascular bed). Should significant and predominantly unilateral pulmonary edema occur following thromboembolectomy with cardiopulmonary bypass, the patient should be returned to cardiopulmonary bypass and a double-lumen endotracheal tube should be inserted so that differential lung ventilation may be used. Finally, significant hypoxemia due to unilateral lung disease may be more easily treated by differential lung ventilation and PEEP. [239]

Techniques of Lung Separation

In general, three types of devices are available for providing one-lung ventilation during anesthesia: double-lumen

endotracheal tubes (DLT), bronchial blockers, and endobronchial tubes. DLTs have come to be considered the lung separation technique of choice for the majority of thoracic surgery cases and are discussed later in detail. Bronchial blockade with the Univent tube and with independently passed bronchial blockers (Fogarty embolectomy catheter) in adults is greatly increasing in use and is also described at length below. Endobronchial tubes are not often used today and are only briefly described at the end of the chapter. The primary reason that DLTs are favored over bronchial blockers or endobronchial tubes for lung separation is that they are more versatile than the other two devices. The most important DLT function not available with a bronchial blocker is independent bilateral suctioning. In addition, it is easier to apply CPAP to the nonventilated operative lung with a DLT than with a bronchial blocker, and it is also easier to rapidly convert from two-lung to one-lung ventilation and vice versa with a DLT than with a bronchial blocker. Endobronchial tubes are very limited in function and only allow one-lung ventilation.

There are two firm disadvantages (contraindications) to the use of a DLT as compared with a bronchial blocker. First, very distorted tracheobronchial tree anatomy, including exophytic and stenotic lesions, as well as tortuosity, may preclude successful correct placement or positioning of a DLT. Second, changing from a DLT to a single-lumen tube during or at the end of an operation can be expected to be a difficult and/or risky procedure on occasion. Such a situation might occur in a patient with a relatively difficult airway before operation who undergoes a long operation requiring considerable intravenous fluids; one would expect the airway to be edematous and thus a postoperative tube change more hazardous in that setting.

There are two relatively minor disadvantages to DLTs, both related to the fact that the lumina of a DLT may be narrow. First, suctioning may be more difficult down a narrow lumen, but this is usually not a problem with the new disposable Robertshaw type of DLTs which have nonadhering suction catheters that slide easily down the lumina. Second, although airway resistance may be increased with a narrow lumen, the increased resistance can be easily overcome by positive-pressure ventilation. [245]

Double-Lumen Endotracheal Tubes

Commonly Used Double-Lumen Endotracheal Tubes

A DLT is essentially two catheters bonded together side by side, with each lumen intended to ventilate one of the two lungs. DLTs are made as left- and right-sided tubes. With a left-sided tube, the left lung catheter is placed into the left mainstem bronchus, whereas the right lung catheter ends in the trachea; therefore, for a left-sided tube, the left lung catheter is longer than the right lung catheter (Fig. 48-14) (Figure Not Available) . With a right-sided tube the right lung catheter is placed into the right mainstem bronchus, whereas the left lung catheter ends in the trachea; therefore, for a right-sided tube, the right lung catheter is longer than the left lung catheter (see Fig. 48-14) (Figure Not Available) . All DLTs have a proximal cuff for the trachea and a distal cuff for a mainstem bronchus; the endobronchial cuff causes separation and sealing off of the lungs from each other, and the tracheal cuff causes separation and sealing off of the lungs from the environment. The part of the right lung catheter of the right-sided DLT that is in the right mainstem bronchus must be slotted to allow ventilation of the right upper lobe (see Fig. 48-14) (Figure Not Available) because the right mainstem bronchus is too short to accommodate both the right lumen tip and the right endobronchial cuff. All double-lumen endotracheal tubes have two curves that lie in planes approximately 90 degrees apart from one another. The distal curve is designed to facilitate placement of the distal catheter tip into the appropriate mainstem bronchus, and the proximal curve is designed to approximate the oropharyngolaryngeal curve.

The DLTs that are now used for lung separation and one-lung ventilation are the Carlens and the Robertshaw. The Robertshaw type of tube is by far the more commonly used, and the disposable polyvinylchloride (PVC) Robertshaw tube has significantly replaced the red rubber Robertshaw tube (the former is easier to pass, is positioned more quickly, and causes less mucosal damage). [246] Consequently, the modern PVC tube will be described in great detail.

The left-sided Carlens tube (Fig. 48-15) (Figure Not Available) was the first DLT used for one-lung ventilation. [247] The tube has a carinal

Note that the left endobronchial lumen and carinal hook straddle the carina. *(From Benumof [604])*

hook to aid in its proper placement and minimize tube movement after placement. Potential problems with carinal hooks include increased difficulty (more rotations) and laryngeal trauma during intubation, amputation of the hook during or after passage, malpositioning of the tube caused by the hook, and physical interference during pneumonectomy. [248] Therefore, some anesthesiologists prefer to use the tube with the hook removed. The tube is available in four sizes: 41, 39, 37, and 35 French (which correspond to an internal diameter of each lumen of approximately 6.5, 6.0, 5.5, and 5.0 mm, respectively). The cross-sectional shape of each lumen is oval, and this accounts for the occasional difficulty in passing a suction catheter down the lumen.

The original Robertshaw DLT, introduced in 1962, was made as a reusable red rubber tube (Fig. 48-16) (Figure Not Available) . [249] This tube was designed to provide the largest possible lumen to decrease airway resistance and facilitate removal of secretions. The lumina are D-shaped and lie side by side, like those of the Carlens tube, but are larger in size. As with the other DLTs, it has two curves (in planes approximately 90 degrees apart), which facilitate intubation and proper endobronchial placement. Both a right- and a left-sided tube are available, and the absence of a carinal hook allows for easier tracheal intubation and perhaps correct positioning. The right-sided tube has a slotted endobronchial cuff to effect ventilation of the right upper lobe. The right upper lobe ventilation slot is relatively long, which facilitates ventilation of this lobe. However, the endobronchial cuff has an additional area of inflation on the nonslotted side above the slot to effect a more reliable seal (see Fig.

48-16 (Figure Not Available) A). On the slotted side, inflation of the endobronchial cuff is restricted. However, the right endobronchial cuff design forces the right upper lobe slot to lie flat against the right upper lobe orifice, and if this slot is not perfectly aligned with the right upper lobe orifice, the ventilation slot will be blocked (obstructed) by the right mainstem bronchial wall (and vice versa). Nevertheless, because of its many good features, the original Robertshaw DLT rapidly gained wide popularity. [250]

The Robertshaw type of tube is now made of a clear nontoxic tissue-implantable plastic (denoted by the marking Z-79) and is disposable (see Fig. 48-14) (Figure Not Available) . The tubes are made in sizes 41, 39, 37, 35, 28, and 26 French (internal diameter

Figure 48-17 (Figure Not Available) Use of left-sided and right-sided double-lumen endotracheal tubes for left and right lung surgery (as indicated by the clamp). (A) When surgery is performed on the right lung, a left-sided double-lumen endotracheal tube should be used. (B) When surgery is performed on the left lung, a right-sided double-lumen endotracheal tube can be used. However, because of uncertainty about the alignment of the right upper lobe ventilation slot with the right upper lobe orifice, a left-sided double-lumen endotracheal tube can also be used for left lung surgery. (C) If the left lung surgery requires a clamp to be placed high on the left main stem bronchus, the left endobronchial cuff should be deflated, the left-sided double-lumen endotracheal tube pulled back into the trachea, and the right lung ventilated through both the lumina (use the double-lumen endotracheal tube as a singlelumen tube). *(From Benumof [604])*

of each lumen is approximately 6.5, 6.0, 5.5, 5.0, 4.5, or 4.0 mm, respectively). The 26 and 28 French tubes are available only as left-sided models. These tubes are relatively easy to insert and have appropriate end-of-lumen and cuff arrangements that minimize lobar obstruction. The endobronchial cuff is colored brilliant blue, which is an important recognition feature when using a fiberoptic bronchoscope. The ends of both lumina have a black radiopaque line, which is an essential recognition marker when viewing a chest radiograph. The tubes have high-volume, low-pressure tracheal and endobronchial cuffs. The slanted doughnut-shaped endobronchial cuff on the Bronchocath model right-sided DLT allows the right upper lobe ventilation slot to ride off (away from) the right upper lobe orifice, which minimizes the chance of right upper lobe obstruction by the tube. The clear tubing is helpful because it permits continuous observation of the tidal movement of respiratory moisture as well as observation of secretions from each lung. The tubes are packaged with malleable stylets and are relatively easy to insert and position. These tubes have large internal to external diameter ratios and therefore are relatively easy to suction through, and they are packaged with their own nonadhering suction catheters. The large internal to external diameter ratio also provides a relatively low resistance to ventilation. For all these reasons, these disposable tubes are now considered the DLTs of choice by most anesthesiologists. Several companies are currently manufacturing them. Reviews of other DLTs are available. [251]

A left-sided DLT should be used for right thoracotomies requiring collapse of the right lung and ventilation of the left lung (Fig. 48-17) (Figure Not Available) . A left- or right-sided tube may be used for left thoracotomies requiring collapse of the left lung and ventilation of the right lung (see Fig. 48-17) (Figure Not Available) . However, because the right upper lobe ventilation slot of a right-sided tube has to be closely apposed to the right upper lobe orifice to allow unobstructed right upper lobe ventilation and since there is considerable anatomic variation in the exact position of the right upper lobe orifice and therefore in the length of the right mainstem bronchus (in fact, it is well known that an anomalous right upper lobe can take off from the trachea), use of a right-sided tube for left lung collapse introduces the risk of inadequate right upper lobe ventilation. For this reason, a left-sided tube is preferable for most cases requiring one-lung ventilation. If clamping of the left mainstem bronchus is necessary, the tube can be withdrawn at that time into the trachea and then used in the same manner as a single-lumen endotracheal tube (ventilation of the right lung with both lumina) (see Fig. 48-17) (Figure Not Available) . Contraindications to use of a left-sided DLT are carinal and proximal left mainstem bronchial lesions that could be traumatized by the passage of a left-sided tube. These lesions include strictures, endoluminal tumors, tracheobronchial disruptions, compression of the airway by an external mass, and tenting of the left mainstem bronchus so that the angle of the take-off from the trachea is approximately 90 degrees. The largest size of tube that can comfortably pass the glottis should be used, as a relatively small DLT may require excessive cuff volume for endobronchial cuff seal and may cause difficulty with suctioning secretions or ventilating the patient. In general, as height and weight increase, the appropriate DLT size (as defined above) increases, although height is much more important than weight. [252]

In summary, the plastic disposable Robertshaw-type tubes are by far the most commonly used DLTs. Because a right-sided tube incurs the risk of inadequate right upper lobe ventilation, left-sided tubes are used far more often. Consequently, the rest of this chapter emphasizes the insertion and precise positioning of the left-sided Robertshaw-type DLT.

Conventional Double-Lumen Tube Intubation Procedure

Before intubation with a double-lumen endotracheal tube, both cuffs and the lumen connections are checked. A 3-mL syringe with stopcock should be placed on the end of the bronchial cuff pilot tube, because proper bronchial cuff inflation rarely requires more than 1 to 2 mL of air; a 5- or 10-mL syringe with stopcock should also be placed on the

Figure 48-18 (Figure Not Available) Schematic diagram depicting the passage of the left-sided double-lumen endotracheal tube in a supine patient. (A) The tube is held with the distal curvature concave anteriorly and the proximal curve concave to the right and in a plane parallel to the floor. The tube is then inserted through the vocal cords until the bronchial cuff passes the vocal cords. The stylet is then removed. (B) The tube is rotated 90 degrees counterclockwise so that the distal curvature is concave anteriorly and the proximal curvature is concave to the left and in a plane parallel to the floor. (C) The tube is inserted until either a mild resistance to further passage is encountered or the end of the common molding of the two lumina is at the teeth. Both cuffs are then inflated, and both lungs are ventilated. Finally, one side is clamped while the other side is ventilated and vice versa. (See text for further explanation.) *(From Benumof [604])*

tracheal cuff pilot tube. Because the high-volume, low-pressure cuffs can be easily torn by teeth, the distal tube is coated with a lubricating ointment (preferably containing a local anesthetic) to minimize this possibility. If a less than optimal view of the larynx is anticipated, the stylet that is packaged with the tube is lubricated, inserted into the left lumen, and appropriately curved. The patient is then anesthetized and paralyzed as described previously. A curved open-phalanged blade (MacIntosh) is usually preferred for laryngoscopy, because it approximates the curvature of the tube and therefore provides the largest possible area through which to pass the tube. However, a straight (Miller) blade may be a better choice in patients with overriding upper teeth or an excessively anterior larynx.

Double-lumen endotracheal tubes with carinal hooks are first inserted through the vocal cords with the hook facing posteriorly. When the tip of the tube has passed the vocal cords, the tube is rotated 180 degrees so that the hook passes anteriorly through the glottis. If this maneuver is not done, then one can damage the vocal apparatus by dislocating an arytenoid cartilage should the hook snare or hang up on the arytenoid cartilage. After the tube tip and hook pass the larynx, the tube is rotated 90 degrees so that the tube tip enters the appropriate bronchus.

The Robertshaw-type DLT is passed with the distal curvature initially concave anteriorly (Fig. 48-18 (Figure Not Available) A). After the tube tip passes the larynx and while anterior force on the laryngoscope is continued, the stylet (if used) is removed, and the tube is carefully rotated 90 degrees (so that the distal curve is now concave toward the appropriate side and the proximal curve is concave anteriorly) to allow endobronchial intubation on the appropriate side (Fig. 48-18 (Figure Not Available) B). Continued anterior force by the laryngoscope during tube rotation prevents hypopharyngeal structures from falling in around the tube and interfering with a free 90-degree distal tube tip rotation. Failure to obtain a near 90-degree rotation of the distal tube tip while the proximal end rotates 90 degrees will cause either a kink or a twist in the shaft of the tube and/or prevent the distal end of the lumen from lying free in the mainstem bronchus (i.e., not up against the bronchial wall). After rotation, the tube is advanced until most of it is inserted [252] (Fig. 48-18 (Figure Not Available) C). When the proper depth of insertion has been achieved (defined as when the cephalad surface of the bronchial cuff is immediately below the carinal bifurcation), the average depth of insertion for both male and female patients 170 cm tall is 29 cm, and for each 10-cm increase or decrease in height, average placement depth is increased or decreased by 1 cm. [252] The correlation between depth of insertion and height is highly significant ($P < .0001$) for both male and female patients. Nevertheless, it should be understood that the depth of DLT insertion at any given height is still normally distributed, and correct DLT position should always be confirmed fiberoptically after initial placement. DLTs may also be passed successfully via tracheostomy, although it should be remembered that the tracheal cuff may be at the tracheal stoma or lie partly outside

the trachea in this situation. [253] [254] Because of this, one may prefer to use a specially manufactured (i.e., short) nondisposable double-lumen endotracheal tube for these particular patients. [255]

Once the tube tip is thought to be in an endobronchial position, the following checklist is used to ensure proper functioning of the tube. Inflate the tracheal and endobronchial cuffs until moderate tension is palpated in the external pilot balloons (the endobronchial cuff should not require more than 1-2 mL of air); deliver several positive-pressure ventilations, auscultate, and observe the chest bilaterally to determine that the trachea rather than the esophagus has been intubated and that both lungs are being ventilated (see Fig. 48-18 (Figure Not Available) C). In addition to seeing the tube go through the vocal cords, check correct intubation position by feeling and observing the anesthesia reservoir bag to make sure it has the appropriate compliance and movement while maintaining normal pulse oximetry and E_T CO_2 values, and perhaps palpating the tracheal cuff in the neck. If only unilateral breath sounds or chest movement is present, it is likely that both lumina of the tube have entered a mainstem bronchus (if both lumina enter the left main stem bronchus, the findings may mimic an esophageal intubation, and vice versa). In this situation, quickly deflate the cuffs, withdraw the tube 1 to 2 cm at a time, inflate the cuffs, and reassess ventilation until bilateral breath sounds are heard. If bilateral breath sounds are not heard and the tube has been withdrawn a significant amount, the entire procedure must be repeated, beginning with establishing the airway and oxygen ventilation via mask, laryngoscopy, and reinsertion of the DLT through the vocal cords. If bilateral breath sounds are present, then one side is clamped and breath sounds and chest movement should disappear on the ipsilateral side and remain on the contralateral side. Breath sounds should be at least as audible anteriorly, at the apex of the lung, as they are along the lateral chest. If they are not heard clearly at the lung apex, it is likely that the tube has been advanced too far distally and that the upper lobe on that side is not being ventilated adequately. In that case the tube must be pulled back 1 cm at a time until apical breath sounds are clearly heard. In addition, when the lumen cap is opened proximal to the clamp, there should be no leakage of air out of that lumen, indicating that the bronchial cuff has effected a proper seal. Next, the clamped side should be unclamped and the lumen cap replaced, and the breath sounds and chest movement should reappear on that side. During unilateral clamping, the breath sounds on the ventilated side should be compared with and calibrated against unilateral chest wall movements and the inspiratory disappearance and expiratory appearance of respiratory gas moisture in the clear tubing of the ventilated side. In addition, the compliance of the lung should be gauged by using hand ventilation. The unilateral clamping and unclamping and removal of the lumen cap proximal to the clamp should then be repeated on the opposite side to ensure adequate lung separation and cuff seal.

In summary, when DLT position is correct, the breath sounds are normal and follow the expected unilateral pattern with unilateral clamping, the chest rises and falls in accordance with the breath sounds, the ventilated lung feels reasonably compliant, no leaks are present, and respiratory gas moisture appears and disappears with each tidal ventilation. Conversely, when the DLT is malpositioned, any or all of the following may occur: the breath sounds may be poor and correlate poorly with unilateral clamping, the chest movements may not follow the expected pattern, the ventilated lung may feel noncompliant, leaks may be present, or the respiratory gas moisture in the clear tubing may be relatively stationary. It is very important to realize, however, that even if the DLT is thought to be properly positioned by clinical signs, subsequent fiberoptic bronchoscopy may reveal an incidence of malpositioning that ranges from 38 to 78 percent. [256] [257]

When it is believed, on the basis of clinical signs, that the DLT is malpositioned, it is theoretically possible to diagnose the malposition of the tube more precisely by a combination of several unilateral clamping, chest auscultation, and left endobronchial cuff inflation-deflation maneuvers (Fig. 48-19) (Figure Not Available) . With reference to a left-sided DLT, there are three possible gross malpositions: in too far on the left (both lumina in left mainstem bronchus), out too far (both lumina in the trachea), and in or down the right mainstem bronchus (at least the left lumen in the right mainstem bronchus). When the right (tracheal) side is clamped and the tube is in too far on the left side, breath sounds are heard only on the left side. When the tube is out too far and the right side is clamped, breath sounds are heard bilaterally. When the tube is in or down the right side and the right side is clamped, breath sounds are heard only on the right side. When the left side is clamped and the left endobronchial cuff is inflated, the right lumen is blocked by the left cuff in all three malpositions. Consequently, with the left side clamped and the left cuff inflated, no or very diminished breath sounds are heard bilaterally in all three of the malpositions. When the left side is clamped and the left cuff is deflated, so that the right lumen is no longer blocked by the left cuff, breath sounds are heard only on the left side when the tube is in too far on the left, bilaterally when the tube is out too far, and only on the right side when the tube is in the right side. The left cuff inflation and deflation findings provide the key diagnostic data because they essentially define the position of the right tracheal lumen by blocking and unblocking it with the left cuff.

There are, however, several situations in which these unilateral clamping, auscultation, and cuff inflation and deflation maneuvers for determining the integrity of lung separation are either unreliable or impossible. First, and most importantly, when the patient is in the LDP, has had a skin preparation, and is draped, access to the chest wall is impossible, and the anesthesiologist cannot listen to the chest. Second, the presence of unilateral or bilateral lung disease, either preexisting before anesthesia and surgery or anesthesia-induced, may markedly obscure the crispness of the chest auscultation end points. Third, the diagnosis of exactly where the DLT is located may be confused when the tube is just slightly malpositioned. Fourth, the tube may have moved as a result of some event, such as coughing, head flexion or extension while turning into the LDP, or tracheal manipulation and hilar retraction by the surgeon. Finally, some combination of these factors may culminate in uncertainty about where the DLT has located. The solution to any uncertainty about the exact position of the DLT is to determine the position by fiberoptic bronchoscopy.

Figure 48-19 (Figure Not Available) There are three major malpositions (involving a whole lung) of a left-sided double-lumen endotracheal tube. The tube can be in too far on the left (both lumina are in the left main stem bronchus), out too far (both lumina are in the trachea), or down the right main stem bronchus (at least the left lumen is in the right main stem bronchus). In each of these three malpositions the left cuff, when fully inflated, can completely block the right lumen. Inflation and deflation of the left cuff while the left lumen is clamped create a breath sound differential diagnosis of tube malposition. (See text for full explanation.) L, left; R, right;
, decreased. *(From Benumof [604])*

Use of Fiberoptic Bronchoscope to Determine Precise Double-Lumen Tube Position

As noted, even when a DLT is thought to be in proper position on the basis of clinical signs, subsequent fiberoptic bronchoscopy will reveal an incidence of malpositioning as high as 78 percent. [256] Indeed, when the position of the DLT is checked only by clinical signs, in up to 25 percent of cases there may be intraoperative problems with either deflating the nondependent lung, ventilating the dependent lung, or completely separating the two lungs. [256] [258] Given the high incidence of malpositioned DLTs when DLT position is determined by only auscultation (i.e., "blindly") and the potentially serious consequences associated with a malpositioned DLT, it is only a matter of simple common sense to routinely use a fiberoptic bronchoscope to easily, quickly, and precisely determine the position of the DLT.

The exact position of a left-sided DLT can be ascertained at any time, in less than a minute, by simply passing a pediatric-size fiberoptic bronchoscope through the tracheal lumen of the DLT. It is rarely necessary also to have to pass the fiberoptic bronchoscope down the left endobronchial lumen. With reference to a left-sided DLT, looking down the right (tracheal) lumen the endoscopist should have a clear straight-ahead view of the tracheal carina, the left lumen going off to the left, and the upper surface of the blue left endobronchial balloon just below the tracheal carina (Fig. 48-20) (Figure Not Available) . Because the distance between the right and left lumen tips for the clear plastic tube (69 mm) is longer than the length of the left mainstem bronchus (average 50 mm) in a typical patient and if the blue upper surface of the endobronchial balloon is not visible, it is possible for the right lumen to be above the tracheal carina while the left lumen tip obstructs the left upper lobe. [259] However, no matter which manufactured tube or size of tube is used and no matter how long or short the left mainstem bronchus is (within the range of extremes observed in extensive studies), [259] when the upper surface of the left endobronchial balloon is just below the tracheal carina, it is not possible for the left lumen tip to obstruct the left upper lobe or for the right (tracheal) lumen to be near a mainstem bronchus. It is important that the volume of air used to fill the left endobronchial cuff not cause the endobronchial cuff to herniate over the tracheal carina or cause the tracheal carina to deviate to the right (see Fig. 48-20) (Figure Not Available) ; both cuff herniation and carinal deviation can be readily appreciated by looking down the tracheal lumen. Looking down the left lumen (as is sometimes done when inserting a left-sided DLT with a fiberoptic bronchoscope [see the section immediately below] and in all cases of bronchopulmonary lavage where perfect tube position and tight cuff seal are extremely critical), the endoscopist should see a very slight narrowing of the left lumen (due to endobronchial cuff pressure) as well as the bronchial carina distal to the end of the tube (see Fig. 48-20) (Figure Not Available) . The endoscopist should not see excessive left luminal narrowing (due to excessive left cuff pressure) (see Fig. 48-20) (Figure Not Available) Thus, aside from gross malposition, important undesirable findings on endoscopy are related to excessive left cuff inflation and pressure and consist of cuff herniation over the tracheal carina, carinal deviation to the right (both of which may block the right mainstem bronchial orifice and impair right lung ventilation), and excessive left lumen constriction (invagination), which may impair left lung ventilation [260] (see Fig. 48-20) (Figure Not Available) . In addition, when an inappropriately undersized tube is used, the large endobronchial cuff volume required for endobronchial cuff seal tends to force the entire DLT cephalad, making a functional bronchial seal more difficult. [261]

With reference to a right-sided DLT, looking down the left (tracheal) lumen, the endoscopist should see a clear straight-ahead view of the tracheal carina and the right lumen going off to the right (Fig. 48-21 (Figure Not Available) A). The upper surface

Figure 48-20 (Figure Not Available) This schematic diagram depicts the complete fiberoptic bronchoscopy picture of left-sided double-lumen endotracheal tubes (both the desired view and the view to be avoided from both of the lumina). (A) When the bronchoscope is passed down the left lumen of the left-sided tube, the endoscopist should see a very slight left luminal narrowing and a clear straight-ahead view of the bronchial carina off in the distance. Excessive left luminal narrowing should be avoided. (B) When the bronchoscope is passed down the right lumen of the left-sided tube, the endoscopist should see a clear straight-ahead view of the tracheal carina and the upper surface of the blue left endobronchial cuff just below the tracheal carina. Excessive pressure in the endobronchial cuff, as manifested by tracheal carinal deviation to the right and herniation of the endobronchial cuff over the carina, should be avoided. *(From Benumof [604])*

of the right endobronchial balloon may not be visible below the tracheal carina. Looking down the right lumen, the endoscopist should see a very slight narrowing of the right lumen as well as the right middle-lower lobe bronchial carina distal to the end of the tube. Most importantly, the endoscopist should locate the right upper lobe ventilation slot and be able to look directly into the right upper lobe orifice through the right upper lobe ventilation slot by simply flexing the tip of the fiberoptic bronchoscope superiorly and laterally (Fig. 48-21 (Figure Not Available) B). There should be no overriding of the right upper lobe ventilation slot on the bronchial mucosa, and the bronchial mucosa should not be covering any of the right upper lobe ventilation slot.

In our experience, in 8 to 9 out of 10 cases, the clinical signs (breath sounds, chest movements, compliance of the lung[s], movement of respiratory gas moisture) indicate that the lungs are apparently clearly and without doubt completely separated when the DLT is first inserted with the patient in the supine position. However, in view of the finding that up to 78 percent of DLTs are malpositioned to some extent in the supine position, even though clinical signs indicate no problem, [256] it is strongly advisable to check the position of the tube with a fiberoptic bronchoscope in the supine position (especially in view of the fact that the procedure takes less than 1 minute). Even if no problem is identified, the procedure still allows the endoscopist to become familiar with the patient's anatomy and facilitates the more important endoscopy after turning the patient into the LDP. In approximately 1 to 2 out of 10 cases, there is a definite doubt about tube location in the supine position, and in these patients

Figure 48-21 (Figure Not Available) This schematic diagram portrays use of a fiberoptic bronchoscope to determine precise right-sided double-lumen tube position. (A) When the fiberoptic bronchoscope is passed down the left (tracheal) lumen, the endoscopist should see a clear straight-ahead view of the tracheal carina and the right lumen going off into the right main stem bronchus. (B) When the fiberoptic bronchoscope is passed down the right (bronchial) lumen, the endoscopist should see the bronchial carina off in the distance; when the fiberoptic bronchoscope is flexed cephalad and passed through the right upper lobe ventilation slot, the right upper lobe bronchial orifice should be visualized. *(From Benumof [604])*

the fiberoptic bronchoscope is always used to correct the DLT malposition. The fiberoptic bronchoscope is again used to confirm DLT position after the patient has been turned into the LDP. Of course, a determined effort is made to prevent dislodgement of the tube during turning by holding on to the tube at the level of the incisors and by keeping the head absolutely immobile in a neutral or slightly flexed position. Head extension can cause movement of the tube in a cephalad direction, which may result in bronchial decannulation; head flexion can cause movement of the tube in a caudad direction, which may result in an upper lobe obstruction or in both luminas being in a mainstem bronchus (see next section). [262] [263] Finally, the fiberoptic bronchoscope is used whenever during the case there is a question about DLT position. This is not an infrequent occurrence and is usually caused by surgical manipulation and traction on the hilum, carina, or trachea.

Use of Fiberoptic Bronchoscope to Insert the Double-Lumen Tube

The insertion of the bronchial lumen of a DLT into the appropriate mainstem bronchus may be aided by the use of a fiberoptic bronchoscope. This may be especially helpful if anatomic variation or a pathologic condition has caused carinal distortion. The DLT is first placed in the trachea in a conventional manner (laryngoscopy, manual tube insertion) until the tracheal cuff just passes the vocal cords, the tracheal cuff is inflated, and both lungs are ventilated through both lumina (the DLT should be used as if it were a single-lumen tube). A pediatric-sized fiberoptic bronchoscope can then be inserted into the bronchial lumen through a self-sealing diaphragm in the elbow connector to the bronchial lumen (which permits continued positive-pressure ventilation through that lumen around the fiberoptic bronchoscope) and passed into the appropriate mainstem bronchus. The tracheal cuff is then deflated and the bronchial lumen is passed over the fiberoptic bronchoscope stylet into the appropriate mainstem bronchus. The fiberoptic bronchoscope is then withdrawn from the bronchial lumen and passed down the tracheal lumen to determine the precise DLT position (see the preceding section).

Alternatively, once the DLT is in the trachea, the fiberoptic bronchoscope can be inserted into the tracheal lumen and passed just proximal to the tracheal carina. While the carina and the two mainstem bronchial orifices are in view, the DLT can be advanced and the degree of lateral rotation adjusted so that the appropriate lumen enters the appropriate mainstem bronchus. Final precise positioning (see the preceding section) can be done with the fiberoptic bronchoscope remaining in the tracheal lumen if a left-sided tube is used. If a right-sided tube is used, precise positioning must be confirmed with the bronchoscope passed through the bronchial lumen.

Relationship of Fiberoptic Bronchoscope Size to Double-Lumen Tube Size

The clear plastic disposable right and left double-lumen endotracheal tubes are manufactured in four sizes: 35, 37, 39, and 41 French. In addition, 26 and 28 French-sized tubes are available only as left-sided models. A 5.6-mm outside diameter diagnostic fiberoptic bronchoscope will not pass down the lumina of any size DLT. A 4.9-mm outside diameter fiberoptic bronchoscope passes easily through the lumina of the 41 French tube and moderately easily with lubrication through the 39 French tube; it causes a tight fit that needs a liberal amount of lubrication and a strong pushing force to pass through the lumen of the 37 French tube and does not pass through the lumen of the 35 French tube. A silicon-based fluid (such as that made by the American Cystoscope Co.) is the best lubricant for a fiberoptic bronchoscope because it does not dry out or crust and does not interfere with the view even if it coats the tip of the bronchoscope. Fortunately, from the point of view of using a 4.9-mm outside diameter fiberoptic bronchoscope, a 37 French tube or larger can be used in almost all adult females and 39 French tube or larger in almost all adult males. A 3.6- to 4.2-mm outside diameter (pediatric-sized) fiberoptic bronchoscope passes easily through the lumina of all adult-sized DLTs and because the bronchoscope has an increased amount of space, the maneuverability of the tip of the bronchoscope is greatly increased. Therefore, the 3.6- to 4.2-mm outside diameter bronchoscope is obviously the bronchoscope of choice for DLTs. Table 48-11 summarizes these fiberoptic bronchoscope-DLT relationships. Several companies (Olympus, Machida, Pentax) presently manufacture 4.9- and 3.6- to 4.2-mm outside diameter fiberoptic bronchoscopes that are of adequate length and have a suction channel.

Use of Chest Radiograph to Determine Double-Lumen Tube Position

The chest radiograph can be used to determine DLT position. The chest radiograph may be more useful than conventional unilateral auscultation and clamping in some patients, but it is always less precise than fiberoptic bronchoscopy. To use the chest radiograph, the DLT must have radiopaque markers at the end of the right and left lumina. The key to discerning DLT position on the chest radiograph

TABLE 48-11 -- Relationship of Fiberoptic Bronchoscope Size to Adult Double-Lumen Endotracheal Tube Size

FIBEROPTIC BRONCHOSCOPE SIZE (OUTSIDE DIAMETER) (mm)	ADULT DLT SIZE (FRENCH)	FIT OF FIBEROPTIC BRONCHOSCOPE INSIDE DLT
5.6	All sizes	Does not fit
	41	Easy passage
	39	Moderately easy passage
4.9	37	Tight fit, need lubricant,* hard push
	35	Does not fit
3.6-4.2	All sizes	Easy passage

Abbreviation: DLT, double-lumen tube.

*Lubricant recommended is a silicon-based fluid similar to that made by the American Cystoscope Co.

Figure 48-22 (Figure Not Available) Schematic diagram showing the air bubble detection method for checking adequacy of the seal of the left endobronchial cuff of a left-sided double-lumen tube. (A) When the left lung is selectively ventilated or exposed to any desired distending pressure and the left cuff is adequately sealed, no air will escape around the left cuff and out the open right suction port, and thus no bubbles will be observed passing through the beaker of water. (B) When the left lung is ventilated or exposed to any desired distending pressure and the left endobronchial cuff is not adequately sealed, air will escape around the left cuff and out the open right suction port, and thus air bubbles will be observed passing through the beaker of water. *(From Benumof [604])*

is seeing where the marker at the end of the tracheal lumen is in relation to the tracheal carina and whether the endobronchial lumen is located in the correct main stem bronchus. The end of the tracheal lumen marker must be above the tracheal carina; however, this does not guarantee correct position because this technique may not reveal a subtle obstruction of an upper lobe. If the tracheal carina cannot be seen (as sometimes happens with portable anteroposterior film), the chest radiograph method of determining DLT position is not usable. Furthermore, the chest radiograph method is time-consuming (for film transport and film development), costly, and awkward to perform and may dislodge the tube (the cassettes are often difficult to place under the operating room table and require moving the patient).

Other Methods to Determine Double-Lumen Tube Position

Three other methods may help to determine the position of a DLT. First, comparison of capnography (waveform and end-tidal CO_2 pressure [PET CO_2] value) from each lumen may reveal a marked discrepancy. For example, with all other conditions equal, one lung may be very poorly ventilated in relation to the other lung (high PET CO_2), indicating obstruction to that lung; one lung may be very overventilated in relation to the other lung (low PET CO_2), perhaps indicating ventilation of just a lobe of that lung; or the capnogram from one lung may have a much steeper slope to the alveolar plateau, indicating expiratory obstruction. [264] [265] Second, continuous spirometric data (Datex Capnomac Ultima) from both lungs and from each lung separately, such as pressure-volume or flow-volume loops, may be displayed and compared with a control loop that is stored in memory. [266] Third, the surgeon may be able to palpate the position of the DLT from within the chest and may be able to redirect or assist in changing its position (by deflecting the DLT away from the wrong lung, etc.). [267]

Quantitative Determination of Cuff Seal Pressure Hold

The use of fiberoptic bronchoscopy to determine DLT position does not provide evidence or a guarantee that the lungs are functionally separated (i.e., against a fluid and/or air pressure gradient). There are times, such as during the performance of unilateral pulmonary lavage, when the anesthesiologist must be absolutely certain that functional separation has been achieved. Complete separation of the lungs by the left endobronchial cuff can be demonstrated in a left-sided tube by clamping the connecting tube to the right lung proximal to the right suction port and attaching a small tube (i.e., intravenous extension tubing) to the open right suction port (by appropriate adaptors) (Fig. 48-22) (Figure Not Available) . The free end of this tube is submerged in a beaker of water. When the left lung is statically inflated to any pressure considered necessary and the left endobronchial cuff is not sealed, air will enter the left lung and will also escape from around the unsealed left cuff, move up the right lumen to the small connecting tube, and bubble through the beaker of water (Fig. 48-22 (Figure Not Available) B). If the left endobronchial cuff is sealed, no bubbles should be observed passing through the beaker of water (Fig. 48-22 (Figure Not Available) A). After demonstration of functional lung separation, the right connecting tube is unclamped, the right suction port closed, and ventilation to both lungs resumed. To test for lung separation with the pressure gradient across the endobronchial balloon reversed, the left airway connecting tube is clamped proximal to the left suction port, the left suction port opened to the beaker of water via the small tube, the right lung statically inflated to any desired pressure, and the absence or presence of air bubbles in the beaker of water noted. It should be remembered that even though the left endobronchial cuff may be adequately sealed, it is possible that during these maneuvers, compression of the nonventilated lung by the ventilated lung may initially cause some small amount of bubbling in the beaker, which will cease with repetitive inflation of the ventilated lung (no bubbles should be seen after several inflations). [251] [260]

TABLE 48-12 -- Endobronchial Cuff Considerations to Minimize Tracheobronchial Wall Damage (Disruption)

1. Be particularly cautious in patients with bronchial wall abnormalities.
2. Pick an appropriately sized tube.
3. Be certain tube is not malpositioned. * Use fiberoptic bronchoscopy to confirm the position of the double-lumen tube (especially if N_2O is introduced into the inspired gases).
4. Avoid overinflation of endobronchial cuff. *
5. Deflate endobronchial cuff during turning.
6. Inflate endobronchial cuff slowly.
7. Inflate endobronchial cuff with inspired gases.
8. Do not allow tube to move during turning. *

*Most important considerations.

The absence of airflow from the nonventilated lung suction port is a very simple but sensitive indicator of functional separation of the two lungs.

Complications of Double-Lumen Endotracheal Tubes

In addition to the impediment to arterial oxygenation that is inherent in the use of DLTs for one-lung anesthesia, the tubes themselves occasionally cause other serious complications. These complications include tracheobronchial tree disruption (with the Carlens tube, [268] the red rubber Robertshaw tube, [269] the red rubber White tube, [270] and the disposable low-pressure cuff plastic tubes [271] [272] , traumatic laryngitis, [248] and suturing of a pulmonary vessel to the DLT. [273] With regard to tracheobronchial tree disruptions, a common thought in the reports cited is that excessive air volume and pressure in the bronchial balloon may be major factors in the genesis of these tears after DLT insertion. Recommendations to minimize tracheobronchial wall damage due to the cuffs include being particularly cautious in the use of DLTs in patients with bronchial wall abnormalities, choosing an appropriately sized clear plastic tube, [246] being certain the tube is not malpositioned, preventing overinflation of the endobronchial cuff, deflating the endobronchial cuff during turning, inflating the endobronchial cuff slowly, inflating the endobronchial cuff with inspired gases if nitrous oxide is used, and preventing the tube from moving during turning (Table 48-12) .

Relative Contraindications to Use of Double-Lumen Endotracheal Tubes

Lung separation by a DLT may be relatively contraindicated in several situations because insertion of the tube is either difficult or dangerous. These situations involve patients who have a full stomach (risk of aspiration); patients who have a lesion (airway stricture, [274] endoluminal tumor) that is present somewhere along the pathway of the DLT and thus could be traumatized; small patients for whom a 35 French tube is too large to fit comfortably through the larynx and for whom a 28 French tube is considered too small; patients whose upper airway anatomy precludes safe insertion of the tube (recessed jaw, prominent teeth, bull neck, anterior larynx); extremely critically ill patients who have a single-lumen tube already in place and who will not tolerate being taken off mechanical ventilation and PEEP even for a short time; and patients having some combination of these problems. Under these circumstances, it is still possible to separate the lungs safely and adequately by using a single-lumen tube and fiberoptic bronchoscopic placement of a bronchial blocker or by fiberoptic bronchoscopic placement of a single-lumen tube in a main stem bronchus.

Bronchial Blockers (With Single-Lumen Endotracheal Tubes)

Lung separation can be effectively achieved with the use of a single-lumen endotracheal tube and a fiberoptically placed bronchial blocker. This is often necessary in children because DLTs are too large to be used in them. The smallest DLT available is a left-sided 26 French tube, which may be used in patients 8 to 12 years old and weighing 25 to 35 kg. Bronchial blockers that are balloon-tipped luminal catheters have the advantage of allowing suctioning and injection of oxygen down the central lumen. The bronchial blocker most widely used for adults is the movable bronchial blocker that is contained in and is an integral part of the Univent single-lumen tube system (made by Fuji Systems Corp., Tokyo) [275] [276] [277] [278] [279] [280] [281] (Fig. 48-23) . The physiology of one-lung ventilation produced by bronchial blockade is identical to that produced by clamping one lumen of a DLT.

Figure 48-23 Single-lumen tube of Univent bronchial blocker system.

Figure 48-24 The sequential steps of the fiberoptic-aided method of inserting and positioning the Univent bronchial blocker (BB) in the left mainstem bronchus are illustrated. One- or two-lung ventilation is achieved by simply inflating or deflating, respectively, the bronchial blocker balloon.

Insertion of the Univent Tube and Positioning of the Bronchial Blocker

The tube is inserted in the following manner. First, the single-lumen tube along with the bronchial blocker (in the fully retracted position) is inserted as a unit into the trachea (Fig. 48-24 A). The cuff on the main endotracheal tube lumen is inflated, and the patient is ventilated and oxygenated (see Fig. 48-24 A). A fiberoptic bronchoscope is inserted through a self-sealing diaphragm in the elbow connector to a single-lumen tube while ventilation is maintained around the bronchoscope (but within the single-lumen tube) (Fig. 48-24 C). The right and left mainstem bronchi are identified (by noting the relationship of the main stem bronchi to the posterior membrane and the anterior cartilaginous rings [Fig. 48-24 B.]), and the tube of the bronchial blocker is located (by moving the bronchial blocker in and out just beyond the end of its own lumen and the main lumina of the Univent tube [Fig. 48-24 .]). The bronchial blocker cuff is colored blue and is easy to see. It will be seen that the bronchial blocker will usually (almost always) enter the right mainstem bronchus if it is simply pushed in (and the main single-lumen tube is not turned). If the left mainstem bronchus is to be blocked, the main single-lumen tube is turned 90 degrees to the left (counterclockwise) so that the concavity of the tube is facing toward the left side (Fig. 48-24 C). (and vice versa for the right side, if necessary). The bronchial blocker can also be rotated a slight amount at its distal end (obtain 1-3 mm of laterality) by twirling the proximal end in the fingers. The bronchial blocker is then advanced into the mainstem bronchus under direct vision (Fig. 48-24 D).. Attempting to advance the bronchial blocker blindly into the appropriate mainstem bronchus (particularly the left) will be unsuccessful 87 percent of the time, and repeated attempts may cause excoriation of the tracheal mucosa. [227] In fact, blindly pushing the somewhat stiff bronchial blocker may result in perforation of the tracheobronchial tree and consequent tension pneumothorax. [278]

TABLE 48-13 -- Advantage/Noteworthy Positive Attributes of the Univent Bronchial Blocker Tube (Relative to a Double-Lumen Tube and Other Bronchial Blockers)

1. Easier to insert and properly position
2. Can be properly positioned during continuous ventilation and in the lateral decubitus position
3. No need to change the tube for postoperative mechanical ventilation
4. No need to change the tube intraoperatively when turning from the supine to the prone position
5. Selective blockade of some lobes of each lung
6. Possible to apply nonventilated operative lung CPAP

Abbreviation: CPAP, continuous positive airway pressure.

The balloon is inflated until the cephalad surface of the balloon is just below the tracheal carina (Fig. 48-24 E). (so that the upper lobe of the blocked lung may also distend if CPAP is applied to the blocked lung [see below], and the fiberoptic bronchoscope is then withdrawn (Fig. 48-24 F).

Advantages and Noteworthy Positive Attributes of the Univent Bronchial Blocker Tube System

The Univent bronchial blocker tube has six important attributes that require special mention (Table 48-13) . First and foremost, the degree of difficulty in inserting the Univent tube is equivalent to a standard single-lumen tube and therefore in many instances will be an easier and quicker way to separate the lungs to obtain simple one-lung ventilation (as compared with a DLT). [91] [93] Thus and as an example, the Univent tube may be preferable when difficult intubation is anticipated and when the patient has been treated with anticoagulants. Second, the patient can be continuously ventilated while the bronchial blocker is being placed into a mainstem bronchus, and the bronchial blocker can be placed into a mainstem bronchus just as easily in the LDP as in the supine position. Third, and provided that the postanesthesia care unit and intensive care unit personnel are instructed in the design and function of the Univent tube (particularly the ventilatory consequence of inflating the bronchial blocker cuff just distal to the main lumen [i.e., the main lumen will be obstructed]), the Univent tube may be left *in situ* for postoperative mechanical ventilation and the risk of a potentially difficult tube change (e.g., from a DLT to a single-lumen tube) thereby avoided. Fourth and similarly, the Univent tube may be left *in situ* if a patient is turned from the supine to the prone position midway through a surgical procedure (a common occurrence with surgery on the thoracic spine). Fifth, the unique characteristic of a movable endobronchial blocker permits the Univent endotracheal tube to create selective partial collapse (e.g., of a lobe) or total collapse of the targeted lung. [282] The capability of selectively blocking lung segments is extremely important in cases of isolated pulmonary hemorrhage. Partial versus total one-lung ventilation may allow for an improvement in Pa O_2 in cases of intraoperative hypoxemia during thoracic operations. Finally, although this is not a distinct advantage over a DLT, it should be noted that it is possible to apply CPAP to the nonventilated operative lung through the lumen of the bronchial blocker, [283] and therefore the Univent tube provides the same best solution to hypoxemia during one-lung ventilation as does a DLT. In fact, except for independent unilateral intermittent positive-pressure ventilation and suctioning, all selective differential lung functions possible with a DLT are possible with a Univent bronchial blocker tube.

Potential Limitations of the Univent Bronchial Blocker Tube System and Solutions to the Limitations

There are several distinct limitations to the Univent bronchial blocker tube system, but fortunately all have a relatively simple remedy (Table 48-14) . First, the small lumen of the bronchial blocker results in slow inflation of the lung if gases are just insufflated (e.g., at a flow rate of 10 L/min, a lung will require at least 20 seconds to reach total lung capacity) or pushed in by conventional positive pressure. The operative lung may be made to expand rapidly if the bronchial blocker cuff is deflated

(the operative lung will expand with one positive-pressure breath from the main single lumen) or if one very short (e.g., <0.5-sec) burst of wall oxygen-powered 20- to 30-psi jet ventilation (reduced from 50 psi) is administered. However, connection of the bronchial blocker lumen to a jet ventilator is potentially dangerous (i.e., it can cause barotrauma) because the lung can expand extremely rapidly, and it is of paramount importance that the anesthesiologist directly observe the lung and that the ventilation be very short or the pressure limited to 20 to 30 psi by an additional in-line regulator. Second, and also because the bronchial blocker lumen is small, the lung will deflate very slowly when blocked. This is easily remedied by deflating the bronchial blocker cuff (which reestablishes continuity between the operative lung and the main single lumen), disconnecting the patient from the ventilator, and

TABLE 48-14 -- Limitations to the Use of the Univent Bronchial Blocker Tube and Solutions to the Limitations

LIMITATION	SOLUTION
1. Slow inflation time	1. (a) Deflate bronchial blocker cuff and administer a positive pressure breath through the main single lumen; (b) carefully administer one short high pressure (20-30 psi) jet ventilation.
2. Slow deflation time	2. (a) Deflate bronchial blocker cuff and compress and evacu-ate the lung through the main single lumen; (b) apply suction to bronchial blocker lumen.
3. Blockage of bronchial blocker lumen by blood, pus	3. Suction, stylet, and then suction.
4. High-pressure cuff	4. Use just-seal volume of air.
5. Intraoperative leak in bronchial blocker cuff	5. Make sure bronchial blocker cuff is subcarinal, increase inflation volume, rearrange surgical field.

leaving the endotracheal tube open to air while the surgeon gently compresses the lung to evacuate air from the operative lung through the main single lumen. After the lung is thus fully collapsed, the blocker balloon is inflated and ventilation resumed. [91] [92] Alternatively, the lumen of the bronchial blocker may be connected to the suction apparatus while the cuff is inflated; a normal amount of wall suction greatly facilitates lung collapse. Third, and also because the bronchial blocker lumen is small, the lumen is relatively easily blocked by blood and/or pus. High suction will occasionally clear the lumen of these materials and total blockage by inspissated secretions can be broken up by a wire stylet. Fourth, the Univent bronchial blocker behaves as a high-pressure cuff when intracuff volume is greater than 2 mL (the resting volume of the cuff) and may be expected to have an intracuff pressure between 150 and 250 mm Hg and a transmural pressure (intracuff pressure within the airway minus intracuff pressure outside the airway [free in the room]) between 50 and 60 mm Hg when intracuff volumes of 4 to 6 mL are used to seal 12- to 18-mm airways against the usual proximal airway pressure. [284] [285] Thus, the order of usual bronchial cuff pressures is left-sided PVC DLT < right-sided polyvinylchloride DLT < Univent Bronchial Blocker cuff < red rubber double-lumen tube. [286] These findings underscore the need to inflate the bronchial blocker cuff with a just-seal volume of air. Fifth, the Univent bronchial blocker has on occasion been reported to have a minor leak during surgery (25% in one series), [277] but this is not understandable in view of experiments showing that the Univent bronchial blocker cuff seals within normal-sized mainstem bronchi against proximal airway pressures as great as 100 cm H_2 O with inflation volumes that are within the manufacturer's recommendation. [285] Consequently, if an intraoperative leak occurs when less than a 6- to 7-mL intracuff volume has been used and the bronchial blocker cuff is completely subcarinal (as determined by fiberoptic bronchoscopy) and intact, the intracuff volume should be increased. If an intraoperative leak develops even though an adequate cuff inflation volume has been used (the bronchial blocker can be seen [fiberoptically] to fill the mainstem bronchus in question) and the bronchial blocker cuff is completely subcarinal (as determined fiberoptically) and intact, the relationship between the mainstem bronchus and the bronchial blocker cuff may no longer be a simple matter of a sphere or ellipsoid being inflated within a cylinder. Under these circumstances the surgeon may need to rearrange the surgical field so that the mainstem bronchus and bronchial blocker cuff are less distorted. Finally, the addition of the lumen for the bronchial blocker results in an endotracheal tube that has a large outside anteroposterior diameter relative to its inside diameter.

Methods to Obtain a Just-Seal Volume in the Bronchial Blocker Cuff

There are two methods to obtain a just-seal volume of air in the bronchial blocker cuff. The first method is the same as that already described for obtaining a just-seal volume of air in the endobronchial cuff of a DLT. It consists of pressurizing the main single lumen until air ceases to escape from the bronchial blocker lumen (detected by connecting the

Figure 48-25 (Figure Not Available) Capnogram tracing showing normal respiratory waveform changing to a straight line as bronchial seal occurs. *(From Essig K and Freeman JA [605])*

bronchial blocker lumen to a catheter that is submerged beneath the surface of a beaker of water; when air bubbles cease to come out, the bronchial blocker cuff has sealed) (see Fig. 48-22) (Figure Not Available) .

The second method appears promising and uses capnography. End-tidal CO_2 analyzers draw gas samples from the anesthesia breathing circuit via tubing that terminates, at the patient end of the tubing, in a standard Luer lock male connector that inserts into a female port in the breathing circuit. The male connector also inserts into/attaches to the female port at the proximal end of the Univent's bronchial blocker. The tracing from a gas analyzer, connected to the blocker with its cuff deflated, shows a typical respiratory waveform. As the cuff of the bronchial blocker is steadily inflated, a point is reached at which the respiratory waveform abruptly ceases, and a straight line is seen, indicating that lung isolation has occurred (Fig. 48-25) (Figure Not Available) . The CO_2 concentration remains near its end-tidal value until the blocked lung has collapsed and then rapidly decreases. The strengths of this method include simplicity, repeatability, and ability to ventilate the unblocked lung continuously throughout the procedure.

Clinical Indications for Use of the Univent Bronchial Blocker System

There are several clinical situations in which use of the Univent bronchial blocker tube is relatively indicated. First, whenever it is anticipated that postoperative ventilation will be necessary (e.g., poor pulmonary function preoperatively, anticipated lung damage or massive fluid and/or blood infusion intraoperatively, anticipated very long case), use of the Univent bronchial blocker tube for lung separation may avoid a risky postoperative DLT to single-lumen tube change. Second and similarly, use of the Univent bronchial blocker tube will avoid a potentially dangerous DLT to single-lumen tube change in cases of surgery on the thoracic spine in which a thoracotomy in the supine or lateral decubitus position is followed by surgery in the prone position. Third, a very severely distorted airway may prevent successful placement of a DLT, whereas such distortion may have much less of an effect on the proper placement of the Univent tube. Finally, but least predictable or compelling, are situations in which both lungs may need to be blocked (e.g., bilateral operations, indecisive surgeons).

Figure 48-26 (Figure Not Available) Lung separation with a single-lumen tube, fiberoptic bronchoscope, and right lung bronchial blocker. The sequence of events is as follows: (A) A single-lumen tube is inserted and the patient is ventilated. (B) A bronchial blocker is passed alongside the indwelling endotracheal tube. (C) A fiberoptic bronchoscope is passed through a self-sealing diaphragm in the elbow connecter to the endotracheal tube and is used to place the bronchial blocker into the right mainstem bronchus under direct vision. (D) The balloon on the bronchial blocker is also inflated under direct vision and is positioned just below the tracheal carina. (E) The fiberoptic bronchoscope is then removed (right lower diagram). During the lower panel sequence (insertion and use of fiberoptic bronchoscope, Figs. C to E) the self-sealing diaphragm allows the patient to continue to be ventilated with positive-pressure ventilation (around the fiberoptic bronchoscope, but within the lumina of the endotracheal tube). LL, left lung; RL, right lung. *(From Benumof [604])*

Bronchial Blockers That Are Independent of a Single-Lumen Tube

The bronchial blocker that is independent of the single-lumen tube most often used for adults is a Fogarty occlusion (embolectomy) catheter with a 3-mL balloon. [287] The Fogarty catheter includes a stylet so that it is possible to place a curvature at the distal tip to facilitate entry into the larynx and either mainstem bronchus (by twirling the proximal end). If no endotracheal tube is in place, the operator exposes the larynx and places a single-lumen tube with a high-volume cuff in the trachea. The Fogarty catheter is then placed either inside [288] [289] or alongside the single-lumen tube (Fig. 48-26) (Figure Not Available) . In either case (bronchial blocker inside or outside the single-lumen tube), a fiberoptic bronchoscope is passed down to the end of the single-lumen tube through a self-sealing diaphragm in the elbow connector (which permits continued positive-pressure ventilation around the fiberoptic bronchoscope), and the Fogarty catheter is visualized below the tip of the

single-lumen tube. The proximal end of the bronchial blocker is then twirled in the fingertips and advanced until the distal tip locates in the desired mainstem bronchus. The catheter balloon is then inflated under direct visualization and the fiberoptic bronchoscope withdrawn through the self-sealing diaphragm.

Finally, other balloon-tipped luminal catheters (such as the Magill or Foley type) may be used as bronchial blockers.

For bronchial blockage in very small children (10 kg or less) a Fogarty embolectomy catheter with a balloon capacity of 0.5 mL or a Swan-Ganz catheter (1-mL balloon) should be used. [29C] Of course, these catheters have to be positioned under direct vision; a fiberoptic bronchoscope method, as depicted in Figure 48-26 (Figure Not Available) , is perfectly acceptable, except the fiberoptic bronchoscope outside diameter must be approximately 2 mm to fit inside the endotracheal tube (3-mm internal diameter or greater). Otherwise, the bronchial blocker must be situated with a rigid bronchoscope. Pediatric patients of intermediate size require intermediate size occlusion catheters and judgment on the mode of placement (i.e., via rigid versus fiberoptic bronchoscope).

Disadvantages of bronchial blockage with a blocker that is independent of the single-lumen tube as compared with DLT lung separation include inability to suction and/or to ventilate the lung distal to the blocker, increased placement time, and the definite need for a fiberoptic or rigid bronchoscope. In addition, if a mainstem bronchial blocker backs out into the trachea, the seal between the two lungs will be lost, and two catastrophic complications may occur. First, if the bronchial blocker was being used to seal off fluid (blood or pus) in one lung, then both lungs may

become contaminated with the fluid. Second, the trachea will be at least partially obstructed by the blocker, and ventilation will be greatly impaired. Therefore, bronchial blockage requires that the anesthetist continuously and intensively monitor the compliance and breath sounds of the ventilated lung.

Endobronchial Intubation With Single-Lumen Tubes

In adults presenting with hemoptysis, endobronchial intubation with a single-lumen tube is often the easiest, quickest way of effectively separating the two lungs, especially if the left lung is bleeding, in which case one can simply take an uncut single-lumen endotracheal tube and advance it inward until moderate resistance is felt. In the vast majority of patients, the single-lumen tube will locate in the right mainstem bronchus, thereby blocking off the bleeding left lung and allowing selective ventilation of only the right lung. Under these circumstances it is highly possible that the right upper lobe bronchus will be blocked off as well, resulting in ventilation of only the right middle and lower lobes. Ventilation of only a soiled right lung or ventilation of only the right middle and lower lobes (even if they are unsoiled) incurs the risk of serious hypoxemia due to the very large transpulmonary shunt that is necessarily created by single-lung endobronchial intubation.

If the right lung is bleeding, there are two ways of selectively intubating the left mainstem bronchus. First, this may be done blindly with approximately a 92 percent success rate by turning the patient's head to the right and passing the single-lumen tube with the concavity of the tube facing posterior (rotated 180 degrees from its normal position and relationship to the trachea). [291] The single-lumen tube enters the right or left mainstem bronchus when the concavity of the tube faces anteriorly or posteriorly, respectively, because the bevel is left- or right-facing, respectively (i.e., a left-facing bevel enters the right mainstem bronchus and a right-facing bevel enters the left mainstem bronchus). [292] Second, a fiberoptic bronchoscope can be passed through a self-sealing diaphragm in the single-lumen tube elbow connector and directed into the left mainstem bronchus. Persistent large, soft catheter suctioning of the carinal area through the single-lumen tube before use of the fiberoptic bronchoscope and suctioning through the fiberoptic bronchoscope (through the single-lumen tube) may be required to visualize the tracheal carina. The single-lumen tube can then be passed over the fiberoptic bronchoscope into the left mainstem bronchus, thereby isolating the bleeding right lung and allowing selective ventilation of the left lung. Passing the fiberoptic bronchoscope through a self-sealing diaphragm allows the continuance of positive-pressure ventilation and PEEP around the bronchoscope. However, it should be realized that visualization of the carina may not be possible when the bleeding is copious and that the only hope for the patient may lie in rapid thoracotomy and control of bleeding from within the chest. In addition, under these adverse conditions, conventional passage of a DLT tube may more rapidly and effectively separate the two lungs than visualization of the anatomy with a fiberoptic bronchoscope.

In summary, use of DLTs is the method of choice for separating the lungs in most adult patients. If there is any question, the precise location of a DLT can be determined by fiberoptic bronchoscopy at any time. There are a number of situations in which insertion of a DLT may be difficult and/or dangerous, and under these circumstances consideration should be given to separating the lungs with a single-lumen tube alone or in combination with a bronchial blocker (e.g., the Univent tube). However, when using a single-lumen tube in a mainstem bronchus or when using a bronchial blocker, ability to suction the operative site and control oxygen uptake (the blocked lung cannot be ventilated with oxygen at any time) is limited. In addition, placement of the single-lumen tube into one or the other mainstem bronchus and proper placement of a bronchial blocker usually require fiberoptic bronchoscopy. Therefore, no matter what method of separating the lungs is chosen, there is a real need for the immediate availability of a small-diameter fiberoptic bronchoscope (for checking the position of the DLT, placing a single-lumen tube in the left mainstem bronchus, and placing a bronchial blocker) that has a suction port to clear secretions and blood from the airway.

Physiology of One-Lung Ventilation

Comparison of Arterial Oxygenation and Carbon Dioxide Elimination During Two-Lung Versus One-Lung Ventilation

As discussed previously, the matching of ventilation and perfusion is impaired during two-lung ventilation in an anesthetized, paralyzed, open-chested patient in the LDP. The reason for the mismatching is relatively good ventilation but poor perfusion of the nondependent lung and poor ventilation and good perfusion of the dependent lung (see Figs. 48-13 (Figure Not Available) and 48-26 (Figure Not Available) A). The blood flow distribution has been seen to be mainly and simply determined by gravitational effects. The relatively good ventilation of the nondependent lung has been seen to be caused, in part, by the open chest and paralysis. The relatively poor ventilation of the dependent lung has been seen to be caused, in part, by the loss of dependent lung volume with general anesthesia and by circumferential compression of the dependent lung by the mediastinum, abdominal contents, and suboptimal positioning effect. The compression of the dependent lung may cause the development of a shunt compartment in this lung (see Fig. 48-13 (Figure Not Available) ; Fig. 48-27 (Figure Not Available) A). Consequently, two-lung ventilation under these circumstances may result in an increased $P(A\text{-}a)_{O_2}$ and impaired oxygenation.

If the nondependent lung is nonventilated, as during one-lung ventilation, then any blood flow to the nonventilated lung becomes shunt flow, in addition to whatever shunt flow might exist in the dependent lung (Fig. 48-27 (Figure Not Available) B). Thus, one-lung ventilation creates an obligatory right-to-left transpulmonary shunt through the nonventilated nondependent lung, which is not present during two-lung ventilation. Consequently, it is not surprising to find that, given the same inspired oxygen concentration (F_{IO_2}) and hemodynamic and metabolic status, one-lung ventilation results in a much larger $P(A\text{-}a)_{O_2}$ and lower Pa_{O_2} than two-lung ventilation. This contention is best supported by one study that compared

Figure 48-27 (Figure Not Available) Schematic representation of two-lung ventilation versus one-lung ventilation. Typical values for fractional blood flow to the nondependent and dependent lungs as well as arterial oxygen tension (Pa_{O_2}) and shunt (Q_S/Q_T) for the two conditions are shown. The Q_S/Q_T during two-lung ventilation is assumed to be distributed equally between the two lungs (5 percent to each lung). The essential difference between two-lung and one-lung ventilation is that during one-lung ventilation the nonventilated lung has some blood flow and therefore has an obligatory shunt, which is not present during two-lung ventilation. The 35 percent of total flow perfusing the nondependent lung, which was not shunt flow, was assumed to be able to reduce its blood flow by 50 percent by hypoxic pulmonary vasoconstriction. The increase in Q_S/Q_T from two-lung to one-lung ventilation is assumed to be solely due to the increase in shunt through the nonventilated, nondependent lung during one-lung ventilation. *(From Benumof [604])*

arterial oxygenation during two-lung and one-lung ventilation, wherein each patient served as his or her own control. [293]

One-lung ventilation has much less of a steady-state effect on Pa_{CO_2} than on Pa_{O_2}. Blood passing through underventilated alveoli retains more than a normal amount of carbon dioxide and does not take up a normal amount of oxygen; blood traversing overventilated alveoli gives off more than a normal amount of carbon dioxide but cannot take up a proportionately increased amount of oxygen because of the flatness of the top end of the oxyhemoglobin dissociation curve. Thus, during one-lung ventilation (the one-lung minute ventilation equals the two-lung minute ventilation) the ventilated lung can eliminate enough carbon dioxide to compensate for the nonventilated lung, and P_{ACO_2} to Pa_{CO_2} gradients are small; however, the ventilated lung cannot take up enough oxygen to compensate for the nonventilated lung, and P_{AO_2} to Pa_{O_2} gradients are usually large. With a constant minute ventilation (two-lung ventilation as compared with one-lung ventilation), the retention of carbon dioxide by blood traversing the nonventilated lung usually slightly exceeds the increased elimination of carbon dioxide from blood traversing the ventilated

lung, and the Pa CO_2 will usually slowly increase (along with the $E_T CO_2$).

The initiation of one-lung ventilation has much more of an acute effect (first 5 minutes) on PET CO_2 . When one-lung ventilation is begun (keeping total tidal volume and respiratory rate constant), the ventilated lung is immediately hyperventilated in relation to its perfusion (i.e., has an increased V/Q ratio) and PET CO_2 from this lung decreases in the first minute (e.g., by 5 mm Hg). [294]

Over the next 5 minutes, HPV in the nonventilated lung shifts blood flow over to the ventilated lung, increases ventilated lung perfusion, decreases ventilated lung V/Q ratio and increases the PET CO_2 back to the baseline two-lung ventilation value. [294] Thereafter, and as discussed previously, PET CO_2 will slowly increase (along with Pa CO_2) because the same total minute ventilation to one lung is not as effective as when it is delivered to both lungs (i.e., there is an increased alveolar dead space within the one ventilated lung). [294]

Blood Flow Distribution During One-Lung Ventilation

Blood Flow to the Nondependent, Nonventilated Lung

Fortunately, both passive mechanical and active vasoconstrictor mechanisms are usually operant during one-lung ventilation that minimize the blood flow to the nondependent, nonventilated lung and thereby prevent Pa O_2 from decreasing as much as might be expected on the basis of the distribution of blood flow during two-lung ventilation. The passive mechanical mechanisms that decrease blood flow to the nondependent lung are gravity, surgical interference with blood flow, and perhaps the extent of preexisting disease in the nondependent lung (Fig. 48-28) (Figure Not Available) . Gravity causes a vertical gradient in the distribution of pulmonary blood flow in the LDP for the same reason that it does in the upright position (see Fig. 48-9) (Figure Not Available) . Consequently, blood flow to the nondependent lung is less than that to the dependent lung. The gravity component of blood flow reduction to the nondependent lung should be constant with respect to both time and magnitude.

Surgical compression (directly compressing lung vessels) and retraction (causing kinking and tortuosity of lung vessels) of the nondependent lung may further passively reduce nondependent lung blood flow. In addition, ligation of pulmonary vessels during pulmonary resection greatly decreases nondependent lung blood flow. The surgical interference component of blood flow reduction to the nondependent lung should be variable with respect to both time and magnitude.

The amount of disease in the nondependent lung is also a significant determinant of the amount of blood flow to the nondependent lung. If the nondependent lung is severely diseased, there may be a fixed reduction in blood flow to this lung preoperatively and collapse of such a diseased lung may not cause much of an increase in shunt. The notion that a diseased pulmonary vasculature might be incapable of HPV is supported by the observations that administration of

Figure 48-28 (Figure Not Available) Schematic diagram of the determinants of blood flow distribution during one-lung ventilation. The major determinants of blood flow to the nondependent lung are gravity, surgical interference with blood flow, amount of nondependent lung disease, and magnitude of nondependent lung hypoxic pulmonary vasoconstriction. The determinants of dependent lung blood flow are gravity, amount of dependent lung disease, and dependent lung hypoxic pulmonary vasoconstriction. *(From Benumof [604])*

sodium nitroprusside and nitroglycerin (which should abolish any preexisting HPV) to COPD patients (who have a fixed reduction in the cross-sectional area of their pulmonary vascular bed) does not cause an increase in shunt, [295] whereas these drugs do increase shunt in patients with acute regional lung disease who have an otherwise normal pulmonary vascular bed. [296] If the nondependent lung is normal and has a normal amount of blood flow preoperatively, collapse of such a normal lung may be associated with a higher nonventilated nondependent lung blood flow and shunt. A higher one-lung ventilation shunt through the nondependent lung may be more likely to occur in patients who require thoracotomy for nonpulmonary disease. [297] Two studies have systematically validated the inverse correlation between the amounts of nondependent lung disease and shunt during one-lung ventilation. [298] [299]

The most significant reduction in blood flow to the nondependent lung is caused by an active vasoconstrictor mechanism. The normal response of the pulmonary vasculature to atelectasis is an increase in PVR (in just the atelectatic lung); this increase, thought to be due almost entirely to HPV, [153] [154] [155] diverts blood flow from the atelectatic lung toward the remaining normoxic or hyperoxic ventilated lung. The diversion of blood flow minimizes the amount of shunt flow that occurs through the hypoxic lung. Figure 48-6 shows the theoretically expected effect of HPV on arterial oxygen tension (Pa O_2) as the amount of lung that is made hypoxic increases. [209] When very little of the lung is hypoxic (near 0%) it does not matter, in terms of Pa O_2 , whether the small amount of lung has HPV operating or not because in either case the shunt will be small. When most of the lung is hypoxic (near 100%) there is no significant normoxic region to which the hypoxic region can divert flow, and again it does not matter, in terms of Pa O_2 , whether or not the hypoxic region has HPV operating. When the percentage of lung that is hypoxic is intermediate (between 30 and 70%), which is the amount of lung that is typically hypoxic during the one-lung ventilation-anesthesia condition, there is a large difference between the Pa O_2 expected with a normal amount of HPV (which is a 50% blood flow reduction for a single lung) [209] as compared with no HPV. In fact, in this range of hypoxic lung, HPV can increase Pa O_2 from hypoxemic levels to much higher and safer values. It is not surprising, then, that numerous clinical studies on one-lung ventilation have found that the shunt through the nonventilated lung is usually 20 to 30 percent of the cardiac output, as opposed to the 40 to 50 percent shunt that might be expected if there were no HPV operating in the nonventilated lung. [297] [300] [301] [302] [303] [304] [305] Thus, HPV is an autoregulatory mechanism that protects the Pa O_2 by decreasing the amount of shunt flow that can occur through hypoxic lung.

Figure 48-29 (Figure Not Available) . outlines the major determinants of the amount of atelectatic lung HPV that might occur during anesthesia. In the following discussion, the HPV issues or considerations are numbered as they are in Figure 48-29 (Figure Not Available) .

1. The distribution of the alveolar hypoxia is probably not a determinant of the amount of HPV; all regions of the lung (either the basilar or dependent parts of the lungs [supine or upright] or discrete anatomic units such as a lobe

   or single lung) respond to alveolar hypoxia with vasoconstriction. [306] However, recent evidence suggests that on a sublobar level, collateral ventilation may be the first line and HPV the second line of defense against the development of arterial hypoxemia. [307]
2. As with low V/Q ratios and nitrogen-ventilated lungs, it appears that the preponderance of blood flow reduction in acutely atelectatic lung is due to HPV and none of it to passive mechanical factors (such as vessel tortuosity). [153] [154] [155] This conclusion is based on the observation that reexpansion and ventilation of a collapsed lung with nitrogen (removing any mechanical factor) do not increase the blood flow to the lung, whereas ventilation with oxygen restores all the blood flow to precollapse values. This conclusion applies whether ventilation is spontaneous or due to positive pressure and whether the chest is open or closed. [154] In canines, a slight amount of further subacute (>30 min) decrease in blood flow to atelectatic lung may have been due to some mechanical effect of the atelectasis on lung blood vessels. [308] However, in humans a prolonged unilateral hypoxic challenge during anesthesia results in an immediate vasoconstrictor response with no further potentiation or diminution of the HPV response. [309]
3. Most systemic vasodilator drugs either inhibit regional HPV directly or have an effect in a clinical situation that is consistent with inhibition of regional HPV (i.e., decreasing Pa O_2 and increasing shunt in patients with acute respiratory disease). The vasodilator drugs that have been shown to inhibit HPV or to have a clinical effect con-sistent with inhibition of HPV are nitroglycerin, [296] [310] [311] [312] [313] [314] [315] [316] nitroprusside, [296] [317] [318] [319] [320] [321] [322] [323] dobutamine, [324] [325] several calcium antagonists, [326] [327] [328] [329] [330] [331] and many beta$_2$ -agonists (isoproterenol,ritodrine, orciprenaline, salbutamol, ATP, and glucagon). [325] [332] [333] [334] [335] [336] [337] [338] Nitric oxide, a potent inhaled pulmonaryvasodilator, has been studied extensively and is considered to inhibit HPV. [339] [340] [341] [342] [343] [344] Aminophylline and hydralazine may not decrease HPV. [345]
4. The effect of anesthetic drugs on regional HPV was previously discussed in the section *Effect of Anesthetics on Hypoxic Pulmonary Vasoconstriction.*
5. The HPV response is maximal at normal and decreased at either high or low pulmonary vascular pressure. The mechanism for high pulmonary vascular pressure inhibition of HPV (whether the cardiac output is high or low [346] [347] is simple; the pulmonary circulation is poorly endowed with smooth muscle and cannot constrict against an increased vascular pressure. Furthermore, in the one-lung ventilation situation in the LDP, it is obvious, with all other factors remaining constant, that the fraction of the cardiac output perfusing the collapsed nondependent lung will increase with increasing pulmonary arterial pressure (i.e., the effect of gravity will be overcome). [348] The mechanism for low pulmonary vascular pressure inhibition of HPV is more complex. For this to occur, the hypoxic compartment must be atelectatic. Under these circumstances, when pulmonary vascular pressure decreases, it is possible for part of the ventilated lung (but not the atelectatic lung) to be in a zone 1 condition (alveolar pressure increases in relation to pulmonary artery pressure) and to experience a

disproportionate increase in PVR, which would divert blood flow back over to the atelectatic lung, thereby inhibiting atelectatic lung HPV. [349]

6. The HPV response also is maximal when Pv O_2 is normal and is decreased by either high or low Pv O_2 . The mechanism for high PvO_2 inhibition of HPV is presumably due to reverse diffusion of oxygen, causing the oxygen tension of either the vessels, the interstitial or alveolar spaces, or all of these to be increased above the HPV threshold. [350] That is, if enough oxygen can reach some receptor in the small arteriole-capillary-alveolar area, then the vessels will not vasoconstrict. The mechanism for low Pv O_2 inhibition of HPV is a result of the low Pv O_2 decreasing alveolar oxygen tension in the normoxic compartment down to a level sufficient to induce HPV in the supposedly normoxic lung. [351] The HPV in the presumably normoxic lung competes against and offsets the HPV in the originally hypoxic lung and results in no blood flow diversion from the more obviously hypoxic lung.
7. Selectively decreasing the F IO_2 in the normoxic compartment (from 1.0 to 0.5 to 0.3) causes an increase in normoxic lung vascular tone, thereby decreasing blood flow diversion from hypoxic to normoxic lung. [351] Indeed, with unilateral lung injury, ventilation of both lungs with a hypoxic gas mixture (F IO_2 of 0.12) induces much more vasoconstriction in the normal, previously nonconstricted lung than in the injured and already hypoxically constricted lung, which redirects blood flow to, increases the shunt through, and increases edema in the injured lung. [352] In addition, the development of systemic hypoxemia, either when bilateral hypoxic ventilation is used or when there is a very largehypoxic compartment and a small normoxic compartment, may indirectly inhibit regional HPV by stimulation of arterial chemoreceptors. [353] At the other extreme, prolonged exposure to hyperoxia (F IO_2 of 1.0) for 68 hours blunts a subsequent whole-lung HPV response. [354]
8. Older studies have suggested that the vasoconstrictor drugs (dopamine, epinephrine, phenylephrine) constrict normoxic lung vessels preferentially, thereby disproportionately increasing normoxic lung [325] [329] [335] PVR. The increase in normoxic lung PVR would be expected to decrease normoxic lung blood flow and increase atelectatic lung blood flow. The HPV-inhibiting effect of vasoconstrictor drugs is similar to that of decreasing normoxic lung F IO_2 (see item 7). In recent years, dopamine has been extensively studied. Although one reasonably straightforward study [355] agrees well with previous studies, [325] [329] [335] [347] most recent studies [356] [357] [358] have shown no significant effect of dopamine on HPV and/or arterial oxygenation. On the basis of these latter more recent studies, dopamine appears to be a reasonable cardiovascular stimulant to use in patients with lung disease provided that arterial oxygenation is monitored.
9. Hypocapnia has been thought to directly inhibit and hypercapnia to directly enhance regional HPV. [346] [359] In addition, during one-lung ventilation conditions, hypocapnia can be produced only by hyperventilation of the one lung. The hyperventilation requires an increased ventilated lung airway pressure, which may cause increased ventilated lung PVR, which in turn may divert blood flow back into thehypoxic lung. Hypercapnia during one-lung ventilation seems to act as a vasoconstrictor by selectively increasing ventilated lung PVR (which would divert blood flow back to the nonventilated lung). In addition, hypercapnia is ordinarily caused by hypoventilation of the ventilated lung, which greatly increases the risk of developing low V/Q and atelectatic regions in the dependent lung. However, it should

be noted as a theoretical possibility that if hypoventilation of the dependent lung is associated with decreased ventilated lung airway pressure, ventilated lung pulmonary vascular resistance may be decreased, thus in turn promoting or enhancing HPV in the nonventilated lung.

10. The effects of changes in airway pressure due to PEEP and tidal volume changes are discussed in detail in the sections *Dependent Lung PEEP* and *Selective Dependent Lung PEEP.* In brief, selective application of PEEP to only normoxic ventilated lung will selectively increase PVR in the ventilated lung and shunt blood flow back into thehypoxic nonventilated lung (i.e., decrease nonventilated lung HPV). [360] [361] On the other hand, high-frequency ventilation of the gas-exchanging lung is associated with low airway pressure and enhancement of HPV in the collapsed lung. [362]

Figure 48-29 (Figure Not Available) Listing of many of the components of the anesthetic experience that might determine the amount of regional hypoxic pulmonary vasoconstriction (HPV). The clockwise numbering of considerations corresponds to the order in which these considerations are discussed in the text. V/Q, ventilation/perfusion ratio; PVP, pulmonary vascular pressure; Pv O_2 , mixed venous oxygen tension; F IO_2 , inspired oxygen fraction; P $AC O_2$, alveolar carbon dioxide tension; PEEP, positive end-expiratory pressure. *(From Benumof [604])*

Finally, there is some evidence that certain types of infections (which may cause atelectasis), particularly granulomatous and pneumococcal infections, may inhibit HPV. [363] [364]

Blood Flow to the Dependent Ventilated Lung

The dependent lung usually has an increased amount of blood flow due to both passive gravitational effects and active nondependent lung vasoconstrictor effects. However, the dependent lung may also have a hypoxic compartment (area of low V/Q ratio and atelectasis) that was present preoperatively or that developed intraoperatively. This hypoxic compartment may develop intraoperatively for several reasons. First, in the LDP the ventilated dependent lung usually has a reduced lung volume resulting from the combined factors of induction of general anesthesia and circumferential (and perhaps severe) compression by the mediastinum from above, by the abdominal contents pressing against the diaphragm from the caudad side, and by suboptimal positioning effects (rolls, packs, chest supports) pushing in from the dependent side and axilla [207] [231] [334] [365] (see Fig. 48-13) (Figure Not Available) . Second, absorption atelectasis can also occur in regions of the dependent lung that have low V/Q ratios when they are exposed to high inspired oxygen concentration. [366] [367] Third, difficulty in secretion removal may cause the development of poorly ventilated and atelectatic areas in the dependent lung. Finally, maintaining the LDP for prolonged periods may cause fluid to transude into the dependent lung (which may be vertically below the left atrium) and cause further decrease in lung volume and increase in airway closure in the dependent lung. [368]

The development of low V/Q ratio and/or atelectatic areas in the dependent lung increases vascular resistance in the dependent lung [365] [369] (because of dependent lung HPV), [306] thereby decreasing dependent lung blood flow and increasing nondependent lung blood flow. [370] Stated differently, the PVR in the ventilated compartment of the lung determines the ability of the ventilated, and supposedly normoxic, lung to accept redistributed blood flow from the hypoxic lung. Clinical conditions that are independent of specific dependent lung disease but that may still increase dependent lung vascular resistance in a dose-dependent manner are a decreasing inspired oxygen tension in the dependent lung (from 1.0 to 0.5 to 0.3) [351] [370] and decreasing temperature (from 40 to 30°C). [371]

Miscellaneous Causes of Hypoxemia During One-Lung Ventilation

Still other factors may contribute to hypoxemia during one-lung ventilation. Hypoxemia due to mechanical failure of the oxygen supply system or the anesthesia machine is a recognized hazard of any kind of anesthesia. Gross hypoventilation of the dependent lung can be a major cause of hypoxemia. Malfunction of the dependent lung airway lumen (blockage by secretions) and malposition of the DLT are, in our experience, frequent causes of increased P(A-a) O_2 and hypoxemia. Resorption of residual oxygen from the nonventilated lung is time-dependent and accounts for a gradual increase in shunt and decrease in Pa O_2 after one-lung ventilation is initiated. [369] With all other anesthetic and surgical factors constant, anything that decreases the Pv O_2 (decreased cardiac output, increased oxygen consumption [excessive sympathetic nervous system stimulation, hyperthermia, shivering]) causes increased P(A-a) O_2 . [372] [373] Finally, transfusion of blood may cause pulmonary dysfunction, and the dysfunction has been attributed to the action of isoantibodies against leukocytes, which causes cellular aggregation, microvascular occlusion, and capillary leakage. Indeed, such a reaction has been described during prolonged one-lung ventilation. [374] Interestingly, the noncollapsed lung was preferentially injured, and the collapsed lung showed only minimal radiologic signs of edema after reexpansion. [374]

Conventional Management of One-Lung Ventilation

The proper initial conventional management of one-lung ventilation is logically based on the preceding determinants of blood flow distribution during one-lung ventilation. In view of the fact that one-lung ventilation incurs a definite risk of causing systemic hypoxemia, it is extremely important that dependent lung ventilation, as it affects these determinants, be optimally managed. This section considers the usual management of one-lung ventilation in terms of the most appropriate F IO_2 , tidal volume, and respiratory rate (Table 48-15) .

Inspired Oxygen Concentration

Although the theoretical possibilities of absorption atelectasis and oxygen toxicity exist, the benefits of ventilating the

TABLE 48-15 -- Initial Conventional Ventilatory Management of One-Lung Anesthesia

1. Maintain two-lung ventilation as long as possible.
2. Use F IO_2 = 1.0.
3. Begin one-lung ventilation with tidal volume of 10 mL/kg.

4. Adjust respiratory rate so that Pa CO_2 = 40 mm Hg.

5. Use continuous monitoring of oxygenation and ventilation.

dependent lung with 100 percent oxygen far exceed the risks. A high F IO_2 in the single ventilated lung may critically increase Pa O_2 from arrhythmogenic and life-threatening levels to safer levels.

In addition, a high F IO_2 in the dependent lung causes vasodilation, thereby increasing the dependent lung capability of accepting blood flow redistribution due to nondependent lung HPV. Direct chemical 100 percent oxygen toxicity does not occur during the operative period, [375] and absorption atelectasis in the dependent lung [375] is unlikely to occur in view of the remaining one-lung ventilation management characteristics (moderately large tidal volumes with intermittent positive-pressure, low-level PEEP). If the anesthesiologist is concerned about and wishes to limit the F IO_2 in patients treated with either bleomycin or mitomycin, it is possible to carefully increase or decrease F IO_2 to both lungs independently in an attempt to have the lowest F IO_2 to both lungs (even when CPAP is administered to the nonventilated lung). [376]

Tidal Volume

The dependent lung should be ventilated with a tidal volume of approximately 10 mL/kg. A much smaller tidal volume might promote dependent-lung atelectasis; a much greater tidal volume might excessively increase dependent lung airway pressure and vascular resistance [369] and thereby increase nondependent lung blood flow (decrease nondependent lung HPV). [360] [377] [378] If a tidal volume of 10 mL/kg causes excessive airway pressure, it should be lowered (after mechanical causes [i.e., tube malfunction] have been ruled out) and the respiratory rate increased (see later).

A dependent-lung tidal volume of 10 mL/kg is in the middle of a range of tidal volumes (8-15 mL/kg) that have been found in one study not to affect arterial oxygenation greatly during one-lung ventilation. [302] In that study, changes in Pa O_2 with alterations in tidal volume (during stable one-lung ventilation conditions) in individual patients were variable and unpredictable in both degree and direction (although the mean value for the group did not change). Thus, it appears that changing the tidal volume from 15 to 8 mL/kg during one-lung ventilation has an unpredictable but usually not great impact on arterial oxygenation. [302]

Dependent Lung PEEP

No, or just a very low level of, dependent lung PEEP (<5 cm H_2O) should be used initially because of concern of unnecessarily increasing dependent lung PVR. Although this is unlikely to occur when dependent lung PEEP is less than 5 cm H_2O, [379] the presence of intrinsic PEEP during one-lung ventilation may make the total PEEP excessive [380] (see the section, *Selective Dependent-Lung PEEP*).

Respiratory Rate

The respiratory rate should be set so that the Pa CO_2 remains at 40 mm Hg. Because a dependent lung tidal volume of 10 mL/kg represents a 20 percent decrease from the usual two-lung tidal volume of 12 mL/kg, the respiratory rate usually has to be increased by 20 to 30 percent to maintain carbon dioxide hemostasis. The trade-off between decreased tidal volume and increased respiratory rate usually results in a constant minute ventilation; although ventilation and perfusion are considerably mismatched during one-lung ventilation, an unchanged minute ventilation during one-lung ventilation (as compared with two-lung ventilation) can continue to eliminate a normal amount of carbon dioxide because of the high diffusibility of carbon dioxide. [369] [381] [382] [383] Hypocapnia should be prevented because use of the airway pressure in the dependent lung necessary to produce systemic hypocapnia may excessively increase dependent lung vascular resistance. Furthermore, hypocapnia may directly inhibit HPV in the nondependent lung. [346] [359]

In summary, at the commencement of one-lung ventilation, 100 percent oxygen, a tidal volume of 10 mL/kg, and a 20 percent increase in respiratory rate are used as initial ventilation settings (see Table 48-15) . Ventilation and arte-rial oxygenation are monitored by use of arterial blood gases, end-tidal carbon dioxide concentration, and pulse oximetry. If there is a problem with either ventilation or arterial oxygenation, one or more of the differential lung management techniques described next are used.

Differential Lung Management of One-Lung Ventilation

Intermittent Inflation of the Nondependent Operative Lung

Intermittent inflation with oxygen of the collapsed lung during one-lung ventilation may be expected to increase Pa O_2 for a variable period of time. In a group of thoracic surgery patients undergoing one-lung ventilation with an inspired nitrous oxide fraction (F IN_2O) of 0.5 and an F IO_2 of 0.5, the collapsed lung was manually inflated with a breath every 5 minutes with 2 L of oxygen and the lung was then allowed to collapse again; Pa O_2 increased by more than 28 mm Hg following each inflation. [384] The beneficial effect of each inflation persisted to a large extent to the next breath even if at a gradually decreasing level. Although Pa O_2 decreased between inflations, it never reached the level observed in controls (no lung inflation) during 19 minutes of one-lung ventilation.

Selective Dependent Lung PEEP

Because the ventilated dependent lung often has decreased lung volume during one-lung ventilation (see Figs. 48-13 (Figure Not Available) , 48-28 (Figure Not Available) , and 48-30) , it is not surprising that several attempts have been made to improve oxygenation by selectively treating the ventilated lung with PEEP. [207] [237] [304] [360] [377] [378] An accepted risk of selective dependent lung PEEP is that the PEEP-induced increase in lung volume can cause compression of the small dependent lung intra-alveolar vessels and increase dependent lung PVR; this diverts blood flow from the ventilated lung to the nonventilated lung (see Fig. 48-30 , upper right panel), increasing the shunt and decreasing the Pa O_2 . That increases

Figure 48-30 Four-part schematic diagram showing the effects of various differential lung management approaches. (A) The one-lung ventilation situation. The DOWN (dependent) lung is ventilated (VENT) but is compressed by the weight of the mediastinum (M) from above, the pressure of the abdominal contents against the diaphragm (D), and by positioning effects of rolls, packs, and shoulder supports (P). The UP (nondependent) lung is nonventilated (NONVENT), and blood flow through this lung is shunt flow. (B) The dependent lung has been selectively treated with PEEP, which improves V/Q relationships in the dependent lung but also increases dependent lung vascular resistance; this diverts blood to, and thereby increases shunt flow through, the nonventilated lung. (C) Selective application of CPAP to the nondependent lung permits oxygen uptake from this lung; even if the CPAP causes an increase in vascular resistance and diverts blood flow to the dependent lung, the diverted blood flow can still participate in gas exchange in the ventilated dependent lung. Consequently, selective nondependent lung CPAP can greatly increase Pa O_2 . (D) With differential lung CPAP (nondependent lung)/PEEP (dependent lung), it does not matter where the blood flow goes, since both lungs can participate in O_2 uptake. With this latter one-lung ventilation pattern, Pa O_2 can be restored to levels near those achieved by two-lung ventilation.

in both PEEP and tidal volume in the dependent ventilated lung have an additive effect in decreasing Pa O_2 during one-lung ventilation greatly supports the one-ventilated lung volume versus vascular resistance hypothesis. [377] Therefore, the effect of dependent lung PEEP on arterial oxygenation is a trade-off between the

positive effect of increasing dependent lung FRC and V/Q ratio and the negative effect of increasing dependent lung PVR and shunting blood flow to the nonventilated lung. Not surprisingly, then, the various one-lung ventilation-PEEP studies have had patients who have had an increase, [304] [377] [385] no change, [377] [385] [386] [387] or a decrease [304] [377] [385] [388] [389] [390] in oxygenation. It may be expected that in patients with a very diseased dependent lung (low lung volume and low V/Q ratio), the positive effects of selective dependent lung PEEP (increased lung volume and increased V/Q ratio) might outweigh the negative effects (shunting of blood flow to the nonventilated, nondependent lung), whereas in patients with a normal dependent lung, the negative effects would outweigh the benefits. Indeed, in one study in which 10 cm H_2O PEEP was selectively applied to the dependent lung, Pa O_2 increased in those patients with an initial Pa O_2 of less than 80 mm Hg (F_{IO_2} of 0.5), whereas Pa O_2 decreased or remained constant in patients with an initial Pa O_2 higher than 80 mm Hg (F_{IO_2} of 0.5). [385] [390] Presumably, in the patients with Pa O_2 lower than 80 mm Hg, the dependent lung had a low FRC (low V/Q ratio and atelectatic regions); therefore, the positive effect of increased dependent lung volume predominated over the negative effect of shunting blood flow to the nonventilated lung. Conversely, the patients with the higher Pa O_2 presumably had a dependent lung with an adequate FRC and V/Q ratio, and the negative effect of shunting blood flow to the nonventilated lung predominated over the positive effect of increased dependent lung volume. Although a dose (ventilated lung PEEP) versus response (Pa O_2, Q_S/Q_T value) relationship has been poorly described, it seems reasonable to postulate on the basis of these results [304] [377] [385] [386] [387] [388] [389] [390] that the therapeutic margin of using PEEP to increase Pa O_2 during one-lung ventilation is quite narrow. PEEP only to the dependent ventilated lung may be delivered by the same anesthesia apparatus that is ordinarily used to deliver PEEP to the whole lung. Other studies have shown that high tidal volumes, [301] variations in the inspiratory/expiratory ratio, [386] and intermittent manual hyperventilation of the lower lung are not beneficial in increasing Pa O_2 during one-lung ventilation. [386]

Low levels of positive pressure can be selectively and statically applied to only the nonventilated, nondependent lung. Because under these conditions the nonventilated lung is only slightly but constantly distended by oxygen, an appropriate term for this ventilatory arrangement is *nonventilated lung CPAP.* The application of CPAP (without tidal ventilation) to only the nonventilated lung significantly increases oxygenation. [388] [391] Also, the institution of 10 cm H_2O nondependent lung CPAP in patients has no significant hemodynamic effect. [385] [389] Low levels of CPAP simply maintain the patency of nondependent lung airways, allowing some oxygen distention of the gas exchanging alveolar space in the nondependent lung (Fig. 48-30 C) without significantly affecting the pulmonary vasculature. In all clinical studies, [385] [388] [389] [392] the application of 5 to 10 cm H_2O CPAP has not interfered with the performance of surgery and may, in fact, facilitate intralobar dissection. This is not surprising in view of the fact that the initial compliance of a collapsed lung is only 10 mL/cm H_2O, and 5 to 10 cm H_2O CPAP should create only a slightly distended lung that occupies a volume of 50 to 100 mL, which is hardly or not at all noticed by the surgeon.

On the other hand, in a canine study, [391] 15 cm H_2O of nondependent lung CPAP caused changes in Pa O_2 and shunt similar to those of 5 to 10 cm H_2O of nondependent lung CPAP, whereas blood flow to the nonventilated nondependent lung decreased significantly. Therefore, high levels of nonventilated lung CPAP act by permitting oxygen uptake in the nonventilated lung as well as by causing blood flow diversion to the ventilated lung, where both oxygen and carbon dioxide exchange can take place (see Fig. 48-30 C). Because low levels of nonventilated lung CPAP are as efficacious as high levels and have less surgical interference and hemodynamic implications, it is logical to use low levels of nonventilated CPAP first.

In all patients in all clinical studies to date, 5 to 10 cm H_2O of nondependent lung CPAP has significantly increased Pa O_2 during one-lung ventilation. [385] [388] [389] [392] [393] [394] [395] It should be concluded that the single most efficacious maneuver to increase Pa O_2 during one-lung ventilation is to apply 5 to 10 cm H_2O of CPAP to the nondependent lung. In our experience, low levels of nonventilated lung CPAP have corrected severe hypoxemia (Pa O_2 <50 mm Hg) more than 95 percent of the time, provided that the DLT was correctly positioned. However, the nondependent lung CPAP must be applied during the deflation phase of a large tidal volume so that the deflating lung can lock into a CPAP level with uniform expansion and obviate the need to overcome critical opening pressures of airways and alveoli.

In both the human [388] and canine [391] studies, oxygen insufflation at zero airway pressure did not significantly improve Pa O_2 and shunt, and this result was probably due to the inability of zero transbronchial airway pressure to maintain airway patency and overcome critical alveolar opening pressures. Although one study in patients has concluded that insufflation of O_2 at zero airway pressure does increase Pa O_2, the study is difficult to interpret, because the patients did not serve as their own controls. [396]

Several selective nondependent lung CPAP systems that are easy to assemble have been described. [389] [393] [394] [395] All these nondependent lung CPAP systems have three features in common (Fig. 48-31) (Figure Not Available) . First, there must be a source of oxygen to flow into the nonventilated lung. Second, there must be some sort of restrictive mechanism (hand-screw valve, pop-off valve, weight-loaded valve) to retard the egress of oxygen from the nonventilated lung so that the nonventilated lung may become distended. Thus, oxygen from a free-flowing pressurized source flows into a lung, but the escape of the oxygen is restricted; the unrestricted flow in and the restricted flow out create a constant distending pressure. Third, the distending pressure must be measured by a manometer. In practice, it is often simplest to keep the restrictive mechanism constant and adjust the distending pressure with a relatively fine sensitivity by changing the oxygen flow rate. If the nondependent lung CPAP system includes a reservoir bag (which is highly desirable),

Figure 48-31 (Figure Not Available) The three essential components of a nondependent lung CPAP system consist of (1) an oxygen source, (2) a pressure relief valve, and (3) a pressure manometer to measure the CPAP. The CPAP is created by the free flow of oxygen into the lung versus the restricted outflow of oxygen from the lung by the pressure relief valve. ZEEP, zero end-expiratory pressure. *(From Benumof [604])*

the reservoir bag will reflect the amount of CPAP (by distention), and the nondependent lung may also be ventilated with intermittent positive pressure whenever desired.

The availability of a commercial nondependent nonventilated lung CPAP device (Mallinckrodt Medical, Inc.) replaces the need for all homemade devices. The Broncho-Cath CPAP System (Fig. 48-32) is similar in concept to the

system shown in Figure 48-31 (Figure Not Available) except that the restrictive mechanism is a continuously vented slot (opening); the larger the vent slot, the lower the CPAP level delivered, and the smaller the vent slot, the higher the CPAP level. The level of CPAP is selected by simply turning an outer calibrated cylinder (calibrated for an oxygen flow rate of 5 L/min), which progressively uncovers the inner (pop-off) slot. Because the dial is calibrated and marked with the CPAP level selected, a pressure manometer is unnecessary. The rest of the CPAP system consists of the other components shown in Figure 48-31 (Figure Not Available) . (oxygen tubing, reservoir bag). A unique feature of the Broncho-Cath CPAP System is the fact that the valve is continuously vented. Because the vent slot cannot be totally occluded, the danger of overpressurization of the nondependent lung is minimized. In addition, the CPAP system is calibrated from 1 to 10 cm H_2O pressure, which permits accurate delivery of very low levels of CPAP. This may be desirable with extremely compliant lungs or where maximum surgical exposure is required. This small, lightweight CPAP device can be included within the DLT package (the DLT is available with or without the CPAP device), is extremely easy to use, and is preassembled, cost-effective, sterile, reliable, and disposable. Perhaps its most important attribute is that a preassembled device is obviously more readily available than devices that require a search for spare parts, and the commercial product has built-in quality assurance that cannot be duplicated by individual remedies.

Differential Lung PEEP/CPAP

In theory and from the preceding considerations, it appears that the ideal way to improve oxygenation during one-lung ventilation is the application of differential lung PEEP/CPAP (see Fig. 48-30 D) (see the following section for the step-by-step approach). In this situation, the ventilated (dependent) lung is given PEEP in the usual conventional manner in an effort to improve ventilated lung volume and V/Q relationships. Simultaneously, the nonventilated (nondependent) lung receives CPAP in an attempt to improve oxygenation of the blood perfusing this lung. Therefore, with differential lung PEEP/CPAP, it does not matter where the blood flow goes nearly as much as during simple one-lung ventilation, because wherever it goes (to either ventilated or nonventilated lung), it has at least some chance to participate in gas exchange with alveoli that are expanded with oxygen. In indirect support of this contention, arterial oxygenation has been increased significantly in patients during thoracotomy in the LDP (using two-lung ventilation) when PEEP has been added to the ventilated dependent lung, while the nondependent lung was also able to participate in gas exchange by virtue of being ventilated at zero end-expiratory pressure (ZEEP). [237] In direct support of this contention, in patients undergoing thoracotomy and one-lung ventilation, arterial oxygenation was unchanged by the application of 10 cm H_2O dependent lung PEEP alone (consistent with an equal positive/negative effect trade-off), was significantly improved by 10 cm H_2O nondependent lung CPAP alone, and was further and even more significantly increased by use of 10 cm H_2O nondependent lung CPAP and 10 cm H_2O dependent lung PEEP together (differential lung PEEP/CPAP ventilation). [385] [389] The use of 10 cm H_2O nondependent lung CPAP together with 10 cm H_2O dependent lung PEEP in patients caused only small, clinically insignificant hemodynamic effects. [385] [389]

There are multiple reports of significant increases in oxygenation obtained with the application of differential lung ventilation and PEEP (either PEEP/PEEP, PEEP/CPAP, or CPAP/CPAP) through DLTs to intensive care unit patients with acute respiratory failure due to predominantly unilateral lung disease. [397] In all cases conventional two-lung therapy (mechanical ventilation, PEEP, CPAP) had been administered via a standard single-lumen tube and either failed to improve or actually decreased oxygenation. In these patients the single-lumen tube was replaced with a DLT. In most cases the amount of PEEP initially administered to each lung was inversely proportional to the compliance of each lung; ideally, this PEEP arrangement should result in equal FRC in each lung. In some cases, the amount of PEEP that each lung received was later adjusted and titrated in an effort to find a differential lung PEEP combination that resulted in the lowest right-to-left transpulmonary shunt. This treatment modality for severe unilateral lung disease is discussed more fully in Chapter 72 .

Recommended Combined Conventional and Differential Lung Management of One-Lung Ventilation

Figure 48-33 summarizes the recommended plan for obtaining satisfactory arterial oxygenation during one-lung anesthesia. Two-lung ventilation is maintained for as long as possible (usually until the pleura is opened). When one-lung ventilation is commenced, a tidal volume of 10 mL/kg is used, and the respiratory rate is adjusted so that Pa_{CO_2} equals 40 mm Hg. A high inspired oxygen concentration (F_{IO_2} of 0.8-1.0) should be used, and Sa_{O_2} should be monitored continuously.

Figure 48-33 An overall one-lung ventilation plan. F_{IO_2}, inspired oxygen concentration; TV, tidal volume; RR, respiratory rate; PEEP, positive end-expiratory pressure; CPAP, continuous positive airway pressure; ASAP, as soon as possible.

TABLE 48-16 -- Characteristics of the Three Types of High-Frequency Ventilation

TYPE OF HFV	RATE/MIN	TYPE OF VENTILATOR	GAS ENTRAINMENT	PROCESS	
				INSPIRATION	EXHALATION
HFPPV	60-100	Volume	No	Active [a]	Passive [a]
HFJV	100-400	Jet pulsation	Yes	Active	Passive
HFOV	400-2,400	Piston pump	Yes	Active	Active

Abbreviations: HFPPV, High-frequency positive pressure ventilation; HFJV, high-frequency jet ventilation; HFOV, high-frequency oscillatory ventilation.

[a] Active, caused by the ventilator. Passive, caused by elastic recoil of lung.

If hypoxemia is present after this initial conventional approach, two major causes of hypoxemia, namely malposition of the DLT and poor hemodynamic status, must be ruled out. Proper tube position should be confirmed via fiberoptic bronchoscopy. If the DLT is correctly positioned and the hemodynamic status is satisfactory, simple tidal volume and respiratory rate adjustments should be made. [302] For example, if the tidal ventilation is thought to be too high, it should be decreased, and if the tidal ventilation is thought to be too low, it should be increased. If these simple maneuvers do not quickly resolve the problem, the studies of selective nondependent lung CPAP [385] [388] [389] [390] [391] [392] [393] [394] [395] and differential lung PEEP [397] dictate that the next treatment should be to apply 5 to 10 cm H_2O of CPAP to the nondependent lung. Nondependent lung CPAP should be applied during the deflation phase of a large tidal volume breath to overcome critical opening pressures in the atelectatic lung. If oxygenation does not improve with nondependent lung CPAP (as it does in the large majority of cases), 5 to 10 cm H_2O of PEEP should then be applied to the ventilated dependent lung. If dependent lung PEEP does not improve oxygenation, nondependent lung CPAP should be increased to 10 to 15 cm H_2O while the dependent lung is maintained at 5 to 10 cm H_2O of PEEP. If arterial oxygenation is still not satisfactory, the nondependent lung CPAP level should be matched with an equal amount of dependent lung PEEP. In this way, a differential lung PEEP/CPAP search for the maximum compliance and a minimum right-to-left transpulmonary shunt are made in an attempt to find the optimal end-expiratory pressure for each lung and the patient as a whole.

If severe hypoxemia persists after the application of differential lung PEEP/CPAP (which would be extremely rare), it should be remembered that the nondependent lung may be intermittently ventilated with positive pressure with oxygen (see Fig. 48-33) . Finally, most of the V/Q imbalance is eliminated during a pneumonectomy by tightening a ligature around the nonventilated lung pulmonary artery as early as possible, thus directly eliminating all shunt flow through the nonventilated lung (see Fig. 48-33) . Indeed, clamping the pulmonary artery to a collapsed lung functionally resects the entire lung, and the Pa_{O_2} is restored to a level not significantly different from a two-lung ventilation or postpneumonectomy one-lung ventilation value.

Because nondependent lung CPAP has been shown to relieve hypoxemia consistently and reliably during one-lung ventilation, [388] [389] its routine use to prevent hypoxemia during thoracic surgery using DLTs should be considered. Low levels of CPAP used in this manner have not compromised surgical conditions and have occasionally improved surgical exposure by facilitating the identification of intralobar planes. [385] [388] [389] [395]

High-Frequency Ventilation Management of Thoracic Surgery

Conventional intermittent positive-pressure ventilation delivers relatively large tidal volumes (10-15 mL/kg) at respiratory rates usually less than 30 breaths/min. In contrast, high-frequency ventilation (HFV) delivers very small tidal volumes (<2 mL/kg) at rates between 60 and 2,400 breaths/min. Because HFV uses much smaller tidal volumes (and much lower peak inspiratory airway pressures), which can be delivered through very small airway catheters, it may be uniquely useful in facilitating the performance of thoracic surgery in the following three ways.

High-frequency ventilation is an umbrella term encompassing different delivery systems and respiratory rate ranges. Current methods used to provide HFV are quite diverse, but by using the criteria of ventilation rate and type of gas delivery mechanism, it is possible to separate HFV into three general categories (Table 48-16) . With regard to oxygenation, all forms of HFV should be regarded as a method of achieving PEEP (or above ambient airway pressure) and thereby minimizing shunt without the necessity of imposing a large volume (and pressure) excursion on top of this to eliminate carbon dioxide. It is conceptually similar to the approach of holding the lung slightly to moderately distended with an increased mean airway pressure and thereby minimizing shunt while removing carbon dioxide by an extracorporeal membrane. [398] [399]

Use in Major Conducting Airway Surgery

The most important advantage of HFV in thoracic surgery is that the small rapid tidal volumes may be delivered through small airway tubes; thus, if a major conducting airway (trachea, carinal area, main stem bronchus) has to be divided, the transit of a small airway tube through the surgical field causes much less interference with surgery than the passage of a large standard or double-lumen endotracheal tube. The small airway catheters present the surgeon with a relatively unobstructed, accessible circumference of trachea

and bronchus, so that the ends of a divided airway can be properly aligned for the construction of an unstressed and airtight anastomosis. Both high-frequency positive pressure ventilation (HFPPV) and high-frequency jet ventilation (HFJV) have been used successfully with small airway catheters for several different types of airway surgery. [400] In contradistinction to these findings with HFPPV, high-frequency oscillatory ventilation delivered through a standard single-lumen tube has been found to cause changes in the diameter of large airways and to produce a large "mediastinal bounce" with each oscillation, which "made surgery on the major airways and around the hilum and mediastinal structures almost impossible." [401] With all types of HFV for airway surgery, the logistics of small catheter placement and securement are formidable, and suctioning the airway and distal lung may be problematic.

Use in Bronchopleural Fistula

The second proposed advantage of HFV for thoracic surgery is that the lower inspiratory pressures and tidal volumes may result in a smaller gas leak through pathologic low-resistance pathways such as bronchopleural fistulas and tracheobronchial disruptions. Consequently, air leaks (loss of tidal volume) and mediastinal and interstitial emphysema may be minimized with this form of ventilatory treatment, and HFV has been successfully used in the treatment of major bronchopleural fistulas and tracheobronchial disruptions. [400] In most of the bronchopleural fistula cases, Pa CO_2 was unacceptably high despite a high minute ventilation on volume-controlled intermittent positive-pressure ventilation, whereas HFJV restored normocarbia. However, it appears that the reduction in air leak flow through the fistula is directly related to reduced airway pressure with HFV as compared with conventional mechanical ventilation; when peak and mean tracheal pressures are decreased by HFV, fistula leak is decreased, and when peak and mean tracheal pressures are increased by HFV, fistula flow increases. Thus, in a report by Albelda et al [402] of seven consecutive patients with an average bronchopleural fistula leak greater than 5 L/min, HFJV (125-150/min) caused only two patients to have clinically important decreases in airway pressure and air leak fistula flow, and none had significant improvement in gas exchange. The authors recommend measurement of tracheal pressures to predict what is happening to air leak fistula flow. [402] Thus, it is likely that investigations in the use of HFV to treat patients with pathologic low-resistance airway pathways will continue.

Use in Minimizing Movement of the Operative Field

The third proposed advantage of HFV for thoracic surgery is to minimize the tidal movement of the operative field; theoretically, the lower peak inspiratory pressures and tidal volumes of HFV should result in much smaller inflation and deflation movements of the lung. Therefore, HFV of the nondependent lung might provide a relatively "quiet" operative lung field, and HFV of the dependent lung could contribute to the quiet lung field by providing a minimally moving mediastinum. [400] Unfortunately, in no report was the use of HFV compared with conventional one-lung ventilation, with or without nondependent lung CPAP, in terms of operating conditions and efficiency of gas exchange.

The studies of selective nondependent lung CPAP indicate that delivery of any amount of oxygen to the nondependent lung alveolar space will cause some oxygen uptake from the nondependent lung and decrease the right-to-left shunt in this lung. Consequently, it is not surprising that selective HFV of the nondependent lung, while the dependent lung is ventilated with conventional intermittent positive-pressure breathing, increases Pa O_2 compared with simple collapse of the nondependent lung and conventional mechanical ventilation of the dependent lung. [403] However, because the same increase in arterial oxygenation and operative conditions may be obtained by selective nondependent lung CPAP with much simpler equipment than HFV apparatus, it is more logical to use selective nondependent lung CPAP than HFV to improve arterial oxygenation and operative conditions during one-lung ventilation.

In one report the dependent lung was selectively ventilated with HFV while the operated lung was completely collapsed. [404] As compared with selective dependent lung intermittent positive-pressure ventilation, selective dependent lung HFV significantly improved arterial oxygenation, presumably because of lower dependent lung PVR (due to either lower dependent lung airway pressures [405] or release of dependent lung vasodilator prostaglandins [406]) and enhanced operating conditions (because of minimal mediastinal movements). However, the use of dependent lung HFV to minimize mediastinal and hilar movements must remain controversial in view of a 1986 report describing a mediastinal bounce with each oscillation, which made surgery around these structures nearly impossible. [401]

In summary, in view of the limitations of HFV, its use as a routine procedure for all three possible thoracic surgery situations (airway surgery, bronchopleural fistulas, minimizing operative field movement) cannot be recommended.

Low-Flow Apneic Ventilation (Apneic Insufflation)

The need for an absolutely quiet surgical field for short periods often arises during a thoracotomy in which a standard endotracheal tube and two-lung ventilation are used. This can be accomplished relatively safely by using the principle of apneic mass-movement oxygenation. Indeed, this method gained considerable popularity around the time DLTs were being introduced into clinical practice. If ventilation is stopped during the administration of 100 percent oxygen and the airway is left connected to a fresh gas supply, oxygen will be drawn into the lung by mass movement to replace the oxygen that crossed the alveolocapillary membrane. There is usually no difficulty in maintaining an adequate Pa O_2 (especially if 5-10 cm H_2O of CPAP is used) during at least 20 minutes of apneic mass-movement oxygenation.

If the flow of oxygen into the lungs is relatively low (<0.1 L/kg/min) almost all the carbon dioxide produced is retained, and the arterial carbon dioxide tension (Pa CO_2) rises approximately 6 mm Hg in the first minute because of the

washin of venous blood into the arterial compartment (venous blood has a carbon dioxide tension 6 mm Hg higher than that of arterial blood) and then 3 to 4 mm Hg each minute thereafter because of normal carbon dioxide production. [407] [408] On the basis of these considerations, if a patient had normal carbon dioxide production, was hyperventilated to a Pa CO_2 of 30 mm Hg, and was then made apneic and had oxygen insufflated into the lungs with a low flow, the Pa CO_2 after 10 minutes of apnea would be 63 to 72 mm Hg. Indeed, one report describes a series of eight patients in whom apneic mass-movement oxygenation was used for 18 to 55 minutes after normal ventilation. [407] Although the lowest arterial saturation that resulted was 98 percent, the Pa CO_2 in the five patients in whom it was measured ranged from 103 to 250 mm Hg, and the pH ranged from 6.72 to 6.97. Although severe degrees of hypercapnia and respiratory acidosis may be well tolerated in some healthy patients, it would appear that the safe period of low-flow apneic oxygenation during thoracotomy would be well below 10 minutes. Although it has not been studied, low-flow apneic oxygenation should theoretically be able to be used when a DLT is used. In all cases in which this technique is used, arterial oxygen saturation monitoring via pulse oximetry is mandatory.

THE POSTOPERATIVE PERIOD

Early Serious Complications Specifically Related to Thoracic Surgery

Herniation of the Heart

An intrapericardial approach may be used for radical pneumonectomy to facilitate access to major vessels and allow a wider hilar dissection. This technique may result in a large pericardial defect that the surgeon is not able to close after the pneumonectomy is completed. There have been several reports of herniation of the heart [409] through the pericardial opening into the empty hemithorax. The herniation can be into either the right or left hemithorax, and herniation into either side can cause profound cardiac functional impairment; the mortality rate is 50 percent.

With herniation, the heart protrudes through the defect into one of the hemithoraces, potentially causing twisting of the superior vena cava (superior vena cava syndrome), inferior vena cava (cardiovascular collapse), distal trachea (wheezing), pulmonary veins (pulmonary edema), and pericardial constriction of the heart (myocardial ischemia and ventricular arrhythmia). These symptoms may occur individually or in various combinations.

In most reports herniation of the heart has occurred either immediately after the patient is turned from the LDP to the supine position (75%) or during the first few hours of postoperative mechanical ventilation. However, this complication can also occur as late as several days after surgery. Events that increase intrapleural pressure in the nonsurgical (ventilated) hemithorax or that decrease intrapleural pressure in the surgical (empty) hemithorax may predispose the patient to cardiac herniation. Placing the patient with the empty hemithorax in a dependent position allows the heart to be pulled by gravity into the empty hemithorax. Use of high levels of pressure and volume during mechanical ventilation of the remaining lung can push the heart into the empty hemithorax. Similarly, coughing can increase pleural pressure in the remaining lung and thereby promote displacement of the heart into the empty hemithorax. Conversely, inadvertently applying suction to a chest drain in the empty hemithorax can pull the heart through a pericardial defect (tension vacuthorax).

The diagnosis of cardiac herniation is made by the sudden appearance of catastrophic symptoms in a patient who had a radical pneumonectomy, the presence of a predisposing condition (see earlier), and a chest radiograph that shows the apex of the heart to be pointing to a lateral chest wall at a right angle. [410] A diagnosis of cardiac herniation almost always necessitates immediate reexploration.

Five conservative measures may improve cardiopulmonary function before and during transfer to the operating room (they are the reverse of the causes of herniation of the heart discussed previously), and they should be instituted as soon as the diagnosis is entertained. First, the patient should be positioned so that the ventilated nonsurgical side is in a dependent position and the empty surgical side is in a nondependent position. Gravity may return the heart and mediastinum to their normal anatomic positions. Even if the heart does not reenter the pericardium, the repositioning may decrease atriocaval kinking and increase cardiac output. Second, avoidance of high levels of pressure and volume in the ventilated lung may allow the return of the heart to the pericardium. Consequently, the tidal volume should be reduced, PEEP should be removed, and the respiratory rate should be increased slightly. Third, suction to the empty hemithorax should be discontinued. Fourth, pharmacologic support of the circulation should be provided as needed. Fifth, injecting 1 to 2 L of air into the surgical hemithorax may push the heart and mediastinum back to a normal anatomic position and perhaps the heart back into the pericardium. Success with this latter technique has been variable. [409]

Pulmonary Torsion

Pulmonary torsion refers to rotation of the parenchyma on its bronchovascular pedicle and is thought to be due to increased mobility of a lobe (as may occur to the remaining lobes in one hemithorax after a lobectomy). Any patient with atelectasis or an expanding intrathoracic mass and perhaps with severe chest pain following thoracotomy should have lung torsion included in the differential diagnosis, which also includes intrathoracic bleeding and progressive atelectasis. Because torsion compromises the pulmonary vasculature (both arteries and veins) as well as the bronchi, prompt recognition and surgical intervention are required to avoid the attendant morbidity and mortality (i.e., infarction and gangrene). [410]

A double-lumen endotracheal tube should be inserted before surgery if pulmonary torsion is suspected because during surgical correction of this condition (either completion pneumonectomy or untwisting and stabilization of the lobe to another lobe or chest wall), massive hemorrhage into

the airways may occur owing to release of entrapped blood and continuing bleeding from necrotic lung tissue (i.e., vessels and airways), drowning the dependent lung and producing severe hypoxia or death. Other intraoperative therapeutic modalities that the anesthesiologist should consider include use of intravenous steroids to decrease any reactive pulmonary inflammation, use of PEEP to reexpand atelectatic lung tissue, and saline lavage for the removal of any excess blood that might form clots in the normal airways and thereby obstruct healthy lung parenchyma.

Major Hemorrhage

Postoperative bleeding that necessitates emergency thoracotomy [409] may occur in as many as 3 percent of all thoracot-omy patients. [411] The mortality of major postoperative bleeding is approximately 23 percent. [411] The potential sources of major postoperative hemorrhage are bleeding from divided pulmonary arteries and veins due to slippage of surgical ligatures, diffuse bleeding from raw surfaces, and systemic arte-rial bleeding (bronchial and intercostal arteries).

The drainage from a patent chest tube is an excellent monitor of the amount of intrathoracic bleeding. In addition, the hematocrit of the usual fluid in the chest drainage is always less than 20 percent, and intrathoracic bleeding increases the hematocrit to some higher value. Significant hemorrhage, of course, is accompanied by the hemodynamic signs of hypovolemia. Significant hemorrhage cannot always be ruled out by the absence of chest tube drainage, because the chest tube may be blocked by clotted blood or otherwise obstructed. Nevertheless, the patient will still show signs and symptoms of hypovolemia and a shift in the mediastinum to the opposite side.

Bronchial Disruption

Development of a bronchopleural fistula is a serious complication of pulmonary resection and as recently as 1978 carried a mortality of 23 percent. [412] The symptoms and signs are variable and depend on the size of the communication, the presence or absence of a chest drain, and the presence of fluid of any sort within the pleural space.

Gross disruption of a bronchial stump is usually signaled by massive bubbling of gas through the chest tube drainage system, if present, tension pneumothorax if the

chest tube is not present, hypoxemia, and hypercapnia. Prompt resuscitation is essential and may need to include mechanical and differential or one-lung ventilation with a DLT and support of the circulation. A functioning chest tube, if not present, must be inserted immediately to evacuate the air (to prevent a tension pneumothorax) and fluid (to prevent further contamination of the opposite lung) from the pneumonectomy cavity; a needle can decompress the hemithorax while a chest tube is being inserted. The patient should be recumbent, with the normal side in a nondependent position. The stump must be closed surgically as soon as possible. [412]

It should be remembered that a tension pneumothorax may occur in the contralateral side if very high inflation pressures are used to expand a previously collapsed lung (as commonly occurs for one-lung ventilation); the tension pneumothorax may become apparent only after closure of the chest. Other causes of acute postoperative contralateral pneumothorax relevant to thoracic surgery include damage to the contralateral pleura during surgery, puncture of the pleura during insertion of a central venous cannula or thoracic epidural needle, or damage to the bronchus by use of an endobronchial catheter.

Development of a chronic bronchopleural fistula may be expected to occur in 1 to 3 percent of pulmonary resection patients. [412] A chronic bronchopleural fistula most frequently becomes evident within the first 2 weeks after operation and may run a fulminating course characterized by sepsis, empyema, purulent sputum, and respiratory insufficiency. Factors that predispose to the formation of a chronic bronchopleural fistula after pulmonary resection are preoperative irradiation, infection, residual neoplasm at the site of the closure, and the presence of a long or avascular stump.

Respiratory Insufficiency

Acute respiratory insufficiency (within 30 days of resection) is probably the most common serious complication after pulmonary resection. Recent data from a large thoracic surgery service indicate an incidence of 4.4 percent after bronchial carcinoma resections, and in this study, the patients who developed acute respiratory failure had a mortality rate of 50 percent. [413] Mortality from respiratory failure after right-sided pneumonectomy is greater than after pneumonectomy on the left side because the remaining functioning lung is smaller. [413] In addition to the usual mechanism of respiratory failure (Ch. 72) , pulmonary resection per se involves additional new mechanisms of hypoxemia and hypercarbia.

First, the remaining lung in either hemithorax may be edematous and/or soiled with blood. The lung that was dependent during surgery may be edematous and/or may have aspirated blood (if a DLT was not used) as a result of gravitational effects (in zones 3 and 4). The lung that was nondependent during surgery may be edematous and hemorrhagic because of surgical compression and trauma. Second, the size of the remaining pulmonary vascular bed is decreased; this decrease can lead to pulmonary edema. The treatment of respiratory insufficiency is discussed in detail in Chapter 72 .

Unilateral Reexpansion (Intraoperative) Pulmonary Edema

Sudden evacuation of a chronic or subacute pneumothorax or pulmonary effusion may cause edema of the ipsilateral lung (reexpansion pulmonary edema). [414] [415] Still other reports describe an even more acute form of reexpansion pulmonary edema associated with lung reexpansion after only several hours of atelectasis, [416] [417] including reexpansion of the nondependent lung after one-lung ventilation to facilitate thoracic surgery [418] [419] [420] [421] and following correction of an inadvertent main stem bronchial intubation. [416] [422]

Most clinical and experimental observations support increased pulmonary vascular permeability as a major factor in the development of reexpansion pulmonary edema. [423] [424] [425]

All the above clinical literature indicates that the rate of reexpansion may be more important than the duration of collapse in the development of reexpansion pulmonary edema. [414] [420] Thus, other mechanisms of reexpansion pulmonary edema include generation of markedly negative intrathoracic pressure during reexpansion and increased pulmonary capillary pressure and flow on lung reexpansion. Therefore, the most important factor in preventing reexpansion pulmonary edema is to reexpand the lung slowly and in a gradual fashion. The treatment of established reexpansion pulmonary edema is mechanical ventilation, PEEP, restriction of fluids, and diuretics.

Right Heart Failure

Major pulmonary resection results in a decrease in the cross-sectional area of the pulmonary vasculature and an increase in right ventricular afterload, which in some patients can result in acute right heart failure. Although patients at risk for developing right heart failure after pulmonary resection can usually be identified preoperatively, right heart failure may also occur if additional stresses, such as infection and increased pulmonary blood flow and new active pulmonary vasoconstriction (such as that caused by hypoxia, acidosis, vasoactive amines and peptides), are placed on the right side of the heart.

The diagnosis of selective right heart failure is established when the right atrial pressure exceeds the left atrial pressure (i.e., the pulmonary artery wedge pressure) in the presence of an abnormally low cardiac output. In addition, pulmonary hypertension with a pulmonary artery diastolic-wedge pressure gradient will usually be present, along with the systemic signs of left heart failure (oliguria, decreased mentation, peripheral edema). The treatment of acute right heart failure follows the same principles used to treat left-sided failure: control heart rate, optimize preload and the inotropic state of the right ventricle, and reduce PVR (Chs. 49 and 51) .

Right-to-Left Shunting Across a Patent Foramen Ovale

Many adults have a patent foramen ovale [409] ; at autopsy, the incidence of a probe-patent foramen ovale is highest at 34 percent during the first 3 decades of life and decreases to 20 percent by the 9th and 10th decades. There is normally no right-to-left shunting across the foramen ovale because left atrial pressure exceeds right atrial pressure; this pressure gradient keeps the one-way flap valve of the foramen ovale pressed against the opening, resulting in a functionally competent seal. If right atrial pressure exceeds left atrial pressure (as may be the result of any factor that increases PVR and right ventricular pressure), the one-way flap valve can open, and right-to-left shunting can occur through the newly opened foramen ovale. [409] Thus, new onset right-to-left shunting across a patent foramen ovale or atrial septal defect after pneumonectomy and lobectomy, as a cause of otherwise unexplained postoperative dyspnea and systemic oxygen desaturation, has occurred. [409] Use of contrast two-dimensional echocardiography combined with a saline bubble injection study is an excellent method of diagnosing this process, if suspected. Contrast angiography and dye dilution curve analysis are other available diagnostic methods. Nonsurgical treatment consists of decreasing right atrial preload and afterload; this procedure permits functional closure of the foramen ovale in the majority of patients.

Neural Injuries

During radical hilar dissection or excision of mediastinal tumors, phrenic, vagus, and recurrent laryngeal nerves may be injured accidentally or may be sacrificed deliberately. [409] Phrenic nerve injury causes respiratory embarrassment by a flail chest effect and also causes elevation of the ipsilateral hemidiaphragm. The diagnosis should be suspected in patients who have relatively clear chest radiographs, have adequate gas exchange, and cannot be weaned from the ventilator. The diagnosis can be confirmed by paradoxic movements of the diaphragm on fluoroscopy. Injury to the vagus nerve causes gastric and intestinal atony, which usually is not problematic in the first few postoperative days. Bilateral partial injury of the recurrent laryngeal nerve causes adductor spasm of the vocal cords, which, after extubation, may result in upper airway obstruction. This must be diagnosed promptly and treated with immediate reintubation and possible tracheotomy until the dysfunction is resolved.

Aside from clamping of the thoracic aorta with resultant ischemia to the spinal cord, there are two other causes of paraplegia after thoracotomy. First, damage to the spinal branches of intercostal arteries by dissection or diathermy at the posterior end of a rib may cause spinal cord ischemia. [427] This is most likely to occur with damage to the intercostal arteries of the left lower lobe. [428] Second, surgical dissection may create a communication between the epidural space and the pleural cavity. Clotted blood, or blood that can later clot, can then enter the epidural space and cause postoperative spinal cord compression and ischemia. [429] Similarly, expansion of hemostatic material (such as Surgisil) may result in cord injury.

Management of Postoperative Mechanical Ventilation

Most relatively healthy patients who have not had extensive thoracic operations may have their tracheas safely extubated in the operating room or shortly after arrival in the recovery room (Chs. 68 , 71 , and 72) . However, patients with severe chronic pulmonary disease who undergo extensive thoracic operations require a period of postoperative mechanical respiratory support. Careful clinical assessment and judgment are necessary for postoperative tracheal extubation of patients who are intermediate in terms of their respiratory health and the extent of their thoracic procedures. Precise criteria for continued intubation and mechanical ventilatory support are presented in Chapters 39 , 68 , and 72 . Whenever doubt exists, we urge caution in removing mechanical ventilatory support too rapidly from these patients; it is safest to support patients until clinical and laboratory data clearly indicate that extubation is safe. The following briefly describes our current practice of mechanical ventilation, weaning, and extubation.

TABLE 48-17 -- Mechanical Ventilation and Weaning Plan

GOAL NO. (TEMPORAL SEQUENCE TO BE FOLLOWED)	GOAL		ACHIEVED PRIMARILY BY
1. F_{IO_2}	$F_{IO_2} < 0.5$	$PaO_2 > 60$ mm Hg	PEEP titration
2. PEEP	$F_{IO_2} < 0.5$ PEEP < 10 cm H_2O	$PaO_2 > 60$ mm Hg	Respiratory care regimen
3. IMV rate	$F_{IO_2} < 0.5$, PEEP < 10 cm H_2O IMV < 1 breath/min	$PaO_2 > 60$ mm Hg	Patient with adequate breathing power

Abbreviations: F_{IO_2} , inspired oxygen concentration; PEEP, positive end-expiratory pressure; IMV, intermittent mandatory ventilation; Pa_{O_2} , arterial oxygen tension.

For most postoperative thoracotomy patients who require respiratory support, controlled mechanical ventilation is initiated after reintubation with a single-lumen tube, with a tidal volume equal to 12 mL/kg, an intermittent mandatory ventilation (IMV) rate so that the Pa_{CO_2} is 40 mm Hg (which usually requires an initial rate of 8 to 12 breaths/min), and with an inspired oxygen concentration of 60 to 100 percent. IMV used in this way is a full-support ventilation modality. The patients may breathe spontaneously, but at this initial ventilator stage, the spontaneous ventilation is not regarded as significantly contributing to the minute ventilation. The spontaneous ventilation with IMV may increase cardiac output and thereby decrease intravenous fluid requirements as well as eliminate the need for paralysis and heavy sedation. IMV may also facilitate the transition to weaning. Arterial blood gas values and chest radiographs are obtained shortly after the institution of mechanical ventilation in the recovery room.

An F_{IO_2} greater than 0.5 is toxic to the lungs, [430] and the first and compelling goal is to reduce the F_{IO_2} to less than 0.5 while maintaining an acceptable Pa_{O_2} (Table 48-17) . The decrease in F_{IO_2} below 50 percent is achieved by performing a dose (PEEP)-response (Pa_{O_2}) titration. PEEP is progressively added (range 0 to 20 mm Hg) until the Pa_{O_2} is relatively normal for that patient (or at least >60 mm Hg) with an F_{IO_2} less than 0.5. PEEP should be raised in increments of 2.5 to 5.0 cm H_2O. The patient should be allowed to stabilize with regard to respiratory mechanics (peak inspiratory pressure and compliance), hemodynamics (pulse rate and rhythm, systemic and central filling pressures, and cardiac and urine output), and gas exchange (arterial blood gases). Usually each PEEP increment requires 0.5 to 1 hour to complete. Consequently, the performance of a PEEP-F_{IO_2}/Pa_{O_2} titration may take several hours. Of course, as the PEEP titration is being performed, other respiratory care modalities (see below), such as suctioning, turning, and administration of antibiotics, are instituted. The advent of fiberoptic bronchoscopy has eliminated the need for use of "super-PEEP" (PEEP >20 to 25 cm H_2O) because regions of collapsed lung that are resistant to opening by PEEP are usually obvious on chest radiograph and can be suctioned and lavaged open under direct vision via a bronchoscope.

If a patient requires more than 10 cm H_2O of PEEP to have a Pa_{O_2} greater than 60 mm Hg with an F_{IO_2} of less than 0.5, the V/Q mismatch is so great that it is illogical to make the patient spontaneously ventilate to any significant degree. In other words, lungs that have a PEEP requirement greater than 10 cm H_2O are inefficient to the point that the work of breathing is likely to be excessive, and the patient will fatigue and fail.

Thus, the second goal is to reduce the PEEP to less than 10 cm H_2O; of course, it is assumed that what was achieved before (F_{IO_2} <0.5, acceptable Pa_{O_2}) is retained. This second goal is achieved primarily by instituting an intensive and aggressive respiratory care regimen. Such a regimen has four components (Table 48-18) , and all four proceed in parallel. Although there are no hard data to prove that any one of these respiratory care treatments is beneficial when used alone, there is a widespread consensus that when used together and in the context of the other care necessary in the postoperative management of respiratory failure, they produce a clearing of atelectasis, eradication of infection, and a decrease in the PEEP requirements. [431] [432]

Use of the respiratory care regimen outlined above usually allows the physician, within a few days, to decrease PEEP to less than 10 cm H_2O with continued maintenance of an adequate Pa_{O_2} along with a low F_{IO_2} . Once the PEEP requirement is less than 10 cm H_2O, no special attempt is made to reduce it further. Maintenance of some PEEP is desirable in terms of maintaining normal FRC and lung compliance and providing a subjective sensation of good

TABLE 48-18 -- Aggressive and Intensive Respiratory Care Regimen

I. Removing secretions
  1. Coughing routines
  2. Tracheal suctioning
  3. Fiberoptic bronchoscopy
  4. Chest percussion and vibration
  5. All of the above aided by posture
  6. Turning frequently

II. Diagnosing and treating infections
  1. Protected brush specimen Accurate culture and sensitivity
  2. Bronchoalveolar lavage
  3. Antibiotics according to culture and sensitivity

III. Dilating the airways
  1. Bronchodilators ($beta_2$ agonists, anticholinergics, aminophylline)
  2. Steroids

IV. Other general/systemic maneuvers
  1. Humidification
  2. Incentive spirometry
  3. Diuretics and fluid restrictions
  4. Inotropics

5. Aminophylline to increase diaphragmatic contractility
6. Inhalation of 60% helium

TABLE 48-19 -- Bedside Physiologic Parameters Conventionally and Commonly Used to Predict Success in Weaning From Ventilatory Support and Weakness of Each Test

TEST	PROBLEM WITH TEST
1. Tidal volume > 5 mL/kg	1. Ignores determining inspiratory reserve
2. Vital capacity > 10-15 mL/kg	2. Requires cooperation
3. Respiratory rate < 25-35 breaths/min	3. Multifactorial
4. Minute ventilation > 10 L/min	4. Multifactorial
5. Maximum voluntary ventilation > 2 × minute ventilation	5. Requires cooperation
6. Maximum inspiratory pressure more negative than 20-25 cm H_2O	6. Ignores respiratory mechanics
7. Respiratory rate/tidal volume ratio	7. Combination of above, but the ratio defines rapid shallow breathing

lung expansion. The achievement of an F_{IO_2} less than 0.5 and a PEEP level less than 10 cm H_2O with an acceptable Pa_{O_2} means that the blood and gas within the lungs are matched well enough that the lungs perform their basic gas exchange function in a reasonably efficient manner. It now makes sense to have the patient do some of the work of breathing on his own, and the patient is now a candidate for weaning from mechanical ventilation.

The third goal is to retain what was achieved before (F_{IO_2} less than 0.5, PEEP less than 10 cm H_2O, and acceptable Pa_{O_2}) and to reduce the IMV rate to less than 1 breath/min. This weaning process is accomplished by a progressive decrease in the IMV rate, allowing a gradual transition rate from 100 to 0 percent ventilator dependence. The rapidity by which the IMV rate can be reduced is dictated by and directly proportional to the vital capacity and peak inspiratory force. Other simple indices of readiness for decreasing the IMV rate are shown in Table 48-19 . When the decrease in IMV rate is begun, the head of the bed should be elevated as much as possible to reduce the pressure of the abdominal contents on the diaphragm and also to allow the patient to reestablish contact with the environment. During the transition, IMV provides a progressively decreasing amount of partial ventilatory support. [433]

As the IMV rate is decreased, the patient is monitored by the spontaneous respiratory rate, vital capacity, peak inspiratory force, and Pa_{CO_2} . In addition, the patient should be asked to indicate whether a sensation of dyspnea is perceived. When the rate of IMV withdrawal is appropriate and is being tolerated, the patient's spontaneous respiratory rate remains constant or only slightly increases, the vital capacity and peak inspiratory force remain constant or improve, the arterial blood gas concentrations do not deteriorate, and the patient remains reasonably comfortable. Conversely, when the IMV withdrawal rate is too rapid and is not being tolerated, the spontaneous respiratory rate increases greatly (which is usually the first indication of tolerance), the vital capacity and peak inspiratory force decrease, and the arterial blood gas values deteriorate; the patient becomes hypertensive and tachycardiac, may have arrhythmias, and communicates a sensation of air hunger.

The patient is ready for extubation when Pa_{O_2} is adequate, with the F_{IO_2} less than 0.5 (goal 1), the PEEP level less than 10 cm H_2O (goal 2), VC greater than 15 mL/kg, peak inspiratory force (PIF) greater than -25 cm H_2O, IMV less than or equal to 1 breath/min, spontaneous respiratory rate less than 20 to 30/min, and Pa_{O_2} approximately 40 mm Hg (goal 3), when no other major organ systems are in acute major failure or are unstable, and when the chest roentgenogram findings are reasonably equivalent to the premorbid findings or are rapidly improving and no new changes have appeared (such as infiltrates or pneumothorax). It should be emphasized that throughout this entire mechanical ventilation and weaning process analgesics and sedatives must be administered and titrated so that the patient is comfortable, is not bucking on the endotracheal tube, and is without active expiratory efforts.

The logic of the preceding approach is that the patient's lungs are first required to have the ventilation and perfusion well enough matched, as indicated by an adequate or reasonable Pa_{O_2} with an F_{IO_2} less than 0.5 and a PEEP level less than 10 cm H_2O, that the lungs function as an efficient gas exchange organ. Next, the patient's lungs are required to sustain this efficient gas exchange without respirator aid as indicated by an adequate or reasonable vital capacity, PIF, spontaneous respiratory rate, respiratory rate to tidal volume ratio of less than 105 breaths/min/L (which defines absence of rapid shallow breathing, [434] and Pa_{CO_2} on a low IMV rate. Finally, the process requires that no new complicating factor has occurred as indicated by lack of new chest radiographic findings, resolution of previous pathologic chest radiographic findings, and the absence of any significant disorder or complication in any of the other major organ systems.

During postextubation, the ideal respiratory care maneuver, a high alveolar inflating pressure is sustained for a relatively long time, and this can be achieved only with a large inhaled volume. Such deep breathing exercises with emphasis on achieving a sustained inspiration to total lung capacity can be accomplished by using the incentive spirometer.

In addition, a variety of other techniques can help to minimize postoperative pulmonary complications. Both upright position in bed and early ambulation increase FRC and help restore a favorable FRC-closing volume relationship. Percussion and postural drainage aid in the mobilization of secretions in patients with chronic bronchitis. Continuing the administration of bronchodilating drugs or steroids that were given preoperatively is important in continuing to keep reactive airways quiescent.

Management of Postoperative Pain

The treatment of pain after thoracotomy (Ch. 69) is important not only to ensure patient comfort, but also to minimize pulmonary complications by enabling patients to breathe normally (without active exhalation and/or splinting) and deeply (so that they can cough) and to ambulate. Normal and deep breathing requires stretching of the skin incision, which is painful. Postoperative patients normally try to prevent stretching of the skin incision by contracting their expiratory muscles (splinting), thus limiting the stretch on the incision during inspiration, and by actively exhaling, thus rapidly diminishing whatever stretch was caused by inspiration. Failure to inspire deeply before a forceful exhalation results in an ineffective cough. Splinting, active exhalation, and failure to cough promote retention of secretions, airway closure, and atelectasis.

Two very efficacious methods of post-thoracotomy pain treatment have become widely used and are considered by many to be the methods of choice. They are cryoanalgesia and administration of epidural narcotics. In addition, interpleural regional analgesia has recently been introduced as an alternative method for treating pain after thoracotomy. This section discusses only these three methods.

Cryoanalgesia

Extremely long-lasting intercostal nerve block may be obtained by intercostal nerve freezing (cryoanalgesia). [435] [436] [437] [438] [439] [440] [441] [442] [443] [444] [445] Direct application of an ice ball to the nerve causes degeneration of nerve axons without damage to the support structure of the nerve (the neurolemma), thereby reversibly disrupting nerve activity. Thus, intraneural and perineural connective tissue are preserved, providing a scaffolding for regenerating capillaries, axons, and Schwann cells. [442] The area of anesthesia is along the dermatomes treated. During the 2 to 3 weeks after nerve freezing, nerve structure and function begin to recover in parallel, and by 1 to 3 months after freezing, they usually are fully restored, without untoward sequelae (neuritis or neuroma formation). The numbness that persists during this period is not especially bothersome. Young women, however, have admitted to some distress during the period of axonal regeneration due to loss of sensation in the nipple

area if the fifth and higher intercostal nerves have been frozen. [441]

Currently used cryoprobes are about the size of a pen; the core of the instrument has an exit port that permits rapid expansion of a gas (usually nitrous oxide). The rapid expansion of gas cools a surrounding metal sheath. Because the metal sheath is in contact with a fluid, an ice ball (temperature -60°C) forms at the tip of the cryoprobe. The intercostal nerves are approached from within the chest, because the probe has to pierce the parietal pleura to reach the intercostal nerves in the subcostal groove. This is easily accomplished by the surgeon's lifting the nerve out of the groove with a small nerve hook. The cryoprobe is applied directly to the nerves as far posteriorly as possible from within the chest at the level of the incision plus two or three interspaces above and below this level, just before closure of the thoracotomy wound. The cryoprobe is activated so that the center of the resultant ice ball encapsulates the nerve. During the freeze, nerve tissue temperature is approximately -20°C. [441] If 2 to 3 mm of tissue remains between the tip of the cryoprobe and the nerve to be blocked, the nerve will not become adequately frozen, and nerve function might not be totally eliminated. If the pleura is thickened, local peeling of the pleura is advisable. [441] Usually two 30-second freeze cycles, which are separated by a 5-second thaw period, are applied to each of the nerves selected. However, recent experience with one 30-second freeze exposure has resulted in no loss of postoperative pain control with a significant reduction in the period of numbness (from 3.0 to 1.2 months). [441]

The use of cryoanalgesia in this way has effectively reduced postoperative narcotic requirements and improved pulmonary function. [434] [437] [438] [439] Cryoanalgesia patients have had moderate pain at the end of the first postoperative day and only slight pain after that (as compared with patients receiving intravenous narcotics, who experience moderate to severe pain at 24 hours). Most of the pain experienced by the cryoanalgesia patients has not been incisional discomfort, but rather shoulder or arm pain secondary to chest tube irritation of the pleura. Further advantage of the cryoanalgesic method can be gained if the chest tubes can be placed within an intercostal space whose nerves have been subjected to cryoanalgesia. [441] Once the chest tubes are removed, usually on the second or third postoperative day, pain in the cryoanalgesia patients has become barely noticeable. Consequently, these patients are more able to cooperate with the postoperative pulmonary physiotherapy maneuvers described in Chapter 72 . Return of sensation occurs in most patients by the thirtieth postoperative day. Long-term follow-up for 6 months has shown that the procedure is associated with a certain worrisome incidence of dysesthesias and intercostal muscle paralysis, [443] but it is impossible to distinguish between injury to the nerves and muscle during surgery (which does occur [e.g., 44% of patients in one long-term follow-up study had persistent post-thoracotomy pain [444]]) and injury due to the cryoprobe [445] as the cause of these problems.

Because cryoanalgesia has been shown to reliably and effectively relieve pain and to allow significant improvements in postoperative pulmonary function, it has become an important addition to the modalities used in the treatment of post-thoracotomy pain. Cryoanalgesia may be a treatment of choice in thoracic pain situations that are expected to last a long time (e.g., pain from chest trauma) and to limit respiratory function significantly.

Epidural Narcotic Administration

Treatment of pain after thoracic surgery with epidural narcotics (Ch. 69) has several important advantages. First, there is no sympathetic blockade and neither motor nor sensory loss; second, success in relieving pain is usually predictable; and third, the duration of pain relief is generally much longer and the quality of pain relief better than those that result from using parenteral narcotics. [446] [447] [448] [449] [450] [451] [452]

Epidural opioids have had a moderately extensive trial in relief of post-thoracotomy pain. The epidural catheter should be placed before the induction of general anesthesia and checked for correct position by using a small dose of local

anesthetic. Alternatively, but less preferably, it may be placed in the lumbar region postoperatively before emergence from anesthesia, while the patient is still in the LDP. The initial injection can be made in the operating room (most usual), recovery room, or intensive care unit. Several important clinical points have emerged from the post-thoracotomy epidural opioid analgesia experience.

First, although the thoracic epidural route has been used, the procedure has risks (primarily dural puncture and spinal cord damage), and the lumbar area for catheter insertion has been found to be equally satisfactory for pain relief if a slightly higher dose of morphine and adequate diluent volumes are used. [448] [451] [452] [453] [454] [455] [456] [457] Morphine can be used with a lumbar epidural injection for the relief of thoracic pain because it is lipophobic and will therefore remain in, and have time to spread throughout, the epidural and cerebrospinal fluid (CSF) spaces. For relief of thoracic pain, instillation of 6 mg of morphine in 10 to 15 mL of diluent (preservative-free normal saline) in the lumbar epidural region has been used successfully. [451] [455] Although studied to a much smaller degree, fentanyl, [458] [459] methadone, [460] hydromorphone, [461] and nalbuphine [462] may also be used by either the thoracic or the lumbar epidural route. Not surprisingly, the lumbar route requires a greater diluent volume to push the narcotic into a wider distribution mechanically, because these lipophilic narcotics bind too quickly to the spinal cord at, and a few dermatomes above and below, the segmental level of introduction. Because the lumbar route is safer than the thoracic route and because fentanyl has not been associated with respiratory depression, use of the lumbar epidural route with fentanyl is considered by many to be the post-thoracotomy pain management technique of choice. It should be noted that low-volume thoracic instillation of fentanyl may be safer than large-volume lumbar morphine and is therefore also a widely used technique. However, there remains a wide selection of drugs (and dosages) for use by the lumbar and thoracic epidural routes (Table 48-20) .

Second, epidural morphine [456] and fentanyl [453] have been reported to be effective after thoracic trauma. In patients with multiple fractured ribs, epidural morphine resulted in well over 6 hours of analgesia with each dose. Alternatively, continuous epidural infusion of fentanyl (1-2 mug/kg/h after a 1- to 2-mug/kg bolus) is a good choice in the thoracic trauma situation (as well as for post-thoracotomy pain) because it has a decreased likelihood of causing respiratory depression. Because there is no sympathetic blockade with epidural opioids, there is no need for the patient to lie supine for top-up doses, and patients with some degree of hypovolemia may be managed more safely than with epidural local anesthetic administration.

Third, in the post-thoracotomy pain relief experience (summarized in Table 48-20) , there have been relatively few significant side effects. Urinary retention is generally not a problem because most patients have a bladder catheter in place.

Fourth, catheters have been left *in situ* and used for as long as 5 days without development of tolerance. [463]

Fifth, pain relief failures have usually been due to improper catheter localization because no pain relief could be demonstrated after injection of local anesthetics. [463]

Sixth, the expected increase in the mean post-thoracotomy expiration flow rate, forced vital capacity, FRC, and ability to tolerate respiratory care maneuvers after epidural pain relief have been demonstrated. [463] Even larger increases in ventilatory capacity have been demonstrated in the much larger experience with epidural pain relief after upper abdominal surgery. [464] These increases are generally greater than or equal to those obtained by parenteral narcotic or epidural local anesthetic administration.

Finally, epidural narcotics have been used to treat intractable pain due to thoracic tumors. [465] Lower dosage is required, and longer duration of analgesia with each intermittent dose is obtained for intractable cancer pain as compared with acute postoperative pain. [465] However, although results have been satisfactory after the first few series of injections for intractable pain, tolerance has developed, and dosages have had to be increased because of continuous bathing of the spinal cord with a CSF concentration

TABLE 48-20 -- Epidural Narcotics That Have Been Used for Postoperative Thoracic Surgery Pain Management: Routes, Dosages, and Pharmacodynamics

SITE OF INCISION	EPIDURAL ROUTE	DRUG	LIPID[a] SOLUBILITY	EPIDURAL DOSE (DILUENT SALINE): CONTINUOUS INFUSION	ONSET (min)	DURATION (h)
Thoracotomy	Thoracic	Morphine	1.4	2-4 mg (8 mL):0.1 mg/h	40-60	12-24
		Meperidine	39	30-75 mg (10 mL)	10	4-8
		Methadone	116	5 mg (10 mL)	15	8-10
		Alfentanil	126	200 mug (10 mL)	10	2
		Fentanyl	813	50-100 mug (10 mL):0.5-1.5 mug/kg/h	10	2-3
		Sufentanil	1778	20-40 mug (10 mL):5 mug/h	5	1-5

	Lumbar	Morphine	1.4	6-8 mg (10-15 mL)	40-60	12-24
		Hydromorphine	8	1-2 mg (10-15 mL)	20	8-12
		Meperidine	39	1 mg/kg (10-15 mL)	10	4-8
		Methadone	116	5-10 mg (10-15 mL)	15	8-10
		Fentanyl	813	1-2 mug/kg (18 mL):1-2 mug/kg/h	10	2-3
		Sufentanil	1778	30-50 mug (20 mL)	5	1-5
Abdominal	Lumbar	Morphine	1.4	6-8 mg (10 mL)	40-60	12-24
		Methadone	116	5-10 mg (10-15 mL)	15	8-10
		Fentanyl	813	1-2 mug/kg (10 mL)/1-2 mug/kg/h	10	2-3

[a] Octanol/water partition coefficient.

of opioid. [453] For treatment of chronic pain, permanent catheters have been implanted in the subarachnoid and epidural space and connected to reservoirs or perfusion pumps. [453] These systems have been found to be effective, but again tachyphylaxis has been observed. [453]

Interpleural Regional Analgesia

Interpleural regional analgesia has recently been introduced for the treatment of pain due to a number of conditions, including rib fractures, [466] pancreatitis, [467] and postoperative pain from mastectomy, cholecystectomy, and renal operations. [468] [469] [470] In addition, this technique has been evaluated in patients who have undergone thoracic procedures. [471] [472] [473] [474]

Interpleural regional analgesia is the percutaneous introduction of a catheter (usually an epidural catheter) into the thoracic cage between the parietal and visceral pleura. Because the catheter tip is located, and a local anesthetic is deposited, between the two layers of the pleura, this technique is better termed *interpleural* rather than intrapleural regional analgesia. [475]

Bupivacaine, in concentrations ranging from 0.25 to 0.5 percent, usually containing epinephrine, is the local anesthetic that has been studied most often. Analgesia is thought to occur as a result of (1) diffusion of local anesthetic through the parietal pleura and the innermost intercostal muscles to reach the intercostal nerves where blockage occurs, (2) blockage of the intrathoracic sympathetic chain, and (3) direct action of local anesthetic on nerve endings within the pleura. A more detailed discussion of this technique can be found in Chapters 43 and 69 .

For thoracic surgery patients, the catheter is usually placed intraoperatively by the surgeon at an interspace just below the level of the incision. [471] [472] [473] Alternatively, and less commonly, a chest tube can be used for the instillation of local anesthetic. [474] The chest tube should be clamped for 5 to 15 minutes after each administration of bupivacaine. If the chest tube is not clamped, approximately 30 to 40 percent of any administered dose of local anesthetic will be lost via the thoracostomy tube. [476] The patient should be kept in a supine position during the injection and for the next 10 to 15 minutes.

Most of the many studies have had good results with interpleural analgesia [466] [467] [468] [469] [470] [471] [472] [473] [474] [475] (good pain relief and/or increased pulmonary function and/or decreased narcotic requirements). However, several reports have been only mildly positive [476] or frankly negative. [472] [477] [478] [479] The most important reason for failure to achieve adequate analgesia after interpleural administration of local anesthetics has been failure to clamp the chest tube before administration causing the local anesthetic to be suctioned out of the pleural space into the chest tube. Indeed, when one group [472] changed technique to include clamping of the chest tube, [480] negative results were converted to positive results. Other reasons for failure of the technique are posterior placement of local anesthetic, preventing adequate analgesia for anterior thoracotomy, dilution of local anesthetic by pleural effusion, blood, and/or infected fluid; loculation of local anesthetic by adhesions, fibrosis, and/or infection; and loss of local anesthetic through a bronchopleural fistula.

A recent review covering a total of 703 cases has detailed the complications of interpleural analgesics. [481] Pneumothorax was the most frequently registered complication (2.0%), followed by signs of systemic toxicity (1.2% [in one patient seizures were thought to be due to rapid uptake because of the presence of a highly inflamed pleura [482]]) and pleural effusion (0.42%). Horner syndrome, pleural infections, and catheter rupture have also been reported. [481]

Because the initial results of treating pain due to thoracotomy with interpleural regional analgesia have been mixed at best, the routine use of this technique cannot be recommended at this time. Its ultimate role in the treatment of post-thoracotomy pain will be determined by the results of further studies.

ANESTHESIA FOR SPECIAL THORACIC SURGERY PROCEDURES

Special Diagnostic Procedures

Mediastinoscopy

Indications

Mediastinoscopy is commonly performed before thoracotomy to establish a diagnosis and/or to determine the resectability of a lung carcinoma. After a suprasternal notch incision, a tunnel is created (through the pretracheal fascia) by blunt dissection along the anterior and lateral walls of the trachea into the mediastinum, behind (posterior to) the aortic arch down to the subcarinal area (Fig. 48-34) . This procedure allows for direct inspection and biopsy of the superior mediastinal lymph nodes, which lie posterior to the aortic arch (the anterior and lateral para-mainstem bronchial, anterior subcarinal, anterior, and lateral paratracheal lymph nodes) (see Fig. 48-34) . Tumors of the thymus and anterior mediastinum are not examined by the usual diagnostic mediastinoscopic approach because they are anterior to the great vessels; thus, an anterior mediastinotomy is required to examine this area (this procedure uses a parasternal second innerspace incision and is a less complicated procedure than mediastinoscopy). Previous mediastinoscopy is a near absolute contraindication to a repeat procedure because scarring eliminates the plane of dissection. Relative contraindications to mediastinoscopy include superior vena cava syndrome, severe tracheal deviation, cerebrovascular disease, and thoracic aortic aneurysm. [483] With the advent of CT and magnetic resonance imaging, the role of mediastinoscopy may diminish considerably in the future because negative scans may obviate the need for invasive staging.

Anesthetic Technique

In addition to the usual preanesthetic evaluation of patients, one should specifically look for the signs and symptoms of the relative contraindications to mediastinoscopy, such as obstruction or distortion of the upper airway and superior vena caval obstruction, signs and symptoms of impaired cerebral circulation (which may be compounded during

Figure 48-34 Schematic diagram showing placement of a mediastinoscope into the superior mediastinum. The mediastinoscope passes anterior to the trachea but behind the thoracic aorta. This location allows for sampling of anterior and lateral para-mainstem bronchial lymph nodes, anterior subcarinal lymph nodes, and anterior and lateral paratracheal lymph nodes. Anatomic structures that can be compressed by the mediastinoscope (see areas marked by *) and that can cause major complications are the thoracic aorta (rupture, reflex bradycardia), innominate artery (decreased right carotid blood flow can cause cerebrovascular symptoms, and decreased right subclavian flow can cause loss of right radial pulse), trachea (inability to ventilate, stimulus to cough), and vena cava (risk of hemorrhage with superior vena cava syndrome).

mediastinoscopy by compression of the innominate artery), and evidence of the myasthenic syndrome caused by lung carcinoma. Because there is the potential risk of hemorrhage, a large-bore intravenous catheter should be inserted, and blood should be immediately available during the procedure. If the superior vena cava is obstructed, a lower extremity intravenous catheter is mandatory.

Although mediastinoscopy can be performed under local anesthesia, [484] [485] general anesthesia with controlled positive-pressure ventilation is preferred because it allows the surgeon more flexibility in the dissection, minimizes the potential for air embolus (see later), and facilitates management of major complications such as massive hemorrhage. [486] However, local anesthesia may be considered for patients with active cerebrovascular disease to continuously monitor cerebral function in the awake state.

After the intravenous induction of general anesthesia and paralysis with either succinylcholine, atracurium, or vecuronium, lidocaine is sprayed directly on the trachea and given intravenously to minimize coughing during orotracheal intubation and the procedure itself. A nonkinking tube should be considered in cases in which tracheomalacia is a possibility. Neuromuscular blockade is also used during the procedure to prevent coughing, venous engorgement from straining, and movement during the procedure. The head-up position minimizes venous engorgement but maximizes the potential for venous air embolism. During mediastinoscopy the anesthesiologist's attention is primarily focused on detecting the occurrence of the complications of the procedure. This is performed by monitoring the right upper extremity blood pressure (vessels most commonly compressed are the innominate and the right subclavian and carotid arteries) and by observing for reflex bradycardia (compression of the aorta), arrhythmias (mechanical stimulation of the aorta), hypovolemia, tension pneumothorax, and compression of trachea (see later). Blood pressure and oxygen saturation should be measured in the left arm; if an arterial line is placed, the right wrist may be preferable because it can immediately signal when compression of the innominate artery has occurred. Alternatively, a pulse oximeter probe placed on a finger of the right hand can be monitored by quantitative changes in signal strength, indicating a diminution of blood flow caused by the mediastinoscope. Immediately after the procedure patients can usually be extubated. Postoperatively patients should be nursed in a head-up position to minimize venous engorgement.

The anesthetic considerations for anterior mediastinotomy are similar to those for mediastinoscopy except that the incision is larger, the incidence of complications is lower because structures can be visualized and controlled more readily, the position of the head is unimportant, and the blood pressure can be measured in either arm because there is little chance of compression of the innominate artery.

Complications

Although overall mortality from this procedure is low (0.1%), [487] and one institution has even undertaken to perform ambulatory (outpatient) mediastinoscopies in a hospital-based surgical suite, [488] serious complications can occur and the anesthesiologist must be prepared to diagnose and

to treat them. In a series of 6,490 patients undergoing mediastinoscopy, the major complications reported (numbers of patients in parentheses) consisted of hemorrhage (48), pneumothorax (43), recurrent laryngeal nerve injury (22), infection (22), tumor implantation in the wound (8), phrenic nerve injury (3), esophageal injury (1), chylothorax (1), air embolism (1), and transient hemiparesis (1). [487] The overall complication rate in various studies has been 1.5 to 3.0 percent. [487] [488] [489] [490] [491] [492] [493] [494] At the time of occurrence, most of the complications listed required a specific anesthetic management response.

Significant (occasionally massive) hemorrhage has been the most frequent major problem encountered during mediastinoscopy. If it occurs, thoracotomy must be performed immediately. While preparations for median sternotomy are in progress, the surgeon should attempt to control hemorrhage by compressing the bleeding site with a sponge forceps or a small pack, although the relative inaccessibility of the operative field may make this maneuver difficult or ineffective. The anesthesiologist should (1) rapidly begin volume replacement thorough one (or more) large-bore intravenous cannulae that have been placed before the induction of anesthesia, (2) send for blood that was reserved for the patient preoperatively, (3) support the circulation pharmacologically until volume replacement is achieved, (4) ensure adequate oxygenation and ventilation, (5) administer atropine for reflex bradycardia from aortic compression (if it occurs), and (6) discontinue or reduce the dose of all anesthetic drugs until normovolemia is reestablished. Rarely, it may be necessary to induce deliberate hypotension to control bleeding in this setting. [490] If hemorrhage originates from a superior vena cava tear, volume replacement and drug treatment may be lost into the surgical field unless they are administered via a peripheral intravenous line placed rapidly in the lower extremity. [490]

Pneumothorax is another relatively frequently encountered complication of mediastinoscopy. It is usually not apparent until the postoperative period, and the majority of patients do not require chest tube decompression. All patients should be monitored for signs of pneumothorax in the postoperative period and a chest radiograph obtained when doubt exists. Pneumothorax that occurs intraoperatively, as evidenced by increased peak inspiratory pressure, tracheal shift, distant breath sounds, hypotension, and cyanosis, requires immediate treatment by chest tube decompression. [495]

When mediastinoscopy causes a recurrent laryngeal nerve injury (see Fig. 48-34) , it is permanent in approximately 50 percent of patients. [487] If injury to the recurrent laryngeal nerve is suspected, the vocal cords should be visualized while the patient is spontaneously breathing (usually at the time of extubation). If the vocal cords are nonmoving and/or are in midline position, consideration has to be given to the problem of postoperative laryngeal obstruction.

During mediastinoscopy, the mediastinoscope tip is located intrathoracically and therefore directly exposed to pleural pressure. Venous air embolism (when venous bleeding is present) can occur much more easily if patients are breathing spontaneously because of the development of negative intrathoracic pressure during inspiration; therefore, controlled positive-pressure ventilation during this procedure minimizes the risk of air embolism.

As noted, the mediastinoscope can exert pressure against the innominate artery and cause diminished blood flow to the right carotid and right subclavian arteries (see Fig. 48-34) . This phenomenon may be of special significance in patients with preexisting compromised cerebral circulation. Compression of the right carotid artery has been proposed as the cause of a left hemiparesis that occurred in one patient and subsequently cleared 48 hours after the procedure. [487] In another patient compression of the right subclavian artery caused the loss of the pulse and blood pressure in the right arm and was misdiagnosed as an intraoperative cardiac arrest. [496] In another study, blood pressure in the right arm was significantly decreased from 15 to 360 seconds in four of seven patients who underwent mediastinoscopy. [497] This last report, therefore, recommended that blood pressure be measured in the left arm and the right radial artery be continuously monitored by palpation or finger plethysmography during mediastinoscopy. A right radial arterial line, of course, would very sensitively and continuously monitor the occurrence of innominate or right subclavian artery compression. An oxygen saturation monitor would do this task less sensitively. Any decrease in the right radial artery pressure requires repositioning of the mediastinoscope, especially in patients with cerebral vascular insufficiency. Preventing excessive extension of the neck, which might contribute to pinching of neck vessels, is also important in this group of patients.

Autonomic reflexes may result from compression or stretching of the trachea, vagus nerve, or great vessels. Sudden changes in pulse and/or blood pressure during mediastinoscopy may initially be empirically treated by repositioning the mediastinoscope. Atropine is given for persistent bradycardia.

Thoracoscopy

Indications

Diagnostic thoracoscopy (pleuroscopy) permits an examination of the intrathoracic cavity and is most commonly performed to aid in the diagnosis of pleural and parenchymal disease, to help establish the staging of suspected neoplasms, and to determine the etiology of recurrent pleural effusions. [498] [499] [500] [501] [502] It is most often performed after thoracocentesis or closed-chest pleural or lung biopsy has been performed and a diagnosis has still not been established.

The development of endoscopic video systems and instrumentation (stapling devices, dissectors, coagulators, autotyping sutures and the neodymium:yttrium-aluminum-garnet [Nd:YAG] laser has permitted therapeutic thoracoscopy for a wide variety of major thoracic procedures. These procedures include biopsy of many intrathoracic structures, peripheral wedge and sublobar resections, lobectomy, removal of mediastinal cysts, closure of persistent/or recurrent pneumothoraces and leaking blebs, pleurodesis, dorsal thoracic sympathectomy, drainage of spinal abscesses, resection of posterior mediastinal neurogenic tumor, retrieval of intrathoracic (pleural) foreign bodies, definitive treatment of a

postpneumonectomy chylothorax, and facilitation of pericardectomy. [503] [504] [505] [506] [507] [508] Thoracoscopy is done by making a small incision in the lateral thoracic wall (usually at the level of the sixth intercostal space) and then introducing a thorascope, laparoscope, or mediastinoscope into the pleural cavity. The procedure allows for complete inspection of the pleural space of a hemithorax. Fluid and biopsy specimens can usually be obtained easily through the incision, although many surgeons prefer to use a separate incision for additional instruments such as biopsy forceps.

Anesthetic Technique

Thoracoscopy can be done with either local, regional, or general anesthesia with one-lung ventilation. Local anesthetic infiltration of the lateral thoracic wall and parietal pleura is the simplest way to provide anesthesia, [509] although some patients may experience considerable discomfort when this method is used. Partial collapse of the lung on the operated side occurs when air enters the pleural cavity. This allows for good visualization of the pleural space by the surgeon. It is both hazardous and unnecessary to insufflate gases under pressure into the hemithorax under examination to increase visualization of the pleural space. Surprisingly, even though many of these patients suffer from advanced pulmonary disease, changes in Pa_{O_2} , Pa_{CO_2} , and cardiac rhythm are usually minimal during the procedure when it is performed under local anesthesia and the patient is breathing spontaneously. [510] [511] However, it is prudent to use a high F_{IO_2} to overcome the loss in lung volume due to the unavoidable pneumothorax.

Intercostal nerve blocks performed at the level of the incision and for two interspaces above and below may provide more complete analgesia for thoracoscopy, especially if they are placed far enough posteriorly to anesthetize the parietal pleura. The addition of an ipsilateral stellate ganglion block helps to prevent the cough reflex that is sometimes elicited during visualization and manipulation of the hilum.

When thoracoscopy is performed under general anesthesia, a DLT should be used. Positive-pressure ventilation seriously interferes with visualization of thoracic contents, and thoracoscopy is therefore a relatively strong indication for one-lung ventilation. If the procedure is short and the ipsilateral lung needs to be deflated for only a brief period, blood gases are not routinely monitored during the procedure. However, for patients with marginal pulmonary status in whom the period of one-lung ventilation lasts for more than a few minutes, the usual monitoring precautions should be taken.

Complications

Complications are rare during this simple procedure, although it is possible that any structure that the surgeon has to manipulate may be damaged. A few critically ill spontaneously breathing patients may experience impaired gas exchange during the procedure. Some air may transiently remain in the pleural space after the procedure, and this situation may require chest tube insertion.

Special Elective Procedures

Tracheal Resection

General Considerations

Tracheal resection is indicated, if technically feasible, in patients who have tracheal obstruction due to a primary tracheal tumor (the majority are carcinomas), prior tracheal trauma (e.g., stenosis due to prolonged intubation), congenital anomalies, and vascular lesions. For patients who have operable tumors, approximately 80 percent have a segmental resection (may include carina or larynx) with primary anastomosis, 10 percent have segmental resection with prosthetic reconstruction, and 10 percent have insertion of a T-tube stent. Adjuncts to surgical extirpation include preoperative and postoperative external radiation, internal radioactive seed radiation (transferred by endobronchial catheter or directly placed by thoracotomy), and preoperative laser debulking therapy.

Many previous technical limitations to the performance of tracheal surgery can now be overcome by careful preoperative delineation of the site and degree of obstruction, close intraoperative communication between the surgeon and anesthesiologist, improved anesthetic management techniques, and meticulous postoperative care. All these components contribute to the ability to provide adequate ventilation throughout the perioperative period. Although the results of this very complicated surgery on primary tracheal tumors depend on tumor cell type, location, and method of resection, it is generally accepted that in the few institutions that have a reasonable degree of surgical experience, a worthwhile survival rate can be achieved in most patients. This section discusses the care of patients undergoing tracheal resection and describes several different methods of airway management [512] [513] [514] [515] [516] [517] [518] [519] [520] [521] [522] [523] [524] [525] [526] [527] [528] [529] [530] [531] [532] [533] [534] [535] [536] (Chs. 39 and 63) .

Anesthetic Considerations

Unless airway obstruction is imminent, pulmonary function should be routinely studied preoperatively. The presence of preoperative lung disease that is severe enough to indicate a need for postoperative ventilatory support is a relative contraindication to tracheal resection, because the trauma of positive airway pressure and an endotracheal tube cuff at the tracheal suture line may cause wound dehiscence. [515] Obtaining a history of position-dependent airway obstruction is important because the induction of anesthesia should be accomplished with those patients in a position that does not cause airway obstruction. Preoperative evaluation should also include tracheal tomograms, CT (to define the exact position of the lesion), bronchoscopy (usually deferred until the time of operation in order not to precipitate airway obstruction due to edema or hemorrhage), flow-volume loops (upper airway obstructions have characteristic shapes to the loop--extrathoracic obstructions cause an inspiratory limb plateau, and intrathoracic obstructions cause an expiratory limb plateau), and arterial blood gas determinations.

During surgery, all patients should have an arterial catheter placed to facilitate analysis of arterial blood gases. It should be placed in the left radial artery because the innominate artery (which supplies the right radial artery) crosses the trachea and may be compressed during surgery. A variety of methods for providing adequate oxygenation and carbon dioxide elimination have been used during tracheal resection and are described in Table 48-21 . These can be divided into five approaches: (1) standard orotracheal intubation, (2) insertion of a tube into the opened trachea distal to the area of resection, (3) HFJV through the stenotic area, (4) HFPPV, and (5) cardiopulmonary bypass.

The first technique uses a standard but uncut long orotracheal tube, which is placed above the tracheal lesion after the induction of general anesthesia and is merely manipulated by the surgeon past (distal to) the area of stenosis or mass. [516] [518] Although this method is relatively easy to use, a large tube may traumatize the lesion and cause bleeding or dislodgement of tissue, resulting in further airway obstruction. Furthermore, the technique is limited to patients with relatively mild stenosis, and the presence of an endotracheal tube in the surgical field makes completing the tracheal anastomosis more difficult.

To overcome these problems, endotracheal or endobronchial tubes have been inserted into the opened trachea distal to the site of resection (second approach). [515] [519] [520] [521] [522] [523] [524] [525] With this second approach, initially either a small endotracheal tube is passed distal to the obstruction or a standard endotracheal tube is placed proximal to it (see Figs. 48-35 (Figure Not Available) A. and 48-36 (Figure Not Available) A.; Fig. 48-37 (Figure Not Available) A). All further tracheal and endobronchial intubations are performed with armored tubes passed into the airway, which is surgically opened distal to the lesion. The surgeon must have a complete set of sizes of endotracheal tubes to choose from because either mainstem bronchus or any lobar bronchus may need to be intubated.

With a high tracheal lesion, a cervical incision, possibly combined with a median sternotomy, provides adequate surgical exposure. An opening is made in the trachea distal to the area to be resected, and a sterile endotracheal tube is inserted by the surgeon into the distal trachea. [515] [519] [520] (see Fig. 48-35 (Figure Not Available) B). This second endotracheal tube is connected to a Y-piece and a second set of anesthetic hoses and handed off to the anesthesiologist in order to continue ventilation. After excision of the tracheal lesion and placement of the posterior tracheal sutures, the second (distal) endotracheal tube is removed from the trachea, the original (first) endotracheal tube is advanced past the anastomosis line and reconnected to the anesthetic circuit, and the anastomosis is completed Figs. 48-35 (Figure Not Available) A. (see Fig. 48-35 (Figure Not Available) C and D).

With a low tracheal lesion, a right thoracotomy provides the necessary surgical exposure. If there is sufficient trachea distal to the area of resection, a Foley catheter with the tip cut off just distal to the balloon may be used as a single-lumen endotracheal tube. It is inserted by the surgeon and secured just above the carina, avoiding endobronchial intubation and the need for one-lung anesthesia. [521] Otherwise, if there is not enough distance between the tracheal lesion and carina to provide placement of even this homemade endotracheal tube, endobronchial intubation and one-lung ventilation are necessary [522] [523] [524] (see Fig. 48-36 (Figure Not Available) B). If oxygenation or ventilation is inadequate, it may be possible to decrease blood flow to the atelectatic lung by tightening reversible snares around the pulmonary artery of the nonventilated lung [515] [516] however, this maneuver may be technically difficult. An alternative technique is to pass a second endobronchial tube into the other bronchus to provide ventilation to both lungs [524] (see later). As with the high tracheal lesion, after the posterior anastomosis is completed, the endobronchial tube(s) is removed and the original endotracheal tube pushed past the site of resection; in this situation, however, it is likely that an endobronchial intubation may again be required to complete the anastomosis (see Fig. 48-36 (Figure Not Available) C and D).

Several methods have been described for managing the airway during carinal resection. [515] [516] [534] While the affected segment is being resected, left lung ventilation may be carried out via an endobronchial intubation of the left mainstem bronchus below this lesion [515] (see Fig. 48-37 (Figure Not Available) B). After the right mainstem bronchus and trachea have been reattached,

Figure 48-35 (Figure Not Available) Airway management and surgical procedure for resection of a high tracheal lesion. (A) Initial intubation above the lesion. (B) Second endotracheal intubation distal to the lesion after the trachea has been opened. (C) Placement of sutures for the posterior anastomosis. (D) The second endotracheal tube has been removed, and the original endotracheal tube has been advanced distal to the anterior anastomosis. *(Modified from Geffin et al [515])*

TABLE 48-21 -- Approaches to Airway Management During Tracheal Resection

GENERAL APPROACH	YEAR	SURGICAL APPROACH	TECHNIQUE	REMARKS
OROTRACHEAL INTUBATION				
Belsey [517]	1950	Right thoracotomy	Orotracheal tube	First description of this type of management--tube advanced distally as resection carried out
Kemvyssi-Dea et al [518]	1975	Right thoracotomy	Orotracheal tube	Tube advanced distally as resection carried out
Beyer and Wilson [532]	1988	Various combinations of right thoracotomy, cervical incision, and median sternotomy	Orotracheal tube	Summarizes the literature (particularly recent) using this approach

INSERTION OF TUBE INTO OPENED TRACHEA DISTAL TO AREA OF RESECTION				
Geffin et al [515]	1969	Cervical incision for high lesion; right thoracotomy for low lesion	Endotracheal tube Endobronchial tube	Excellent review article described experience with 31 patients; stressed avoiding tracheostomy and cardiopulmonary bypass for this procedure
Debrand et al [519]	1979	Cervical incision	4-mm endotracheal tube into distal trachea	Patient 4 months old
Boyan and Privitera [520]	1976	Median sternotomy	Cuffed endotracheal tube into distal tracheal stump	Stressed preoperative forced vital capacity loop of airflow versus volume to confirm diagnosis of airway obstruction
Abou-Madi et al [521]	1979	Median sternotomy	28 Foley catheter into distal tracheal stump	End cut off just distal to balloon allowed bilateral lung ventilation through short tracheal stump
Lippman and Mok [522]	1977	Right thoracotomy	Left endobronchial tube	Tube quickly inserted following intra operative tracheal resection
Akdikmen and Landmesser [523]	1965	Right thoracotomy	Right endobronchial tube	Patient died postoperatively; authors suggested use of cardiopulmonary bypass for this procedure
Dodge et al [524]	1977	Right thoracotomy.	Right and left endobronchial tubes	Two anesthesia circuits used

Figure 48-36 (Figure Not Available) Airway management and surgical procedure for resection of a low tracheal lesion. (A) Initial intubation above the lesion. (B) Left endobronchial intubation distal to the lesion after the trachea has been opened. (C) Placement of sutures for the posterior anastomosis. (D) The endobronchial tube has been removed, and the original endotracheal tube has been advanced distal to the anterior anastomosis into an endobronchial position. *(Modified from Geffin et al [515])*

the left endobronchial tube is removed, and the original endotracheal tube is advanced distal to the suture line. The right lung is then ventilated via this tube, while the left main bronchus is reanastomosed to the trachea at a different point of origin (see Fig. 48-37 (Figure Not Available) C and D). Again, blood flow to the nonventilated lung can be reduced by tightening ties placed around the appropriate pulmonary artery. An alternate method of ventilation during carinal resection is to perform endobronchial intubation of both severed bronchi, a technique that allows two-lung ventilation for a much longer period during the procedure. [516] This latter technique requires the use of two ventilating systems. As the posterior anastomosis is being made, ventilation is achieved through both the distal mainstem bronchi. During repair of the anterior wall, ventilation is performed via the original endotracheal tube (above the anastomosis site). The air leak that initially occurs through the anastomosis site diminishes progressively as the anterior sutures are placed. If the anastomosis site leak is excessive, the endotracheal tube can be pushed into an endobronchial position until the placement of additional sutures reduces the leak.

It is apparent that the conventional techniques of airway management for tracheal resection are fraught with hazard. During operation a slight head-down tilt helps to minimize aspiration of blood and secretions. Intermittent sighs help prevent bronchiolar obstruction and atelectasis. A high F_{IO_2} is used, as an oxygen-filled FRC permits a few extra minutes to correct relatively common episodes of airway obstruction and/or tube displacement. Ventilation is continuously monitored by pulse oximetry, capnography, auscultation and observation of the chest, measurement of compliance (peak inspiratory pressure), and arterial blood gas determinations.

Figure 48-37 (Figure Not Available) Airway management and surgical procedure for resection of a carinal lesion. (A) Initial intubation above the lesion. (B) Left endobronchial intubation distal to the lesion after the left mainstem bronchus has been severed. (C) The trachea is anastomosed to the right mainstem bronchus. (D) The left endobronchial tube has been removed to allow for anastomosis between the trachea and left mainstem bronchus. Ventilation is accomplished via the original endotracheal tube. *(Modified from Geffin et al [515])*

Several different sizes of armored endotracheal tubes must be available for use throughout the procedure. Finally, close communication must exist between the surgery and anesthesia teams. Disadvantages of these complex airway techniques include soiling of the lung with blood and debris, the presence of tubes in the surgical field, and the occasional necessity for using one-lung (or less) ventilation.

In an effort to overcome these problems, a third approach to airway management during tracheal resection was developed, which consists of HFJV through small-bore endotracheal tubes or catheters. [525] [526] [527] [528] [529] [533] With this technique a small-bore uncuffed catheter is placed through the stenotic area, and ventilation is accomplished by exposing the lung to rapid intermittent, high-flow, fresh gas through the catheter. Oxygen jets entrain ambient air, which in turn provides the volume necessary for adequate ventilation. With this technique, acceptable blood gases have been maintained, and there have been no deleterious effects on the circulation. With only a small catheter in the field, the surgeon can more easily perform the tracheal resection and anastomosis. The disadvantages of this technique, however, include possible inadequate escape of air around the jet catheter during exhalation when the catheter is passed through a tight stenotic area, plugging of the catheter with blood, displacement of the catheter, aspiration of blood, and technical difficulties with high-pressure injectors.

The fourth approach to airway management during tracheal resection uses HFPPV. [514] This technique uses small tidal volumes (50-250 mL) delivered via a small catheter at relatively rapid rates (50-150/min). Advantages of using HFPPV for tracheal resection include a relatively unobstructed surgical field, no interruption of ventilation during operation, minimized contamination of the lungs from blood and debris by a continuous outflow of gas, and minimized lung and mediastinal movement. In addition, production of CPAP lessens the risk of alveolar collapse. This technique has been used successfully by others for both tracheal [512] [513] and carinal resections. [512] During carinal operations HFPPV to the left lung alone generally provides adequate oxygenation and ventilation, although a system of two catheters and bilateral HFPPV could be used if necessary. [514]

The fifth approach to airway management during tracheal resection, especially in cases of carinal resection, has been the institution of cardiopulmonary bypass either at the time of resection [530] or before the start of surgery. [531] After resection, anesthesia can be continued by conventional techniques using a standard endotracheal tube. Although many surgical teams perform difficult tracheal resections with the cardiopulmonary bypass team standing by, the risk of intrapulmonary hemorrhage due to heparinization precludes its use in most cases. [515]

Helium-oxygen breathing mixtures can significantly decrease the resistance to gas flow through stenotic areas and may be considered preoperatively for some of these patients. [531] However, the use of helium-oxygen mixtures prevents the use of a high F_{IO_2} during anesthesia, and it is therefore not often recommended. [515]

Postoperatively, most patients are kept in a position of head flexion to reduce tension on the suture line. If ventilatory support is necessary postoperatively, the endotracheal tube must be positioned so that the cuff does not rest on any suture line. Early extubation is highly desirable to minimize the compromise of blood flow to the trachea, which might be caused by an inflated tracheal cuff. Chest physiotherapy to remove secretions should not be too vigorous and may need augmentation by fiberoptic bronchoscopy. Systemic antibiotics or steroids are not routinely given unless infection or excessive edema, respectively, is strongly anticipated. If massive bleeding into the airway or chest occurs postoperatively, it is likely due to erosion into the pulmonary artery or aorta (high incidence after insertion of a tracheal prosthesis) and is usually fatal.

Giant Bullous Emphysema and Air Cysts

General Considerations

A *bulla* is defined as an air-filled, thin-walled space within the lung that results from the destruction of alveolar tissue. The walls of bullae are formed by connective tissue septa, compressed lung parenchyma, or pleura. A bulla usually represents a local end-stage area of emphysematous destruction. As separate but related entities, air cysts in the lung have their own epithelial margins, and they may also be associated with COPD [537] or found in the absence of other pulmonary pathology. [538]

Bullectomy is the surgical resection of one or more bullae and is performed only in selected patients. The most important physiologic effect of the bullae is to compress the surrounding lung, and the release of lung compression following bullectomy is considered to be the most important factor in symptom relief (rather than eliminating dead space ventilation). Indications for bullectomy in COPD patients include intolerable breathlessness even after full medical therapy, rapidly enlarging bullae, and repeated occurrence of pneumothorax. [539] Patients with otherwise healthy lungs may undergo removal of a giant air cyst or bulla if it compresses a large area of normal lung and causes functional impairment. The compression of a large area of lung can be visualized on the chest roentgenogram (as well as on an angiogram) as the crowding together of pulmonary vessels. A strong case for functional impairment can be made if radioisotope studies show that the compressed area has good perfusion and some, but reduced, ventilation. [540] [541]

The goal of surgery is to remove the bullae while preserving as much functioning lung as possible. Therefore lobectomy is not only undesirable but often unnecessary. Patients who are considered too compromised to tolerate an open approach may tolerate a closed thoracoscopic approach; the reason thoracoscopic carbon dioxide laser ablation of bullae has been so successful is that it maximizes preservation of normal lung better than any open thoracotomy approach. It is likely that this approach to bullectomy will be used with increasing frequency in the next few years. [542]

Anesthetic Considerations

Anesthesia for the removal of bullae involves several specific ventilation hazards. First, most of these patients have severe generalized chronic lung disease with little or no

ventilatory reserve. Thus, ventilation (which must be controlled once the chest is opened) of one severely diseased lung (the one without the giant bullae) may be hazardous and entails the risks of hypoxemia, hypercarbia, and pneumothorax on the ventilated side. If the ventilated lung also contains bullae, the risks are obviously even greater. In addition, because general anesthesia is necessary for the procedure, most patients with severe lung disease will be committed to at least a short period of postoperative mechanical ventilatory support. Second, when a bulla or air cyst is in communication with a bronchus, positive-pressure ventilation may cause it to increase in size. [543] If a significant portion of the tidal volume enters the bullous cavity, alveolar dead space ventilation will be greatly increased, and unless there is an equivalent increase in minute ventilation, the rest of the lung may be inadequately ventilated. This complication is most likely to occur when the chest is opened, because the chest wall no longer limits the expansion of the bulla. Third, because of the rapidity with which closed air spaces take up nitrous oxide and expand in size, [544] this agent is best avoided (especially in patients whose bullae are thought to have poor communication with the bronchial system). [545] Fourth, if a check valve is present in the airway that communicates with the cavity, overinflation and air trapping may occur within the cavity. Fifth, positive pressure within a bulla might cause it to rupture, creating a pneumothorax, which would likely be under tension if the chest were closed (especially in patients whose bullae are thought to have good communication with the bronchial system). [543] Tension pneumothorax in these patients is usually a catastrophic event because of the impairment of venous return and cardiac output as well as further compromise of ventilation. Insertion of a chest tube at this point would create, in effect, a large bronchopleural cutaneous fistula that could divert much of the ventilation out through the chest tube. HFV with low tidal volumes and airway pressure has been used successfully to prevent positive-pressure rupture of a bulla according to a 1985 report. [546] Sixth, after bullectomy the remaining lung may be so overexpanded (as a result of residual bullae and/or bronchospasm) that considerable force is required to "stuff" the lung back into the hemithorax. The resultant obstruction of venous return and physical encroachment on the heart may require the use of inotropes to maintain adequate hemodynamics. Seventh, it is common for multiple small air leaks to be present after bullectomy. Collectively, these leaks cause considerable loss of delivered tidal ventilation through a chest tube. Effective ventilation and oxygenation are accomplished by trial and error using a variety of tidal volumes, airway pressures, inspiratory/ expiratory ratios, flow rates, and ventilation rates or, alternatively, HFV.

The cornerstone of the anesthetic management of patients with giant bullae or cysts is the insertion of a DLT to allow differential treatment of the two lungs. Thus, in patients with unilateral disease, the DLT can allow adequate ventilation of the nondiseased side while preventing rupture of the diseased side. In patients with bilateral disease the DLT still allows differential lung treatment to maximize gas exchange as well as providing an increased capability to deal with the complications of a ruptured bulla. For example, a DLT allows all possible permutations of HFV, CPAP, PEEP, and ZEEP to the two lungs, depending on the pathology in each lung. In addition, as each bulla is resected, the DLT allows ventilation to the operated lung to be reestablished for short periods, enabling the surgeon to identify and suture any air leaks that may be present. The versatility of the DLT is particularly important in thoracoscopic procedures, which may average 3 hours in duration. [542]

A DLT can be inserted with the patient either awake with the airway topically anesthetized (for those with histories of repeated pneumothorax and/or severe bilateral bullae) or under general anesthesia (for the majority of patients) to isolate the affected lung and provide positive-pressure ventilation to the contralateral lung. [547] [548] While the depth of general anesthesia is being increased, spontaneous ventilation may be maintained (primarily indicated in patients with a history of repeated pneumothorax or bilateral bullae), but it should be realized that spontaneously breathing patients with significant pulmonary disease under general anesthesia may

not be able to ventilate themselves adequately. Alternatively, and preferably in the majority of patients, the patient can be anesthetized and both lungs ventilated by using a limited amount of positive airway pressure; gentle ventilation by hand is the best way to ensure low airway pressures. If a major air leak develops intraoperatively while positive pressure ventilation is being used with a volume cycled ventilator, inadequate ventilation may occur (the machine delivers the preset volume but it does not go into the lungs). Under these circumstances a pressure cycled high inspiratory flow ventilator must be used (e.g., Siemens Servo 900C, Solna, Sweden). [542]

If limited positive-pressure ventilation is chosen, it is important that the anesthesiologist be able to diagnose and treat a pneumothorax rapidly. External stethoscopes should be attached over each hemithorax at the points where breath sounds are maximal to monitor for pneumothorax on each side. [549] However, advanced bullous disease may completely prevent breath sounds from being heard externally at all. In addition to a decrease in breath sounds, a pneumothorax or check-valve mechanism in a cyst may be signaled by an increase in airway pressure, tracheal shift to the opposite side, or hypotension disproportionate to the depth of anesthesia. Thus, equipment for chest tube placement must be immediately available for these patients.

Theoretically, after bullectomy the patient's pulmonary status should be improved since the "healthy" lung tissue that was previously compressed by the bullae should now be able to expand. However, in our experience and that of others, [542] the weaning and extubation process often takes up to several days in those patients with advanced disease. When mechanical ventilation is required postoperatively, positive airway pressure should again be minimized to decrease the possibility of producing a pneumothorax from rupture of suture lines and/or residual bullae [550] and to minimize air leaks from remaining lung tissue.

When bilateral bullectomy is performed because of extensive disease in both lungs, a sternal splitting incision with the patient supine is usually made. [551] However, sequential posterolateral thoracotomies may be planned if it is desired to see how the patient responds to the first bullectomy. With bilateral bullectomy, the same anesthetic principles apply as with unilateral bullectomy.

Lung Volume Reduction Surgery

General and Surgical Considerations

Advanced emphysema is a debilitating lung disease that afflicts 2 million people in the United States. [552] In emphysema, the lungs are hyperinflated with poor elastic recoil, the airways are dynamically compressed, the flattened diaphragms contract poorly, and cardiac filling may be impaired. These pathophysiologic changes result in hypoxemia, hypercapnia, an increased work of breathing, and a debilitating shortness of breath. The goal of lung volume reduction surgery is to partially reverse these pathophysiologic mechanisms. [553]

Current approaches to bilateral lung volume reduction surgery include median sternotomy and thoracoscopy, using either a linear cutting stapler or laser ablation, and reinforcement of incised lung parenchyma with exogenous buttressing materials (such as bovine pericardial strips). [553] The lung tissue to be resected is determined by visual assessment of the most diseased lung (which remains inflated during contralateral one-lung ventilation); it most often consists of multiple small regions, is nonanatomic, and usually composes 20 to 30 percent of that lung. [553] In some patients, however, only a few large blebs or bullae are resected. In either case, the most abnormally appearing tissue is resected to allow expansion of the more normal remaining lung tissue. The majority of patients who have undergone this operation have experienced improvement in lung function and quality of life. The two principal causes of morbidity and mortality in patients undergoing this procedure are respiratory impairment due to the induction of general anesthesia and the trauma of the operative incision in these already critically ill patients, and the complications arising from the resection of emphysematous lung tissue, most notably persistent air leaks.

Anesthetic Management

The overriding goal of anesthetic management is to have the patient adequately and quietly breathing spontaneously as soon as possible at the end of surgery to minimize positive pressure-induced lung air leaks. The main components of the anesthetic management that allow achievement of this goal are to use general anesthesia supplemented with thoracic epidural anesthesia intraoperatively and continued after surgery to provide postoperative analgesia, minimal to no intravenous narcotics, fluid restriction, and often a prolonged emergence and recovery (can be a few hours) with mask ventilation assistance is required in the operating room.

Essential invasive monitoring consists of arterial and central venous catheters. The usual indications for a pulmonary artery catheter remain. A thoracic epidural catheter is placed before induction of general anesthesia and the position of the catheter pharmacologically and/or fluoroscopically determined. Optimally the catheter tip is at an upper thoracic (T3-T5) level, being located in the mid-dermatome area of the incision. These very respiratorily debilitated patients are either unpremedicated or receive only small doses of midazolam, if they are anxious. Anesthesia is induced intravenously (without narcotics), the patient paralyzed, a left-sided double-lumen tube passed, and the position confirmed with fiberoptic bronchoscopy. Anesthesia is maintained via the thoracic epidural catheter and a propofol infusion, with or without an added low-dose of volatile anesthetic. During one-lung ventilation, the tidal volume should be adjusted to achieve a peak inspiratory pressure of approx-imately 25 cm H_2O and long expiratory times utilized. With these ventilator settings, hypercapnia is often unavoidable and entirely permissible as long as patients are normo-xemic. [554] After periods of one-lung ventilation, the previously atelectatic lung should be very slowly and gently reexpanded. Hypotension is treated with vasopressors and fluid infusion is restricted to less than 1,000 mL (blood loss is usually minimal). The patients are usually tracheally extubated in a surgical plane of anesthesia and adequate gas exchange maintained via assisted mask ventilation until adequate spontaneous ventilation returns. During the prolonged assisted emergence, intensive respiratory care, consisting of bronchodilators and chest physical therapy, may be required/desired. Postoperatively pain control is achieved by infusion of a dilute local anesthetic solution (e.g., 0.125 percent bupivacaine) in an effort to block afferent pain signals with minimal effect on motor function (Ch. 69) . If required, a very low dose of narcotic can be added to the infusion for a synergistic analgesic effect.

Unilateral Bronchopulmonary Lavage

General Considerations

Unilateral bronchopulmonary lavage, or massive irrigation of the tracheobronchial tree of one lung, has been used with good success in patients with pulmonary alveolar proteinosis as a means of removing the enormous accumulations of alveolar lipoproteinaceous material characteristically present in these patients. [555] [556] [557] [558] [559] The lipoproteinaceous material is thought to be surfactant, [560] and the abnormal accumulation is due to failure of clearance mechanisms rather than to enhanced formation. [561] The abnormal accumulation of alveolar lipoproteinaceous material is bilateral and symmetric and causes the classic chest radiographic picture of air space consolidation with patchy, poorly defined shadows throughout the lung. [562] The radiographic picture reflects the course of the disease. The air space consolidation causes progressive hypoxemia and shortness of breath (first on exertion and then at rest), [562] [563] and the lungs have a low compliance. The diagnosis of alveolar proteinosis is made by correlating the clinical, radiologic, and laboratory data with the results of a lung biopsy. The indication for lung lavage is Pa o_2 less than 60 mm Hg at rest or hypoxemic limitation of normal activity. [564] [565] Infrequently, lung lavage may be performed in patients with asthma, cystic fibrosis, and radioactive dust inhalation. [552] [557] [565] [566] [567]

Unilateral lung lavage is performed under general anesthesia with a double-lumen endotracheal tube, allowing lavage of one lung while the other lung is ventilated (Fig. 48-38) (Figure Not Available) . In patients with alveolar proteinosis, lavage is performed on one lung and then, after a few days' rest, on the

Figure 48-38 (Figure Not Available) Technique for providing unilateral bronchopulmonary lavage. A left clear plastic double-lumen endotracheal tube allows ventilation to the left lung during lavage of the right lung (and vice versa). Normal saline is infused and drained by gravity; clamps on the connection tubes determine direction of fluid flow. (See text for details.) *(From Benumof [604])*

other lung. After lung lavage these patients usually have marked subjective improvement, which correlates with increases in Pa o_2 during rest and exercise, increased vital capacity and diffusion capacity, and clearing of the chest radiograph. [568] [569] Some patients require lavage every few months, whereas others remain in remission for several years, and the disease may even eventually completely remit. [568] [569]

Anesthetic Considerations

This section discusses the technique for anesthetic management of bronchopulmonary lavage in patients with pulmonary alveolar proteinosis. [260] When the patient is admitted to the hospital, V/Q scans of the lung are obtained. Ventilation can be maximized during lung lavage by performing the first lavage on the most severely affected lung, allowing the "better" lung to provide gas exchange. If the scan indicates relatively equal involvement (as is usually the case), the left lung is lavaged first, leaving the larger right lung to support gas exchange.

After several minutes of preoxygenation (see below), general anesthesia is induced with thiopental in divided doses and inhalation of either isoflurane or halothane in 100 percent oxygen. Isoflurane is relatively indicated in patients in whom therapeutic levels of theophylline (and the risk of arrhythmias) are present. Neuromuscular blockade is induced with a nondepolarizing muscle relaxant. When a suitable level of anesthesia has been reached, the trachea is intubated with the largest left-sided DLT that can be passed atraumatically through the glottis. A clear plastic disposable left-sided DLT is used because of the ease and certainty with which it is correctly positioned, the reliable left cuff seal obtained (the right endobronchial cuff is small and inflates asymmetrically), and the ability to continuously observe the tidal movements of respiratory gas moisture (ventilated lung) and the lavage drainage fluid for leaking air bubbles (lavaged lung). The largest tube is used because the left endobronchial cuff will make contact over a greater bronchial mucosal area with less air in the left cuff (as compared with a small DLT). In addition, a large tube facilitates suctioning, which is an important consideration at the end of the case when the lungs must be made as clear as possible. Precise placement of the tube and detection of leaks are essential because of the serious hazard of spillage during the lavage procedure. The position of the DLT must be confirmed with a fiberoptic bronchoscope, and left cuff seal must be demonstrated to hold against 50 cm H_2O left lung air pressure by a right lumen to catheter-under-water technique (see the section *Quantitative Determination of Cuff Seal Pressure Hold*).

The question of patient position during unilateral lung lavage is important, for there are major advantages and disadvantages related to each position (Table 48-22) . The LDP with the lavaged lung dependent minimizes the possibility of accidental spillage of lavage fluid from the dependent lavaged lung to the nondependent ventilated lung. However, during periods of lavage fluid drainage, pulmonary blood flow, which is gravity-dependent, would preferentially perfuse the nonventilated dependent lung, and the right-to-left transpulmonary shunt would be maximal. The LDP with the lavaged lung nondependent minimizes blood flow to the nonventilated lung, but, on the other hand, increases the possibility of accidental spillage of lavage fluid from the lavaged lung to the dependent ventilated lung. As a compromise, the supine position is used to balance the risk of aspiration with the risk of hypoxemia.

After insertion and checking of the DLT and positioning of the patient, baseline total and individual lung compliances are measured. Airway pressure can be electronically transduced and continuously recorded on a paper write-out, and a Wright spirometer should be placed in the expiratory

TABLE 48-22 -- Unilateral Lung Lavage: Position of Lavaged Lung

Supine position
Balances spillage and blood flow distribution problems

limb of the anesthesia circle system to measure tidal volume accurately. A volume ventilator that can deliver relatively high inflation pressures is required, because these patients have diseased and noncompliant lungs. Prelavage total dynamic compliance (chest wall and lung) of both lungs together (using 15 mL/kg tidal volume) and then of each lung separately (using 10 mL/kg tidal volume) is measured. After measurement of total and individual lung compliance and with the patient breathing 100 percent oxygen, baseline arterial blood gases are measured.

The patients are completely preoxygenated before induction of anesthesia and lavage for two reasons. First, as with the induction of general anesthesia in any patient, an oxygen-filled FRC greatly minimizes the risk of hypoxemia during the apneic period required for laryngoscopy and endotracheal intubation. This consideration has added importance for patients with alveolar proteinosis because they are already severely hypoxemic. Second, preoxygenation eliminates nitrogen from the lung that is to be lavaged. Alveolar gas is then composed only of oxygen and carbon dioxide. During fluid filling, these gases will be absorbed, allowing the lavage fluid maximal access to the alveolar space. Failure to remove nitrogen from the lung before filling the lavage fluid may leave peripheral nitrogen bubbles in the alveoli and thus limit the effectiveness of the lavage.

Warmed isotonic saline is used as the lavage fluid and is infused by gravity from a height of 30 cm above the midaxillary line. After the lavage fluid ceases to flow (i.e., lung filling is complete), drainage is accomplished by clamping the inflow line and unclamping the drainage line, which runs to a collection bottle placed 20 cm below the midaxillary line (see Fig. 48-38) (Figure Not Available) . The inflow and outflow fluid lines are connected to the appropriate endotracheal tube lumen by a Y-adapter. Each tidal lavage filling is accompanied by mechanical chest percussion and vibration to the lavaged hemithorax before drainage. The lavage fluid that is drained is typically light brown, and the sediment layers out at the bottom of the collection bottle after a short time. Filling and drainage of approximately 500- to 1,000-mL aliquots are repeated until the lavage effluent clears (see Fig. 48-38) (Figure Not Available) . Volumes delivered to and recovered from each tidal lavage are recorded. Total lavage fluid volumes of 10 to 20 L are usually used.

Most patients studied have been hemodynamically stable throughout the entire lavage procedure. In particular, lavage itself has caused no significant changes in systemic and transmural pulmonary artery pressures and cardiac output. [570] In these patients, the arterial saturation, as measured by pulse oximetry, has increased and decreased, with each lung filling and drainage, respectively. [570] In addition, cardiac output has decreased and increased with each lung filling and drainage, respectively. Arterial saturation increases during lung filling because blood flow to the nonventilated lung is decreased by the lavage fluid infusion pressure. [571] The opposite set of events (increased nonventilated lung blood flow, decreased arterial oxygen saturation) occurs during lung drainage. [571] Not surprisingly, the cardiac output decreases with each lavage fluid instillation because of the increase in PVR. [570] The opposite set of events (increased nonventilated lung blood flow, decreased arterial oxygen saturation) occurs during drainage. [571] In addition, with drainage of the lavage fluid, PVR decreases and cardiac output increases. [570] An adequate degree of neuromuscular blockade must be maintained because unexpected vigorous coughing during the procedure could alter DLT position and allow spillage of fluid from the lavaged lung to the ventilated lung.

If a small leak should occur during lavage, the following may be observed sequentially: (1) the appearance of bubbles in the lavage fluid draining from the lavaged lung, (2) rales and rhonchi in the ventilated lung, (3) a difference between lavage volumes administered and those drained from the lavaged lung (the former exceeds the latter), and (4) a fall in arterial oxygen saturation. If a small leak is suspected or detected by any of these signs and the lavaged lung has been only minimally treated, the lavaged lung should be drained of all fluid, and the position of the DLT, the adequacy of cuff seal, and separation of the lungs should be rechecked with a fiberoptic bronchoscope. Before beginning the lavage procedure again and no matter what the DLT malposition was, the functional separation of the two lungs and adequacy of cuff seal should be tested and found adequate by using the previously described air bubble leak detection method.

Massive spillage of fluid from the lavaged lung to the ventilated lung is not a subtle event and results in a dramatic decrease in ventilated lung compliance and a rapid and profound decrease in arterial oxygen saturation. Under these circumstances, the lavage procedure must be terminated no matter how much treatment has been accomplished. The patient should be moved quickly to the LDP with the lavaged side dependent, and the operating room table should be placed in a head-down position to facilitate removal of lavage fluid. Vigorous suctioning and inflation of both lungs should be carried out. The DLT should be changed to a standard single-lumen tube, and the patient should additionally receive a period of mechanical ventilatory support with PEEP. Timing of further unilateral lung lavage attempts will be dictated by the patient's subsequent clinical course and gas exchange status.

After the effluent lavage fluid becomes clear, the procedure is terminated. The lavaged lung is thoroughly suctioned, and ventilation to that lung is resumed. Because the compliance of the lavaged side will be much less than that of the ventilated side at this time, large tidal ventilations (sighs) (15-20 mL/kg) to that side alone (with the nonlavaged side temporarily nonventilated) are necessary to reexpand alveoli. Arterial blood oxygenation may decrease precipitously during this time, but this can be minimized by clamping the nonlavaged side after a large inspiration of 100 percent oxygen.

After lavage, the recovery procedure consists of repetitive periods of large tidal ventilations, suctioning and chest wall percussion to the previously lavaged side, conventional two-lung ventilation with PEEP, and bilateral suctioning and postural drainage while intermittently measuring combined (total) and individual lung dynamic compliance. As the compliance of the lavaged lung returns to prelavage values, ventilation with an air-oxygen mixture may help lavaged lung alveoli with low V/Q ratios to remain open. When the compliance of the hemothorax of the lavaged side returns to its prelavage value, the neuromuscular blockade is reversed. Mechanical ventilation and extubation guidelines are the same as for any patient with pulmonary disease; most patients are able to be extubated while still in the operating room.

In the immediate postlavage period, deep breathing (incentive spirometry), coughing exercises, chest percussion, and postural drainage are used to remove remaining fluid and secretions and to reexpand the lavaged lung further. After 3 to 5 days of recovery, the patient is returned to the operating room to have the opposite side lavaged. The anesthetic considerations for the second lavage are the same as for the first lavage, although oxygenation is usually not nearly as severe a problem as during the first lavage because the treated and now near normal lung will be used to support gas exchange.

Special problems associated with pulmonary lavage that may be encountered are that a few very critically ill patients may be unable to tolerate the conventional procedure, and unilateral lavage through a DLT is not easily done in children. Alternative (and more complicated) ways of accomplishing lung lavage in these patients include use of extracorporeal membrane oxygenation and lobar lavage via a fiberoptic bronchoscope inserted under topical anesthesia. [260]

Tumors at the Confluence of the Superior, Anterior, and Middle Mediastinum

General Considerations

At the confluence of the superior, anterior, and middle mediastinum are the middle portion of the superior vena cava, the tracheal bifurcation, the main pulmonary artery, the aortic arch, and parts of the cephalad surface of the heart. [260] In adults, the majority of tumors in this region originate from involvement of the hilar lymph nodes with bronchial carcinoma or lymphoma, whereas in babies the masses are most often benign bronchial cysts, esophageal duplication, or teratoma. Tumors of this region can cause compression and obstruction of three of the vital mediastinal structures: the tracheobronchial tree in the region of the tracheal carina, the main pulmonary artery and atria, and the superior vena cava. A CT scan of the chest is probably the single most important diagnostic procedure because it defines the size and degree of compression of these vital structures. The most common complication that occurs during anesthesia for masses involving these three vital mediastinal structures is airway obstruction; this was a feature in 20 of 22 patients recently reviewed (1969-1983) and succinctly summarized. [572] Although airway obstruction has been predominant in terms of symptomatology, it is not uncommon for compression of two or three of the major organs to be present in varying degrees and to cause complications in the same patient. [572] Each of these complications is life-threatening and can cause acute deterioration and death during anesthesia if not handled with the most extreme caution and expertise. Each major complication and anesthetic management problem is discussed separately below, and Figure 48-39 (Figure Not Available) shows the overall strategy for managing these three problems.

Figure 48-39 (Figure Not Available) Flow diagram showing the essential management strategies for the three major anesthetic problems that mediastinal masses may cause. TBT, tracheobronchial tree; SVC, superior vena cava; PA, pulmonary artery; FOB, fiberoptic bronchoscopy; ETT, endotracheal tube; CPB, cardiopulmonary bypass. *(From Benumof [604].)*

Compression of the Tracheobronchial Tree

Most anterior mediastinal masses that cause airway obstruction [260] are lymphomatous in origin. However, a number of benign conditions such as cystic hygroma, teratoma, thymoma, and thyroid tumors can occur in a similar fashion. A tissue diagnosis, therefore, should be made before radiation or chemotherapy can be undertaken. Thus, most patients with a mediastinal mass causing airway obstruction will first require anesthesia for a diagnostic procedure (e.g., cervical or scalene node biopsy, staging laparotomy for Hodgkin's disease). Importantly, not all patients who have developed severe intraoperative respiratory problems have respiratory symptoms and signs preoperatively.

The anesthetic management of these patients is based on two overriding considerations. First, the obstruction of major airways by a tumor is usually life-threatening because the obstruction usually occurs around the bifurcation of the tracheobronchial tree and is therefore distal to the endotracheal tube. The loss of spontaneous ventilation seems to precipitate the airway obstruction. It may be that loss of chest wall tone and the distending forces of active inspiration after administration of muscle relaxants release extrinsic support of a critically narrowed airway. Alternatively, intubation in the presence of distortion or compression of the trachea may cause complete obstruction if the orifice of the tube impinges on the tracheal wall or if the lumen of the tube is occluded where it passes a narrowed section or turns a sharp angle. In view of the potential for fatal airway obstruction during general anesthesia, all possible attempts to perform the procedure under local anesthesia should be undertaken.

Second, the response of lymphomatous tumors to radiation or chemotherapy is normally dramatic. Chest radiographs reveal a marked decrease in tumor size, and the symptoms are usually improved. Consequently, it behooves the treating physicians to use radiotherapy or chemotherapy if at all possible (sometimes the cell type can be known with a reasonable degree of certainty without a biopsy) before general anesthesia is used. [573] [574] It should be noted that during radiation, a small window can be created to spare some tissue for adequate histologic diagnosis. [575] [576]

The following management plan is based on the principles outlined [560] [572] [573] [574] [575] [576] (Table 48-23 and see Fig. 48-39) (Figure Not Available) . If a patient with a mediastinal mass near the confluence of the superior, anterior, and middle mediastinum exhibits dyspnea and/or intolerance of the supine position and is scheduled for biopsy, it should be performed under local anesthesia if at all possible. If the cell type is thought to be radiosensitive or chemosensitive, appropriate types of therapy should be undertaken before any further surgery is performed. After these types of therapy, the radiologic appearance of the tumor must be reviewed along with a dynamic evaluation of pulmonary function (see later).

If the patient does not have dyspnea or intolerance of the supine position (i.e., is asymptomatic), a CT scan, flow-volume loop, and echocardiogram should be obtained to evaluate the anatomic and functional position of the tumor. If any of these three tests has positive results, local anesthesia should be used for biopsy even if the patient is asymptomatic.

TABLE 48-23 -- Important Management Principles for Tumors at the Confluence of the Superior, Anterior, and Middle Mediastinum

1.	Perform all procedures under local anesthesia if possible.
2.	Use radiation and/or chemotherapy if possible before general anesthesia.
3.	If general anesthesia is required, consider inspection of tracheobronchial tree with fiberoptic bronchoscope and intubate awake.
4.	If general anesthesia is required, maintain spontaneous ventilation.

If general anesthesia is to be used, the airway should be evaluated by fiberoptic bronchoscopy with topical anesthe-sia before induction of general anesthesia. [576] The fiberoptic bronchoscope should be jacketed with an armored endotracheal tube, and after the fiberoptic bronchoscopy examination has been completed, the patient is intubated. General anesthesia should be induced with the patient in the semi-Fowler position. The patient should be allowed to breathe spontaneously

throughout the procedure; muscle relaxants should be avoided. Large changes in intrathoracic pressure, which may promote collapse of a weakened tracheobronchial tree, must be prevented. The operating room team should retain the capability of changing the patient's position rapidly to the lateral or prone position. A rigid ventilating bronchoscope should be on hand to bypass distal tracheal and carinal obstructions, and the appropriate personnel and equipment for cardiopulmonary bypass also should be available.

These patients must be watched extremely closely in the first few postoperative hours. Airway obstruction requiring reintubation and mechanical ventilation has occurred, possibly secondary to an increase in tumor size due to tumor edema after instrumentation.

Compression of the Pulmonary Artery and Heart

Compression of the pulmonary artery and heart is very rare, because the pulmonary trunk is more or less protected by the aortic arch and tracheobronchial tree; there are only a few case reports of this problem in the literature. [260]

Principles similar to those for compression of the tracheobronchial tree apply to compression of the pulmonary artery. Most patients have their first anesthetic experience because they require a diagnostic procedure (e.g., a biopsy). These patients should be evaluated preoperatively in a manner similar to that used for patients with compression of the tracheobronchial tree. If the cell type is known or is highly suspected, preoperative irradiation should be seriously considered. All diagnostic procedures should be performed under local anesthesia if at all possible. If general anesthesia is required and if the symptoms worsen in the supine position, the sitting, leaning forward, or even face-down position is advised, and spontaneous ventilation should be maintained throughout the procedure. Measures to maintain venous return, pulmonary artery pressure, and cardiac output, such as volume loading and use of ketamine, should be considered. Arrangements for extracorporeal oxygenation should be completed preoperatively.

Superior Vena Cava Syndrome

The superior vena cava syndrome is caused by mechanical obstruction of the superior vena cava. The causes of superior vena caval obstruction, in order of decreasing incidence, are bronchial carcinoma (87%), malignant lymphoma (10%), and benign causes (3%), such as central venous hyperalimentation and pacemaker catheter-induced thrombosis of the superior vena cava, idiopathic mediastinal fibrosis, mediastinal granuloma, and multinodular goiter. [260] The classic features of the superior vena cava syndrome include dilated distended veins in the upper half of the body due to increased peripheral venous pressure (which can be as high as 40 mm Hg); edema of the head, neck, and upper extremities; dilated venous collateral channels in the chest wall; and cyanosis. Venous distention is most prominent in the recumbent position, but in most instances the veins do not collapse in the normal manner with the patient upright. Edema can be so great as to cause swelling of periorbital fissures, preventing patients from opening their eyes. Such advanced cases of edema usually obscure the dilated veins as well. The majority of patients have respiratory symptoms (shortness of breath, cough, orthopnea), which are due to obstruction of the airways by engorged veins and mucosal edema, and these are ominous signs. Similarly, a change in mentation, due to cerebral venous hypertension and edema, is a sign of particularly significant obstruction. In some cases the superior vena cava becomes occluded quite slowly, and the signs and symptoms may be insidious in onset. When the occlusion occurs relatively rapidly, all clinical manifestations are more prominent. The most common radiologic sign is widening of the superior mediastinum. Venography confirms the diagnosis (but not the cause). Determination of etiology may require thoracotomy, sternotomy, bronchoscopy, lymph node biopsy, etc.

Most patients with superior vena cava syndrome due to a malignant process are treated with irradiation and chemotherapy (for patients with incomplete obstruction). [577] However, in patients with near complete to complete obstruction (who usually have signs of cerebral venous hypertension and/or airway obstruction) or in whom irradiation or chemotherapy proves ineffective, surgical bypass or resection of the lesion via median sternotomy is indicated. [577] These operations are usually technically quite difficult because tissue planes are poorly delineated, anatomy is grossly distorted, central venous pressures are abnormally high, and varying degrees of fibrosis are present.

The preoperative anesthetic evaluation of a patient for superior vena caval decompression should include careful assessment of the airway. The same degree of edema that is present externally in the face and neck can be expected to be present in the mouth, oropharynx, and hypopharynx. In addition, the airway may be compromised by external compression, fibrosis limiting normal movement, or recurrent laryngeal nerve involvement. If tracheal compression is suspected, it should be evaluated by CT.

The patient is transported to the operating room in the head-up position to minimize airway edema. A radial artery catheter is inserted in all patients and depending on the medical condition of the patient, a central venous or pulmonary artery catheter is inserted via the femoral vein before induction of anesthesia. At least one large-bore intravenous cannula should be inserted into the leg or femoral vein before operating. Premedication is best limited to an antisialagogue to reduce airway secretions. The method chosen for induction of anesthesia and intubation depends on the preoperative airway evaluation. If it is necessary for the patient to maintain the sitting position to achieve adequate ventilation before induction, intubation with the patient awake may be facilitated by using a fiberoptic laryngoscope or bronchoscope.

The most significant intraoperative problem encountered is bleeding. Substantial venous blood loss results from the abnormally high central venous pressure. Further, unexpected arterial bleeding may occur because of the difficulty of dissecting in a distorted surgical field. Crossmatched blood should therefore be available in the operating room at the time of sternotomy.

Postoperatively, especially after diagnostic procedures such as mediastinoscopy and bronchoscopy wherein the superior vena caval obstruction has not been relieved, acute severe respiratory failure requiring intubation and mechanical ventilation may occur. [260] The mechanisms of the acute respiratory failure are obscure, but the most likely ones that are unique to the superior vena cava syndrome are acute laryngospasm and/or acute bronchospasm (both due to continued and perhaps increased obstruction of the superior vena cava), impaired respiratory muscle function (patients with malignant disease may have an abnormal response to muscle relaxants), and increased airway obstruction by the tumor (due to tumor swelling). Consequently, these patients must be closely monitored in the first few postoperative hours.

Emergency Thoracic Procedures

Massive Hemoptysis

General Considerations

Massive hemoptysis [578] is uncommon, occurring in less than 0.5 percent of patients admitted to a large pulmonary medicine service. It has been arbitrarily defined, on the basis of the amount of daily volume of blood expectorated, as 200 to 600 mL in 24 to 48 hours, or from the standpoint of causing acute airway obstruction or major hypotension. [578]

More than 90 percent of reported cases of massive hemoptysis have a chronic infectious cause [579] because chronic inflammation leads to profuse vascularization of the high-pressure bronchial artery system. Subsequently, any erosion or rupture of enlarged bronchial arteries will result in massive hemoptysis. Active tuberculosis is the most common and bronchiectasis the second most common infection causing massive hemoptysis. [580] The majority of the remaining causes of hemoptysis are due to bleeding neoplasms.

Surgical Considerations

In a series of 55 pulmonary resections performed for massive hemoptysis (600 mL in 16 hours), a mortality rate of 18 percent was reported [581] ; this was markedly better than with conservative treatment, which resulted in a mortality rate of

Figure 48-40 (Figure Not Available) Treatment algorithm for massive hemoptysis. The most important function of emergency bronchoscopy is to establish or to diagnose the cause and site of bleeding. In addition, the amount and spread of bleeding can be controlled during emergency bronchoscopy (see items listed in the algorithm under "Diagnosis of Cause"). *(Modified from Benumof [604])*

75 percent in patients who bled 600 mL or more in 16 hours and 54 percent in those who bled 600 mL or more in 48 hours. [582] [583] However, routine use of surgery has been debated, as other authors have found that somewhat lesser degrees of hemoptysis may be successfully managed conservatively regardless of the amount of bleeding in the first 24 hours. [578] Nevertheless, surgery (resection) is probably indicated in patients who require multiple transfusions, in those in whom bleeding results in progressive impairment of pulmonary function (aspiration should be evaluated by serial chest radiographs and arterial blood gases), and in those in whom hemoptysis persists for several days despite optimum medical treatment. Contraindications to surgery include inoperable carcinoma of the lung, inability to localize the bleeding site, and the presence of severe bilateral pulmonary disease and systemic disease (debilitation). These patients are candidates for bronchial artery embolization (Fig. 48-40) (Figure Not Available) (see later).

Bronchoscopy during active bleeding is the single most important technique for determining the cause and location of bleeding and should be performed in all patients; the procedure should be done in the operating room so that immediate resection can be performed [583] (see Fig. 48-40) (Figure Not Available) . Most surgeons use a rigid bronchoscope because of the much greater suctioning and ventilating capability. However, the flexible fiberoptic bronchoscope may be used if there is no active bleeding and/or the site of bleeding is thought to be in the upper lobes.

The surgeon may be able to control bleeding and the spread of bleeding during bronchoscopy (see Fig. 48-40) (Figure Not Available) . Topical iced saline and vasoconstrictors can be administered through the bronchoscope to control bleeding, provided the bleeding is not so massive as to preclude visualization of its origin. [584] Control of spread of blood from one lung to the other can be achieved by use of a bronchial blocker (e.g., balloon-tipped Fogarty catheter) in the main bronchus of the bleeding side or by use of a gauze packing of the bleeding segment or side. [578] The Nd:YAG laser has proved efficacious in the treatment of hemoptysis in patients with lung cancer. [585] [586] In a very exciting new development in pulmonary medicine, two recent reports describe complete cessation of bleeding in almost all patients by selective intrabronchial spraying of fibrin precursors through a catheter in the suction port of a fiberoptic bronchoscope without any adverse effect. [587] [588] During bronchoscopy, the surgeon should frequently restore adequate oxygenation and ventilation by intubating the uninvolved main stem bronchus. If the patient can withstand surgery and has an identified operable lesion, surgery should be performed. If the patient cannot withstand surgery and/or has an inoperable lesion,

bronchial embolization should be attempted (see Fig. 48-40) (Figure Not Available) .

Anesthetic Considerations

There are several important preoperative priorities. For patients with massive hemoptysis, asphyxiation must be prevented by administering 100 percent oxygen; placing the bleeding lung in a dependent position; separating the lungs with a DLT, endobronchial single-lumen tube, or bronchial blocker; and using intermittent positive-pressure ventilation and vigorous suction. After the airway is secured and the bleeding lung isolated, the patient is placed so that the bleeding lung is in a nondependent position.

Coughing may increase bleeding. The advisability of using sedatives and cough suppressants is time-dependent. In the unintubated patient, the ability to cough may be lifesaving, and suppressants should be avoided. In the intubated patient, suctioning can replace the cough mechanism, and suppression of cough may decrease bleeding. A coagulation profile should be drawn early; if any abnormalities are noted, they should be corrected. During and after bronchoscopy, the surgeon and pulmonologist can control bleeding by iced saline lavage, placement of topical vasoconstrictors, placement of a bronchial blocker or gauze packing, laser coagulation, fibrin seal, and use of bronchial artery embolization (see earlier).

As soon as possible, several large-bore intravenous cannulae are inserted. The patient's blood is typed and cross-matched for adequate amounts of blood products (whole blood, packed red blood cells, platelets, fresh frozen plasma). Transfusion should begin if appropriate. Antibiotics are administered preoperatively, and antituberculous drugs are started in patients with tuberculosis. Finally, the appropriate monitoring (e.g., arterial line, central venous line) is instituted. Many of these procedures should be undertaken simultaneously.

If the patient with massive hemoptysis is without an indwelling endotracheal tube, preoxygenation should be instituted immediately. Adequate suctioning must be available. It may be necessary for the patient to be awake for intubation during massive, active, spontaneous bleeding to prevent the hazard of trying to visualize a blood-obscured airway in a paralyzed patient. Intubation performed in the semiupright position may minimize coughing that results in the presence of blood in the upper airway and thereby may provide a clearer field of vision.

If the patient without an indwelling endotracheal tube is to be anesthetized, aspiration precautions (e.g., cricoid pressure) should be used, because many patients have swallowed expectorated blood. Because these patients are likely to be hypovolemic, the induction of anesthesia should be accomplished with a small dose of short-acting barbiturate or ketamine or with narcotics followed in rapid sequence by relaxation. If the larynx can be visualized, insertion of a DLT is preferable to insertion of a single-lumen tube. It should be remembered that if the patient is not actively bleeding but has a blood-filled cavity (i.e., a hemorrhagic lobe), this cavity will likely empty its contents into the dependent unsoiled lung when the patient is turned to the LDP; therefore, this situation is a strong indication for placement of a DLT. If a single-lumen tube is inserted, it might as well be the Univent bronchial blocker tube, which additionally allows lung separation.

If a single-lumen tube is already in place, consideration should be given to conversion to a DLT, addition of a bronchial blocker, and/or achieving an endobronchial position of the existing tube. Once the airway has been secured, the patient must be placed in the LDP with the bleeding lung in the nondependent position. Use of this position, of course, emphasizes the importance of separating the lungs. In all situations if active tuberculosis is present or suspected, contamination precautions should be taken.

At the end of surgery, the endotracheal tube should be left in place and the patient should be ventilated mechanically. Most of these patients will have impaired gas exchange postoperatively as a result of preexisting lung disease, the probability that the nonbleeding lung has been soiled by the recent hemoptysis from the diseased lung, and the physiologic consequence of having just undergone a major anesthetic and surgical experience.

Bronchopleural Fistula

General Considerations

A bronchopleural fistula may be caused by the rupture of a lung abscess, bronchus, bulla, cyst, or parenchymal tissue (as in the case of high levels of PEEP during mechanical ventilation) into the pleural space; by erosion of a bronchus by a carcinoma or chronic inflammatory disease; and by breakdown of a bronchial suture line after pulmonary resection.

Surgical Considerations

The diagnosis of bronchopleural fistula is usually made clinically. In early postpneumonectomy patients, the diagnosis is based on sudden dyspnea, subcutaneous emphysema, contralateral deviation of the trachea, and disappearance of the fluid level on radiographs of the chest. In patients after lobectomy, persistent air leak, purulent drainage, and expectoration of purulent material are usually diagnostic. When the fistula appears after removal of the chest tube, the diagnosis of a bronchopleural fistula is made on the basis of fever, purulent sputum, and a new air fluid level in the pleural cavity on the chest radiograph. The diagnosis is confirmed by bronchoscopic examination in most, bronchography in a few, and sinograms (of the fistula) in occasional patients. [589] Other methods consist of injection of an indicator such as methylene blue into the pleural space and its recovery from the sputum, accumulation of radionuclide in the pleural space after inhalation of

xenon, or a bronchogram showing spillage of contrast into the vacant hemithorax.

In postpneumonectomy patients, if the disruption occurs early, it is possible to resuture the stump. Late postpneumonectomy bronchial disruption associated with empyema has been managed by conservative drainage, but definitive operative closure is now considered the treatment of choice.

In non-postpneumonectomy cases, if the lung expands to fill the thoracic cavity, the leak can usually be controlled with chest tube drainage alone. However, if the fistula is

large and a significant leak through a large persistent pleural space occurs, it is unlikely that the fistula will close, and surgical resection is usually necessary. [589] An empyema complicating a bronchopleural fistula should, if possible, be drained before surgery (see next section).

Finally, a spontaneous pneumothorax (no prior lung resection involved) is pathophysiologically similar to a bronchopleural fistula. There are three situations in which definitive surgical treatment is indicated in management of spontaneous pneumothorax. First, surgery is required when conventional tube drainage and suction have been unsuccessful in clearing the pleural space and when, in effect, a bronchopleural fistula has formed. Second, surgical intervention is usually indicated when a second ipsilateral or first contralateral spontaneous pneumothorax occurs. Third, considering that a spontaneous pneumothorax has a recurrence rate of 10 to 25 percent, if after the initial event the patient's life-style is such that a recurrence might be life-threatening or highly inconvenient, definitive treatment is indicated. Surgical procedure options are pleurectomy and chemical pleurodesis. [590]

Anesthetic Considerations

Preoperatively, it is useful to estimate the loss of tidal volume through the bronchopleural fistula. This may be done in two ways. First, one should determine whether air bubbles intermittently or continuously through the chest tube. If air bubbles intermittently, it means the fistula is small. In contrast, when a patient has a large, low-resistance bronchopleural fistula or bronchial rupture, air may bubble continuously through the water seal chamber of the chest tube drainage system. Second, the size of the bronchopleural fistula may be quantitated by the difference between inhaled and exhaled tidal volumes. In the nonintubated patient, this may be determined with a tight-fitting mask and a fast-responding spirometer; in the intubated patient it is determined by direct attachment of the spirometer to the endotracheal tube. The larger the leak, the greater need to isolate the bronchopleural fistula (DLT, bronchial blocker).

There have been several nonsurgical approaches (use of various mechanical ventilation-chest tube drainage systems) to the treatment of patients with bronchopleural fistula. These approaches consist of one-lung ventilation and differential lung ventilation, including HFV, PEEP to the pleural cavity equal to the intrathoracic PEEP, and unidirectional chest tube valves.

For patients undergoing operative repair, the ability to deliver intraoperative positive-pressure ventilation adequately must be carefully considered preoperatively. If a fistula is obviously small, chronic, and uninfected, a standard endotracheal tube can likely be used safely. When in doubt, positive-pressure ventilation can be tested, and if it is found inadequate, the standard endotracheal tube can be replaced with a DLT. During the induction of anesthesia, suction on the chest tube should be discontinued to decrease the loss of tidal volume with the initiation of positive-pressure ventilation. If, after the chest is opened, an excessive leak is encountered when using a standard endotracheal tube, ventilation can be improved by lung packing and manual control of the air leak. [591]

For large fistulas or fistulas of unknown size and for those in which an associated abscess or empyema is known or suspected to be present, intraoperative use of a DLT has the dual benefits of permitting positive-pressure ventilation of the normal lung without loss of the minute ventilation through the fistula and preventing the hazard of contamination of the uninfected lung with infected material when the patient is turned to the LDP. [592] [593] [594] Indeed, in one series of 22 patients undergoing operations for bronchopleural fistula after pulmonary resection for tuberculosis or tuberculous empyema, management with a single-lumen endotracheal tube, despite intubation in the head-up position and frequent suctioning, resulted in extensive contamination of normal lung in two patients. [595] In one patient the operation had to be terminated, and in the other emergency bronchoscopy had to be performed. The use of a DLT effectively isolates the leaking and perhaps infected lung cavity from the normal lung. For patients who cannot have a DLT (e.g., very small children, patients with inability to tolerate being taken off the ventilator, those with anatomic difficulties), bronchial blockade and endobronchial intubation are less satisfactory alternatives.

Lung Abscesses and Empyema

General Considerations

Pulmonary aspiration secondary to alcoholic stupor has classically been reported as the most common factor that precipitates lung abscess. Other historical factors that predispose patients to lung abscess formation consist of abuse of other drugs, prior pneumonia, lung carcinoma, immunosuppression with steroid drugs, diabetes mellitus, the presence of a distant septic focus (hematogenous spread), and COPD. [596]

Empyema is the accumulation of pus in the pleural cavity. All the causes of a lung abscess described above may produce empyema. Empyema may also be caused by infection of residual clotted blood after a hemothorax (which was treated by chest tube placement) and after diagnostic thoracentesis, especially if there is a concurrent intra-abdominal injury or infection. [597] Both a lung abscess and an empyema may erode a bronchus and cause a bronchopleural fistula (see earlier).

Surgical Considerations

Simple empyemas (without abscess) may be treated by repeat thoracentesis, tube thoracostomy, thoracoscopy, or open drainage with rib resection. [598] In any patient who does not improve with any of these therapies, an open drainage procedure followed by either lobectomy or segmentectomy is required. [599] [600]

Anesthetic Considerations

If a surgical procedure is to be performed with the patient under general anesthesia in a patient with either a lung abscess or an empyema, DLT intubation is absolutely indicated

to prevent contamination of the uninfected lung by the infected lung. In addition, if an empyema is to be treated with thoracoscopy, collapse of the diseased lung greatly aids access to the empyema. [601] [602] The seal of the endobronchial cuff should be tight and can be quantitated by a bubble-underwater technique. The position of the tube should be determined by fiberoptic bronchoscopy. Both these maneuvers should be done before the patient is turned to the LDP.

During the surgical procedure, the diseased side should be suctioned frequently (fiberoptically if necessary). Whenever possible, but particularly at the end of the procedure, the diseased lung should be fully expanded manually. When the lung has been fully expanded, the surgeon should check carefully for the presence of a bronchopleural fistula. The pleural cavity may be irrigated with antibiotics at the end of the procedure, and one must be mindful of the neuromuscular blockade effects of antibiotics.

Chapter 49 - Anesthesia for Adult Cardiac Surgery *

Jack S. Shanewise
Carl C. Hug Jr.

INTRODUCTION

There have been and continue to be major changes in anesthesia care of cardiac surgical patients. Life expectancy of the general population continues to increase, and the proportion of the population that is elderly and retired is growing. Technologic developments have extended the limits of diagnostic and therapeutic capabilities and created the possibility of rescuing almost all patients from the ravages of cardiovascular disease. At the same time, the costs of medical care have been increasing at a prodigious rate and have approached or exceeded the limits of what individuals, employees, and governments are willing and able to pay. There has been an increasing emphasis on relating cost to outcome. With more than 37 percent of medical care expenditures occurring in the last 6 months of life, serious consideration is being given to developing criteria of patient eligibility for expensive procedures and to establishing medical practice guidelines that will limit the application of diagnostic techniques and therapeutic measures beyond those required for relief of pain and suffering of the terminally ill and those incapable of a meaningful life (e.g., those with senile dementia).

A number of factors specifically affect the care of patients with cardiovascular disease, particularly coronary artery disease (CAD). The outcome studies of the late 1970s and early 1980s by the U.S. Veterans Administration and the Collaborative Study in Coronary Artery Surgery (CASS group) questioned the value of coronary artery bypass grafting (CABG) operations in prolonging life in most groups of CAD patients. [1] [2] New drugs (e.g., calcium channel blockers, angiotensin-converting enzyme inhibitors) are available to control the symptoms of angina pectoris and congestive heart failure. Percutaneous transluminal coronary angioplasty (PTCA) has become the first line of intervention for obstructive lesions in coronary arteries for many patients, and the insertion of stents has increased the success rate and possibly the time until another intervention is required. Percutaneous coronary artery arthrectomy is now being used to reduce obstructive lesions not amenable to PTCA. The consequences of these changes are that greater proportions of cardiac surgical patients are older, are sicker in general, and have more advanced cardiovascular disease. Hence, there is a conflict between the demand for expensive, sophisticated procedural interventions and the costs of such care with the prospect of only modest extension of longevity.

The issues of costs versus outcome are focusing on individual institutions as they compete for managed care contracts and on individual physicians. Even the popular press is publishing mortality data for individual cardiac surgeons in certain metropolitan areas, and medical journal articles are presenting data on the contributions of individual anesthesiologists to morbidity and mortality. [3] [4] [5] Within institutions, quality improvement programs are presenting data comparing the impact of individual practitioners on productivity and utilization of resources (e.g., economic credentialing) and on the incidence of morbidity and mortality. On top of all of this, there is a progressive reduction of physician compensation by government programs, insurance carriers, and managed care plans. In the short term, there is little doubt that cardiothoracic anesthesiologists and surgeons will be working harder for less remuneration.

Successful management of anesthesia and life support for patients undergoing cardiac surgery requires the same knowledge and skill as any other type of surgery plus a detailed understanding of cardiac disease, the current functional status of the patient's cardiovascular system, and the special requirements of the intended surgery. To provide satisfactory anesthetic conditions for both patient and surgeon and to maintain optimal cardiovascular function, all details of the anesthetic plan must be carefully considered. Communication with the cardiologist and the cardiac surgeon is essential. They should both be made aware of the circumstances that the anesthesiologist faces in meeting the objectives cited, the role that the anesthesiologist is prepared to play in seeing the patient successfully through the perioperative period, and the advances that have been made in the anesthesia, monitoring, and life support of patients undergoing cardiac surgery. Incidentally, the principles underlying the management of patients with cardiac disease are the same for cardiac and noncardiac surgery. The last point is particularly important in light of the prevalence of cardiac diseases in the general population. [6]

The incidence of death attributable to cardiovascular disease is summarized in Table 49-1 . The most prevalent form of cardiovascular disease is CAD, and coronary artery surgery represents approximately 80 percent of the total adult cardiac operations in most medical centers in the United States. Given the prevalence of heart disease, especially that involving the coronary arteries, the anesthesiologist can expect to spend a great deal of time and effort caring for patients with these problems. [7]

This chapter considers anesthesia for cardiac surgery from three points of view--the patient, the surgery, and the anesthetic plan--focusing on adult patients. The chapter provides an overview; the details can be found in the many textbooks on this subject that have been published since the early 1980s.

** See Appendix 1, Practice Guidelines for Pulmonary Artery Catheterization and Practice Guidelines for Perioperative Transesophageal Echocardiography*

TABLE 49-1 -- Causes of Death in the United States, 1990

CAUSES OF DEATH	NUMBER OF DEATHS (× 1,000)		
	ALL AGES	45- 74 YEARS	> 75 YEARS
Total number: all causes	2,148	849	1,065
All cardiovascular diseases	916	327	567
Diseases of the heart	720	269	433
Ischemic	489	185	296
Hypertensive	21.1	9.0	11.3
Rheumatic	6.0	2.9	2.8
All others	201	71	122
Cerebrovascular disease	144	41	99

Congenital heart disease, less than 1 year of age: 2.6

Total deaths all causes, less than 1 year of age: 38.3

From National Center for Health Statistics [6]

THE PATIENT

Anxiety

Although anxiety is common to all patients facing surgery, those with cardiac disease often have a higher than usual level of apprehension because of awareness of the life-threatening risks and adverse consequences and the symbolic significance of the heart in many aspects of life. Unfortunately, the patient's condition may limit the use of certain drugs to suppress anxiety. The physicians and nurses caring for the patient can reduce apprehension by discussing the usual circumstances of the perioperative period; by assuring the patient that all needs, especially pain relief, will be attended to promptly by experienced personnel; by explaining the procedures that will be followed; and by answering questions. Minimizing anxiety is important not only for patient comfort, but also for reduction of stress reactions (e.g., sympathetic activation) that may adversely affect cardiovascular function. The use of premedicant drugs is discussed later as part of the anesthetic plan.

Hemodynamic Status

In most cases, the specific nature of the cardiac disease and required surgery is defined preoperatively by laboratory examinations (Table 49-2) . These tests can provide information about the functional status of the heart. Still, the functional status of the patient should be estimated by a critical historical interview and a selective physical examination. These are especially important when the laboratory examinations are remote in time and the patient's condition may have changed, when the data from the examinations are incomplete, and when other factors that have not been evaluated in the laboratory (e.g., arrhythmias, labile hypertension) may be present. The major items of interest are listed in Tables 49-3 and 49-4 . Textbooks of medicine should be consulted for methods of discovering and estimating the severity of these problems.

Of prime importance is the presence of cardiac failure, either compensated or not, because it is the major factor affecting the outcome of the surgery as well as the choice of hemodynamic monitoring techniques and anesthetic drugs. Because the degree of failure may be minimal at rest, cardiac reserve should be estimated through questioning about exertional tolerance. Patients in acute distress at rest (i.e., those short of breath, orthopneic, or showing evidence of increased sympathetic nervous system tone) should be approached with extreme caution. The stresses imposed by operative conditions can be as demanding on cardiac function as physical exertion (e.g., hypertensive responses, changes in circulating blood volume, alterations of oxygen demand). Indications of limited cardiac reserve--poor ventricular function--are summarized in Table 49-5 .

Noncardiac Diseases

Those noncardiac diseases that have a significant impact on cardiovascular function need to be evaluated and appropriately treated (Table 49-6 ; Ch. 27) . Clinical scoring systems in part based on the presence of noncardiac medical conditions have been devised that estimate the risk of morbidity and mortality from cardiac surgery. [8] When the surgery is elective, such noncardiac diseases should be treated preoperatively so that the patient is in the best possible condition to withstand the stresses of the perioperative

TABLE 49-2 -- Laboratory Tests of Cardiac Function That Provide Information of Value to the Anesthesiologist

TEST	INFORMATION ABOUT CARDIAC FUNCTION
	Coronary artery disease and ventricular function
Exercise electrocardiography	1. Heart rate and systolic blood pressure at which ischemia was evident; a lower heart rate and perhaps a lower blood pressure should be maintained in the perioperative period
	2. ECG leads showing ischemic changes; suggestive of the most useful leads to monitor during anesthesia
	3. Evidence of ventricular dysfunction (e.g., premature ventricular contractions, hypotension, rales); indicates potential problems, which determine monitoring, anesthetic, and therapeutic plans
Echocardiography	1. Condition of aorta and main coronary arteries (dissection, obstruction, plaque)
	2. Global ventricular function ± stress (dobutamine challenge): ejection fraction
	3. Regional wall motion abnormalities
	4. Mitral valvular regurgitation (due to left ventricular dilation or due to papillary muscle dysfunction or rupture)
Coronary angiography and left ventriculography	1. Location of lesions indicative of most useful ECG leads to monitor and of potential complications (e.g.,arrhythmias, ventricular dysfunction)
	2. Condition of IMA and SVGs from previous CABG operations; presence of stents and complications of PTCA
	3. Diffuseness of obstructive disease and condition of distal portions of coronary arteries; incomplete revascularization increases risk of complications after cardiopulmonary bypass
	4. Adequacy of previous angioplasty procedures
	5. Observation of coronary artery spasm (see discussion of Prinzmetal angina in text)
	6. Evidence of ventricular dysfunction; areas of hypokinesis, akinesis, dyskinesia, aneurysm; left ventricular enddiastolic pressures >15 mm Hg or increasing by >5 mm Hg after contrast injection; ejection fraction <0.5
Radionuclide angiocardiography	1. Myocardial perfusion (thallium uptake) ± stress (exercise, dobutamine)
	2. Infarction detection (technetium uptake)
	3. Ventricular function (equilibrium-gated blood pool imaging); estimation of ejection fraction
	4. Evidence of inducible myocardial ischemia (stress thallium scanning shows reperfusion to ischemic areas)
	Valvular disease and ventricular function
Echocardiography	1. Specific valvular abnormalities and dysfunction

	2. Cardiac chamber enlargement and hypertrophy
	3. Ventricular dysfunction (e.g., regional wall motion abnormalities, low ejection fraction)
	4. Presence of intracardiac masses (e.g., tumor or thrombus)
Radionuclide angiocardiography	1. Pulmonary vascular abnormalities (e.g., emboli)
	2. Valvular dysfunction, shunts (first-pass imaging)
	3. Cardiac chamber enlargement and hypertrophy
	4. Ventricular dysfunction, ischemia, infarction
Cardiac catheterization	1. Pulmonary vascular pressures and resistances
	2. Diagnosis of shunts and quantitation of shunt flow
	3. Pressure gradients across valves and shunts; degree of regurgitation
	4. Estimates of valvular luminal area
	5. Determination of cardiac output and vascular resistance
	6. Estimates of ventricular pressures, volumes, and ejection fraction

ECG, electrocardiograph; IMA, internal mammary artery; SVGs, saphenous vein grafts; PTCA, percutaneous transluminal coronary angioplasty

period. Eradication of systemic or localized infection, control of hypertension and diabetes mellitus, correction of coagulopathy and anemia, pulmonary therapy to achieve maximal function, treatment of primary renal insufficiency or dialysis, and reduction of excessive obesity are helpful in the successful completion of cardiac surgery with the minimum possible morbidity, mortality, and expense. Obviously the burden of managing most of those conditions will fall primarily on the internist. However, the anesthesiologist may need to offer encouragement and enlightenment about the benefits to be derived by careful and thorough preparation of the patient for anesthesia and surgery. Such preparation probably minimizes the risks of complications and facilitates postoperative care, in which the internist will also participate.

The cardiac surgeon and anesthesiologist are especially challenged by the patient with two or more cardiovascular problems amenable only to surgery. For example, patients present regularly with evidence of both CAD and an abdominal aortic aneurysm. Questions arise as to which lesion should be repaired first or whether both should be repaired at the same time. It is our experience that the patient's condition is more carefully monitored and more precisely controlled during anesthesia than at any other time in the perioperative period. For these reasons, we have found the combined carotid and coronary artery operative procedures to be appropriate for some patients. [9] [10] In most cases, separate operations are planned in the sequence that is judged to present the least risk to the patient. One analysis suggests that proceeding directly to infrainguinal vascular surgery would result in a better outcome than routinely performing coronary arteriography and the indicated coronary revascularization. [11] Unrelenting angina with impending myocardial infarction or cardiogenic shock gives priority to coronary revascularization. In any event, the anesthesiologist has to consider all cardiovascular problems in developing the anesthetic plan. Certainly the anesthesiologist is the key person in maintaining adequate perfusion to all body organs while one or the other lesion is being repaired.

TABLE 49-3 -- Assessment of Cardiac Performance by History and Symptoms

Coronary artery disease
Chest pain and discomfort with characteristics of angina pectoris; factors precipitating and relieving angina; stable versus unstable angina
Previous myocardial infarction and its complications
Prior coronary angioplasty or aortocoronary bypass grafting
Heart failure
Dyspnea, cyanosis, edema, nocturia, fatigue
History of infarction, rheumatic fever, congenital heart disease, cardiovascular complications of pregnancy
History of recurrent bronchitis, pulmonary infection
Arrhythmias
Syncope, dizziness, palpitations
Hypertension and vascular disease
History and symptoms of stroke, claudication, renal disease, diabetes mellitus
Phlebitis, pulmonary embolus
Drugs or therapy for any of the above
Responses to therapy
History of symptoms of diseases affecting cardiovascular function (see Table 49-6)

TABLE 49-4 -- Assessment of Cardiovascular Function by Physical Examination in Preparation for Anesthesia and Cardiac Surgery

Blood pressure (BP): measurement in both arms, range of BP through the day (from data on chart)
Heart rate (HR) and rhythm
Responses to exercise, if appropriate: HR, BP, angina, dyspnea
Arterial pulse quality at different locations, suitable cannulation sites with evidence of collateral flow (Allen test) [a]
Capillary filling, cyanosis
Peripheral edema, hepatomegaly
Venous filling, distention, pulsation; suitable cannulation sites, anatomy of neck at sites of internal and external jugular venous cannulation
Precordial pulsations, cardiac borders
Auscultation of heart and lungs
Ventilatory rate and pattern
Evidence of peripheral vascular disease (temperature of hands and feet, aneurysm, bruits, retinal changes)
Body temperature
Body weight, height, surface area

[a] One group of investigators concluded that an abnormal Allen test result was not a predictor of complications from short-term cannulation of radial artery. [29] Until this conclusion is supported by data from other institutions and obtained under other conditions, it is prudent to continue to evaluate collateral flow.

Chronic Drug Therapy

Certain drugs given in the perioperative period have potential benefits and risks for any patient undergoing anesthesia for any type of surgery. However, drug therapy for a patient with heart disease, particularly for one facing cardiac surgery, should be scrutinized in the special light of the disease and the surgical conditions anticipated. Drugs commonly encountered in patients with heart disease are listed in Table 49-7 , along with the potential benefits and risks of continuing or discontinuing their use before surgery. The following details are of special importance in the management of patients undergoing cardiac surgery.

TABLE 49-5 -- Indications of Poor Ventricular Function

Dyspnea
At rest, with exertion, nocturnal, with angina, orthopnea
Edema
Peripheral swelling, recurrent bronchitis or pneumonia, rales, hepatomegaly
Veins
Distention and engorgement, hepatojugular reflux
Hypoperfusion
Confusion (CNS), oliguria and increased serum creatinine and blood urea nitrogen (kidney), fatigue (muscle), angina (heart), anorexia (gut, CNS), cyanosis and poor capillary refilling (skin, mucous membranes)
Hypotension
Especially with exertion (indicates ischemic dysfunction)
With signs of sympathetic autonomic activity (tachycardia, diaphoresis)
Enlarged heart
Gallop rhythm
S_3 indicates cardiac decompensation
Electrocardiogram
Evidence of ischemia or infarction
Hemodynamics during dysrhythmia(s)
Data from laboratory examination of cardiac function
Areas of hypokinesis, akinesis, dyskinesia, aneurysm of the ventricle
Left ventricular end-diastolic pressures >15 mm Hg
Ejection fraction <0.5
Cardiac index <2.5 L/min/m^2

TABLE 49-6 -- Noncardiac Diseases Affecting Cardiac Function

Congenital anomalies
Nutritional deficiencies, obesity
Endocrine
Diabetes mellitus, hypothyroidism and hyperthyroidism, pheochromocytoma, aldosteronism, adrenocortical insufficiency
Hematologic
Anemia, coagulopathy, sickle cell disease and other hemoglobinopathies
Pulmonary
Asthma, chronic bronchitis, emphysema, pneumonia, tuberculosis, alveolar disease, pulmonary embolism, phlebitis
Renal failure, hypertension
Cirrhosis, portal hypertension, ascites
Psychiatric
Drug abuse and dependence, alcoholism, tobacco smoking
Connective tissue diseases

Discontinuation of beta-adrenergic receptor-blocking therapy before anesthesia and surgery is dangerous because of the high incidence of rebound exacerbation of angina pectoris (including infarction) and hypertension. [12] Moreover, discontinuation of such therapy is unnecessary in terms of its potential interactions with anesthetic drugs; and in fact, its continuation may be beneficial in limiting the intraoperative occurrence of tachycardia, dysrhythmias, hypertension, and myocardial ischemia. [13] [14] Some internists may elect to taper large doses if the patient remains at rest and does not experience angina while awaiting surgery. The following details are of special importance in the management of patients undergoing cardiac surgery. Except for long-acting

TABLE 49-7 -- Chronic Drug Therapy in Cardiac Disease: Advantages and Disadvantages of Continuing Therapy up to Time of Surgery [a]

DRUG CATEGORY	PERIOPERATIVE POTENTIAL	
	ADVANTAGES	DISADVANTAGES
Calcium channel blockers	Control dysrhythmias Prevent coronary artery spasm Reduce hypertension	Reduced responses to inotropes and vasopressors; atrioventricular conduction block Peripheral vasodilation after CPB
beta-Adrenergic receptor blocking drugs	Less tachycardia, dysrhythmias, and hypertension	Bronchospasm; less inotropic response to beta-stimulants; greater vasoconstriction to sympathomimetics (nonselective $beta_1$ -and $beta_2$ -blocking drugs)
Antihypertensive drugs	Less hypertension	Drug interactions Peripheral vasodilation after CPB
Diuretics	Probably none	Hypokalemia, hypovolemia
Digitalis glycosides	Inotropic effect Control of ventricular response to rapid atrial rates	Arrhythmias, conduction abnormalities, other toxicity Exacerbation of hypokalemia risks

Antiarrhythmic drugs	Suppression of dysrhythmias	Enhanced toxicity with changes in pH and electrolytes
Insulin	Less hyperglycemia and ketoacidosis	Hypoglycemia (easily treated)
Aspirin	Reduced risk of thrombosis	Increased risk of excessive bleeding
Antidepressants	None	Drug interactions, especially with sympathomimetic drugs, arrhythmias

CPB, cardiopulmonary bypass

[a] Also see Chapter 14 .

drugs (e.g., nadolol), the patient's usual morning dose is often given orally along with other preanesthetic medications on the morning of surgery, and intravenous doses may be given in the operating room as needed to control heart rate and angina.

The calcium entry blocking drugs are being prescribed widely for patients with cardiovascular disease, including angina pectoris, dysrhythmias, and hypertension. [15] Although their role in preventing intraoperative ischemia has been questioned [13] [16] and data on their interactions with anesthetic drugs are limited, the generally accepted practice is to continue their chronic administration up to the morning of surgery. [13] [17]

Antihypertensive medications should also be continued through the night before or the morning of surgery because they contribute to less perioperative hemodynamic stress and their interactions with anesthetic and cardiovascular drugs are manageable. [18] [19] Episodes of rebound hypertension occur when antihypertensive therapy is abruptly discontinued; this is especially so in the case of clonidine (Catapres). [18] [20] Of course, potassium deficiency should be corrected before elective surgery in patients taking diuretic-type antihypertensive drugs. Evidence of digitalis toxicity in a patient scheduled for elective surgery is a substantial reason to consider postponing the surgery. [21]

Angiotensin-converting enzyme inhibitor (ACEI) drugs are frequently prescribed to patients with cardiovascular diseases. [22] They are not only effective antihypertensive agents, but have been shown to decrease the incidence of congestive heart failure (CHF) and mortality when given chronically to patients with impaired ventricular function following myocardial infarction (MI). [23] [24] The concern of possible severe, intractable hypotension during cardiac surgery in patients taking ACEI drugs was originally raised in case reports. [25] A large, prospective series did find that ACEI therapy increased the chance that multiple pressor infusions would be used after cardiopulmonary bypass (CPB), but this effect was not present postoperatively in the intensive care unit (ICU). [26] Patients on ACEI therapy do have a blunted blood pressure response to catecholamine infusions [27] and may require higher doses than usual, but these effects are easily managed when recognized, and our practice is to continue ACEI therapy until surgery and reinstitute it as soon as possible postoperatively.

Most other drugs administered on a chronic basis may be continued up to the day before surgery, and the anesthesiologist should be prepared to deal with their potential toxicities, including their interactions with drugs used in anesthesia. [19] [28]

Previous Surgical and Diagnostic Procedures

In addition to the usual preoperative evaluation for any type of anesthesia and surgical operation, the cardiac anesthesiologist should pay particular attention to the following considerations.

Use of the brachial artery for cardiac catheterization or its involvement in trauma or surgery may have produced changes in vascular resistance at that point, so that arterial blood pressures measured at more distal sites may not accurately reflect central aortic pressures. A normal rate of refilling of the palmar arterial arch should occur when either the radial or ulnar artery occlusion is released (a modified Allen test). However, Slogoff et al [29] have suggested that the Allen test is not necessary before cannulation of the radial (or ulnar) artery.

Previous surgery in the neck (e.g., carotid endarterectomy, thyroidectomy) may complicate cannulation of the internal jugular vein. The landmarks for localizing the vein may be distorted, the anatomic course of the vein and carotid artery may be abnormal, the "feel" of the probing needle is altered, there is increased resistance to insertion of the blunt dilator and cannula, and any accidental holes in the carotid artery or jugular vein may not be sealed off readily. Ultrasonographic localization of the vein may facilitate this process. [30]

Vein stripping procedures in the legs may necessitate the use of one or both arms to obtain suitable vein grafts for aortocoronary bypass surgery. Under such conditions, alternate sites for venous and arterial cannulation may have to be used.

Prior surgery on the mediastinum and heart increases the surgical difficulty and risks associated with opening the sternum and exposing the heart. A longer time before CPB will ensue unless femoral artery-femoral vein bypass is used. There is risk of sudden blood loss from tearing of the heart or vessels during sternotomy and greater hemorrhage from large areas of scarred surfaces in the operative site. Intravenous access should be available through the right arm or neck because injury to the innominate vein during opening of the chest will cause fluids infused into the left arm or neck to extravasate into the surgical field. Dysrhythmias from dissection of the pericardium and manipulation of the heart are common, and loss of atrial augmentation of ventricular filling (e.g., atrial fibrillation) and ventricular tachycardia or fibrillation are best treated by electric cardioversiondefibrillation. The application of low-impedance conductive gel defibrillation electrodes to the patient's posterior and lateral chest wall before induction of anesthesia allows synchronous cardioversion or defibrillation to be done rapidly without disrupting the surgical field in patients with scarring that prevents insertion of internal defibrillator paddles on the heart. These electrodes may also be used for transthoracic cardiac pacing if necessary.

Laboratory Data

Information obtained from reviewing the chart and interviewing and examining the patient may indicate the need for one or more special laboratory investigations. Of particular interest to the anesthesiologist are those findings related to disease states and therapeutic measures that affect cardiovascular function and the conduct of anesthesia and surgery. In the absence of abnormal findings in the historical or physical examinations, certain laboratory examinations are performed routinely and thought to be worthwhile for the patient scheduled for cardiac surgery (Table 49-8) . However, efforts to reduce costs are causing many practitioners to rethink the need for some of these tests.

Reasons to Postpone Surgery

Depending on the urgency of the planned surgery (Table 49-9) , the requirements listed in Table 49-10 should be met

TABLE 49-8 -- Laboratory Examination of the Cardiac Surgical Patient

TYPE OF TEST	INDICATION
Hematocrit/hemoglobin	Oxygen supply to myocardium (and other tissues)
	Primary determinant of blood viscosity (important element of total peripheral resistance)
	Reduced markedly by CPB hemodilution
	If elevated, pre-CPB removal of blood for autologous transfusion after CPB should be considered
White blood cell differential count [a]	Indications of infection, immune reactivity

Electrolytes: K^+	Affects cardiac irritability
	May be low with diuretic or antihypertensive therapy
	Altered by CPB and potassium cardioplegia, ventilation, etc.
Arterial blood-gas analysis [b]	Assessment of ventilatory function, acid-base balance
SMA-12 screening	LDH, SGOT, CPK enzyme elevations may indicate myocardial damage; further studies are indicated to determine if enzyme elevation is due to myocardial specific isoenzyme (CPK, MB, LDH 1 and 2)
	Total protein and albumin may be low and will be reduced further by CPB; replacement may be indicated
	Elevated BUN or serum creatinine suggests impaired renal function, which is at risk during and after surgery
	Blood glucose (fasting) elevation may indicate diabetes mellitus, which is exacerbated by surgical stress and which complicates management of fluid, potassium, and acid-base balance
Coagulation survey [a]	Clotting abnormalities require diagnosis and possibly correction before elective surgery
Prothrombin time	Coagulopathy increases perioperative hemorrhage and requires specific therapy
Partial thromboplastin time	
Platelet count and morphology	
Bleeding time	
Urinalysis [a]	Abnormal renal function; diabetes mellitus or insipidus
	Urinary tract infection

CPB, cardiopulmonary bypass; LDH, lactic dehydrogenase; SGOT, serum glutamine-oxaloacetic transaminase, also known as aspartate aminotransferase (AST); CPK, creatine phosphokinase, BUN, blood urea nitrogen

[a] Not recommended or required by all practitioners
[b] May be obtained in the operating room after arterial cannulation and before anesthetic induction for the patient without pulmonary disease; should be obtained 1 or more days before surgery for the patient with signs and symptoms of clinically significant lung disease

TABLE 49-9 -- Indications for Emergency Cardiac Surgery

TYPE OF SURGERY	INDICATIONS
Aortocoronary artery bypass grafting	Unremitting angina in patient with isolated obstruction(s) of coronary blood flow to a large mass of normal ventricular muscle
	Acute occlusion or dissection of coronary artery as a complication of coronary angiography or angioplasty
Valvular replacement	Acute, rapidly developing cardiac failure in patient with sudden malfunction of a valve or valvular prosthesis
Pericardiotomy	Acute cardiac tamponade with hypotension; may be ameliorated temporarily by pericardiocentesis
Pacemaker implantation	Persistent or recurring bradycardia associated with syncopal episodes, cardiac failure, and inability to establish or maintain endocardial pacing with a temporary transvenous pacemaker
Pulmonary embolectomy	Demonstration of large (surgically accessible) embolic obstruction of a pulmonary artery by pulmonary angiography, lung scan, or echocardiography
Thoracic aortic aneurysmal repair	Acute dissection of the thoracic aorta with risk of impairment of heart, brain, spinal cord, kidney, or splanchnic organ function

before transferring the patient to the operating room. When they are not met, the decision to proceed or to delay may be difficult. Obviously, the best chances for making a correct decision exist when knowledgeable, reasonable, and cooperative anesthesiologists, surgeons, and cardiologists discuss the circumstances together. The anesthesiologist should foster and, if necessary, demand the discussion before accepting responsibility for the patient. Where disagreements exist, they should be documented in the chart along with the contingency plans for the patient in question.

THE SURGERY

In this section, the major features of certain types of cardiac disease and surgery that may affect the management of anesthesia and vital functions by the anesthesiologist in the preoperative, intraoperative, and postoperative periods are stressed. The reader is referred to specialized textbooks for more detailed discussions of disease states and surgical procedures. The section is divided into the more common types of surgical procedures that are performed.

Surgery for CAD

CAD may be defined as obstruction in the coronary arterial blood flow to the myocardium and is almost always caused by the process of atheromatous arteriosclerosis. It is the most common cause of death in the United States, accounting for approximately 500,000 deaths per year. [6] [7] The primary pathophysiologic effect of CAD is disruption of the

TABLE 49-10 -- Checklist of Requirements for Cardiac Surgery That Should Be Met Before the Patient is Transferred to the Care of the Anesthesiologist in the Operating Room

Chart contains documentation of diagnosis and detailed information about cardiac performance as determined by specialized tests (e.g., echocardiography, cardiac catheterization, angiography)
History and physical examination completed and recorded
Laboratory data
Hemogram
Electrolytes
SMA-12 screening [a]
Coagulation survey [a]
Electrocardiogram
Chest roentgenograph
Consultation and other data concerning noncardiac diseases affecting the outcome of anesthesia and cardiac surgery (e.g., carotid bruit, coagulopathy, pulmonary disease, renal dysfunction)
Patient (or guardian) is informed and has given written consent to the operation and all related procedures, including anesthesia
Medications received in hospital and chronic drug therapy before hospitalization are recorded
Prophylactic antibiotics are administered or available for administration on arrival in operating room
Skin shaving and preparation are completed (controversial: practice varies)
Blood products are available for transfusion
Time of last intake of food or drink is recorded; if recent, does the urgency of the surgery justify the risks of aspiration and airway protection procedures?

[a] Not recommended or required by all practitioners

normal balance of myocardial oxygen supply and demand due to narrowing or obstruction by atheroma and thrombus in one or more branches of the coronary arterial tree.

The clinical manifestations of CAD fall into four categories:

1. Angina pectoris (literally, "chest pain"). Several types of angina are recognized.
2. Stable angina: Chest pain predictably occurring with an increase in myocardial oxygen demand (exertion, anxiety) that is not met with an adequate increase in supply, resulting in ischemia. Relieved promptly by rest or medication.
   a. Unstable angina: Chest pain induced by progressively decreasing exertion or occurring at rest, without evidence of infarction. Patients with unstable angina are at high risk of myocardial infarction and should be evaluated for urgent revascularization. Also called crescendo angina or preinfarction angina.
   b. Angina equivalent: Occasionally myocardial ischemia manifests with symptoms other than chest pain, such as dyspnea and easy fatigability. This may be secondary to transient left ventricular (LV) dysfunction due to ischemia.
   c. Prinzmetal or variant angina: Chest pain associated with ST changes on the electrocardiogram (ECG) due to coronary artery spasm. It responds well to vasodilator therapy, but it is important to note that 50 percent of these patients have significant atheromatous coronary lesions.
   d. Silent ischemia: Many episodes of myocardialischemia in CAD patients are asymptomatic. [31]

   They may be detected by ECG, thallium scanning, or echocardiography. This carries the same prognostic implication as symptomatic ischemia and is more common in patients with diabetes mellitus.
3. Myocardial infarction: Sudden, complete obstruction (usually by thrombus formation) of a coronary artery resulting in necrosis of a portion of myocardium. Death from MI may be due to (1) dysrhythmia (ventricular tachycardia [VT] or ventricular fibrillation [VF]); (2) ventricular dysfunction; or (3) ventricular rupture.
4. Sudden death: VT or VF not associated with premonitory symptoms and not due to infarction. Usually initiated by myocardial ischemia.
5. Ischemic cardiomyopathy: The syndrome of CHF and cardiac dilation due to impaired ventricular function as a consequence of one or more MIs.

The severity of CAD is determined by the location and degree of narrowing caused by the obstructing atheromas and is assessed by coronary arteriography. A lesion causing a 75 percent or greater reduction in the cross-sectional area of the vessel is significant. This is equivalent to a 50 percent decrease in the vessel diameter in a two-dimensional view of the arteriogram. Proximal, discrete obstructions are more amenable to revascularization than diffuse lesions involving more distal branches of the coronary arterial tree. Obstruction of the left main coronary artery or of its two primary branches, the left anterior descending and circumflex arteries ("left main equivalent") (Fig. 49-1) (Figure Not Available) places a majority of the left ventricle (LV) muscle in jeopardy. Most patients presenting for CABG surgery have significant obstruction of all the major branches of both the right and left coronary arteries (triple- or multiple-vessel disease) and may have most or all of their

myocardium at risk for ischemia.

It is important to evaluate LV function in any patient with CAD. MI impairs the cardiac pumping action by causing loss of function of the involved myofibrils. The function of those in the central area of necrosis is lost permanently owing to cell death; the function of those in the surrounding ischemic area may recover if the ischemia is reversed ("hibernating myocardium"). Perhaps less obvious is the fact that contractile function is impaired by myocardial ischemia even in the absence of infarction and necrosis. [32] Indeed, loss of contractile function occurs almost immediately with ischemia and may persist for prolonged periods in otherwise viable myocardium after the resolution of ischemia ("stunned" myocardium). [33] Viable myocardium that is noncontractile due to chronic ischemia is said to be "hibernating" and an important but often difficult aspect of evaluation of ventricular function in CAD is to distinguish irreversibly damaged scar from potentially recoverable, hibernating myocardium. Dobutamine stress echocardiography and positron emission tomography scan are two imaging techniques that have been applied to this problem.

Chronic cardiac failure that may result from infarction is characterized by easy fatigability, dyspnea on exertion, orthopnea, peripheral edema, and generalized impairment of function in many organs. The pathogenesis, therapeutic management, and functional characteristics of patients with chronic heart failure with variable degrees of compensation are well described in most textbooks of medicine. [34] Briefly, noninfarcted portions of the left ventricle may hypertrophy in compensation for the nonfunctioning myocardium. [35] Chronic hypertrophy eventually leads to systolic and diastolic dysfunction of noninfarcted muscle, which lowers cardiac reserve and raises diastolic filling pressures, leading to sympathetic and neuroendocrine responses that produce the syndrome of CHF.

Acute, transient episodes of cardiac failure associated with ischemia may be subtle in their presentation. They may be evident as shortness of breath during or after an episode of angina. Acute failure may be precipitated by the recumbent position (angina decubitus, nocturnal angina), which increases the return of venous blood to the heart and increases LV end-diastolic volume (LVEDV), thereby increasing oxygen demand. There may be a sudden, large increase in LV end-diastolic pressure (LVEDP) (a more than 5 mm Hg increase) during ventriculography when injection of contrast material (with a low oxygen content) displaces blood from the coronary circulation. Such information may provide at least a crude estimate of the risk of similar episodes of altered cardiac pumping during anesthesia and surgery. Most important, such episodes indicate the need for precise hemodynamic monitoring to detect and treat the LV failure precipitated by ischemia, which may not otherwise be evident in the anesthetized patient.

In terms of developing an anesthetic plan, it is useful to summarize cardiac pumping function as good or poor (Table 49-11) . Most patients presenting for elective CABG surgery will have some objective measurement of LV function (e.g., ventriculogram, echocardiogram, radionuclide angiogram) available to the anesthesiologist. When such evidence is not available (e.g., emergency surgery), a suspicion of impaired ventricular pumping is an indication for advanced monitoring techniques, including the use of a pulmonary artery catheter (PAC) or transesophageal echocardiography (TEE) to obtain the missing information and to be prepared to detect and promptly treat myocardial ischemia and its consequences.

The primary goals of surgery (and indeed, of medical treatment) for CAD are (1) to relieve anginal symptoms and thereby improve the quality of life and (2) to prevent MI, preserve ventricular function, and improve long-term survival. Outcome studies have demonstrated CABG surgery's effectiveness in relieving anginal symptoms. Improved survival after CABG has been shown for patients with significant

TABLE 49-11 -- Classification of Left Ventricular Function

GOOD FUNCTION	POOR FUNCTION
No history, symptoms, signs of congestive heart failure	Congestive heart failure
Hypertension	Recent or multiple infarctions
Normal cardiac index (>2.5 L/min/m^2)	Cardiac index <2 L/min/m^2
Normal LVEDP (<12 mm Hg)	LVEDP > 15 mm Hg
Normal ventriculogram	Ventricular dysrhythmias
Normal wall motion and thickening (echocardiogram)	Areas of hypokinesis, akinesis, dyskinesia, or aneurysm in ventriculogram or echocardiogram

LVEDP, left ventricular end-diastolic pressure

Figure 49-1 (Figure Not Available) Anatomy of the *(A)* left and *(B)* right coronary arteries showing the nomenclature recommended by the American Heart Association. LAD, left anterior descending; SA, sinoatrial; RCA, right coronary artery; AV, atrioventricular; LV, left ventricular. *(From King SB III, Douglas JS: Coronary arteriography and left ventriculography. In Hurst JW (ed): The Heart. 4th ed. New York, McGraw-Hill, 1978.)*

left main coronary artery obstruction and those with involvement of three or more coronary arteries. [36]

CABG surgery involves the anastomosis of blood-bearing conduits to the involved coronary arteries distal to the obstructing atheromas. Conduits are usually autologous saphenous veins or internal mammary arteries; the latter have better long-term patency than vein grafts when placed to the left anterior descending coronary artery. [37] The gastroepiploic and inferior epigastric arteries may be used as conduits and theoretically have the same advantages as internal mammary grafts, but this remains to be documented with long-term patency studies. On rare occasions, autologous arm veins, prosthetic material, or animal-derived conduits have been used, but these have proved to be less satisfactory. More recent developments in surgery for CAD includes minimally invasive direct coronary artery bypass surgery through a limited thoracotomy without using cardiopulmonary bypass. Challenges to the anesthesiologist include providing a slowly beating quiet heart to assist the surgeon in performing the coronary anastomosis while maintaining adequate overall hemodynamics. In our experience, unless unexpected problems develop, almost all of these patients can be extubated in the operating room at the end of the case.

The primary goal of the anesthetic management of a patient for CABG surgery (or any patient with CAD) is the

avoidance of myocardial ischemia and MI. This is accomplished (1) by preventing ischemia through measures that improve the myocardial oxygen supply-demand balance, primarily by controlling the patient's hemodynamics, and (2) by detecting and treating myocardial ischemia when it does occur.

Myocardial Oxygen Supply-Demand Balance

Even in the normal individual at rest, the myocardium extracts most of the oxygen from the blood flowing through the coronary arteries. Increased cardiac work for any reason (e.g., physical exertion, emotional stress, hypertension) increases myocardial oxygen demand, which is met in the healthy person by the increased coronary blood flow. [38] [39] With CAD the arteries are narrowed and the maximal rate of coronary blood flow is reduced. When oxygen demand by the myocardium exceeds its oxygen supply, myocardial ischemia develops and may be manifest in one or more ways. Prevention and treatment of myocardial ischemia are based on improving oxygen supply and reducing oxygen demand. Conditions detrimental to myocardial oxygen balance (Table 49-12) are important to know because they are encountered frequently in the perioperative period, and most factors contributing to an imbalance can be manipulated to some degree by the anesthesiologist.

The following are important points:

1. Tachycardia is especially detrimental to myocardial oxygen supply-demand balance, increasing demand while decreasing supply. Heart rate is a major determinant of myocardial oxygen consumption, and tachycardia increases oxygen demand. On the other side of the supply-demand balance, tachycardia decreases coronary blood flow. About 80 percent of coronary artery blood flow occurs during diastole [40] ; by decreasing the duration of diastole more than that of systole, tachycardia results in less time for coronary artery flow during the cardiac cycle. [41]
2. Increases in LV preload (LVEDV and LVEDP) also increase oxygen demand while diminishing supply. Elevation in preload raises LV wall tension, which

increases oxygen consumption. Higher preload diminishes coronary flow by decreasing the coronary artery perfusion pressure (diastolic arterial pressure minus LVEDP).

3. With fixed coronary artery obstruction, increasing arterial pressure above normal produces minimal increase in coronary flow because the perfusion pressure would have to be increased drastically to overcome the reduction in lumen size of the artery (blood flow perfusion pressure/resistance; resistance varies inversely with the fourth power of the radius). However, elevated arterial pressure significantly increases oxygen demand by raising LV wall tension and therefore has a net detrimental effect on oxygen supply-demand balance.
4. Hypotension simultaneously lowers oxygen supply and demand but clearly has a net detrimental effect and is more likely than hypertension to cause ischemia.

TABLE 49-12 -- Conditions Detrimental to Myocardial Oxygen Balance

DECREASED OXYGEN SUPPLY	INCREASED OXYGEN DEMAND
Decreased coronary blood flow	Tachycardia
Tachycardia (↓ diastolic perfusion time)	Increased wall tension
Hypotension (especially diastolic)	↑ Increased preload ↑ Increased afterload (hypertension)
Increased preload (↓ perfusion pressure)	Increased myocardial contractility
Hypocapnia (coronary vaso-constriction)	
Coronary artery spasm	
Decreased oxygen content and availability	
Anemia	
Hypoxemia	
Reduced oxygen release from hemoglobin (e.g., ↓ pH, ↑ 2,3-DPG, ↑ temperature)	
2,3-DPG, 2,3-diphosphoglycerate	

The ideal hemodynamic state for the patient with CAD is a low heart rate, low filling pressures, normal (or usual for the particular patient) arterial blood pressure, and normal to low inotropic state.

Prevention of Ischemia

Prevention of perioperative ischemia begins with the continuation of the patient's chronic antianginal therapy into the immediate preoperative period. Abrupt discontinuation of beta-adrenergic receptor blocker therapy may precipitate ischemia or infarction. Oral nitrates, beta-blocking agents, and calcium channel entry blocking medication may be given the morning of the surgery with a sip of water. Topical nitrates should be left on the patient in the immediate preoperative period, at least until intravenous nitroglycerin (NTG) is available. Patients with unstable angina controlled with infusions of NTG and/or heparin should have these medications continued until arriving in the operating room. Although there may be concern about the risk of inserting vascular cannulas into an anticoagulated patient, the risk of myocardial ischemia due to discontinuation of a heparin infusion is more important. [42]

The anxiety that may be caused by the prospect of major surgery, as well as the pain and discomfort caused by the insertion of vascular cannulas, may precipitate angina in the unpremedicated patient. We prefer to see our CABG patients calm, even somnolent, in the preoperative period and prescribe sedatives and narcotic analgesics accordingly. Care should be taken to minimize any discomfort caused by insertion of invasive monitoring devices, and consideration should be given to placing some or all of them after the induction of anesthesia, especially if the patient is experiencing myocardial ischemia. Oxygen saturation should be monitored by pulse oximetry and supplemental oxygen provided while the patient is prepared for surgery. Unstable patients with ongoing ischemia should be lifted from the stretcher to the operating table rather than being asked to move themselves in order to minimize exertion and myocardial oxygen demand.

Maintenance of stable hemodynamics is an important factor in prevention of myocardial ischemia. Induction of anesthesia should be cautious to avoid hypotension, but an adequate depth of anesthesia must be achieved before tracheal intubation. Endogenous catecholamines released in response to noxious stimulation produce many undesired effects, namely tachycardia, hypertension, and increased myocardial contractility, all of which increase oxygen demand. Adequate anesthesia will diminish the sympathetic response to noxious stimulation (i.e., laryngoscopy and surgery). Beta blockers can be used to inhibit tachycardia, and NTG can be infused to reduce both arterial vasoconstriction (hypertension) and venoconstriction (increased preload) induced by sympathetic and endocrine responses to noxious stimulation. Slower heart rates, lower filling pressures, and normal systemic blood pressures are desirable. Finally, the oxygen-carrying capacity of the blood (adequate hemoglobin and oxygen saturation) needs to be maintained at adequate levels to prevent myocardial ischemia.

Detection of Ischemia

Chest pain in the awake patient, especially if similar to previous anginal pain, indicates the presence of myocardial ischemia. This may occasionally be confused with biliary spasm caused by an opioid medication given in the preoperative period. Biliary pain will be relieved with naloxone and angina will not. A small dose of naloxone will competitively and transiently antagonize the opioid effects, both biliary spasm and analgesia. NTG can be used to relieve true angina, and if necessary, a larger dose of opioid can be given as needed to treat anginal pain once the differential diagnosis is made.

ECG-ST analysis is the most common method to monitor for myocardial ischemia. Continuous ECG monitoring of CAD patients undergoing surgery showed that lead V_6 detected 82 percent of episodes documented by 12-lead recordings, V_5 72 percent, V_4 54 percent, and lead II 33 percent. [43] [44] Lead II is useful for diagnosis of atrial dysrhythmias. Ischemia is manifest usually as ST depression but can cause ST elevation, which is not entirely specific but highly suggestive of ischemia in a patient with known CAD. Some monitors continuously measure ST segment depression or elevation in several leads and can be configured to give an alarm when significant changes occur. [45] ST trend analysis cannot be done in patients with left bundle branch block or ventricular pacing.

Hemodynamic changes that indicate myocardial ischemia producing impaired global LV function include elevated pulmonary artery occlusion pressure (PAOP), the appearance of large V waves in the PAOP tracing (which may be due to altered LV compliance and papillary muscle dysfunction manifest as mitral valvular regurgitation), and a fall in cardiac output. The last is probably the least sensitive way to monitor for ischemia. [46]

TEE can be used to detect ischemia. The appearance of a new ventricular regional wall motion abnormality (RWMA) in a patient with known CAD is highly suggestive of myocardial ischemia. [47] TEE is more sensitive than ECG in that it will detect more episodes than ECG, but the two methods may be complementary in that some episodes not detected by one may be apparent with the other. TEE monitoring equipment is expensive and cannot be automated as yet. In addition, proper use of TEE requires significant training and skill, and it is not suitable for continuous monitoring throughout the perioperative period.

Use of these more sensitive techniques to detect ischemia in CABG patients has shown that most episodes are not associated with acute hemodynamic perturbations. [48] Pre-CPB ischemia is less common than post-bypass episodes, and different authors disagree as to whether they are associated with adverse outcomes. [49] [50] Ischemic episodes in the post-bypass period are more common and are clearly related to adverse clinical outcomes (perioperative MI, malignant ventricular

dysrhythmias, and death). [49]

Treatment of Ischemia

Although it seems intuitively obvious, it has not been conclusively demonstrated that the detection and successful treatment of perioperative ischemic events improve outcome in CABG patients. [7] Nonetheless, we feel that the prompt recognition and treatment of this condition is an important aspect of the anesthetic management of patients with CAD. Following are several methods to treat myocardial ischemia; most often several will be instituted simultaneously.

Correction of hemodynamic abnormalities: This first step includes decreasing tachycardia and increasing arterial blood pressure if low or decreasing it if high.

Intravenous NTG: This is the mainstay of medical treatment for myocardial ischemia. NTG is especially helpful when the arterial pressure and filling pressures are high. However, it may cause hypotension and reflex tachycardia. Part of its benefit may be due to inhibition of platelet function. [51]

beta-Adrenergic receptor blockers: These drugs diminish myocardial oxygen demand by decreasing heart rate and contractility. They have been shown to reduce recurrent ischemia and MI in patients with unstable angina. They should be used with caution in patients with impaired LV function or bronchospastic pulmonary disease.

Heparin: Pathologic thrombosis plays a prominent role in myocardial ischemia, and heparin has been shown to be effective in reversing ischemia and preventing infarction. Patients must be heparinized before CPB anyway, and prompt anticoagulation should be accomplished if there is ischemia in the pre-bypass period.

Calcium channel blockers: These drugs may provide effective treatment for myocardial ischemia, especially if due to coronary artery spasm or associated with hypertension. However, they have been shown to be effective only if combined with other forms of therapy, such as anticoagulation or beta-blockade. [15]

Cardiopulmonary bypass: Patients for CABG surgery with myocardial ischemia who are hemodynamically unstable should be supported with CPB as soon as possible. Those with ischemia refractory to the usual treatments should be placed on CPB also. While on CPB, the heart is emptied of blood and allowed to "rest," which greatly diminishes myocardial oxygen demand while coronary perfusion pressure is maintained by CPB. Once CPB is instituted, betablocking

---

drugs may be given without fear of causing hemodynamic instability.

Intra-aortic balloon pump (IABP): This device has been shown to be effective therapy for ischemia refractory to medical management. [52] It improves myocardial oxygen supply-demand balance by decreasing impedance to LV ejection, thereby decreasing myocardial work, and by raising diastolic arterial pressure, which increases coronary blood flow. An IABP may be inserted preoperatively in patients with persistent symptoms. However, the insertion of an IABP should not cause a delay in placing an unstable patient on CPB. Insertion of an IABP should be considered for patients with evidence of refractory ischemia after CPB, especially if the hemodynamics are marginal or inadequate.

After CPB, the adequacy of revascularization should be evaluated if there is evidence of myocardial ischemia. A new RWMA seen with TEE may help direct attention to a problem graft. Grafts should be inspected for kinks and other technical problems. Spasm of an internal mammary artery graft may respond to vasodilator and/or calcium channel blocker therapy. Occasionally, return to CPB and placement of additional bypass grafts may be of benefit. Air embolization is another possible cause of ischemia after CPB, especially in the distribution of the right coronary artery, and the resulting right ventricular failure is best managed by returning to CPB and resting the heart while maintaining a relatively high coronary perfusion pressure and giving a coronary dilator such as NTG.

Choice of Anesthetic Technique

Does the choice of anesthetic affect the incidence of perioperative myocardial ischemia or infarction? To date, there is no substantial evidence that it does. [53] [54] [55] [56] [57] However, this answer has to be qualified by the following considerations:

1. Few real outcome studies have been made. Measurement of the presence or absence of intraoperative hemodynamic changes in relation to a particular anesthetic technique does not allow prediction of outcome (e.g., perioperative MI). [58] Also, it is not possible to separate the effects of anesthesia from those of the surgical operation. [59]
2. Few patients are anesthetized with a single anesthetic drug. Preanesthetic and intraoperative medications, including central nervous system (CNS) and cardiovascular drugs, modify the patient's response to the primary anesthetic in ways that are still largely unknown or at least not accurately determined in a controlled manner. [13] [53]
3. Monitoring and treatment of potentially adverse hemodynamic changes might improve outcome, and it is clear that no anesthetic technique does away with the need for such monitoring and therapy. It is important to note that most perioperative MIs related to noncardiac surgery occur in the postoperative rather than the intraoperative period. [60]
4. Theoretical concerns related to a specific anesthetic (e.g., coronary steal produced by isoflurane) have not been found to be detrimental in clinical practice. [57] [61] [62] [63] [64] [65] [66] Perhaps this is because of offsetting pharmacologic effects of the anesthetic (e.g., isoflurane raises the threshold heart rate to pacing-induced ischemia), use of supplemental drugs that reduce the dose of the anesthetic required, careful monitoring, and prevention or treatment of even moderate hemodynamic changes.
5. Finally, it is important to remember a basic principle of scientific scrutiny: Coincidence of events in time is not proof of a cause-and-effect relationship. [58] [59]

Valvular Surgery

Determinants of Cardiac Output

Blood pressure is the product of cardiac output (Ch. 16) and total peripheral resistance (BP = CO × TPR). Blood pressure alone is not a reliable indicator of cardiac performance, because blood pressure can be maintained by increased peripheral vascular resistance even with a marked reduction of cardiac output. Cardiac output is an indicator of overall cardiac performance because it represents the volume of blood available for perfusion of body tissues, which is the purpose of cardiac function.

Table 49-13 lists factors affecting cardiac output, which is the product of stroke volume and heart rate (CO = SV × HR). Decreases in stroke volume can be compensated by increasing heart rate until the tachycardia encroaches on the minimum diastolic time required for adequate ventricular filling and perfusion of the subendocardium. Dysrhythmias usually decrease cardiac output and make the work of the heart less efficient. Coordinated activity of ventricular myofibrils is essential for development of maximum pressure

TABLE 49-13 -- Factors Affecting Cardiac Output[a]

Rate
Proportional increase in cardiac output unless shortening of diastolic time reduces ventricular preload or impairs contractility as a result of reduced coronary perfusion
Cardiac output is rate-dependent with fixed stroke volume (ventricular and valvular dysfunction)
Rhythm
Coordinated ventricular contraction essential (impaired by conduction abnormalities and ventricular pacing)
Properly timed atrial contraction augments ventricular preload, especially important with impaired diastolic ventricular function (compliance) (lost with atrial fibrillation, first-degree heart block, ventricular pacing)

Preload
Increased ventricular filling stretches myofibrils and increases contractility (Frank-Starling principle)
Overdistention of ventricle increases oxygen demand and impairs contractility
Afterload
Determined in part by vascular resistance and indicative of the pressure work the ventricle must do to overcome the impedance to ejection
Reduction of afterload increases cardiac output unless hypotension reduces coronary perfusion and impairs contractility
Reduced by increased ventricular wall thickness--compensatory hypertrophy
Ventricular contractility (inotropic state)
Intrinsic state of cardiac muscle that can be described by cardiac performance curves
Affected by myocardial metabolism, oxygen supply, ionized calcium concentration, drugs, hypertrophy, and myocardiopathies

[a] Also see Chapters 16 and 30 .

Figure 49-2 Frank-Starling principle: measures of left ventricular performance (vertical axis) increase up to a maximal level as ventricular preload (horizontal axis) is increased. Low-perfusion states exist when cardiac output is insufficient to meet the oxygen demand of all body tissues. Pulmonary and venous congestion results when capillary hydrostatic pressure increases and produces a net transfer of water and electrolytes out of capillary blood into the interstitial spaces of the lung. Measures of ventricular performance are LVSWI, left ventricular stroke work index; SV, stroke volume; CO, cardiac output; CI, cardiac index; and in some cases blood pressure, BP. Measures of ventricular preload are LVEDV, left ventricular end-diastolic volume; LVEDP, left ventricular end-diastolic pressure; LAP, left atrial pressure; PCWP, pulmonary capillary wedge pressure; or PAOP, pulmonary artery occlusion pressure; and in some cases central venous pressure, CVP, especially with right ventricular (RV) dysfunction.

by the ventricle. An effective atrial contraction properly timed with ventricular diastole is usually essential for optimal loading of the ventricle just before the onset of systole.

Stroke volume depends on the interaction of three factors:

1. Preload determines the degree of stretch of ventricular fibers and thereby determines the amount of work that can be done by the ventricle at any particular level of contractility.
2. Contractility is an intrinsic property of cardiac myofibrils and represents the amount of work they can produce at any end-diastolic fiber length (preload). The relationship between preload and contractility is best illustrated by cardiac performance curves based on the Frank-Starling principle (Fig. 49-2) .
3. Afterload represents the tension developed in the ventricular well and determines the relationship between pressure and volume work during ventricular systole. Afterload is determined in part by vascular resistance in the absence of aortic or pulmonic valvular stenosis. High levels of vascular resistance mean that proportionately greater amounts of ventricular work will be expended for pressure development (to overcome resistance); correspondingly, lesser proportions of ventricular work will go toward the actual ejection of blood (stroke volume). Increase in ventricular diameter will also increase wall tension and afterload.

Appropriate management of hemodynamic problems depends on the anesthesiologist's understanding the role of each of the factors and of the interactions among them in health and disease. All anesthetic drugs affect one or more of the individual factors and in some cases alter their interrelationships. Furthermore, with modern drugs and advanced monitoring techniques, it is possible to choose therapeutic measures directed somewhat selectively at one or more of these determinants of cardiac output. These determinants also operate in compensatory mechanisms for acute and chronic cardiovascular disease.

Compensatory Changes in Disease

Acute hemodynamic alterations elicit reflex changes directed toward maintenance of cardiac performance. Chronic problems may elicit reflex activity and also lead to long-lasting or permanent alterations in organ structure and function. Reflex changes tend to be more readily measured, more susceptible to therapeutic intervention, and more rapidly reversible with correction of the basic problem than those involving structural alterations.

All types of valvular heart disease reduce the effective (forward) stroke volume. A number of compensatory mechanisms may be called into play (Table 49-14) ; the most important for each type of valvular heart disease are discussed below. Several points should be emphasized in relation to these compensatory mechanisms.

Each mechanism produces symptoms and signs, the intensities of which are not necessarily correlated with the severity of valvular disease or the functional status of cardiac muscle. These symptoms depend on both the severity of the mechanical overload and the degree of impairment of contractility secondary to the valvular disease or due to coexisting myocardial disease (e.g., coronary atherosclerosis, cardiomyopathy). It is necessary to evaluate both valvular

TABLE 49-14 -- Mechanisms of Compensation for Reduced Left Ventricular Stroke Work and Ejection Volume [a]

Increased sympathetic nervous system activity
Results from hypotension leading to decreased arterial baroreceptor inhibition of autonomic centers in the brain stem
Increases heart rate and contractility (depending on the functional status of ventricular myofibrils)
Produces arterial vasoconstriction and increases systemic and pulmonary vascular resistances
Stimulates release of renin, which increases vascular resistance and promotes salt and water retention through release of aldosterone
Frank-Starling mechanisms of increased left ventricular diastolic volume (preload)
Results from reduced stroke volume and accumulation of venous return
Increases stroke volume (depending on functional status of ventricular myofibrils)
Provides geometric mechanical advantage; the same stroke volume can be ejected with less circumferential shortening of myofibrils (but may reduce right ventricular volume and function)
Is supplemented by the retention of salt and water by the kidney
Ventricular hypertrophy
Results from increased intramyocardial tension caused by increased pressure or volume overloading of the ventricle
Ventricular thickness increases and compliance decreases
Increased number of sarcomeres tends to increase stroke work and to maintain stroke volume
Increased wall thickness decreases systolic wall tension and thereby reduces afterload (tension = pressure × radius/ wall thickness)

[a] Also see Chapter 16 .

disease and ventricular contractility objectively, usually by cardiac catheterization.

Certain compensatory processes (e.g., ventricular hypertrophy, increased pulmonary vascular resistance [PVR]) alter the relationships between blood pressure and blood volume or flow. Pressure values outside the range of normal are commonly seen in patients with cardiac disease. It is important to recognize that the abnormal values are part of the compensatory processes and that it may be necessary to maintain them at the abnormal but usual level for that particular patient both before and after surgery. Under such circumstances the anesthesiologist should be guided more by trends of change than by absolute values--hence the importance of continuous, precise monitoring techniques.

On the other hand, the sudden replacement of a diseased valve with a more normally functioning valvular prosthesis may acutely alter the impact of compensating mechanisms on cardiovascular (and other organ) functions and indicate therapy aimed at neutralizing those mechanisms that have suddenly become detrimental to cardiovascular function.

Finally, the stress imposed by anesthesia and surgery may exceed the upper limits of cardiovascular reserve even after the primary problem has been corrected. The anesthesiologist should be prepared to initiate the appropriate therapy intraoperatively. This responsibility obviously requires a thorough understanding of the drugs and devices (e.g., pacemakers, IABPs) that may be needed.

Valvular Versus Contractile Functions

Valvular diseases interfere mechanically with cardiac function and ultimately lead to abnormalities of ventricular contractility. As indicated previously, the evaluation of contractility may be complicated by the valvular malfunction and by the chronic compensatory changes that result. The indexes of good and poor ventricular function stated here for patients with CAD may not apply to those with valvular disease. For example, ventricular end-diastolic pressure is not a good index of ventricular function in the presence of aortic or mitral regurgitation because LVEDP and LVEDV are determined by both the contractile state of the heart and the severity of regurgitation. LVEDP is also a function of ventricular compliance. In the presence of aortic stenosis with ventricular hypertrophy and stiffness, LVEDP may increase out of proportion to LVEDV and with only minor reductions in contractility. Potentially elevated LVEDP may be reduced to normal levels by a reduction of the circulating blood volume.

Preoperatively, the ejection fraction is probably the best index of contractility that is usually available, although it too has limitations. [67]

As the ejection fraction falls progressively below 0.5, it is indicative of progressively more severe impairment of ventricular function, especially if the systemic vascular resistance is normal or low at the time of measurement. In the presence of mitral valvular insufficiency, the ejection fraction is not a reliable indicator of LV reserve because much of the ejected volume is regurgitant flow against low resistance.

Intraoperatively, the determination of ventricular function relationships (see Fig. 49-2) is probably the most efficient means of defining optimal or maximal cardiac performance. The change in cardiac output in response to different degrees of ventricular loading, as indicated by the LVEDV or LVEDP, left atrial pressure (LAP), PAOP, or in the case of the right ventricle, central venous pressure, defines the ventricular status and indicates the need for specific therapeutic measures.

Specific Valvular Diseases

Under each of the following headings, only the pathophysiologic features of immediate importance to the anesthetic management of patients with valvular heart disease

are summarized. More detailed and comprehensive treatises are available.

Mitral Stenosis

Mitral stenosis is almost always rheumatic in origin and usually follows a prolonged course of development. Symptoms appear early but usually progress slowly until there is a suddenly increased demand for cardiac output (e.g., because of pregnancy or infection) or until atrial fibrillation supervenes. Atrial contraction contributes up to 40 percent of LV filling in the presence of mitral stenosis as compared with 15 percent in the normal heart. Estimation of the severity of the stenosis in terms of the end-diastolic pressure gradient between the left atrium and ventricle is not reliable because the gradient is dependent on heart rate, blood flow, and other variables. Estimates of mitral valve area provide a somewhat more reliable indication of the severity of the disease. [68] The area of the normal adult mitral valve ranges from 4 to 6 cm^2 , and stenosis is graded as mild (1.5-2.5 cm^2), moderate (1.1-1.5 cm^2), or severe (1 cm^2). The pathophysiologic progression is summarized in Figure 49-3 (Figure Not Available) .

Several features of the disease are especially important in terms of maintaining cardiac output:

1. Heart rate is the primary consideration. It should be maintained in a normal range. Bradycardia markedly reduces cardiac output because the stroke volume is limited by the stenotic valve and by the relatively small size of the left ventricle. Tachycardia can be even more detrimental because it severely reduces LV preload (decreased diastolic filling rate due to the stenotic valve) and cardiac output. Pulmonary edema can develop suddenly if atrial fibrillation occurs with a rapid ventricular response; the latter must be treated aggressively (i.e., cardioversion, diltiazem, or beta blocker). Continuation of maintenance therapy with a cardiac glycoside through the time of surgery is indicated to control the ventricular rate in the presence of atrial arrhythmias.
2. Near maximally tolerated LAP should be maintained, yet pulmonary edema should be prevented. Precise monitoring of LAP or PAOP is obviously desirable. However, increased PVR and pulmonary hypertension entail the following effects: (1) the risk of pulmonary artery (PA) rupture by inflation of the balloon on a PAC is probably increased; (2) it may not be possible to obtain a PAOP tracing; (3) the PA diastolic pressure is not an accurate estimate of either LAP or LVEDP (although the pressures may show similar trends of change); and (4) it is sometimes difficult to float the catheter tip into the PA. For these reasons, in certain patients it may be advisable to ask the surgeon to insert a left atrial catheter for LAP monitoring, especially before attempting to discontinue extracorporeal circulation. An LAP to LVEDP mean gradient of 4 to 7 mm Hg is to be expected across most prosthetic mitral valves. [69] [70]
3. Progression of the disease to include PA hypertension has two other consequences. Increased PVR may limit left atrial and LV filling, and the right ventricle (RV) may fail as it works to overcome impedance to its ejection of blood. It is advisable to monitor pulmonary artery pressure and to eliminate factors that increase it (e.g., hypercarbia, hypoxia, and nitrous oxide). It is also important to monitor right atrial or central venous pressure (CVP) to detect signs of RV failure.

Incidentally, contractility of the chronically underloaded, usually small LV is seldom a problem in otherwise uncomplicated mitral valvular surgery for "pure" mitral stenosis. However, LV output may be inadequate in the presence of RV failure because of (1) inadequate LV filling due to low pulmonary blood flow and (2) RV dilation with bulging of the interventricular septum into the LV cavity, thereby reducing LVEDV and impairing LV ejection. [71] [72]

4. Pulmonary hypertension, RV failure, and tricuspid regurgitation usually improve in the days and weeks following correction of mitral stenosis. However, structural changes due to long-standing disease limit the extent of improvement. [73]

Figure 49-3 (Figure Not Available) Pathophysiology of mitral stenosis. *(Modified from Thomas SJ, Lowenstein E: Anesthetic management of the patient with valvular heart disease. Int Anesthesiol Clin*

17:67, 1979.)

In summary, the important cardiovascular management goals for mitral stenosis are (1) to prevent tachycardia and maintain a sinus rhythm; (2) to maintain LV preload and stroke volume while preventing pulmonary edema; and (3) to prevent further increases in PVR and treat RV failure if it occurs.

Mitral Regurgitation

Mitral regurgitation has numerous causes and may occur suddenly (e.g., because of papillary muscle rupture) or develop gradually and progressively (e.g., in association with mitral stenosis of rheumatic origin). Mitral regurgitation produces volume overloading of the left ventricle.

In the acute case, sudden and dramatic hemodynamic changes may result from the increased LAP and the reduction of cardiac output. Elevated LAP is transmitted to the pulmonary circulation and can cause pulmonary congestion, pulmonary hypertension, and right heart failure. Compensating increases in sympathetic nervous system activity lead to tachycardia and increased systemic vascular resistance, which exacerbates the regurgitant flow. The outcome of surgery is guarded relative to the severity and suddenness of hemodynamic stress, especially when there is an associated impairment of LV function (e.g., infarction, endocarditis, or cardiomyopathy).

Chronic mitral regurgitation is compensated by the more gradual processes of LV hypertrophy and dilation (increased compliance) and left atrial dilation. Generally, there is minimal involvement of the pulmonary vasculature and RV until late in the progress of the disease, when severe CHF may develop and a rapid downhill course ensues. The contrasts between acute and chronic mitral regurgitation are illustrated in Figure 49-4 (Figure Not Available) .

The severity of mitral valvular incompetence is estimated in terms of the regurgitant fraction, which expresses the regurgitant volume as a fraction of the total stroke volume; a regurgitant fraction greater than 0.6 is associated with CHF. Although these volumes can be estimated by either indicator dye dilution or ventriculography, it is usually adequate and more convenient to grade the amount of contrast material entering the left atrium during ventricular systole as part of ventriculography. A grading scale analogous to that used for aortic regurgitation (see later) can be applied. Semiquantitative assessment of the severity of mitral valvular regurgitation is possible with echocardiography, which may also identify the etiology of the regurgitation. Estimates of ventricular ejection fraction may be misleading because blood is leaving the ventricle by two routes. The incompetent mitral valve provides a low-pressure, low-resistance route, and the regurgitant volume can be greater than the blood volume entering the aorta. If only the aortic route were available, the degree of ventricular emptying would be less. [74]

The functional features of mitral regurgitation of most importance to the anesthesiologist are the following:

1. Heart rate should be maintained at normal or elevated levels to maintain cardiac output. Bradycardia is associated with increased LV volume, increased regurgitant fraction, and reduced systemic cardiac output. Many patients with chronic mitral regurgitation are in atrial fibrillation.
2. Increases in systemic vascular resistance should be prevented because they increase regurgitant flow. The use of arterial vasodilators to reduce systemic vascular resistance and increase "forward" cardiac output while decreasing regurgitant flow through the mitral valve may be beneficial, provided that excessive hypotension is avoided. [75]
3. Myocardial contractility is impaired in both acute and chronic mitral regurgitation and sensitive to cardiac depressant drugs. Increasing ventricular preload in an attempt to maintain or increase stroke volume has the disadvantages of dilating the compliant LV and increasing the regurgitant flow.
4. After mitral valvular replacement, there is a risk toLV integrity, especially in elderly patients. [76] Transverse rupture of the LV has occurred on resumption of ventricular pumping soon after valvular replacement and is thought to result from loss of ventricular support by the mitral valve apparatus. Many surgeons now preserve the posterior leaflet and attached chorda tendinea during initial valve replacement to help avoid this complication. (The apex of the heart is supported by attachment to the annulus by the papillary muscles, chordae tendinae, and valve leaflets.) The possibility of rupture is also increased by the loss of ventricular tone due to the residual effects of the cardioplegia solution administered for myocardial preservation during surgery. Measures to reduce the risk of ventricular disruption include operating on the beating heart unloaded by CPB but avoiding the use of cardioplegia, prolongingthe period of rest on CPB after valvular placement to allow recovery of ventricular tone, and using vasodilators to limit ventricular pressure and distention during diastole. [76] Vasodilators may also be needed to facilitate LV ejection after mitral valvular replacement, which eliminates restricted ventricular filling in the case of stenosis and stops the low-resistance regurgitant flow in the case of regurgitation. Insertion of an IABP may serve a similar purpose in this situation.

The goals of cardiovascular management of the patient with mitral regurgitation are (1) maintenance of a normal to slightly elevated heart rate, (2) reduction of systemic vascular resistance to the degree that it will promote systemic flow and reduce regurgitation without compromising cerebral and coronary perfusion, and (3) preservation of ventricular contractility while not increasing preload excessively.

Figure 49-4 (Figure Not Available) The syndrome of mitral regurgitation. (A) Acutely developing mitral regurgitation into small left atrium produces high pressures and changes in the left atrium (LA), pulmonary vein (PV), pulmonary artery (PA), right ventricle (RV), and right atrium (RA). (B) Chronic, slowly progressive mitral regurgitation produces dilation of the left atrium, so that pressures remain low and there is little change in the pulmonary vessels or right side of the heart. *(Modified from Roberts WC, Perloff JK: Mitral valvular disease. Ann Intern Med 77:939, 1972.)*

Aortic Insufficiency

Aortic insufficiency develops acutely from bacterial endocarditis, aortic aneurysmal dissection, connective tissue disease, and trauma. Chronic aortic regurgitation results from rheumatic disease, hypertension, syphilis, and other causes. The pathophysiology is outlined in Figure 49-5 (Figure Not Available) .

Acute aortic insufficiency places a sudden volume overload on the LV and raises both LVEDP and PAOP (unless there is premature closure of the mitral valve when LVEDP is greater than LAP). Tachycardia and peripheral vasoconstriction result from sympathetic stimulation and produce a further decrease in forward cardiac output. Acute LV failure can develop and progress rapidly.

Chronic aortic insufficiency results in ventricular hypertrophy and dilation (increased compliance). A competent mitral valve protects the pulmonary circulation until late in the disease process, when contractility becomes impaired, forward cardiac output falls, and peripheral vascular resistance increases. The progress of the disease is gradual, often without the development of symptoms for 10 to 20 years, but there is rapid deterioration once LV failure occurs. [77] [78] Surgery is usually recommended as soon as there is evidence that the ventricle is enlarging.

Figure 49-5 (Figure Not Available) Pathophysiology of aortic insufficiency. *(Modified from Thomas SJ, Lowenstein E: Anesthetic management of the patient with valvular heart disease. Int Anesthesiol Clin 17:67, 1979.)*

The severity of aortic valvular regurgitation is graded angiographically after contrast injection in the aortic root as follows:

1+: Small amount of contrast material enters LV during diastole, but LV is cleared with systole.

2+: LV is faintly opacified during diastole and not cleared with systole.

3+: LV is progressively opacified.

4+: LV is completely opacified during the first diastole and remains so for several beats.

In terms of regurgitant volume, 1 to 3 L/min is mild, 3 to 5 L/min is moderate, and more than 6 L/min is considered to be severe; regurgitant volumes up to 25 L/min have been reported. Other indicators of severe chronic aortic insufficiency are a sudden increase in ventricular size and the onset of CHF, often with the development

of secondary mitral insufficiency. [79]

Salient features of aortic insufficiency include the following:

1. A slightly higher than normal heart rate is often beneficial because it reduces ventricular distention (reduced time for diastolic regurgitation) and oxygen consumption (effect of smaller LVEDV outweighs that of increased heart rate) while improving subendocardial blood flow (higher diastolic blood pressure with lower LVEDP). Bradycardia should be prevented.
2. Arterial blood pressure often is labile and very responsive to vasoactive drugs. Nevertheless, with careful monitoring of blood pressure and left ventricular filling pressures (i.e., PAOP), vasodilators can be used to advantage to increase forward cardiac output and to decrease LV distention, secondary mitral regurgitation, and pulmonary venous pressure. [80] [81] Diastolic hypotension with the lowering of coronary perfusion should be prevented. After aortic valvular replacement, vasodilators may be needed to control hypertension.
3. Ventricular contractility is usually impaired in patients undergoing valve replacement for either acute or chronic aortic regurgitation. [82] Myocardial oxygen demand is increased only moderately by aortic insufficiency, because volume work increases oxygen use by only 5 to 10 percent and LV wall tension increases only slightly until the late stages of the disease (see Fig. 49-5) (Figure Not Available) .

In summary, the cardiovascular management goals are to maintain a higher than normal heart rate (80-100 beats/min), reduce afterload appropriately, and avoid myocardial depressants.

The presence of aortic regurgitation has significant implications during cardiopulmonary bypass. Once the heart ceases to eject blood (as with ventricular fibrillation), the left ventricle will quickly distend as the pressure between the aorta and LV equalize through the incompetent aortic valve. Administration of a beta blocker (e.g., 50-100 mg esmolol, 5-10 mg metoprolol, 2-5 mg propranolol) IV 3 to 5 minutes before initiating CPB can significantly delay the onset of ventricular fibrillation during cooling of the heart on CPB. The surgeons may decompress the LV with a vent, but this may result in a low arterial pressure if the aortic regurgitation is severe and result in a significant portion of the pump flow passing from the aorta through the LV and back to the bypass machine through the vent, not perfusing the patient. Application of the aortic cross-clamp may be the only way to remedy this situation. Significant aortic regurgitation will also make the delivery of cardioplegia in the antegrade mode difficult or ineffective.

Aortic Stenosis

Aortic stenosis (Fig. 49-6) (Figure Not Available) usually occurs as a result of thickening or degeneration and calcification of a congenitally abnormal valve. It can also be of rheumatic origin, usually in association with mitral valvular disease. Stenosis of the aortic valve places a pressure overload on the LV, which hypertrophies but does not dilate; that is, there is low ventricular compliance. [83] Major consequences of decreased ventricular compliance include the following:

Figure 49-6 (Figure Not Available) Pathophysiology of aortic stenosis. *(Modified from Thomas SJ, Lowenstein E: Anesthetic management of the patient with valvular heart disease. Int Anesthesiol Clin 17:67, 1979.)*

1. Higher filling pressures are needed for optimal cardiac performance, and these are reflected into the pulmonary circulation and can result in pulmonary congestion if they become too high. Precise monitoring of PAOP and cardiac output is important. In the noncompliant ventricle, the mean PAOP underestimates the LVEDP, which is more closely approximated by the a-wave on the PAOP tracing. [84]
2. A normal sinus rhythm is very beneficial because the atrial "kick" may account for up to 40 percent of ventricular filling. Cardioversion should be done promptly for an acute onset of atrial fibrillation. It should be noted that cardiopulmonary resuscitation is extremely difficult in the patient with aortic stenosis and ventricular hypertrophy. Dysrhythmias should be prevented and treated promptly. A moderate

heart rate (70-90 beats/min) is probably best to maintain cardiac output and to prevent myocardial ischemia.
3. Pressure overloading of the LV and the resulting hypertrophy lead to major alterations of myocardial oxygen demand and supply. Demand is increased by the increased mass of the ventricle and increased ventricular pressure work. Supply is reduced by decreased diastolic perfusion time (longer systole for ejection of stroke volume through the stenotic valve), increased LVEDP (impaired subendocardial perfusion), and decreased systemic blood pressure (lower coronary perfusion pressure). In addition, the density of capillaries may be decreased in the hypertrophied ventricular muscle, and CAD frequently coexists with aortic stenosis. [85] [86] Patients with aortic stenosis experience angina even without CAD and have little or no coronary flow reserve. They are especially at risk from peripheral vasodilation, which can produce sudden and profound hypotension that can impair both cerebral and coronary perfusion.

The severity of aortic stenosis is most accurately stated in terms of the estimated valve area, which normally is 2.5 to 3.5 cm^2. Areas less than 1 cm^2 indicate surgical correction; angina and syncope due to arrhythmias or to an inability to meet a sudden demand (e.g., exertion) for an increased cardiac output are common with areas less than 0.7 cm^2 and pose a risk of sudden death. [84] Other signs of severe disease are systemic arterial pulse pressure less than 30 mm Hg and CHF. A low aortic valvular pressure gradient may indicate LV failure; high systolic blood pressure suggests less severe disease. A low LV ejection fraction may be misleading, because a strong ventricle may be pumping against a very high impedance to ejection.

The cardiovascular management goals for patients with aortic stenosis are (1) to maintain a sinus rhythm at a normal rate, (2) to maintain systemic diastolic blood pressure and coronary perfusion, and (3) to maintain cardiac output by appropriately high preload and by avoidance of myocardial depressants. The potential benefit of attempting to reduce myocardial work and oxygen demand by depressant anesthetics is offset by the risk of lowering diastolic and coronary perfusion pressures; the overall benefit-risk relationship is unknown.

Diseases Resembling Aortic Stenosis

Several disease processes resemble aortic stenosis in their hemodynamic effects.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is a genetically transmitted disease that results in increase in ventricular mass, which may result in obstruction of the LV outflow tract in some patients. [87] Hypertrophic obstructive cardiomyopathy is often referred to as idiopathic hypertrophic subaortic stenosis (IHSS), an asymmetric hypertrophy of the interventricular septum. The obstruction to ventricular ejection is due to abnormal anterior movement of the mitral valve leaflet across the left ventricular outflow tract to contact the septum during systole. This produces a highly variable and dynamic amount of functional aortic stenosis as well as mitral regurgitation. Factors that increase the degree of obstruction and the pressure gradient between the LV and aorta include lower arterial pressure, lower LV volume, and increased ejection velocity. As a result of the obstruction, myocardial oxygen consumption increases, the LV hypertrophies and becomes less compliant, and the higher filling pressures are reflected to the atrium, which is often dilated and hypertrophied. The obstruction is usually progressive, and eventually LV failure occurs. [87] There is a high incidence of conduction abnormalities associated with the disease and also occurring after surgery (ventriculomyotomy and myomectomy) that involves dissection of the hypertrophied septum near the atrioventricular conduction system. With improved medical therapy, including beta-adrenergic receptor and calcium channel blocking drugs, and the effectiveness of atrioventricular sequential pacing, indications for surgical correction have been present less frequently. [88] [89]

Should surgery be indicated, hemodynamic management is directed toward minimizing the systolic pressure gradient between the LV and the aorta. Hence, arterial blood pressure and ventricular volume should be maintained or increased and ejection velocity should be reduced. [90] [91] Vasoconstrictors (e.g., phenylephrine), beta-adrenergic receptor blockers (e.g., propranolol), and myocardial depressant anesthetics (e.g., halothane [92]) have proven to be useful. Reductions in venous return (e.g., by high airway pressure) and dysrhythmias are poorly tolerated. Mitral regurgitation may occur with IHSS as a result of the abnormality of the anterior mitral leaflet and the high ventricular pressures. It must be remembered that pharmacologic interventions affect mitral regurgitation occurring with IHSS in a manner opposite to their effects in other forms of mitral regurgitation (i.e., inotropes and vasodilators worsen and vasoconstrictors improve ventricular ejection).

Other Diseases

Other diseases that lead to pressure overloading of the LV and the resultant hypertrophic and compliance changes include chronic systemic arterial hypertension and

coarctation of the aorta. Management of patients with these diseases is discussed in Chapters 16 , 50 , and 51 . Control of the acute LV pressure overloading resulting from clamping the aorta (e.g., during aortic surgery) is also important (Ch. 50) .

Tricuspid Regurgitation

Tricuspid regurgitation as an isolated cardiac abnormality is rare, although its incidence is rising as a complication of endocarditis from intravenous drug abuse. It imposes volume overload on the RV, which is tolerated well unless it is combined with a pressure overload such as that caused by high PVR or LV failure. [93] Purely functional tricuspid regurgitation can occur in the late stages of aortic and mitral valvular diseases and usually is markedly reduced or eliminated by correction of the primary disease. It is sometimes necessary to examine the tricuspid valve at the time of surgery to determine whether it should be repaired or replaced, because accurate preoperative evaluation of its function

is difficult with the relatively low pressure gradients existing across the valve. TEE can be used intraoperatively to assess tricuspid valvular regurgitation.

Hemodynamic considerations should be directed toward maintaining moderately high CVP and preventing increases in PVR. Anything that reduces forward RV output reduces LV filling and output. [71] [72]

Other Types of Cardiac Disease and Surgery

Cardiomyopathy and Transplantation

By strict definition, the term *cardiomyopathy* includes any and all structural and functional abnormalities of the ventricular myocardium. In common parlance, the term is more often focused on advanced cardiac disease not amenable to medical or surgical treatment. There are multiple etiologies (e.g., familial, infectious, ischemic, alcoholic, pregnancy-related) and several subtypes (i.e., dilated, hypertrophic, restrictive, and obliterative). Dilated cardiomyopathy is the most common form and is the most common indication for cardiac transplantation.

Issues of recipient and donor selection, organization and coordination of transplantation teams (which include anesthesiologists), perioperative evaluation, anesthetic management and life support of the recipient and donor, and immunosuppressive and antibiotic therapy are beyond the scope of this chapter. However, with the progressively increasing frequency of heart transplantation, all anesthesiologists are likely to encounter donors and recipients in their practice. Hence, they should have ready access to a current text or other reference that details the anesthetic and life support objectives and guidelines for care of these patients. [94] In the case of the donor (brain dead), the focus is on maintaining ventilation, circulation, body temperature, and acid-base and electrolyte balance until organs can be harvested. For the heart transplant recipient, the challenge is to maintain cardiac and other vital functions at the best possible level until CPB is established. After the transplanted heart is in place, weaning from CPB follows the same principles as for any other cardiac surgical patient with emphasis on two particular aspects of the transplanted heart: (1) the heart must be denervated and (2) its RV frequently has to pump against an elevated PVR that has developed in response to long-term progressive worsening of LV function in the recipient's diseased heart.

Congenital Heart Disease

Congenital heart disease (Ch. 50) includes a large number of defects, some of which involve complicated anatomic and functional abnormalities that are beyond the scope of the usual practices of anesthesia and surgery outside of a highly specialized medical center. The particular functional and anatomic features influence the choice of anesthetic drugs and techniques. Moreover, there are very specialized conditions and requirements related to the pediatric patient and especially to the newborn infant (e.g., physician-child-parent relationships, monitoring techniques appropriate for the small body size, and criteria for blood replacement). Only conditions encountered in the adult population are described here.

Atrial Septal Defects

Atrial septal defects in the absence of any other anomalies usually have few hemodynamic consequences, and their signs are often discovered incidentally during a physical examination. Such a defect has three potentially detrimental consequences: (1) embolic material (e.g., air and bacteria) ordinarily filtered by the lung may enter the systemic circulation through the defect; (2) the defect may offer a site for lodgement and growth of microorganisms; and (3) a left-to-right shunt will develop progressively because differences in pulmonary and systemic vascular resistances lead to differences in ventricular diastolic pressures, which are reflected into the atria. When there is significant left-to-right blood flow, there is an increase in PVR, the development of RV hypertrophy follows, and CHF can occur.

The anesthesiologist has two goals in managing a patient with an atrial septal defect: to prevent the intravenous introduction of air or contaminated substances and to prevent any increase in and perhaps to reduce systemic vascular resistance.

Ventricular Septal Defects

Ventricular septal defects are encountered in infants as a congenital defect and in adults as the consequence of rupture of the septum after infarction. In both instances, the large systolic pressure gradient between the ventricles leads to a left-to-right shunt, which overloads the pulmonary circulation and reduces systemic vascular perfusion.

In the adult with MI, the situation develops acutely and usually is accompanied by cardiogenic shock. Under such conditions, the surgical mortality rate exceeds 50 percent. Better results have been reported in patients who could be maintained for a period of days or weeks by medical management aimed at reducing left-to-right shunt and increasing systemic perfusion (e.g., inotropic and vasodilator drugs and IABP). Under conditions of left-to-right shunting, cardiac output determinations made with a thermodilution PAC are misleading; they do not represent LV output to the systemic circulation.

Anesthetic management of such patients is really an extension of their intensive care and involves extensive monitoring, continuation of measures for hemodynamic support, and use of anesthetic drugs that do not impair ventricular contractility or increase cardiac work.

Cardiac Tamponade and Chronic Constrictive Pericarditis

Cardiac tamponade and chronic constrictive pericarditis produce similar hemodynamic alterations at different rates. Cardiac tamponade involves accumulation of fluid or blood in the closed pericardial space, and the urgency of the condition is determined by the rate and degree of accumulation.

Chronic constrictive pericarditis results in a gradual obliteration of the pericardial space. In either case, diastolic filling of both ventricles is restricted so that stroke volume and cardiac output are reduced. [95] Myocardial function may be further depressed by inadequate oxygen delivery as a result of systemic hypotension, elevated ventricular diastolic pressure, compression of epicardial vessels, and tachycardia. [96] Tachycardia and arterial and venous vasoconstriction occur as a result of reflex sympathetic activation. When the compensatory tachycardia is unable to maintain cardiac output in the face of declining stroke volume, cardiogenic shock results. In some cases of acute tamponade, cardiovascular collapse may occur within minutes, and death can be prevented only by immediately relieving the intrapericardial pressure by subxiphoid insertion of a needle or a subxiphoid pericardial incision under local anesthesia.

Consideration of the preceding hemodynamic alterations is essential to the development of an appropriate anesthetic plan. This plan should include monitoring of the important hemodynamic variables, and it should omit drugs and minimize manipulations that decrease venous return, reduce heart rate, produce hypotension, result in hypoxemia, or impair ventricular contractility. [97] Particular attention should be paid to the mode of ventilation; positive pressure ventilation further embarrasses

venous return and cardiac output. Spontaneous ventilation should be maintained until the tamponade is relieved. [98] [99] Positive measures such as expansion of the circulating blood volume, infusion of an inotrope, and maintenance of a high oxygen content of arterial blood are often beneficial. [100] Antidysrhythmic drugs and extracorporeal circulation may be needed during pericardiectomy when surgical manipulation of the heart leads to dysrhythmias and impairs cardiac output.

Pacemaker Implantation

Pacemaker implantation may be temporary or permanent. [101] Temporary pacemaker leads are introduced through a central venous cannula inserted percutaneously under local anesthesia, with the pulse generator remaining outside the body. Permanent pacemaker leads may be inserted transvenously after surgically exposing a vein or may be placed on the epicardial surface through a subxiphoid or lateral thoracotomy incision; the pulse generator is implanted subcutaneously over the upper anterior thorax or lower abdomen. Permanent pacemaker insertion may be performed under local or general anesthesia.

The indications for a permanent pacemaker are complete heart block, which may be congenital, acquired by disease or by an ablation procedure for treatment of supraventricular tachycardia; sick sinus syndrome; and bradycardia with symptoms. Most often, patients with continuous or frequently recurring slow ventricular rates enter the operating room with a temporary pacemaker in place. Under such circumstances, the choice of anesthetic technique can be made primarily with regard to other cardiac and noncardiac diseases that the patient may have. With a slow ventricular rate and no pacemaker in place, anesthetic techniques that maintain or even increase the rate of cardiac depolarization and conduction should be used. Depression of the sympathetic nervous system can be prevented and activity of the vagal nerves can be blocked by atropine. In all cases, a temporary pacemaker should be immediately available for insertion, and if possible, a central vein should be cannulated in advance to facilitate rapid insertion of the temporary pacing leads if they are needed. The anesthesiologist should be familiar with the operation of temporary and permanent pacemakers that may be used. Continuous ECG monitoring is essential not only to detect bradycardia, but also to recognize the dysrhythmias that frequently occur on placement of the leads. Because many of the patients in need of pacemakers have other systemic diseases, their anesthetic management should be planned accordingly.

Dysrhythmia Surgery

The development of sophisticated techniques for electrophysiologic study of the heart makes it possible to identify abnormal conduction pathways responsible for dysrhythmias involving an impulse reentry mechanism. [102] [103] Such pathways may represent a congenital abnormality (e.g., Wolff-Parkinson-White syndrome) or may be the consequence of myocardial ischemia and infarction (e.g., recurrent ventricular tachycardia). When pharmacologic therapy is unsuccessful in suppressing the dysrhythmias, the patient may be a candidate for surgical or electric ablation of an accessory pathway or an abnormally conducting area of the ventricle or for implantation of an automatic implantable cardioverter-defibrillator (AICD). [104] [105] [106]

The development of steerable catheters that can be inserted percutaneously under local anesthesia and directed into cardiac chambers to identify and then electrically ablate accessory pathways has virtually eliminated the surgical treatment of preexcitation dysrhythmias. [107] Occasionally the anesthesiologist is requested to administer sedation for patient comfort and cooperation or to provide brief general anesthesia on an urgent basis in the electrophysiology laboratory for external cardioversion of atrial tachycardia or fibrillation during the ablation procedure done by the cardiologist.

AICD systems (transvenous endocardial leads, epicardial or subcutaneous patches, abdominal subcutaneous implanted generator) may be inserted in an operating room or electrophysiology laboratory by a surgeon or a cardiologist. General anesthesia is required for the insertion (multiple skin incisions and subcutaneous tunneling or thoracotomy) and for functional testing of the leads and generator, a process that involves multiple episodes of inducing ventricular tachycardia/fibrillation and electrical defibrillation. Patients whose dysrhythmias result from ischemia or infarction often undergo CABG and ventricular aneurysmectomy along with the antidysrhythmic procedure through a median sternotomy.

The anesthesiologist's challenges in anesthesia and life support are (1) to avoid precipitation of the dysrhythmias before the electrophysiologic study; (2) to avoid drugs that might interfere with the electrophysiologic study; and (3) to deal with the adverse hemodynamic consequences of the dysrhythmia, chronic antidysrhythmic therapy (e.g., amiodarone [108] [109]), and the operation. The principles underlying anesthesia and life support for patients undergoing these operations are based on common sense, a few laboratory experiments,

and case reports; definitive clinical investigations are lacking because of the obvious difficulties in controlling all the variables affecting the diagnosis and therapy of dysrhythmias. The details of current practices in the limited number of major cardiac surgical centers at which these operations are performed have not been published. A variety of anesthetic drugs have been used without evidence that any one technique is to be preferred. [105]

A few practical points arising from our practices at Emory University Hospital are the following:

1. The preoperative preparation of the patient scheduled for AICD implantation is carried out as for any other patient with the following points in mind. The decision to continue or discontinue chronic antidysrhythmic therapy is left to the cardiologist, who has to balance the risk of spontaneous onset of a dysrhythmia preoperatively against the need to induce the dysrhythmia intraoperatively while testing the AICD system and against the need to program the AICD according to the defibrillation threshold that will exist under the postoperative drug regimen. It is prudent for the anesthesiologist to avoid heavy preoperative sedation that may lead to hypoxemia and hypercarbia, which may precipitate a dysrhythmia.
2. Monitoring of the patient for AICD insertion includes ECG leads best suited to evaluate cardiac rhythm and ischemia, an intra-arterial catheter for systemic blood pressure monitoring on a beat-to-beat basis, and a central venous cannula for rapid injection of drugs into the central circulation. The decision to use a PAC balances its disadvantages against its advantages. A PAC may induce dysrhythmias, may complicate fluoroscopic localization of the transvenous leads, and when it is removed may become entangled and dislodge the leads. Most patients tolerate repeated brief episodes of ventricular fibrillation and defibrillation without substantial deterioration in cardiac function. If the latter should occur, a PAC can be inserted at that time. A PAC is seldom of immediate benefit when resuscitating a patient from ventricular fibrillation or asystole; rather, its value is in adjusting hemodynamic therapy after successful resuscitation. We have found TEE to be a useful monitor during AICD implantation, allowing direct, real-time assessment of cardiac function throughout the procedure.
3. Provisions for postoperative analgesia as well as intraoperative reduction of anesthetic dose requirements may include the preoperative insertion of a thoracic epidural catheter.
4. A choice of general anesthetic technique has not been demonstrated to be critical in the intraoperative testing of the AICD system, although full anesthetic doses of the potent volatile agents have modified fibrillation thresholds and suppressed ventricular tachycardia in animal models. Whether or not low concentrations of the potent volatile anesthetics modify AICD testing significantly remains to be demonstrated. If nitrous oxide is to be used, the risk of pneumothorax has to be recognized when the insertion procedure will not involve a thoracotomy. Also, it is advisable to administer 100 percent oxygen during the induction of ventricular fibrillation in order to maximize the oxygen availability to tissues. In choosing anesthetic drugs, we plan for the recovery of spontaneous ventilation and extubation of the trachea at the end of the operation.
5. Low-impedance conductive gel defibrillation electrodes are routinely applied to the patient's chest and back before the induction of anesthesia to allow synchronous cardioversion or defibrillation to be performed conveniently and quickly during any phase of general anesthesia and the operation. An external cardioverter defibrillator should be immediately available at all times perioperatively, even af-ter completion of the insertion of the AICD system, which is turned off for several days postoperatively to avoidits inappropriate triggering by supraventricular tachycardias common in the immediate postoperative period. The AICD battery has a limited amount of energy (300 shocks), which should not be wasted. The cardiologist should activate and program the AICD device several days postoperatively.
6. The AICD module should be deactivated during periods of electrocauterization, which will trigger it.
7. The avoidance of antidysrhythmic drugs does not preclude the judicious use of a local anesthetic (e.g., 1% procaine or 0.5% lidocaine) to infiltrate the skin before vascular cannulation.
8. Although definitive data to support the practice are lacking, we avoid drugs with anticholinergic (e.g., atropine, pancuronium) or sympathomimetic (e.g., ketamine) properties.
9. Finally, although every effort is made to comply with the guidelines noted, the patient's overall welfare remains the first priority. Fortunately, the anesthesiologist has multiple options in providing comfort for procedures done with local anesthesia or general anesthesia, maintaining vital functions, and limiting the extremes of hemodynamic compromise imposed by the operation.

Thoracic Aortic Aneurysms

The management of patients undergoing surgical repair of certain types of thoracic aortic aneurysms has many similarities to the management of those undergoing cardiac operations. [110] [111] [112] Hypothermic CPB is used, aortic valvular insufficiency may be present, CAD is prevalent, and cardiac function is at risk from the surgical procedure imposed on preexisting disease.

Four major types of problems involving the thoracic aorta are of concern to the anesthesiologist: dissection, aneurysm, traumatic rupture, and coarctation. There are several classification schemes for aortic dissections and aneurysms, but from the point of view of surgical correction there are three major types: (1) ascending aorta with or without aortic valvular involvement (Debakey type II, Stanford type A); (2) ascending aorta and aortic arch (Debakey type I, Stanford type A); (3) descending aorta (i.e., distal to the left subclavian artery; Debakey type III, Stanford type B). The last is discussed in Chapters 48 and 51 .

Monitoring considerations for patients undergoing repair of the ascending aorta with or without aortic valve replacement include placement of the arterial cannula for systemic blood pressure monitoring in the left upper extremity or a lower extremity because of the potential need to cross-clamp the innominate artery. A thermodilution PAC is indicated because of the high risk of impaired ventricular function (LV wall stress, ischemia, aortic insufficiency)

---

and the need to guide blood volume replacement and the use of vasodilators to decrease afterload, limit aortic dissection, reduce tension on aortic suture lines, and reduce bleeding. TEE is useful in identifying the site of intimal tear and the extent of dissection, and in assessing cardiac function. [113] [114] In operations to repair the aortic arch, deep hypothermia (15-18°C) and circulatory arrest are used. The electroencephalogram (EEG) is useful to verify complete suppression of cerebral cortical electrical activity by hypothermia with or without the use of thiopental.

Vascular cannulation for CPB usually involves cannulation of the femoral artery and occasionally the femoral vein before sternotomy, after which more complete venous return can be achieved by cannulation through the right atrium. When aortic valvular insufficiency is present, an LV vent is used.

A number of specific issues require the attention of the anesthesiologist caring for patients undergoing deep hypothermia and circulatory arrest for operations on the aortic arch. [111] In addition to thiopental to produce and maintain EEG burst suppression during cooling and rewarming, it is common practice to administer methylprednisolone, mannitol, and furosemide to limit cerebral edema and to promote diuresis. The use of phenytoin or nimodipine for cerebral protection continues to be investigated. Before reestablishing circulation, the patient should be placed in the deep Trendelenburg position to minimize the risks of cerebral embolization of air and debris. Nitrous oxide is to be avoided because of its expansion of air emboli, which are certain to be present in the arterial circulation. Complete muscular paralysis is used to limit oxygen utilization and to minimize the risk of the gasping response to deep hypothermia. Severe degrees of hyperglycemia should be avoided by omission of dextrose-containing intravenous fluids, intermittent measurement of blood glucose concentrations, and administration of insulin as necessary to maintain serum glucose in the 100 to 250 mg/dL range.

Because of the long periods of time required for rewarming during CPB with heparinization, the loss of blood is very large, and the need for transfusion of red blood cells and coagulation factors is great. In anticipation of the need to replace large volumes of blood rapidly after the completion of CPB, when hemorrhage usually persists for a considerable time, it is wise to insert two large-bore venous cannulas before commencement of the surgical operation. Renal function is at risk for obvious reasons during this type of operation, and renal blood flow should be sustained by adequate volume replacement and the use of mannitol; furosemide and a dopamine infusion may be required to maintain adequate urine flow.

Incidentally, aortic dissection is a relatively rare complication of aortic cannulation for any type of operation involving CPB. [112] It is now common practice to reduce the risk of this complication by deliberately lowering systolic and mean arterial blood pressures with a central intravenous bolus dose of nitroprusside or NTG at the time of aortic cannulation as well as at the time of removal of the aortic cannula. In addition, the surgeon should ask the perfusionist to reduce the arterial inflow from the CPB circuit at times when the aortic cross-clamp is applied and removed.

THE ANESTHETIC PLAN

The anesthesiologist's responsibility to the patient begins with the preoperative visit and extends through the time required for complete recovery from the effects of anesthetic drugs and procedures, including any complications that may be related to anesthesia, monitoring, and intraoperative life-supporting therapy. To prepare for effective and safe management of the patient through the perioperative period, an anesthetic plan should be developed based on a good understanding of the patient and the disease, the operation and surgeon, the anesthetic drugs and procedures, and the personnel and facilities available before, during, and after surgery. What follows is a discussion of the more important aspects of the anesthetic plan.

With the focus on reducing costs by shortening the length of stay in the ICU, the anesthesiologist is encouraged to design an anesthetic plan that not only fulfills the requirements of general anesthesia (i.e., unconsciousness, autonomic, and somatic reflex suppression) during intense noxious stimulation intraoperatively but also allows an appropriately rapid recovery of consciousness and spontaneous ventilation postoperatively. In the uncomplicated case, the goal is to allow tracheal extubation very soon after the patient's condition is stabilized in the ICU, usually within 2 to 4 hours postoperatively. Hence, there is continuing effort to develop rapid-onset, short-acting anesthetics, opioids, hypnotics, and muscle relaxants that allow efficient titration of dose (infusion rate) according to the individual patient's needs both intra- and postoperatively.

Monitoring

Many of the hemodynamic monitoring techniques used by the current well-trained anesthesiologist are invasive and expensive. Their use should be justified by a reasonable cost-benefit analysis that includes the risks of not using them and the costs of using the alternatives. It is wise to indicate in the preoperative note a summary of the anesthetic plan, including monitoring techniques to be used, and to justify the need for any unusual monitors. Such documentation helps the anesthesiologist to focus critically on the patient's problems and presents justification for the risks and expense incurred by the patient.

Essential Monitoring

Essential monitoring for any patient undergoing cardiac surgery includes the procedures discussed below.

Arterial Blood Pressure

Arterial blood pressure (Ch. 30) is monitored continuously and directly by way of an arterial cannula. Sudden changes in blood pressure are encountered routinely during cardiac surgery as a consequence of hemodynamic instability related to the patient's disease, surgical manipulation of the heart and great vessels, marked changes in circulating

blood volume, and frequent use of potent drugs that affect the cardiovascular system. Such monitoring is essential for mean blood pressure measurement while blood flow is nonpulsatile during CPB. The intra-arterial cannula facilitates convenient blood sampling for the laboratory determinations discussed below. A continuous oscillographic display or recording of the arterial pressure waveform provides valuable clues about cardiac contractility, cardiac output, and systemic vascular resistance and gives instantaneous indications of the hemodynamic consequences of dysrhythmias, electrical pacing, artificial ventilation, surgical manipulations, and other interventions.

Electrocardiogram

The ECG (Ch. 32) is monitored continuously, preferably with a properly standardized recorder to capture selected events for precise analysis (e.g., P-R interval, dysrhythmias, ST-T segment changes) and for comparison with earlier and later findings. Changes in rhythm occur at least transiently in every cardiac operation as a result of surgical manipulation and electrolyte, metabolic, and temperature alterations. Moreover, cardiac disease often predisposes the heart to abnormalities of rate and rhythm and to ischemia. Modern monitors can automatically measure and trend ST segment changes in multiple leads and may be configured to alarm if significant ischemic changes are detected. [115] [116] With CAD, two ECG leads usually are observed simultaneously (e.g., V_5 for anterolateral and II or aVf for inferior ischemia). Valvular surgery carries the risk of at least temporary impairment of the cardiac conduction system; diagnosis of conduction problems and monitoring of the effectiveness of pacemaker devices or other therapy require continuous ECG monitoring.

Ventricular Preload

Preload (Ch. 30) , an important determinant of cardiac function, changes dramatically throughout cardiac surgery. Fundamentally, preload is defined as the degree of stretch placed on the myofibrils at end-diastole. Intraoperative assessment of preload may be by direct visual inspection of the heart, filling pressure measurements, and TEE.

The heart is visible throughout most of a cardiac surgical procedure, and a gross estimation of the preload can be made based on its appearance (empty, full, or overdistended). This requires some experience and usually provides information primarily about the preload of the RV, as most of the LV is not visible through a median sternotomy incision.

Ventricular filling pressures are the most common means of assessing preload during cardiac surgery. The CVP directly reflects RV filling and function and is a reasonable, indirect measurement of LV preload in the absence of pulmonary vascular disease and LV dysfunction. The CVP is also useful in the early detection of superior vena cava obstruction by the vena cava cannula draining blood into the CPB reservoir. When there are discrepancies in the functional status of the right and left ventricles (e.g., poor LV function [see Table 49-11]) , it is important to determine the PAOP or the LAP to adjust the LV preload to an optimal level and to detect elevated pressures before they lead to pulmonary edema. A left atrial catheter (inserted by the surgeon) may be used cautiously (avoidance of systemic air emboli) to monitor LAP and to infuse drugs for their systemic effects while minimizing their actions on the pulmonary circulation.

Images of the ventricular chambers obtained by TEE allow measurement of end-diastolic volume, a more direct reflection of preload than end-diastolic pressure. Significant abnormalities and acute changes in ventricular compliance (change in volume as a function of change in pressure) during surgery may cause the filling pressures to be elevated despite inadequate preload. We have found this to be particularly true in cases with concentric hypertrophy of the LV, such as occurs with aortic stenosis. TEE allows this situation to be detected and provides a more accurate assessment of the hemodynamic status than pressure measurements alone.

Cardiac Output

Determinations of cardiac output (Ch. 30) are helpful in the management of patients with impaired ventricular function. Because blood pressure reflects the product of cardiac output and peripheral vascular resistance, cardiac output determinations are the only reliable means of rapidly assessing overall cardiac performance. This is usually done by the thermodilution technique with a PAC containing a thermistor, but it may also be accomplished by a PAC with continuous RV cardiac output measurement capability, and in a qualitative manner with TEE. Normal or elevated blood pressure may be found in the presence of inadequate cardiac output and compensating vasoconstriction. The inadequacy of tissue perfusion will eventually appear as failure of organ function, which is the cause of long-term morbidity and mortality. With estimates of cardiac output and peripheral vascular resistance, drug therapy can be directed effectively and safely to improve cardiac output and tissue perfusion.

Urine Output

Measurements of urine output (Ch. 34) are helpful in adjusting fluid balance. The volume and quality of urine (e.g., specific gravity) are good indicators of the adequacy of renal function. Renal function is closely linked to renal perfusion, which may be altered during cardiac operations by extracorporeal circulation, variations in cardiac output, cardiovascular drug therapy, and many other factors. Radiocontrast media used in preoperative radiographic studies and hemolysis during CPB pose direct threats to renal integrity. Preservation of renal function is essential for long-term survival. Furosemide and dopamine (low-dose rate) may be needed to improve renal blood flow, sustain diuresis, and promote the excretion of excess potassium and edema fluid.

Body Temperature

Body temperature (Ch. 37) should be monitored for any patient undergoing general anesthesia and surgery in which

the risks of hypothermia and malignant hyperthermia are substantial. A special indication exists when extracorporeal circulation is used with or without deliberate hypothermia. The temperature of the central circulation is commonly monitored with a nasopharyngeal or esophageal probe or by using the thermistor in the PAC. Either the rectal or urinary bladder temperature should be monitored, and finger or toe temperature should be estimated by palpation or actual measurement to determine the temperature gradients that exist between the body's central core and peripheral tissues; such gradients should be estimated to evaluate the completeness of rewarming during CPB after hypothermia. A large gradient indicates the likelihood of recooling after discontinuation of CPB as heat moves down its gradient from central to more peripheral tissues. It is important to avoid hyperthermia, which increases the risk of ischemia due to increased metabolic rate, especially in the CNS and heart. Limiting the temperature of blood entering the aorta to 38°C and monitoring nasopharyngeal temperature, which should remain below 38°C, is essential to reduce the incidence of CNS injury. [117]

Esophageal Stethoscope

An esophageal stethoscope can be inserted to evaluate heart and breath sounds (i.e., to detect bronchospasm, pulmonary edema, etc.). Modifications of the esophageal stethoscope include the incorporation of a thermistor to measure core temperature, two electrical leads to facilitate the recording of the ECG, and possibly two electrodes to enable transesophageal cardiac pacing. An esophageal stethoscope provides valuable information, especially if the electronic monitoring device fails during transfer of the patient from the operating room to the ICU (i.e., breath sounds, heart rate, rhythm, contractility). The anesthesiologist must remember to remove it once the ICU monitoring protocol is established.

It is our practice to insert an oro- or nasogastric tube after tracheal intubation and before placement of an esophageal stethoscope to remove any gastric air and fluid that may accumulate during surgery. A nasogastric tube is better tolerated than an oral tube, but the nasal approach is avoided in patients with abnormal coagulation preoperatively and abandoned if nasal obstruction is encountered. With normal coagulation, any bleeding produced by insertion of a nasogastric tube usually has time to stop before administration of heparin before CPB. Removal of gastric air and fluid improves TEE images, reduces the risk of tracheal aspiration, removes gastric distention as a potential cause of decreased pulmonary compliance, and seems to reduce patient discomfort (e.g., gastric distention, hiccupping, nausea, abdominal cramping) in the postoperative period.

Blood Gas Analysis

Blood gas (Ch. 38) and serum potassium analyses are essential for precise adjustments of artificial ventilation and gas flows in the CPB circuit oxygenator. Devices are available that can continuously monitor on a real time basis blood gas tensions, oxygen saturation of hemoglobin, and hematocrit in the blood passing through the bypass circuit. Determinations of mixed venous oxygen tension (or hemoglobin oxygen saturation) and acid-base balance are helpful in evaluating the adequacy of peripheral perfusion and detecting excessive oxygen consumption (e.g., by skeletal muscle shivering during hypothermia).

Coagulation Analysis

Measurement of anticoagulant activity is essential in the management of CPB to verify the adequacy of heparinization and to minimize the risks of thrombosis, embolism, and the one absolutely fatal complication of CPB, namely, clotting of the extracorporeal and intravascular blood volume. Such measurements are also needed to verify the adequacy of heparin antagonism by protamine to minimize postoperative hemorrhage. Tests of coagulability are important, because patients vary considerably in their response to the initial dose of heparin as well as in their rate of elimination of heparin under hypothermic and normothermic conditions. The activated clotting time (ACT) [118] and a heparin assay (Hepcon) [119] are usually used intraoperatively. Rapid access to laboratory analysis of coagulation should be available for the diagnosis and management of post-bypass coagulopathy. Thromboelastography has been used to assess coagulation during cardiac surgery, [120] but its exact role and usefulness remain to be defined. [121] [122] It should be remembered that aprotinin can prolong the ACT when done with celite-containing tubes; the use of kaolin-containing tubes for ACT determinations minimizes the problem, but some recommend the administration of additional heparin doses every 2 hours in patients receiving aprotinin.

Specialized Monitoring

Specialized monitoring is indicated under certain circumstances in some patients undergoing cardiac surgery.

Echocardiography

Echocardiography (Ch. 31) , [123] [124] [125] especially two-dimensional, can provide direct images of the anatomy and function of the heart and its surrounding structures, including the aorta and pericardium. Anatomic and pathologic landmarks are relatively easy to recognize when displayed on a video screen in real time or on a videotape recording. The addition of contrast (microbubbles of air) or use of Doppler techniques (especially color mapping) facilitates recognition of the direction and velocity of blood flow within the cardiovascular system. In the operating room, the anesthesiologist is able to use TEE for continuous monitoring of cardiac function and diagnosis of abnormalities. With views of all four cardiac chambers, the ascending aorta, aortic arch, and descending thoracic aorta, and the pericardium, it is relatively easy to obtain qualitative and semiquantitative information about chamber filling and contractility, intracardiac shunting, valvular function, air emboli, aortic dissection, and blood flow velocity. Such information can be useful in detecting myocardial ischemia as segmental wall motion and

wall thickening abnormalities or as papillary muscle dysfunction, indicating the need for further surgical revascularization, assessing valvular repair or replacement, and guiding medical therapy (e.g., balancing inotropic and vasodilator therapy with intravascular volume replacement). Because ventricular compliance and contractility may change frequently and dramatically in the perioperative period, it is not surprising that marked changes in ventricular filling and contraction may be

seen without proportionally dramatic changes in blood pressures (systemic arterial blood pressure, PAOP, CVP). On-line evaluation of valvular function, intracardiac shunts, coronary perfusion, pericardial constriction, and aortic dissection allows the surgeon to judge the adequacy of the operation (e.g., valvuloplasty) or to identify the need for modification of the surgical plan (e.g., valve replacement) immediately after CPB, with obvious benefits to the patient and savings in time and costs. In some cases, two-dimensional TEE with color Doppler has aided in the intraoperative recognition of a previously undiagnosed problem and allowed definitive correction along with the planned operation. The device is expensive, but its judicious use should create sufficient savings in hospital costs to justify its purchase for a busy cardiac surgical program. A committee made up of representatives of the Society of Cardiovascular Anesthesiologists and the American Society of Anesthesiologists has published guidelines for training and experience of those using TEE for diagnosis in addition to monitoring.

Serum Electrolyte and Glucose Determinations

Serum electrolyte and glucose determinations are indicated in patients with diabetes mellitus and those suspected of hypokalemia (e.g., preoperative use of diuretics). They are also essential for the safe intraoperative use of digitalis glycosides and glucose-insulin-potassium infusions. [126] Hyperkalemia occurs as a result of hyperkalemic cardioplegia and excessively rapid repletion of potassium; hypokalemia may exist preoperatively and is exacerbated by diuresis during CPB. Measurement of serum magnesium is not routine in the operating room, but recognition of hypomagnesemia as a factor contributing to dysrhythmias, especially in patients treated with digitalis, has led to the administration of intravenous doses (2-4 g, 4-8 mEq) to patients with problematic dysrhythmias in the operating room and ICU. Magnesium administration immediately after CPB has been shown to decrease ventricular dysrhythmias and to increase cardiac index. [127] It seems reasonable to expect such therapy to be guided by knowledge of serum magnesium concentrations. [128] [129] Occasionally low ionized calcium concentration may contribute to poor ventricular contractility and coagulopathy. [130]

The body's stress responses to surgery and CPB are usually manifest by increasing blood glucose concentrations after CPB. Catecholamine infusions also produce insulin resistance and hyperglycemia. In diabetic patients and in patients managed with normothermic CPB and cardioplegia, serum glucose may exceed 300 mg/dL and metabolic acidosis and hypokalemia may develop. In insulin-dependent diabetics, perhaps all diabetics, it is prudent to infuse regular insulin at 2 to 5 U/h from the very beginning of the operation and to add intravenous bolus doses as needed to control hyperglycemia and to maintain normal acid-base and electrolyte balance. Hypoglycemia rarely occurs; if it does, it is easily corrected by administration of glucose, 10 to 20 g IV, while continuing the insulin infusion at a lower rate. Measurements of serum glucose on an hourly basis are usually sufficient to monitor this therapy.

Cerebral Monitoring

EEG monitoring (Ch. 35) has been used during cardiac surgery since its early years, primarily in an attempt to detect and modify events leading to postoperative neurologic injury. Modern devices are available that process the raw EEG signal into an easily interpretable, graphic display, making the technology generally accessible. However, significant controversy remains about the practical benefits of monitoring the EEG during heart surgery, [131] [132] except to ensure electric silence of the brain during deep hypothermia with total circulatory arrest and during the use of cerebral protective doses of barbiturates. [133] [134]

New forms of neurologic monitoring such as transcranial Doppler [135] and transcranial oximetry [136] require further evaluation before their roles in cardiac surgery can be defined.

Controversial Topics

Controversy exists in relation to two aspects of hemodynamic monitoring: costs versus benefits and establishment of invasive monitoring before or after induction of anesthesia.

A cost-benefit analysis is difficult to obtain and so must be decided individually. The benefits of monitoring are cited above, and the potential complications are summarized in Chapters 28 to 38 . Economic costs are substantial and have to be included in the overall evaluation of each device and procedure. It is also necessary to estimate the costs of not using a particular technique or device. Not only do "cheaper" alternatives have some intrinsic costs, but they may be less useful in some situations, often those occurring suddenly and unexpectedly. It does not require many improperly diagnosed and treated conditions that extend the duration of intensive care or cost patient lives to wipe out the savings of not using a monitoring technique that could have warned of the adverse trend and allowed prevention of the complication, or at least facilitated the correct diagnosis and choice of therapy.

Although many centers advocate routine placement of PACs in most cardiac surgical patients, studies have failed to demonstrate consistent benefits in their routine use over central venous catheters and some have suggested that PACs per se are associated with increased morbidity, unnecessary therapy, and mortality. [137] PACs allow the measurement of left-sided cardiac filling pressures, mixed venous oxygen saturation, and thermodilution cardiac output, which taken together, provide a more complete evaluation of a patient's hemodynamic status and may lead to modification of therapy in about half the patients in an ICU setting. [138] The American Society of Anesthesiologists has published guidelines

regarding the use of PACs and recommends considering (1) the health status of the patient, (2) the type of surgical procedure, and (3) the characteristics of the practice setting in deciding whether to use a PAC. [139] Clearly, further controlled studies evaluating outcomes are needed to shed light on this complex topic. Our current approach in many patients is to insert an introducer sheath with a single lumen catheter into a central vein, allowing continuous infusion of fluids while monitoring CVP. If unexpected problems develop during the case, the single lumen catheter may be easily exchanged for a PAC.

Whether invasive monitoring should be established before or after the induction of anesthesia has been debated with respect to insertion of central venous and PA catheters and perhaps cannulation of peripheral arteries. These procedures are considered to be a source of stress and risk because of pain, uncomfortable positioning, and distraction of anesthesia personnel from monitoring ventilation and other vital signs while inserting the cannulas. [140] Conversely, induction of anesthesia is a period of instability in multiple organ systems and is frequently associated with stressful conditions. An untoward event is more readily detected and properly treated if data from the monitoring devices are immediately available. [137] [141] Stress from anxiety and discomfort can be reduced or eliminated by careful patient instruction preoperatively, judicious use of sedative and analgesic drugs before the patient enters the operating room, and supplementation as needed after an intravenous fluid infusion is established. [142]

In a life-threatening emergency situation in which survival of the patient's heart and nervous system is dependent on establishing extracorporeal circulation as rapidly as possible, there is no doubt that only basic monitoring of blood pressure, ECG, and ventilation (oximetry and exhaled carbon dioxide) are necessary to begin anesthesia and surgery. Sophisticated monitoring and vascular cannulation can be accomplished after CPB is established. If necessary, the surgeons can insert intravenous and arterial cannulas (e.g., in femoral vessels) with sterile tubing passed off the sterile field to the anesthesiologist. Left and right atrial cannulas can be inserted by the surgeon to measure filling pressures, and a TEE probe can be inserted by the anesthesiologist to evaluate cardiac contractility and filling. Once the patient is stabilized after CPB or after the operation, a PAC can be inserted via a jugular or subclavian vein. Hence, multiple options are available to meet monitoring needs, which should not delay the measures essential to the patient's survival in the best possible condition.

Premedication

The cardiac anesthesiologist uses drugs acting on the CNS to allay anxiety, produce amnesia, and minimize pain associated with vascular cannulation in the preanesthetic period without producing dangerous degrees of ventilatory or cardiac depression. These objectives are no different from those for any type of patient or surgery, but the choice of drugs and especially the doses prescribed are affected by the nature of the cardiac disease, the coexistence of lung and other diseases, chronic drug therapy, and the type of anesthesia planned for cardiac surgery.

Patients with CAD, adequate LV function at rest, and no pulmonary insufficiency are generally premedicated heavily with an opioid and any one of many sedative-hypnotic-tranquilizer-type drugs. A typical inexpensive prescription might read as follows:

Diazepam, 0.1 to 0.2 mg/kg, orally with a sip of water 1 to 2 hours before transfer to the operating room

Morphine, 0.1 mg/kg, intramuscularly ½ hour before transfer.

Another approach involves lorazepam 25 to 50 mug/kg PO 1 to 2 hours before transfer to the OR and intravenous doses of fentanyl 0.5 to 1 mug/kg administered by the anesthetist according to the patient's needs after the first IV cannula is inserted.

This premedication also provides amnesia (diazepam), which may be desirable intraoperatively when light levels of anesthesia can be associated with awareness. [143] [144] [145] [146] [147] The use of relatively larger doses of long-acting drugs is indicated by anticipation of a long duration of operation. Even if tracheal extubation soon after surgery is planned, the continuing effects of these premedicant drugs are beneficial. The cardiac depressant effects of this prescription are minimal or nil. Respiratory depression is generally within acceptable limits, but close observation of the patient and occasional encouragement to take a deep breath may help counteract the development of atelectasis and hypercarbia. It may be beneficial for the patient to breathe oxygen-enriched air (by nasal prongs or face mask) during preparation for anesthesia and surgery.

For patients with valvular heart disease and especially those with impaired ventricular function at rest and minimal cardiac reserve, lesser amounts of preanesthetic medication are usually sufficient, and heavy premedication may be dangerous. Some patients with limited cardiac output may be more susceptible to depressant drugs and at greater risk when even mild ventilatory depression is superimposed on their compromised cardiopulmonary function. A typical prescription might include only intramuscular morphine (0.05-0.08 mg/kg) with or without scopolamine (0.002- 0.003 mg/kg) 1 hour or less before surgery. Although scopolamine has sedative, amnesic, and antiemetic actions (especially advantageous in combination with an opioid) some clinicians prefer to avoid scopolamine because of its intense antisialagogue action, which makes some patients very uncomfortable, and because of its potential to cause prolonged postoperative confusion, especially in the elderly. If the degree of sedation proves inadequate, supplemental drugs can be administered intravenously while the patient is under constant observation by the anesthesiologist.

In addition to drugs acting on the CNS, the anesthesiologist should consider the benefits (and risks) to the patient of including in the premedication scheme drugs affecting other organ systems. Patients with CAD, especially those with unstable angina and good ventricular function, may have less risk of myocardial ischemia if a dose of a beta-adrenergic receptor blocker is administered orally 1 to 2 hours before surgery. It tends to suppress tachycardia, hypertension, and dysrhythmias before CPB. Moderate doses of propranolol administered up to that time do not complicate the discontinuation of extracorporeal circulation. [14] Therapeutic and prophylactic NTG should be continued until and perhaps beyond the induction of anesthesia, and supplemental

doses (e.g., sublingual or intravenous) should be at hand to treat symptoms and signs of ischemia.

Continuation of therapy with calcium channel blocking drugs up to the time of surgery is controversial. Controlled clinical investigations of this issue are still incomplete, and one study has demonstrated no benefit of either nifedipine or diltiazem in the prevention of perioperative ischemia. [13] [147] However, intravenous infusion of nifedipine decreased the incidence of ischemia and myocardial infarction in patients undergoing CABG operations. [148] We believe that it is preferable to continue such therapy up to the time of surgery, including an oral dose on the morning of the cardiac or noncardiac operation, for the following reasons:

1. If the calcium channel blocking therapy has been successful in controlling angina pectoris, hypertension, or dysrhythmias, these benefits should be continued into the operative period when the patient is exposed to stresses that can be expected to provoke myocardial ischemia, hypertension, and dysrhythmias.
2. Knowledge of the principal side effects of the calcium channel blockers (e.g., reduced systemic vascular resistance, atrioventricular conduction block) and their interactions with anesthetic and cardiovascular drugs allows the anesthesiologist to treat untoward effects should they occur. [16] [149] [150]
3. In the management of patients for emergency aortocoronary surgery who have just received unusually large doses of nifedipine in an attempt to dilate coronary arteries after an angioplasty complication, we have noted the need for larger than usual doses of vasopressors but no qualitative difference in responses to such therapy. [151]

It may be beneficial to order the first daily dose of other drugs taken routinely by the patient. This is especially true when the surgery is scheduled for late morning or afternoon. Such medications may include adrenergic receptor and calcium channel blockers, as well as long-acting nitrates, certain antihypertensive drugs, and possibly antidysrhythmic agents, including digoxin in the patient with a normal or elevated heart rate who is at risk from a rapid ventricular response to atrial dysrhythmias (see Table 49-7) . This practice must be individualized, with a complete understanding of the patient's cardiovascular status and knowledge of drug toxicity and interactions, and it should be accompanied by precise communications between the anesthesiologist and other persons caring for the patient.

Clonidine, an alpha$_2$ -adrenergic agonist, is an antihypertensive medication that has received a great deal of attention for its ability to improve hemodynamics and decrease anesthetic requirements in a number of clinical settings. [152] Premedication of CABG patients with clonidine has been suggested by Flacke et al [153] as a means of reducing opioid dosage and shortening the period of postoperative mechanical ventilation. Other authors have not seen the same benefits and have noted problems with low systemic vascular resistance, requiring vasopressor support postoperatively in patients premedicated with clonidine. [154] Further study of this issue is warranted.

The ACEIs are thought to be responsible, at least in part, for the low blood pressure and its refractoriness to vasopressors during CPB. Because the ACEIs are long lasting, omitting them on the day of surgery is appropriate, but the patient may still require large doses of phenylephrine (0.5-1 mg) or norepinephrine to treat hypotension intraoperatively.

Other common problems that can benefit from appropriate preanesthetic medication are peptic ulcer and esophageal reflux. The combined administration of oral antacids and antisecretory drugs (e.g., cimetidine and glycopyrrolate) can prevent symptoms and minimize mucosal damage in the perioperative period. Patients with narrow-angle glaucoma should instill pilocarpine or their usual eye drops the morning of surgery, and additional doses should be administered according to the usual schedule throughout the perioperative period. The use of systemic anticholinergic drugs is not contraindicated in glaucoma if topical miotic therapy is continued.

The management of insulin-dependent diabetes mellitus is controversial in practice but obviously essential for the patient. [155] This is a particularly important and sometimes challenging task in the overall management of the patient undergoing hypothermic CPB. The most important aspect of any routine is the monitoring of serum glucose throughout the perioperative period to maintain serum concentrations between 100 and 250 mg/dL. [156] The sympathetic-endocrine stress responses to CPB and the administration of sympathomimetic inotropes produce resistance to insulin and can lead to marked hyperglycemia, especially if intravenous fluids contain glucose. High intravenous bolus doses and infusion rates of insulin may be required to lower serum glucose concentrations to acceptable levels and prevent the consequences of severe hyperglycemia (e.g., excessive diuresis, hyperosmolar coma, exacerbation of ischemic insult to the CNS). As a matter of routine, we infuse regular insulin 2 to 5 U/h in diabetic patients (insulin-dependent or not) from the beginning of the operation, monitor serum glucose hourly, administer 10 to 20 g glucose if the serum level falls below 100 mg/dL (a very rare occurrence), and adjust the insulin infusion rate upward with the addition of intravenous bolus doses of 10 to 20 units of regular insulin as necessary after CPB so as to maintain serum glucose in the range of 100 to 200 mg/dL.

Anesthesia Induction and Maintenance

For convenience, the usual preparations for management of a patient undergoing cardiac surgery are summarized in Table 49-15 . Only certain aspects of the preparations are discussed here; more comprehensive treatises should be consulted for details.

Good Versus Poor Cardiac Performance

Patients can be divided into two groups based on their cardiac performance at rest without acute therapeutic support. Those with an ejection fraction greater than 0.5, a normal cardiac index (2.5 L/min/m^2), a normal stroke volume index (40-60 mL/beats/m^2), and no preoperative evidence of abnormal ventricular function can be considered to have good cardiac performance. Those with an ejection fraction less

TABLE 49-15 -- Checklist of Special Preparations by Anesthesiologist for Managing Patients Scheduled for Cardiac Surgery

CATEGORY	SPECIAL CONSIDERATIONS
Airway management	Soft cuffed endotracheal tube for potentially prolonged intubation
Monitors	Arterial cannula for pulse pressure tracing and blood sampling
	Central venous cannula for pressure measurement and drug administration
	Pulmonary artery (Swan-Ganz) catheter for pressure measurements (PAP, PAOP), cardiac output determinations by thermodilution, and sampling of mixed venous blood; special catheters for specific indications (e.g., cardiac pacing, diagnosis of atrial and ventricular dysrhythmias, continuous oximetry, right ventricular ejection fraction)
	Electrocardiogram with multiple lead selection (i.e., to facilitate diagnosis of arrhythmias and ischemia)
	Transesophageal echocardiogram (if indicated)
Anesthetic drugs	Ready availability of drugs to supplement or to substitute for primary anesthetic choice
Cardiovascular drugs	Ready availability of drugs to treat
	Rate and rhythm disturbances
	Hypo- and hypertensive episodes
	Cardiac failure and metabolic acidosis
	Myocardial ischemia, decreased ventricular compliance
	Pulmonary hypertension
	Oliguria
	Hypo- and hyperkalemia
Other drugs	Heparin and protamine, epsilon-aminocaproic acid (Amicar), desmopressin (DDAVP), antibiotics, steroids
Blood products	Cell saver available to process shed blood
	Packed red blood cells
	5% albumin or hetastarch
	Coagulation factors (platelets, fresh frozen plasma, cryoprecipitate)

PAP, pulmonary artery pressure; PAOP, pulmonary artery occlusion pressure

than 0.3 or a low cardiac index (<2.0 L/min/m^2 with normal or elevated ventricular preload) because of either abnormal ventricular contractility or mechanical abnormalities (e.g., valvular heart disease) are characterized as having poor cardiac performance. In addition to ejection fraction and cardiac index, it is important to consider the type of cardiac disease, their response to stress, and the presence of other disease processes (such as hypertension) affecting cardiac function. It may be helpful to determine cardiac index, stroke index, and other hemodynamic variables in the operating room before inducing anesthesia to devise the anesthetic plan most appropriate for that particular patient. This determination is especially needed when evaluation of the cardiovascular status is incomplete, uncertain, or remote in time.

Regional wall motion abnormalities (e.g., hypokinesis) may not be evident in such global measures as ejection fraction, cardiac output, and stroke volume; yet they may be clinically important and become manifest when additional work is demanded of the heart. Regional dysfunction may be detected by transthoracic (before anesthesia) or transesophageal (after induction of anesthesia) two-dimensional echocardiography. [123] [124] [157] [158]

An important principle to remember is that the hemodynamic responses to most anesthetic drugs are dose-related. Hence a drug that may be unsatisfactory when used as the primary anesthetic may nevertheless serve a useful role as a supplemental drug. For example, a full anesthetic dose of isoflurane (1-3 volume %) may be unacceptable because of its depression of cardiac performance, but supplemental concentrations (0.25-0.5 volume %) may be useful in limiting responses to noxious stimulation (e.g., tracheal intubation and skin incision). In any case, it behooves the anesthesiologist to remain flexible and to be prepared to change the anesthetic drugs should the responses to the initial selections prove unsatisfactory.

If the characteristics of the specific disease are known and the hemodynamic status of the particular patient has been determined, any one of a combination of anesthetic drugs can be selected on the basis of both their anesthetic properties and their hemodynamic effects. Summaries of the hemodynamic actions of anesthetic drugs are found in Chapters 6 and 8 to 10 . A somewhat simplified approach to the choice of anesthetic drugs is to consider the use of a potent inhaled anesthetic (e.g., isoflurane) versus an opioid (e.g., fentanyl). It is most often true in clinical practice that a combination of inhaled and intravenous drugs is used (see later). It also is a common but often unnecessary (and sometimes unwise [143] [144] [145]) practice to use fully paralyzing doses of muscle relaxants throughout the operation regardless of the choice of primary anesthetic.

Potent Inhaled Anesthetics

Potent inhaled anesthetics (Chs. 4 and 5) such as halothane or isoflurane may be used as primary anesthetics in patients with good cardiac performance. Desflurane and sevoflurane, new potent inhaled anesthetics with very rapid onset and rapid recovery, have been used for cardiac surgery and appear to have hemodynamic effects similar to those of isoflurane. [159] The volatile anesthetics are especially useful in patients with CAD and normal ventricular function. Their advantages include the ability to fulfill all the objectives of anesthesia: unconsciousness and muscular relaxation, rapid recovery of ventilatory function so that tracheal extubation can be accomplished early in the postoperative period, and

dose-related decreases in ventricular work and oxygen consumption. [160] Their principal disadvantages are their limited ability to provide suppression of reflex responses (e.g., sympathetic, airway) to noxious stimulation (but this is easily managed by their supplementation with moderate doses of an opioid), excessive cardiovascular depression under some conditions, lack of analgesia in subanesthetic concentrations during the recovery phase, and postoperative shivering and increased oxygen demand due to heat loss exaggerated by peripheral vasodilation in the exposed patient. [161]

Isoflurane has come under scrutiny because of the demonstration of its association with coronary artery steal under certain conditions. [61] [62] [63] [64] [65] [66] In the presence of a critical coronary artery stenosis, isoflurane dilates normal coronary arterioles and lowers overall coronary perfusion pressure with the consequences that flow through normal arteries increases and flow through stenotic arteries and their distal arterioles is reduced (steal phenomenon). Becker [162] has concluded that isoflurane should be avoided in patients with coronary artery stenosis as well as in any patient at risk for CAD (virtually everyone over 50 years of age in industrialized societies). This recommendation is extreme and unreasonable for several reasons. [63] First, the phenomenon of coronary steal has not been demonstrated under typical clinical conditions, and isoflurane has even been shown to protect against ischemia induced by electrical pacing in patients with coronary stenosis. [163] Second, isoflurane is seldom used alone at high concentrations for general anesthesia in patients with cardiovascular disease. Third, isoflurane can be used to advantage as a supplement to other anesthetic agents (e.g., nitrous oxide, opioids) to suppress undesirable sympathetic and hemodynamic responses to noxious stimuli and to compensate for the deficiencies of the other anesthetics. [64] Fourth, there is no evidence of different outcomes for coronary revascularization operations in patients anesthetized primarily with isoflurane, enflurane, halothane, or sufentanil. [54] Finally, isoflurane has certain unique pharmacologic properties that may be beneficial to

some patients. At the moment, the judicious approach is not to abandon the use of isoflurane but to take advantage of its benefits and limit the dosage.

It is a common practice to administer an opioid or other drug, either as part of preanesthetic medication or intraoperatively, to reduce the concentration of an inhaled anesthetic that is required to produce a satisfactory depth of anesthesia and thereby to minimize the incidence and intensity of side effects from the inhaled anesthetic. In turn, the potent inhaled anesthetics are useful as supplemental agents to provide unconsciousness in the patient receiving primarily opioids for anesthesia, to increase anesthetic depth temporarily in anticipation of strong noxious stimulation, and to control hypertension and tachycardia.

Our experience suggests that most cardiac patients tolerate potent inhalation anesthesia well, even those with moderate impairment of ventricular function. By placing a vaporizer in the gas circuit of the CPB machine, these drugs may also be used to maintain anesthesia during bypass.

Opioids

Opioids (Ch. 10) have become the anesthetic mainstay for patients with impaired cardiac performance. Their characteristics

TABLE 49-16 -- Opioid Anesthesia for Cardiac Surgery[a]

Advantages
Absence of direct effects on heart; no change in
Contractility
Automaticity (but vagal activity)
Conduction
Sensitivity to catecholamines
No interference with autonomic or cardiovascular drug actions
Preservation of blood flow autoregulation in CNS, heart, kidneys
Few moment-to-moment adjustments required
Easily supplemented with intravenous hypnotic and inhaled anesthetics
Increased patient tolerance of endotracheal tube and airway manipulation (e.g., suctioning, nasogastric tube)
Postoperative analgesia
No organ toxicity
Disadvantages
Bradycardia and hypotension during induction, especially when combined with any hypnotic
Muscular rigidity during induction and sometimes during emergence
Awareness may go unrecognized if patient is totally paralyzed; recall of intraoperative events may occur without concurrent administration of an amnesic drug
Prolonged recovery time, especially for spontaneous ventilation (can be minimized by careful titration of dosage of opioid and other CNS depressants to the needs of the individual patient)

[a] Also see Chapter 10 .

are summarized in Table 49-16 . With the exception of meperidine (and possibly its congeners, anileridine and alphaprodine), the opioids are noted for their lack of direct cardiac depressant effects. They have actions that indirectly influence cardiac performance: bradycardia mediated by the vagus nerves; arterial and venous dilation as a result of selective suppression of sympathetic reflexes (e.g., orthostatic hypotension); and in the case of morphine, meperidine, and some of their congeners, histamine release. These indirect actions can be prevented or treated readily and do not contraindicate the use of large doses of opioids for anesthetic purposes. The indirect effects can be prevented or treated: anticholinergic drugs (e.g., atropine, glycopyrrolate) can prevent or antagonize bradycardia; only minor hypotension is seen in a normovolemic patient maintained in the supine position and given an opioid intravenously at a slow rate (e.g., morphine at 5 mg/min in the adult); and the hemodynamic consequences of histamine release can be prevented by pretreatment with a combination of histamine $_1$ and histamine$_2$ receptor blocking drugs. [164] Furthermore, hypotension responds to a legs-up position, intravenous infusion of fluids, and if necessary, a vasoconstrictor such as phenyl-ephrine; ephedrine is indicated for hypotension related to vasodilation and bradycardia.

Currently, fentanyl is the most commonly used opioid; used alone in very large doses (20-50 mug/kg to start plus 2-3 mug/min), it can produce profound analgesia, sleep, and usually unconsciousness (see later). Equivalently large doses of morphine, meperidine, and most other currently available opioids are usually avoided because of their side effects in such large doses. However, moderate doses of morphine (0.5-3 mg/kg) and its congeners are useful for anesthetic purposes in chronically ill patients [165] or when combined with a hypnotic or volatile anesthetic. Among the major disadvantages of the opioids are the following:

1. With the exception of remifentanil, [166] a new and very short-acting fentanyl derivative hydrolyzed by tissue esterases, the elimination of opioids from the body is relatively slow, and consequently, the times for recovery of consciousness and spontaneous ventilation can be prolonged after large doses. [167] Prolonged recovery is not a problem and may even be an advantage when mechanical support of ventilation is to be continued into the postoperative period for several hours or overnight. The use of opioid antagonists can be hazardous, especially in patients with cardiovascular disease. [168] [169]
2. Opioids can induce both apnea and skeletal muscular rigidity that impedes positive-pressure ventilation. If the patient has been breathing pure oxygen before and during the induction of anesthesia, there is no need to panic if rigidity prevents positive-pressure ventilation. First of all, when the lungs are filled with oxygen, apneic oxygenation is effective in preventing desaturation of oxyhemoglobin for a much longer time than will be required to relieve the rigidity. Also, the rise in carbon dioxide tension will be moderate over a few minutes' time and is tolerated without incident by most patients. Of course, it is prudent to correct the hypercarbia and the associated hemodynamic changes (systemic hypotension and elevated PA pressure) promptly upon relieving the rigidity. Second, attempts to force positive-pressure ventilation of the patient with markedly decreased thoracic compliance will further embarrass cardiovascular function by increasing intrathoracic pressure, which impedes the venous return of blood and creates a tamponade-like condition for the heart. Rigidity can be relieved within 1 to 2 minutes by a fully paralyzing dose of a muscle relaxant administered intravenously.

Rigidity can occur during the induction of anesthesia and also during emergence. [170] [171] In our opinion, the rigidity represents a phenomenon of disinhibition occurring at the threshold for unconsciousness. The intensity of rigidity is probably reduced by treatment with a small dose of a muscle relaxant and can be relieved by a paralyzing dose of muscle relaxant (or by naloxone, which is inappropriate in most cases). The manifestations of rigidity are varied and in some instances may be thought to represent seizures. There are substantial data to speak against the production of seizures even by the highest doses of fentanyl used for anesthetic purposes in humans. [172] (It is true that seizures are produced by extremely high doses of opioids in rodents.)

TABLE 49-17 -- Signs of Inadequate Anesthesia

Somatic (obscured by relaxants)
Movement, especially in association with noxious stimulation [a]
Coughing, bucking on endotracheal tube
Increased electromyographic activity

Hemodynamic (obscured by cardiovascular disease and drug therapy)	
Increase in blood pressure, especially a sudden increase in association with noxious stimulation	
Increase in heart rate (less common than increase in blood pressure)	
Other sympathetic signs	
Sweating	
Tearing	
Mydriasis (requires careful observation and interpretation in presence of drugs affecting autonomic nervous system)	
Endocrine (not measurable on-line)	
Increased release of stress-related hormones	
Electrical activity of CNS	
Arousal patterns in electroencephalogram	
Recovery of evoked potentials (e.g., auditory)	

[a] Very intense noxious stimuli include tracheal intubation and subsequent manipulation of the endotracheal tube, skin incision, sternotomy, electrocauterization of skin and especially periosteum, and movement of the patient (e.g., transfer from operating table to bed).

1. Awakening of the patient, especially in response to intense noxious stimulation, can occur during the operation, despite administration of the usual dose at the induction of anesthesia. [144] [145] [146] In most cases, the recovery of consciousness can be related to the decline of drug concentration to less than that required to maintain unconsciousness in the particular patient under the particular conditions or intensity of stimulation. [173] The possibility of awakening is of great concern because (1) the paralyzed patient cannot exhibit somatic signs of inadequate anesthesia [144] and (2) autonomic and hemodynamic responses are not reliable indicators of the patient's awakening. [144] [145] [174] [175] A reliable guide to anesthetic depth in the paralyzed patient is needed; special processing of the EEG is being investigated as a possibility (Ch. 29) , but as yet, its reliability remains to be demonstrated. [176] The anesthesiologist can minimize the possibility of awareness by (1) administering sufficient preanesthetic medication [146] or intraoperative anesthetic supplement (e.g., benzodiazepine), (2) titrating the induction dose to effect and then maintaining the drug concentrations by infusion or less efficiently by intermittent injections, [173] [177] [178] (3) using muscle relaxants only when necessary and then only in the minimum required doses, and (4) remaining acutely aware of all signs of inadequate anesthesia (Table 49-17) .

Is the administration of an amnesic drug (e.g., benzodiazepine, scopolamine) to induce lack of recall of intraoperative events a satisfactory solution to the problem of intraoperative awareness? In our view, it is not for several reasons. First of all, if the patient and the anesthesiologist agree on general anesthesia, then the anesthesiologist is obligated by the verbal contract with the patient to produce and to maintain unconsciousness for the duration of the operation. Second, even though the patient experiences no pain because of the analgesic efficacy of the opioid, awakening in a paralyzed state during the operation is a frightful experience because the patient cannot communicate anxiety or escape from the situation. Whether or not the awakening is recalled later, the patient experiences the anxiety and fright at the time of awakening. Finally, there are indications that intraoperative awakening can lead to sleep disturbances, anxiety attacks, and other undesirable consequences in the postoperative period even when the patient does not recall the episode. [143] [145]

Hypnotics and Tranquilizers

Because of the inability of opioids to produce unconsciousness reliably in all patients, a large number of drugs have been used in combination with them (Ch. 9) . Because of minimal effects on the cardiovascular system, midazolam has emerged as a popular drug with which to supplement opioids in anesthesia. Its depressant effect on myocardial

contractility is mild and probably not dose-dependent. [179] Etomidate maintains sympathetic nervous tone and reflex responsiveness, but its use has been limited by concerns about its inhibition of steroid synthesis. [180] Propofol produces vasodilation and mild negative inotropy but has the advantages of rapid control of responses to noxious stimulation and a short recovery time. [181] Thiopental resembles propofol but has a longer recovery time.

There are several important features of the interactions of hypnotics (including barbiturates, benzodiazepines, etomidate, propofol, and probably all other intravenously administered sleep-inducing drugs) and opioids:

1. Although the hypnotics may reduce the dosage requirements of an opioid, the length of the recovery time may not be shortened. And if the doses of both the hypnotic and the opioid are not reduced by careful titration to effect, the recovery time can be longer than that attributable to either drug alone.
2. There is a synergistic interaction between opioids and sleep (natural or drug-induced) in regard to ventilatory depression. This is most dangerously manifest in the postoperative period after the intensity of noxious stimulation is reduced and the patient is less carefully monitored for signs of ventilatory depression. [182]
3. When opioids in anesthetic doses are combined with any one of the hypnotics during the induction of anesthesia, a reduction of systemic blood pressure is frequently observed. [183] Conversely, a very small dose of an opioid (e.g., 75 mug of fentanyl or 20 mug of sufentanil) injected after unconsciousness is produced by a hypnotic usually results in a decline of systemic blood pressure, sometimes to a dangerously low level. Clinically significant hypotension usually responds to a sympathomimetic vasopressor.
4. Because it is easy to recognize and treat hypotension, we usually combine a hypnotic and an opioid to ensure unconsciousness during periods of total paralysis when it is not possible to have somatic signs of arousal. If a patient is so critically ill that mild to moderate decreases in blood pressure are potentially dangerous, it is prudent to avoid the opioid-hypnotic effects on hemodynamics. [144]
5. Sudden unexpected arousal of the central somatic and sympathetic nervous systems can occur, especially with intense noxious stimulation (see Table 49-17) . The most effective and immediate treatment of arousal is accomplished with a drug having a very short latency to the peak CNS effect of an intravenous bolus dose (e.g., thiopental 50-150 mg, propofol 25-75 mg, alfentanil 15-50 mug/kg, remifentanil 0.5-2 mug/kg). CNS drugs are to be preferred to sympatholytics and vasodilators because of the possibility of awareness (with or without pain) associated with the somatic and/or sympathetic manifestations.

Nitrous Oxide

Nitrous oxide (Chs. 4 and 5) can be used to supplement both potent inhaled anesthetics and intravenous anesthetics. It is often the primary anesthetic used in conjunction with muscle relaxants. Its effects on the cardiovascular system are mild but can be detrimental, especially in patients with poor cardiac performance. Nitrous oxide tends to decrease cardiac output and increase systemic vascular resistance when given alone or in combination with an opioid. In some patients, the degree of hypotension and myocardial depression may be sufficient to require that nitrous oxide be discontinued; recovery of cardiac function is usually evident within a few minutes, during which time most of the nitrous oxide is exhaled. The rapid onset and recovery allow the patient's tolerance of its effects to be tested safely; if the responses are undesirable, they are rapidly reversed by discontinuing nitrous oxide. A recent finding relevant to the care of patients with CAD is the potential for nitrous oxide to induce ischemia in an area supplied by a critically stenotic coronary artery and thereby induce regional myocardial dysfunction. [184] Clinical studies, however, have not found nitrous oxide to cause ischemia when used to supplement fentanyl anesthesia in CABG patients with either good or poor ventricular function. [185] [186]

Besides its direct cardiac depressant effects, nitrous oxide has other actions that may be detrimental to the patient undergoing cardiac surgery. It expands air-filled spaces, including air emboli, which may occur in the arterial circulation as a result of failure to eliminate air trapped in cardiac chambers or in saphenous vein grafts during surgery. Some advise the complete avoidance of nitrous oxide in cardiac operations involving extracorporeal circulation because of the ever-present risk of air emboli; microemboli of air are always present during CPB with hypothermia. Certainly, if arterial air embolization is suspected, nitrous oxide administration should be discontinued and avoided for the remainder of the anesthetic. [187] Also, nitrous oxide should not be used in the presence of a pneumothorax unless a functioning thoracotomy tube is in place. Nitrous oxide may potentiate truncal rigidity induced by small to moderate doses of opioids. Nitrous oxide limits the inspired oxygen

concentration in relation to its own concentration in the inspired gas mixture and does not allow for apneic oxygenation.

The advantages of nitrous oxide as a rapid onset/offset inhaled anesthetic are now shared with desflurane and sevoflurane, which do not have the problematic side effects related to nitrous oxide expansion of air-filled spaces.

Muscle Relaxants

Muscle relaxants (Ch. 12) are almost always used as a part of an anesthetic plan for cardiac surgery. The usual indications for their use are to facilitate endotracheal intubation, to counteract rigidity induced by opioids, to suppress body movement in response to electrical defibrillation or cardioversion, to limit oxygen consumption, to prevent shivering associated with hypothermia, and to facilitate the surgeon's work and prevent sudden, unexpected movement during delicate and critical portions of the operation. Their customary use to maintain paralysis throughout the intraoperative period is predicated on the avoidance of sudden body or diaphragmatic movements under light levels of general anesthesia. Even if prolonged paralysis occurs, these patients routinely receive mechanical ventilatory support for at least a short time in the postoperative period. The drawback of continuous muscular paralysis is its interference with somatic signs of light anesthesia. [144] [145]

The choice of a particular neuromuscular junction-blocking drug is usually based on its autonomic and hemodynamic side effects. For example, pancuronium-induced tachycardia may be useful in the patient with excessive bradycardia due to the vagotonic effects of an opioid superimposed on the residual effects of a beta-adrenergic receptor-blocking drug. Tachycardia is an undesirable side effect of sympathomimetic inotropes and is enhanced by pancuronium, which may make it a poor choice near the end of CPB and afterward. The generally benign effects of vecuronium, pipecuronium, and doxacurium make them agents of choice for the hemodynamically unstable patient with limited cardiovascular reserve. [188] [189] Proper dosing of the long-acting relaxants is necessary to avoid prolonged recovery and delayed tracheal extubation. Concerns about drug costs enter into the choice of relaxants; proper comparisons of costs need to take into account the total dose requirements and indirect costs of their administration (e.g., infusion devices) during operations typically lasting more than 3 hours.

Local and Regional Anesthesia

Local and regional anesthetics (Chs. 42 - 44) have limited roles in cardiac surgery, although they may be the anesthetics of choice for various types of noncardiac surgery in patients with heart disease. The risks of patient anxiety and discomfort (e.g., due to positioning and surgical manipulation) leading to sympathetic responses and hemodynamic instability under regional anesthesia must be weighed against the potential benefits of avoiding the systemic effects of general anesthetic drugs. Also, the supplementation of local or regional anesthesia with systemic hypnotics and analgesics can be risky because ventilation, protective airway reflexes, and other functions may be depressed as they would be by general anesthesia; but there is a false sense of security associated with the concept that the patient is "only undergoing local anesthesia and sedation." Often there is a fine line between "conscious sedation" and general anesthesia (unconsciousness), and the anesthesiologist must be prepared to intervene and establish the conditions of monitoring and life support that would be indicated for general anesthesia in the particular patient. Local anesthesia is useful for the prevention of pain associated with vascular cannulation (e.g., cutaneous puncture or surgical cut-down for venous and arterial cannulation, transvenous pacemaker implantation and pacemaker battery replacement procedures, and femoral vessel cannulation for CPB or insertion of an IABP). Topical anesthesia of the pharynx and trachea is useful in reducing the sympathetic responses to endotracheal intubation and airway manipulation in the lightly anesthetized patient. Local anesthetic infiltration of the stellate ganglion has been suggested as a means of preventing and controlling postoperative hypertension, which is common after cardiac surgery and especially common after CABG. [190] Epidural analgesia has been used during cardiac surgery to decrease systemic anesthetic requirements and for postoperative analgesia. [191] However, the risk of hemorrhagic complications associated with systemic heparinization and post-bypass coagulopathy, and the lack of clearly documented clinically significant benefit hindered the widespread adoption of this technique. [192] Similarly, although intrathecal opioids have been used in cardiac surgery patients, [193] [194] evidence of a benefit justifying the extra effort and risk is lacking.

The Cardiovascular System During Cardiac Surgery

The anesthesiologist assumes primary responsibility for intraoperative management of the cardiovascular system. This responsibility is entirely appropriate because the surgeon's attention should be focused primarily on the surgical operation, and the anesthesiologist is in the best position to monitor and respond to hemodynamic alterations whatever their cause. Of prime importance is coordination of the entire surgical team, which requires active communication, mutual respect, and cooperation. Effective interactions are facilitated by a common understanding of each other's objectives, procedures, knowledge, and skills. The anesthesiologist should be well informed about the patient's disease status, the surgeon's operative plans, and the specific aspects of cardiac surgery discussed later.

Intravascular Volume

Intravascular volume is a key factor in determining the hemodynamic responses not only to anesthetic drugs but also to surgical manipulations, such as cannulation of the venae cavae. Patients coming to cardiac surgery often have a surprisingly low circulating blood volume, reflecting limited intake of fluids and foods in the days preceding surgery. This limited intake may result from anxiety and physical inactivity or from a requirement to abstain from food and drink before anesthesia. Patients are usually ordered to abstain after midnight, but many hospitalized patients ingest little or nothing after their early evening meal, and some may not have surgery until the next afternoon. Vigorous diuretic therapy to eliminate CHF before surgery produces reductions in circulating blood volume. Hypovolemia can be detected before and during induction of anesthesia by monitoring hemodynamic variables and their responses to positional changes, positive-pressure ventilation, and anesthetic drugs. Small volume and high specific gravity of urine obtained during catheterization of the bladder provide additional clues to the presence of hypovolemia. It may be necessary to treat hypotension by a legs-up position and vasopressors until hypovolemia can be corrected by infusion of fluids.

During CPB, diuresis usually is induced by several factors: inclusion of mannitol (an osmotic diuretic) in the CPB reservoir prime solution; hypothermia, which interferes with renal tubular reabsorption mechanisms; and good perfusion of renal glomeruli with blood low in protein as a result of hemodilution by the CPB prime solution. A minimally acceptable urine flow is 1 mL/kg/h to ensure that adequate renal perfusion has occurred and to minimize any renal insult from hemoglobinuria caused by hemolysis during CPB.

At the conclusion of CPB with hypothermia, peripheral vasoconstriction commonly occurs as a result of persistent peripheral hypothermia. Consequently, the vascular capacity is below normal until rewarming of the entire body is completed. Venodilators (e.g., NTG) may be infused and the

Figure 49-7 (Figure Not Available) Cardiopulmonary bypass from the vena cava (1) to the ascending aorta (2a) or, alternatively, to the femoral artery (2b). Blood is also carried to the reservoir from the left ventricular vent cannula (3) and from suckers (4) used to clear the operative site. *(Modified from Nose Y: Manual on Artificial Organs. Vol. 3. The Oxygenator. St Louis, CV Mosby, 1973.)*

patient placed in the reverse Trendelenburg position to increase venous capacitance, thereby facilitating the return of most or all of the blood in the CPB reservoir to the patient. Not only does this conserve the patient's own red blood cells, but it ensures continuing diuresis and minimizes the discrepancy between vascular capacity and circulating blood volume as rewarming occurs.

Cardiopulmonary Bypass

CPB (also termed extracorporeal circulation) is a complex subject, a complete discussion of which is beyond the scope of this text. Several comprehensive reviews of the topic are available. [195] [196] The following is a brief summary, with an emphasis on issues of importance to the anesthesiologist.

Extracorporeal Systems

Extracorporeal perfusion systems consist of the basic components shown in Figure 49-7 (Figure Not Available) , in an arrangement similar to that illustrated. Several varieties of each component are available commercially, the most important differences being those between the two basic types of oxygenators in common use today, namely bubble and membrane oxygenators. Bubble oxygenators have advantages over the membrane type in terms of simplicity, lower cost, lower priming

volume, ease of CPB circuit assembly, and greater oxygenation efficiency. However, the turbulence and foaming created by gas bubbling in blood promote disruption of blood cells, which occurs progressively during CPB. When prolonged CPB (90 to 120 minutes) is anticipated, a membrane-type oxygenator is preferable. [197] [198] Newer types of membrane oxygenators are cost-effective and convenient to use.

Because of the disruption of blood cells during CPB and the risks of infusing debris and air bubbles into the circulatory system of the patient, the use of filters on both the venous return tubing and the arterial inflow tubing is essential. A 27-mm pore filter in the arterial tubing is recommended because it removes most of the debris without marked impedance to the flow of blood. [199] [200] Filters cause a loss of platelets. [201]

A nonocclusive roller pump developed by DeBakey is the type most commonly used, but other types continue to be developed in attempts to reduce blood cell trauma and provide pulsatile flow. [202] [203] The costs and complexity have not been shown to be justified by the limited benefits of pulsatile flow.

The most common routine for establishing extracorporeal circulation for cardiac operations is to drain venous blood from the venae cavae and to pump arterialized blood into the ascending aorta (see Fig. 49-7) (Figure Not Available) . Other arrangements (Table 49-18) are indicated for special circumstances; for example, femoral artery and vein cannulation (with a long

TABLE 49-18 -- Arrangements of Cardiopulmonary Bypass Circuits

Venous return
Superior and inferior venae cavae
Femoral vein (requires long cannula to reach right atrial level or subsequent atrial cannulation to obtain more complete venous return to cardiopulmonary bypass circuit)
Left atrium (left ventricular-aortal bypass; uses patient's lungs for oxygenation of blood)
Arterial infusion
Ascending aorta
Femoral artery--descending aorta
Pulmonary artery (right heart bypass; patient's lungs oxygenate blood)
Types of cardiopulmonary bypass
Partial (venous blood can flow past cannula into right heart)
Total (all systemic venous blood flows into venous cannulas because venae cavae are occluded around cannulas; coronary sinus and bronchial artery flows continue to drain into pulmonary circulation; see Fig. 49-7) (Figure Not Available)

venous cannula inserted to the level of the right atrium to drain the superior vena cava) may be used in the hemodynamically unstable patient in whom rapid access to the great vessels is not possible because of scarring from a previous mediastinal operation.

CPB is considered to be total if tapes are drawn snugly around both the superior and inferior venae cavae to prevent any flow of systemic venous blood around the cannulas into the right atrium (see Table 49-18) . Total CPB is used when the cardiac chambers are to be opened or when the systemic venous blood return to the heart proves troublesome. Partial CPB is satisfactory for most aortocoronary bypass grafting operations or other procedures in which the heart is not opened. Partial CPB allows blood to enter the heart and this can be used to advantage for the following purposes: (1) to check the CPB system before establishing total CPB (if a problem exists, the patient's spontaneous circulation can be immediately restored); (2) to fill the heart to its usual size and facilitate more precise estimation of coronary graft length; (3) near the end of CPB to allow some pulsatile flow (provided by the patient's heart) to improve tissue perfusion, facilitate rewarming of peripheral tissues, and for washout of cardioplegia components from the heart; (4) to assess the heart's function at the end of CPB by increasing its filling and work gradually to prevent excessive ventricular distention and failure; and (5) to allow coronary sinus blood to drain into the venae cavae and reduce flow into the pulmonary vasculature and left heart.

LV venting (see Fig. 49-7 (Figure Not Available) , site 3) through a catheter (usually inserted by way of a pulmonary vein and left atrium) may be necessary to prevent harmful ventricular distention due to (1) an incompetent aortic valve (also prevented by cross-clamping the ascending aorta), (2) large blood flow from the coronary sinus and bronchial circulation into the pulmonary veins, and (3) surgical positioning of the heart to cause displacement of blood into it or to prevent its backward flow into the venae cavae. Venting of either the ventricle or PA also reduces the risks associated with elevated pulmonary capillary pressures. Monitoring PA pressures during CPB facilitates early detection of elevated pressures.

Signs of potential complications of CPB are listed in Table 49-19 . The anesthesiologist, surgeon, and perfusionist must work closely together to detect real or potential problems as early as possible and to correct them promptly and safely. A checklist (e.g., Table 49-20) may be useful in the prevention and early detection of problems. Three of the most serious complications that indicate immediate cessation of CPB and reestablishment of the patient's own cardiac output are aortic dissection, [204] superfusion of a carotid artery, and air in the aortic inflow tubing. [205] [206] The extracorporeal system is usually primed with a heparinized and buffered physiologic salt solution to which may be added (1) an osmotically active substance (e.g., albumin, hetastarch) to normalize colloid osmotic pressure, (2) an osmotic diuretic (e.g., mannitol), (3) an antibiotic, and (4) aminocaproic acid (Amicar) or aprotonin if indicated. If the patient's hematocrit level is unusually low, it may be appropriate to add packed red blood cells to the priming fluid in anticipation of hemodilution. It is usually desirable to maintain a hematocrit level in the range of 20 to 25 percent during hypothermic CPB. [207] [208] [209] [210]

Heparin Anticoagulation

Heparin anticoagulation of the patient's blood is the single most important preparative step for CPB; failure to establish heparin anticoagulation means death to the patient on initiation of CPB. The usual initial dose of heparin is 300 to 400 U/kg (equivalent to 3-4 mg/kg) administered into a central venous catheter (after verifying its intravascular position by blood withdrawal) by the anesthesiologist or into the aorta by the surgeon several minutes before insertion of any CPB cannula. Because of variability among patients in their response to heparin, it is customary to use an *in vitro* test of coagulation (e.g., ACT). The ACT should remain above 400 seconds for the duration of CPB cannulation and should return to the preheparin baseline level (usually 90-120 seconds) after administration of protamine following decannulation. [211] [212] The ACT is markedly prolonged during hypothermia and celite-based ACT determinations are prolonged by aprotinin. Such prolongations may give a false impression of adequate heparin concentrations. Under such circumstances, it is advisable to administer supplemental heparin doses at regular intervals (e.g., 100 U/kg every 90 minutes). The elimination of heparin is slowed by hypothermia but rapidly recovers to a normal rate with rewarming. [213] Therefore, it is important to verify the adequacy of heparin anticoagulation frequently (every half hour) during normothermic CPB. Important signs of inadequate anticoagulation are accumulation of fi-brin on the walls of the CPB reservoir and thickening of blood in the pericardium. Obviously, the presence of any blood clot during CPB indicates the need for immediate administration of additional heparin. The one uniformly lethal and irreversible complication of CPB is clotting of blood in the patient and the CPB circuit. The other consequence of inadequate heparinization during CPB is the clinically inapparent activation of coagulation with consumption of the clotting factors, leading to subsequent coagulopathic bleeding. Aprotinin inhibits inflammatory responses to CPB and surgery that are responsible for platelet activation and consumption during CPB. Preservation of functional platelets improves blood coagulation after CPB.

TABLE 49-19 -- Signs of Potential Complications of Cardiopulmonary Bypass (CPB)

High aortic tubing pressure

- Aortic tubing occlusion by kinking, clamp
- Improperly positioned aortic cannula (e.g., aortic dissection, cannula tip inserted into branch of aorta)
- Aortic cannula too small for required CPB flow

Low venous return

- Aortic dissection
- Bleeding from an open blood vessel
- Pooling of blood in dependent portions of body
- Anaphylactic or anaphylactoid reaction
- Obstruction of vena caval cannula (malposition)
- Insufficient difference in height of vena cava versus CPB reservoir for gravity drainage
- Obstruction of venous tubing (e.g., kinking, air lock, clamp)
- Leak in venous return tubing, connectors, CPB reservoir

Hypotension

- Anything limiting CPB pump flow (e.g., low venous return)
- Aortic dissection
- Low peripheral resistance (e.g., anaphylactic or anaphylac-toid reaction, hematocrit <18-20%, drug [anesthetic, va-sodilator] effect)

Abnormal blood gases

- Oxygenator failure (Pa_{O_2} , Pa_{CO_2})
- Inadequate perfusion (pH, base deficit, Pv_{O_2} < 40 mm Hg,venous hemoglobin saturation <50%)
- Increased oxygen demand (e.g., due to shivering, inadequate skeletal muscle relaxation)

Suffusion, plethora, cyanosis or edema of head, face, eyelids, and conjunctiva

- If unilateral, aortic cannula flow into carotid artery
- Obstruction of superior vena caval cannula
- Obstruction of jugular venous drainage by caval cannula, head position, neck compression

Isoelectric encephalogram

- Inadequate cerebral perfusion (e.g., due to carotid artery occlusion, hypotension, hypoxemia)
- High anesthetic concentration (thiopental used for cerebral protection [134])
- Extreme hypothermia

Oliguria or anuria

- Aortic dissection

Fibrin deposition or clot in CPB reservoirs or in operative field

- Inadequate heparin concentration (e.g., dose too low, rapid elimination at normothermia)
- Insufficient heparin cofactor (antithrombin III)

Abdominal distention

- Obstruction of inferior vena caval cannula
- Intra-abdominal hemorrhage, ascites
- Gastrointestinal distention by gas, fluid

Elevated central venous pressure

- Obstruction of vena caval cannula

Elevated pulmonary artery pressure, distention of heart

- Obstruction of vena caval cannula (on partial CPB)
- Incompetent aortic valve (before aortic cross-clamping)
- Excessive coronary sinus and bronchial artery flow
- Malposition of heart

Diaphragmatic movement

- Hypercarbia
- Inadequate muscular relaxation or inadequate anesthesia

Hypertension

- Excessive CPB flow
- Inadequate anesthesia
- Drug-induced

Hemodynamic Changes

Hemodynamic changes become evident with the initiation of hypothermic CPB. Initially, peripheral resistance falls as the cold CPB priming fluid, which has low viscosity, low oxygen content, and no hormonal vasoconstrictors, enters the vascular system. Hypotension may not become evident until LV ejection stops. As the pump-priming fluid mixes with the patient's blood and vascular tone recovers, the mean perfusion pressure begins to rise, in some cases to above 110 mm Hg, which indicates arterial vasoconstriction and impaired perfusion of some tissues. Hypertension carries the risk of intracerebral hemorrhage. The range of acceptable perfusion pressures and flows during CPB is controversial, [214] [215] [216] concern having been registered about the adequacy of cerebral and coronary perfusion if mean arterial pressures are not maintained in the usual range for the patient at rest. Some have suggested the routine use of vasopressors as necessary to maintain a mean arterial blood pressure 70 mm Hg or greater in all adult patients during CPB. Yet, practitioners who routinely accept low perfusion pressures report no increased incidence of complications from CPB. Until this debate is settled, the following guidelines represent a middle-of-the-road approach to the problem.

1. The first objective is to maintain tissue perfusion. Thus, the pump flow should be set at the calculated normal resting cardiac output for that patient. Mean blood pressure can then be adjusted into a range of 50 to 100 mm Hg by the use of vasopressors (e.g., phenylephrine, norepinephrine) and vasodilators (e.g., isoflurane, NTG, nitroprusside). Flow can be reduced in relation to the degree of hypothermia and slowing of metabolism. [216]
2. Vasopressors are not without complications. They can reduce renal perfusion, produce spasm of peripheral arteries, and lead to metabolic acidosis due to

underperfusion of peripheral tissues. Therefore, it may be better to forego the administration of large doses of vasopressors and accept a lower blood pressure as long as tissue perfusion appears to be adequate.

3. Signs of inadequate tissue perfusion include oliguria, progressive metabolic acidosis, venous oxygen tension less than 40 mm Hg, venous hemoglobin saturation less than 60 percent, and wide discrepancies between temperatures measured in the nasopharynx or esophagus and those measured in the urinary bladder, rectum, skeletal muscle, or skin. Careful monitoring of the pupils and EEG may reveal subtle changes indicative of inadequate cerebral perfusion, but the significance of such changes has to be related to all the other factors that may cause them.
4. Factors affecting total peripheral resistance should be monitored. Low hematocrit level and consequent low viscosity of blood can result in hypotension; at moderate hypothermia (26-30°C), the hematocrit level can remain between 20 and 25 percent during CPB. Hypercarbia

produces vasodilation, as does an anaphylactoid response (e.g., to blood products, dextran, or antibiotics). Insufficient anesthesia can result in increased sympathetic activity and vasoconstriction in response to noxious stimulation and hypothermia.

5. Discrepancies between radial artery and central aortic blood pressures, especially systolic pressures, have been noted at the end of CPB. [217] The favored explanation is marked vasodilation in the extremity analogous to the situation existing distal to an arteriovenous shunt. One way to determine the degree of discrepancy is to compare the pulse pressure tracings from the radial arterial catheter with those obtained through a needle inserted into the ascending aorta by the surgeon, who passes sterile extension tubing to the anesthetist for attachment by a stopcock to the same arterial pressure transducer. If there is a substantial difference in the systolic pressures, the surgeon can insert a femoral arterial catheter and connect it to the extension tubing for continuous monitoring thereafter or until the peripheral vasculature recovers its normal tone. Another means of verifying the accuracy of radial artery pressures is to determine the upper arm cuff pressure at which Korotkoff sounds or arterial pulse waves return (the so-called return-to-flow pressure).

TABLE 49-20 -- Checklist of Preparations for Initiating Cardiopulmonary Bypass (CPB)

I. Before aortic and vena caval cannulation
  A. Heparin dose
    Activated clotting time (ACT) >300 s (Hemochron)
  B. Hemodynamics
    Systemic blood pressure appropriate for aortic cannulation (systolic <100 mm Hg)
    ECG recorded before and after sternum spread open (especially V_5 lead)
    Central venous pressure adequate to sustain preload during vena caval cannulation
  C. Ventilation
    Compliance evaluated (for post-CPB comparison)
    Lung inflation appropriate (for surgical access to internal mammary arteries and venae cavae)
    Arterial blood gases and acid-base balance satisfactory (for current status and for comparison during and after CPB)
II. Before turning on CPB pump
  A. Anesthetic depth and CNS status
    Adequacy judged by presence or absence of responses to sternotomy
    Muscular paralysis to limit shivering (O_2 demand) and dangerous movement
    Examination of face (color), eyes (pupils), and EEG recording (if used)
  B. Aortic cannula and tubing
    No evidence of air
    Correct orientation of cannula in aorta
    Clamps off aortic and venous CPB tubing
    Normal aortic tubing pressure with infusion of 100-200 mL pump prime (checked by perfusionist)
  C. Fluid balance
    Intravenous fluid administration stopped and pre-CPB fluid administration recorded
    Pre-CPB urine output recorded
III. First few minutes of CPB
  A. CPB function (before beginning hypothermia)
    Aortic tubing pressure normal
    Systemic blood pressure as expected
    Venous return satisfactory
    Bright red color of blood in aortic cannula
  B. Ventilation of lungs
    Discontinued when ventricular ejection stops
    O_2 flow continued and lung inflation appropriate (i.e., avoid obstruction of surgical field by distended lungs)
  C. Arterial blood analysis
    Gases, pH, and acid-base balance
    ACT
IV. Monitoring during CPB
  A. Heparin
    ACT (>400 s)
    Inspection of CPB reservoir, pericardial fluid (evidence of fibrin)
  B. Blood gases, pH, acid-base balance
    Arterial
    Venous (Pv_{O_2} > 40 mm Hg; Sv_{O_2} > 60%)
    Hematocrit (18-22%)
  C. Blood pressures
    Systemic arterial (40-90 mm Hg)
    Pulmonary arterial (<15 mm Hg [usually close to or below zero])
    Central venous (normally below zero)

D. Temperatures

Pharyngeal, esophageal

Peripheral (skin, toe, muscle)

Rectal, urinary bladder

Myocardial (if probe used)

Pericardial iced superfusion fluid running (if used)

E. ECG

Quiescent (i.e., isoelectric, absence of fibrillation)

F. CNS status

Color of face, edema formation?

Pupil size, conjunctival swelling

EEG activity appropriate for CPB conditions (hypothermia, anesthesia)

Muscle paralysis adequate (normal Pv o_2 and Hb saturation)

G. Urine output

Volume (>1 mL/kg/h)

Color (evidence of hemolysis?)

H. CPB conditions

Aortic tubing pressure (appropriate for flow and aortic cannula size)

Pump flow (1.5-2.5 L/min/m^2)

Venous return satisfactory

Fluid balance appropriate

ECG, electrocardiogram; CNS, central nervous system; EEG, electroencephalogram; Pv o_2 , mixed venous O_2 pressure; Sv o_2 , mixed venous O_2 saturation

THE ANESTHETIC PLAN - continued

The Cardiovascular System During Cardiac Surgery

Cardiopulmonary Bypass

Myocardial Preservation

Myocardial preservation [218] [219] includes (1) myocardial cooling by hypothermic CPB, by epicardial surface cooling with ice and pericardial irrigation with iced fluid, and by intracoronary infusion of cold cardioplegia solution or continuous direct hypothermic coronary perfusion by the CBP pump; (2) myocardial arrest by hyperkalemic cardioplegia solution; and (3) prevention of ventricular distention and edema by venting of the left ventricle and inclusion of mannitol in the cardioplegia solution. Improvement in myocardial preservation since the early 1970s has been evident in the markedly better cardiac contractility at the termination of CPB and in the reduced need for inotropic drugs. [218] [219] Recent advances in cardioplegia techniques include insertion of a special cannula into the coronary sinus for retrograde perfusion of the coronary vasculature with cardioplegia solution, [220] and the use of normothermic, blood-containing cardioplegia solutions. [221]

The role of cardioplegia solutions in myocardial preservation has been discussed by Buckberg. [222] These solutions have some manageable side effects. There is an increased incidence of atrioventricular conduction block due to intramyocardial hyperkalemia, which usually resolves within the first hour after CPB and can be treated temporarily by atrioventricular sequential pacing. The rate of recovery can be speeded by administration of calcium and of insulin with or without glucose as needed. The ventricular flaccidity due to hyperkalemia may be responsible for transverse LV rupture in elderly patients undergoing mitral valve replacement (see previously). Resting of the ventricle on CPB for a time sufficient to allow recovery of membrane function, electrolyte gradients, myocardial metabolism, ventricular tone, administration of calcium and other inotropes, and control of LVEDV with vasodilators facilitates the recovery of ventricular pumping function.

Discontinuation of Cardiopulmonary Bypass

Discontinuing CPB requires preparations by the anesthesiologist. A checklist of the essential steps is shown in Table 49-21 . Several points deserve emphasis.

During the rewarming phase the anesthesiologist may easily overlook the paralyzed patient's return to consciousness and the need to administer additional anesthetic drugs that do not have cardiac depressant effects (e.g., an opioid or benzodiazepine). The recovery of metabolic functions speeds the elimination of heparin, and the adequacy of anticoagulation should be verified more frequently (every half hour) at normothermia.

In discontinuing CPB, the perfusionist gradually allows the heart to fill and pump blood by progressively occluding the venous return cannula while decreasing the pump arterial inflow as the patient's heart ejects more and more blood. This process may be done rather quickly when there is good heart function, but with poor cardiac performance, sufficient time should be taken in discontinuing CPB to allow recovery of cardiac electrolyte and metabolic balance, to evaluate cardiovascular function, and to establish the appropriate therapeutic regimen. It is not enough that blood pressure be within the normal range--overall cardiac performance should be assessed by measuring cardiac output and calculating stroke volume in relationship to preload (see Fig. 49-2) ; optimal conditions, including heart rate and rhythm (Table 49-22) , preload, and vascular resistance, should be established; and if necessary, drug therapy should be begun before extracorporeal circulatory assistance is discontinued. It is extremely important to avoid injury to the ventricles by overdistention. Reasonably satisfactory and stable hemodynamic conditions should be maintained for a time after discontinuing CPB and before removing the vena caval and aortic cannulas. The ability to reestablish CPB rapidly should be preserved (i.e., the CPB circuit maintained and cannulation devices available and ready to use). An algorithm that may aid the anesthesiologist and surgeon in their analysis and management of low cardiac output is shown in Figure 49-8 . Inotropic, vasopressor, and vasodilator drugs that may be useful are listed in Tables 49-23 through 49-27 . [223]

After CPB has been terminated, a number of potential problems may occur, two of which, air embolism and complications of heparin neutralization, deserve special mention.

Sudden embolization of air lodged in one of the left chambers of the heart or in the aorta can occur when the orientation of the heart and great vessels is altered by manipulation of the heart, closure of the sternum, or movement of the patient (e.g., transfer from the operating table to the ICU bed). Embolization to the brain or heart can lead to obvious undesired consequences. Temporary CNS functional deficits resembling a cerebrovascular accident may result; they usually resolve several days after surgery as the air is resorbed provided that irreversible ischemic damage has not occurred. Air embolism into the coronary arteries, most frequently the right coronary artery, may be manifested by ST-T segment elevation, bradycardia, conduction abnormalities, dysrhythmias, ventricular fibrillation, and impaired contractility. Treatment of air embolism involves resuscitative measures as indicated, maintenance of a high perfusion

TABLE 49-21 -- Checklist of Preparations for Discontinuing Cardiopulmonary Bypass (CPB)

I. Rewarming
- A. Responsiveness of patient
- B. Adequacy of heparin anticoagulation
- C. Oxygenation and CO_2 elimination
- D. Metabolic acid-base balance
- E. Vasodilation to facilitate warming of peripheral tissues (e.g., toe temperature)
- F. Defibrillation (spontaneous, lidocaine, electric)
- G. Recalibration of monitoring devices

II. Just before discontinuing CPB
- A. Arterial pH, P_{CO_2} , P_{O_2}
- B. Hematocrit level
  1. O_2 delivery

2. Viscosity (peripheral resistance)

C. Serum potassium

1. Urine flow
2. Insulin ± glucose (to decrease K^+ > 6 mEq/L)
3. Calcium (to antagonize K^+ > 6 mEq/L)
4. Furosemide (to decrease K^+ > 6 mEq/L)

D. Body temperatures

1. Core versus peripheral tissues

E. Heart rate and cardiac rhythm (see Table 49-22)

1. Cardiovascular/defibrillation
2. Pacemaker (atrial, ventricular, atrioventricular sequential)
3. Antidysrhythmic drugs

F. Mean systemic arterial pressure

1. Vasodilator/vasopressor

G. Venous and pulmonary artery pressures

1. Vasodilators
2. Blood volume in CPB reservoir

H. Ventilation of lungs

1. Air flow (wheezing, air trapping)
2. Compliance (pulmonary edema, gastric distention, tense diaphragm)
3. Elimination of atelectasis
4. Pneumothorax, hydrothorax (irrigation fluid)

I. Venting of arterial air

1. Cardiac chambers (verification by TEE if used for other purposes)
2. Aorta
3. Saphenous vein grafts
4. Head-down position, carotid artery compression with ventricular ejection

III. Gradual discontinuation of CPB (see Fig. 49-8)

A. Preload

1. PAOP or LAP
2. CVP

B. Ventricular ejection

1. dP/dt on arterial pressure tracing
2. Cardiac output
3. TEE imaging
4. Inotropic drugs

Catecholamine injection/infusion

5. Vasodilators

C. Return of CPB reservoir blood to patient

1. Venodilator and head-up position

IV. After discontinuation of CPB, surgical control of major bleeding, and decannulation of venae cavae and aorta

A. Protamine antagonism of heparin

B. Maintenance of circulating blood volume and coagulation

1. Transfusion of packed red blood cells
2. Fresh frozen plasma
3. Platelets
4. epsilon-Aminocaproic acid, desmopressin (?)
5. Cryoprecipitate

C. Hemodynamic adjustments

D. Anesthesia

E. Preparations for transfer of patient from operating room to intensive care unit

1. Monitoring
2. Ventilation
3. Hemodynamic therapy
4. Anesthesia-analgesia

TEE, transesophageal echocardiography; PAOP, pulmonary artery occlusion pressure; LAP, left atrial pressure; CVP, central venous pressure

TABLE 49-22 -- Therapy of Abnormal Heart Rate and Rhythm at End of Cardiopulmonary Bypass

DIAGNOSIS	THERAPEUTIC STEPS

Asystole or heart block due to potassium cardioplegia, surgery (trauma to nodal and conducting tissues), or preoperative pathophysiology	Pacemaker: atrial, ventricular, atrioventricular sequential Calcium chloride, 1-2 g Sodium bicarbonate, 50 mEq Insulin, 10 units, regular, ±glucose, 10 g Furosemide, start with 3 mg and increase doses logarithmically (10, 30, 100) every 15 min up to 100 mg as needed to establish diuresis Temporary epicardial pacing wires for postoperative use Atropine, incremental doses up to total of 2-2.5 mg/70 kg over 5-10 minutes Isoproterenol, 0.5-10 mug/min
Supraventricular tachyarrhythmia	Increase core temperature to 37°C Correct electrolyte abnormalities (K^+, Mg^{2+}) Correct arterial pH, P_{CO_2}, and hematocrit level Check position of CVP or other monitoring catheters Overdrive atrial pacing Synchronous cardioversion (internal paddles, 5-10 watt-seconds) Adenosine initial 6 mg rapidly IV, then 12 mg if needed to diagnose dysrhythmia Ouabain, 0.1-0.2 mg, or digoxin, 0.25-1 mg Propranolol, 0.5-3 mg; esmolol 25-75 mg bolus plus 5-200 mug/kg/min infusion Diltiazem 5-25 mg IV over 1-3 min plus infusion Procainamide 100 mg IV every 5 min to effect (5-15 mg/kg total), then 1-4 mg/min infusion
Recurrent ventricular tachycardia or fibrillation	Increase core temperature to 37°C Correct electrolyte abnormalities (K^+, Mg^{2+}) Correct arterial pH, P_{CO_2}, P_{O_2}, and hematocrit level Check position of pulmonary artery catheter Maintain satisfactory BP, PAOP, CO Lidocaine 1-2 mg/kg bolus plus 2-4 mg/min infusion Defibrillation (internal paddles, 10-60 watt-seconds) Procainamide (see above) Bretylium 5-10 mg/kg IV over 10 min plus 1-2 mg/min infusion

CVP, central venous pressure; BP, blood pressure; PAOP, pulmonary artery occlusion pressure; CO, cardiac output.

Figure 49-8 Algorithm for therapy of low cardiac output. PAOP is an indirect measure of LVEDP; PAOP greater than 15 mm Hg may be necessary in patients with a pressure gradient across the mitral valve and in those with elevated PAOP before surgery as a result of low ventricular compliance. BP, blood pressure; CVP, central venous pressure; PAOP, pulmonary capillary wedge pressure; CO, cardiac output; TPR, total peripheral resistance; WNL, within normal limits;
, increase. Measurement units are mm Hg for pressure, dynes/cm^5 /s for resistance, and L/min for CO.

TABLE 49-23 -- Vasopressors[a]

DRUG	INITIAL[b] DOSE	ADRENERGIC RECEPTOR STIMULATION		
		VASCULAR		
		alpha	beta $_2$	HEART, beta $_1$
Methoxamine (Vasoxyl)[c]	2-100 mg	+++	0	0
Phenylephrine (Neo-Synephrine)	50-100 mug	++	0	±
Metaraminol (Aramine)	100 mug	++	±	+
Ephedrine[d]	5-25 mg	+	±	+
Norepinephrine (Levophed)	1-4 mug	+++	0	+++

0, no effect; ±, may or may not have an effect; +, weakest effect; ++, moderate effect; +++, strongest effect

[a] Also see Chapter 14 .
[b] Geometric (1,2,4,8 x) or logarithmic (1,3,10,30 x) increases in dose may be required to achieve desired degree of response. An infusion may be required to sustain the effect.
[c] Methoxamine is rarely used because of its long duration of action.
[d] Ephedrine doses above 50 mg are seldom used because of its limited efficacy; infusions are not used.

TABLE 49-24 -- Inotropic Therapy

DRUG	INTRAVENOUS BOLUS	INFUSION	LIMITATIONS
Amrinone (Inocor)	1.5-3 mg/kg[a]	5-10 mug/kg/min	Hypotension (TPR)
Milrinone (Primacor)	50-75 mug/kg	0.4-0.8 mug/kg/min	Hypotension (TPR)
Dobutamine (Dobutrex)	--	2-20 mug/kg/min	Tachycardia Dysrhythmias
Dopamine (Intropin)	--	2-15 mug/kg/min	Tachycardia Dysrhythmias Vasoconstriction
Epinephrine (Adrenalin)	2-50 mug[b]	2-60 mug/min	Tachycardia Vasoconstriction
Norepinephrine (Levophed)	1-10 mug[b]	1-60 mug/min	Vasoconstriction Tachycardia
Isoproterenol (Isuprel)	1-5 mug[b]	0.5-5 mug/min	Hypotension Tachycardia Dysrhythmias

TPR, total peripheral resistance

[a] Higher dose than recommended in package insert is necessary to achieve effective drug concentrations. [223]
[b] Per 70-kg individual

TABLE 49-25 -- Other Inotropic Drugs

DRUG	DOSE[a]	LIMITATIONS
Calcium chloride [b]	0.25-1 g	Dysrhythmias, AV block
Digoxin		
Initial	1-1.5 mg	Dysrhythmias
Maintenance (daily)	0.125-0.5 mg	Bradycardia
Ouabain	0.3-0.5 mg	AV block
Glucagon	3-10 mg	Tachycardia
		AV block (ventricular rate)
		Hyperglycemia

, increase;
, decrease; AV, atrioventricular

[a] Per 70-kg individual
[b] Inotropic effect is weak and superseded by vasoconstriction, which is a more prominent effect. Intravenous bolus dose is useful to increase systemic blood pressure transiently without increasing heart rate.

TABLE 49-26 -- Relative Efficacy of Intravenous Vasodilators on Hemodynamic Variables

VASODILATOR	DILATION			
	VENOUS	PULMONARY ARTERIAL	SYSTEMIC ARTERIAL	CARDIAC OUTPUT
Nitric oxide	0	+++	0	±
Nitroglycerin IV (Tridil)	+++	+	+	[a]
Nitroprusside (Nipride)	+++	+++	+++	[a]
Phentolamine (Regitine)	+	+	+++	
Hydralazine (Apresoline)	0	?	+++	
Nicardipine (Cardene)	0	?	+++	
Amrinone [b] (Inocor)	+	+	+	
Milrinone [b] (Primacor)	+	+	+	
Prostaglandin E_1 [c]	+	+++	+++	[a]

0, none; ± small, variable; + mild; +++ strongest effect of that particular drug.

[a] Effect on cardiac output depends on net balance of effects on preload, afterload, and myocardial oxygenation.
[b] Inodilators have inotropic plus vasodilating effects; see Table 49-24 .
[c] Almost always requires left atrial infusion of norepinephrine to sustain adequate systemic blood pressure.

TABLE 49-27 -- Dosage of Vasodilators

DRUG	DOSING REGIMEN[a]	
	INITIAL	MAXIMUM
Administered as infusion:		
Nitroglycerin (Tridil) [b]	50 mug/min	500 mug/min [c]
Nitroprusside (Nipride) [d]	10-25 mug/min	8 mug/kg/min
Nicardipine	100-300 mug	3-5 mg/h
Trimethaphan (Arfonad)	0.3 mg/min	6 mg/min
Phentolamine	10-100 mug/min	7 mug/kg/min
Prostaglandin E_1	0.05 mug/kg/min	0.5 mug/kg/min
Administered as intravenous bolus:		
Chlorpromazine (Thorazine)	1 mg	5-25 mg/24 h [e]
Droperidol (Inapsine)	2.5 mg	10-20 mg/24 h [e]
Hydralazine (Apresoline)	5 mg	40 mg over 1 h [f]

Phentolamine (Regitine)	1 mg	0.5 mg/min [g]

[a] Per 70-kg individual
[b] IV bolus doses of 25-100 mug may be useful to produce transient effect rapidly.
[c] Highest dose rate reported; no maximum yet defined in terms of toxicity or efficacy.
[d] IV bolus doses of 20-200 mug (geometric or logarithmic progression) are useful for rapid reduction of systemic blood pressure lasting 2-3 minutes, with more or less complete recovery depending on degree of reduced venous return.
[e] Limits are suggested because higher doses are probably no more effective in controlling hypertension and may lead to marked and prolonged CNS effects.
[f] Peak effects may not occur until 30 to 60 minutes after injection; seldom will more than 40 mg be needed to produce effects lasting several hours. Temporarily withdrawn from market by manufacturer, who is trying to develop a more economical formulation.
[g] Intravenous bolus doses of 5 to 10 mg may be used, depending on the situation; a maximum infusion rate has not been defined in terms of efficacy or toxicity but rarely is more than 0.5 mg/min.

pressure in the hope of flushing the emboli out of the arterial circulation, and perhaps administration of corticosteroids.

To prevent arterial air embolism, the following have been suggested for CABG surgery: fine-gauge needle puncture at the highest level of each saphenous vein graft and massage of the graft to express air before allowing aortocoronary blood flow; large-bore needle puncture at the highest level of the aorta, with the patient's head at a slightly lower level than the ascending aorta; and positive-pressure ventilation before, with passive Valsalva maneuver maintained during, removal of the LV vent cannula. To prevent air entry into the heart, some surgeons omit the LV vent cannula provided that ventricular distention and elevated pulmonary vascular pressures do not occur during CPB. For open-heart surgery, additional measures include massage of the left atrium and ventricle by the surgeon, lateral rotation of the patient (operating table) back and forth along the long axis of the body, and omission of nitrous oxide administration after CPB. In cases of left atrial enlargement--especially with chronic atrial fibrillation, LV aneurysms, and aortic valvular vegetation or calcification--embolization of air, clot, and other debris

can occur. [224] [225] [226] TEE is being used to assess the presence of potential emboli in the heart and aorta.

Protamine administration after removal of the aortic and vena caval cannulas should be done carefully and slowly (infusion or small intermittent doses) because of the risk of hypotension due to myocardial depression, histamine release, systemic vasodilation, pulmonary vasoconstriction, and anaphylactic or anaphylactoid reactions. [227] [228] The last two categories can also be associated with bronchospasm and pulmonary edema. An anaphylactic reaction with severe hemodynamic consequences requires immediate administration of heparin and reestablishment of CPB. It appears that intra-aortic or left atrial administration of protamine reduces (but does not eliminate) its hemodynamic and pulmonary side effects. [228] [229] The hemodynamic effects may be due to the protamine-heparin complex rather than to protamine per se. [230]

The adequacy of heparin neutralization can be verified by *in vitro* testing of the coagulability of the patient's blood (e.g., ACT). There is the possibility of recurrent heparin anticoagulation from the breakdown of heparin-protamine complexes by sulfatases and from late reperfusion of vascular beds containing heparinized blood. [119] [231] Platelet function and, less commonly, clotting factors may be deficient after CPB, and these possibilities should be considered in the differential diagnosis of excessive bleeding in the post-CPB period. [119] Thromboelastography is being used for rapid assessment of coagulation deficiencies. [119] [120]

Other Systems During and After Cardiac Surgery

The same concerns about preservation of organ function are required for cardiac as for any other type of surgery. However, a few topics are of particular importance in relation to the patient with cardiac disease and to the conditions associated with cardiac surgery. These are briefly summarized here.

Ventilation and the Lung

Complete oxygen saturation of hemoglobin is essential to providing the maximum supply of oxygen to the myocardium. Normocarbia is preferable to either hypercarbia (sympathetic stimulation, systemic vasodilation, pulmonary vasoconstriction) or hypocarbia (cerebral and coronary vasoconstriction). It is essential to achieve these ventilatory goals (Chs. 15 and 33) even if there are a number of obstacles. Tidal volume may need to be reduced at certain points in the procedure to prevent interference with the surgery. Moreover, a number of problems with pulmonary function can arise as a result of the use of vasoactive drugs (alterations of ventilation-perfusion relationships), accumulation of cellular and other debris in the pulmonary capillaries, interstitial and frank pulmonary edema, pneumothorax, atelectasis, and improper operation or function of the CPB pump oxygenator. Arterial blood gases (ABG) should be analyzed as often as necessary to allow optimal settings of the ventilator before and after CPB and optimal adjustment of gas and blood flow conditions during CPB. At a minimum, it is advisable to obtain ABG analyses after tracheal intubation, soon after initiation of CPB, during rewarming, just before discontinuing CPB, and after CPB. If the patient's condition is unstable, more frequent ABG analysis may be indicated to guide life-support therapy. Devices are continuing to be developed to allow continuous monitoring of arterial and mixed venous pH and gas tensions.

Continuous monitoring by mixed venous (PA) oximetry is potentially useful for judging the overall adequacy of ventilation and circulation and also for providing an early warning of adverse changes (e.g., degree and rapidity of hemoglobin desaturation during pulmonary suctioning via the endotracheal tube). [232] A careful and complete differential diagnosis may be required to correct every factor that may impair optimal ventilation and adequate oxygenation of tissues.

The controversy about the appropriateness of temperature correction of ABG values for the hypothermic state remains unsettled. [216] [233] [234] [235] The data available for cardiac surgical patients suggest that there are relatively minor hemodynamic consequences of omitting versus adding carbon dioxide to the CPB reservoirs in an attempt to maintain the hypothermic pH at 7.4 and the temperature-corrected Pa CO_2 close to 40 mm Hg. However, the majority opinion has swayed to the viewpoint of Rahn, [233] that ABG results (measured at 37°C) should not be corrected for the body temperature of the hypothermic patient. The latter option can be implemented by simply telling the blood gas laboratory technician that the patient's temperature is 37°C, regardless of what the patient's actual temperature is; this is known as the Alpha-Stat management of carbon dioxide during CPB.

Postoperatively, endotracheal intubation and mechanical ventilatory assistance should be maintained (usually intermittent mandatory ventilation) until the following are accomplished: the patient is transferred to the intensive care setting, reasonable hemodynamic stability is evident, postsurgical bleeding is at an acceptable (low) rate, body rewarming is complete, the patient is conscious and able to respond to commands (e.g., to cough), and there is evidence (e.g., normal muscle strength, acceptable ventilatory mechanics) that the patient can maintain satisfactory spontaneous ventilation and protect the airway. Antagonists to arouse the patient (e.g., physostigmine) and to restore neuromuscular function (e.g., neostigmine with atropine) can be used with cautious regard for their potentially adverse consequences. However, we believe that the use of naloxone or any other opioid antagonist to restore ventilatory function is to be discouraged in the immediate postoperative period for several reasons: the opioid antagonist unmasks pain and causes discomfort; it results in sympathetic stimulation with potentially adverse hemodynamic consequences; it increases the incidence of nausea, retching, and vomiting, all of which contribute to ventilatory and circulatory instability; and it makes restoring analgesia and calm difficult until the antagonist is eliminated from the body. [168]

Urine Output and the Kidney

During hypothermic CPB, renal tubular function is depressed, [236] and a large volume of dilute urine (Chs. 18 and 34) is usually produced as a result of hemodilution, mannitol

(in CPB priming solution), and maintenance of renal glomerular perfusion and filtration. If urine volume is less than 1 mL/kg/h during CPB, mechanical obstruction to urine flow through the bladder catheter drainage system should be excluded before undertaking steps to increase renal perfusion and to promote urine output, which is essential for the excretion of potassium administered as a component of the cardioplegic solution. If hemolysis is occurring, it is especially important to maintain a high-volume urine flow to prevent the accumulation of hemoglobin and its metabolites in the renal tubules. Usually, renal tubular function is restored rapidly after CPB

provided that good renal perfusion is maintained (i.e., adequate cardiac output, minimal renal vasoconstriction). As always, renal failure is an ominous and life-threatening complication. [237]

Body weight gain due to accumulation of fluid is typical of patients after cardiac surgery. Usually patients experience a spontaneous diuresis during the second or third postoperative day, which continues until body fluids are brought into balance by the resumption of normal homeostatic mechanisms. [238] [239] Anticipation of the spontaneous diuresis is thought by some to indicate curtailment of the administration of potent diuretics such as furosemide unless there is another indication (e.g., pulmonary edema, CHF). Unnecessary use of diuretics leads to a variety of problems with fluid and electrolyte balance, creates hemodynamic instability, and interferes with the return of normal renal function. Excessive diuresis contracts circulating blood volume and entails the risk of reduced renal perfusion. Infusion of dopamine at a low dose rate may be useful to maintain renal perfusion and to promote diuresis. [240] [241]

Body Temperature and Metabolism

Hypothermia affects all cellular functions (Ch. 37) . These changes are reversible when normal body temperature is restored. Of special concern during the rewarming phase are the recovery of consciousness and the requirement of additional anesthetic drugs (potent inhaled anesthetics may be tolerated only in low concentrations because of their myocardial depressant properties and nitrous oxide should be avoided because of the risk of expansion of air emboli); an increased rate of biotransformation of heparin and increased coagulability of blood; and the uptake of potassium by cells, leading to hypokalemia. [242] With regard to potassium uptake, use of 500 to 1,000 mL of cardioplegic solution (approximately 25 mEq K^+/L) provides 12.5 to 25 mEq, some of which enters the circulation when coronary perfusion resumes. However, this amount of potassium may not equal that lost in urine during CPB. [242]

Two other important considerations are the possible difficulty in defibrillating the heart and maintaining a regular cardiac rhythm until the body core temperature exceeds 34°C, and the danger of body recooling unless the CPB rewarming time is sufficient to bring most of the body mass to a normal temperature. Persistence of temperature gradients (e.g., nasopharyngeal versus skin) is an indication of the inadequacy of rewarming and of the risk of recooling after CPB is discontinued. Surface rewarming by a heating blanket is inefficient and cannot be relied on to maintain body temperature, let alone to correct heat deficits in the adult patient. Pulsatile perfusion improves rewarming and can be accomplished by allowing the patient's heart to eject before discontinuing CPB. [243] Peripheral tissue perfusion and rewarming can be facilitated by use of a vasodilator. [244]

Persistent hypothermia contributes to postoperative problems, including coagulopathy, hypertension, and tachycardia, reflecting increased sympathetic activity, and shivering, which increases oxygen demand. [245] Muscle relaxants may be necessary to counteract the detrimental effects of shivering and excessive oxygen utilization in the critically ill patient.

Hypothermia, stress reactions, and administration of sympathomimetic inotropes decrease the response to insulin and may result in hyperglycemia, which can be exacerbated by the intravenous infusion of fluids containing dextrose. [246] [247] These conditions are exacerbated in the diabetic patient. Hyperglycemia contributes to diuresis and, if severe, can produce coma. Also, hyperglycemia may be detrimental to CNS and cardiac recovery in the event of a global or a focal ischemic insult. [248] [249] A satisfactory range of serum glucose is 100 to 250 mg/dL. Certainly, serum glucose should be determined regularly during the operative and postoperative periods in any diabetic patient, in any patient given insulin (with or without glucose) in the treatment of hyperkalemia or poor cardiac performance, and in persistently comatose patients.

Hyperthermia due to rapid or excessive rewarming on discontinuing CPB is dangerous because it increases metabolism and risks the development of ischemia in all tissues and organs, especially the CNS and heart. The temperature of arterial inflow during CPB should not exceed 38°C.

Protection of the Central Nervous System

The CNS (Chs. 19 and 35) , being very vulnerable to hypoxemia and hypoperfusion, is at risk from hemodynamic instability during cardiac surgery. In elderly patients, especially those with atherosclerosis, the cerebral circulation may be tenuous under normal conditions. Perfusion may be compromised by changes in arterial blood pressure and flow (e.g., changes produced by hypothermic CPB, [216] hypocarbia, vertebral or carotid artery occlusion by certain positions of the neck), by increases in venous blood pressure (such as superior vena caval obstruction by the CPB cannula), and by embolization of air, thrombus, and debris from the operative site.

At present, the EEG is the only practical means of monitoring the integrity of the CNS in the cardiac surgical patient. Whether the EEG should be monitored routinely is debatable. Some have suggested that if cerebral perfusion is satisfactory, overall perfusion of the body is probably also satisfactory. However, the issue remains controversial because (1) the full 21-lead EEG used by the neurologist for diagnosis is impractical as a monitoring device and anything less leaves open the possibility of missing regional CNS ischemia; and (2) processing of the EEG to produce easily recognizable patterns of abnormality makes EEG monitoring more useful to the anesthesiologist, but the devices are expensive and usually suitable for monitoring only two pairs of leads. Bilateral placement of these leads allows comparison of a similar point in both cerebral hemispheres, which

may be sufficient to detect global reductions in cerebral perfusion. [249] One clear indication for global EEG monitoring is to guide the use of thiopental for CNS protection against incomplete ischemia. Such protection requires thiopental doses sufficient to produce EEG burst suppression and the corresponding reduction in cerebral metabolic rate. Patients vary considerably in their thiopental requirements, and it is advisable to use the lowest necessary dose to minimize the side effects of thiopental on the cardiovascular system. [134] [250]

Hypothermia during CPB has a protective effect on the CNS as well as on other body organs. However, the risks to CNS integrity noted previously are present both before and after the period of hypothermia, and some surgeons see benefits in maintaining near-normal body temperatures for cardiac operations, although most now allow the body temperature to "drift" to 33° to 34°C, which reduces CNS metabolism and provides a measure of CNS protection. Other measures to prevent or minimize the consequences of CNS insult may be needed. The use of thiopental to protect against CNS ischemia has been noted. [250] [251]

Other preventive measures may include diagnostic evaluation of symptomatic carotid bruits and possible endarterectomy before heart surgery [10] ; maintenance of usual or slightly higher than usual mean arterial pressure during surgery and CPB, especially in patients with known cerebrovascular disease [252] ; scrupulous prevention of air embolization and avoidance of nitrous oxide after hypothermic CPB, which always produces micro air emboli; and possibly the unproven use of prophylactic corticosteroids in patients at particular risk (e.g., cerebrovascular disease, valvular surgery). The tradition of manually compressing the common carotid arteries during the first minute of resumed LV ejection, when embolization is most likely to occur, may be helpful; but it carries the risk of reducing cerebral blood flow and of dislodging carotid arterial atherosclerotic plaque. It is best to prevent hyperglycemia, which can exacerbate a global (and perhaps even a focal) ischemic insult to the CNS. [247] [248] Incidentally, a recent cerebrovascular accident is believed by some to be an absolute contraindication to the use of anticoagulants and therefore to cardiac surgery involving CPB. Treatment of potential catastrophic events is outlined in Chapter 56 .

Coagulation System

Management of blood coagulation (Ch. 46) during and after cardiac surgery is of critical importance from several standpoints. The coagulation cascade must be inactivated with heparin before initiating CPB and the heparin neutralized by protamine after CPB to prevent uncontrolled bleeding. CPB itself has several deleterious effects on the coagulation system that can contribute to post-bypass hemorrhage, thereby increasing blood product administration (with the attendant risks of transfusion reaction and transmission of infectious disease) and occasionally necessitating return to the operating room for reexploration.

Several measures may be taken to minimize bleeding and transfusion requirements after cardiac surgery. Preoperative donation of autologous blood has safely and effectively been used to decrease homologous blood transfusion. [253] Withdrawal of 1 to 2 units of the patient's blood via a central venous cannula before CPB should be considered for large patients with a normal hematocrit level and stable hemodynamics. The blood is collected in citrate phosphate dextrose (CPD) containing bags, periodically mixed by rotation, and reinfused after CPB. The intraoperative collection of shed blood for separation, washing, and readministration to the patient is routinely used in many cardiac centers [254] and can significantly reduce the use of bank blood. [255] The pre-bypass withdrawal of autologous platelet-rich plasma by pheresis for reinfusion after bypass [256] and hemoconcentration by ultrafiltration during CPB [257] are other bloodconserving techniques used during heart surgery.

Several drugs have been used in attempts to decrease bleeding after cardiac surgery. Desmopressin, a synthetic analogue of vasopressin, which stimulates the release of von Willebrand factor from vascular endothelial cells, does not appear to diminish bleeding when used on a routine basis [258] but may be effective in certain subgroups of patients, such as those taking aspirin [259] or with evidence of preexisting platelet dysfunction. [260] Two synthetic drugs that inhibit fibrinolysis, epsilon-aminocaproic acid (EACA) [261] and tranexamic acid, [258] have been shown to decrease postoperative blood loss when given during and after CPB, but questions remain regarding the ability of these drugs to lessen the amount of banked blood ultimately transfused to a patient. We give EACA to patients expected to have long and potentially complicated operations such as repeat surgery, multiple valve replacement, or combined valve-CABG surgery. Aprotinin, a naturally occurring polypeptide, which inhibits the inflammatory response and activation of several proteolytic enzymes, has been shown to decrease both bleeding and transfusion requirements when given to cardiac surgical patients. [262] Aprotinin's primary beneficial effect is believed to be preservation of platelet function during CPB, but it also inhibits fibrinolysis by blocking the action of plasmin. [263] Aprotinin is expensive, can confuse interpretation of the ACT, and has been associated with severe anaphylactic reactions. Hence, it is recommended that a test dose be given to all patients and that aprotinin not be used in first-time, uncomplicated heart operations in order to avoid sensitizing the patient who may later benefit from its use during a reoperation.

The diagnosis and treatment of coagulopathy associated with cardiac surgery are ideally guided by objective laboratory data that provide a rational basis for intervention. [119] [264] The routine prophylactic administration of coagulation factors is to be discouraged but appears to be a common practice. [265] As a practical matter, however, situations arise in the operating room in which bleeding is clearly due to coagulopathy, and treatment is needed before a complete laboratory analysis of the problem is available. Knowledge of the common coagulation defects after CPB is useful in deciding about empiric therapy.

The severity of coagulopathy caused by CPB is related to CPB duration; CPB lasting longer than 2 hours should alert one to the possibility of bleeding problems. Suturing sites of surgical bleeding and complete antagonism of heparin are the first and second steps in treating post-bypass bleeding. Inadequate platelet function is the most common cause of abnormal coagulation after CPB once heparin anticoagulation has been reversed. [266] Bypass causes both a decrease in

the number of circulating platelets and function of those platelets remaining may be impaired by CPB and by drugs (e.g., aspirin) taken preoperatively by the patient. Therefore, platelet transfusion should be the next therapeutic intervention if coagulopathic bleeding is present. Less commonly, CPB causes clinically significant depletion of the coagulation proteins, especially factors V and VIII, for which fresh frozen plasma is the treatment of choice. Fibrinogen levels below 100 mg/dL should be treated with cryoprecipitate. Administration of desmopressin and antifibrinolytic drugs such as EACA should be considered if bleeding persists and is severe. Severe coagulopathy after CPB, especially after very prolonged bypass, is usually multifactorial and often seems to improve only with the rapid, almost simultaneous administration of all of the above.

Postoperative Considerations

The anesthesiologist's responsibility to the patient does not end until there is complete recovery from anesthetic effects and complications (Chs. 68 and 69) . Nursing and other personnel in the ICU and wards can be helpful in discharging this responsibility. [267] Their cooperation should be elicited by the anesthesiologist through a recognition of their professional standing, maintenance of a respectful attitude, acknowledgment and appreciation of their services to the patients, and support of their professional needs (e.g., timely responses to inquiries about the patient, participation in their in-service training programs).

Transfer of the Patient

Transferring the patient from the operating room to the ICU involves a continuation of the monitoring and life-support procedures established during anesthesia and surgery. In all cases it is desirable to make the following provisions for the transfer: (1) portable oxygen and the means of delivering positive-pressure ventilation; (2) continuous monitoring of arterial blood pressure and the ECG, using a stethoscope (preferably esophageal) as a backup means of assessing ventilation and heart rate, rhythm, and contractility; (3) maintenance of constant intravenous infusion of drugs needed for support of the circulation; (4) ready accessibility of the pacemaker controls (if one is in place) and of resuscitative drugs and devices, including a defibrillator; (5) another physician or assistant experienced in the resuscitation and care of cardiac surgical patients; (6) analgesic and sedative drugs; (7) direct route for the transfer, free of any delays (i.e., an elevator waiting for the patient, not vice versa); and (8) advance notification of ICU personnel of imminent transfer of the patient from the operating room.

On arrival in the ICU, the monitoring and life-support procedures should be continued by the anesthesiologist until the orderly transfer of these functions to the nurse and the intensive care specialist physician is completed. The specialist and nurse should be informed of any unusual events or complications that occurred before and during surgery and any problems that are anticipated in the postoperative period. They should be given a summation of the patient's vital signs, optimal hemodynamic variables, ventilatory status, fluid and electrolyte balance, adequacy of blood replacement and coagulability, and anesthetic and drug therapy. All orders should be written clearly and reviewed by the nurse to detect any ambiguities before the anesthesiologist leaves the patient. Furthermore, the nurse should be informed of the means of contacting the anesthesiologist if any questions or problems arise.

Anticipation of Problems Early in the Postoperative Period

From observations in the operating room, the anesthesiologist probably knows more than anyone else about the patient's condition in the early postoperative period. Valuable insight can be provided to the physicians and others caring for the patient in the intensive care setting.

Pain Management

Detailed discussions of postoperative acute and chronic pain therapy [268] and specifically of pain management after thoracotomy are found in Chapters 69 and 70 . Most cardiac surgical operations today are performed through a median sternotomy. In general, midline surgical incisions are less painful, and there is a widely held clinical impression that the intensity of pain following a median sternotomy is considerably less than that experienced after thoracotomy. In fact, most patients undergoing CABG surgery complain more about the discomfort in their legs from which saphenous vein grafts have been harvested. In addition to the localized discomfort of a median sternotomy, there are sometimes painful complications of spreading the sternotomy, which results in fractured and dislocated ribs, intercostal nerve trauma, and myofascial pain involving the costochondral junctions, rib-vertebral joints, shoulder girdle, and anterior chest muscles. In addition, visceral-type pain can arise from persistent angina pectoris, pericarditis, pleuritic chest pain aggravated by the presence of chest tubes, and pain from other mediastinal and thoracic structures such as the esophagus, lungs, and aorta. The latter sources need to be kept in mind in terms of differential diagnosis.

Given the dispersed sources of discomfort to the cardiac surgical patient in the early postoperative period, from discomfort due to the endotracheal tube and shoulder pain to leg incisional pain, there are a limited number of options for pain management. [268] The use of spinal-epidural anesthesia-analgesia intraoperatively and postoperatively is contraindicated by the use of fully anticoagulating doses of heparin and the risk of persistent coagulopathy postoperatively and by marked changes in circulating blood volume, body temperature, and other variables that affect or are dependent on sympathetic nervous system activity. Therefore, systemic administration of opioids is by far the most frequently used analgesic therapy. In the immediate postoperative period, the residual effects of opioids administered intraoperatively as part of the anesthetic are supplemented by intermittent intravenous injections as needed or by a low-dose continuous infusion until the patient's vital functions are stabilized and the weaning of mechanical ventilation is anticipated. Thereafter, patient-controlled analgesia may be useful as the

patient regains consciousness and is able to operate the control device. At that point, the continuous epidural analgesia can be considered but seldom is used in practice. Rather, oral analgesics, including the nonsteroidal anti-inflammatory drugs, are administered as the indications for intravenous opioids diminish.

Learning About Anesthetic Complications

Even though the patient usually remains in the hospital for several days after cardiac surgery, it is difficult for the busy anesthesiologist to follow the patient carefully enough to become aware of complications that may be related to intraoperative events. Again, cooperation and communication with those caring for the patient on a

daily basis are helpful; thus the anesthesiologist should ask about problems and complaints that have been encountered postoperatively. The surgeon and cardiologist can provide the necessary feedback of information, especially that discovered during a follow-up visit after the patient's discharge from the hospital. Usually they will be eager to communicate and share the problems once they are aware of the anesthesiologist's interest and concern. This concern, in and of itself, often fosters a mutual feeling of respect.

All the preceding communications do not preclude the necessity of a personal visit to the patient by the anesthesiologist in the postoperative period. Such a visit should ideally include a survey of the patient's chart, a discussion with the responsible nurse, and an interview with the patient. After some general questions, the anesthesiologist may find it useful to ask the patient about specific items related to the following: recall of surgical events (many patients relate dreams and ICU experiences to the intraoperative period) [269] ; problems with vision (prolonged effects of drugs on the pupils and accommodation may contribute to visual difficulties); pharyngeal discomfort and complications related to airway management (these are no different than for other types of surgery); discomfort related to positioning of the body and extremities during surgery (this may lead to greater awareness of the problems and improvement in positioning techniques); and complaints related to needle puncture sites, phlebitis, arterial cannulation and its complications, skin burns and irritation, etc. These should be fully discussed with the patient and noted on the chart. Obviously, any indicated therapy should be provided. Even though such procedures may be time-consuming, they reward the anesthesiologist and patient by better rapport between physicians and patients, an improved image of the anesthesiologist by the public, and a reduced incidence of malpractice suits.

Chapter 50 - Anesthesia for Pediatric Cardiac Surgery

William J. Greeley
James M. Steven
Susan C. Nicolson
Frank H. Kern

INTRODUCTION

Cardiac surgery is an established and effective treatment for children with congenital heart defects. Early successes in surgical treatment have led to a new therapeutic era in the management of congenital heart disease and have fostered the development of the subspecialties pediatric cardiology and cardiac surgery and their collaboration. Through this cooperative effort, tremendous progress in medical diagnosis and surgical treatment has been achieved. In turn, these accomplishments gave rise to the development of pediatric cardiac anesthesiologists, individuals who understand the pathophysiology of congenital heart malformations, the diagnostic and surgical procedures used to treat heart disease, and the principles of pediatric and cardiac anesthesia as well as intensive care medicine. Pediatric cardiac anesthesia continues to evolve as an exciting and technically demanding subspecialty in which anesthetic management is based on physiologic principles.

Congenital cardiovascular surgery and anesthesia are often performed under unusual physiologic conditions. Rarely in clinical medicine are patients exposed to such biologic extremes as during congenital heart surgery. Commonly, patients are cooled to 15 to 18°C, acutely hemodiluted by more than 50 percent of their extracellular fluid volume, and undergo periods of total circulatory arrest lasting up to 1 hour. The ability to manage patients under these physiologic extremes is a vital function of the pediatric cardiovascular anesthesiologist. As with other areas of medicine, the application and management of technology preceded a comprehensive understanding of its physiologic effects. Relevant clinical information, primarily generated from investigations in pediatric intensive care units (ICUs) as well as in operating rooms, has been especially valuable in contributing to the understanding of anesthetic management for children undergoing cardiac surgery.

Clearly, the perioperative management of these complex cases requires a group of physicians (surgeon, anesthesiologist, cardiologist, critical care specialist) and nurses to work as a team. This team orientation is essential to the achievement of an optimal outcome. Although the quality of the surgical repair, the effects of cardiopulmonary bypass, and postoperative care are the major determinants of outcome, meticulous anesthetic management is also imperative. Ideally,

despite the complexity of the cases and the marked physiologic changes attributed to cardiopulmonary bypass (CPB) and the surgical procedures, anesthetic care should never contribute substantially to morbidity or mortality. [1] The challenge is to understand the principles underlying the management of patients with congenital heart disease and to apply them to clinical anesthesia. Assuming the reader already understands the fundamentals of adult cardiac and general pediatric anesthesia, detailed in Chapters 49 and 59 , respectively, the first section of this chapter provides an overview of some of the unique features of the pediatric patient, congenital heart disease, and the surgical procedures, which are essential to understanding the anesthetic management of children undergoing cardiac surgery. The second section addresses the perioperative anesthetic management for procedures requiring CPB. The last section discusses closed-heart procedures and anesthesia for interventional catheterization.

UNIQUE FEATURES OF PEDIATRIC CARDIAC ANESTHESIA

Although many of the principles governing modern pediatric cardiovascular anesthesia are similar to those that guide anesthetic management of the adult cardiac patient, several important differences do exist. It is essential to consider the differences that make pediatric cardiovascular management unique (Table 50-1) . Broadly, certain characteristics of the patient, congenital heart disease, and surgery account for these unique features, and are reviewed below. These differences are attributable to normal organ system maturation in the neonate and young infant, differing pathophysiologic

TABLE 50-1 -- Unique Characteristics of Pediatric Cardiac Anesthesia

Patient
Normal organ system development and maturational changes of infancy
Cardiovascular: blood flow patterns of circulation at birth, myocardial compliance, systemic and pulmonary vasculature, and beta-adrenergic receptors
Pulmonary: respiratory quotient, closing capacity, chest compliance
Central nervous system: brain growth, cerebral blood flow, autonomic regulation
Renal: glomerular filtration rate, creatinine clearance
Hepatic: liver blood flow, microsomal enzyme activity
Disease-growth interrelationship
Effects of systemic disease alter somatic and organ growth
Compensatory ability of developing organs to recover from injury
Immunologic immaturity of the infant
Obligatory miniaturization (i.e., small patient size and body surface area)
Congenital heart disease
Diverse anatomic defects and physiologic changes
Altered ventricular remodeling owing to myocardial hypertrophy and ischemia
Chronic sequelae of congenital cardiac disease
Surgical procedures
Diversity of operations
Frequent intracardiac and right ventricular procedures
Use of deep hypothermia and circulatory arrest during repair
Trend toward repair in early infancy
Evolution of surgical techniques to avoid residua and sequelae
Trend toward wider application of certain operations

conditions in congenital heart disease, the diversity of surgical repairs, and the use of specialized cardiopulmonary bypass techniques such as deep hypothermia and total circulatory arrest.

Physiologic Considerations and Maturational Features of the Pediatric Patient

Recognition of the changes associated with growth and development is fundamental to understanding the pediatric patient. All the major organ systems of the neonate and young infant undergo maturational changes that involve a dynamic change in physiologic function. Only those changes associated with the cardiovascular system are presented (for a more detailed discussion of the maturation of other organ systems, see Chapter 59 on general pediatric anesthesia).

The cardiovascular system changes markedly at birth because of a dramatic alteration in blood flow patterns (Fig. 50-1) . [2] During fetal life, blood flow returning to the right atrium bypasses the unventilated fluid-filled lungs. Blood is then preferentially shunted across the patent foramen ovale into the left atrium or passes from the right ventricle (RV) across the patent ductus arteriosus (PDA) to the systemic circulation. At birth, physiologic closure of the PDA and of the foramen ovale brings about the normal adult circulatory pattern. The presence of certain congenital heart defects or pulmonary disease can disrupt this normal adaptive process, creating a transitional circulation, in which right-to-left shunting persists across the foramen ovale or the PDA. Under such circumstances, the continued presence of a transitional circulation can lead to severe hypoxemia, acidosis, and hemodynamic instability, which are poorly tolerated in the neonate. By contrast, when initially treating some forms of congenital heart disease, the prolongation of this transitional circulation is actually beneficial, promoting systemic or pulmonary blood flow and postnatal viability. An example of the latter is pulmonary atresia, in which pulmonary blood flow is supplied via the PDA. In the absence of collateral vessels, closure of the PDA eliminates the principal source of pulmonary blood flow, resulting in hypoxemia and death. Ductal patency can be maintained with the administration of prostaglandin E_1 . Importantly, the transitional circulation can be manipulated by pharmacologic ventilatory strategies, thereby promoting hemodynamic stability in the young patient.

Another unique feature of the normal neonatal and infant cardiovascular system is the reduced myocardial reserve, as compared with that in the healthy adult. The newborn left ventricular function is restricted by a reduced number of beta-receptors, high resting levels of circulating catecholamines, limited recruitable stroke work, an immature calcium transport system, and decreased ventricular compliance. [3] This limits contractile reserve and results in a left ventricle with a high level of resting tone. [4] Although the resting performance of the neonatal myocardium may be greater than in adults and older children, there is a greater sensitivity to beta-blockade and only modest increases in cardiac performance to the beta-agonist drugs dobutamine and isoproterenol. [5]

On the ultrastructural level, a variety of cellular synthetic functions are occurring in immature myofibrils, which dominate

Figure 50-1 Course of the fetal circulation in late gestation. Note the selective blood flow patterns across the foramen ovale and the ductus arteriosus.

the newborn heart. [4] Large nuclei, mitochondria, and surface membranes predominate within the myofibrils. In neonates, there is a 50 percent reduction in the number of myofibrils, and myofibrils are arranged in a nonlinear, disordered array. As a direct result, the contractile mass of the heart is effectively reduced, resulting in a ventricle with low compliance. [6] Preload augmentation is effective at low filling pressures (1-7 mm Hg). However, when left-sided filling pressures exceed 7 to 10 mm Hg, further increases in left ventricular stroke volume are minimal. [3] As a consequence, neonates are more dependent on heart rate and, to a lesser extent, on preload, to maintain cardiac output at filling pressures of 7 to 10 mm Hg or greater. [7] [8]

In addition to a reduced contractile mass, the calcium transport system in the neonatal myocardium is underdeveloped. The transverse tubular system is absent, and the sarcoplasmic reticulum, which has to store and release calcium, is small and inefficient. the neonatal heart is therefore more dependent on extracellular calcium levels than the adult myocardium. [9] [10] [11] [12] Because intracellular calcium concentrations play a central role in myocardial contractility, normal or even elevated plasma levels of ionized calcium may be necessary to augment or maintain an effective stroke volume. [13] This is in contrast to adult cardiac patients in whom calcium use during cardiac surgery has fallen in to some disfavor owing to direct concerns over myocardial ischemia and reperfusion injury.

Another unique feature relates to the pulmonary circulation. The pulmonary circulation undergoes significant change during the first months of life. These changes are largely characterized by regression of the hypertrophied medial smooth muscular layer in the pulmonary arteries

that exists in utero, resulting in a concomitant drop in pulmonary vascular resistance (PVR). [14] In the immediate newborn period, the large decrease in PVR is due to lung expansion and the vasodilatory effects of a higher Pa O_2 than existed in utero. Further decline in PVR throughout the next 2 months of life is attributable to regression of the smooth muscle layer in the pulmonary arterioles. A corresponding fall in pulmonary artery pressure occurs as PVR declines. Acute physiologic stress in the newborn period, such as hypoxemia or acidosis, can increase pulmonary artery pressure and thus PVR. If the resulting RV hypertension causes reduced RV compliance, right-to-left shunting can occur at the foramen ovale. Once PVR exceeds systemic vascular resistance (SVR), right-to-left shunting develops at the PDA. Either phenomenon will worsen the hypoxemia and eventually limit tissue oxygen delivery to the point of lactic acidosis. By contrast, left-to-right shunts, such as with a ventricular septal defect (VSD), produce intimal changes in the pulmonary vasculature and delay regression of medial muscle hypertrophy. [14] This results in persistent elevation of PVR.

Size differences between adult and pediatric cardiac patients require miniaturization. Anatomically, pediatric patients have small upper and lower airways, small veins and arteries, and a decreased body surface area, as compared with adult patients. There are several anesthetic implications related to patient size. Some centers believe that the placement of arterial catheters by cutdown in neonates and infants represents the most expedient approach, particularly when optimal sites are limited. Pulmonary artery catheters are used infrequently, both because of the technical difficulties in positioning the tip in the pulmonary artery and because of the fundamental fact that pulmonary flow bears no obligatory relationship to systemic output in children with either intra- or extracardiac communications. Transthoracic catheters for pressure monitoring and delivery of vasoactive substances are commonly placed from the surgical field. Adequacy of the repair and function can be assessed by transesophageal or epicardial echocardiography with Doppler color flow imaging. [15] [16] Cardiopulmonary bypass serves as another example of the influence of patient size on management. The ratio of pump priming volume to patient blood volume is considerably higher in small children than in adults, resulting in a greater degree of hemodilution. Several studies have demonstrated a heightened inflammatory response to CPB in children when compared with adults. [17] [18] This effect is related to the disproportionate exposure to the nonendothelialized surfaces of the pump circuit per body surface area. Greater damage to the formed blood elements and plasma proteins is incurred, resulting in activation of the mediators of inflammation.

Finally, in pediatric patients with congenital heart disease, the cardiovascular system often represents the sole cause of the medical problem. This is in contrast to the multiplicity of diagnoses and organ system involvement frequently found in adults with acquired cardiovascular disease. Moreover, there is a special disease-growth interrelationship unique to growing infants and children that does not exist in adults. This special interrelationship permits developing organs to compensate for and modify existing disease processes. Reparative and recuperative processes in children are greater as a result of this compensatory ability of developing organ systems. Adult cardiac patients unfortunately do not exhibit the same recuperative ability. And although children adapt well to cardiovascular pathology, there are some negative aspects to longstanding heart disease. Congenital heart disease has detrimental effects on somatic growth as well as on the growth and development of the brain, myocardium, and lung.

Congenital Heart Disease

The marked array of anatomic and physiologic conditions seen with congenital heart disease distinguish these processes from acquired adult cardiac disease. The spectrum of intracardiac shunts, valve pathology (stenoses, regurgitation, or atresia), disrupted great artery connections, and the absence of one or more chambers of the heart preclude a uniform anesthetic approach to patients with congenital heart disease. Moreover, there are myocardial changes resulting from the hemodynamic impact and increased cardiac work incurred by these defects. Functionally, these myocardial changes place the ventricles at great risk for the development of intraoperative ischemia and failure. Therefore, an understanding of the isolated defect, associated myocardial changes, and hemodynamic consequences is fundamental to planning an appropriate anesthetic. [6] Too often, because of the complexity and diversity of the defects, the anesthesiologist, cardiologist, and surgeon are focused on the specific anatomic considerations and the physiologic implications are overlooked. Distilling congenital heart disease into a finite number of physiologic categories enables the anesthesiologist to construct a strategy that employs the qualitatively predictable impact of pharmacologic agents, ventilatory management, and fluid administration to optimize cardiovascular performance. Although an isolated heart malformation may be identified, the entire cardiopulmonary system is usually affected.

Physiologic Approach to Congenital Heart Disease

Although the structural variations seen in congenital heart disease constitute an encyclopedic list of malformations, anesthetic management is more logically designed to achieve physiologic goals. A general physiologic classification is listed in Table 50-2 . Fortunately, although structurally complex, these defects can be understood in a more limited physiologic spectrum. Identification and classification on the basis of physiology provide an organized framework for the intraoperative anesthetic management and postoperative care of children with complex congenital cardiac defects. In general, congenital heart lesions fit into one of four categories: shunts, mixing lesions, flow obstruction, and regurgitant valves (see Table 50-2) . Each category imposes at least one of three pathophysiologic states: ventricular volume overload, ventricular pressure overload, or hypoxemia. Ultimately, these pathophysiologic conditions can result in myocardial failure or pulmonary vascular disease. Medical and surgical perioperative management strategies should be focused on minimizing the pathophysiologic consequences of these lesions.

TABLE 50-2 -- Classification of Congenital Heart Defects

PHYSIOLOGIC CLASSIFICATION	PULMONARY BLOOD FLOW	COMMENTS
Shunts		
Left-to-right		
VSD		Volume-overload ventricle
ASD		Develop CHF
PDA		
AV canal		
Right-to-left		

Tetralogy of Fallot		Pressure-overloaded ventricle
Pulmonary atresia/VSD		Cyanotic
Eisenmenger complex		Hypoxemia
Mixing lesions		
Transposition/VSD	Generally	Variable pressure versus volume loaded
Tricuspid atresia		Usually cyanotic
Anomalous venous return	but variable Qp/Qs	
Univentricular heart		
Obstructive lesions		
Interrupted aortic arch		Ventricular dysfunction
Critical aortic stenosis		Pressure-overloaded ventricle
Critical pulmonic stenosis		Ductal dependence
Hypoplastic left heart syndrome		
Coarctation of the aorta		
Mitral stenosis		
Regurgitant lesions		
Ebstein's anomaly		Volume overloaded
Other secondary causes		Develop CHF

Abbreviations: ASD--atrial septal defect; AV canal--atrioventricular canal; CHF--congestive heart failure; PDA--patent ductus arteriosus; Qp--pulmonary blood flow; Qs--systemic blood flow; VSD--ventricular septal defect

Shunt Lesions

Shunts are intracardiac connections between chambers or extracardiac connections between a systemic and pulmonary artery; examples are an atrial septal defect (ASD), a VSD, and a PDA. The direction of blood flow through the shunt is dependent on the relative resistances on either side of the shunt and on the size of the shunt orifice. [19] With a nonrestrictive VSD or PDA that does not impede blood flowing freely in each direction, the main determinant of blood flow is the resistance of the pulmonary and systemic vascular beds. The direction and magnitude of shunt at the atrial level are governed by the relative differences in ventricular compliance and respective atrioventricular (AV) valve function. The effect a shunt lesion has on the cardiovascular system depends on its size and direction, either right-to-left or left-to-right. Left-to-right shunts occur when the pulmonary vascular resistance is lower than the systemic vascular resistance and blood flow is preferentially directed toward the lungs, resulting in increased pulmonary blood flow. In patients with large left-to-right shunts and low pulmonary vascular resistance, a substantial increase in pulmonary blood flow can occur. This results in three pathophysiologic problems: (1) congestion of the pulmonary circulation; (2) volume overload with resulting increased cardiac work for the left ventricle, which is required to increase stroke volume and heart rate to ensure adequate systemic perfusion; and (3) excessive pulmonary blood flow, resulting in progressive elevation in PVR. Volume overload causes ventricular dilation that places the heart at a mechanical and physiologic disadvantage, resulting in reduced diastolic compliance. [20] These diastolic changes lead to engorgement of the respective venous beds, which produces the signs and symptoms of clinical congestive heart failure early in the natural history of volume-overload condition. The demand for increased cardiac output placed on the left ventricle (LV) is limited in the infant by virtue of its immature structure, so that large left-to-right shunts may outstrip the capacity of the left heart to maintain adequate systemic perfusion, and congestive heart failure will result. Surgical closure of a hemodynamically significant VSD usually provides immediate benefit by dramatically lowering LV volume output demands. Occasionally, the sudden increase in wall stress imposed on a dilated ventricle that must now pump solely against systemic vascular resistance can produce worsening ventricular failure during the early postoperative period after eliminating the low resistance "popoff" into the pulmonary circulation. If the left-to-right shunt is not repaired, prolonged exposure to increased pulmonary blood flow results in progressive elevations in PVR. Fixed changes in pulmonary arterioles may occur, leading to pulmonary vascular obstructive disease. Table 50-2 lists the common left-to-right shunt lesions.

Right-to-left shunts occur when pulmonary vascular or right ventricular outflow tract resistance exceeds systemic vascular resistance, thereby reducing pulmonary blood flow. The systemic circulation receives an admixture of deoxygenated blood via the shunt and manifests clinically as cyanosis and hypoxemia. Pure right-to-left shunting due to raised PVR is seen in the Eisenmenger complex and in persistent pulmonary hypertension of the newborn with atrial and ductal level shunting. More commonly, PVR is low, and a more complex lesion with obstruction to pulmonary outflow, proximal to the pulmonary vasculature, produces right-to-left shunting. Defects such as tetralogy of Fallot represent classic right-to-left shunts. The shunting occurs

through the VSD because of pulmonary outflow obstruction. Systemic perfusion is generally normal with right-to-left shunting lesions unless hypoxemia becomes severe enough to impair oxygen delivery to tissue. Thus, there are two pathophysiologic problems: (1) reduced pulmonary blood flow resulting in systemic hypoxemia and cyanosis, and (2) an increased impedance to RV ejection resulting in pressure overload, which may ultimately lead to ventricular dysfunction and failure of the RV. However, the physiologic mechanisms designed to compensate for pressure overload rarely create abnormalities in systolic or diastolic function early in the natural history of the disease process. In contradistinction to lesions that produce ventricular volume overload, ventricular dysfunction and failure typically take years to develop in the context of isolated pressure overload.

Mixing Lesions

Mixing lesions constitute the largest group of cyanotic congenital heart defects (see Table 50-2) . In these defects, the mixing between the pulmonary and the systemic circulation are so large that they essentially act as a common chamber. The pulmonary-to-systemic flow ratio (Qp/Qs) is independent of shunt size and totally dependent on vascular resistance or outflow obstruction. The pulmonary and systemic circulations tend to be in parallel with one another rather than in series (see Table 50-2) . In patients with no outflow obstruction, flow to the systemic or pulmonary circulation is dependent on the relative vascular resistances of both circuits, such as with univentricular hearts or double-outlet RV. If SVR exceeds PVR, as in the typical circumstance, the tendency is toward excessive pulmonary blood flow, and the predominant pathophysiologic process is left-to-right shunting. These patients have increased pulmonary blood flow, ventricular volume overload, and a gradual elevation of PVR over time. If PVR exceeds SVR, as may occur episodically in ductal-dependent lesions such as hypoplastic left heart syndrome, systemic blood flow predominates and pulmonary blood flow dramatically decreases, causing progressive hypoxemia (Table 50-3) . In patients with a mixing lesion and LV outflow obstruction, pulmonary blood flow may be sufficiently excessive to impair systemic perfusion. In patients with mixing lesions and an RV outflow obstruction such as a single ventricle with subpulmonic stenosis, systemic-to-pulmonary flow can vary from balanced flow to significantly decreased pulmonary blood flow in which the severity of hypoxemia depends on the degree of obstruction. Typical mixing lesions include truncus arteriosus, univentricular

TABLE 50-3 -- Ductal-Dependent Lesions

PDA PROVIDES SYSTEMIC FLOW	PDA PROVIDES PULMONARY FLOW
Coarctation of the aorta	Pulmonary atresia
Interrupted aortic arch	Critical pulmonary stenosis
Hypoplastic left heart syndrome	Severe subpulmonic stenosis with VSD
Critical aortic stenosis	Tricuspid atresia with pulmonic stenosis

Abbreviations: PDA--patent ductus arteriosus; VSD--ventricular septal defect

heart, total anomalous pulmonary venous return, pulmonary atresia with large VSD, and single atrium.

Obstructive Lesions

Obstructive lesions range from mild to severe. Severe lesions present in the newborn period with a pressureoverloaded, diminutive, or profoundly dysfunctional ventricle proximal to the obstruction. These lesions include critical aortic stenosis, critical pulmonic stenosis, coarctation of the aorta, or interrupted aortic arch. Although aortic and pulmonary atresia represent the most extreme variants of outflow tract obstruction, they are associated with such extreme hypoplasia of the ventricle (hypoplastic left heart syndrome and certain pulmonary atresia with intact ventricular septum, respectively) that the ventricle's function does not contribute to the circulatory physiology. As with other critical obstructive lesions, these extreme variants have ductal-dependent circulations, but beyond that similarity, they are perhaps better understood as univentricular hearts for which the management characteristics of a mixing lesion dominate in importance. In critical neonatal left-sided obstructive defects, systemic perfusion is dependent on blood flow (desaturated) from the RV via the PDA, and coronary perfusion is supplied by retrograde flow from the descending aorta (see Table 50-3) . In right-sided lesions, pulmonary blood flow is supplied from the aorta via the PDA, and RV function is impaired. Pathophysiologic problems in critical neonatal left heart obstructive lesions include (1) profound LV failure, (2) impaired coronary perfusion with an increased incidence of ventricular ectopy, (3) systemic hypotension, (4) PDAdependent systemic circulation, and (5) systemic hypoxemia. The pathophysiologic problems of critical neonatal right heart obstructive lesions include (1) RV dysfunction, (2) decreased pulmonary blood flow, (3) systemic hypoxemia, and (4) PDA-dependent pulmonary blood flow. Apart from the most extreme variants that become evident in the neonatal period, infants and children with outflow obstruction (e.g., mild to moderate aortic or pulmonary stenosis, coarctation of the aorta) manifest the effective compensatory mechanisms for pressure overload, often remaining clinically asymptomatic for many years.

Regurgitant Valves

Regurgitant valves are uncommon as primary congenital defects. Ebstein's malformation of the tricuspid valve is the only pure regurgitant defect presenting in the newborn period. However, regurgitant lesions are frequently associated with an abnormality of valve structure, such as incomplete or partial atrioventricular canal defect, truncus arteriosus, or tetralogy of Fallot with an absent pulmonary valve. The pathophysiology of regurgitant lesions includes (1) volume-overloaded circulation and therefore (2) progression toward ventricular dilation and failure.

Summary

When considering the incidence of all the congenital heart defects, three uncomplicated left-to-right shunts

(VSD, ASD, PDA) and two obstructive lesions (pulmonic stenosis, coarctation) constitute 60 percent of all congenital cardiac defects. Mixing lesions, complicated obstructive defects, and right-to-left shunting lesions account for the vast majority of the remaining 40 percent. The latter group of defects, which are more difficult to manage, are more labor intensive and have a significantly higher morbidity and mortality rate. This observation is directly attributed to the complexity of the cardiovascular abnormalities seen in this 40 percent group, in which there is an absence of a chamber or a major ventricular-arterial connection.

Chronic Consequences of Congenital Heart Disease

The chronic effects of congenital heart disease are a consequence of the imposed hemodynamic stress of the defect or the residua and sequelae after cardiac surgery. These effects continue to alter normal growth and development of the cardiovascular system as well as other organ systems throughout life. [21] Complete surgical cures are rarely achieved, and some repairs are palliative rather than corrective; therefore, abnormalities before and after repair produce long-term effects in patients with congenital heart disease. [22] Although the overall outlook for these patients is good in most instances, every defect has associated myocardial changes, and every repair leaves certain obligatory abnormalities. Many of the abnormalities are trivial and have no major import. Others affect major organ system processes, such as ventricular function, central nervous system growth, the conduction system of the heart, or pulmonary blood flow. Under these circumstances, the long-term quality of life is affected. Whether anesthetizing these patients for their primary or subsequent cardiac repair or for noncardiac surgery, these chronic changes should be ascertained and reflected in the anesthetic plan.

The myocardium is continually remodeled by specific hemodynamic stresses in utero and throughout life. Right ventricular growth and development are influenced by the low-resistance afterload of the pulmonary circulation. The LV is coupled to the high-resistance systemic circulation, which accelerates its rate of growth and development. This situation gives rise to the adult condition in which LV dominance of myocardial muscle mass occurs. This entire developmental process is referred to as dynamic ventricular modeling. [6] Abnormal hemodynamic loading conditions associated with congenital heart disease interrupt the normal ventricular modeling process (Fig. 50-2) . [23] Abnormal ventricular remodeling typically begins in utero and stimulates an increase in ventricular mass. Increased ventricular mass is due to both hyperplasia and hypertrophy of myocytes in response to altered wall stress on the developing ventricle. The resultant biomechanical deformation of the ventricle alters its geometry, affecting normal systolic and diastolic function.

Abnormalities of ventricular performance at rest and with exercise can be detected in patients with chronic hemodynamic overload and complex cyanotic lesions. These abnormalities in ventricular function are the consequences of chronic ventricular overload, repeated episodes of myocardial ischemia and residua or sequelae of surgical treatment

Figure 50-2 Comparison of ventricular hypertrophy patterns demonstrating altered ventricular remodeling in two different congenital heart defects. *(A)* Note the right ventricular hypertrophy and the diminutive left ventricle (LV) in tetralogy of Fallot. *(B)* Note the severe left ventricular hypertrophy and septal bulging into the right ventricle (RV) in aortic stenosis.

(ventriculotomy, altered coronary artery supply, inadequate myocardial protection). [21] The physiologic adaptive responses to chronic hypoxemia and ventricular pressure or volume overload are the primary stimuli producing the long-term ventricular dysfunction. Although chronic volume overload of the LV as seen with left-to-right shunts or a chronic pressure-loaded LV due to left-sided obstructive lesions result in congestive heart failure, the compensatory mechanisms for pressure overload create less physiologic disturbance, particularly in diastolic function. Consequently, congestive heart failure occurs later in the natural history of isolated obstructive lesions that do not require treatment in the neonatal period. Similarly, chronic RV volume overload as seen in pulmonic insufficiency after tetralogy of Fallot repair is more likely to be associated with chronic ventricular dysfunction and failure than a pressure-loaded RV manifests with residual pulmonic stenosis. [24] In fact, the most potent combination for inducing ventricular dysfunction and failure occurs when a pressure overload is superimposed on a dilated, volume-overloaded ventricle (e.g., postoperative tetralogy of Fallot with pulmonary insufficiency and branch pulmonary artery stenosis). The mechanism for the dysfunction and failure is multifactorial. Initial manifestations of congestive heart failure reflect alterations in ventricular compliance that result from a variety of biophysical responses to abnormal loading conditions. The ventricular dilation and compensatory hypertrophy that accompany volume overload provide effective compensation to preserve

Figure 50-3 (Figure Not Available) Changes in ventricular physiology that accompany abnormal pressure and volume loading in human adolescents and adults. Schematic represents the changes in cross-sectional ventricular geometry that accompany abnormal pressure and volume loads. Data are measured and derived from catheterization and echocardiography of 30 adolescent and adult human subjects. Pressure overload triggers significant increases in wall thickness and wall thickness:radius ratio (h/r), but these compensatory mechanisms preserve sigma within normal limits. Whereas volume overload causes dilation and enough hypertrophy to preserve normal sigma $_S$, diastolic function deteriorates significantly. LVp--left ventricular pressure; h--LV posterior myocardial wall thickness; r--radius of the LV chamber; sigma$_S$ --peak systolic wall stress; sigma$_D$ --end-diastolic wall stress; * *P* <.01. *(From Grossman et al [20])*

normal systolic wall stress, but alterations in diastolic wall stress become evident (Fig. 50-3) (Figure Not Available) . [20] Ultimately, chronic or severe pressure loads

manifest similar changes as the resultant myocardial hypertrophy outgrows vascular supply and results in ischemia and fibroblast proliferation. Permanent changes in myocardial structure and function are the end result.

In patients with cyanotic conditions, the long-term compensation for chronic hypoxemia shows a major redistribution of organ perfusion with selected blood flow to the heart, brain, and kidney, and decreased flow to the splanchnic circulation, skin, muscle, and bone. Chronic hypoxemia is associated with increased work of breathing in an attempt to increase oxygen uptake and delivery. The most dramatic complications are the decreased rate of somatic growth, increased metabolic rate, and an increase in hemoglobin concentration seen in children with palliated or unrepaired defects.

Surgical Procedures and Special Techniques

The ultimate objectives for congenital heart surgery are (1) the physiologic separation of the circulation, (2) relief of outflow obstruction, (3) the preservation or restoration of ventricular mass and function, and (4) normalization of life expectancy and maintenance of quality of life. The available surgical procedures to accomplish these objectives are diverse and complex (Table 50-4) . Compared with cardiac operations in adult patients, congenital heart repairs involve more intracardiac surgery with a greater preponderance performed via the right atrium and right ventricle. In general, operations performed for congenital heart defects can be divided into palliative and corrective procedures. [25] The type and timing of repair depend on the age of the patient, the specific anatomic defect, and the experience of the surgeon and the team (see Table 50-4) . Palliation in infancy is usually performed when there are missing anatomic parts, as in pulmonary atresia (absent RV and pulmonary artery), tricuspid atresia (absent RV and tricuspid valve), hypoplastic left heart syndrome (aortic atresia and hypoplastic LV), univentricular heart (absent RV or LV), or mitral atresia (absent LV). These palliative procedures can be further subdivided into those that will increase pulmonary blood flow (PBF), those that decrease PBF, and those that increase mixing (see Table 50-4) . Palliative procedures that increase PBF include shunts (Blalock-Taussig, central, or Glenn), outflow patch, and enlargement of the VSD. Those that decrease PBF include pulmonary artery banding or ligation of a PDA. Those that improve intracardiac mixing include atrial septostomy (balloon, blade, or Blalock-Hanlon).

The improvements in surgical technique, coupled with advancements in anesthetic and technologic support, make repair in early infancy not only feasible but in many cases preferable. [26] Currently, repair in infancy can be offered for a number of congenital heart defects, as shown in Table 50-4 . The timing of surgical intervention reflects medical necessity, physiologic and technical feasibility, and optimal outcome. Cardiac defects that require a PDA to sustain sufficient systemic or pulmonary blood flow (e.g., pulmonary atresia, hypoplastic left heart syndrome, interrupted aortic arch, critical aortic stenosis, and critical pulmonic stenosis) require an intervention in the neonatal period. A variety of defects are optimally repaired in early infancy. Lesions like transposition of the great arteries may exhibit better LV function if the arterial switch operation is performed in the first few weeks of life when the PVR has recently been high

TABLE 50-4 -- Congenital Cardiac Defects and Their Repair

ANATOMIC DEFECTS	PALLIATION	COMPLETE REPAIR
Tetralogy of Fallot		VSD closure and RVOT patch
With PA atresia	Shunt	
With anomalous right coronary	Rastelli	
HLHS	Norwood I/transplant	
Transposition of the great arteries		Arterial switch
Unfavorable coronary anatomy	Atrial switch (Senning)	
Tricuspid atresia	Shunt followed by Fontan	
Pulmonary atresia with VSD	Shunt followed by Fontan	
With intact septum	Shunt followed by Fontan	
Critical aortic stenosis		Aortic valvotomy
Interrupted aortic arch		End-end anastomosis/reverse subclavian flap/tube graft
Total anomalous pulmonary venous return		Anastomosis of pulmonary veins to left atrium and ASD closure
Single ventricle/normal PAs	Band followed by Fontan	
With small PAs	Shunt followed by Fontan	
Truncus arteriosus		RV-PA conduit and VSD closure
Atrioventricular canal		Repair valve clefts/patch closure of ASD/attach valves to patch

Abbreviations: ASD--atrial septal defect; HLHS--hypoplastic left heart syndrome; PA--pulmonary artery; RV--right ventricle; RVOT--right ventricle outflow tract; VSD--ventricular septal defect

enough to increase LV systolic pressure, whereas other repairs may manifest less volatile postoperative physiology if deferred a few weeks or months until PVR has consistently fallen (e.g., tetralogy of Fallot, AV canal defect). Each defect may have mitigating factors for which deferred definitive repair will enable optimal surgical result (e.g., tetralogy of Fallot with aberrant coronary branching pattern or multiple VSDs; transposition of the great arteries with VSD and severe LV outflow tract obstruction). Although some lesions merit repair whenever they are diagnosed (e.g., total anomalous pulmonary venous return, coarctation of the aorta), others exhibit such a wide spectrum of physiologic disturbance that the timing of an intervention must be made individually (e.g., VSD, aortic stenosis, pulmonic stenosis). A few cardiac malformations produce pathophysiologic changes that are sufficiently mild that repair is typically deferred to later infancy or childhood (e.g., isolated ASD). Palliative surgery is entertained when a physiologic derangement requires intervention, but circumstances preclude definitive repair.

In general, the recent trend in pediatric cardiovascular surgery has been to repair defects in infancy rather than palliate. [26] This trend reflects improved technical capabilities coupled with a desire to limit the morbidity and mortality associated with long-term medical management and the sequelae of multiple palliative operations. Early corrective surgery is expected to decrease the incidence of the chronic complications of congenital heart disease, such as the problems associated with ventricular overload, cyanosis, and pulmonary vascular obstructive disease. [27] Early infant repair may also have the selective advantage of enhancing organ system protection during repair because of poorly understood factors promoting resistance to injury and enhanced recovery potential (i.e., enhanced plasticity). With the continued improvement in surgical techniques and the early treatment of congenital heart disease, specific organ systems such as the brain, heart, and lungs will be spared the detrimental effects of chronic derangements of hemodynamics and oxygen delivery.

Procedures for the treatment of congenital heart disease continue to evolve to decrease long-term morbidity and enhance survival. For example, the long-term problems with RV dysfunction and failure associated with the Mustard procedure for repair of transposition of the great arteries encouraged many surgical groups to develop the neonatal arterial switch operation. [28] Early indications suggest that the latter procedure provides an anatomic correction with better long-term results. A second example of the continuing evolution of technique is surgery for tetralogy of Fallot. Longstanding pulmonary insufficiency after RV outflow repair for tetralogy of Fallot is associated with RV dysfunction and failure. Preservation of the pulmonary valve at initial repair using a combined transatrial and transpulmonary approach during correction or the early insertion of a pulmonary homograft in the setting of pulmonary insufficiency are techniques being used in an attempt to avoid the long-term problems of RV dysfunction and failure. [29] Surgery for hypoplastic left heart syndrome, once considered a fatal disease, has achieved significant long-term survival in a growing number of institutions after a series of staged reconstructive procedures. [30] [31]

Surgical management has evolved in a broader application of certain surgical procedures initially designed for a specific defect. For example, modifications of the Fontan operation, which was originally devised for patients with tricuspid atresia, are now being used to repair a variety of univentricular hearts, including hypoplastic left heart syndrome. [32] [33] Initially, the wider application of the Fontan operation to include complex defects once considered inoperable was associated with a rise in morbidity and mortality. However, this trend has been reversed in recent years by several groups who have demonstrated improved outcome with the creation of a fenestration between the right and left atrium at the time of the Fontan operation. [34] The communication allows for right-to-left shunting, thereby preserving cardiac

output at lower systemic venous pressure in the early postoperative period. When necessary, once the patient has convalesced from the acute postoperative changes, the fenestration can be closed at the bedside with a snare placed at the time of the operation or in the catheterization

laboratory with a clamshell device. In a substantial proportion of cases, these fenestrations close spontaneously without further intervention.

Ingenuity and innovation such as that demonstrated with the difficult Fontan patient has permitted continued improvements in survival for all patients with congenital heart disease. As incisions in the myocardium become smaller and sutures more precisely placed, and improvements in surgical techniques continue to evolve, the complications of ventricular dysfunction, arrhythmias, and residual obstruction should decline, contributing to improved patient quality of life.

One final difference unique to congenital heart surgery that has a major impact on anesthetic management relates to the type of cardiopulmonary support. Because of the complexity of repair in small patients, surgery often requires significant alterations in the bypass techniques, such as the use of deep hypothermic CPB at temperatures between 15 and 18°C and total circulatory arrest. [35] [36] Many operations are undertaken in this setting of extreme biologic conditions of temperature and perfusion. Current methods of CPB management in neonates, infants, and children involve extensive alterations in temperature, hemodilution, systemic perfusion pressure, and flow. Despite widespread use of these techniques during bypass, their physiologic effects on major organ system function are just beginning to be understood. These effects are discussed in subsequent sections.

In summary, there are unique features that need to be considered when caring for children with congenital heart disease who are undergoing pediatric cardiac surgery. These features include the patient's growth and development, unique features of the developing cardiovascular system of the young, the pathophysiology of congenital heart disease, the surgical procedures, and the CPB techniques. A basic understanding of these differences coupled with the fundamental knowledge of adult and pediatric cardiac anesthesia principles underlie the approach to the perioperative management of these patients.

PREOPERATIVE MANAGEMENT

Preoperative Evaluation

Caring for children with congenital heart disease presents the anesthesiologist with a wide spectrum of anatomic and physiologic abnormalities. Patients range from young, healthy, asymptomatic children who are having a small ASD closed to the newborn infant with hypoplastic left heart syndrome requiring aggressive perioperative hemodynamic and ventilatory support. Intertwined with the medical diversity of these patients are the psychologic factors affecting both the patient and the parents. Preparation of the patient and the family is time consuming, but omitting or compromising this aspect of patient care is a major deterrent to a successful outcome and patient/parental satisfaction. This approach mandates that cardiac surgeons, cardiologists, anesthesiologists, intensivists, and nurses work as a team in preparing the patient and the family for surgery and postoperative recovery. This team-oriented approach also serves as a safeguard to prevent errors and omissions in the exacting perioperative care necessitated by the complexity of cardiac surgery for congenital heart disease. The preoperative visit offers the family the opportunity to meet the surgeon and anesthesiologist.

The preoperative evaluation should always start with a careful history and physical examination. The history should concentrate on the cardiopulmonary system. Parents should be questioned about the general health and activity of their child. Fundamentally, a child's general health and activity will reflect cardiorespiratory reserve. Deficiencies may point toward cardiovascular or other systems that may influence anesthetic or surgical risk. It is important to determine whether the child has normal or impaired exercise tolerance. Is he or she gaining weight appropriately or exhibiting signs of failure to thrive on the basis of cardiac cachexia? Does the child exhibit signs of congestive heart failure (diaphoresis, tachypnea, poor feeding, recurrent respiratory infections)? Is there progressive cyanosis or new onset of cyanotic spells? Any intercurrent illness such as a recent upper respiratory tract infection or pneumonia must be ascertained. Lower respiratory tract infections may require a delay in proposed surgery, based on the negative impact that airway reactivity and elevations in PVR may have on surgical outcome. Recurrent pneumonia is frequently associated with pulmonary overcirculation altered lung compliance in patients with increased pulmonary blood flow.

A good history must delineate previous surgical and cardiologic interventions. These may have an impact on both surgical and anesthetic plans for the current procedure. Patients who have had their subclavian artery sacrificed for a subclavian flap angioplasty to correct coarctation or a Blalock-Taussig shunt will not accurately display systemic arterial pressure or perhaps even pulse oximetry when the monitoring is applied to the left arm. Likewise, children who have femoral venous occlusion following catheterization are not optimal candidates for femoral venous access, particularly for femoral CPB should sternotomy prove impossible. It is equally important to ascertain current medications, previous anesthetic problems, or family history of anesthetic difficulties.

In the modern era of echocardiography and cardiac catheterization, physical examination rarely contributes additional anatomic information about the underlying cardiac lesion. However, it is extremely useful in assessing the overall clinical condition of the child. For example, an illappearing, cachectic child in respiratory distress has limited cardiorespiratory reserve, and the use of excessive premedication or a prolonged inhalational induction could result in significant hemodynamic instability.

Laboratory evaluation should include analysis of hemoglobin, hematocrit, pulse oximetry, and, in selected patients (e.g., those on diuretics or with renal impairment), serum electrolytes. An elevated hematocrit in a normovolemic child gives an indication of the magnitude and chronicity of their hypoxemia. Levels above 60 percent may predispose to capillary sludging and secondary end organ damage, including stroke. [37] Despite these risks, liberalized nothing-by-mouth guidelines that permit children to consume clear liquids up to 2 hours before anesthetic induction have virtually eliminated the need to admit these patients for preoperative intravenous hydration. [38] [39]

Echocardiography with Doppler color flow imaging is an invaluable tool that provides a noninvasive means of assessing

intracardiac anatomy, blood flow patterns, and estimates of physiologic data. [40] For many cardiac defects, more invasive studies are generally not required if a good echocardiographic assessment is made. Echo-Doppler is especially helpful for defining intracardiac abnormalities. Extracardiac abnormalities, such as pulmonary artery or vein stenosis, are more difficult to define by echo-Doppler and often require cardiac catheterization. The ability to interpret anatomy and physiology accurately requires a skilled echocardiographer, reaffirming the need for a well-integrated interactive team. Although the complexities posed by extreme anatom-ic variation and changing loading conditions render intraoperative echo-Doppler challenging even for experienced echocardiographers, the pediatric cardiac anesthesiologist should develop some familiarity with its capabilities and limitations to participate in critical intraoperative management decisions.

Cardiac catheterization remains the gold standard for assessing anatomy and physiologic function in congenital heart disease. Although many anatomic questions can now be reliably answered noninvasively, cases that present complex anatomic questions or those for which physiologic data are required, catheterization remains a vital tool. Important catheterization data for the anesthesiologist include the following:

1. Child's response to sedative medications.
2. Pressure and oxygen saturation in all chambers and great vessels.
3. Location and magnitude of intra- and extracardiac shunt (Qp:Qs)
4. Pulmonary vascular resistance, systemic vascular resistance.
5. Chamber size and function.
6. Valvular anatomy and function.
7. Distortion of systemic or pulmonary arteries related to prior surgery.
8. Coronary artery anatomy.
9. Anatomy, location, and function of previously created shunts.
10. Acquired or congenital anatomic variants that might have an impact on planned vascular access or surgery.

Careful review of the cardiac catheterization data and an understanding of its pontenital impact on the operative and anesthetic plan are essential. Not all the medical problems can be evaluated and corrected preoperatively; the surgeon, cardiologist, and anesthesiologist must discuss the potential management problems and any need for further evaluation or intervention before arrival in the operating room. Appropriate communication and cooperation between the two physicians will optimize patient care and facilitate perioperative clinical management. Typically, institutions have a regularly scheduled combined cardiology/cardiac surgery meeting to discuss candidates for surgery during which all of the essential information is displayed and discussed. Such a meeting provides an invaluable opportunity for learning about specific patients proposed for surgery as well as a continuing educational forum that promotes an interdisciplinary exchange directed at contemporary concepts in congenital heart disease and its treatment, both medical and surgical.

Premedication

By 6 months of age, pentobarbital (2-4 mg/kg) can be administered orally. A calm, cooperative, sedated child is the usual result. Alternatively, children over 9 months of age may receive a benzodiazepine as an oral premedication. The authors' current preference is midazolam 0.3 to 0.7 mg/kg by mouth 10 to 20 minutes before induction. The higher dose is used in the smallest patients.

INTRAOPERATIVE MANAGEMENT

Operating Room Preparation

Advanced, careful preparation of the operating room is essential. The anesthesia machine must have the capacity to provide air as well as oxygen and nitrous oxide to help balance pulmonary and systemic blood flow. Intravenous tubing must be free from air bubbles to prevent paradoxical air embolism. Resuscitative drugs, labeled and ready for administration, should include calcium gluconate or calcium chloride, sodium bicarbonate, atropine, phenylephrine, lidocaine, and epinephrine. An inotropic infusion, usually dopamine, should be premixed and ready for administration in high-risk cases, but additional infusions are prepared if their need is strongly suspected. For all pediatric cases, certain anesthetic drugs are made available for use on an emergency basis (thiopental, propofol, ketamine, succinylcholine, and atropine). These drugs are selected because of the potential for airway reactivity, hypotension, and bradycardia during anesthetic induction. In pediatric cardiac anesthesia, many patients have limited reserve as well as high endogenous catecholamine levels released in an adaptive response to their underlying cardiac disease. The resuscitative drugs should therefore be prepared and immediately available prior to anesthetic induction.

For congenital heart surgery, the ability to alter body temperature rapidly for cooling and rewarming is essential. During deep hypothermic CPB, patients are cooled to 15 to 18°C. Surface cooling with a heating/cooling water mattress and an efficient room ambient temperature control system are important in the operative management of these patients.

Physiologic Monitoring

The monitoring used for any specific patient should depend on the child's condition and the magnitude of the planned surgical procedure. The perioperative monitoring techniques available are listed in Table 50-5 . Noninvasive monitoring is placed prior to induction of anesthesia. In the crying pediatric patient, the anesthesiologist may elect to defer application of monitoring devices until immediately after the induction of anesthesia. Standard monitoring includes an electrocardiographic system, pulse oximetry, capnography, precordial stethoscope, and an appropriate-sized blood pressure cuff (either oscillometric or Doppler). Additional monitoring includes an indwelling arterial catheter, temperature probes, and an esophageal stethoscope. Foley catheters are generally employed when surgical

intervention entails cardiopulmonary bypass or might produce renal ischemia, or when the anesthetic management includes a regional technique associated with urinary retention. Some centers routinely employ central venous pressure monitoring for major cardiovascular surgery. Alternatively, the authors typically use directly placed transthoracic atrial lines to obtain that information for separation from cardiopulmonary bypass and the postoperative period. In that setting, the benefits of the information or access provided by percutaneous central venous pressure catheters in the pre-bypass period must be weighed against the risks they pose.

Continuous monitoring of arterial pressure is only possible through an indwelling intra-arterial catheter. In young children cannulation of the radial artery with a 22-gauge catheter is preferred. In older children and adolescents, a 20-gauge catheter may be substituted. Careful inspection, palpation, and four-extremity noninvasive blood pressure determinations help ensure that previous or currently planned operative procedures, such as a previous radial artery cutdown, subclavian flap for coarctation repair, or a Blalock-Taussig shunt, do not interfere with the selected site of arterial pressure monitoring. Other sites available for cannulation include the ulnar, femoral, axillary, or umbilical (in neonates) arteries. Cannulation of the posterior tibial or dorsalis pedis arteries is not usually sufficient for complex operative procedures. Peripheral arterial catheters, principally of the distal lower extremities, function poorly after CPB and do not reflect central aortic pressure when distal extremity temperature remains low. [41]

Myocardial and cerebral preservation is principally maintained through hypothermia; therefore, the accurate and continuous monitoring of body temperature is crucial. Rectal and nasopharyngeal temperatures are monitored, as they reflect core and brain temperature, respectively. Monitoring of esophageal temperature is a good reflection of cardiac and thoracic temperature. Tympanic probes, although a useful reflection of cerebral temperature, can cause tympanic membrane rupture.

Pulse oximetry and capnography provide instantaneous feedback concerning adequacy of ventilation and oxygenation. They are useful guides in ventilatory and hemodynamic adjustments to optimize Qp:Qs before and after surgically created shunts and pulmonary artery bands. Peripheral vasoconstriction in patients undergoing deep hypothermia and circulatory arrest renders digital oxygen saturation probes less reliable. The use of a tongue sensor has been advocated in the newborn to provide a more central measure of oxygen saturation, with less temperature-related variability. [42]

The use of transthoracic (in the right or left atrium, pulmonary artery) or transvenous pulmonary artery catheters is determined on an individual basis based on the disease process, physiologic state, and surgical intervention. For example, in children undergoing a Fontan procedure for tricuspid atresia or univentricular heart, these measurements are especially useful. Following a Fontan operation, pulmonary blood flow must occur without benefit of a ventricular pumping chamber. Subtle changes in preload, PVR, and pulmonary venous pressure will influence pulmonary blood flow and thus systemic cardiac output. Data derived from systemic venous and left atrial pressure (LAP) help distinguish the relative importance of intravascular volume (central venous pressure [CVP]), PVR (CVP-LAP gradient), or ventricular compliance (LAP), each of which requires a different therapeutic approach.

As a general guideline, a transvenous pulmonary artery catheter (PAC) may be placed using the internal jugular approach in children weighing more than 7 kg. A 5.0 Fr PAC is used between body weights of 7 and 25 kg; a 7.0 French PAC for children weighing greater than 25 kg. For infants weighing less than 7.0 kg, percutaneous placement of a PAC can be performed from the femoral vein. Occasionally the latter technique will require fluoroscopy. The use of intraoperative transthoracic monitoring lines and echo-Doppler limit the need for transvenous pulmonary artery catheters in most cases.

Special Monitoring

Intraoperative Echocardiography

In recent years, newer techniques for monitoring patients during pediatric cardiovascular surgery have been introduced. The most promising of these techniques is echocardiography with Doppler color flow imaging. Several re- ports have described the usefulness of intraoperative echo-Doppler during congenital heart surgery. [43] [44] [45] Twodimensional echocardiography combined with pulsed-wave Doppler ultrasonography and color flow mapping is able to provide detailed morphologic as well as physiologic information in the majority of operative cases. Using echo-Doppler in the operating room, anatomic and physiologic data can be obtained prior to CPB, thus refining the operative plans.

Pre-bypass echo-Doppler precisely defines anesthetic and surgical management. [16] [44] Because of the unrestricted epicardial and transesophageal echocardiography (TEE) approaches in anesthetized patients, new findings are frequently discovered and management plans changed accordingly (Fig. 50-4) . Post-bypass echo-Doppler evaluation is able to immediately assess the quality of the surgical repair as well as assess cardiac function by examining ventricular wall motion and systolic thickening. [16] [44] This technique can show residual structural defects after bypass, which can be immediately repaired in the same operative setting and prevents leaving the operating room with significant residual structural defects that will require reoperation at a later time (Fig. 50-5) . By identifying patients with new RV and LV contraction abnormalities after bypass, as determined by a change in wall motion or systolic thickening, echo-Doppler provides guidance for immediate pharmacologic interventions. Importantly, post-bypass ventricular dysfunction and residual structural defects identified by echo-Doppler are associated with an increased incidence of reoperation and higher morbidity and mortality rate. [46] Thus this monitoring tool is helpful in assessing surgical outcome and identifying operative risk factors. Whether early identification of these abnormalities, which directs appropriate medical and surgical interventions, will improve outcome remains to be determined.

Two techniques for intraoperative echo-Doppler have been described: TEE and epicardial. Using TEE, the probe is placed after induction of anesthesia and intubation and is then available for monitoring of the patient. The advantage of this technique is its utility as a continuous monitor of cardiac structure and function, without interrupting surgery. [16] [47] Because of its ideal imaging location, TEE has been especially helpful in evaluating pulmonary venous return and the integrity of the left AV valve following mitral valvuloplasty, complete AV valve repair, and correction of complex congenital heart disease. Early limitation in views

Figure 50-4 Intraoperative pre-cardiopulmonary bypass epicardial echocardiogram in the long-axis view. Note the insertion of the papillary muscle of the tricuspid valve on the interventricular septum. Based on this view, the surgeon decided that ventricular septal defect (VSD) closure was possible in a child thought preoperative to be only a candidate for palliation. RV, right ventricle; LV, left ventricle; LA, left atrium.

Figure 50-5 *(A)* Echocardiogram with a Doppler flow map in the long-axis view illustrating a residual ventricular septal defect (VSD) resulting from patch dehiscence after initial repair. Turbulent flow through the VSD appears as a mosaic of white particles (arrow). This finding necessitated immediate reinstitution of cardiopulmonary bypass and re-repair. *(B)* Repeat Doppler flow map in the long-axis view illustrates patch closure (arrow) of the VSD after re-repair. Note the absence of turbulent flow with the loss of the mosaic of white, RV, right ventricle; LV, left ventricle; LA, left atrium; Ao, aorta.

have been virtually eliminated with clinical experience and improved biplane images. Pediatric biplane TEE probes have extended the patient size limits to neonates between 2.5 and 3 kg. [48] Potential hazards of TEE that merit particular vigilance include descending aorta and airway compression due to probe size or during probe flexion.

The second technique for intraoperative echocardiographic analysis in children is the epicardial approach. [17] [44] [48] This approach requires that a clean, shortfocused 5.0- or 7.0-MHz transducer be passed over the anesthesia screen into a sterile sheath, where it then can be placed on the epicardial surface of the heart. This technique best facilitates the probe manipulations necessary for thorough interrogation of the major structures and dynamic function of the heart. The advantage of this approach is that all views can be obtained in any size patient. Among the disadvantages are the need for sufficient operator skill and experience for manipulations, [46] the need to interrupt surgery to manipulate the probe, and any deleterious impact of direct myocardial mechanical manipulation. With the current TEE capabilities, epicardial imaging is rarely employed.

Specialized Central Nervous System Monitoring

The primary goal of brain monitoring is to improve our understanding of cerebral function and dysfunction during cardiac surgery so that effective brain protection

strategies can be developed. Because many of the determinants of normal brain perfusion become externally controlled by the cardiac team during CPB, such as flow rate (cardiac output), perfusion pressure, temperature, hematocrit, and Pa CO_2 , a knowledge of the effect of these factors on the brain in neonates, infants, and children is essential. Furthermore, the examination of the brain under unusual biologic circumstances, such as after deep hypothermic circulatory arrest (DHCA) or during continuous-flow CPB at deep hypothermia (15 to 18°C), permits a unique opportunity to describe cerebrovascular physiology and pathophysiology. Processed electroencephalography, transcranial Doppler (TCD), cerebral blood flow, and metabolism measurements have provided important information during pediatric cardiovascular surgery.

Electroencephalography is helpful in monitoring physiologic function of the central nervous system during deep hypothermic bypass and total circulatory arrest. For example, during deep hypothermia and before total circulatory arrest, the processed electroencephalogram can identify residual cerebral electrical activity. [49] Isoelectric silence can then be induced by further cooling, and any further brain activity detected by electroencephalography. Since this residual electrical activity during arrest is associated with ongoing cerebral metabolism, an isoelectric state may prevent ischemic injury to the brain during circulatory arrest. The electroencephalogram may also be useful in detecting the level and depth of anesthesia. Postoperative electroencephalographic analysis has demonstrated subclinical seizure activity in a number of high-risk patients, potentially linking these abnormalities with poorer neuropsychologic outcome. The value of intraoperative electroencephalographic monitoring after CPB and the significance of the findings remain to be determined.

TCD is one of a number of methods currently being used to monitor cerebral blood flow (CBF) during pediatric cardiac surgery. [50] [51] TCD technology uses the Doppler principle to detect shifts in the frequency of reflected signals from blood in the middle cerebral artery to calculate blood flow velocity. [52] Since the diameter of this large cerebral artery is relatively constant, flow velocity should approximate CBF. There are several advantages of TCD: (1) it is noninvasive, (2) it does not require radiation exposure, and (3) it is a continuous monitor. An additional advantage of this technique is the capability of assessing rapid alterations in blood flow velocity due to temperature or perfusion changes, as commonly occur during cardiac surgery. The limitations of transcranial Doppler monitoring include (1) reproducibility, especially at low flows, where minute movement of the patient's head can dramatically alter signal intensity and alter baseline measurements, and (2) the lack of validating studies of TCD during hypothermic CPB, when temperature, reduced flow rates, and the laminar flow characteristics of nonpulsatile perfusion may limit the accuracy of CBF velocity measurements. Although CBF velocity measurements by TCD have reasonable correlation with more standard meas-ures of CBF during normothermia, there have been some studies examining its validity during hypothermic CPB. [53]

TCD has been used to investigate the effect of CPB and deep hypothermic circulatory arrest on cerebral hemodynamics in children as well as to assess the incidence of cerebral emboli. Recent studies examining the brain using TCD have enabled several investigative groups to provide important information regarding questions of normal and abnormal brain perfusion during cardiac surgery in children. Questions regarding cerebral perfusion pressure, autoregulation, effect of Pa CO_2 , and temperature have been addressed using TCD in children and are discussed subsequently. [50] [51] [53] TCD has also provided qualitative information regarding the presence of gaseous emboli in the middle cerebral artery during cardiac surgery. [54] [55] Quantification of this important mechanism of cerebral injury during cardiac surgery would be instructive. Future investigations using TCD should address this mechanism of injury as well.

CBF studies using xenon clearance technology have improved the understanding of cerebrovascular dynamics in young children during CPB and especially during deep hypothermia and after periods of circulatory arrest. [56] [57] [58] [59] [60] In general, this investigational tool has described the effects of CPB, temperature, and various perfusion techniques on CBF and, indirectly, on brain metabolism (Fig. 50-6) (Figure Not Available) . Studies using this methodology have shown that some of the mechanisms of cerebral blood flow autoregulation, such as pressure-flow regulation, are lost with deep hypothermia and that cerebral reperfusion is impaired after a period of total circulatory arrest.

There now exists the capability of measuring cerebral metabolic activity during cardiac surgery. Methods for monitoring cerebral metabolic activity include determining the cerebral metabolic rate for oxygen (CMR O_2), jugular venous bulb saturation, and the use of near-infrared spectroscopy (NIRS). Using CMR O_2 as a metabolic index, the effects of temperature and DHCA on brain metabolism have been described. [58] The primary effect of cooling during cardiac surgery is to reduce energy metabolism so that low-flow states and DHCA can be used. Monitoring the efficacy of brain cooling can be performed by measuring the venous oxygen saturation of the brain. The higher the saturation level during cooling, the greater the oxygen metabolic suppression and the protective cooling effects. This catheter is easily placed in the right internal jugular vein and threaded retrograde to the venous bulb, positioned to assess the cerebral venous effluent. [60] Using this technique, potential mechanisms for brain injury have been identified and effective protection strategies developed. NIRS has the capability of measuring regional brain tissue oxyhemoglobin and cytochrome a,a_3 , the terminal mitochondrial enzyme in the respiratory chain. Using NIRS intracellular brain tissue, oxygen delivery and utilization during CPB have been preliminarily observed. [62] These growing improvements in our knowledge of the effects of CPB on the brain are of great importance, since the last major area of morbidity associated with cardiac surgery is neurologic in origin.

Induction and Maintenance of Anesthesia

The principles of intraoperative management of cardiothoracic surgical procedures are based on an understanding of the pathophysiology of each disease process and a working

Figure 50-6 (Figure Not Available) Bar chart of the changes in cerebral blood flow (CBF) before, during, and after CPB in 67 infants and children (mean ± SD). Group A underwent repair with moderate hypothermic bypass (MoCPB) at 28 to 32°C; group B, with deep hypothermic bypass (DHCPB) at 18 to 22°C; group C, with total circulatory arrest at 18°C. Stage I, pre-bypass; stages II and III, during hypothermic bypass; stage IV, rewarmed on bypass; stage V, after bypass. Note the impaired cerebral reperfusion after TCA (group C). *(From Greeley et al [61])*

knowledge of the effects of the various anesthetic and other pharmacologic interventions on a particular patient's condition. Selecting an induction technique is dependent on the degree of cardiac dysfunction, the cardiac defect, and the degree of sedation provided by the premedication. In children with good cardiac reserve, induction techniques can be quite varied as long as induction is careful and well monitored. The titration of induction agents is more important than the specific anesthetic technique in patients with reasonable cardiac reserve. A wide spectrum of anesthetic induction techniques with a variety of agents has been used safely and successfully, such as sevoflurane, halothane, and nitrous oxide; intravenous or intramuscular ketamine; or intravenous propofol, fentanyl, midazolam, or thiopental. [63] For neonates undergoing open heart surgery, opioidrelaxant inductions are most prevalent, whereas older children with sufficient cardiac reserve typically receive inhalation inductions with either halothane or sevoflurane. The application of Emla cream (emulsion of lidocaine 2.5 percent and prilocaine 2.5 percent) at the site of intravenous cannula insertion facilitates cannulation and minimizes patient pain and stress. Ketamine has been the most popular agent for anesthetic induction in patients with cyanotic conditions because it increases systemic vascular resistance and cardiac output, thereby diminishing the magnitude of right-to-left shunting. Administration of ketamine can be intravenous or intramuscular. An intramuscular injection may result in pain, agitation, and subsequent arterial desaturation.

Inhalation inductions are generally well received and tolerated by most children. An inhalation induction with halothane or sevoflurane can easily and safely be performed even in cyanotic patients such as those with tetralogy of Fallot (Fig. 50-7) (Figure Not Available) . In these patients, who are at risk of right-to-left shunting and systemic desaturation, oxygenation is well maintained with a good airway and ventilation, despite halothane-induced reduction in systemic arterial pressure. [64] Skilled airway management and efficiency of ventilation are an equally essential component of anesthetic induction. Although it is essential to understand the complexities of shunts and vascular resistance changes, airway and ventilation effects on the cardiovascular system are of primary importance during the induction of anesthesia.

After anesthetic induction, intravenous access is established or augmented as appropriate. A nondepolarizing muscle relaxant is usually administered and an intravenous opioid and/or inhalation agent chosen for maintenance anesthesia. The child is preoxygenated with 100 percent Fi O_2 and a lubricated nasal endotracheal tube is carefully positioned. A nasal tube is usually selected because most patients require a period of postoperative mechanical ventilation and the nasal route provides greater stability and patient comfort compared with the oral route. Some degree of alveolar preoxygenation is recommended, even in the infant whose systemic perfusion might be jeopardized by lowering PVR with resulting increase in pulmonary blood flow. This maneuver delays desaturation during intubation. If the

Figure 50-7 (Figure Not Available) Comparative changes in arterial oxygen saturation (Sa O_2) and mean blood pressure (MAP) during mask halothane N_2O (*n* = 7) and intramuscular ketamine (*n* = 7) inductions in children with tetralogy of Fallot at risk of right-to-left shunting. Note the maintenance of Sa O_2 in the halothane group despite the significant drop in MAP. *(From Greeley et al [64])*

child arrives in the operating room with an endotracheal tube in place, it is our practice to change it. Inspissated secretions in a tube with a small internal diameter can cause significant obstruction to gas flow. During periods of bypass when humidified ventilation is discontinued, significant endotracheal tube obstruction can occur. This can be minimized by placing a new endotracheal tube at the beginning of the procedure.

Because of the diverse array of congenital heart defects and surgical procedures, an individualized anesthetic management plan is essential. The maintenance of anesthesia in these patients depends on the age and condition of the patient, the nature of the surgical procedure, the duration of cardiopulmonary bypass, and the need for postoperative ventilation. An assessment of the hemodynamic objectives designed to lessen the pathophysiologic loading conditions should be developed for each patient, taking advantage of the known qualitative effects of specific anesthetic agents and ventilatory strategies. These individualized plans must also integrate with the overall perioperative goals to configure the optimal anesthetic. In patients with complex defects requiring preoperative inotropic and mechanical ventilatory support, a carefully controlled hemodynamic induction and maintenance anesthetic with a potent opioid is generally chosen. In patients with a simple ASD or VSD, a potent inhalation agent is preferred as the principal anesthetic agent. This allows for early postoperative extubation and a less prolonged period of intensive care monitoring. More important than the specific anesthetic techniques and drugs is the skilled execution of the anesthetic plan, taking into account patient response to drugs, the changes associated with surgical manipulation, and early recognition of intraoperative complications.

The reported changes in blood pressure and heart rate for the inhalation agents in normal children are observed in pediatric cardiac surgical patients as well. Although both halothane and isoflurane decrease blood pressure in neonates, infants, and children, the vasodilatory properties of isoflurane may improve overall myocardial contractility, compared with the effects of halothane. [65] Despite improved cardiac reserve with isoflurane, the incidence of laryngospasm, coughing, and desaturation during induction of anesthesia limits its use as an induction agent in children with congenital heart defects. [66] The use of potent inhalation agents as primary anesthetics should be reserved for the child with adequate cardiovascular reserve who is a candidate for early postoperative extubation. In these patients, the myocardial depression and hypotension associated with the use of inhalation agents is well tolerated. Examples include closure of an ASD or VSD, excision of a discrete subaortic membrane, pulmonic or aortic stenosis, ligation of a PDA, and repair of coarctation of the aorta.

Desflurane has cardiorespiratory properties similar to those of isoflurane. [67] Its main advantage is a low blood and tissue solubility. This allows for rapid equilibration between the inspired and alveolar concentrations and rapid decrease of alveolar concentrations during elimination. [68] This provides greater precision in drug dosing during the operative period and may make desflurane a more titratable adjunctive drug for pediatric cardiac anesthesia. The three main disadvantages of desflurane are potency, pungency, and negative inotropic effect. [69] [70] Studies in normal infants and children suggest that 1 minimum alveolar concentration of desflurane requires concentrations of 8 to 10 percent. [71] [72] Desflurane is also quite pungent and, although its uptake is rapid, early experience with this drug for inhalation induction in children has reported a fairly high incidence of airway reactivity and laryngospasm. [71] [73] [74] Although its negative inotropic effect is significantly less potent than that of halothane, desflurane should not be used as the sole anesthetic in patients with significant cardiac dysfunction. [74]

Sevoflurane offers a more tolerable aroma without the magnitude of myocardial depression that accompanies halothane. [75] In addition, its blood gas solubility is nearly as low as desflurane. Hemodynamically, sevoflurane tends to produce some tachycardia, particularly in older children, and preserve systemic arterial pressure. [76] Reductions in heart rate and systemic arterial pressure are more modest in infants anesthetized with sevoflurane than in control subjects anesthetized with halothane, and the former exhibit echocardiographic evidence of normal contractility and cardiac index. [77] [78] Controversies continue to surround the potential toxic byproducts of sevoflurane anesthesia, related both to patient metabolism and to the production of Compound A in the anesthesia breathing circuit. Although the importance of Compound A in adult practice remains uncertain, evidence suggests that production of this toxin is significantly diminished in children. [79]

Children with complex congenital heart disease and limited cardiac reserve demand an anesthetic technique that provides hemodynamic stability. Inhalation agents are less well tolerated as a primary anesthetic in patients who have limited cardiac reserve, especially after cardiopulmonary bypass. Fentanyl and sufentanil are excellent induction and maintenance anesthetics for this group of patients. Low to moderate doses of these opioids can be supplemented with inhalation anesthetics. Adding low concentrations of inhalation agents to smaller doses of opioids shortens or eliminates the need for postoperative mechanical ventilation while maintaining the advantage of intraoperative hemodynamic stability. Postoperative mechanical ventilation will be required when a high-dose opioid technique is used. The hemodynamic effects of fentanyl at a dose of 25 mug/kg with pancuronium given to infants in the postoperative period after operative repair of a congenital heart defect include no change in left atrial pressure, pulmonary artery pressure, pulmonary vascular resistance, and cardiac index and a small decrease in systemic vascular resistance and mean arterial pressure. [80] Higher doses of fentanyl at 50 to 75 mug/kg with pancuronium result in a slightly greater fall in arterial pressure and heart rate in infants undergoing repair for complex congenital heart defects. [81] Despite the wide safety margin exhibited by these opioids, a selected population of infants and children with marginally compensated hemodynamic function sustained by endogenous catecholamines may manifest more extreme cardiovascular changes with these doses. Fentanyl has also been shown to block stimulusinduced pulmonary vasoconstriction and contributes to the stability of the pulmonary circulation in neonates after congenital diaphragmatic hernia repair. [82] Thus, the use of fentanyl may be extrapolated to the operating room where stabilizing pulmonary vascular responsiveness in newborns and young infants with reactive pulmonary vascular beds is crucial to weaning from cardiopulmonary bypass and stabilizing shunt flow.

Sufentanil and pancuronium provide the same cardiovascular stability as fentanyl and pancuronium in pediatric cardiovascular patients. Children receiving a sufentanil induction as a single dose of 5 to 20 mug/kg have a stable preintubation period. [83] [84] Intubation and other stimuli such as sternotomy do not produce clinically significant alterations in hemodynamics, although changes are greater than with equipotent doses of fentanyl. The use of fentanyl as an infusion (.1 mug/kg/min) produces fewer alterations in heart rate and blood pressure. This is particularly important in infants in whom significant hemodynamic changes are poorly tolerated. For neonates with critical congenital heart disease, sufentanil anesthetic and postoperative infusion have been shown to reduce morbidity after cardiac surgery when compared with a halothane anesthetic and routine morphine postoperatively. [85] The blunting of the stress response observed in this study probably accounted for the differences in morbidity; there was no comparison group representing a more typical dose of a phenylpiperidine opioid (e.g., fentanyl 50-75 mug/kg) to permit conclusions as to whether such large opioid doses are optimal.

Alfentanil is a short-acting potent opioid that has also been used for cardiac surgery in children; it shows some promise in selected pediatric anesthesia cases because of its short elimination half-life and hemodynamic stability. As a primary anesthetic in children undergoing cardiopulmonary bypass, however, it must be continuously infused because of its short half-life. Also, when alfentanil infusion is discontinued, the release of stress hormones may increase at a more rapid rate compared with longer-acting opioids such as fentanyl. The use of alfentanil in congenital cardiac patients may therefore be limited to simple repairs such as an ASD, in which the bypass time is short and temperature extremes are less severe, and prompt tracheal extubation is a goal.

Compared with other agents in its class, remifentanil, a new ultrashort-acting opioid, offers the unique advantage of metabolism via nonspecific and tissue esterases thereby limiting the potential for accumulation related to protracted elimination. [86] Remifentanil may provide the advantages of alfentanil in the selected group for whom the blunting of endogenous responses is desirable intraoperatively, but potentially deleterious at the end of the procedure. A randomized controlled trial comparing equipotent doses of alfentanil and remifentanil for outpatient pediatric surgery revealed delayed emergence, requiring naloxone only in the alfentanil group. [87] In both adults and children, remifentanil is associated with qualitative hemodynamic changes similar to other opioids, a variable tendency to bradycardia as well as a small reduction in systolic blood pressure. [87] [88] [89]

Because of the widespread use of the opioids for pediatric cardiac surgery and the availability of invasive monitoring, the pharmacokinetics and pharmacodynamics of these drugs have been well studied. [84] [90] In general, the clinical pharmacology of fentanyl and sufentanil share the same age-related pharmacokinetic and pharmacodynamic features. For example, sufentanil has increased clearance in patients aged 1 month to 12 years, achieved comparable adult clearance in adolescents (12-16 years of age), and decreased clearance during the neonatal period (newborn to 1 month) (Table 50-6) . [73] [78] Furthermore, sequential sufentanil anesthetics in neonates with congenital heart disease show marked increases in clearance and elimination between the 1st week and the 3rd or 4th week of life [75] (Fig. 50-8) . The latter observation is most likely attributable to maturational changes in hepatic microsomal activity and improved hepatic blood flow from closure of the ductus venosus. The variability in clearance and elimination, coupled with limited cardiovascular reserve in the neonate during the first month of life, makes opioid dosing difficult in this age group. Careful titration of 5 to 10 mug/kg of fentanyl or 1 to 2 mug/kg of sufentanil or a continuous infusion technique provides the most reliable method of achieving hemodynamic stability and an accurate dose response. Cardiopulmonary bypass, different institutional anesthetic practices, and individual patient differences all influence pharmacokinetic and pharmacodynamic disposition of the opioids in ways that are not predictable. Even certain disease

states such as tetralogy of Fallot [80] or pathophysiologic conditions such as increased intraabdominal pressure [81] alter pharmacokinetic processes.

CARDIOPULMONARY BYPASS

Differences Between Adult and Pediatric CPB

The physiologic effects of CPB on neonates, infants, and children are significantly different than the effects on adults (Table 50-7) . During CPB, pediatric patients are exposed to biologic extremes not seen in adults, including deep hypothermia (15-20°C), hemodilution (3- to 15-fold greater dilution of circulating blood volume), low perfusion pressures (20-30 mm Hg), wide variation in pump flow rates (ranging from highs of 200 mL/kg/min to total circulatory arrest), and differing blood pH management techniques (alpha-stat or pH-stat, or both sequentially). These parameters significantly differ from normal physiology and affect preservation of normal organ function during and after

TABLE 50-6 -- Sufentanil Pharmacokinetics in Pediatric Cardiovascular Patients [a]

AGE GROUP	t½ a (min)	t½ b (min)	CLEARANCE (mL/kg/min)	Vd_{as} (L/kg)
1-30 d	23 ± 17	737 ± 346	6.7 ± 6.1	4.2 ± 1.0
1-24 mon	16 ± 5	214 ± 41	18.1 ± 2.7	3.1 ± 1.0
2-12 y	20 ± 6	140 ± 30	16.9 ± 2.2	2.7 ± 0.5
12-18 y	20 ± 6	209 ± 23	13.1 ± 0.4	2.7 ± 0.5

Abbreviations: t½ a--slow distribution half-life; t½b--elimination half-life; Vd_{as} --volume of distribution at steady state

CPB. In addition to these prominent changes, subtle variations in glucose supplementation, cannula placement, presence of aortopulmonary collaterals, and patient age may also be important factors affecting organ function during cardiopulmonary bypass. Adult patients are infrequently exposed to these biologic extremes. In adult cardiac patients, temperature is rarely lowered below 25°C, hemodilution is more moderate, perfusion pressure is generally maintained at 50 to 80 mm Hg, flow rates are maintained at 50 to 65 mL/kg/min, and pH management strategy is less influential because of moderate hypothermic temperatures and rare use of circulatory arrest. Variables such as glucose supplementation rarely pose a problem in adult patients owing to large hepatic glycogen stores. Venous and arterial cannulas are larger and less deforming of the atria and aorta, and their placement is more predictable. Although superficially similar, the conduct of CPB in children is considerably different from that in adults. One would therefore expect marked physiologic differences in the response to CPB in the child.

Prime Volume

The priming solutions used in pediatric CPB take on great importance because of the disproportionately large prime volume/blood volume ratio in children. In adults, the priming volume is equivalent to 25 to 33 percent of the patient's blood volume, whereas in neonates and infants, the priming volume may exceed the patient's blood volume by 200 percent. Even contemporary low-volume bypass circuits rarely reduce this figure much below 150 percent in the smallest neonates. Care must be taken, therefore, to achieve a physiologically balanced prime and limit the volume as much as possible. Most pediatric priming solutions, however, have quite variable levels of electrolytes, calcium, glucose, and lactate. Electrolytes, glucose, and lactate levels may be quite high if the prime includes large amounts of banked blood, or quite low if a minimal amount of banked blood is added. Calcium levels are generally very low in pediatric prime solutions; this may contribute to the rapid

TABLE 50-7 -- Differences Between Adult and Pediatric Cardiopulmonary Bypass

PARAMETER	ADULT	PEDIATRIC
Hypothermic temperature	Rarely below 25-32°C	Commonly 15-20°C
Use of total circulatory arrest	Rare	Common
Pump prime		
Dilution effects on blood volume: addi-tional additives in pediatric primes	25-33%	150-300% Blood, albumin
Perfusion pressures	50-80 mm Hg	20-50 mm Hg
Influence of alpha- vs. pH-stat management strategy	Minimal at moderate hypothermia	Marked at deep hypothermia
Measured Pa CO_2 differences	30-45 mm Hg	20-80 mm Hg
Glucose regulation		
Hypoglycemia	Rare--requires significant hepatic injury	Common--reduced hepatic glycogen stores
Hyperglycemia	Frequent--generally easily controlled with insulin	Less common--rebound hypoglycemia may occur

slowing of the heart with the initiation of bypass. The main constituents of the priming solution include crystalloid, banked blood (to maintain a temperature-appropriate hematocrit), and colloid. Other supplements that may be added to the prime are mannitol, a buffer (sodium bicarbonate or tris [hydroxymethyl] aminomethane), and steroids. Many institutions add colloid or fresh frozen plasma to the pump prime in neonates and small infants or use whole blood in the priming solution. Low concentrations of plasma proteins have been shown experimentally to impair lymphatic flow and alter pulmonary function by increasing capillary leak. [94] [95] Although adding albumin to pump prime has not been shown to alter outcome in adults during CPB, one study suggested that maintaining normal colloid osmotic pressure may improve survival in infants undergoing CPB. [96] [97] The addition of fresh frozen plasma or whole blood is an attempt to restore the level of procoagulants, which are severely diluted with CPB in infants. For neonates and infants, blood must be added to the priming solution. Most institutions use packed red blood cells in their prime solution, but some use whole blood. The use of whole blood supplements both red blood cells and the coagulation factors with a single donor exposure. In fact, lowvolume bypass circuits may enable perfusionists and anesthesiologists to share a single unit of whole blood, thereby limiting the donor exposure to one throughout the entire perioperative course. The addition of any blood products will cause a much higher glucose load in the prime. Hyperglycemia may increase the risk of neurologic injury if brain ischemia occurs. Mannitol is added to promote an osmotic diuresis and to scavenge oxygen free radicals from the circulation. Steroids are added to stabilize membranes to produce the theoretical advantage of reducing ion shifts during periods of ischemia. Steroids, however, may raise glucose levels and this may be detrimental if there is a period of cerebral ischemia. Steroids remain one of the more controversial additives in priming solutions.

Temperature

Hypothermic CPB is used to preserve organ function during cardiac surgery. Three distinct methods of CPB are used: moderate hypothermia (25-32°C), deep hypothermia (15-20°C), and DHCA. The choice of method of bypass is based on the required surgical conditions, patient size, the type of operation, and the potential physiologic impact on the patient.

Moderate hypothermic CPB is the principal method of bypass employed for older children and adolescents. In these patients, venous cannulae are less obtrusive, and the heart can easily accommodate superior and inferior vena cava cannulation. Bicaval cannulation reduces right atrial blood return and improves the surgeon's ability to visualize intracardiac anatomy. Moderate hypothermia may also be chosen for less demanding cardiac repairs in infants, such as an ASD or an uncomplicated VSD. Most surgeons are willing to cannulate the inferior and superior venae cavae in neonates and infants. In these patients, however, this approach is technically more difficult and likely to induce brief periods of hemodynamic instability. Additionally, the pliability of the cava and the rigidity of the cannulas may result in caval obstruction, impaired venous drainage, and elevated venous pressure in the mesenteric and cerebral circulation.

Deep hypothermic CPB is generally reserved for neonates and infants requiring complex cardiac repair. However, certain older children with complex cardiac disease or severe aortic arch disease benefit from deep hypothermic temperatures. For the most part, deep hypothermia is selected to allow the surgeon to operate under conditions of low-flow CPB or total circulatory arrest. Low pump flows (50 mL/kg/min) improve the operating conditions for the surgeon by providing a near bloodless field. DHCA allows the surgeon to remove the atrial or aortic cannula. Utilizing this technique, surgical repair is more precise because of the bloodless and cannula-free operative field. Arresting the circulation, even at deep hypothermic temperatures, introduces the concern of how well deep hypothermia preserves organ function, with the brain being at greatest risk. [98]

Hemodilution

Although hemoconcentrated blood has an improved oxygen-carrying capacity, its viscosity reduces efficient flow through the microcirculation. With hypothermic temperatures, blood viscosity increases significantly and flow decreases. Hypothermia, coupled with the nonpulsatile flow of CPB, impairs blood flow through the microcirculation. Blood sludging, small vessel occlusion, and multiple areas of tissue hypoperfusion may result. Therefore, hemodilution is an important consideration during hypothermic CPB. The appropriate level of hemodilution for a given hypothermic temperature, however, is not well defined. Experimental evidence suggests that reducing hematocrit levels to as low as 15 percent provides a sufficient quantity of oxygen delivery to the myocardium at normothermia, provided intravascular volume, colloid osmotic pressure, and normotension are maintained. [99] At hypothermic temperatures, hematocrit levels reduced to as low as 10 percent provide adequate oxygen delivery during CPB, as long as flow rates and perfusion pressure are maintained. [100] [101] Because red blood cells serve as the major reservoir of oxygen during circulatory arrest, hematocrit values closer to 20% are generally preferred for deep hypothermia when this technique is contemplated. Most centers maintain hematocrit levels at 20±2 percent during deep hypothermia (15-20°C) and will allow the hematocrit level to drift as low as 18 percent before transfusing additional red blood cells. Although this is an arbitrary limit, lower hematocrit values have not been systematically evaluated to ensure adequate oxygen delivery to tissue. Cerebral oxygen delivery is an especially important consideration, since cerebral autoregulation is impaired at deep hypothermic temperatures and after DHCA.

To achieve a hematocrit level of 20 to 25 percent in neonates and infants, banked blood should be added to the priming solution. A calculation of the mixed hematocrit level on CPB (the hematocrit level of the total priming volume plus the patient's blood volume) can be calculated by the following formula:

where Hct_{CPB} is mixed Hct (TPV + BV $_{pt}$), BV_{pt} is patient's blood volume (weight in kg × estimated blood volume in mL/kg), TPV is total priming volume, and Hct_{pt} is starting hematocrit level of the patient. This calculation allows an estimate of the hematocrit level of the patient using an asanguineous prime and is therefore useful for older children and adolescents. In neonates and infants, the perfusionist must add blood to the pump prime to achieve a desired hematocrit level during hypothermic CPB. The following formula estimates the amount of red blood cells that must be added to achieve this hematocrit level:

where *added RBCs* represents milliliters of packed red blood cells added to the prime volume, BV_{pt} is patient's blood volume, TPV is total priming volume, *Hct desired* is the desired hematocrit level on CPB, and Hct_{pt} is the starting hematocrit level of the patient.

Currently, no evidence exists for defining the optimal hematocrit level after weaning from CPB. Decisions concerning post-CPB hematocrit levels are made based on the patient's post-repair function and anatomy. Patients with residual hypoxemia or those with moderate to severe myocardial dysfunction benefit from the improved oxygencarrying capacity of hematocrit levels of 40 percent or higher. Patients with a physiologic correction and excellent myocardial function may tolerate hematocrit levels of 20 to 25 percent. [99] In children with mild to moderate myocardial dysfunction, accepting hematocrit levels between these extremes seems prudent. Therefore, in patients with physiologic correction, moderately good ventricular function, and hemodynamic stability, the risks associated with blood and blood product transfusion should be strongly considered during the immediate post-bypass period.

Initiation of CPB

Arterial and venous cannulation of the heart prior to initiating CPB may result in significant problems in the peribypass period. A malpositioned venous cannula has the potential for vena caval obstruction. The problems of venous obstruction are magnified during CPB in the neonate because arterial pressures are normally low (20-40 mm Hg), and large, relatively stiff cannulas easily distort these very pliable venous vessels. [94] [95] [96] A cannula in the inferior vena cava may obstruct venous return from the splanchnic bed, resulting in ascites from increased hydrostatic pressure or directly reduced perfusion pressure across the mesenteric, renal, and hepatic vascular beds. Significant renal, hepatic, and gastrointestinal dysfunction may ensue and should be anticipated in the young infant with unexplained ascites. Similar cannulation problems may result in superior vena cava obstruction. This condition may be more ominous during bypass. Under these circumstances, three problems may ensue: (1) cerebral edema, (2) a reduction in regional or global cerebral blood flow, and (3) reduced proportion of pump flow reaching the cerebral circulation, causing inefficient brain cooling. In the operating room, it is advisable to monitor superior vena cava pressures via an internal jugular catheter or by looking at the patient's head for signs of puffiness or venous distention after initiating bypass. Discussions with the perfusionist regarding adequacy of venous return and large cooling gradients between the upper and lower body should alert the anesthesiologist and the surgeon to potential venous cannula problems. Patients with

anomalies of the large systemic veins (persistent left superior vena cava or azygous continuation of an interrupted inferior vena cava) are at particular risk for problems with venous cannulation and drainage.

Problems with aortic cannula placement also occur. The aortic cannula may slip beyond the takeoff of the innominate artery and therefore selectively flow to the right side of the cerebral circulation. Also, the position of the tip of the cannula may promote preferential flow down the aorta or induce a Venturi effect to steal flow from the cerebral circulation. This problem has been confirmed during cerebral blood flow monitoring by the appearance of large discrepancies in flow between the right and left hemisphere after initiating CPB. Other clues to cannula misplacement include better cooling in the lower body than the upper body. The presence of large aortic to pulmonary collaterals, such as a large PDA, may also divert blood to the pulmonary circulation from the systemic circulation thereby reducing CBF and the efficiency of brain cooling during CPB. [102] The surgeon should gain control of the ductus either prior to or immediately after instituting CPB to eliminate this problem and, if possible, large aortopulmonary collaterals should be embolized in the cardiac catheterization laboratory prior to the operative procedure. Neonates with significant aortic arch abnormalities (e.g., aortic atresia, interrupted aortic arch) may require radical modifications of cannulation techniques, such as placing the arterial cannula in the main pulmonary artery and temporarily occluding the branch pulmonary arteries to perfuse the body via the PDA, or even dual arterial cannulation of both the ascending aorta and main pulmonary artery. Such adaptations require careful vigilance to ensure effective, thorough cooling of vital organs.

Once the aortic and venous cannulae are positioned and connected to the arterial and venous limb of the extracorporeal circuit, bypass is initiated. The arterial pump is slowly started, and, once forward flow is ensured, venous blood is drained into the oxygenator. Pump flow rate is gradually increased until full circulatory support is achieved. If venous return is diminished, arterial line pressure high, or mean arterial pressure excessive, pump flow rates must be reduced. High line pressure and inadequate venous return are usually caused by malposition or kinking of the arterial and venous cannulas, respectively. The rate at which venous blood is drained from the patient is determined by the height difference between the patient and the oxygenator inlet and the diameter of the venous cannula and line tubing. Venous drainage can be enhanced by increasing the height difference between the oxygenator and the patient or by using a larger venous cannula. Venous drainage can be reduced by either decreasing the height difference between the oxygenator and the patient or by partially clamping the venous line.

In neonates and infants, deep hypothermia is commonly used. For this reason, the pump prime is kept cold (18-22°C). When the cold perfusate contacts the myocardium

during the institution of CPB, heart rate slows immediately and contraction is impaired. The contribution of total blood flow pumped by the infant's heart rapidly diminishes. Therefore, to sustain adequate systemic perfusion at or near normothermic temperatures, the arterial pump must reach full flows quickly. CPB is initiated in neonates and infants by beginning the arterial pump flow first. Once aortic flow is ensured, the venous line is unclamped and blood is siphoned out of the right atrium into the inlet of the oxygenator. Flowing before unclamping the venous line prevents the potential problem of exsanguination if aortic dissection, or misplacement of the aortic cannula occurs. Neonates and infants have a low blood volume/prime volume ratio, and intravascular volume falls precipitously if the venous drainage precedes aortic inflow. Once aortic cannula position is verified, pump flow rates are rapidly increased to maintain effective systemic perfusion. As coronary artery disease is rarely a consideration, the myocardium should cool evenly unless distortion caused by the cannulas compromises the coronary arteries. When a cold prime is used, caution must be exercised in using the pump to infuse volume prior to initiating CPB. Infusion of cold perfusate may result in bradycardia and impaired cardiac contractility before the surgeon is prepared to initiate CPB.

Once CPB begins, careful observation should be focused to ensure appropriate circuit connections, myocardial perfusion, and optimal cardiac decompression. Ineffective venous drainage can rapidly result in ventricular distention. This is especially true in infants and neonates, in whom ventricular compliance is low and the heart is relatively intolerant of excessive preload augmentation. If ventricular distention occurs, pump flow must be reduced and the venous cannula repositioned. Alternatively, the heart may be decompressed by placing a cardiotomy suction or small vent in the appropriate chamber.

Pump Flow Rates

Recommendations for optimal pump flow rates for children have historically been based both on the patients' body mass and on evidence of efficient organ perfusion as determined by arterial blood gases, acid-base balance, and whole body oxygen consumption during cardiopulmonary bypass. [49] [103] At hypothermic temperatures, metabolism is reduced. Pump flow rates can therefore be reduced and still meet or exceed the tissue's metabolic needs (see the discussion of low-flow CPB in the following section.

Special Techniques

Deep Hypothermic Circulatory Arrest

Neonates and small infants weighing less than 8 to 10 kg who require extensive repair of complex congenital heart defects may have their repair using DHCA. This technique facilitates precise surgical repair under optimal conditions, free of blood or cannulas in the operative field, providing maximal organ protection, and often resulting in shortened total CPB time. The scientific rationale for the use of deep hypothermic temperatures rests primarily on a temperature-mediated reduction of metabolism. Whole body and cerebral oxygen consumption during induced hypothermia decreases the metabolic rate for oxygen by a factor of 2 to 2.5 for every 10°C reduction in temperature. [104] These results are consistent with in vitro models, which relate temperature reduction to a decrease in the rate constant of chemical reactions, as originally described by Arrhenius using the equation $k = Ae^{-RT}$. The reduction in oxygen supply during deep hypothermic low-flow CPB is associated with preferential increases in vital organ perfusion (e.g., to the brain) and increased extraction of oxygen. [105] Therefore, to some extent, deep hypothermic low-flow CPB exerts a protective effect by reducing the metabolic rate for oxygen, promoting preferential organ perfusion, and increasing tissue oxygen extraction.

Extensive clinical experience using DHCA has shown that the safe circulatory arrest period may last 35 to 40 minutes. [98] Beyond this duration, the incidence of permanent and transient neurologic sequelae may increase. Both the duration of the arrest period and variations in perfusion technique during cooling and rewarming influence the development of these problems. The effect of deep hypothermia on tissue metabolism and oxygen consumption and extraction clearly does not explain the entire protective effect of "safe" DHCA, however. Cortical P_{O_2} and P_{CO_2} levels indicate basal cerebral metabolic activity during DHCA (i.e., anaerobic metabolism). During brain ischemia, excitatory amino acids such as glutamate and aspartate are released and are putative mediators of ischemic damage. [49] [100] [101] [103] [106] [107] Hypothermia has been shown to significantly decrease the release of excitatory amino acids, suggesting another mechanism besides metabolism reduction for its protective effect. [108] In addition, membrane changes that transform a normal semiliquid to a semisolid form during hypothermia may act to prevent calcium influx during reperfusion and thereby account for additional protection noted in some experimental models. [109]

Although all organ systems are at risk for the development of ischemic and reperfusion injury, as manifested by lactate and pyruvate production during DHCA, the brain appears to be the most sensitive and the least tolerant of these effects. Brain stem and cortical evoked potentials as well as processed electroencephalogram are altered after DHCA. [110] [111] [112] The abnormalities in the evoked potentials appear to be related to the duration of DHCA and are attributed to altered metabolism. During reperfusion after the arrest period, CBF and metabolism remain depressed in neonates and small infants (Fig. 50-9 and see Fig. 50-6) (Figure Not Available) . [56] Importantly, during the use of these extremes of temperature, it appears that autoregulation is lost and cerebral perfusion becomes highly dependent on the conduct of extracorporeal perfusion and presumably post-bypass hemodynamic performance.

Current controversy exists regarding the immediate-term and long-term neuropsychologic effects of DHCA. Early reports regarding the long-term consequences of DHCA on brain development and intelligence were conflicting. [113] Transient neurologic dysfunction and other reversible cerebral injuries have been reported. These transient, subtle neuropsychologic disturbances have led investigators to examine more systematically the long-term outcome after DHCA.

Figure 50-9 Bar graph of variations in cytochrome oxidase (cyt a,a_3) NIR signals and cerebral metabolic rate for oxygen ($CMRO_2$) in hypothermic bypass with total circulatory arrest subjects (DHCA). Each point of cyt a,a_3 represents mean ± SE in six subjects; $CMRO_2$ values are mean ± SD. Negative values in cyt a,a_3 represent relative decreases in quantity of oxidized enzyme. *$CMRO_2$

and cyt a,a_3 are significantly different from control, P <.05. Measurement points are identical to those in Figure 54-6.

More recently, a number of more sophisticated studies examining the outcome after DHCA have been performed. In a recent randomized clinical trial comparing the incidence of brain injury following DHCA or low-flow CPB, DHCA was demonstrated to have longer electroencephalographic recovery times and a higher incidence of clinical seizures in the early postoperative period. [114] Patients in the DHCA group also had a higher incidence of neurologic abnormalities and poor motor function at 1 year of age and poor expressive language and motor development at 2½ years, particularly those who exhibited early postoperative seizures. [115] Recent reports from the same clinical trial show that patients in the DHCA cohort continued to have worse motor coordination and planning and speech abnormalities at 4 years of age. [116] [117] [118] Of interest, both the DHCA and the low-flow CPB groups have lower cognitive and motor performance compared to a general population. This latter finding suggests that factors outside DHCA and low-flow bypass, but within the perioperative period, are associated with poor neuropsychologic development.

A recent clinical study has suggested that a pH-stat blood gas management strategy during CPB is associated with an improved neuropsychologic outcome in children. [117] This study was a retrospective developmental study with a core of patients who have undergone surgery for transposition of the great arteries. The authors found a strong positive correlation between arterial P CO_2 during cooling before circulatory arrest and developmental score. This suggested that children undergoing alpha-stat blood gas management strategy had a worse developmental outcome than those in whom a pH-stat strategy was employed. In a recent randomized clinical trial of neonates undergoing cardiac surgery using deep hypothermic circulatory arrest, pH-stat management was noted to have faster electroencephalographic recovery times and fewer postoperative seizures compared with an alpha-stat bypass group. [119] [120] The beneficial effect of pH-stat management clinically remains preliminary.

Certain experimental studies have also suggested the superiority of pH-stat strategy (Fig. 50-10) (Figure Not Available) . In one recent study, pH-stat animals had greater cerebral blood flow during cooling and better recovery of cerebral adenosine triphosphate (ATP) and intracellular pH after arrest and reperfusion. [122] Brain water content was also less in the pH-stat group. These studies suggested that pH-stat CPB may have protective mechanisms due to an increased rate of brain cooling. In more recent experimental studies comparing pH-stat and alpha-stat cardiopulmonary bypass on cerebral oxygenation, the cerebral protective effect of pH-stat management was demonstrated and indicated that the kinetics of cerebral deoxygenation might contribute to the mechanism of protection (Fig. 50-11) (Figure Not Available) . [123] [124] [125] Clearly more work needs to be done in this area before pH-stat is definitively recommended. [126] However, preliminary experimental and clinical studies suggest a superiority of this technique in certain patient groups, especially those with aortopulmonary collateral circulation.

Because of the potential for neurologic dysfunction after DHCA, some institutions use low-flow deep hypothermic CPB as an alternative technique. [26] Since low-flow bypass can produce ischemia if flow is too low and because it lengthens the CPB time, as compared with DHCA, serious concerns over this technique have also arisen. [127] [128] A recent experimental study demonstrated worse brain injury with low-flow bypass than with DHCA. [129]

Other factors such as surface cooling, anesthetic agents, and cerebral protective agents may influence and modify the effects of deep hypothermic low-flow CPB and DHCA. The potential use of certain pharmacologic agents such as anesthetic drugs, barbiturates, lidocaine, and calcium channel blockers is unknown. There are no clinical studies in children systematically examining the influence of these pharmacologic agents on cerebrovascular physiology or neurologic outcome. Therefore, the use of these agents remains entirely speculative and unfounded. Clearly, further study of the long-term effects of DHCA on neuropsychologic outcome in children is necessary. Fundamental questions regarding DHCPB with low-flow versus DHCA also need to be addressed further. Equally important, the manner in which the patient is cooled and rewarmed may affect outcome [58] [59] and merits further investigation, even before the testing of pharmacologic therapies.

Figure 50-10 (Figure Not Available) Cortical and basilar brain temperature at the end of circulatory arrest (90 minutes) in animals with systemic-pulmonary shunts. Note the significantly lower brain temperatures in the pH-stat animals. *(From Kirshbom et al [121])*

Effects of CPB

Glucose Regulation

In recent years, a substantial amount of clinical and experimental data have shown conclusive evidence of the detrimental effects of hyperglycemia during complete, incomplete, and focal cerebral ischemia. [130] [131] [132] The role of glucose in potentiating cerebral injury appears to rest on two factors: ATP utilization and lactic acidosis. [133] [134] The anaerobic metabolism of glucose requires phosphorylation and the expenditure of two molecules of ATP before ATP production can occur. This initial ATP expenditure may result in a rapid depletion of ATP and may explain why hyperglycemia worsens neurologic injury. Lactic acidosis is also important in glucose-augmented cerebral injury. An important role, however, may be as a glycolytic enzyme inhibitor. Lactate slows anaerobic ATP production by inhibiting glycolysis

Figure 50-11 (Figure Not Available) Cortical oxygen saturation (ScO_2) during deep hyothermic circulatory arrest in the pH-stat and the alpha-stat groups. The ScO_2 half-life during arrest was significantly greater in the pH-stat than in the alpha-stat group. *(From Kurth et al [125])*

immediately after ATP is consumed in the phosphorylation of glucose. [135]

Hyperglycemia

Although a strong scientific argument can be made for the detrimental effects of hyperglycemia during ischemia, there is very little evidence supporting worsening neurologic outcome in hyperglycemia during CPB or DHCA in children. A retrospective review of 34 children undergoing DHCA suggested a worse neurologic outcome in the hyperglycemic children; however, the results were reported as a nonsignificant statistical trend. [136] A pathologic review of acquired neurologic lesions in patients undergoing the Norwood Stage I procedure for hypoplastic left heart syndrome suggested hyperglycemia as a significant associated finding in patients with extensive cerebral necrosis or intraventricular hemorrhage. Although associated, a host of other potentially damaging factors (e.g., periods of hypoxia, low diastolic and systolic pressure, and thrombocytopenia) were statistically associated with the observed neuropathology. [137] Since hyperglycemia accompanies a generalized stress response, this literature has failed to distinguish whether glucose directly contributes to neurologic injury or merely serves as a marker for a high-risk population who ultimately suffer neurologic insult as a result of other factors.

Hypoglycemia

Hypoglycemia is a frequent concern in neonates during the perioperative period. Reduced hepatic gluconeogenesis coupled with decreased glycogen stores place the newborn at increased risk of hypoglycemic events. In newborns with congenital heart disease, reduced systemic perfusion (e.g., critical coarctation, hypoplastic left heart syndrome, critical aortic stenosis) may result in worsening hepatic biosynthesis, further impairing glucose production. These patients may be fully dependent on exogenous glucose; therefore, it is not uncommon for them to require 20 to 30 percent dextrose infusions to maintain euglycemia in the pre-bypass period. Older children are not immune to hypoglycemic events and are therefore susceptible to hypoglycemia-induced neurologic injury. Patients with low cardiac output states (cardiomyopathies, pretransplant patients, critically ill postoperative patients) requiring reoperation and on substantial inotropic support are at risk of reduced glycogen stores and intraoperative hypoglycemia. [138]

The impact of hypoglycemia during bypass is further complicated by the consequences of hypothermia, CO_2 management, and other factors that may modify normal cerebrovascular responses during bypass. In a dog model, insulin-induced hypoglycemia to 30 mg/dL does not alter the electroencephalographic findings. However, after 10 minutes of hypocapnic hypoglycemia, the electroencephalogram becomes flat. [115] When regional blood flow was examined in these animals, cortical and hippocampal blood flow remained normal, whereas other regions of the brain had reduced flow. The loss of electroencephalographic activity from hypoglycemia alone does not normally occur above glucose levels of 8 mg/dL. [139]

During deep hypothermic CPB and DHCA, CBF and metabolism are altered. The additive effect of hypoglycemia, even if mild, may cause alterations in cerebral

autoregulation and culminate in increased cortical injury. [137] [140] The common practice of using hyperventilation to reduce pulmonary vascular resistance in neonates and infants during weaning from CPB and in the early post-bypass period could further exacerbate hypoglycemic injury. Glucose monitoring and rigid maintenance of euglycemia are an important part of CPB management in the congenital heart patient.

Renal Effects

After CPB, the combined effects of hypothermia, nonpulsatile perfusion, and reduced mean arterial pressure cause release of angiotensin, renin, catecholamines, and antidiuretic hormone. [141] [142] [143] These circulating hormones promote renal vasoconstriction and reduce renal blood flow. Yet despite the negative impact of CPB on renal function, studies have been unable to link low-flow, low-pressure, nonpulsatile perfusion with postoperative renal dysfunction (Table 50-8) . [141] [144] The factors that best correlate with postoperative renal dysfunction are preoperative renal dysfunction and profound reductions in post-CPB cardiac output. Preoperative factors include primary renal disease, low cardiac output, and dye-related renal injury after cardiac catheterization. [143]

The incidence of acute renal insufficiency after pediatric cardiac surgery is approximately 8 percent. Multiple causative factors are involved, the final common pathway of which is oliguria and an elevated serum creatinine. Diuretics have been the mainstay of promoting urine flow after pediatric cardiopulmonary bypass. Furosemide in a dose of 1

TABLE 50-8 -- Sequelae of Pediatric Cardiopulmonary Bypass

END-ORGAN INJURY	ETIOLOGY/SIGNS
Renal injury	Organ immaturity, pre-existing renal disease
	Post-cardiopulmonary bypass low CO, use of DHCA
	Renal dysfunction: characterized by reduced GFR and ATN
Pulmonary injury	Endothelial injury, increased capillary leak, complement activation, and leukocyte degranulation
	Pulmonary dysfunction: characterized by reduced compliance, reduced FRC, and increased A-a gradient
Cerebral injury after DHCA	Loss of autoregulation, suppressed metabolism and cerebral blood flow, cellular acidosis, and cerebral vasoparesis
	CNS dysfunction: characterized by seizures, reduced developmental quotients, choreoathetosis, learning disabilities, behavioral abnormalities

Abbreviations: ATN--acute tubular necrosis; CNS--central nervous system; CO--cardiac output; DHCA--deep hypothermic circulatory arrest; GFR--glomerular filtration rate

to 2 mg/kg or ethacrynic acid 1 mg/kg every 4 to 6 hours, or both, induces a diuresis and may reverse renal cortical ischemia associated with CPB. After DHCA, it is not unusual to observe a 24-hour period of oliguria or anuria that resolves over the next 12- to 24-hour period. The use of diuretics is effective only after spontaneous urine output has been initiated in these patients.

Glomerular filtration rate, creatinine clearance, and medullary concentrating ability are substantially reduced in neonates and young infants. Therefore, the use of CPB in these patients is associated with greater fluid retention than is typically seen in older children and adult patients. The net result may be increased total body water, increased organ weight (e.g., lungs, heart), and greater difficulty with postoperative weaning from ventilatory support. The use of ultrafiltration during rewarming or after CPB is effective in reducing total body water, limiting the damaging effects of CPB, and decreasing the postoperative ventilation period. [145] [146]

Pulmonary Effects

While cardioplegia protects the heart, there is no parallel protection afforded the lung during bypass. Pulmonary dysfunction is common after cardiopulmonary bypass and its pathogenesis is poorly understood (see Table 50-8) . In broadest terms, lung injury is mediated in one of two ways: first, an inflammatory response due to leukocyte and complement activation, and second, a mechanical effect culminating in surfactant loss, atelectasis with resultant ventilation/perfusion mismatch, loss of lung volumes, and altered mechanics of breathing.

Pulmonary function after cardiopulmonary bypass is characterized by reduced static and dynamic compliance, reduced functional residual capacity, surfactant deficiency, and an increased A-a gradient. [147] [148] Atelectasis and increased capillary leak due to hemodilution, and hypothermic CPB are the most likely etiologies. Hemodilution reduces circulating plasma proteins, reducing intravascular oncotic pressure, and favors water extravasation into the extravascular space. Hypothermic CPB causes complement activation and leukocyte degranulation. [149] Leukocytes and complement are important in causing capillary-alveolar membrane injury and microvascular dysfunction through platelet plugging and release of mediators, which increase pulmonary vascular resistance. The technique of modified ultrafiltration is highly effective in reducing lung water and pulmonary morbidity during the postoperative period.

Stress Response and CPB

The release of a large number of metabolic and hormonal substances, including catecholamines, cortisol, growth hormone, prostaglandins, complement, glucose, insulin, endorphins, and other substances, characterizes the stress response during hypothermic CPB. [18] [150] [151] The likely causes for the elaboration of these substances include contact of blood with the nonendothelialized surface of the pump tubing and oxygenator, nonpulsatile flow, low perfusion pressure, hemodilution, hypothermia, and light anesthesia depth. Other factors that may contribute to elevations of stress hormones include delayed renal and hepatic clearance during hypothermic CPB, myocardial injury, and exclusion of the pulmonary circulation from bypass. The lung is responsible for metabolizing and clearing many of these stress hormones. The stress response generally peaks during rewarming from cardiopulmonary bypass. There is strong evidence that the stress response can be blunted by increasing the depth of anesthesia. [18] [150] [151]

It is unclear at what level elevated circulating stress hormones, a normal neonatal adaptive response, become detrimental. There is little question that these substances could mediate undesirable effects such as myocardial damage (catecholamines), systemic and pulmonary hypertension (catecholamines, prostaglandins), pulmonary endothelial damage (complement, prostaglandins), and pulmonary vascular reactivity (thromboxane). The benefits of controlling the stress response with fentanyl in premature infants undergoing PDA ligation and with sufentanil in neonates with complex congenital heart disease have been demonstrated. [85] [152] Although blunting the stress response seems warranted, there is additional evidence suggesting that the newborn stress response, especially the endogenous release of catecholamines, may be an adaptive metabolic response necessary for survival at birth. [153] Thus the complete elimination of an adaptive stress response may not be desirable. To what extent acutely ill neonates with congenital heart disease are dependent on their stress response for maintaining hemodynamic stability is currently unknown.

It is, therefore, prudent to maintain a depth of anesthesia adequate to attenuate the stress response, but to attempt to block the response altogether may not be necessary. Acceptable anesthesia during CPB may be best accomplished by either the continuous administration of an inhalation anesthetic via a vaporizer connected to the pump oxygenator, careful titration of incremental doses of opioids, or the precise administration of an opioid or opioid and benzodiazepine by a continuous infusion technique. Primary opioid anesthetic techniques result in reduced stress hormone release and decreased postoperative metabolic acidosis and lactate production when compared with primary halothane anesthesia and may therefore be a preferred technique in complex congenital heart disease. [85] If depth of anesthesia is accomplished by the administration of excessively large doses of opioids (e.g., fentanyl or sufentanil), postoperative mechanical ventilation will be necessary. By contrast, residual levels of inhalation anesthetic drugs (e.g., halothane or isoflurane) can produce transient myocardial depression at the termination of CPB, complicating separation from CPB.

Discontinuation of CPB

When weaning from CPB, blood volume is assessed by direct visualization of the heart and monitoring right atrial or left atrial filling pressures. When filling pressures

are adequate, the patient fully warmed, acid-base status normalized, heart rate adequate, and sinus rhythm achieved, the venous drainage is stopped and the patient can be weaned from bypass. The arterial cannula is left in place so that a slow infusion of residual pump blood can be used to optimize filling pressures. Myocardial function is assessed by direct

cardiac visualization and either a transthoracic left or right atrial catheter, by a percutaneous internal jugular catheter, or by the use of intraoperative echocardiography. Pulse oximetry can also be used to assess the adequacy of cardiac output. [154] Low systemic arterial saturation or the inability of the oximeter probe to register a pulse may be a sign of very low output and high systemic resistance. [155]

After the repair of complex congenital heart defects, the anesthesiologist and surgeon may have difficulty separating patients from cardiopulmonary bypass. Under these circumstances, a diagnosis must be made and includes (1) an inadequate surgical result with a residual defect requiring repair, (2) pulmonary artery hypertension, and (3) right or left ventricular dysfunction. Two general approaches are customarily used, either independently or in conjunction with one another. An intraoperative "cardiac catheterization" can be performed to assess isolated pressure measurements from the various great vessels and chambers of the heart (i.e., catheter pullback measurements or direct needle puncture to evaluate residual pressure gradients across repaired valves, sites of stenosis and conduits, and oxygen saturation data to examine for residual shunts). [156] Alternatively, echo-Doppler may be used to provide an intraoperative image of structural or functional abnormalities to assist in the evaluation of the postoperative cardiac repair. [16] [157] If structural abnormalities are found, the patient can be placed back on CPB, and residual defects can be repaired before the patient leaves the operating room. Leaving the operating room with a significant residual structural defect adversely affects survival and increases patient morbidity (see Fig. 50-5) . [16] [157] For the anesthesiologist, echo-Doppler can rapidly identify right and left ventricular dysfunction and suggest the presence of pulmonary artery hypertension. In addition, echo-Doppler can identify regional wall motion abnormalities due to ischemia or intramyocardial air that will direct specific pharmacologic therapy and provide a means of assessing the results of these interventions (Fig. 50-12) . [158]

Modified Ultrafiltration

One important factor affecting morbidity and mortality after cardiac surgery in children is the effect of CPB. During the initiation of CPB, considerable hemodilution occurs. This hemodilution is the result of the priming volume required for the CPB circuit. Under many circumstances this hemodilutional effect is intentional, decreasing blood viscosity and thereby preventing sludging when the patient is cooled to temperatures below 20°C. After CPB, hemodilution is associated with tissue edema and organ dysfunction. Because blood elements are exposed to the nonendothelialized circuitry of CPB, there is also a significant inflammatory response as a result of CPB. Both these effects of hemodilution and inflammation are exaggerated in neonates, infants, and young children because of their disproportionate exposure to the circuit relative to their body size. This inflammatory response leads to an increase in capillary permeability, leading to an overall increase in total body edema postoperatively.

Efforts to reduce the hemodilution and inflammatory effects of CPB have included reducing priming volume, perioperative anti-inflammatory and diuretic therapies, and the use of postoperative peritoneal dialysis. The technique of modified ultrafiltration (MUF) was first used clinically as an alternative method to reduce the adverse effects of CPB in children. [159]

The technique of MUF is performed after CPB is complete and allows filtration of both the patient and remaining contents of the CPB circuit, including the venous reservoir. [160] [161] [162] Using the MUF technique, an ultrafilter is interposed in the CPB circuit between the aortic arterial line and the venous canula, which is located in the right atrium. After weaning from CPB, the blood is removed from the patient via the aortic canula and fed through the ultrafilter along with blood from the venous reservoir and oxygen. The outlet of the ultrafilter is fed to the right atrium of the patient. Blood flow through the ultrafilter approximates 200 mL per

Figure 50-12 *(A)* Two-dimensional echocardiogram in the short-axis view across the ventricles demonstrating the presence of intramyocardial air (arrow) in the ventricular septum and right ventricular (RV) wall. The intramyocardial air appears as a dense, "snowy" echogenic area. Note the associated wall motion abnormality appearing as flattening of the ventricular septum. *(B)* The patient was treated with phenylephrine, increasing systemic and coronary perfusion pressure, resulting in clearance of the air and the echogenic density and restoration of normal left ventricular (LV) wall motion and configuration.

minute, which is maintained by a roller pump. Suction is applied to the filter port of the ultrafilter, resulting in an ultrafiltration rate of 100 to 150 mL per minute. A constant left atrial or right atrial pressure is maintained, achieving continued hemodynamic stability in the patient. Ultrafiltration is carried out with the end point being either time (15-20 minutes) or the achievement of a hematocrit value of approximately 40. [161]

Ultrafiltration appears to offer two major advantages. First, total body water is reduced as a direct result of removing the ultrafiltrate. [159] This effect counteracts the hemodilution effects associated with the institution of CPB. In addition, the hematocrit is raised after cardiopulmonary bypass, enhancing oxygen delivery to the tissues. Secondly, MUF has been shown to remove some of the deleterious vasoactive substances associated with inflammatory response to CPB. [163] [164] This effect is mediated by reducing circulating cytokines, which are associated with capillary leak syndrome. Examination of the ultrafiltrate shows that it contains low-molecular-weight inflammatory mediators, including C3a, C5a, interleukin-6alpha, interleukin-8alpha, tumor necrosis factor, myocardial depressant factor, and various other cytokines. Several studies have shown that, compared with control patients, patients who undergo MUF after CPB have substantially less increase in total body water, demonstrate less complement and interleukin release, require fewer blood transfusions, and show a faster recovery of systolic blood pressure (Fig. 50-13) (Figure Not Available) . [159] [161] [165]

In a clinical study examining the effect of MUF on left ventricular systolic function in children, MUF was associated with an increase in intrinsic left ventricular systolic function and a decrease in end-diastolic pressure, thereby improving left ventricular compliance. [166] In an experimental study, MUF has also been demonstrated to improve CBF, cerebral metabolic activity, and cerebral oxygen delivery after DHCA (Fig. 50-14) (Figure Not Available) . [167] This last effect acutely improves cerebral metabolism after DHCA and may reduce and reverse the known deleterious effects of DHCA on brain function after CPB. In another clinical study MUF was demonstrated to reduce postoperative blood use, chest

tube drainage, plural effusions, and hospital stay in patients after cavopulmonary operations. [168]

An alternative to MUF is conventional filtration during the rewarming period of CPB. In an experimental model examining MUF versus conventional ultrafiltration, only MUF was effective in reducing weight gain and myocardial edema, and was associated with improving left ventricular function. [169] Possible complications of MUF include air embolus, patient cooling during ultrafiltration, and bleeding. [161] These theoretical and technical potential complications appear not to be of substantial concern. It is the view of most groups that the benefits of MUF far exceed the risk. [162]

In summary, MUF is a safe adjunct, reversing the deleterious effects of hemodilution and the inflammatory response associated with CPB in children. Perioperative blood loss and blood use is significantly reduced when MUF is used. MUF also improves left ventricular function and systolic blood pressure and increases oxygen delivery. Pulmonary compliance and brain function after CPB are also improved. Therefore, the use of MUF is becoming more routine in pediatric patients after CPB.

Specific Problems Encountered in Discontinuing CPB

Left Ventricular Dysfunction

The contractile state of the LV may be reduced after pediatric cardiac surgery. This is due to surgically induced ischemia during the repair, the preoperative condition of the myocardium, the effects of deep hypothermia and circulatory arrest on myocardial compliance, and new altered loading conditions on the LV caused by the repair. [170] [171] [172] LV dysfunction can be treated by optimizing preload, increasing heart rate, increasing coronary perfusion pressure, correcting ionized calcium levels, and adding inotropic support. The neonate's heart rate-dependent cardiac output, reduced

myocardial compliance, and diminished response to calcium and catecholamines are factors influencing the need for inotropic support. Inotropic support is usually begun with dopamine (3-10 mug/kg/min). Several studies suggest that the effect of dopamine in children is age-dependent. In young children after cardiac surgery, dopamine increases cardiac output, which correlates more with elevations in heart rate than augmentation of stroke volume, [173] whereas in young adults, dopamine clearly increases stroke volume. [13] Nonetheless, infants and neonates respond favorably to dopamine infusions with increased systemic blood pressure and cardiac output and improved systemic perfusion.

Calcium supplementation is also important in augmenting cardiac contractility. Although calcium has fallen into some disfavor because of concerns over reperfusion injury, calcium supplementation remains an important therapy after pediatric cardiac surgery. Fluctuations in ionized calcium levels occur commonly in the immediate post-CPB period in children. This is most often due to the relatively large transfusions of citrate and albumin-rich blood products such as whole blood, fresh frozen plasma, platelets, and cryoprecipitate necessary for hemostasis, all of which bind calcium. [174] Routine calcium supplementation during the early post-CPB period is especially helpful in patients with diminished LV function. In patients with a slow sinus or junctional rate, calcium must be administered cautiously, as marked slowing of AV conduction may occur.

Epinephrine (0.02-0.2 mug/kg/min) is useful in patients with significant LV dysfunction who remain hypotensive with high left atrial filling pressures or echo-Doppler evidence of reduced contractility or regional ischemia. [175]

Amrinone is a nonglycoside, noncatecholamine inotropic drug whose mechanism of action is through the inhibition of phosphodiesterase, which prevents the breakdown of cyclic adenosine monophosphate and results in increased calcium transport. Amrinone causes an increase in myocardial contractility and systemic and pulmonary artery vasodilation. [176] [177] Neonates and infants show considerable benefit from the phosphodiesterase inhibitors, especially those whose myocardium is afterload sensitive, such as postoperative arterial switch patients. [177] Pharmacokinetic studies suggest that loading dosages for children are twice the recommended adult dose (i.e., 2-4.5 mg/kg). [178] In the authors' experience, amrinone in loading doses of 2 to 3 mg/kg and infusion rates of 5-15 mug/kg/min are very useful in the management of low cardiac output states in neonates, infants, and children. Higher loading doses (3-4 mg/kg) have been associated with a profound systemic vasodilation in the pediatric cardiac patient. Because the onset of peripheral vasodilation precedes the increase in inotropy during the loading phase, significant hypotension may occur if amrinone is loaded too rapidly. It may therefore be prudent to load slowly or while the patient is on CPB. In so doing, however, upward adjustment in the loading dose becomes necessary to compensate for the substantially larger circulating volume and the fact that 20 percent of the dose is bound to the CPB circuit. [179]

Milrinone, a more potent phosphodiesterase-3 inhibitor, is also an effective inotrope-vasodilator in infants and children. Studies in neonates after open heart surgery reveal significant reductions in SVR and PVR and increases in cardiac index, primarily due to larger stroke volume. [180] Infants and children demonstrate a larger volume of distribution and clearance of milrinone compared to adults; thus, the loading dose necessary to achieve therapeutic levels may be as high as 100 mug/kg. [181] When loading occurs on CPB, appropriate adjustment should be made (~.3 mg/L priming volume), but unlike amrinone, milrinone does not appear to bind the bypass circuit.

Dobutamine is an effective, albeit weaker, inotropic agent in children. Although it is reported to have fewer chronotropic effects than dopamine, in neonates, significant tachy-arhythmias may occur. This may relate to structural similarities between dobutamine and isoproterenol. [175] In children after cardiac surgery, dobutamine increases cardiac output primarily through increased heart rate. The efficacy of dobutamine seems to be reduced in immature animals. [182] This is consistent with reduction in beta-receptors and a higher level of circulating catecholamines in newborns.

Right Ventricular Dysfunction

Primary RV dysfunction is a common finding after CPB in neonates, infants, and children. For example, after repair of tetralogy of Fallot, pre-existing RV hypertrophy, a right ventriculotomy, and the placement of a transannular patch across the RV outflow tract, resulting in acute pulmonary regurgitation and RV volume overload, are common causes of postoperative RV dysfunction. [23] The treatment of RV dysfunction consists of measures directed at lowering PVR and preserving coronary perfusion without distending the RV. Metabolic acidosis should be addressed and inotropic agents selected for their vasodilating properties (e.g., dopamine, amrinone, or milrinone). In cases of extreme ventricular dysfunction, low-dose epinephrine (0.01-0.03 mug/kg/min) may provide inotropy without vasoconstriction. [171] [183] [184] Mechanical ventilation should be adjusted to assist RV function and minimize PVR.

In contrast to the LV, the low intracavitary pressure of the normal RV receives two-thirds of its coronary filling during ventricular systole. [185] In patients with RV dysfunction, maintaining a normal or slightly elevated systolic arterial pressure maximizes coronary perfusion to the RV and augments contractility. If the need for inotropic support persists after the early post-CPB period, a critical evaluation for other structural and functional abnormalities should be aggressively pursued. Preload should be maintained at a normal to slightly elevated level. Since RV contractility is reduced, it is important to maximize preload to the highest portion of the Starling curve. [183] Overdistention of the RV, however, is not well tolerated owing to diminished ventricular compliance and diastolic dysfunction. Excessive volume loading may result in significant diastolic dysfunction, tricuspid regurgitation, and worsening forward flow. Generally, CVPs much above 12 to 14 mm Hg are poorly tolerated in neonates and infants with RV dysfunction. [186] If RV dysfunction is severe, the sternum should be left open. [187] This eliminates the impedance imposed by the chest wall and mechanical ventilation, allowing the RV to maximize its end-diastolic volume. An additional strategy in neonates, infants, and children with significant post-CPB RV dysfunction is to allow right-to-left shunting at the atrial level. Typical patients who would benefit from this strategy include neonates

undergoing repairs for tetralogy of Fallot and truncus arteriosus. Allowing an atrial communication to remain open, with blood shunting in a right-to-left direction, preserves cardiac output and oxygen delivery to the systemic circulation. Although these patients have somewhat diminished systemic oxygen saturation, as their effective cardiac output and tissue oxygen delivery are enhanced, systemic perfusion pressure improves and coronary perfusion of the RV is maintained. As RV function improves, right atrial pressure falls, right-to-left shunting decreases, and systemic arterial saturation rises.

If RV dysfunction persists to the extent that systemic cardiac output is compromised, consideration should be given to extracorporeal life support (ECMO). When ECMO is used for circulatory support, venoarterial cannulation is chosen. Venous and arterial access may be achieved through a large central artery and vein, usually the carotid artery and internal jugular vein, or by direct chest cannulation. Recovery from severe ventricular dysfunction is predicated on the concept that the myocardium has sustained a transient injury (i.e., "stunned myocardium") and is capable of recovery with time. [188] [189] ECMO is used to decrease ventricular wall tension, increase coronary perfusion pressure, and maintain systemic perfusion with oxygenated blood. ECMO may also be used for LV failure, although success with this condition is less common than that seen with RV dysfunction or pulmonary artery hypertension. Patients placed on ECMO because they fail to separate from CPB demonstrate significantly higher mortality than those for whom ECMO was instituted later in the postoperative course. [190] The children who consistently suffer the lowest survival are those who require ECMO after a Fontan operation. [191] The role of ECMO in patients with myocardial injury or pulmonary hypertension is to provide adequate systemic oxygen transport and systemic perfusion while allowing the ventricles to rest and recover. ECMO may even provide an effective means of resuscitation for postoperative cardiac patients, particularly if instituted promptly. [192] In larger infants and children with predominantly RV dysfunction and satisfactory pulmonary function, a selective RV assist device may be preferable to ECMO. [193]

Pulmonary Artery Hypertension

Therapy for elevated pulmonary artery pressures is directed at lowering PVR and unloading the RV. Reduction of PVR is accomplished by altering ventilation pattern, inspired oxygen concentration, and blood pH. Specifically, manipulating the pulmonary vascular bed in newborns and infants is a matter of regulating Pa $_{CO_2}$, pH, Pa $_{O_2}$, P $_{AO_2}$, and ventilatory mechanics. [194] [195] Pa $_{CO_2}$ is a potent mediator of PVR, especially in the newborn and young infant. Reducing Pa $_{CO_2}$ to 20 mm Hg and increasing pH to 7.6 produces a consistent and reproducible reduction in PVR in infants with pulmonary artery hypertension. [194] Manipulating serum bicarbonate levels to achieve a pH of 7.5 to 7.6 while maintaining a Pa $_{CO_2}$ of 40 mm Hg has equal salutary effects on PVR. [196] Both the Pa $_{O_2}$ and the P $_{AO_2}$ decrease PVR as well. [197] In the circumstance of intracardiac shunts, changes in Fi $_{O_2}$ have little effect on Pa $_{O_2}$. Thus, by inference, a reduction in PVR induced by increasing the inspired oxygen concentration is probably a direct pulmonary vasodilatory effect of P $_{AO_2}$ rather than Pa $_{O_2}$.

Ventilatory mechanics also play a major role in reducing PVR. [198] [199] Newborns and infants have a closing volume above functional residual capacity. Thus, at the end of a normal breath, some airway closure occurs. [200] This process results in areas of lung that are perfused and yet underventilated. As these lung segments become increasingly hypoxemic, secondary hypoxic vasoconstriction occurs. The net effect is an increase in PVR. Therefore, careful inflation of the lungs to maintain functional residual capacity will selectively reduce PVR. In practice, this is accomplished with relatively large tidal volumes and low respiratory rates, which produce an exaggerated chest excursion. Generally, tidal volumes of 15 to 25 mL/kg are required. Respiratory rates of 15 to 25 breaths per minute are used for newborns and infants. A reduced ventilatory rate with large tidal volumes reduces mean airway pressure and provides a longer expiratory phase of ventilation. Since pulmonary blood flow occurs predominantly during the expiratory phase of the respiratory cycle, the ventilatory pattern should be adjusted to allow an adequate distribution of gas throughout the lung during inspiration and a more prolonged expiratory phase to promote blood flow through the lungs. End-expiratory pressure must be applied cautiously during the post-CPB period. Low positive end-expiratory pressure (3-5 mm Hg) prevents narrowing of the capillary and precapillary blood vessels, thereby reducing PVR. [201] Higher positive endexpiratory pressure or excessive mean airway pressure results in alveolar overdistention and compression of the capillary network in the alveolar wall and interstitium. This condition elevates PVR and reduces pulmonary blood flow. [147]

The final and perhaps the least well-recognized use of the mechanical ventilator is to assist in unloading the RV. During inspiration, intrathoracic pressure increases and creates an increased pressure gradient from the lung to the left atrium, promoting cardiac output. This ventilatory assist is commonly seen in patients with pulmonary artery hypertension or RV dysfunction. An augmentation of the arterial pressure trace during inspiration is seen. The use of the ventilator to augment systemic blood flow is very similar to the thoracic pump concept used to explain blood flow during CPR. [202] The inspiratory assist must be balanced by the potential negative effects of increased mean airway pressure on PVR and RV afterload. To maximize these cardiopulmonary interactions, high tidal volume with low respiratory rates should be employed.

Attempts to manipulate PVR through pharmacologic interventions have been generally unsatisfactory. Drugs that have shown the greatest promise in decreasing PVR both clinically and experimentally have been the phosphodiesterase inhibitors. Amrinone and milrinone are the only drugs of this class currently available in the United States. Both reduce PVR and systemic vascular resistance and increase RV contractility. [177] [178] Isoproterenol has mild pulmonary artery vasodilating properties in the normal pulmonary circulation. [203] Isoproterenol reduces PVR in adults after cardiac transplantation, but there are very few data to support PVR reduction in infants and young children after cardiac surgery. In immature animals, the myocardium is less responsive to isoproterenol and causes tachycardia and

increased myocardial oxygen consumption. [204] [205] These latter effects may reduce coronary perfusion and result in relative myocardial ischemia. Both prostaglandin E_1 and prostacyclin have a pulmonary vasodilating effect [206] [207] however, both drugs produce systemic hypotension, which severely limits their use.

Because of the lack of specificity of vasodilator drugs on the pulmonary bed, newer pharmacologic methods of controlling pulmonary artery hypertension and elevated PVR are being sought. Two new concepts include ultra-shortacting intravenous vasodilators and inhaled vasodilating agents such as nitric oxide. Ultra-short-acting intravenous vasodilators are nonspecific potent vasodilators, with a half-life measured in seconds. Infusion of these drugs into the right side of the circulation produces a potent short-lived relaxation of the pulmonary artery smooth muscle. Once the drug reaches the systemic circulation, it is no longer functional. Adenosine and ATP-like compounds have these properties and may have clinical applicability in pulmonary artery hypertension in the future. [208]

Nitric oxide, an endothelium-derived vasodilator that is administered as an inhaled gas, represents the most promising development in the therapy of elevated PVR in patients with congenital heart disease. Although nonselective, it is rapidly inactivated by hemoglobin and, when inhaled, produces no systemic vasodilation. [209] Nitric oxide reduces pulmonary artery pressure in adult patients with mitral valve stenosis and in selected pediatric cardiac patients with pulmonary artery hypertension. [210] [211] [212] The congenital cardiac patient population in whom nitric oxide appears to be effective are those patients with acute PVR elevations following open heart surgery, as well as preoperative pulmonary hypertension accompanying specific anatomic conditions (e.g., total anomalous pulmonary venous return, congenital mitral stenosis). [211] [212] Because it acts directly on vascular smooth muscle, nitric oxide remains effective despite the post-CPB endothelial injury frequently encountered in children. [213] Some centers routinely employ nitric oxide in low dose (1-5 ppm) following Fontan operation when the CVP-left artrial pressure gradient exceeds 10 mm Hg. [214] Finally, nitric oxide can provide diagnostic information that helps distinguish reactive pulmonary vasoconstriction from fixed anatomic obstructive disease either in the postoperative surgical patient or in the patient undergoing pretransplant evaluation. [215] [216] In the latter, the distinction between pulmonary vasoconstriction and advanced pulmonary vascular occlusive disease will influence the prediction as to whether a child with pulmonary hypertension in association with either congenital heart disease or cardiomyopathy will survive a heart transplant or requires replacement of both heart and lungs.

ANTICOAGULATION, HEMOSTASIS, AND BLOOD CONSERVATION

Modern pediatric cardiac anesthesia must include the principles and practice of effective anticoagulation, hemostasis, and blood conservation. Bleeding after cardiopulmonary bypass remains a significant problem in pediatric cardiac surgery. [217] Continuing blood loss post-CPB requiring blood component replacement is associated with hemodynamic compromise as well as morbidity from multiple donor exposures. In pediatric patients, restoration of hemostasis has proved difficult; diagnosis of the problem and treatment are marginally effective.

Neonates, infants, and children undergoing cardiac surgery with CPB have a higher rate of postoperative bleeding than that seen in older patients. [217] This is due to several factors. First, there is disproportionate exposure to the nonendothelialized extracorporeal circuit, which produces an inflammatory-like response. [17] This inflammatory response to cardiopulmonary bypass is inversely related to patient age; the younger the patient, the more pronounced the response. [17] [18] As complement and platelet activation are linked to the activation of other protein systems in the blood (i.e., fibrinolytic), it is probable that this hemostatic activation, which results in impaired hemostasis and increased bleeding tendency, plays a major role during pediatric cardiac surgery. Second, the type of operations performed in neonates and infants usually involves more extensive reconstruction and suture lines, creating more opportunities for surgical bleeding than in adult cardiac patients. Operations are also frequently performed using deep hypothermia or circulatory arrest, which may further impair hemostasis. [218] Third, the immature coagulation system in neonates may also contribute to impaired hemostasis. [219] While procoagulant and factor levels may be reduced in young patients with congenital heart disease due to immature or impaired hepatosynthesis, [220] functional bleeding tendencies are usually not present before surgery. Finally, patients with cyanotic heart disease demonstrate an increased bleeding tendency before and after CPB. [221]

Cardiopulmonary bypass is a significant thrombogenic stimulus requiring anticoagulation with heparin prior to its initiation. Heparin is usually administered empirically based on patient weight, and its effect is followed by activated clotting time monitoring. Because heparin effect is primarily due to coupling with antithrombin III and because there are age-related differences in quantitative differences in procoagulants and inhibitors, variability of heparin dosing and its effect have been a concern. High heparin sensitivity is observed in the 1st week of life and then decreases progressively until about 3 years of age, when values approach those observed in adults. [222] These findings are consistent with evidence in infants of variable quantities of both procoagulants and inhibitors, especially prothrombin and antithrombin III. [223] Heparin administration to the patient must also include a consideration of the quantity and composition of the priming volume for CPB, especially if fresh frozen plasma is added. The authors recommend a heparin dose of 200 U/kg plus an additional dose of 1 to 3 U/mL of prime and maintaining the activated clothing time above 400 seconds.

Heparin is neutralized with protamine dosed according to the quantity of heparin administered or based on body weight. Protamine excess may actually contribute to postoperative bleeding. [224] It appears that the protamine dose requirement is high for neonates and decreases with age. The relatively increased protamine requirement for young as compared with older children and adults is indicative of higher circulating heparin levels after CPB. [225] Delayed hepatic clearance of heparin due to organ immaturity and the predominant use of hypothermic circulatory arrest in the young will decrease metabolism and excretion of heparin.

We typically administer 4 mg/kg protamine in neonates, whereas 2 mg/kg usually restores the activated clotting time to baseline values in adolescents and adults. Interpatient variability mandates some form of individual assessment to guide drug dose, to prevent excess protamine. [224]

Neonates and young infants with congenital heart disease will have low circulating levels of procoagulants and inhibitors. The thrombogenic and dilutional effects of CPB further contribute to hemostatic abnormalities after CPB. Formed blood elements such as leukocytes and platelets may be activated and procoagulants diluted by CPB. Furthermore, deep hypothermic circulatory arrest causes increased clotting and fibrinolytic activity. The lower the temperature, the higher the degree of hemostatic activation. Therefore, the causes of bleeding post-CPB are many. Injudicious use of blood products to correct individual coagulation abnormalities separately can further exacerbate dilution of existing procoagulants as well as carry the risks of multiple donor exposure. Because the transfusion of blood products is associated with numerous complications, transfusion is to be assiduously avoided, unless specifically indicated by an impairment in tissue oxygenation or documented coagulopathies with clinically significant bleeding. All efforts at blood conservation during cardiac surgery should be routinely employed by all members of the operative team, intraoperatively as well as postoperatively.

Bleeding after CPB is not an unusual occurrence. The surgeon should first attempt to identify any obvious source of surgical bleeding at the sites of repair. Next, adequate protamine reversal of heparin is assessed by measuring an activated clotting time. In general, standard coagulation tests show a prolongation of the partial thromboplastin time, prothrombin time, hypofibrinogenemia, and dilution of other procoagulants as well as a prolonged bleeding time in many pediatric patients, with and without bleeding (Fig. 50-15) . The most common reason for persistent bleeding is platelet dysfunction. [226] [227] Under such circumstances, administration of platelets is warranted in the presence of bleeding. Routine administration of blood products to correct laboratory coagulation abnormalities in the absence of bleeding is never clinically indicated. After platelets have been given and if bleeding is still present, reassessment and repeat platelet infusion or the administration of cryoprecipitate or fresh frozen plasma may be beneficial. Under most circumstances, meticulous surgical technique, appropriate administration of protamine, adequate patient temperature, and platelet infusion will correct excessive bleeding. In neonates, excessive bleeding as well as the escalating dilutional effects of selective component therapy on the remaining procoagulants in small patients make the treatment of bleeding difficult. The use of fresh whole blood may be warranted under these circumstances. The administration of fresh whole blood (less than 48 hours old) after CPB can meet all the hematologic requirements with minimum donor exposure. The efficacy of whole blood in restoring hemostasis and reducing blood loss after CPB has been demonstrated in patients younger than 2 years of age undergoing complex surgical repairs. [217]

Many attempts have been made to reduce bleeding after CPB by pharmacologic interventions. Desmopressin acetate [228] [229] and the antifibrinolytics aminocaproic acid and tranexamic acid [230] have been tried with variable success in significantly reducing postoperative blood loss after cardiac surgery. However, the most impressive results have been demonstrated with the use of aprotinin. [231] A proteinase inhibitor, aprotinin has antifibrinolytic properties in low concentrations and acts as kallikrein inhibitor at higher levels. CPB causes increased kallikrein by contact activation, promoting thrombus and fibrin generation, which promotes fibrinolysis. The inhibition of kallikrein results in an inhibition of the contact phase of coagulation, and the inhibition of fibrinolysis reduces bleeding. Reduced thrombin generation leads to a diminished platelet stimulation. Better preserved platelet function has been described for patients with aprotinin. [231]

Figure 50-15 Plot of blood coagulation profile changes before, during, and after cardiopulmonary bypass (CPB) in 25 children. Clotting times and coagulant factors are shown as percent change from control. Stage I, baseline, before CPB; stage II, post-CPB, before protamine reversal of heparin; stage III, after protamine; stage IV, just prior to leaving the operating room; stage V, after 3 hours in the intensive care unit (ICU). PTT, partial thromboplastin time; PT, prothrombin time.

Not surprisingly, then, aprotinin significantly reduces the intraoperative and postoperative blood loss in cardiac surgery. [232] [233] [234] [235] Aprotinin use during pediatric cardiac surgery attenuates fibrinolytic activation in a dosedependent fashion, reducing the formation of fibrinsplit products. [218] [236] Higher doses of aprotinin reduce thrombin/antithrombin III complex and F1/F2 fibrin fragments, supporting the hypothesis of suppression of clotting activation with higher aprotinin doses and plasma concentrations. Although several studies have demonstrated efficacy in reducing hemorrhage and donor exposures after congenital heart surgery, this benefit may not be evident with simple primary cardiac repairs (e.g., VSD, ASD, tetralogy of Fallot). [237] [238] To date, the use of aprotinin for congenital heart surgery has been generally confined to certain patients requiring re-operation, such as Ross procedure, and in cardiac/lung transplantation procedures.

The techniques of blood conservation must be continued during the postoperative period. Isolated coagulation abnormalities are often present in the uncomplicated postoperative cardiac patient (see Fig. 50-15) . Usually these coagulation abnormalities self-correct during the first postoperative day and are not associated with excessive bleeding. Therefore, routine correction of these abnormalities with infusion of blood products is not warranted. Administration of blood products should not occur in the absence of clinical evidence of bleeding and the identification of a specific defect requiring targeted component therapy. Routine use of blood products for volume replacement is also to be avoided; lactated Ringer's or saline solution can be satisfactorily administered at a reduced cost without the hazards associated with transfusion.

POSTOPERATIVE MANAGEMENT

Immediate postoperative care of the pediatric patient who has undergone cardiothoracic surgery is an important period in the overall sequence of anesthetic and surgical management. Although the primary influence on outcome is determined by the conduct of the operation, postoperative care is an important factor. As a member of the operative team, it is necessary that the anesthesiologist understand and become involved during the immediate postoperative period. Detailed principles of postoperative management of the pediatric cardiac surgical patients are beyond the scope of this chapter. However, a few general guiding principles and approach are given to provide some fundamental knowledge for the anesthesiologist.

The postoperative period can be characterized by a series of physiologic and pharmacologic changes as the body convalesces from the abnormal biologic conditions of CPB and cardiac surgery. [239] During this period, the effects of the cardiac operation, the patient's underlying diseases, the effects of hypothermic CPB, and special techniques such as DHCA may create special problems. In the immediate postoperative setting, abnormal convalescence and specialized problems must be recognized and managed appropriately. Fortunately, most patients are able to balance the cost imposed by the physiologic trespass created by the surgical repair and the effects of CPB against the benefit of reduced pathophysiologic loading conditions, resulting in low morbidity and mortality. Therefore, the guiding principle in the management of the postoperative patient is an understanding of both normal and abnormal convalescence after anesthesia and cardiac surgery. The immediate postoperative period, even that of normal convalescence, is one of continuous physiologic change because of the pharmacologic effects of residual anesthetic agents and the ongoing physiologic changes secondary to abrupt alteration in hemodynamic loading conditions, surgical trauma, and extracorporeal circulation. Anesthesia and surgery affect not only the patient's conscious state but also cardiovascular, respiratory, renal, and hepatic function; fluid and electrolyte balance; and immunologic defense mechanisms. In spite of all these changes, postoperative care should be predictable and standardized for most patients undergoing cardiac procedures.

In general, there are four temporal phases of postoperative management in the cardiac patient: (1) transport to the ICU, (2) stabilization in the ICU, (3) weaning from inotropic and ventilatory support, and (4) mobilization of fluids. Patients proceed through these phases at variable rates based on such factors as underlying disease process, preoperative medical condition, sequelae of the surgical procedure, duration of CPB, and presence or absence of intraoperative complications. One of the most important functions of the ICU team is to identify postoperative complications in the patient who convalesces abnormally and to provide interventional therapy. Because physiologic change after cardiac surgery is dramatic but self-limiting during normal convalescence, recognition of abnormal processes can be difficult. Under such circumstances a uniform, multidisciplinary approach with experienced clinicians and nurses facilitates the identification of any abnormalities in convalescence. These abnormalities often are indications for closer observation, more invasive monitoring, pharmacologic intervention, and increased cardiopulmonary technical support. Complications include hypovolemia, residual structural heart defect, right and left ventricular failure, hyperdynamic circulation, pulmonary artery hypertension, cardiac tamponade, arrhythmias, cardiac arrest, pulmonary insufficiency, oliguria, seizures, and brain dysfunction. It is critical to detect these departures from the normal convalescent course and to treat them aggressively.

One important area in which the anesthesiologist can aid the recovery of the cardiac patient is pain control. Pain and sedation are among the most common problems requiring ICU intervention. Many factors influence the onset, incidence, and severity of postoperative pain. The attenuation of the stress response in the immediate postoperative period using infusions of potent opioids in the critically ill infant reduces morbidity. [85] Attenuation of postoperative pain can be attempted with a preoperative medication and an intraoperative anesthetic management technique that includes the use of potent opioids. Patients who receive no opioid preoperatively or during the operative procedure will require analgesics in the immediate postoperative period once the inhalation anesthetic is eliminated. Most cases of postoperative pain can be managed by the administration of small intravenous doses of opioids, usually morphine. This is important in a patient being weaned from the ventilator during the early postoperative period. Patients who are intubated and ventilated overnight should receive adequate sedation and pain control until ventilatory weaning is begun. This is

---

usually accomplished by a continuous infusion of a benzodiazepine and an opioid. Continuous infusion of sedatives and analgesics results in a more consistent and reliable control of postoperative pain. When separated from mechanical ventilation, the patient is concurrently weaned from the sedatives and analgesics. Under these circumstances, careful titration of opioids often results in prompt pain relief. In patients with reactive pulmonary artery hypertension, opioids have been shown to prevent hypertensive crisis. [82]

Regional anesthesia may be used for postoperative pain control in infants and children after thoracotomies, sternotomies, and simple procedures requiring CPB. This method avoids opioid-induced respiratory depression from intravenous doses of these drugs. The administration of opioids in the epidural space is a very effective approach to pain management. This technique is used in children for postoperative pain control when given in the epidural space via the caudal route as a "single shot" or via a small caudal catheter. Morphine or Dilaudid provides effective analgesia with a duration of 6 to 12 hours, with no significant respiratory depression. Caudal morphine diluted in 0.05 to 0.075 mg/kg delivered in a total volume of 1.25 mL/kg of sterile saline has been used with good success in our practice. The use of regional anesthesia for postoperative pain appears to be best suited for the child extubated in the early postoperative period. Relative contraindications of this technique include hemodynamic instability and patients with abnormal clotting profiles with continued active bleeding. Using this regional technique, better arterial oxygenation, a more rapid ventilator wean, and decreased postoperative respiratory complications may be expected. However, urinary retention occurs frequently in patients without a bladder catheter. Generally, no treatment is required. Children requiring large thoracotomies of a bilateral thoracosternotomy incision (i.e., "clamshell") merit consideration for thoracic epidural analgesia. This technique significantly reduces the respiratory depression and pulmonary mechanics abnormalities that accompany the quantity of systemic opioids that would be necessary to provide adequate analgesia for these excruciatingly painful incisions. If the procedure requires systemic heparinization, we will typically defer placement of these catheters until the heparin effect is neutralized. For patients undergoing heart/lung transplantation, a thoracic epidural can be placed early in the postoperative period (8-16 hours after surgery) to facilitate early extubation and excellent pain control.

ANESTHESIA FOR HEART AND LUNG TRANSPLANTATION

Although perioperative management for thoracic organ transplantation is considered elsewhere in this text, the application of these procedures to children requires some specific modification. Differences include the characteristics of the candidates, preparation of these children, anesthetic management, surgical considerations, post-bypass management, and outcome.

Even though some of the earliest heart transplants were performed for congenital heart malformations, this indication became rare by the early 1980s. In 1984, over 60% of the few pediatric heart transplants were performed in patients with cardiomyopathy, usually adolescents. In the next decade, a dramatic rise in the number of infants and young children with congenital heart malformations treated with heart transplantation resulted in a marked shift in the demographics (Fig. 50-16) .[240] By 1995, over 70% of the children receiving heart transplants were under 5 years of age, half of those under age 1. The overwhelming majority of these infants undergo transplant for congenital heart malformations for which reconstructive options either have failed or are not believed to exist (Fig. 50-17) .[240] The implications of this shift reach into every element of perioperative management.

Children considered for heart transplantation are more likely to have pulmonary hypertension than adults. Most adult transplant programs will not offer heart transplant therapy to patients with PVR over 6 Wood units/m^2 .[241] The exclusion threshold in infants and children remains controversial. Some programs accept patients with PVR as high as 12 Wood units/m^2 , particularly if the pulmonary vasculature responds to vasodilators such as oxygen, NO, calcium channel blockers, or prostacycline.[242] Neonates are generally assumed to have elevated PVR, but outcome data from some programs suggest that the importance of this factor on postoperative outcome is substantially less in the first year of life, perhaps because the infant donor hearts, having recently undergone transitional circulation, are better prepared to cope with the right ventricular pressure load that elevated PVR imposes.[243]

The anesthetic plan for pediatric heart transplantation must accommodate a wide spectrum of pathophysiologies. Recipients with congenital heart malformations benefit from the same analysis of loading conditions and optimizing hemodynamics discussed previously. Although a few of these patients undergo heart transplant because the natural history of reconstructive heart surgery poses greater risk despite reasonable ventricular function, most candidates exhibit some manifestations of impaired ventricular performance. As such, they require careful titration of anesthetic agents with minimal myocardial depressant characteristics to avoid cardiovascular collapse. In this fragile population, even modest doses of opioids can be associated with marked deterioration in systemic hemodynamics, presumably by reducing endogenous catecholamine release. As with most congenital heart patients, skilled management of the airway and ventilation represent crucial elements in a satisfactory induction, particularly in the face of elevated PVR. No matter how elegant the anesthetic plan in conception and implementation, a certain proportion of these children will decompensate upon induction, necessitating resuscitative therapy.

Although orthotopic heart transplantation poses some technical challenges in neonates and young infants, the replacement of an anatomically normal heart is less complex than several reconstructive heart procedures commonly performed in patients at this age. However, the need to adapt this procedure to incorporate repair of major concurrent cardiovascular malformations requires the consummate skill and creativity that remain the province of the few exemplary congenital heart surgeons.[244] [245] Having withstood extended ischemic periods, heart grafts are extraordinarily intolerant of superimposed residual hemodynamic loads that might accompany imperfect vascular reconstruction.

Figure 50-16 Demographic data for pediatric heart transplantation by age. Stacked bar graph illustrates the total number and age distribution for heart transplantation in patients less than 16 years of age. Note the rapid rise in transplants performed during the late 1980s, with particular growth in the population of children aged 5 years and under. Having peaked in the mid 1990s, the total number of transplants (both adult and pediatric) has declined slightly, but the relative age proportions within the pediatric population remain relatively constant. *(Data from the Registry of the International Society for Heart and Lung Transplantation [246])*

The extensive vascular repair and, particularly in older children with long-standing hypoxemia, the propensity to coagulopathy together elevate hemorrhage to a major cause of morbidity and even mortality in pediatric heart transplantation. Nevertheless, once successfully implanted, these grafts will respond to physiologic factors that stimulate growth and adaptation in the developing infant and child.[246]

Management considerations during separation from CPB and the early postoperative period are primarily focused on three pathophysiologic conditions; myocardial preservation,

Figure 50-17 Indication for heart transplantation in children. Over the past 14 years, the major indications for pediatric heart transplantation are nearly equally divided between congenital malformation and cardiomyopathy. In recent years, pediatric recipients with congenital malformations assumed a slight plurality due to shifting age demographics. As illustrated, younger children are more likely to undergo heart transplant because of congenital malformation. *(Data from the Registry of the International Society for Heart and Lung Transplantation [240])*

denervation, and PVR. Even expeditious transplants usually force the heart to endure ischemic periods that exceed those encountered for reconstructive surgery. Although some centers believe the infant heart is more tolerant of extended ischemia,[243] these hearts will demonstrate a period of reperfusion injury and virtually all require pharmacologic, and in some cases mechanical, support. In addition, endogenous adaptive responses and exogenous pharmacologic agents that act via myocardial sympathetic activation are ineffective in the denervated graft. Since the majority of children presenting for heart transplantation exhibit some element of elevated PVR, even with isolated end-stage cardiomyopathy, the RV of a newly implanted heart is particularly vulnerable to failure.

As such, ventilatory and pharmacologic interventions are usually configured to exert a favorable impact on PVR and provide inotropic and chronotropic support. Once the lungs are fully expanded, we ventilate to Pa CO_2 values in the low 30s using an Fi O_2 of 1. Virtually all recipients receive low-dose dopamine (3-5 mug/kg/min) and isoproterenol (0.02-0.05 mug/kg/min) to promote inotropy, chronotropy, and lower PVR. In the event that these do not provide sufficient inotropy in the face of more significant postischemic dysfunction, additional agents are added (e.g., milrinone, epinephrine). Most transplant centers have a specific regimen for immunosuppression to be initiated in the perioperative period. As with adults, pediatric transplant programs typically employ triple drug immunosuppression with a calcineurin inhibitor (e.g., cyclosporine, tacrolimus), antimetabolite (e.g., azathioprine), and steroid. Following an interval without rejection, some pediatric programs will taper and discontinue one or even two of these agents, particularly

in neonates in whom they believe some element of tolerance develops. [247] [248]

National statistics indicate that the outcome from pediatric heart transplant is slightly less favorable than comparable adult results. [240] The principal risk factors are age under 1 year and congenital heart defects. Since these factors are highly related (i.e., the vast majority of infants under 1 undergo transplantation for congenital heart defect), it is difficult to determine the independent effect of age. Concurrent repair of structural cardiovascular anomalies substantially increases perioperative risk of hemorrhage, residual hemodynamic loading conditions, and right heart failure from elevated PVR. Taken together, infants under 1 year of age have an operative mortality rate (at <30 days) of 24%, more than twice that of older children. [240] Beyond the early postoperative period, mortality rates are quite comparable for all age groups. Nevertheless, the sequelae of rejection and the consequences of the requisite immunosuppression result in significant ongoing morbidity and mortality. Since even the best transplant recipients have only achieved a 28% 14-year survival rate, these procedures must be considered palliative for children. [240]

Lung and heart-lung transplantation have achieved respectable operative survival rates in children. [249] [250] They remain the only viable surgical therapy for infants and children with severe pulmonary vascular disease and selected progressive pulmonary diseases. These remain uncommon procedures in pediatrics. Lung transplantation carries the additional morbidity of obliterative bronchiolitis, a debilitating small airway disease that results in gradual deterioration in flow-related pulmonary functions over time. Despite an operative mortality rate that is currently less than 20%, the 3-year survival rate is only 50% to 60%. [240] [250]

ANESTHESIA FOR CLOSED HEART OPERATIONS

Early corrective repair in infancy has significantly reduced the number of noncorrective, palliative closed heart operations. Corrective closed heart procedures include PDA ligation and repair of coarctation of the aorta. Noncorrective closed heart operations include pulmonary artery banding and extracardiac shunts such as the Blalock-Taussig shunt. These procedures are performed without cardiopulmonary bypass. Therefore, venous access and intra-arterial monitoring are important in evaluating and supporting these patients. A pulse oximeter remains an invaluable monitor during intraoperative management.

Ligation of PDA is typically performed through a left thoracotomy, although video-assisted thoracoscopic techniques are increasingly common. [251] [252] Physiologic management is that of a left-to-right shunt producing volume overload. Patients with a large PDA and low PVR generally present with excessive pulmonary blood flow and congestive heart failure. Neonates and premature infants also run the risk of having substantial diastolic runoff to the pulmonary artery, potentially impairing coronary perfusion. Thus patients range from an asymptomatic healthy young child to the sick ventilator-dependent premature infant on inotropic support. The former patient allows for a wide variety of anesthetic techniques culminating in extubation in the operating room. The latter patient requires a carefully controlled anesthetic and fluid management plan. Generally a trial of medical management with indomethacin and fluid restriction is attempted in the premature infant prior to surgical correction. In the premature infant, transport to the operating room can be especially difficult and potentially hazardous, requiring great vigilance to avoid extubation, excessive patient cooling, or venous access disruption. For these reasons, many centers are now performing ligation in the neonatal ICU. Intraoperatively, retractors may interfere with cardiac filling and ventilatory management so that hypotension, hypoxemia, and hypercarbia occur. Complications include inadvertent ligation of the left pulmonary artery or descending aorta, recurrent laryngeal nerve damage, and excessive bleeding due to inadvertent PDA disruption. After ductal ligation in premature infants, worsening pulmonary compliance can precipitate a need for increased ventilatory support, and manifestations of an acute increase in LV afterload should be anticipated, especially if LV dysfunction has developed preoperatively. More recently, PDA ligation has been performed in infants and children using thoracoscopic surgical techniques. This approach has the advantage of limited incisions at thoracoscopic sites, promoting less postoperative pain and discharge from the hospital the same day of surgery.

Coarctation of the aorta is a narrowing of the descending aorta near the insertion of the ductus arteriosus. Obstruction to aortic flow is the result and this may range from severe obstruction with compromised distal systemic perfusion to mild upper extremity hypertension as the only manifestation. Associated anomalies of both the mitral and aortic valves can occur. In the neonate with severe coarctation, systemic perfusion is dependent on right-to-left shunting across the PDA. In these circumstances, LV dysfunction is very common and prostaglandin E_1 is necessary to preserve sufficient systemic perfusion. Generally, a peripheral intravenous line and an indwelling arterial catheter, preferably in the right arm, are recommended for intraoperative and postoperative management. In patients with LV dysfunction, a central venous catheter may be desirable for pressure monitoring and inotropic support. The surgical approach is through a left thoracotomy, whereby the aorta is cross-clamped and the coarctation repaired with an onlay prosthetic patch, a subclavian artery flap, or resection of the coarctation with an end-to-end anastomosis. During cross-clamp, we usually allow significant proximal hypertension (20-25% increase over baseline), based on evidence that vasodilator therapy may jeopardize distal perfusion and promote spinal cord ischemia. [253] Intravascular volume loading with 10 to 20 mL/kg of crystalloid is given just before removal of the clamp. The anesthetic concentration is decreased, and additional blood volume support is given until the blood pressure rises. Post-repair rebound hypertension due to heightened baroreceptor reactivity is common and often requires medical therapy. After cross-clamp, aortic wall stress due to systemic hypertension is most effectively lowered by institution of beta blockade with esmolol or alpha/beta-blockade with labetalol. [254] Propranolol is useful in older patients but can cause severe bradycardia in infants and young children. Although it actually increases calculated aortic wall stress in the absence of beta blockade by accelerating dP/dT, the addition of sodium nitroprusside

---

may become necessary to control refractory hypertension. Captopril or an alternative antihypertensive regimen is begun in the convalescent stage of recovery in those patients with persistent hypertension.

The management of infants undergoing placement of extracardiac shunts without cardiopulmonary bypass centers around goals similar to those of other shunt lesions: balancing pulmonary and systemic blood flow by altering Pa $_{CO_2}$, Pa $_{O_2}$, and ventilatory dynamics. Central shunts are usually performed through a median sternotomy, while Blalock-Taussig shunts may be performed through a thoracotomy or sternotomy. In patients in whom pulmonary blood flow is critically low, partial cross-clamping of the pulmonary artery required for the distal anastomosis causes further reduction of pulmonary blood flow and desaturation, necessitating meticulous monitoring of pulse oximetry. Careful application of the cross-clamp to avoid pulmonary artery distortion will help maintain pulmonary blood flow. Under circumstances in which severe desaturation and bradycardia occur with cross-clamping, CPB will be required for the procedure. Intraoperative complications include bleeding and severe systemic oxygen desaturation during chest closure, usually indicating a change in the relationship of the intrathoracic contents that results in distortion of the pulmonary arteries or kink in the shunt. Pulmonary edema may develop in the early postoperative period in response to the acute volume overload that accompanies the creation of a large surgical shunt. Measures directed at increasing PVR, such as lowering inspired O_2 to room air, allowing the Pa $_{CO_2}$ to rise, and adding positive end-expiratory pressure are helpful maneuvers to decrease pulmonary blood flow until the pulmonary circulation can adjust. Decongestive therapy such as diuretics and digoxin may alleviate the manifestations of congestive heart failure. Under such circumstances, early extubation is inadvisable.

Pulmonary artery banding is used to restrict pulmonary blood flow in infants whose defects are deemed uncorrectable for either anatomic or physiologic reasons. These patients are generally in congestive heart failure with reduced systemic perfusion and excessive pulmonary blood flow. The surgeon places a restrictive band around the main pulmonary artery to reduce pulmonary blood flow. Band placement is very imprecise and requires careful assistance from the anesthesia team to accomplish successfully. Many approaches have been suggested. We place the patient on 21 percent inspired oxygen concentration and maintain the Pa $_{CO_2}$ at 40 mm Hg, to simulate the postoperative state. Depending on the malformation, a pulmonary artery band is tightened to achieve hemodynamic (e.g., distal pulmonary artery pressure 50-25% systemic pressure) or physiologic (e.g., Qp:Qs approaching 1) goals. Should the attainment of these objectives produce unacceptable hypoxemia, the band is loosened.

Blalock-Hanlon atrial septectomy is now an uncommon procedure for enlarging an intra-atrial connection. This procedure is done by occluding caval flow and creating an intra-atrial communication through the atrial septum. In patients with hypoplastic left heart syndrome with an intact atrial septum, this procedure is life-saving and must be performed within hours of birth. Balloon atrial septostomies (Rashkind procedure) and blade septectomies performed in the cardiac catheterization laboratory have replaced surgical intervention, except when left atrial size is very small or the atrial septum is thickened. Improved safety of CPB has led to the virtual elimination of such intracardiac procedures using inflow occlusion. Surgical septectomies, because they are currently confined to the most difficult subset, are rarely performed without benefit of CPB.

/das/book/view/29494766/875/568.html

ANESTHESIA FOR INTERVENTIONAL OR DIAGNOSTIC CARDIAC PROCEDURES

Advances in interventional and diagnostic cardiac catheterization techniques are significantly changing the operative and nonoperative approach to the patient with a congenital heart defect. Nonoperative interventional tech- niques are being used instead of procedures requiring surgery and CPB for safe closure of secundum ASDs, VSDs, and PDAs. Stenotic aortic and pulmonic valves, recurrent aortic coarctations, and branch pulmonary artery stenoses can be dilated in the catheterization lab, avoiding surgical intervention as well. [255] [256] [257] [258] These techniques shorten hospital stay and are particularly beneficial to patients with recurrent coarctation and muscular or apical VSDs, who are at a higher risk of operative intervention. Many patients with complex cardiac defects are poor operative risks. Innovative interventional procedures improve vascular anatomy, reduce pressure loads on ventricles, and decrease the operative risk for these patients. For example, in tetralogy of Fallot with hypoplastic pulmonary arteries, balloon angioplasty and vascular stenting procedures create favorable pulmonary artery anatomy and reduce pulmonary artery pressure and right ventricular end-diastolic pressure. High-risk patients undergoing diagnostic evaluation of pulmonary artery hypertension in anticipation of heart-lung transplantation also require anesthetic management. Despite the attendant high risks of the procedure in these patients with suprasystemic RV pressure, these patients are best managed with general anesthesia and controlled ventilation.

Anesthetic management of interventional or diagnostic procedures in the catheterization laboratory must include the same level of preparation that would apply in caring for these patients in the operating room. The patients have the same complex cardiac physiology and, in some cases, greater physiologic complexity and less cardiovascular reserve because they are deemed high operative risks. Interventional catheterization procedures can impose acute pressure load on the heart during balloon inflation. Large catheters placed across mitral or tricuspid valves create acute valvular regurgitation or, in the case of a small valve orifice, transient valvular stenosis. When catheters are placed across shunts, severe reductions in pulmonary blood flow and marked hypoxemia may occur. [258] [259] The anesthetic plan must consider the specific cardiology objectives of the procedure and the impact of anesthetic management in facilitating or hindering the interventional procedure. In general, there are three distinct periods involved in an interventional catheterization: the data acquisition period, the interventional period, and the post-procedural evaluation period.

During the data acquisition period, the cardiologist performs a hemodynamic catheterization to evaluate the need

for and extent of the planned intervention. Catheterization data are obtained under normal physiologic conditions; that is, room air, physiologic Pa CO_2 , and spontaneous ventilation are preferred. Increased Fi O_2 or changes in Pa CO_2 may obscure physiologic data. During the procedural period, the patient is usually intubated and mechanically ventilated. A secured airway allows the anesthesiologist to concentrate on hemodynamic issues. Positive-pressure ventilation also reduces the risk of air embolism. During spontaneous ventilation, a large reduction in intrathoracic pressure can entrain air into vascular sheaths and result in moderate to large pulmonary or systemic air emboli. Precise device placement is also facilitated with muscle relaxants that eliminate patient movements and controlled ventilation, thereby reducing the respiratory shifting of cardiac structures. Substantial blood loss and changes in ventricular function occur commonly during the intervention. Blood volume replacement and inotropic support may be necessary during or immediately after the interventional procedure. In the postprocedural period, the success and the physiologic impact of the intervention are evaluated. Blood pressure, mixed venous oxygen saturation, ventricular end-diastolic pressure, and cardiac output, when available, are used to assess the impact of the intervention. Persistent severe hemodynamic derangement indicates the need for ICU monitoring and respiratory or cardiovascular support. Because of the hemodynamic variability of many of these patients, as well as changing anesthetic requirements, continuous intravenous infusion with ketamine/midazolam or, more recently, propofol, is appropriate. Potent inhaled anesthetics are generally not used as the primary anesthetic and are reserved for adjunctive anesthesia.

A brief description of some of the interventional procedures and the associated anesthetic implications follows. The success of these interventions will undoubtedly result in widespread availability and use over the next few years.

Transcatheter Technique for ASD Closures

A collapsed double-umbrella clamshell device is loaded into a large introducer sheath placed through the femoral vein, advanced to the right atrium, and placed across the atrial septal defect into the left atrial chamber. Each side of the device consists of a Dacron mesh patch suspended in six spring-loaded arms that open like an automatic umbrella. Using biplane fluoroscopy and TEE, the catheter is positioned in the left atrium away from the mitral valve. [257] The sheath is pulled back to open the six distal arms and its Dacron mesh cover into the left atrium. The sheath and device are then pulled back so the distal arms contact the left atrial septum. Fluoroscopy and TEE are used to confirm that the arms are on the left atrial side and do not interfere with mitral valve motion. Once adequately seated, the sheath is pulled further back to expose the proximal side of the device and the proximal arms, which spring open to engage the right side of the atrial septum. When proper positioning is certain, the device is released. [257] In a recent report of 122 children undergoing transcatheter ASD closures, there was a 9 percent incidence of procedural complications, resulting in hemodynamic complications requiring treatment. [258] Despite nearly a decade of experience, these devices remain under investigational protocol and are therefore available only at a limited number of study centers.

Transcatheter VSD Closure

Most VSDs that are electively closed in the catheterization laboratory are mid-muscular or apical VSDs that are either difficult to close in the operating room or would require a left ventriculotomy. Left ventriculotomies are associated with a high incidence of LV dysfunction and have been relegated to a position as the least desirable surgical option. The transcatheter approach requires a blade atrial septostomy and a retrograde catheter placed through the femoral artery and advanced to the left atrium. This catheter is pulled across the atrial septum into the right atrium and is used to guide a superior vena cava catheter (placed through the internal jugular vein) across the atrial septal defect into the left atrium, across the mitral valve, and into the left ventricle. The ventricular septal defect is approached from the LV side. The large sheath containing the double-umbrella clam-shell device prevents closure of the mitral valve, resulting in acute mitral regurgitation or, in cases in which the VSD is large or the mitral annulus small, acute severe mitral stenosis. In this latter case, systemic output is decreased and a period of severe hypotension is unavoidable. Judicious use of vasoconstrictors to maintain coronary perfusion may be required during the catheter placement, followed by volume and inotropic resuscitation after the VSD device is deployed. This highly specialized application of the clamshell device is confined to very few pediatric centers in the United States.

Angioplasty of Branch Pulmonary Artery Stenosis

One of the most important areas of interventional catheterization has been the dilation and stenting of hypoplastic or stenotic branch pulmonary arteries. In patients with tetralogy of Fallot with hypoplastic pulmonary arteries, pulmonary atresia, or single ventricle with surgically induced peripheral stenoses, the use of balloon angioplasty and stenting procedures creates favorable pulmonary artery anatomy and reduces the risk of subsequent surgical repairs (Fig. 50-18) . Balloon angioplasty is accomplished by tearing the vascular intima and media, allowing the vessel to remodel and heal with a larger diameter. The balloon is placed across

the stenotic lesion so the middle of the balloon is at the stenosis. The balloon is inflated until the waist of the balloon is eliminated. Ideally, the most stenotic lesions are dilated first to minimize the impact on pulmonary blood flow and cardiac output. When the balloon is inflated, pulmonary blood flow is reduced, RV afterload is increased, and cardiac output falls. In patients with an associated VSD or ASD, right-to-left shunting and desaturation occur with balloon inflation. Occasionally, balloon catheters must be placed across aortopulmonary shunts, significantly reducing pulmonary blood flow. The procedure is successful in approximately 60percent of patients. In an early series, complications

Figure 50-18 *(A)* Severe bilateral branch pulmonary artery stenoses at the distal end of a conduit in a patient with pulmonary trunk atresia and ventricular septal defect. Stents were placed in right and left pulmonary arteries. *(B)* Follow-up angiogram in the same projection and magnification showed marked improvement of both right and left stenoses.

include hypotension (40 percent), pulmonary artery rupture (3 percent), unilateral reperfusion pulmonary edema (4 percent), aneurysmal dilation of the dilated pulmonary vessel (8 percent), death (1.5 percent), and transient post-procedural RV dysfunction. [260] Improved techniques and patient selection have favorably influenced the results with superior balloon catheters and stents, while significantly reducing serious complications. Anesthetic sup- port minimizes hemodynamic compromise by anticipating changes in blood flow patterns, treating transient hypotension, and providing airway support to minimize the risks associated with pulmonary artery disruption and acute unilateral pulmonary edema. [260]

Balloon Valvulotomies

Balloon valvulotomies conducted in well-compensated infants and children can often be accomplished without anesthetic support. Exceptions include neonates with critical aortic or pulmonary stenosis and patients with significant ventricular dysfunction who exhibit unstable hemodynamics.

Coil Embolization

Transcatheter methods can also be adapted to occlude undesired vascular structures. Intravascular coils have been used to close PDAs, aortopulmonary collaterals, and some arteriovenous malformations. In selected instances, to minimize the risk that coils escape to threaten vital organ perfusion, cardiologists may request general anesthesia with a muscle relaxant.

Radiofrequency Ablation of Accessory Pathways

Radiofrequency ablation is a nonsurgical approach designed to eliminate atrial or ventricular re-entrant tachyarrhythmias. The technique requires pathway mapping and precision ablation of the aberrant pathway using a radiofrequency ablation catheter. During the ablation, unexpected patient movement may result in catheter dislodgment and damage to normal conducting tissue, so general anesthesia is usually required in younger children. Anesthetic agents and techniques should be chosen to maintain circulating catecholamines and avoid suppression of arrhythmogenesis, for identification of the aberrant pathway. Our current preference is a propofol continuous intravenous anesthetic, although low-dose volatile anesthetics are equally satisfactory. Rapid atrial pacing and, occasionally, an isoproterenol infusion are required during the mapping procedure. Severe post-procedural cardiomyopathy has been described but is very unusual. An underlying cardiomyopathy from frequent episodes of supraventricular tachycardia and myocardial oxygen imbalance caused by prolonged periods of rapid atrial pacing and isoproterenol infusions are the presumed causative factors. An arterial line is helpful during these lengthy procedures for continuous monitoring of blood pressure and blood gases.

Chapter 51 - Anesthesia for Vascular Surgery

Edward J. Norris
Steven M. Frank

INTRODUCTION

The perioperative management of patients undergoing vascular surgery is one of the most challenging and controversial areas in the field of anesthesiology. Given the high incidence of coexisting disease, the hemodynamic and metabolic stress associated with cross-clamping and unclamping, and the ischemic insults to the brain, heart, kidneys, and spinal cord, it is not surprising that perioperative morbidity is exceedingly high relative to that of other surgical procedures. The controversy associated with routine preoperative screening for coronary artery disease (CAD) has been fueled by issues related to cost containment and managed care. Ongoing controversy continues over anesthetic technique and outcome because vascular procedures often lend themselves to local, regional, general, or combined regional/general anesthetics.

Much progress has been made in the management of vascular patients in the past 3 decades. In the 1970s, it was recognized that vascular surgery, relative to other surgeries, was a risk factor for perioperative cardiac morbidity. In the 1980s, the focus shifted to risk stratification in an effort to identify patients who were at greatest risk for morbid outcomes. In the 1990s, there have been numerous clinical trials studying anesthetic technique, sympatholytic drugs, hemodynamic control, and analgesic regimens that provide insight into the prevention, treatment, and mechanisms of cardiac and other morbidity. The goal of this chapter is to review issues related to the perioperative care of the vascular surgery patient and to address the underlying controversies. For simplicity, each of four major categories of vascular procedures is discussed separately: (1) abdominal aortic surgery, (2) thoracoabdominal aortic surgery, (3) lowerextremity vascular surgery, and (4) carotid surgery. Additional sections on preoperative and postoperative issues specific to each category of surgical procedure are included.

ATHEROGENESIS

Atherosclerosis is a disease process that compromises the arterial blood supply to any or all of the vital organs or the extremities. Risk factors include hypercholesterolemia, diabetes, hypertension, male sex, cigarette smoking, and family history. Because atherosclerosis is usually without early warning signs, prevention and/or risk modification is difficult until the patient has progressed to an advanced stage of disease. The progression of atherosclerosis occurs in three stages. [1] As early as the 2nd decade of life, fatty streaks begin to occur beneath the normal endothelium. These consist of lipid-laden macrophages (foam cells), smooth muscle cells, and elastic and collagen fibers. The fatty streak progresses to a fibrous plaque consisting of degenerated foam cells covered by a layer of proliferated smooth muscle cells. Unlike

the fatty streak, these lesions may compromise blood flow through a vascular bed and cause ischemia or thrombosis to the vital organs or extremities. The complex lesion of atherosclerosis represents a progression of the fibrous plaque with an expanded lipid-rich core, accumulation of calcium, disruption of endothelial integrity, and platelet thrombus and hemorrhage into the lesion.

The exact mechanism of atherogenesis and the explanation for the anatomic distribution of lesions are unknown. One theory is the "response to injury hypothesis," which was proposed by Virchow [2] 150 years ago and has come back into favor. [3] [4] The hypothesis is that endothelial injury is caused by a variety of chemical and physical factors, leading to desquamation and exposure of the subendothelium. Platelet adherence and degranulation stimulate arterial smooth muscle migration from the media into the intima, a phenomenon that promotes intimal smooth muscle proliferation. Other theories include the monoclonal hypothesis of atherogenesis proposed by Benditt and Benditt [5] in 1973, which suggests that each lesion is derived from a single smooth muscle cell that proliferates around a focus. This hypothesis draws an analogy to malignancy whereby a cell proliferates uncontrollably in response to a mutagen or, possibly, a virus to produce a lesion. The clonal senescence hypothesis proposed by Martin and Sprague [6] also focuses on smooth muscle cell proliferation that is controlled by local feedback from inhibitory hormones. In aging vessels, a decrease in inhibitory feedback stimulates growth of these cells and formation of the lesion.

The anatomic distribution of atherosclerotic lesions is shown in Figure 51-1 (Figure Not Available) . The most common sites are the coronary arteries, the carotid bifurcation, the abdominal aorta, and the iliac and femoral arteries. [1] It is known that atherosclerotic lesions tend to develop near arterial branch points and along the outer surfaces of arterial curves. Their development may be related to increased shear stress and injury to the endothelial surface. [7] Estrogens protect against atherosclerosis in part by increasing high-density lipoproteins and decreasing low-density lipoproteins. [8] Some evidence supports the role of antioxidants in preventing atherosclerotic lesions. Vitamins C and E, carotenoids, and folic acid may be beneficial in this regard. [9] Aspirin, by means of its anti-inflammatory and antiplatelet effects, is effective in preventing stroke and myocardial infarction (MI). When cholesterol level is lowered to less than 150 mg/dL, lipids are mobilized from atherosclerotic lesions, and regression gradually occurs. [10] A review of risk and prevention of arterial aging has been published [9] and is also available on the Internet. [11]

PREOPERATIVE EVALUATION

Coexisting Disease

Patients having peripheral vascular surgery are a select group of patients with a high incidence of coexisting disease (Ch. 25) associated with advanced age, cigarette smoking, diabetes mellitus, and hypertension, all of which should be assessed and optimized before surgery (Ch. 23) . It is also well recognized that CAD is the leading cause of perioperative mortality at the time of peripheral vascular surgery and

Figure 51-1 (Figure Not Available) Distribution of atherosclerotic lesions. Plaques occur at the origins of large vessels and at bifurcations. Distribution and relative severity differ based on risk factors. *(From Zwolak and Cronenwett [1])*

that long-term survival after vascular procedures is significantly limited by a high incidence of morbid cardiac events. [12] Given the systemic nature of atherosclerotic disease, less than 10 percent of patients who present for vascular surgery have normal coronary arteries, and more than 50 percent of patients have advanced or severe CAD. [13] The preoperative period thus presents an opportunity to perform diagnostic and therapeutic interventions that may affect not only perioperative survival but also long-term morbidity from cardiac events.

Perioperative and Long-Term Morbidity

To appreciate the importance of preoperative evaluation, one must consider the incidence of MI and death in patients

TABLE 51-1 -- Rates of Myocardial Infarction and Death for Patients Undergoing Vascular Surgery

AUTHOR (REFERENCE)	MI (%)	DEATH (%)	COMMENTS
SHORT-TERM FOLLOW-UP (IN HOSPITAL)			
Ouyang et al [59]	8	0	Small study
Raby et al [437]	2.3	0.06	Aortic, lower extremity, carotid
Mangano et al [62]	4.1	2.3	Vascular patients only reported
Bode et al [304]	4.5	3.1	All lower extremity vascular
Christopherson et al [54]	4.0	2.0	All lower extremity vascular
Mangano et al [51]	5.0	0	Vascular patients only reported
Fleisher et al [94]	6.0	3.0	Vascular patients only reported
Hertzer [438]	8.8		Older study (1982)
Pasternack et al [61]	4.5	1.0	Aortic, lower extremity, carotid
Krupski et al [28]	2.1	2.9	Aortic, lower extremity
Average	5.0	1.6	
LONG-TERM FOLLOW-UP (IN HOSPITAL + AFTER DISCHARGE)			
Raby et al [437]	7.4	5.1	20-month follow-up
Mangano et al [62]	4.7	3.5	15-month follow-up
Mangano et al [439]	19.4	13.5	24-month follow-up
Hertzer et al [77]		12	5-year follow-up
Krupski et al [29]	3.9	11.2	24-month follow-up
Average	8.9	9.1	3-4 year average follow-up

For short-term follow-up, outcomes are reported for the duration of the hospital stay, and death from MI was classified as both "MI" and "Death." For long-term follow-up, "MI" was not included as a subset of "Death," because often the cause of death was unknown. Thus, the incidence of MI is underestimated in the long-term table.

undergoing peripheral vascular surgery (Table 51-1) (Ch. 22) . When multiple studies are pooled, the overall prevalence of perioperative MI and death is 5.0 percent and 1.6 percent, respectively. When outcomes are assessed over the long-term postoperative period (3-4 years), the prevalence of MI and death is 8.9 percent and 9.1 percent, respectively.

The challenge for clinicians is to accurately assess risk for cardiac morbidity while maintaining a cost-effective strategy. After risk assessment, there is the additional challenge of modifying perioperative management to reduce risk by (1) adjusting cardiac medication, (2) direct coronary intervention with percutaneous transluminal coronary angioplasty (PTCA) or coronary artery bypass grafting (CABG), or (3) modifying perioperative management. Coordination is essential between surgeons, anesthesiologists, and cardiologists, each of whom may have different criteria for risk modification. Although some investigations have enthusiastically promoted the use of preoperative testing, cardiologists, surgeons, and anesthesiologists do not agree on which patients should be tested and how. The cost of these tests is a limiting feature; Mangano [12] estimated that annual health care costs would rise by $100 million if preoperative dipyridamole thallium imaging (DTI) were used for only half of all vascular surgery patients. Even when selective criteria are used to determine which vascular patients need preoperative testing, one estimate is that $2,936 per patient would be the average cost of testing, with subsequent coronary intervention by PTCA or CABG for patients with correctable CAD. [14]

Because both PTCA and CABG have inherent risks, additional controversies arise. Also, because it is ethically difficult or impossible to study these preoperative interventions in a randomized clinical trial, no such trials have been performed. In interpreting the few published outcome studies, one must recognize that overall mortality must include both the mortality related to the coronary intervention and the mortality related to the vascular surgery procedure itself, and that improved

survival following vascular surgery after PTCA or CABG may merely represent the elimination of patients who are less likely to survive surgery. [13]

An excellent review of the literature and recommendations for preoperative evaluation were published by the American College of Cardiology and the American Heart Association (ACC/AHA). [15] This document was produced by a task force that included cardiologists, internists, anesthesiologists, and surgeons. Preoperative testing is discussed, preoperative risk variables are identified, and anesthetic care and hemodynamic monitoring are reviewed. An explicit algorithm for preoperative testing is outlined in these guidelines.

Risk Assessment and Optimization

Risk Indices

Assessing cardiac risk in patients before vascular surgery is a controversial and difficult task (Ch. 22) . In the mid 1970s, Goldman and colleagues [16] pioneered the concept of a risk index to account for the multifactorial nature of contributors to risk for cardiac morbidity. In this landmark study, 1,000 patients scheduled for major surgical procedures were prospectively enrolled, and a multivariate model was used to determine the independent risk contribution of each of several clinical variables. Independent predictors of morbidity were identified as (1) age >70 years; (2) MI in the previous 6 months; (3) an S_3 gallop or jugular venous dis- tention; (4) any preoperative cardiac rhythm other than sinus; (5) aortic stenosis; (6) general medical problems (abnormal arterial blood gases, electrolytes, creatinine); and (7) emergency, intrathoracic, or intra-abdominal surgery. Limitations of Goldman et al's [16] study include a relatively low-risk population (only 8% were vascular surgery patients), which limits the application of the risk index for this group of patients.

Since the publication of Goldman et al's [16] paper, several other investigators have published risk indices in an attempt to increase the sensitivity and specificity for predicting perioperative morbidity. [17] [18] [19] [20] [21] The patients in these series were also relatively low risk because only a small percentage underwent vascular surgery. Although risk indices are a cost-effective screening method for determining which patients require further cardiac evaluation, the high pretest probability of CAD in vascular surgery patients makes the risk index less useful. For this reason, the remainder of this section focuses on risk assessment specifically for vascular surgery patients.

The history and physical examination are not very reliable for detecting CAD in the general population. In patients with peripheral vascular disease whose exercise tolerance is limited by claudication, the history and physical are even less reliable. In addition, the symptoms of ischemic heart disease are often not manifested in diabetic patients, and silent myocardial ischemia goes unrecognized. [22] Nonetheless, several risk indicators can be obtained from the history and physical examination. History of a previous MI or congestive heart failure has been shown in multiple studies to predict risk for perioperative cardiac morbidity. [16] [23] [24] [25] Exercise tolerance is valuable information that may eliminate the need for further testing. [26] Patients with adequate lower-extremity blood flow (e.g., patients with isolated carotid disease) may have exercise tolerance that indicates good left ventricular function and low likelihood of significant CAD.

It is not clear whether any specific category of vascular disease is associated with a greater likelihood of coexisting CAD. Some investigators have shown a similar incidence and severity of CAD in patients with aortic, lower-extremity, and carotid disease. [27] Others have shown that patients with lower-extremity vascular disease are more likely to have significant CAD and to experience perioperative morbidity. [28] [29] [30] In the ACC/AHA guidelines, aortic and lowerextremity procedures are considered high risk and carotid procedures intermediate risk for perioperative cardiac morbidity. The difference in these subgroups of vascular patients is related not to the incidence or the severity of coexisting disease but rather to the invasiveness of the surgery.

Hypertension

Although hypertension is well recognized as a risk factor for atherosclerotic disease, multiple studies have shown that moderate hypertension is not an independent risk factor for perioperative cardiac morbidity. [18] [31] [32] Hypertensive patients may be more hemodynamically labile intraoperatively and postoperatively. [33] In addition, because of anxiety, patients often have acutely elevated blood pressures on admission to the hospital, especially the morning of surgery, and this should be taken into account before patients are diagnosed with or treated for hypertension. [34] Patients should be maintained with their usual antihypertensive medications throughout the perioperative period, with an oral dose given the morning of surgery and parenteral doses given thereafter in patients unable to take oral medications. Care should be taken to prevent withdrawal from beta-adrenergic blockers and clonidine to avoid a rebound increase in heart rate and blood pressure. The perioperative use of beta blockers and the control of heart rate have been shown to reduce the incidence of perioperative myocardial ischemia and subsequent cardiac morbidity. [12] [35] [36] [37] [38] [39] Clonidine decreases anesthetic requirements, catecholamine levels, and blood pressure lability. [40] [41] The effect of calcium channel blockers on perioperative cardiac morbidity has not been studied in a randomized fashion, but there is evidence that the incidence of myocardial ischemia is unaffected. [35] Because angiotensin-converting enzyme inhibitors may lead to intraoperative hypotension, it has been recommended that these drugs be avoided in the immediate preoperative period. [42] If necessary, blood pressure can be controlled with shorter-acting acute therapy during the intraoperative and postoperative periods.

Previous Myocardial Infarction

Patients who have had prior MI are at greater risk for reinfarction in the perioperative period than others (Table 51-2) . Studies from the 1970s reported prevalence of perioperative MI of about 30 percent, 15 percent, and 5 percent in patients who had a prior MI less than 3 months, 3 to 6 months, and more than 6 months before the procedure, respectively. [16] [23] [24] [25] In the 1980s, Rao et al [43] demonstrated that risk for perioperative reinfarction could be reduced with careful intraoperative and postoperative care that included invasive hemodynamic monitoring with arterial and pulmonary artery catheters, control of hemodynamic parameters, and intensive care following surgery. With this "extra care," the risk of reinfarction was reduced to 6 percent, 2.5 percent, and 1.5 percent in patients who had had a prior MI less than 3 months, 3 to 6 months, and more than 6 months before the procedure, respectively. [43] Nevertheless, this study had significant limitations, including the retrospective design, the lack of careful outcome surveillance, and the unidentified changes in practice over time that may have influenced outcome given the historical control group.

TABLE 51-2 -- Reinfarction Rates in Patients With Previous Myocardial Infarction

TIME ELAPSED BETWEEN PRIOR MYOCARDIAL INFARCTION AND OPERATION (MONTHS)	TARHAN ET AL[25]	RAO ET AL[43]		SHAH ET AL[44a]
	1972	*BEFORE 1977*	*1977 AND AFTER*	*1990*
0-3	37	36	5.8	4.3
4-6	16	26	2.3	0
>6	5.6	5	1.5	5.7
Time unknown	--	--	--	3.3

Despite these limitations, the study by Rao et al is often cited as justification for invasive monitoring and intensive care in patients with significant cardiac risk. Table 51-2 shows the significant decrease in reinfarction rates over the past 2 decades, indicating an overall improvement in our ability to care for these high-risk patients.

Given the increased risk for morbidity in patients with recent MI, traditional anesthetic practice dictates that elective surgery be postponed until a 6-month interval has passed. Vascular surgery, however, is often not elective. Urgent surgery is often necessary for patients experiencing transient ischemic attacks from carotid stenosis or limb-threatening ischemia from iliac or femoral disease. For this reason, each patient with recent MI must be assessed from the riskbenefit standpoint.

Assessment of Cardiovascular Risk

Electrocardiogram

A preoperative electrocardiogram (ECG) should be obtained for all patients undergoing vascular surgery. This ECG is necessary for comparison if myocardial ischemia or infarction is suspected postoperatively. If Q waves or other evidence of prior MI is present, then previous records should be reviewed to determine the timing of the infarct for the purposes of risk stratification. Dysrhythmias should be evaluated preoperatively to optimize risk, for example, rate control for patients in atrial fibrillation. The presence of a cardiac rhythm other than sinus indicates risk for perioperative cardiac morbidity, [16] [20] although it is unclear whether treatment of dysrhythmias reduces risk. Approximately 50 percent of patients with CAD have a normal resting ECG, and therefore the ECG lacks sensitivity for predicting cardiac morbidity. [44]

Exercise ECG

Exercise stress testing is a widely available and costeffective method of screening for CAD in the general population. A substantial proportion of vascular surgery patients (30-70%), however, cannot attain target heart rates that allow detection of ischemia. [45] In addition, many elderly patients are limited by knee and hip disorders or previous stroke that limit their exercise capacity. One alternative is arm exercise, [46] but fatigue often precedes the increase in heart rate, and there has been little enthusiasm for this technique. If vascular surgery patients are able to exercise and are able to achieve 85 percent of their maximal heart rate, they are at substantially lower risk for perioperative morbidity. [47] One small study demonstrated a 5-fold increase in risk for patients who were able to attain the target heart rate with significant ST changes, but other, larger, studies do not support these findings, showing poor predictive values for exercise stress testing. [48] [49]

Dipyridamole Thallium Imaging

Dipyridamole thallium imaging is the most commonly used noninvasive test to screen vascular surgery patients for CAD and risk for perioperative cardiac morbidity. Thallium 201, a radioactive potassium analogue, is distributed into perfused areas of myocardium after intravenous injection. Areas of myocardium that are hypoperfused show up on scintigraphic scanning as a relative "cold spot." Dipyridamole vasodilates normal coronary arteries by blocking reuptake of adenosine, but stenotic vessels have a fixed diameter and cannot dilate. This creates a "steal phenomenon," whereby blood flow is redirected away from diseased coronary vascular beds. Thallium imaging is usually performed to detect hypoperfused areas of myocardium soon after the dipyridamole is given. A second image is obtained 3 to 6 hours later after the vasodilator effect has dissipated (redistribution phase). There are three general outcome results from this test. The first is a normal test result with complete perfusion on the first and second images. The second is one that shows myocardium at risk ("redistribution"), with the first image showing a hypoperfusion defect and the second image showing normal perfusion. This indicates coronary narrowing and ischemia that is induced by the vasodilator. The anatomic location of the area at risk can usually be assessed on the images. The third is a fixed perfusion defect indicating an old infarction that has scarred the myocardium to such a degree that blood flow is absent.

There is ongoing controversy over the value of DTI for risk stratification in patients scheduled for vascular surgery. Two large studies in vascular surgery patients showed low sensitivity for DTI's predicting cardiac morbidity. [50] [51] This may be related to the fact that the population in these large studies had a lower risk than that of populations in other studies, in which selected patients were enrolled who had clinical risk factors (a higher pretest probability of morbidity). Table 51-3 illustrates the predictive value for DTI in vascular surgery patients.

The most rational use of DTI was proposed by Eagle et al [52] in 1989. In this study, vascular surgery patients were stratified by clinical variables and then studied with DTI (Fig. 51-2). (Figure Not Available) The clinical variables were (1) Q waves on ECG, (2) history of ventricular ectopic activity, (3) diabetes, (4) advanced age (>70 years), and (5) angina. In patients with one or two of these variables, a positive DTI result was associated with a tenfold greater incidence of cardiac morbidity. The authors recommended proceeding to coronary angiography in these patients. Patients with three or more clinical risk variables had such a high risk for morbidity that the authors recommended not using DTI but instead proceeding directly to cardiac catheterization. Patients with no clinical variables had such a low risk for morbidity that DTI did not add significantly to risk assessment, and it was stated that DTI is unnecessary. Despite ongoing debate, DTI remains the most widely used test for risk stratification in patients scheduled for vascular surgery.

Ambulatory Electrocardiographic Monitoring

Ambulatory electrocardiographic (AECG) monitoring has been used for many years to detect dysrhythmias, but only recently has ambulatory monitoring for myocardial ischemia been used to predict risk for perioperative cardiac morbidity. As with DTI, the sensitivity of AECG monitoring is

[a] *n* indicates the number of patients that underwent surgery.
[b] Patients with fixed DTI perfusion defects were omitted from calculations of positive and negative predictive value.

greatest in patients with high pretest probability. Preoperative ST segment changes consistent with myocardial ischemia occur in 20 to 40 percent of vascular surgery patients, and 80 to 90 percent of these ischemic episodes are silent. [53] [54] [55] The advantage of AECG monitoring over DTI is that AECG is approximately one-third the cost of DTI. [55] Disadvantages include the inability to test patients with significant ECG abnormalities that preclude ECG monitoring for ischemia (left bundle branch blocks, pacemaker dependency, and left ventricular hypertrophy with significant strain or digitalis effect). [56] Silent myocardial ischemia is known to predict adverse outcomes not only as a preoperative

Figure 51-2 (Figure Not Available) Algorithm for combining clinical variables and dipyridamole-thallium results to stratify cardiac risk in vascular surgery patients. Cardiac events include unstable angina, myocardial infarction, ischemic pulmonary edema, or cardiac death. Clinical variables are Q wave on electrocardiogram, age >70 years, history of angina, ventricular ectopic activity requiring treatment, and diabetes mellitus requiring treatment. *(From Eagle et al [52])*

test but also in other clinical settings. Silent ischemia predicts morbidity after MI [57] and in unstable angina. [58] Postoperative silent ischemia is also predictive of cardiac morbidity [59] and mortality [60] after peripheral vascular surgery.

Studies by Pasternack et al [61] and Raby et al [55] that included only vascular surgery patients found AECG to be highly sensitive (0.80-0.90) and specific (0.70-0.90). Other studies, including the largest series (474 patients) by Mangano et al, [62] included general surgery patients, as well with a resulting lower sensitivity (0.30-0.50) and a similar specificity (0.70-0.80). Fleisher et al [53] found that preoperative AECG monitoring had predictive value similar to that of DTI, although the two tests together provided more predictive ability than either test alone. Two disadvantages of AECG testing follow: (1) the highest-risk patients could not be monitored, because of baseline ECG abnormalities, and (2) the risk was not quantifiable by the severity of ischemia on AECG but was quantifiable by DTI. Table 51-3 compares the results of several studies on AECG monitoring for risk stratification before vascular surgery.

Echocardiography

Two-dimensional echocardiography is a noninvasive, relatively inexpensive technique that provides measurements of left ventricular function, ejection fraction, regional wall motion, and valvular function. Although the left ventricular function measured by echocardiography is a more qualitative measure than a quantitative one, this method is generally less expensive than radionuclide ventriculography, which is more quantitative. [63] Echocardiography has limited ability to measure ejection fraction. These measurements are dependent on loading conditions (both preload and afterload). [64] In addition, measurements of ventricular function are often made in the acute post-MI setting, resulting in patients' being labeled with a poor ejection fraction long after the myocardium has recovered from the ischemic insult. Although studies have correlated left ventricular function with outcome in patients with acute MI, [65] the value of echocardiographic assessment as a predictor of perioperative cardiac morbidity is unknown.

Pharmacologic Stress Echocardiography

Echocardiography can be used with pharmacologic stress testing to provoke myocardial ischemia, as detected by new or worsening wall motion abnormalities. For the preoperative assessment of patients for vascular surgery, dobutamine stress echocardiography (DSE) has a sensitivity of 80 to 90 percent and a specificity of 80 to 90 percent for predicting perioperative cardiac morbidity. [66] [67] [68] [69] [70] DSE does not add risk discrimination for patients with no clinical markers according to the criteria of Eagle et al, [52] because morbid events are rare in this subgroup. [71] DSE does stratify patients with one or two clinical markers, and perioperative cardiac events are unlikely to occur in patients with a negative result on stress echocardiogram in this subgroup. [71] A meta-analysis found DSE to be the best predictor of cardiac morbidity (relative risk [rr] =6.2), followed by DTI (rr=4.6), radionuclide ventriculography (rr =3.7), and AECG (rr =2.7). [72] Table 51-3 compares the results for several studies on DSE for risk stratification before vascular surgery.

Radionuclide Ventriculography

Radionuclide ventriculography provides an accurate assessment of left ventricular function during rest or with exercise. The test is performed by quantitative analysis of sequential count densities of gated blood-pool images. In patients undergoing lower-extremity arterial bypass or abdominal aortic resection, radionuclide ventriculography has been shown to be an independent predictor of perioperative cardiac morbidity. Pasternack et al [73] [74] found that an ejection fraction of less than 35 percent was associated with a 75 to 85 percent rate of perioperative MI, and an ejection fraction of greater than 35 percent was associated with a 19 to 20 percent rate. Other investigators, however, have not been able to reproduce these results by use of radionuclide ventriculography either at rest or with exercise. [75] [76]

In summary, all three of the most commonly used preoperative tests (DTI, AECG, and DSE) have relatively high negative predictive values. Thus, if a patient tests negative on these screening tests, it is unlikely that a morbid cardiac event will occur. None of the tests, however, has high positive predictive value, indicating that many patients with positive test results will not have a morbid event. Because the primary reason for testing before surgery is for screening purposes, these tests serve their purpose. Further risk assessment requires cardiac catheterization.

Cardiac Catheterization

The largest series on outcome in vascular surgery patients is that of Hertzer and colleagues [27] from the Cleveland Clinic. These investigators performed cardiac catheterization in 1,000 consecutive patients presenting for peripheral vascular surgery (aortic, carotid, or lower-extremity revascularization). The incidence and severity of CAD was assessed according to the following classification: (1) normal coronary arteries; (2) mild-to-moderate CAD with no lesion exceeding 70 percent stenosis; (3) advanced, compensated CAD with one or more lesions exceeding 70 percent stenosis but with adequate collateral circulation; (4) severe, correctable CAD with greater than 70 percent stenosis in one or more coronary arteries; and (5) severe inoperable CAD with greater than 70 percent stenosis in one or more coronary arteries with severe distal disease or poor ventricular function. The most remarkable findings were that only 8.5 percent of patients had normal coronary arteries and that 60 percent of patients had advanced or severe coronary lesions (>70% stenosis). [27] Even when CAD was not suspected by clinical history, more than one-third of patients had advanced or severe coronary lesions. The results are shown in Table 51-4 .

In Hertzer et al's series, the patients with severe correctable CAD were offered coronary bypass surgery, and if they consented, this surgery was performed before their peripheral vascular procedure. Patients who had normal or mild-to-moderate CAD went on to undergo vascular surgery, and those with severe inoperable disease were treated on an individual basis. Combined mortality rates

CAD, coronary artery disease

Data from Hertzer et al [27]

over the immediate and long-term (4.6-year follow-up) postoperative periods are shown in Table 51-5 (Table Not Available) . [77] Of the 216 patients who underwent coronary revascularization (CABG), 12 (5.5%) died after this surgery. This mortality rate is greater than the mortality rate reported for patients undergoing CABG surgery without peripheral vascular disease (1-2%), which suggests that the risks of CABG should be seriously considered as part of the preoperative evaluation of these patients. When overall early and late mortality (>5 years) are considered in Hertzer et al's series, death occurred in 12 percent, versus 26 percent of patients who underwent CABG or did not undergo CABG, respectively. [77] Although these data appear to support the beneficial effect of CABG on outcome, the mortality from CABG itself (5.5%) reduces its apparent benefits. It is important to recognize that no large-scale randomized trial has been performed to determine the impact of routine coronary angiography (with subsequent PTCA or CABG) before vascular surgery.

Prior Coronary Artery Bypass

Patients who have undergone prior coronary artery bypass who are without current symptoms of angina or heart failure appear to have a relatively low incidence of perioperative cardiac morbidity. When 12 studies were pooled to include more than 2,000 patients, the prevalence of postoperative MI was 0 to 1.2 percent versus 1.1 to 6 percent, and the mortality rate was 0.5 to 0.9 percent versus 1 to 2.4 percent in patients with and without prior bypass surgery, respectively. [12] From the registry of the Coronary Artery Surgery Study, perioperative mortality from noncardiac surgery was 0.9 percent and 2.4 percent in patients with and without previous bypass surgery, respectively. [78] Evidence suggests that survivors of successful CABG surgery have mortality rates similar to those of patients without coronary disease when undergoing noncardiac surgery (0.9 versus 0.5%, respectively). [12]

Prior Percutaneous Transluminal Coronary Angioplasty

An even more difficult question is the role of interventional cardiology in the preoperative management of the vascular surgery patient. Patients with peripheral vascular disease are often not ideal candidates for PTCA, because this procedure requires a large-diameter introducer sheath in the femoral artery, which predisposes to pseudoaneurysms

TABLE 51-5 -- Perioperative and Late Cardiac Deaths After Peripheral Vascular Reconstruction Among 846 Patients Followed Up Over 5 Years

(Not Available)

From Hertzer et al [77]

and compromised blood flow to the lower extremities. It is technically difficult to perform PTCA through the brachial artery. No randomized trials have been performed to determine the effects of PTCA on subsequent risk for cardiac morbidity in patients undergoing noncardiac surgery. In the past 3 to 5 years, atherectomy and intracoronary stents have improved both short-term and long-term results. There is evidence from published series of high-risk patients who were treated with PTCA that risk of perioperative morbidity is relatively low. In a retrospective review of 148 patients undergoing noncardiac surgery an average of 90 days after PTCA, only one patient had an MI. [79] In another series with 50 patients whose surgery was performed an average of 9 days after PTCA, there were three MIs and one death. These patients had class 3 and 4 angina before their PTCA. [80] Because many of these patients did not have peripheral vascular disease, PTCA may have been technically easier to perform than in vascular patients.

Assessment of Pulmonary Function and Risk

Respiratory complications are potentially serious in patients undergoing vascular procedures. Given the prevalence of cigarette smoking in this population, chronic obstructive pulmonary disease and chronic bronchitis are common. When clinical assessment suggests severe pulmonary compromise, pulmonary function tests are useful in evaluating and optimizing respiratory function (Ch. 24) . Preoperative blood gas determination can be used to establish a baseline for postoperative comparison. Baseline hypercapnia (partial pressure of arterial carbon dioxide >45 mm Hg) indicates a higher risk for postoperative morbidity. [81] Given proper pulmonary care, even patients with severe pulmonary insufficiency, however, may undergo surgery with acceptable morbidity and mortality. Preoperative treatment with a short course of glucocorticoids (prednisone, 40 mg/day for 2 days) is helpful for patients with significant chronic obstructive pulmonary disease or asthma. [82] Although there is limited evidence for improved pulmonary outcome with regional anesthesia, [83] patients with sig- nificant pulmonary disease may benefit from epidural anesthesia/analgesia that is maintained into the postoperative period because this technique avoids respiratory depression from systemic opiates.

Assessment of Renal Function

Underlying renal disease is common in vascular surgery patients. Hypertension itself may cause renal insufficiency or failure. Atherosclerotic disease in the abdominal aorta or renal arteries may compromise renal blood flow and renal function. Conversely, renal artery stenosis causes hypertension through renin-induced and angiotensin-induced vasoconstriction. Diabetic nephropathy is also common. Superimposed on baseline abnormalities in renal function are the angiographic dye load, which is directly nephrotoxic, [84] and the interruption in renal blood flow from aortic crossclamping. Even with infrarenal aortic cross-clamps, there can be a significant reduction in renal blood flow despite a normal systemic arterial blood pressure and cardiac output. [85] Embolic plaque can be showered into the renal arteries, especially when suprarenal aortic cross-clamps are applied and released. [86] Fluctuations in intravascular volume and cardiac output can compromise renal perfusion during the intraoperative and postoperative periods. In one series of more than 500 patients, the prevalence of acute renal failure was 7 percent after abdominal aortic reconstruction. [87]

PERIOPERATIVE MYOCARDIAL ISCHEMIA

Etiology and Prevention

Ischemic cardiac morbidity is the most common cause of perioperative (and nonperioperative) death in the United States. [12] Myocardial ischemia results from an imbalance between myocardial oxygen supply and demand, for which there are many causes during the perioperative period. [88] The determinants of supply and demand are shown in Figure 51-3 (Figure Not Available) The most detrimental changes (tachycardia, hypervolemia, and anemia) are those that simultaneously decrease oxygen supply and increase oxygen demand.

Figure 51-3 (Figure Not Available) Determinants of myocardial oxygen supply and demand that lead to myocardial ischemia. During the perioperative period, virtually every determinant is altered by factors such as fluid shifts, blood loss, pain, catecholamines, altered coagulability, and ventilatory insufficiency. *(Adapted from Beattie and Fleisher [86])*

Tachycardia increases myocardial oxygen demand by increasing myocardial work, while at the same time myocardial oxygen supply is decreased because diastole is shortened and most coronary blood flow occurs during diastole. Intravascular volume is equally important. Hypervolemia increases ventricular wall tension and thus myocardial oxygen demand. At the same time, coronary perfusion (oxygen supply) is reduced in the distended ventricle because the increased left ventricular end-diastolic pressure limits coronary flow. Anemia can also upset both sides of the supply/demand equation. [89] Decreased oxygen content decreases supply, whereas increased heart rate and cardiac output from anemia increase demand. The prevention and treatment of perioperative myocardial ischemia require careful control of these and other determinants of myocardial oxygen supply and demand as well as other perioperative physiologic changes that can precipitate ischemia.

When the entire perioperative period is considered, myocardial ischemia occurs most commonly postoperatively, and less commonly preoperatively and intraoperatively. [90] [91] The incidence of intraoperative ischemia is relatively low because anesthesia suppresses adrenergic tone, [92] and there is minute-to-minute control of the hemodynamic and other determinants of myocardial oxygen supply and demand. In the postoperative period, the patient is transferred from the operating room to the postanesthetic care unit or intensive care unit, where the ratio of physicians or nurses to patients is reduced and control of these variables is less complete. The early postoperative period is associated with pain, tachycardia, hypertension, third spacing, intravascular volume changes, and hypercoagulability. Most postoperative myocardial ischemia is silent (asymptomatic) as a result of masking by surgical pain or by opioid analgesia. [59] [93] [94] [95] The peak incidence of ischemia probably occurs on postoperative day 3, [90] which may correlate with the release of patients to the surgical wards, where they receive less attention from the medical staff. Table 51-6 summarizes five studies showing the relative incidence of preoperative, intraoperative, and postoperative myocardial ischemia.

Several clinical studies have increased our understanding of the clinical variables that precipitate myocardial ischemia. There has been a long-standing debate over whether the rate pressure product (heart rate × mean arterial blood pressure) [96] [97] or the pressure/rate quotient (mean arterial blood pressure divided by heart rate) [98] [99] is most correlated with ischemic episodes. Work by Buffington [100] supports the pressure/rate quotient, showing in a canine model that a quotient of less than 1.0 was associated with ischemia. In simpler terms, hypotension and tachycardia are a dangerous combination. In patients undergoing CABG surgery, the pressure/rate quotient was not predictive of ischemia in two different studies. [101] [102] Nonetheless, the importance of heart rate is well recognized as a determinant of myocardial ischemia in the vascular surgery patient. After vascular surgery, unlike CABG, patients leave the operating room with the same coronary disease they came in with, only to experience the stress of the postoperative period. Some vascular patients exhibit heart rate-related myocardial ischemia at "subtachycardic" heart rates. [6C] In certain high-risk patients, heart rates of
85 beats per minute consistently trigger ischemic ST segment changes (Fig. 51-4) (Figure Not Available) The primary role of the anesthesiologist is not merely to control heart rate but also to diagnose and treat the underlying cause of heart rate changes.

The optimal hematocrit value for vascular surgery patients is unknown. In the mid 1980s, the tendency was to withhold transfusion to avoid the risk of human immunodeficiency virus and hepatitis infection. In 1988, the National Institutes of Health indicated that no "threshold" hemoglobin concentration could be defined for routine transfusion. [103] The American College of Physicians then stated that hemoglobin concentrations of greater than 7.0 g/dL are well tolerated in patients without cardiovascular disease. [104] These guidelines, however, did not include recommendations for patients with CAD or risk factors for CAD. Although there are no controlled trials, there appears to be an increased incidence of myocardial ischemia and cardiac morbidity in vascular surgery patients if hemoglobin concentrations are less than 9.0 g/dL in the early postoperative period. [105] [106] This evidence, along with our understanding of the effects of anemia on myocardial oxygen supply and demand, [89] supports the practice of maintaining hemoglobin concentrations above 9.0 g/dL in the vascular patient, especially patients at significant risk for ischemic cardiac morbidity.

Monitoring for Myocardial Ischemia

There are three methods used to detect myocardial ischemia during the perioperative period: (1) surface ECG, (2) transesophageal echocardiography (TEE), and (3) pulmonary artery catheterization (Chs. 30 - 32). The sensitivity and specificity for ischemia detection, the level of training required, and the cost of these methods differ and are important

considerations. Evidence suggests that ischemia monitoring is important during and after vascular surgery. Ischemia may lead to infarction, [33] especially when the ischemia is sustained over time (>2 hours). [107] Although no controlled clinical trials have demonstrated a reduction in perioperative morbidity with ischemia monitoring and treatment, the anesthesiologist should optimize the clinical determinants of myocardial oxygen supply and demand in an attempt to resolve the ischemic condition.

Electrocardiographic monitoring for ischemia is the least expensive method and requires the least training. Subendocardial ischemia is the most common type of ischemia in the perioperative setting and is manifested by ST segment depression on the ECG. [108] Transmural ischemia is less common and is usually accompanied by ST segment elevation in the leads facing the injury, with reciprocal ST segment depression in one or more of the other 12 leads. A variety of independent measures of ischemia, including abnormalities of myocardial perfusion, [109] regional left ventricular dysfunction, [110] and pulmonary and left ventricular pressure changes, [111] have been correlated with ST segment changes that meet the following criteria (1×1×1 rule): [112] (1) horizontal or downward sloping ST segment depression, 60 to 80 milliseconds after the J point of at least 1 mm from the isoelectric baseline, (2) duration of at least 1 minute, and (3) separation from other discrete episodes by at least 1 minute of normal baseline.

Electrocardiographic monitoring should be performed in the diagnostic mode (0.05-Hz low-frequency cutoff) rather than the monitoring mode (0.5-Hz cutoff). [112] The increased filtering in the monitoring mode can create artifactual ischemic changes as a tradeoff for decreased baseline wandering. ECG morphology should always be assessed from a printed hard copy because monitors do not accurately show ECG morphology. [113] ECG changes consistent with ischemia are difficult to detect in patients with right bundle branch blocks, left ventricular hypertrophy with a strain pattern, or atrial fibrillation. [112] Ischemia monitoring by ECG is not possible in patients with left bundle branch block or pacemaker dependency. [112] In one large study, [55] 15 percent of vascular surgery patients had ECG abnormalities that precluded ischemia monitoring. During the intraoperative period, London and colleagues [114] studied noncardiac surgery patients and concluded that although V5 was the single most sensitive lead for detecting intraoperative ischemic changes (75% of episodes were evident in this lead), the sensitivity was increased to only 80% by monitoring leads II and V5 together. With a three-lead system (leads II, V4, and V5) 96 percent of ischemic changes were detected.

Over the past decade, computerized ST segment analysis has become one of the most valuable tools for ischemia monitoring. There is, however, no computerized system that is reliable enough to use without the interpretation of a trained clinician who can differentiate true ischemic changes from artifact. Computers are often fooled by baseline ST segment depression from abnormalities such as left ventricular hypertrophy and strain patterns. In addition, these systems are not sophisticated enough to analyze morphology (slope of the ST segment), and they rely primarily on the degree of change from an isoelectric baseline. Nonetheless, the most reliable way to monitor for ischemia is to follow the trend for ST segment elevation or depression over time by use of a computer algorithm. Computerized ST segment analysis, when used properly, is one of the most significant advances in perioperative monitoring.

Two-dimensional TEE has emerged over the past decade to become one of the most sensitive monitors of cardiac function. Evidence suggests that segmental wall motion abnormalities occur earlier than ECG changes at the onset of ischemia. [115] The echocardiographic changes during

ischemia are characterized by decreased ventricular wall thickening during systole, but the clinician needs to be relatively well trained to recognize such changes. Another drawback is the significant cost of the echocardiographic equipment. Although it is possible to perform TEE in awake or sedated patients, the procedure is often not well tolerated, making this technique less desirable during regional anesthesia or during the postoperative period.

Detection of ischemia is possible by use of a pulmonary artery catheter, but this technique is a distant third choice when compared with other methods (TEE or ECG). Episodes of ischemia are manifested as an abnormal pulmonary capillary wedge pressure waveform or an absolute increase in mean pulmonary capillary wedge pressure of 10 mm Hg or greater. [116] This technique has low feasibility because ideally the balloon-tipped catheter needs to be constantly or frequently inflated to detect such changes.

HEMODYNAMIC MONITORING

The appropriate level of invasive hemodynamic monitoring (Ch. 30) for the patient undergoing vascular surgery is a controversial issue. Multiple considerations determine the need for monitoring, and it is difficult to generalize for all vascular patients. Given the frequency of coexisting disease, the potential for fluid shifts and blood loss, and the physiologic changes associated with cross-clamping and unclamping, virtually all patients undergoing major vascular surgery should be monitored with an intra-arterial catheter. This allows not only beat-to-beat blood pressure monitoring but also arterial blood sampling for diagnostic purposes. The radial artery is most commonly selected for cannulation because of its superficial location and the presence of collateral circulation. The need to verify collateral blood flow is questionable. The Allen test [117] can be used to assess collateral flow in the palmar arch, but there is evidence that ischemic injury can occur in patients with a normal Allen test result [118] and that no injury occurs in patients with an abnormal Allen test result when the radial artery is cannulated. [119] When the radial artery is difficult to cannulate, the ulnar or axillary arteries are alternative sites. The axillary artery can be cannulated by use of the Seldinger technique, but care should be taken to avoid air injection when flushing an axillary catheter because the tip may lie close to or inside the aortic arch, allowing air to enter the cerebral circulation. Whenever possible, the femoral arteries should be avoided in patients with peripheral vascular disease.

Vascular surgery patients often have a large discrepancy in arterial blood pressure between the right and left arms as a result of atherosclerotic lesions in the subclavian or axillary arteries, resulting in a falsely low pressure in the ipsilateral arm. [120] We have seen patients with systolic differences as great as 100 mm Hg between arms, and 20 to 40 mm Hg differences are common. Patients scheduled for carotid surgery have the greatest incidence of right/left arm blood pressure differences. To avoid "pseudohypotension," the blood pressure should be verified in both arms, and the arm with the higher pressure should be monitored during surgery. It is possible that both arms would have falsely low blood pressures as a result of bilateral disease. In this case, the femoral artery may be the best option for monitoring.

There is significant controversy over the utility of central venous and pulmonary artery catheters for monitoring patients during vascular surgery. The surgical procedure determines the degree of fluid shifting and blood loss and thus the usefulness of these monitors. The patient's underlying cardiac condition also needs to be considered. The indications for central venous pressure and pulmonary artery catheter monitoring are discussed in further detail in the subsequent sections.

ABDOMINAL AORTIC RECONSTRUCTION

Anesthesia for abdominal aortic reconstruction requires an understanding of the pathophysiology, an extensive knowledge of the surgical procedure, an ability to interpret sophisticated hemodynamic data, and a skillful pharmacologic control and manipulation of hemodynamics. Preoperative and intraoperative communication with the surgical team is essential. All operative procedures on the abdominal aorta and its major branches require large incisions and extensive dissection, clamping and unclamping of the aorta and/or its major branches, varying duration of organ ischemia, significant fluid shifts and temperature fluctuations, and activation of the neuroendocrine stress response. The major objectives of surgical treatment are to relieve symptoms, reduce the frequency of associated complications, and, in the case of aortic aneurysm, prevent rupture.

Natural History and Surgical Mortality

Abdominal Aortic Aneurysm

Abdominal aortic aneurysm is a multifactorial disease associated with aortic aging and atherosclerosis. [121] Although no unified concept of pathogenesis exists, there are genetic, biochemical, metabolic, mechanical, and hemodynamic factors that may contribute to the development of abdominal aortic aneurysmal disease. [122] [123] Adventitial elastin degradation (elastolysis), a hallmark of abdominal aortic aneurysm formation, may be the primary event. [124] The incidence of abdominal aortic aneurysms appears to be rising. [125] Concomitant aortoiliac occlusive disease is present in approximately 20 to 25 percent of patients with abdominal aortic aneurysms. [126] Approximately 5 percent of patients undergoing abdominal aortic resection have inflammatory aneurysms. [126] Rare causes of abdominal aortic aneurysm disease include trauma, mycotic infection, syphilis, and Marfan syndrome.

The natural history of abdominal aortic aneurysmal disease is one of progressive enlargement and ultimate rupture and death. In 1950, Estes [127] published a classic study of the natural history of abdominal aortic aneurysms in 102 patients. Only 19 percent of these patients survived 5 years, and rupture was the cause of death in 63 percent. The first successful abdominal aortic aneurysm resection and graft replacement (homograft implantation) was accomplished by Dubost and colleagues [128] in 1951. In 1966, Szilagyi et al [129] confirmed the principle of elective graft replacement to prevent

the eventual rupture of abdominal aortic aneurysm and to prolong life. Perioperative mortality from elective infrarenal aortic aneurysm resection has progressively declined from 18 to 20 percent during the 1950s, to 6 to 8 percent in the mid-1960s, to 5 to 6 percent in the early 1970s, to 2 to 4 percent in the 1980s, when it plateaued. [130] A publication of 1,000 consecutive elective infrarenal aneurysms over a 15-year period reported a perioperative mortality rate of 2.4 percent. [131] For ruptured abdominal aortic aneurysms, perioperative mortality has not changed significantly and remains nearly 50 percent [132] [133] [134] with few exceptions. [135] If one takes into consideration patients with rupture who die before reaching a hospital, the overall mortality rate after rupture may very well exceed 90 percent. [134]

The diameter and rate of expansion of abdominal aortic aneurysms are currently the best predictors of the risk of rupture. [136] [137] There is near-uniform agreement that elective repair should be undertaken in all abdominal aortic aneurysms with a diameter of 6 cm or greater. [129] Although some controversy exists regarding elective abdominal aortic aneurysm repair when diameter is in the 5.0- to 5.9-cm range, [138] most agree that the risk of rupture for a 5-cm aneurysm (per year) is equal to or greater than perioperative mortality, and thus surgical repair is indicated. The natural history of abdominal aortic aneurysms 4 to 5 cm in diameter is not well defined, and significant controversy exists regarding surgical repair. [139] [140] [141] However, surgical repair is recommended if such aneurysms become symptomatic or expand more than 0.5 cm in a 6-month period. Aneurysms less than 4 cm in diameter are felt to be relatively benign in terms of rupture and expansion. [142] Late survival after repair of nonruptured abdominal aortic aneurysms is 92 percent at 1 year and 67 percent at 5 years. [134]

Aortoiliac Occlusive Disease

As noted earlier, the infrarenal aorta and the iliac arteries are two of the most common sites of chronic atherosclerosis. [143] Because of the diffuse and progressive nature of aortoiliac atherosclerosis, plaque enlargement may reduce blood flow to the lower extremities below a critical level, resulting in symptoms of ischemia. Unlike patients with aortic aneurysmal disease, patients undergo surgery for aortoiliac occlusive disease only if they are symptomatic. Surgical intervention is indicated for disabling intermittent claudication and limb-threatening ischemia. Intervention is directed toward restoring peripheral pulsatile circulation to relieve claudication and toward preventing amputation. Patients with localized aortoiliac occlusive disease typically present with claudication because collateral circulation adequate to prevent critical lower-extremity ischemia usually exists. [144] Most patients undergoing aortoiliac reconstruction for limb-threatening ischemia have multilevel occlusive disease with infrainguinal involvement, [145] and the indication for surgery is more often limb salvage rather than relief of claudication. [144] [146] Perioperative mortality is lower for patients undergoing aortoiliac reconstruction than for those undergoing abdominal aortic surgery. [146] [147]

Therapeutic options for managing aortoiliac occlusive disease include anatomic or direct reconstruction (aortobifemoral bypass), extra-anatomic or indirect bypass grafts (axillofemoral bypass), and catheter-based endoluminal techniques (percutaneous transluminal angioplasty with or without stent insertion). Aortobifemoral bypass is viewed as the gold standard in treating aortoiliac occlusive disease. [147] Extra-anatomic bypass grafts are usually reserved for specific indications, usually involving infection, failure of previous reconstruction, or prohibitive risk patients. Reduced long-term patency and inferior functional results are frequently the tradeoff for lower perioperative morbidity and mortality. [148] [149] Catheter-based endoluminal techniques, such as percutaneous transluminal angioplasty, are used for relatively localized disease and may be reasonable alternatives to aortobifemoral bypass in 10 to 15 percent of patients with aortoiliac occlusive disease. [147]

Renal and Visceral Arterial Insufficiency

Atherosclerosis is the most common cause of renal artery stenosis. Occlusive lesions are located almost exclusively in the proximal segment and orifice of the renal artery and are usually an extension of aortic atherosclerosis. Fibromuscular dysplasia involving the renal arteries occurs primarily in the distal two-thirds. Hemodynamically significant renal artery stenosis may cause hypertension via activation of the renin-angiotension system, and bilateral involvement may result in renal failure. Indications for intervention include control of hypertension and salvage of renal function. Operative interventions include aortorenal bypass, extra-anatomic bypass (hepatorenal or splenorenal bypass), or transaortic endarterectomy. Percutaneous transluminal angioplasty of the renal artery is used as the first-line treatment in selected patients. Suprarenal or supraceliac aortic cross-clamping is frequently required for operative interventions. Patients with renovascular hypertension frequently have poorly controlled hypertension despite maximal medical therapy.

Stenosis at the origin of the celiac and mesenteric arteries occurs from extension of aortic atherosclerosis. The inferior mesenteric artery is by far the most commonly involved, followed by the superior mesenteric artery and the celiac artery. Occlusion of a single vessel rarely causes ischemic symptoms because of the extensive nature of visceral collateralization. However, occlusion or significant stenosis of any two vessels may sufficiently compromise collateral flow and give rise to chronic visceral ischemia. Operative repair of visceral artery stenosis is reserved for symptomatic patients. Operative interventions include transaortic endarterectomy and/or

bypass grafts, which frequently require supraceliac aortic cross-clamping. For reasons that are unclear, this condition affects women about four times as often as men. [133] Mortality rates for such procedures range from 7 to 18 percent. Acute mesenteric artery occlusion can be caused by embolus or, less commonly, thrombosis. To avoid the extremely high mortality associated with this condition, diagnosis and surgical intervention must occur before gangrene of the bowel develops.

Aortic Cross-Clamping

The pathophysiology of aortic cross-clamping and unclamping is complex and depends on many factors, including

the level of cross-clamp, the extent of CAD and myocardial function, the degree of periaortic collateralization, the blood volume and distribution, the activation of the sympathetic nervous system, and the anesthetic agents and techniques. Most abdominal aortic reconstructions require clamping at the infrarenal level. However, clamping at the suprarenal and supraceliac levels is required for suprarenal aneurysms and renal/visceral reconstructions and is frequently necessary for juxtarenal and inflammatory aneur-ysms and aortoiliac occlusive disease with proximal extension. These higher levels of aortic occlusion have a significant impact on the cardiovascular system as well as on other vital organs rendered ischemic or hypoperfused. Ischemic complications may result in renal failure, hepatic ischemia and coagulopathy, bowel infarction, and paraplegia.

Hemodynamic and Metabolic Changes

The hemodynamic changes associated with aortic cross-clamping and unclamping are summarized in Tables 51-7 and 51-8 . The systemic cardiovascular consequences of aortic cross-clamping can be dramatic, depending primarily on the level at which the cross-clamp is applied. Arterial hypertension

is the most consistent component of the hemodynamic response to aortic cross-clamping at any level. Cross-clamping of the aorta at or above the diaphragm can result in profound increases in arterial blood pressure [150] [151] unless diverting circulatory support and/or intravenous vasodilators are used. [150] [152] This increase in arterial blood pressure is most likely due to the sudden increase in impedance to aortic blood flow and the resultant increase in systolic ventricular wall tension or afterload. However, factors such as myocardial contractility, preload, blood volume, and sympathetic nervous system activation may also be important. Changes in cardiac output and filling pressures with aortic cross-clamping are not consistent and require an integrated approach in an attempt to understand the direction and magnitude of such changes (Fig. 51-5) (Figure Not Available) .

Cross-clamping of the proximal descending thoracic aorta increases mean arterial, central venous, mean pulmonary arterial, and pulmonary capillary wedge pressures by 35 percent, 56 percent, 43 percent, and 90 percent, respectively, and decreases cardiac index by 29 percent. [150] Heart rate and left ventricular stroke work are not significantly changed. Supraceliac aortic cross-clamping increases mean arterial pressure by 54 percent and pulmonary capillary wedge pressure by 38 percent. [151] Ejection fraction, as determined by two-dimensional echocardiography, decreases by 38 percent. Despite normalization of systemic and pulmonary capillary wedge pressures, supraceliac aortic cross-clamping causes significant increases in left ventricular end-systolic and end-diastolic areas (69% and 28%, respectively), as well as wall motion abnormalities indicative of ischemia in 11 of 12 patients (Table 51-9) (Table Not Available) . Aortic cross-clamping at the suprarenal level causes similar but smaller cardiovascular changes, and clamping at the infrarenal level is associated with only minimal changes and no wall motion abnormalities.

The marked increases in pulmonary capillary wedge pressure with high aortic cross-clamping have been attributed to

Figure 51-5 (Figure Not Available) Systemic hemodynamic response to aortic cross-clamping. *Preload does not necessarily increase with infrarenal clamping. Depending on splanchnic vascular tone, blood volume can be shifted into the splanchnic circulation and preload will not increase. AoX, aortic cross-clamping; Ao, aortic; R art, arterial resistance. *(From Gelman [176])*

blood volume redistribution and increased afterload. A substantial body of evidence supports the hypothesis of blood volume redistribution during thoracic aortic cross-clamping. The splanchnic circulation, an important source of functional blood volume reserve, is central to this hypothesis. Primarily because of a lower splanchnic venous capacitance, blood volume is redistributed from vascular beds distal to the clamp to the vascular beds proximal to the clamp (see Fig. 51-5 (Figure Not Available)). Cross-clamping the aorta above the splanchnic system results in passive recoil of the venous circulation distal to the clamp. Thoracic aortic cross-clamping results in significant increases in plasma epinephrine and norepinephrine, [153] [154] which may enhance venomotor tone both above and below the clamp. Several animal studies that support the blood redistribution hypothesis merit mention. Cross-clamping the thoracic aorta in dogs resulted in marked increases in mean arterial and end-diastolic left ventricular pressures (84% and 188%, respectively) and no significant change in stroke volume. [155]

In this same experimental model, simultaneous cross-clamping of the thoracic aorta and the inferior vena cava resulted in no significant change in preload or mean arterial pressure (Fig. 51-6) (Figure Not Available) . Stroke volume was reduced by 74 percent. By transfusing blood during this period of simultaneous clamping, the authors reproduced the hemodynamic effect of thoracic aortic cross-clamping alone. This study also demonstrated that thoracic aortic cross-clamping is associated with a significant and dramatic increase (155%) in blood flow above the level of the clamp, whereas no change occurred with simultaneous aortic and inferior vena cava clamping. In another animal model, the proximal aortic hypertension and increased central venous pressure occurring after thoracic aortic cross-clamping were reversed by phlebotomy. [156] Lastly, aortic cross-clamping at the thoracic and suprarenal levels both resulted in proximal aortic hypertension, but only occlusion at the thoracic level increased central venous pressure. [157] In addition, thoracic aortic occlusion increased blood volume in organs and tissues proximal to the clamp, whereas no such increase occurred with suprarenal aortic cross-clamping. These experimental data strongly support the hypothesis of blood volume redistribution during aortic cross-clamping and help to explain the marked differences in hemodynamic responses observed after aortic cross-clamping at different levels. [151]

Afterload-dependent increases in preload also occur with aortic cross-clamping, usually in the setting of impaired myocardial contractility and reduced coronary

reserve. The impaired left ventricle may respond to increased afterload with an increase in end-systolic volume and a concomitant reduction in stroke volume (afterload mismatch). The reduction in stroke volume may be due to limited preload reserve, myocardial ischemia, and/or inability of the heart to generate a pressure-induced increase in contractility (the Anrep effect). If right ventricular function remains normal, the preclamp right ventricular stroke volume is added to the elevated left ventricular end-systolic volume, resulting in left ventricular dilation and elevated end-diastolic volume. If corrective measures are not undertaken, overt left ventricular overload may result, with severe peripheral organ dysfunction and pulmonary edema.

Most clinical studies indicate that cardiac output decreases with thoracic aortic cross-clamping, whereas most animal studies show no significant change. The normal heart can withstand large increases in afterload without significant ventricular distention or dysfunction. Although impaired myocardial contractility and reduced coronary reserve are rare in animal experiments, such disorders are frequent in the elderly population undergoing aortic reconstruction. As

discussed earlier, the increase in proximal aortic pressure seen with thoracic and supraceliac cross-clamping [150] [151] may increase left ventricular wall stress (afterload), with resultant acute deterioration in left ventricular function and/or myocardial ischemia. Impaired subendocardial perfusion caused by high intramyocardial pressure may be the cause of wall motion abnormalities and changes in ejection fraction. Reflex mechanisms causing immediate feedback inhibition may also explain the reduction in cardiac output with aortic cross-clamping. For example, baroreceptor activation resulting from increased aortic pressure should depress heart rate, contractility, and vascular tone.

The metabolic effects of cross-clamping and unclamping are summarized in Tables 51-7 and 51-8 . Cross-clamping of the thoracic aorta decreases total body oxygen consumption by approximately 50 percent. [158] [159] For reasons that are unclear, oxygen consumption decreases in the tissues above the clamp. [158] In clinical studies, increased mixed venous oxygen saturation occurs with aortic cross-clamping above the celiac axis. [160] [161] This increase in mixed venous oxygen saturation may be explained by a reduction in oxygen consumption that exceeds the reduction in cardiac output, thus decreasing total body oxygen extraction. [161] Central hypervolemia [155] and/or increased arteriovenous shunting [162] in the tissues proximal to the aortic clamp may play a role in reducing total body oxygen extraction.

Arterial blood pressure, blood flow, and oxygen consumption distal to a thoracic aortic cross-clamp decrease by 78 to 88 percent, [154] [163] [164] 79 to 88 percent, [155] [158] and 62 percent, [158] respectively, from baseline values before clamping. Blood flow through tissues and organs below the level of aortic occlusion is dependent on the perfusion pressure and is independent of cardiac output. [163] Administration of sodium nitroprusside in order to maintain proximal aortic pressure above the cross-clamp at preclamp levels has been shown to further reduce arterial pressure distal to the clamp by 53 percent. [163] As is discussed later in the chapter, these data may have significant implications regarding vital organ protection during aortic cross-clamping.

The cardiovascular response to infrarenal aortic cross-clamping is less significant than with high aortic cross-clamping (see Table 51-9 (Table Not Available)). Although several clinical reports have noted no significant hemodynamic response to infrarenal cross-clamping, [165] [166] the hemodynamic response generally consists of increases in arterial pressure (7-10%) and systemic vascular resistance (20-32%) with no significant change in heart rate. [167] [168] [169] Cardiac output is most consistently decreased by 9 to 33 percent. [166] [167] [169] [170] Reported changes in ventricular filling pressures have been inconsistent. [151] [165] [166] [167] [168] [169] [170] [171] Blood volume redistribution may affect preload with infrarenal aortic cross-clamping (see Fig. 51-5 (Figure Not Available)). In this situation, blood volume below the clamp shifts to the compliant venous segments of the splanchnic circulation above the clamp, dampening the expected increase in preload. Preload changes with infrarenal aortic crossclamping may also be dependent on the status of the coronary circulation. [167] [171] An early report found that patients with severe ischemic heart disease responded to infrarenal aortic cross-clamping with significantly increased central venous (35%) and pulmonary capillary (50%) pressures, whereas patients without CAD had decreased filling pressures. [167] Echocardiographically detected segmental wall

motion abnormalities occur in up to 30 percent of patients during infrarenal aortic reconstruction, [172] with 66 percent occurring at the time of aortic cross-clamping. [172] [173] Clinical studies imply that patients with aortoiliac occlusive disease have less hemodynamic response to infrarenal aortic cross-clamping than patients with abdominal aortic aneurysmal disease, [169] [174] perhaps as a result of more extensive periaortic collateral vascularization. [175]

Renal Function and Protection

Acute renal failure occurs in approximately 3 percent of patients undergoing elective infrarenal aortic reconstruction, and mortality resulting from postoperative acute renal failure is greater than 40 percent. [176] Thus, preservation of renal function is of significant importance during aortic reconstructive surgery. Adequacy of renal perfusion cannot be assumed by urine output, because intraoperative urine output does not predict postoperative renal function. [177] Procedures requiring aortic cross-clamping above the renal arteries dramatically reduce renal blood flow. Experimental studies report an 83 to 90 percent reduction in renal blood flow during thoracic aortic cross-clamping. [163] [178] Infrarenal aortic cross-clamping in humans is associated with a 75 percent increase in renal vascular resistance, a 38 percent decrease in renal blood flow, and a redistribution of intrarenal blood flow toward the renal cortex. [166] These rather profound alterations in renal hemodynamics occurred despite no significant change in systemic hemodynamics, and they persisted after unclamping. The sustained deterioration in renal perfusion and function during and after infrarenal aortic cross-clamping has been attributed to renal vasoconstriction, but the pathophysiology remains unknown. [85] [166] Renal sympathetic blockade with epidural anesthesia to a T6 level does not prevent or modify the severe impairment of renal perfusion and function that occurs during and after infrarenal aortic cross-clamping. [85] Although plasma renin activity is increased during aortic cross-clamping, [179] pretreatment with converting enzyme inhibitors before infrarenal aortic cross-clamping does not attenuate the decreased renal blood flow and glomerular filtration rate. Other mediators, such as plasma endothelin, myoglobin, and prostaglandins, may contribute to the decreased renal perfusion and function after aortic cross-clamping.

Acute tubular necrosis accounts for nearly all renal dysfunction and failure after aortic reconstruction. Intravascular volume depletion, embolization of atherosclerotic debris to the kidneys, and surgical trauma to the renal arteries all contribute to renal dysfunction. Mannitol, loop diuretics, and dopamine are used clinically in an attempt to preserve renal function during aortic surgery. Significant controversy exists regarding the use of these agents as well as the mechanisms by which they may offer a protective effect. Despite studies demonstrating little or no benefit, [180] [181] [182] many clinicians administer these drugs. The use of mannitol (12.5 g/70 kg) to induce an osmotic diuresis before aortic crossclamping is ubiquitous in clinical practice. Mannitol improves renal cortical blood flow during infrarenal aortic cross-clamping. [183] In addition, mannitol can reduce ischemia-induced renal vascular endothelial cell edema and vascular congestion. [184] Other mechanisms by which mannitol may be beneficial include acting as a scavenger of free radicals, decreasing renin secretion, and increasing renal prostaglandin synthesis. [185] Loop diuretics and low-dose dopamine (1-3 mug/kg/min) have been advocated to protect the kidneys from aortic cross-clamp-induced injury by increasing renal blood flow and urine output intraoperatively. Some clinicians advocate the routine use of these agents for patients with preoperative renal insufficiency and for procedures requiring suprarenal aortic cross-clamping. Intraoperative use of these agents requires increased surveillance of intravascular volume and electrolytes during the postoperative period. Therapy with these agents could actually be harmful because of hypovolemia and resultant renal hypoperfusion. In addition, dopamine's positive inotropic and chronotropic activity may cause tachycardia and may increase myocardial oxygen consumption in patients with limited coronary reserve.

Most clinical studies suggest that optimization of systemic hemodynamics, including maintenance of intravascular volume, is the most effective means of renal protection during and after aortic cross-clamping. [186] [187] [188] [189] In providing such therapy, it is equally important to avoid overhydration, which may lead to inappropriate increases in preload and/or pulmonary edema in patients with decreased myocardial reserve. The degree of preoperative renal insufficiency, the extent of aortic reconstruction, the duration of cross-clamping, and the severity of juxtarenal atherosclerosis are important factors that may contribute to the development of renal failure.

Therapeutic Strategies

Patients with preexisting impaired ventricular function and reduced coronary reserve are most vulnerable to the stresses imposed on the cardiovascular system by aortic cross-clamping. Rational therapeutic strategies to prevent the deleterious effect of aortic cross-clamping primarily include measures to reduce afterload and normalize preload. Coronary vasodilators, positive and negative inotropes, and controlled volume depletion (phlebotomy) may be utilized selectively.

Patients with impaired ventricular function requiring supraceliac aortic cross-clamping are the most challenging. Myocardial ischemia, reflecting an unfavorable balance between myocardial oxygen supply and demand, may result from the hemodynamic consequences of aortic crossclamping. Controlled supraceliac aortic cross-clamping is important to avoid abrupt and extreme stresses on the heart. Afterload reduction, most commonly accomplished by use of sodium nitroprusside (predominantly an arteriolar dilator), is necessary to "unload" the heart and reduce ventricular wall tension. In a large series of patients requiring cross-clamping of the descending thoracic aorta, stable left ventricular function was maintained during cross-clamping with sodium nitroprusside. [152] The authors also concluded that sodium nitroprusside allowed adequate volume loading before unclamping, which resulted in stable unclamping hemodynamics. Normalization of preload involves careful fluid titration and/or vasodilator administration. Infusion of nitroglycerin during abdominal aortic surgery has been shown to maintain ventricular function during the cross-clamp period. [190]

During thoracic aortic cross-clamping, isoflurane can provide hemodynamics comparable to those provided by sodium nitroprusside. [159] Amrinone provides hemodynamic control equivalent to that of sodium nitroprusside during abdominal aortic surgery. [191] Blood flow below the clamp, which is pressure dependent, [163] decreases during therapy with vasodilators. [158] [163] Vital organs and tissues distal to the clamp are thus exposed to reduced perfusion pressure and blood flow. In patients without evidence of left ventricular decompensation or myocardial ischemia during supraceliac aortic cross-clamping, a proximal aortic mean arterial pressure of up to 120 mm Hg is acceptable. Although infrequent, maintenance of adequate cardiac output may require active intervention with inotropic agents. In general, anesthetic agents that depress myocardial function are avoided during aortic procedures.

Aortic Unclamping

The hemodynamic and metabolic effects of unclamping are listed in Table 51-8 . The hemodynamic response to unclamping depends on the level of aortic occlusion, the total occlusion time, the use of diverting support, and the intravascular volume. Hypotension, the most consistent hemodynamic response to aortic unclamping, can be profound after removal of a supraceliac cross-clamp (Fig. 51-7) (Figure Not Available) . Reactive hyperemia distal to the clamp and the resultant relative central hypovolemia are the dominant mechanisms of the hypotension. Washout of vasoactive and cardiodepressant mediators from ischemic tissues, as well as humoral factors, may also contribute to the hemodynamic responses after unclamping the aorta. These humoral factors and mediators, which may also play a role in organ dysfunction after aortic occlusion, include lactic acid, renin-angiotensin, oxygen free-radicals, prostaglandins, neutrophils, activated complement, cytokines, and myocardial-depressant factors. [176]

The avoidance of significant hypotension with unclamping requires communication with the surgical team, awareness of the technical aspect of the surgical procedure, and appropriate administration of fluids and vasoactive agents. It is essential that preoperative fluid deficits, intraoperative maintenance requirements, and replacement of blood loss be accomplished before unclamping. Vasodilators, if utilized, should be gradually reduced and/or discontinued before unclamping. Potent inhalational agents should be decreased. Moderate intravascular volume loading (approximately 500 mL) during the immediate prerelease period is indicated for infrarenal unclamping. [165] [192] More aggressive volume loading is required in the period immediately preceding supraceliac unclamping. Volume loading in an attempt to maintain an elevated central venous or pulmonary capillary wedge pressure during the cross-clamp period is not indicated and may result in significant overtransfusion of fluids and blood products. Gradual release of the aortic clamp and reapplication or digital compression if significant hypotension results are important measures in maintaining hemodynamic stability during unclamping. Although vasopressors are rarely required after release of the infrarenal clamp, they are frequently required after removal of

Figure 51-7 (Figure Not Available) Systemic hemodynamic response to aortic unclamping. AoX, aortic cross-clamping; Cven, venous capacitance; R art, arterial resistance; Rpv, pulmonary vascular resistance. *(From Gelman [176])*

supraceliac clamps. Caution must be observed when vasopressor support is utilized because profound proximal hypertension may occur if reapplication of the cross-clamp is required above the celiac axis. In addition, hypertension should be avoided to prevent damage to, or bleeding from, the vascular anastomoses.

Anesthetic Management

Intraoperative Monitoring

The potential for significant and rapid blood loss cannot be underestimated. We most commonly utilize one 8.5 French internal jugular catheter and one or two large-bore peripheral catheters. A hemostatic valve with a side port is placed on the 8.5 French catheter to accept either a central venous or a pulmonary artery catheter. Placement of arterial catheters should be routine for all patients undergoing abdominal aortic reconstruction. As with other vascular procedures, the radial artery is most commonly selected for cannulation because of its superficial location, easy accessibility, and low complication rate. A noninvasive blood pressure cuff should be placed on the arm contralateral to the arterial catheter in the event of catheter malfunction.

Placement of central venous catheters is routine for all aortic procedures. Such catheters allow central venous pressure monitoring and administration of drugs into the central circulation. The routine, nonselective use of pulmonary artery catheter monitoring is not recommended for all patients undergoing infrarenal abdominal aortic reconstruction. For these procedures, pulmonary artery catheters should be considered for patients with significant left ventricular dysfunction (ejection fraction <30 percent), history of congestive heart failure, significant renal impairment (preoperative creatinine >2.0 mg/dL), or cor pulmonale. In patients with good left ventricular and pulmonary function, central venous pressure correlates well with left ventricular filling pressures. [193] A pulmonary artery catheter should be inserted for all patients requiring suprarenal aortic cross-clamping. The invasive monitoring catheters can be placed before or after the induction of anesthesia. The advantage of preinduction catheter placement is assessment of the awake ("baseline") cardiovascular status, which allows correction of severe abnormalities in cardiac filling and function before induction.

Two-dimensional TEE has been used intraoperatively to assess global ventricular function, guide fluid therapy, and monitor for myocardial ischemia. Continuous monitoring of ventricular function is commonly obtained from a single short-axis view at the level of the midpapillary muscle. Using this same view, visualization of the left ventricle at enddiastole allows rapid assessment of ventricular filling (preload). Ejection fraction area can be calculated by use of left ventricular end-diastolic and end-systolic areas. In patients undergoing abdominal aortic reconstruction, echocardiographic short-axis left ventricular end-diastolic area, end-systolic area, and ejection fraction area correlate closely with changes in corresponding left ventricular volumes and ejection fraction obtained by radionuclide angiography. [194] [195] Patients requiring supraceliac aortic cross-clamping have significant increases in end-diastolic area and significant decreases in ejection fraction by echocardiography that are not completely normalized with vasodilators and frequently are not detected by pulmonary artery catheter monitoring. [151]

Transesophageal echocardiography can also reveal abnormalities of left ventricular wall motion and wall thickening. The relationship between these abnormalities and coronary perfusion has been established experimentally [196] [197] and clinically, [198] [199] and such abnormalities may precede ECG evidence of ischemia. [115] The short-axis view at the level of the midpapillary muscles allows assessment of all three major coronary distributions. TEE-detected segmental wall motion abnormalities may occur in up to 37 percent of patients during infrarenal aortic reconstruction [200] and in more than 90 percent of patients requiring supraceliac aortic cross-clamping. [151] [172] The natural history of echocardiographic segmental wall motion abnormalities was studied in 156 patients at risk for cardiac morbidity undergoing noncardiac surgery. [200] The 24 patients undergoing aortic surgery had the highest incidence of new segmental wall motion abnormalities (38%). Surprisingly, the incidence of new segmental wall motion abnormalities did not differ for patients with known CAD and those with cardiac risks factors only. Ischemic episodes detected by TEE correlated poorly with postoperative cardiac complications. The authors also reported a discordant relation between new segmental wall

motion abnormalities and ECG ischemic changes. In a subsequent report, a subset of 285 patients who were at high risk for cardiac complications and were undergoing noncardiac surgery were studied with continuous intraoperative use of two-lead ECG, 12-lead ECG, and TEE for the detection of ischemia. [201] A lack of concordance was found between the three different ischemia monitors. When compared with preoperative clinical data and intraoperative monitoring in which two-lead ECG was used, routine monitoring for myocardial ischemia with TEE or 12-lead ECG during noncardiac surgery had little incremental clinical value in identifying patients at high risk for perioperative ischemic outcomes. Thus, available data are insufficient to define the sensitivity and specificity of segmental wall motion abnormalities as a marker for myocardial ischemia or as a predictor of perioperative ischemic outcomes.

The optimal intraoperative monitoring techniques for patients undergoing abdominal aortic reconstruction have not been established. Existing clinical studies offer insufficient data to conclusively answer the question of whether pulmonary artery catheter or TEE monitoring improves outcome. The clinical usefulness of any monitoring technique ultimately depends on patient selection, accurate interpretation of data, and appropriate therapeutic intervention.

Autotransfusion during aortic surgery reduces exposure to allogeneic blood products and the associated risks of transfusion-related complications (Chs. 46 and 47). However, the equipment is expensive and requires significant training and expertise. Although there are no randomized prospective trials, one study showed a 25 to 57 percent reduction in the number of allogeneic blood products given. [202] The routine use of autotransfusion (Cell Saver, Haemonetics, Braintree, MA), however, may not be costeffective ($250-$350 per case), and thus it should be reserved for a select group of patients with high expected blood loss. [203]

Anesthetic Drugs and Techniques

A variety of anesthetic techniques and drugs, including general anesthesia, regional (epidural) anesthesia, and combined techniques, have been used successfully for abdominal aortic reconstruction. Combined techniques most commonly employ a lumbar or low thoracic epidural catheter in addition to a "light" general anesthetic. Local anesthetics, opioids, or more commonly, a combination of the two, may be administered by bolus or by continuous epidural infusion. Some evidence suggests that maintenance of vital organ perfusion and function by the provision of stable perioperative hemodynamics is more important to overall outcome than the choice of anesthetic agent or technique. Therefore, the specific anesthetic technique for patients undergoing abdominal aortic reconstruction is important insofar as it allows rapid and precise control of hemodynamic parameters. Given the high incidence of cardiac morbidity and mortality in patients undergoing aortic reconstruction, special emphasis must be placed on factors that influence ventricular work and myocardial perfusion. In general, a balanced anesthetic using relatively short-acting agents maximizes management flexibility, which is most desirable in this patient population.

Induction of general anesthesia should proceed in a controlled fashion such that stable hemodynamics are maintained during loss of consciousness, laryngoscopy and intubation, and the immediate postinduction period. A variety of intravenous hypnotic agents (thiopental, etomidate, propofol) are suitable. The addition of a short-acting, potent opioid, such as fentanyl (3 to 8 mug/kg) usually provides stable hemodynamics during and after induction. Halogenated agents may be administered in low concentration before intubation during assisted ventilation as an adjunct to blunt the hyperdynamic response to laryngoscopy and intubation. Esmolol (10-25 mg), sodium nitroprusside (5-25 mug), nitroglycerin (50-100 mug), and phenylephrine (50-100 mug) should be available for bolus administration during induction if needed to maintain appropriate hemodynamics.

Anesthetic maintenance may be accomplished with a combination of a potent opioid (fentanyl or sufentanil) and an inhaled anesthetic (sevoflurane, desflurane, or isoflurane). Patients with severe left ventricular dysfunction may benefit from a pure opioid technique, but a balanced anesthetic technique allows the clinician to take advantage of the most desirable characteristics of potent opioids and inhalational agents while minimizing their undesirable side effects. We typically use low-dose isoflurane in 50 percent nitrous oxide and 20 to 25 mug/kg of fentanyl. Approximately 50 percent of the opioid dose is administered during induction and before skin incision. When epidural local anesthetics are used, we employ the same balanced technique and reduce the fentanyl dose to 8 to 10 mug/kg.

Nitrous oxide can be used to supplement either an opioid or an inhalational-based anesthetic. In general, nitrous oxide has a tendency to decrease cardiac output and arterial pressure while increasing systemic vascular resistance. One report indicated that in patients undergoing abdominal aortic surgery, nitrous oxide increased the need for vasodilator therapy to treat increases in pulmonary capillary wedge pressure and myocardial ischemia. [204] We typically use 50 percent nitrous oxide as part of a balanced anesthetic technique, particularly when extubation is planned at the termination of the procedure.

Various regional anesthetic and analgesic techniques have been used effectively during and after aortic reconstruction. An overview of the advantages and limitations of regional techniques for vascular surgery is included in the discussion of lower-extremity vascular surgery, and the discussion here is limited to the clinical issues specific to abdominal aortic reconstruction. Over the past decade considerable interest has been focused on the use of regional anesthetic and analgesic techniques to reduce the incidence of perioperative morbidity in patients undergoing aortic reconstruction. The benefits of combined general-epidural anesthesia intraoperatively, with or without epidural analgesia continued into the postoperative period, remain controversial, and conflicting results have been reported. [205] [206] [207] [208] Moreover, studies that have reported improved outcome do not determine whether the benefit results from the intraoperative anesthetic technique or from the postoperative pain regimen (or from a combination of the two). In a randomized trial using epidural morphine in patients undergoing aortic surgery, Breslow et al [209] found an attenuation of the adrenergic response and a lower incidence of hypertension in the postoperative period. The effects of anesthetic/analgesic techniques on the incidence of perioperative myocardial ischemia have also received considerable attention. Three publications, with nearly 200 combined patients undergoing aortic reconstruction, failed to demonstrate a reduction in the incidence of perioperative, [210] intraoperative, [173] or postoperative [208] myocardial ischemia when epidural techniques were employed.

Clinical studies have identified several disadvantages in the use of epidural local anesthetics in combination with general anesthesia during aortic reconstruction, including significant hypotension at the time of aortic unclamping [165] and increased fluid [211] and vasopressor [207] requirements. Supraceliac aortic cross-clamping may significantly exaggerate these disadvantages, and as a result, some clinicians avoid epidural local anesthetics for such procedures. We frequently use epidural opioids without local anesthetics for procedures requiring supraceliac aortic cross-clamping. Epidural local anesthetic can be given later, after reperfusion, when hemodynamics and intravascular volume have stabilized. For low thoracic or high lumbar epidural catheters, we limit the initial bolus to 6 to 8 mL of local anesthetic. Additional local anesthetic is administered via continuous infusion at 4 to 6 mL/h with adjustments based on hemodynamics and inhalational anesthetic requirements during surgery. Although elective aortic reconstruction via the retroperitoneal approach using straight epidural anesthesia (no general anesthetic) has been reported, [212] [213] this technique is not recommended for routine use.

We begin preparation for emergence from anesthesia after restoration of circulation and establishment of adequate organ perfusion. Hemodynamic, metabolic, and temperature homeostasis must be achieved before skin closure; otherwise, patients are transported to the intensive care unit intubated, with their ventilation controlled. Extubation of the trachea is generally not attempted in patients with supraceliac aortic cross-clamp times greater than 30 minutes, patients with poor baseline pulmonary function, or patients

requiring large volumes of blood or crystalloid during surgery. At the start of skin closure, inhaled anesthetics are discontinued, nitrous oxide is increased to 70 percent, and residual neuromuscular blockade is reversed. We routinely place a large nasal airway after induction but before systemic heparinization in all patients for whom extubation is planned in the operating room. Hypertension and tachycardia are aggressively controlled during emergence by use of short-acting agents, such as esmolol, nitroglycerin, and sodium nitroprusside. Patients are placed in a recumbent, head-up position, and nitrous oxide is discontinued. If spontaneous ventilation is adequate, the trachea is extubated. Some centers advocate extubation of all patients in the intensive care unit after a period of stability has been established. In these cases, mild sedation with a benzodiazepine such as midazolam is appropriate.

Temperature Control

Postoperative hypothermia is associated with many undesirable physiologic effects [214] [215] [216] [217] and may contribute to adverse outcome (Ch. 37) . [218] [219] [220] [221] We maintain normothermia before skin incision by increasing ambient temperature in the operating room, applying warm cotton blankets, and warming the intravenous fluids. If significant hypothermia occurs early in the procedure, normothermia is extremely difficult to achieve, and emergence and extubation may be delayed. During surgery, all fluids and blood products should be warmed before administration. We routinely apply a forced-air warming blanket over the upper body. The lower body

should not be warmed, because doing so can increase injury to ischemic tissue distal to the cross-clamp by increasing metabolic demands.

THORACOABDOMINAL ANEURYSM SURGERY

Thoracic aortic surgery and thoracoabdominal aneurysm (TAA) repair are perhaps the most challenging surgical cases in terms of overall anesthetic and perioperative management. To successfully care for these patients, the anesthesiologist must be knowledgeable in the areas of one-lung ventilation; extracorporeal circulatory support, including circulatory arrest; renal and spinal cord protection; induced hypothermia; TEE; massive transfusion; and management of coagulopathy. Intraoperative management requires a team effort with intimate cooperation between surgeons, anesthesiologists, perfusionists, nurses, and electrophysiologic monitoring staff. Even in centers where numerous procedures are performed, morbidity and mortality are high, especially in patients with dissecting or ruptured aneurysms.

Etiology and Classification

A true aortic aneurysm is a dilation of the entire aorta, as measured across from one endothelial wall to the other. A false aneurysm is one with a normal internal diameter with the bulk of the aneurysm originating from a dissected channel. Although atherosclerosis accounts for 95 percent of abdominal aortic aneurysms, only one-half of thoracic and thoracoabdominal aortic aneurysms are atherosclerotic in origin. [222] The remainder are caused either by trauma or by connective tissue diseases involving the aortic wall from conditions such as Marfan syndrome, cystic medial degeneration, Takayasu arteritis, or syphilitic aortitis. [223] Patients with aneurysmal disease have a poor prognosis without surgery. Nutritional blood flow to the aorta is compromised, and the increasing diameter is associated with increased wall tension, even when arterial pressure is constant (law of LaPlace).

The most popular classification schemes are those of Crawford [224] and DeBakey. [225] The Crawford classification defines aneurysms as types I, II, III, and IV according to their anatomic location (Fig. 51-8) (Figure Not Available) . Type I includes aneurysms involving most of the descending thoracic and the upper abdominal aorta. Type II includes aneurysms involving most of the descending thoracic and most of the abdominal aorta. Type III involves the lower portion of the thoracic aorta and most of the abdominal aorta, and type IV includes most or all of the abdominal aorta. Types II and III are most difficult to repair because they involve both the thoracic and the abdominal segments of the aorta. Patients with Crawford type II aneurysms are at greatest risk for paraplegia and renal failure from ischemia to the spinal cord and kidneys during cross-clamp. Even with extracorporeal circulatory support, there is an obligatory period of time when blood flow to these organs is interrupted because the origin of the blood flow is between the cross-clamps. For this reason, protective measures to prevent ischemic injury are important in reducing morbidity.

The DeBakey classification defines dissecting aneurysms as types I, II, and III (Fig. 51-9) (Figure Not Available) . [225] Type I aneurysms begin in the ascending aorta and extend throughout the entire aorta. These lesions are usually repaired by use of a two-stage approach, with the first procedure on the ascending aorta and arch and the second procedure on the descending portion. Type II aneurysms are confined to the ascending aorta. Both types I and II often involve the aortic valve, causing aortic regurgitation, and sometimes involve the ostia of the coronary arteries. Type III aneurysms begin just distal to the left subclavian artery and extend either to the diaphragm or to the aortoiliac bifurcation. DeBakey type III B is a subclass that indicates dissection of the aneurysm wall involving both the thoracic and the abdominal aorta. Type III B has the greatest risk of spinal cord and renal injury with surgical repair.

Morbidity and Mortality

The incidence of paraplegia in patients undergoing surgical repair of TAA is reported to be from 5 to 40 percent, depending on the anatomic location, the duration of cross-clamp, the use of protective measures, the degree of dissection, and whether the aneurysm has ruptured. [226] [227] [228] Renal failure is reported to occur in 3 to 30 percent of patients, depending on similar factors. [224] [229] [230] Overall, approximately 6 percent of patients need postoperative dialysis after TAA repair, which is associated with high mortality (30-60%). [230] Advances in surgical practice and in anesthetic

---

Figure 51-8 (Figure Not Available) The Crawford classification of thoracoabdominal aortic aneurysms is defined by anatomic location and the extent of involvement. *(From Crawford [224])*

management have reduced overall mortality from TAA repair to approximately 5 to 15 percent. [231]

Preoperative Preparation and Monitoring

Surgical TAA repair requires extensive preoperative planning. The evaluation and management of coexisting cardiac and pulmonary disease are previously discussed in this chapter. Before the day of surgery, the anesthesiologist and the vascular surgeon should discuss the following issues: extent of the aneurysm and technique of surgical repair, plans for extracorporeal support (if any), spinal cord ischemia monitoring, renal and spinal cord protection, hemodynamic monitoring, and ventilation strategy.

At least 15 units of packed red blood cells and 15 units of thawed fresh frozen plasma should be immediately available, and additional units should be obtainable. We use a large cooler to store blood products on ice in the operating room so that they can be returned to the blood bank if they are not used. Platelets should be available. A dedicated critical care technician is helpful in assisting with laboratory testing and retrieving products from the blood bank.

Large-bore intravenous access is obviously important, especially if partial bypass (in contrast to full bypass) is planned, because it is difficult or impossible for the perfusionist to administer fluid or blood products into the closed circuit. We usually insert three 8.5 French catheters into either the internal jugular or the antecubital veins. One of these accepts the pulmonary artery catheter, and the other two are connected to the rapid infuser system (RIS, Haemonetics, Braintree, MA). This system allows the delivery of up to 1,500 mL/min of blood products at a temperature of 37 to 38°C. A right radial arterial catheter is used for aneurysms of the descending thoracic aorta because occasionally the cross-clamp is placed proximal to the left subclavian artery, thus occluding flow to the left upper extremity. When left atrial-to-femoral artery (LA-FA) bypass is planned, a right femoral artery catheter is placed to monitor arterial blood

Figure 51-9 (Figure Not Available) The DeBakey classification of dissecting aneurysms of the aorta. Type I has an intimal tear in the ascending aorta with dissection extending down the entire aorta. Type II has an intimal tear in the ascending aorta with dissection limited to the ascending aorta. Type III has an intimal tear in the proximal descending thoracic aorta with dissection either limited to the thoracic aorta, or extending distally to the abdominal aorta or bifurcation (Type IIIB). *(From DeBakey et al [225])*

---

pressure distal to the cross-clamps. This catheter monitors perfusion pressure to the kidneys, spinal cord, and mesenteric circulation during the time when the

cross-clamps are high on the descending aorta and the lower body is perfused by the bypass circuit. The radial and femoral arterial pressures should be simultaneously displayed on the anesthesiologist's monitor, which should be visible to the surgeons and the perfusionists. TEE is often helpful during TAA repair. When used by a properly trained individual, the assessment of left ventricular end-diastolic volume, myocardial ischemia, and valvular function is possible. It is also possible to determine the size and the extent of the aneurysm.

A double-lumen endobronchial tube should be inserted for the purposes of one-lung ventilation because surgical exposure is optimal when the left lung is deflated. A left-sided endobronchial tube is ideal because there is risk of occluding the right upper lobe bronchus with a right-sided tube. Occasionally, when the left mainstem bronchus is compressed by a large aneurysm, [232] the lumen does not accommodate an endobronchial tube. In this situation, a right-sided endobronchial tube might be necessary. Rarely, the right mainstem bronchus may be compressed by a large aneurysm. [233] The double-lumen tube is usually changed to a single-lumen tube by use of a tube-changing catheter at the completion of surgery. This facilitates intensive care unit management of pulmonary hygiene and reduces the resistance to breathing during weaning in the postoperative period. The airway is often edematous after surgery, and it may be difficult or impossible to change the tube without a tube-changing catheter.

Many centers use electrophysiologic monitoring with somatosensory evoked potentials (SSEP) and motor evoked potentials to monitor for spinal cord ischemia (Ch. 35) . These monitoring techniques may be helpful in identifying the important intercostal arteries that perfuse the spinal cord so they can be implanted into the graft. If ischemia is identified, cross-clamps can often be moved, upper or lower body blood pressure can be increased to provide perfusion through collaterals, or other measures may be taken to protect the cord (cerebrospinal fluid [CSF] drainage, induced hypothermia, or intrathecal papaverine). These techniques are discussed later. There are three general problems with SSEP monitoring. First, sensory monitoring is more likely to detect posterior column ischemia and is a poor monitor for the anterior columns. As a result, paraplegia can occur in spite of normal SSEP signals. [234] Second, inhaled anesthetics [235] and hypothermia [236] can interfere with SSEP signals. Third, ischemia affects peripheral nerves, and ischemia to the lower extremities delays conduction from the usual stimulation sites (posterior tibial nerve). [237] To eliminate the peripheral nerves as a confounding factor, we use spinal stimulation via a lumbar epidural electrode, which is more specific for ischemic injury than is peripheral monitoring. [237] Motor evoked potentials have been used successfully to monitor the anterior columns of the spinal cord. [238] [239] Stimulation over the motor cortex or the cervical spine with sensing over the popliteal nerve is the most commonly used technique. Although this technique appears to be useful in monitoring for ischemia, it is somewhat technically demanding. Also, hypothermia and inhaled anesthetics interfere with the signals.

Body temperature should be monitored at two sites (core and peripheral) to assess cooling and warming on bypass. There is an important difference, however, between full and partial bypass with regard to temperature monitoring. [240] With full bypass, perfusion is usually into the ascending aorta, and typically the upper body core temperature (nasopharynx or esophagus) cools and warms fastest, whereas the lower body temperature changes more slowly. With partial bypass, the opposite is true. The blood from bypass is returned into the femoral artery, and the lower body (rectum or bladder) changes before the upper body changes. This difference is important to recognize in order to achieve complete cooling and warming because the lagging temperature should be the end point for cooling and warming.

Intraoperative Management

Extracorporeal Support

Thoracic and thoracoabdominal aortic surgery can be performed without extracorporeal support. Large series of the "clamp and run" technique have been published with relatively favorable outcomes, but these cases are from institutions with the greatest clinical experience and the shortest cross-clamp times. [226] [228] Other than the location and the extent of the aneurysm, the duration of cross-clamp on the aorta is the single most important determinant of paraplegia and renal failure when bypass is not employed. Clamp times of less than 20 to 30 minutes are associated with almost no paraplegia. [228] [241] When clamp times are between 30 and 60 minutes (the vulnerable interval), the incidence of paraplegia increases from
10 percent to
90 percent as time progresses. [242] [243] Because clamp times are typically in this range or longer, efforts are usually made to perfuse the distal aorta to protect the viscera, kidneys, and spinal cord from ischemic injury.

The simplest method of providing distal perfusion is a passive conduit or shunt. The heparin-bonded Gott shunt [244] was developed to avoid the need for systemic heparinization and is used to divert flow passively from the left ventricle or the ascending aorta to the distal aorta. Partial bypass (left heart bypass) is more commonly used; this technique allows the adjustment of blood flow (Fig. 51-10). This method, which is sometimes referred to as LA-FA bypass, usually draws blood from the left atrium and returns blood into the left femoral artery. For Crawford type I aneurysms, there should be little or no ischemia for the gut, spinal cord, or kidneys because blood flows retrograde up the aorta. A centrifugal pump is used (Biomedicus, Eden Prarie, MN), and there is no need for full-dose heparin because the circuit is heparin-coated. The typical heparin dose for LA-FA bypass is 100 units/kg. An oxygenator is unnecessary because only the left side of the heart is bypassed. Insertion of a heat exchanger into the circuit allows for cooling and warming, which is beneficial but not essential. [245] Variations of left heart bypass include cannulating the aortic arch instead of the left atrium. With this circuit, the left ventricle is relieved of the increased afterload during aortic cross-clamp. With left atrial cannulation, the ventricle is relieved of preload. Either way, the work of the ventricle is decreased during cross-clamp, and perfusion is provided to the distal aorta. We have had even greater success with cannulation of a pulmonary vein instead of the left atrium; this method accomplishes

Figure 51-10 Diagram of left heart (LA-FA) bypass. The left atrium and the left femoral artery are cannulated, and a centrifugal pump is used with heparin-coated tubing. A heat exchanger may be added into the circuit for cooling and rewarming.

the same effect as atrial cannulation but is associated with less atrial irritability. When hypothermia is combined with atrial cannulation, approximately 15 percent of patients experience new atrial fibrillation that usually reverts to sinus rhythm on rewarming but sometimes requires direct cardioversion. [240]

During left heart bypass, it is helpful to monitor arterial blood pressure above and below the aortic cross-clamps. We simultaneously display the radial and femoral artery pressures and aim for a mean arterial pressure of 70 to 80 mm Hg for both. [240] Careful control of intravascular volume, pump flow, and vasoactive drugs is required to achieve the target blood pressures. This requires communication and cooperation between the anesthesiologist and the perfusionist because, unlike during full cardiopulmonary bypass, both individuals manage the hemodynamics together during LA-FA bypass.

Aneurysms involving the aortic arch often require deep hypothermic circulatory arrest (DHCA) because cerebral blood flow is transiently interrupted during surgery. This can be accomplished by cannulation of the femoral artery and the femoral vein (fem-fem bypass). Some centers also use anterograde (innominate artery) or retrograde (internal jugular vein) selective cerebral perfusion with cold oxygenated blood to extend the safe maximum duration of DHCA. [246] Without this technique, 45 to 60 minutes is thought to be the safe limit of DHCA, but 90 minutes has been reported with selective cerebral perfusion. [247] DHCA may be necessary for patients with previous aortic arch repairs that are scheduled for a descending aortic repair because adhesions and scarring make application of the proximal aortic cross-clamp difficult or impossible. In this situation, DHCA allows a bloodless field for the proximal aortic anastomosis. After the anastomosis is finished under DHCA, full cardiopulmonary bypass can be instituted to complete the thoracic and/or the abdominal aortic anastomoses because it is difficult to complete an entire TAA repair during the safe period of DHCA.

Anesthetic Technique

There is no single best anesthetic technique for TAA repair. Usually, a balanced anesthetic is given with a combination of an opioid, a low-dose potent inhalation agent, a benzodiazepine, and a long-acting muscle relaxant. The induction should be slow and controlled without hypotension or hypertension because stress on the aneurysm can cause rupture. Heart rate should be maintained near baseline because myocardial ischemia is often heart rate related. As discussed in the section on abdominal aortic surgery, postoperative analgesia may be accomplished by use of an epidural catheter. Caution is necessary when the epidural is placed because surgery should be canceled and rescheduled in the event of a bloody tap because of the risks of spinal/epidural hematoma.

Spinal Cord Ischemia and Paraplegia

Paraplegia is a devastating complication of aortic surgery. The incidence of paraplegia is reported to be 0.5 to 1.5 percent for coarctation repair, zero to 10 percent for

thoracic aneurysm repair, 10 to 20 percent for thoracoabdominal repair, and as high as 40 percent for extensive dissecting TAA repair. [225] [248] [249] [250] [251] [252]

The spinal cord receives its blood supply from two posterior arteries and one anterior spinal artery (Fig. 51-11) (Figure Not Available) . The anterior spinal artery, which supplies the motor tracts in the spinal cord, is formed by two branches of the intracranial portion of the vertebral arteries. [253] The upper cervical segment of the spinal cord receives most of its blood flow from the vertebrals. [254] [255] The thoracic portion of the anterior spinal artery is supplied by the radicular arteries (one or two cervical, two or three thoracic, and one or two lumbar). [256] The largest of the radicular arteries is called the arteria radicularis magna or the artery of Adamkiewicz. The origin of this artery is variable but is located between T9 and T12 in 75 percent of cases. [257] [258] The variation in origin of the arteria radicularis magna explains why even with infrarenal aortic aneurysm repair, a 0.25 percent incidence of paraplegia has been reported. [243] The posterior spinal arteries, which supply the sensory tracts in the spinal cord, receive flow from the posterior and inferior cerebellar arteries, the vertebral arteries, and the radicular arteries. [255] [259]

Various methods have been used to prevent ischemic injury to the spinal cord. Distal perfusion with extracorporeal support has been shown to reduce the incidence of paraplegia. [260] [261] [262] Some form of bypass is likely to be beneficial when the anticipated cross-clamp time is greater than 30 minutes but is probably not beneficial when cross-clamp time is less than 20 to 30 minutes. CSF drainage is frequently used to improve spinal cord perfusion during TAA

Figure 51-11 (Figure Not Available) Diagram of the blood supply to the spinal cord showing the anterior and posterior radiculomedullary branches seen in a lateral view. The primary blood supply to the thoracolumbar portion of the spinal cord is derived from the artery of Adamkiewicz, which is variable in its origin, but usually branches off the aorta in the T-9 to T-12 region. *(From Djindjian [259])*

repair. Spinal cord perfusion pressure is defined as distal mean aortic pressure minus CSF pressure (or central venous pressure), whichever is greatest. Autoregulation of spinal cord blood flow is similar to cerebral autoregulation, and blood flow is relatively constant over the range of 50 to 125 mm Hg. [263] During hypoxia or hypercarbia, autoregulation is lost, and flow becomes linearly related to perfusion pressure. Thus, significant flow may remain, even at very low perfusion pressures. Drainage of CSF is thought to be important because CSF pressure often increases (by 10-15 mm Hg) with application of thoracic aortic cross-clamps, which increases the likelihood of ischemic spinal cord injury. [264]

Despite evidence from animal studies that CSF drainage protects the spinal cord, [265] the clinical use of this technique is controversial. Some studies have shown a reduced incidence of paraplegia, [266] but others have not. [267] [268] The most encouraging evidence in support of CSF drainage is from studies in which this technique is used in combination with other adjuncts, such as intrathecal papaverine [269] and hypothermia and partial bypass. [229] [237] [240] [270]

Hypothermia is probably the most reliable method of neuroprotection from ischemic injury. By reducing oxygen requirements by
5 percent for each degree centigrade, [217] a twofold prolongation of tolerated cross-clamp time is achieved by cooling even to mild hypothermia (34°C). [271] Because the reduction in metabolic rate is linearly related to temperature, moderate or profound hypothermia provides even greater protection. Both systemic and local spinal cord cooling have been shown to be beneficial. Systemic hypothermia can been achieved with either full cardiopulmonary bypass (with or without DHCA) [272] or partial bypass. [240] [270] Cooling to 30 to 32°C with LA-FA bypass in combination with CSF drainage was associated with no permanent neurologic sequelae in our series of 20 patients, despite a relatively long average cross-clamp time (
70 minutes). [240] We have since used this technique in more than 50 patients cooled to 32°C, with a 5 percent incidence of paraplegia. Although some risk is incurred when a beating heart is subjected to moderate hypothermia, the benefits appear to outweigh the risks. Both supraventricular and ventricular dysrhythmias respond well to cardioversion and/or mild warming to
33 to 34°C. Localized cooling of the spinal cord by cold perfusion of the artery of Adamkiewicz with blood [273] or crystalloid [274] provides significant protection during spinal ischemia in animal models. Local cooling has been shown to be beneficial in humans who received epidural infusions of 4°C saline. [275] Even if active cooling is not used, it is advantageous to allow patients to passively cool to 33 to 34°C during TAA repair. With passive cooling, the challenge is rewarming after the surgical repair. This is most easily accomplished by use of a forced-air blanket over the upper body. The lower body should not be actively warmed, because warming ischemic tissue increases metabolic requirements, acidosis, and ischemic injury.

A variety of drugs have been the focus of laboratory and clinical investigation in an attempt to reduce the incidence of ischemic spinal cord injury. Barbiturates have been shown to provide significant protection. [276] [277] Corticosteroids have been shown to provide protection in dogs [278] but were beneficial in humans only when they were combined with CSF drainage. [279] Calcium channel blockers were protective against spinal cord ischemia in some studies [280] [281] but not in others. [282] [283] *N*-methyl- D-aspartame receptor antagonists have been investigated because ischemic injury appears to be related to increased levels of excitatory amino acids (particularly glutamate), which allow increased permeability to calcium ions and high intracellular calcium concentrations. Dextrorphan (a noncompetitive *N*-methyl- D-aspartame antagonist) shows promise during spinal cord ischemia. [284] Magnesium, another *N*-methyl- DV-aspartame receptor blocker, improves recovery from spinal cord ischemia in rat and dog models when administered intrathecally. [285] [286] Naloxone appears to be protective in patients with traumatic spinal cord injuries [287] and in a rabbit model of spinal ischemia. [288] [289] Naloxone also shows promise when combined with CSF drainage in patients undergoing TAA

repair. [290] Intrathecal papaverine appears to be protective [269] especially when combined with CSF drainage. [291]

Renal and Mesenteric Ischemia and Protection

Renal failure following TAA repair results from preexisting renal dysfunction, ischemia during cross-clamp, thrombotic or embolic interruption in renal blood flow, and hypovolemia and hypotension. Approximately 6 percent of patients require postoperative dialysis, even in centers with the most clinical experience. [230] The primary predictor of postoperative renal failure is preoperative renal dysfunction. The duration of the cross-clamp time is also very important. Hypothermia, by reducing oxygen requirements, protects the kidneys during ischemia. The role of pharmacologic protection is somewhat controversial. Mannitol (12.5-25.0 g/70 kg) is often given before cross-clamp. Mannitol improves renal cortical blood flow and glomerular filtration rate in animal models of ischemia. [292] Endothelial cell swelling is decreased, and an osmotic diuresis occurs. [184] There is evidence of free radical scavenging with mannitol and subsequent protection from ischemia in animals. [185] Loop diuretics are sometimes given, but these drugs have been less effective than mannitol in experimental models. [293] In clinical studies, the prophylactic use of loop diuretics has not been shown to improve outcome or to reduce the need for dialysis for patients with acute renal failure. [294] [295] Dopamine given in low doses (3 mug/kg/min) dilates renal blood vessels and increases renal blood flow and urine output. Despite these beneficial effects, these is no clear evidence from clinical trials that dopamine provides renal protection during ischemia. Optimal patient care for renal protection during TAA surgery should rely on mild hypothermia, mannitol, and selective use of low-dose dopamine in patients at risk for renal failure. Intravascular volume must also be maintained to prevent hypotension and hypoperfusion of the kidneys.

Coagulation and Metabolic Management

Coagulopathy is a frequent complication during TAA repair. A dilutional coagulopathy develops during massive transfusion in which platelets become deficient after 1 blood volume of replacement. At somewhere between one and two blood volumes of replacement, coagulation factors are diluted to levels low enough to increase bleeding. Other contributing factors are residual heparin, ischemia to the liver where most coagulations factors are produced, and hypothermia that persists after weaning from bypass. By using a one-to-one ratio of packed red blood cells to fresh frozen plasma throughout the surgical procedure, coagulation factors are usually maintained. The prothrombin time, partial thromboplastin time, fibrinogen, and platelet counts should be measured frequently. Cryoprecipitate may be necessary to correct coagulopathy, especially when the prothrombin time and partial thromboplastin time are prolonged and hypervolemia prevents the administration of significant volumes of fresh frozen plasma. When coagulopathy persists despite these efforts, epsilon-aminocaproic acid is beneficial as antifibrinolytic therapy, and desmopressin can be given in order to increase circulating levels of von Willebrand factor and factor VIII. Normothermia should be achieved by complete rewarming before separation from bypass, increasing the ambient temperature after separation from bypass, and by forced air warming over the upper body skin surface. Arterial blood gases and electrolyte levels should be measured frequently. Sodium bicarbonate should be given to treat the metabolic acidosis that occurs during and after crossclamping. Hyperkalemia should be aggressively treated, especially in oliguric or anuric patients. Calcium chloride and sodium bicarbonate are the primary acute treatments for hyperkalemia.

Endovascular Stents

A development in the field of invasive radiology is the use of the endovascular stent to treat thoracic aortic aneurysms. [296] [297] These stents, which are individually constructed, expandable, Dacron-covered stainless steel tubes, are introduced through the femoral artery by use of a 26 French outer-diameter introducer catheter. The stents are placed in the operating room with the patient under general anesthesia. After anatomic positioning is confirmed with fluoroscopy and TEE, the stent is released into place. The stent supports the wall of the aneurysm and prevents rupture. The anesthesiologist should be prepared with large-bore intravenous access for the possibility of aneurysm rupture or open surgical repair. For thoracoabdominal aortic aneurysms, the thoracic segment may be stented and the abdominal segment surgically repaired as a combined procedure.

LOWER-EXTREMITY REVASCULARIZATION

Indications and Surgical Approach

Arterial insufficiency in the lower extremities can present with either acute or chronic limb ischemia. Acute ischemia is often due to embolism, thrombus, or pseudoaneurysm following invasive procedures in which the femoral artery is cannulated. Patients with acute ischemia need to be rapidly evaluated because irreversible tissue injury occurs within 4 to 6 hours. [298] Chronic ischemia is most often secondary to atherosclerotic plaque and presents with claudication. The ankle/arm index is a simple, noninvasive method of evaluating the severity of arterial insufficiency and is defined as the ankle systolic blood pressure divided by the brachial systolic blood pressure. Normally, the ankle/arm index is greater than 1.0. In patients with claudication, the ankle/arm index is often less than 0.6, and in patients with rest pain, the ankle/arm index is often less than 0.25. [299] Arteriography is used to determine the severity and the anatomic location of arterial occlusion. Angioplasty and/or thrombolytic therapy is occasionally performed in conjunction with arteriography. Patients are then often given thrombolytic drugs and/or heparin overnight and are scheduled for lower-extremity bypass surgery the following day, pending evaluation of

lower-extremity blood flow. This practice has significant implications for the anesthesiologist because regional anesthesia is associated with significant risk of spinal/epidural hematoma and is not an option in the anticoagulated patient.

There are several surgical approaches to patients with lower-extremity arterial insufficiency. For occlusion distal to the inguinal ligament, the femoral popliteal bypass with reverse saphenous vein graft is most often the procedure of choice. Graft patency with this approach is reported to be 59 percent at 5 years and 38 percent at 10 years. [300] The saphenous vein may be used *in situ* (not reversed), but this technique requires excision of the valves to allow adequate flow. Human umbilical vein and polytetrafluoroethylene (Gore-Tex) can be used when saphenous vein is unavailable, which is often the case when patients have had previous coronary artery bypass or lower-extremity bypass. In patients with aortoiliac disease who are not candidates for aortobifemoral bypass because of coexisting medical diseases, an extra-anatomic procedure (axillofemoral or femorofemoral bypass) is an alternative approach that is thought to be a less stressful procedure. [301]

Significant complications from femoral arteriography occur in 1.7 percent of patients, with death occurring in 0.03 percent. Puncture site hematoma, thrombosis or dissection of the vessel wall, hemorrhage, and pseudoaneurysm are the most common surgically correctable complications. A pseudoaneurysm is an area of chronic hemorrhage that has developed an organized thrombotic wall. Pseudoaneurysms communicate with the vessel lumen but are not surrounded by any vessel layers. Although surgical repair of these angiographic complications is considered to be relatively noninvasive, these patients are high-risk surgical candidates because they often have severe coronary disease that brought them to angiography originally, as well as other coexisting diseases.

Preoperative Preparation and Monitoring

Preoperative assessment and optimization of cardiac risk have been previously discussed in this chapter. It is extremely important that long-term cardiac and respiratory medications be given the morning of surgery. beta-Adrenergic blockers are most important because they have been shown to reduce the incidence of perioperative myocardial ischemia and subsequent cardiac morbidity. [36] [37] [38] [39] Monitoring for lower-extremity arterial revascularization should include an intra-arterial catheter that permits (1) continuous blood pressure monitoring to optimize coronary artery perfusion, (2) continuous blood pressure monitoring to optimize lower-extremity graft perfusion, and (3) blood sampling for diagnostic laboratory testing. A urinary bladder catheter is usually adequate for assessing intravascular volume and cardiac output, and central venous catheters are not necessarily helpful in routine cases. They should, however, be considered for patients with significant renal dysfunction in whom intravascular volume should be carefully monitored, and for patients with significantly impaired ventricular dysfunction or CAD. In these patients, a pulmonary artery catheter may be helpful, but given the relatively low potential for blood loss and third-space fluid losses with lower-extremity vascular procedures, the pulmonary artery catheter is usually reserved for patients with active congestive heart failure or unstable angina. Our criteria for using invasive hemodynamic monitoring have been previously described. [54] As discussed earlier in this chapter, computerized ST segment monitoring is helpful in monitoring for myocardial ischemia.

Anesthetic Management

Regional Versus General Anesthesia

The question of whether regional or general anesthesia is preferable for vascular surgery has been debated for years, but only in the past decade have well-designed prospective randomized trials been completed. Earlier nonrandomized trials were prone to bias because many clinicians had the unfounded belief that regional anesthesia was safer for patients with advanced cardiac or pulmonary disease. Even the prospective studies must be cautiously interpreted. It should be recognized that most clinical trials have optimized the delivery and management of the anesthetic techniques, which may mask the true risks of the anesthetic. An example of this is the strict hemodynamic control, transfusion thresholds, and postoperative analgesia regimens that have been used in clinical trials. It is often best to choose the anesthetic technique that is most familiar to a particular institution because, for example, unfamiliarity and mismanagement of epidural catheters can cause serious complications.

Occasionally, surgical procedures, such as embolectomy and femoral pseudoaneurysm repair, can be completed with the patient under local anesthesia with intravenous sedation. Because these procedures often progress to more invasive arterial reconstruction, a regional or general anesthetic initiated before the procedure begins avoids an unplanned conversion to general anesthesia.

In some conditions, one anesthetic technique (regional or general) is preferable to the other. Patients who undergo anticoagulation with heparin, warfarin (Coumadin), or thrombolytic drugs before surgery should not be given regional anesthesia, because spinal/epidural hematoma is a devastating complication that can lead to permanent neurologic injury. Regional anesthesia may be used in patients who are given anticoagulants during the surgical procedure, but it has been recommended that surgery be canceled when blood is obtained through the needle on placement of the regional block. [302] It has also been recommended that epidural catheters not be removed until anticoagulants have been discontinued in the postoperative period. [302] The use of low-molecular-weight heparins has increased, and there is evidence to suggest a significant risk of spinal/epidural hematoma when regional anesthesia is used in conjunction with these drugs. [303] Long-term use of aspirin is a controversial topic, and regional anesthesia should be chosen only when the advantages outweigh the risks. Some centers routinely check a bleeding time in patients who have taken aspirin in the 7 days before a planned regional anesthetic. When possible, spinal anesthesia is preferable to epidural anesthesia for patients with any question of a coagulation abnormality, and the smallest-diameter needle should be used. [303]

TABLE 51-10 -- Cardiac and Vascular Outcomes in Studies of Regional Versus General Anesthesia in Vascular Surgery Patients

AUTHOR	*n*	CONGESTIVE HEART FAILURE		MYOCARDIAL INFARCTION		DEATH		VASCULAR GRAFT OCCLUSION

Bois et al [208]	124	5%	0%	4%	8%	0%	0%	--	--

GA, general anesthesia; RA, regional anesthesia

There has traditionally been a prevailing belief that regional anesthesia is preferable in patients with significant pulmonary disease. It is true that instrumentation of the airway may precipitate bronchospasm or may increase the risk of nosocomial infection; however, there is little evidence from well-designed clinical studies to demonstrate improved pulmonary outcome with regional anesthesia.

Cardiac morbidity is the most common cause of death in patients undergoing surgery, and the incidence of perioperative cardiac morbidity is 10 times greater in vascular surgery patients than in nonvascular surgery patients. [12] Five prospective randomized trials have examined the effects of regional versus general anesthesia on cardiac outcomes in vascular surgery patients. Two studies (Christopherson et al [54] and Bode et al [304]) compared pure regional versus general anesthetic techniques in lower-extremity vascular patients. Three others (Tuman et al, [305] Baron et al, [206] and Bois et al [208]) compared combined regional/general versus general anesthetics in aortic and/or lower-extremity surgical patients. The results of these studies are shown in Table 51-10 . In summary, only Tuman et al's study revealed a difference in cardiac outcome. Even in Tuman et al's series, outcome was significantly improved by regional anesthesia only when more subtle outcomes, such as congestive failure and dysrhythmias, were included. Christopherson and colleagues [54] (the PIRAT Study) found no difference in cardiac events or myocardial ischemia as detected by continuous Holter monitor over a 3-day postoperative period. In this study, strict intraoperative and postoperative protocols were used to manage hemodynamics and postoperative analgesia. Bode and colleagues [304] reported on the largest randomized trial, which included a spinal anesthesia group in addition to general and epidural groups. Again, there were no differences in cardiac events in any of the three groups. The studies by Bois et al [208] and Baron et al [206] also showed no differences in cardiac morbidity with regional anesthesia/analgesia.

Perhaps the most interesting and clinically significant finding in these randomized trials is the beneficial effect of regional anesthesia on lower-extremity graft patency in the postoperative period. Two of the studies (Tuman et al [305] and Christopherson et al [54]) reported a fivefold greater incidence of graft occlusion following general (relative to regional) anesthesia. Most graft occlusions occurred in the first 1 to 3 days following surgery, after which the established difference in the incidence of graft occlusion between anesthetic techniques was maintained over time (6 weeks and beyond) (Fig. 51-12) (Figure Not Available) . This time course suggests that anesthetic technique played a role in graft occlusion. Bode et al [306] reported an overall very low incidence of graft occlusion, but differences in hemodynamic management, surgical technique, and the patient population may explain these findings. For example, intraoperative intravascular angioscopy was used to inspect the grafts to confirm patency before completion of surgery, and all patients were cared for in an intensive care setting for 48 hours after surgery.

The proposed mechanism for the benefits of regional anesthesia are the effects of anesthetic technique on coagulation. General anesthesia is associated with a hypercoagulable state in the early postoperative period, whereas regional anesthesia attenuates this effect. [307] Tuman et al [305] demonstrated this nicely by thromboelastography, and Rosenfeld et al, [307] by increased plasminogen activator inhibitor and fi-brinogen levels following general anesthesia. Thus, it appears that fibrinolysis is decreased after general anesthesia and is normal after regional anesthesia. These findings are probably related to attenuation of the stress response with regional anesthesia because there appears to be a link between stress, catecholamines, and acute phase reactants, such as plasminogen activator inhibitor and fibrinogen. [308] [309]

Figure 51-12 (Figure Not Available) Cumulative probability of reoperation for regrafting, thrombectomy, or amputation over a 6-week follow-up period. Reoperation was significantly more frequent after general than after epidural anesthesia. *(From Christopherson et al [54])*

Platelet reactivity is also enhanced in the presence of a stress response. [309] Another important mechanism for increased lower-extremity graft patency with regional anesthesia may be the increased lower-extremity blood flow associated with sympathectomy. [310]

In the postoperative period, Breslow et al [92] demonstrated differences in the adrenergic response with general compared with regional anesthesia (Fig. 51-13) (Figure Not Available) . Both epinephrine and norepinephrine are increased after general anesthesia relative to regional anesthesia. The cortisol response following general anesthesia is also greater than that following regional anesthesia. [92] This "stress response" is associated with increased blood pressure and hemodynamic lability during the intraoperative and early postoperative periods following general anesthesia compared with regional anesthesia. [54] [311] When the hemodynamic parameters are controlled pharmacologically, however, there is no difference

Figure 51-13 (Figure Not Available) Plasma norepinephrine and epinephrine concentrations before induction of anesthesia (P), at skin closure (C), and at 1, 6, 12, and 18 hours after lower extremity revascularization. related to anesthetic technique in myocardial ischemia or cardiac morbidity. [54] [304]

Anesthetic Technique

General anesthesia for lower-extremity vascular surgery is usually delivered by use of a balanced technique with opioids, potent inhalation anesthetics, nitrous oxide, and neuromuscular blockade. Virtually all patients are extubated in the operating room, so high doses of opioid are generally avoided. The goal is to avoid hemodynamic extremes in order to prevent myocardial ischemia during the intraoperative and postoperative periods. Judicious use of beta-adrenergic blockers and vasoactive drugs is often necessary.

Regional anesthesia can be accomplished with either spinal or epidural techniques. Disadvantages of spinal anesthesia include the limited duration of action because the surgical procedures are somewhat unpredictable in length and complexity. Also, the level of sympathetic block is somewhat less controllable than that of the epidural block, and hypotension can occur. An additional advantage of an epidural technique is the ability to continue drug delivery into the postoperative period for analgesia and attenuation of the stress response. A lumbar epidural catheter is ideal for lower-extremity vascular procedures. The dermatomes that need to be anesthetized are innervated at the same level where the catheter is inserted because the incision is usually in the L1 to L4 region. Small volumes of local anesthetic are required because a T10 block is usually sufficient. Usually, 10 to 12 mL (including the test dose) is sufficient for the initial dose, and more drug is given as needed. Because vascular surgery patients are generally advanced in age and because elderly patients are prone to higher block levels, larger doses may result in high blocks with total sympathectomy and severe hypotension. A high sympathetic block is problematic because of decreased coronary perfusion and excessive fluid and vasopressor requirements. Congestive heart failure may result in the postoperative period when the sympathectomy resolves and the intravascular space contracts. When the test dose is given, careful attention should be directed at both the heart rate and the blood pressure because many vascular surgery patients take beta-adrenergic blockers and little or no heart rate change is noticed when epinephrine is given through an intravascular catheter. When hypotension results from sympathectomy, a low-dose phenylephrine infusion is helpful in reducing intravenous fluid requirements. This approach is also more physiologic than administration of large fluid volumes.

Postoperative Management

Pain and anxiety should be carefully controlled in the postoperative period because the stress response and myocardial ischemia are of greatest concern at this time. Intravascular volume should be optimized, anemia avoided (hemoglobin <9.0 g/dL), and heart rate and blood pressure should be carefully controlled. Computerized ST segment analysis is helpful in identifying ischemic changes. Peripheral pulses should be checked frequently to verify lowerextremity graft patency. Blood pressure manipulation and/or

---

anticoagulants may be necessary when peripheral perfusion is limited. Urgent surgery may be required to reopen clotted or stenotic grafts.

Postoperative analgesia can be provided by intravenous or epidural opioids delivered by patient-controlled analgesia or epidural opioids with local anesthetics delivered by continuous infusion or patient-controlled analgesia. For epidural patient-controlled analgesia, a dilute concentration of local anesthetic should be utilized to allow neurologic evaluation of the lower extremities to rule out spinal/epidural hematoma. Bupivacaine (0.0625%) is ideal in this regard. Fentanyl (5 mug/mL) can be added and the solution infused at 2 mL/h, with an on-demand (patient-controlled analgesia) bolus of 2 to 4 mL and a lockout interval of 10 minutes.

CAROTID ENDARTERECTOMY

Indications

Stroke is the third leading cause of mortality in the United States. [312] Annually, there are more than 500,000 hospitalizations and 150,000 deaths due to stroke. [313] The aggregate lifetime cost associated with an estimated nearly 400,000 first strokes in 1990 was $40.6 billion. [314] Despite a welldocumented decline in stroke mortality, the annual incidence rate of stroke may be increasing. [315]

The strong association between stroke and carotid artery occlusive disease is well known. The principal cause of occlusive disease is atherosclerosis, which most commonly involves the bifurcation of the common carotid artery, with frequent extension into both the internal and the external carotid arteries. [316] Cerebrovascular sequelae of carotid atherosclerosis may result from either embolization of thrombus and/or atheromatous debris or reduction in flow (hypoperfusion) secondary to stenosis. The latter probably accounts for less than 10 percent of the cerebrovascular sequelae of carotid atherosclerosis. [317] Although much is known about the genesis and evolution of atherosclerosis, significantly less is known about the circumstances that lead to plaque instability and rupture. Regardless of the mechanism, the degree of cerebral injury depends on such factors as plaque morphology, characteristics of the embolus, duration of hypoperfusion, cerebrovascular vasoreactivity, integrity of the circle of Willis, and cerebral collateral circulation. Clinical manifestations of carotid disease represent a spectrum of conditions, with fatal or debilitating stroke secondary to cerebral infarction at one end of the spectrum, ranging successively through nondebilitating stroke, reversible ischemic neurologic deficit, transient ischemic attack, and amaurosis fugax (transient attack of monocular blindness), to an asymptomatic bruit.

Endarterectomy of the carotid bifurcation has been used to reduce symptoms and prevent stroke for nearly 40 years. Carotid endarterectomy is the most common major vascular surgical procedure performed in the United States. More than 90,000 carotid endarterectomies are performed annually, [318] and this number is increasing. The rate and number of carotid endarterectomies have fluctuated significantly since the early 1970s. With marked growth in the specialty of vascular surgery and an expanding list of surgical indications, the number of carotid endarterectomies performed in nonfederal hospitals increased from 15,000 in 1971 to 107,000 in 1985, [319] then declined over the next 5 to 6 years. [320]

In 1992, a marked increase in the number of carotid endarterectomies occurred after the results of two large-scale, prospective, randomized trials were published. [320] The North American Symptomatic Carotid Endarterectomy Trial and the European Carotid Surgery Trial both reported definitive results for symptomatic patients with high-grade carotid stenosis (70-99%). [321] [322] In the North American Symptomatic Carotid Endarterectomy Trial, the long-term stroke rate for surgical patients was 9 percent, compared with 26 percent for medical patients. [322] In the European Carotid Surgery Trial, the long-term stroke rate was 2.8 percent for surgical patients, excluding a perioperative stroke and death rate of 7.5 percent, and 16.8 percent for medically managed patients. [321]

The efficacy of carotid endarterectomy in asymptomatic patients with carotid stenosis has been evaluated in four randomized trials. [323] [324] [325] [326] A fifth, the European Asymptomatic Carotid Surgery Trial, is ongoing. [327] The Carotid Artery Surgery Asymptomatic Narrowing Operation Versus Aspirin trial, the first to publish its results, concluded that carotid endarterectomy was not indicated for asymptomatic patients with 50 to 90 percent carotid stenosis. [323] Unfortunately, this study was seriously flawed and the results questioned. The Mayo Asymptomatic Carotid Endarterectomy trial was terminated early because of a significantly increased number of MIs and transient cerebral ischemic events in the surgical group. [324] Most of these events were not related to surgery itself but rather to the absence of aspirin in the surgical group. The Department of Veterans Affairs trial was designed to compare the effects of carotid endarterectomy plus aspirin with medical treatment (aspirin) in asymptomatic male patients with 50 percent or greater carotid stenosis. [326] This trial demonstrated a significant reduction in ipsilateral neurologic events in the surgical group (8%) compared with the medical group (20.6%). However, the combined incidence of stroke and death was not different between study groups. The Asymptomatic Carotid Atherosclerosis Study, the largest of the five trials, demonstrated that patients with asymptomatic carotid stenosis (
60%) who were treated with carotid endarterectomy and aspirin have a reduced 5-year risk of ipsilateral stroke compared with patients treated with aspirin alone (5.1% versus 11.0%). [325] These results reflect only a 5.9 percent absolute risk reduction in 5 years, which is just above 1 percent per year.

Perioperative Morbidity

For carotid endarterectomy, most centers report a perioperative stroke rate of between 3 percent and 5 percent. [328] [329] [330] [331] [332] [333] The incidence of perioperative stroke is highest for patients diagnosed with stroke, lower for patients with transient ischemic attack, and lowest in asymptomatic patients. [334] [335] [336] Neurologic deficits occur most commonly in patients with poorly controlled preoperative hypertension or in those with hypertension or hypotension postoperatively. [337] [338] More than half of these deficits occur more than 4 hours postoperatively. [337] The incidence of perioperative

MI in patients undergoing carotid endarterectomy ranges from zero to 4 percent. [328] [329] [331] [332] [333] [337] [339] MI is the leading cause of both perioperative and late mortality following carotid endarterectomy.

Preoperative Evaluation

As discussed previously, the successful evaluation of patients with arterial occlusive disease must address the systemic and progressive nature of atherosclerosis. CAD is common in patients presenting for carotid endarterectomy and is the leading cause of both early and late mortality. Despite the known high incidence of CAD in patients presenting for carotid endarterectomy, we rarely request preoperative studies (DTI or DSE) aimed at the evaluation of myocardial function or ischemic potential. Exceptions to this practice are patients with unstable angina, recent MI with evidence of ongoing ischemia, decompensated congestive heart failure, and significant valvular disease. It is our contention that unless the surgical plan can be altered, the perioperative management improved, or the mortality reduced, specialized studies are not appropriate in most patients presenting for carotid endarterectomy. Our approach is based on the following rationale. First, randomized trials have definitively established that carotid endarterectomy can prevent stroke in appropriately selected patients. Second, an alternative, or less stressful, procedure is not an option at the present time. Percutaneous transluminal angioplasty of the carotid artery may evolve into an appropriate alternative for high-risk patients, but at present, it is still experimental. [340] Third, based on the previous two reasons, it would be unlikely that the results of specialized testing would result in the procedure's being canceled. Fourth, because careful intraoperative and postoperative monitoring and medical management is standard for all patients undergoing carotid endarterectomy, specialized testing has little potential to alter perioperative management. Last, we do not believe that preoperative strategies leading to coronary angiography and ultimately coronary revascularization are appropriate in patients undergoing carotid endarterectomy, given the rates of perioperative cardiac morbidity and mortality. Reduction in short-term mortality has not been shown with prophylactic coronary revascularization before noncardiac surgery. Thus, in patients with asymptomatic or stable CAD, we believe that the best strategy is to proceed with carotid endarterectomy without additional studies. This approach does not take into consideration the potential long-term benefits from aggressive preoperative cardiac assessment and ultimate coronary revascularization. However, there is no convincing evidence that such benefit exists.

Patients with both unstable CAD and severe carotid artery occlusive disease represent somewhat of a management dilemma [341] because it is often unclear which disease should be treated first. The severity of cerebrovascular and coronary disease must be evaluated in terms of clinical symptoms and anatomic lesions, and a decision must be made for either a combined or a staged procedure. A staged approach with carotid endarterectomy as the first procedure may result in significant mortality from cardiac causes. [330] Conversely, coronary revascularization first may result in a high incidence of fatal stroke. [342] For patients with both unstable CAD and symptomatic carotid artery disease, a combined procedure has been advocated. [343] Unfortunately, no randomized trials have been performed to assess the benefit of combined verses staged procedures.

Anesthetic Management

Anesthetic management goals for carotid endarterectomy include protection of the heart and brain from ischemic injury, control of heart rate and blood pressure, and ablation of the surgical pain and stress responses. These goals must be achieved with another goal in mind--to have an awake patient at the end of surgery for the purposes of neurologic examination. The preoperative visit is particularly important in patients undergoing carotid surgery. During this visit, a series of blood pressure and heart rate measurements is obtained from which acceptable ranges for perioperative management can be determined. Patients are instructed to continue all long-term cardiac medications up to and including the morning of surgery. Unless contraindications exist, aspirin therapy should be continued throughout the perioperative period. As noted earlier, discontinuation of aspirin therapy may be related to an increased rate of MI and transient ischemic events in patients undergoing carotid endarterectomy. [324] When patients arrive at the hospital on the day of surgery, they are queried regarding any new cardiovascular or cerebrovascular symptoms. Any long-term cardiovascular medications not taken at home are administered in our preoperative holding area whenever possible. Patient reassurance is particularly important at this time because anxiety is associated with increases in heart rate, systemic vascular resistance, and myocardial oxygen consumption, which in this patient population could precipitate significant cardiac morbidity. [96] [344]

We routinely monitor leads II and V5 for detection of rhythm disturbances and ST segment changes. On-line ST segment analysis is particularly helpful and is used routinely. Placement of an intra-arterial catheter for beat-to-beat blood pressure monitoring is utilized in all patients. Central venous and pulmonary artery catheters are usually unnecessary for carotid surgery. If such monitors are used, the subclavian or femoral insertion sites are most practical because inadvertent carotid puncture could compromise blood flow as a result of hematoma. In our experience, the most common reason for central access is difficult or inadequate peripheral access. Intravenous access for fluid and drug administration can be accomplished with a single, secure, medium-bore (16-gauge) catheter. Given that both arms will be tucked to the patient's side, the intravenous catheter must run well after patient positioning.

General Anesthesia

Any of the commonly used induction agents, maintenance anesthetics, and short- to intermediate-acting nondepolarizing muscle relaxants can be safely used during carotid endarterectomy, given that stable hemodynamics are maintained and the patient is awake at the end of the procedure. Our induction technique using sufentanil is as follows. After placement of routine monitors and oxygen by face mask, a

---

sufentanil infusion (0.5-1.0 mug/kg) is initiated. If the patient becomes at all sedated during the planned 10- to 15-minute infusion period, as evidenced by slowed speech or delayed response to questioning, the infusion is discontinued. No additional opioids are administered intraoperatively. Induction of anesthesia is accomplished with incremental doses of thiopental (
8 mg/kg) followed by succinylcholine, unless contraindications exist. Etomidate or propofol may also be used. Esmolol is particularly effective in blunting the increases in heart rate and blood pressure during laryngoscopy and intubation and is used liberally during the induction period. [345] Blood pressure responses during and after endotracheal intubation are unpredictable in this patient population, and the clinician must be prepared for immediate treatment of extremes in blood pressure. Our preference is to use short-acting drugs, such as phenylephrine (50-100 mug) for hypotension and sodium nitroprusside (5-25 mug) for hypertension. Patients with poorly controlled hypertension (diastolic blood pressure >100 mm Hg) require special care. These patient are often intravascularly volume depleted and may have significant hypotension with induction. Administration of fluids intravenously (5 mL/kg), careful titration of anesthetics, and immediate treatment of hypotension are especially important.

Anesthesia is maintained with 50 percent nitrous oxide in oxygen and low-dose (less than one-half MAC) potent inhaled anesthetics. Isoflurane may be preferred because fewer ischemic electroencephalographic (EEG) changes occur during carotid occlusion when compared with halothane [346] [347] or enflurane. [346] [347] [348] In addition, studies utilizing EEG and regional cerebral blood flow measurements suggest that the critical cerebral blood flow (the threshold below which cerebral ischemia develops) is lower for isoflurane than for halothane or enflurane. [346] [347] Although the newer low-solubility agents (sevoflurane and desflurane) may facilitate a more rapid emergence, their use has not been reported for patients undergoing carotid endarterectomy. We typically use vecuronium for muscle relaxation because the procedure rarely lasts longer than 90 minutes. We do not utilize cervical plexus block or request local anesthetic infiltration for skin incision because the surgical stimulation is minimal and is frequently necessary to support blood pressure.

Despite only modest surgical stimulation, hemodynamic fluctuations are common during carotid endarterectomy. Blood pressure and heart rate are controlled within predetermined and individualized ranges during the surgical procedure with short-acting agents whenever possible (esmolol, phenylephrine, nitroglycerin, and sodium nitroprusside). It is generally accepted that blood pressure should be maintained in the high-normal range throughout the procedure and particularly during the period of carotid clamping in an attempt to increase collateral flow and to prevent cerebral ischemia. In patients with contralateral internal carotid artery or severe stenosis, induced hypertension to approximately 10 to 20 percent above baseline is advocated during the period of carotid clamping when neurophysiologic monitoring is not utilized. Blood pressure preservation and/or augmentation can be accomplished by maintaining light levels of general anesthesia or by administering sympathomimetic drugs, such as phenylephrine and ephedrine. Caution must be exercised when utilizing vasopressors to augment blood pressure during carotid endarterectomy because the increases in blood pressure and heart rate may increase myocardial oxygen requirements and increase the risk of myocardial ischemia [349] or infarction. [350] The restrictive use of vasopressors for specific instances of cerebral ischemia has been advocated. [351] In one report, induced hypertension during the period of carotid occlusion was not associated with myocardial ischemia. [352]

Surgical manipulation of the carotid sinus with activation of baroreceptor reflexes can cause abrupt bradycardia and hypotension. Cessation of surgical manipulation promptly restores hemodynamics, and infiltration of the carotid bifurcation with 1 percent lidocaine usually prevents further episodes. [353] Infiltration may increase the incidence of postoperative hypertension. [354]

With closure of the deep fascial layers in the neck, isoflurane is discontinued, nitrous oxide is increased to 70 percent, and ventilation is controlled manually. On application of the surgical dressings, neuromuscular reversal agents are administered, and oxygen is increased to 100 percent. At this time, we decrease external stimuli to the patient by quieting the room, turning off overhead surgical lights, and placing the patient in a head-up recumbent position. Ventilation is gently assisted until the patient spontaneously opens his or her eyes or moves. With rare exceptions, all patients are extubated after neurologic integrity is established. Neurologic deficits on emergence require immediate discussion with the surgeon as to the need for angiography and/or reoperation. The period of emergence and extubation may be associated with marked hypertension and tachycardia, which may require aggressive pharmacologic intervention. Tight hemodynamic control during this period is likely to be more demanding than during induction. [352] Greater hemodynamic stability and decreased pharmacologic intervention during emergence have been reported in patients undergoing carotid endarterectomy with propofol as compared with isoflurane. [352] In addition, a significantly lower incidence of myocardial ischemia on emergence was found in the propofol group compared with the isoflurane group (one of 14 versus six of 13). Of particular note, all patients with myocardial ischemia on emergence had systolic blood pressures greater than 200 mm Hg.

Regional and Local Anesthesia

Regional and local anesthetic techniques for carotid endarterectomy have been in use for more than 35 years, [355] and many centers consider these to be the techniques of choice. [356] [357] Regional anesthesia is accomplished by blocking the C2 to C4 dermatomes by use of a superficial and deep cervical plexus block (Ch. 43) . Subcutaneous infiltration of the surgical field can also provide the necessary sensory blockade. Regional anesthesia allows continuous neurologic assessment of the awake patient, which is believed to be the most sensitive method for detecting inadequate cerebral perfusion and function. Other advantages that have been reported include avoidance of expensive cerebral monitoring, reduced need for shunting, [337] [358] [359] greater stability of blood pressure and decreased vasopressor requirements, [339] [359] and reduced hospital costs. [333] [358] [360]

Local or regional anesthesia requires significant patient cooperation throughout the procedure and is best maintained with constant communication and gentle handling of

tissues. Supplemental infiltration of local anesthetic by the surgeon, especially at the lower border and ramus of the mandible, is frequently helpful. Sedation, if used at all, must be kept to a minimum to allow continuous neurologic assessment. Levels of consciousness, speech, and contralateral hand grip are assessed throughout the procedure. We control blood pressure at or near preoperative levels by use of the same agents used for patients receiving general anesthesia. Blood pressure augmentation with phenylephrine is employed when patients have neurologic changes during carotid artery test clamping or after shunt placement. A 2- to 3-minute test clamp in the awake patient allows prompt identification of patients who would benefit from shunt placement. [361] Patient acceptance of regional anesthesia is high, as evidenced by a 92 percent preference for repeat cervical plexus block for future carotid endarterectomy. [362] The surgical drapes are "tented" over the head and face areas to minimize claustrophobic anxiety. It has been suggested that no absolute contradiction to regional anesthesia for carotid endarterectomy exists. [356] In our practice, we avoid regional anesthesia under the following circumstances: a strong preference for general anesthesia is expressed by the patient (i.e., claustrophobia), language barriers that make communication difficult, and difficult vascular anatomy. Difficult anatomy is usually manifested by a patient with a short neck and a high (more cephalad) bifurcation and may require vigorous submandibular retraction.

Regional Versus General Anesthesia

Most reports comparing local or regional anesthesia with general anesthesia indicate no differences in perioperative stroke or death rate on the basis of anesthetic tech-nique. [333] [356] [357] [358] [360] [363] [364] [365] Three reports have found an increased incidence of perioperative stroke in patients under general anesthesia. [339] [366] [367] An increased incidence of cardiopulmonary complications in patients under general anesthesia has been reported in three studies. [358] [363] [366] Potential disadvantages of local or regional anesthesia include (1) inability to use pharmacologic cerebral protection with anesthetics, (2) patient panic and/or loss of cooperation, (3) seizure or loss of consciousness with carotid clamping, and (4) inadequate access to the airway should conversion to general anesthesia be necessary. Although the incidence of serious complications from cervical plexus block is low, near-toxic levels of local anesthetic have been reported in nearly half of patients after superficial and deep cervical plexus block. [369] Although no major complications related to local anesthetic toxicity were reported, some caution should be used when requesting that a surgeon supplement with additional local anesthetic. Phrenic nerve paresis is common after cervical plexus block [370] and is of little clinical consequence except in patients with severe chronic obstructive pulmonary disease or contralateral diaphragmatic dysfunction. Rates of conversion from regional anesthesia to general anesthesia of approximately 2 to 3 percent have been reported. [356] [371] In patients undergoing carotid endarterectomy under cervical plexus block, ST segment depression occurring during clamping or shortly after declamping was highly predictive of adverse cardiac complications. [372]

Intraoperative neurologic changes during carotid endarterectomy under local or regional anesthesia occur in 2.4 to 24 percent of patients. [371] [373] [374] Patients undergoing carotid endarterectomy under cervical plexus block who experience intraoperative neurologic changes are six times more likely (6.6% versus 1.1%) to have a postoperative stroke. [371] Compared with general anesthesia, regional anesthesia for carotid endarterectomy may be associated with increased levels of blood catecholamines. [375] A high incidence of tachycardia has been reported in patients undergoing regional anesthesia for carotid endarterectomy. [362] To date, no large-scale, prospective, randomized trials have evaluated whether neurologic or cardiac outcomes differ with regional versus general anesthesia. The ultimate decision to use one technique over the other must be based on the surgeon's and the anesthesiologist's experience and the patient's preference.

Carbon Dioxide and Glucose Management

Control of ventilation and carbon dioxide is a matter of some controversy. Hypocapnia is associated with cerebral vasoconstriction, whereas hypercapnia may cause a "steal" phenomenon. It is common practice, therefore, to maintain normocapnia during carotid endarterectomy. There is evidence of increased ischemic injury to neural tissue when ischemia occurs in the presence of hyperglycemia. Although there are no good outcome studies in humans, it is appropriate to maintain a blood glucose level below 250 mg/dL in patients undergoing carotid endarterectomy. [376] Glucose level should be carefully monitored, especially during general anesthesia, to avoid the dangers of hypoglycemia.

Neurologic Monitoring and Cerebral Perfusion

Intraoperative monitoring for cerebral ischemia and/or hypoperfusion, and more recently cerebral emboli, during carotid endarterectomy is controversial (Chs. 19 and 35). Monitoring techniques includes internal carotid artery stump pressure determinations, regional cerebral blood flow measurements, EEC, SSEP measurements, and transcranial Doppler (TCD) imaging. The rationale for the use of such monitoring is based on the need to prevent intraoperative strokes. The primary clinical utility of cerebral monitoring is to identify patients in need of carotid artery shunting; secondarily, the method is used to identify patients who may benefit from blood pressure augmentation.

The internal carotid artery stump pressure represents the back pressure resulting from collateral flow through the circle of Willis via the contralateral carotid artery and the vertebrobasilar system. The advantages of carotid stump pressure monitoring are that it is inexpensive, is relatively easy to obtain, and is continuously available during carotid clamping (dynamic stump pressure). Few centers employ stump pressure monitoring because the accuracy in determining adequacy of collateral flow and the need for selective shunting have been questioned. [374] [377] [378] [379] [380] Although the critical stump pressure is unknown, pressures below 50 mm Hg are thought to be associated with hypoperfusion. [381]

Regional cerebral blood flow measurements during carotid endarterectomy are obtained by intravenous or ipsilateral

carotid artery injection of radioactive xenon and analysis of decay curves obtained from detectors placed over the area of the ipsilateral cortex supplied by the middle cerebral artery. Measurements are typically obtained before, during, and immediately after carotid clamping. This technology, combined with EEG monitoring, has provided important insight into the relationship between regional cerebral blood flow and EEG evidence of cerebral ischemia and the critical regional cerebral blood flow associated with various anesthetics. [347] [348] The expense and the expertise required to make and interpret these blood flow measurements have limited the use of this technology to only a few centers.

Many centers advocate the intraoperative use of EEG monitoring for the detection of cerebral ischemia and subsequent selective shunting. The full 16-channel strip-chart EEG and the processed (compressed spectral array) EEG monitor are utilized for this purpose. Although the processed EEG is more easily interpreted, it is less sensitive than the raw EEG. Significant ischemic EEG changes occur in 10 to 20 percent of monitored patients during carotid clamping under general anesthesia. [351] [382] [383] [384] [385] [386] The presence of a contralateral carotid occlusion may increase the rate of significant ischemic EEG changes to nearly 50 percent during carotid clamping. [385] Ischemic EEG changes may be seen with shunt malfunction, hypotension, or cerebral emboli.

The clinical usefulness of intraoperative EEG as an ischemia monitor during carotid endarterectomy is limited by several factors. [384] First, the EEG may not detect subcortical or small cortical infarcts. Second, false-negative results (neurologic deficit with no ischemic EEG changes intraoperatively) are not uncommon. Patients with preexisting stroke or reversible neurologic deficits may have a particularly high incidence of such results. Third, the EEG is not ischemia specific and may be affected by changes in temperature, blood pressure, and anesthetic depth. Fourth, false-positive results (no perioperative neurologic deficit with significant ischemic EEG changes intraoperatively) occur because not all cerebral ischemia uniformly proceeds to infarction. Last, intraoperative EEG monitoring is inherently limited because most intraoperative strokes are felt to be thromboembolic and most perioperative strokes occur postoperatively. At present, no consistent data demonstrate that EEG is clearly superior to other methods of intraoperative cerebral monitoring or that the use of EEG monitoring improves outcome.

Somatosensory evoked potential monitoring is based on the response of the sensory cortex to electrical impulses from peripheral sensory nerve stimulation. The sensory cortex, being primarily supplied by the middle cerebral artery, is at risk during carotid artery clamping. SSEP monitoring, unlike EEG, is able to detect subcortical sensory pathway ischemia. Characteristic SSEP tracings (decrease in amplitude and/or increase in latency) occur with decreased regional cerebral blood flow and are abolished in primates when flow decreases to less than 12 mL/100 g of brain tissue per minute. [387] No specific amplitude reduction or increase in latency

has been established as a physiologic marker of impaired regional cerebral blood flow under operative conditions in humans. Anesthetics, hypothermia, and blood pressure may affect SSEP significantly, and false-negative results have been reported. [388] The validity of SSEP as an intraoperative monitor of cerebral ischemia during carotid endarterectomy has not been definitively established.

Transcranial Doppler ultrasonography allows continuous measurement of mean blood flow velocity and detection of embolic events in the middle cerebral artery. These param-eters have important clinical implications because most perioperative neurologic deficits are felt to be thromboembolic in origin. [389] With TCD, intraoperative embolization has been detected in more than 90 percent of patients undergoing carotid endarterectomy. [390] [391] Most intraoperative emboli are characteristic of air and are not associated with adverse neurologic outcome. TCD may provide useful information regarding shunt function, malfunction, and incidence of emboli during shunt insertion. Embolization during carotid artery dissection may indicate plaque instability and the need for early carotid artery clamping. [391] One center has reported that combined TCD monitoring and completion angiography resulted in a reduction in intraoperative stroke rate from 4 percent to 0 percent. [392] Early postoperative embolization has been detected in more than 70 percent of patients after carotid endarterectomy [391] and is exclusively particulate in nature. [393] Most TCD-detected emboli occur in the first 2 to 3 hours after surgery. [394] Persistent particulate embolization in the early postoperative period has been shown to predict thrombosis and development of major neurologic deficit. [390] Frequent early postoperative TCD embolic signals have been shown to be highly predictive of early postoperative ipsilateral focal cerebral ischemia. [391] Intervention with dextran has been shown to reduce and ultimately stop sustained embolization after carotid endarterectomy. [394] TCD monitoring has also been reported to detect early asymptomatic carotid artery occlusion and hyperperfusion syndrome after carotid endarterectomy. [395] Although TCD monitoring holds much promise, conclusive evidence demonstrating improved outcome has not been reported.

Postoperative Considerations

Most neurologic complications (transient and permanent) after carotid endarterectomy are explained by intraoperative embolization, hypoperfusion during carotid clamping, and embolization or thrombosis from the endarterectomy site. Other important, but less common, factors include intracerebral hemorrhage and hyperperfusion. Thromboembolic rather than hemodynamic factors appear to be the major mechanism of perioperative neurologic complications, [337] [389] [396] and most perioperative neurologic deficits occur in the postoperative period. [337] [396] [397] [398] [399] It is generally accepted that most neurologic complications are related to surgical technique. Hemodynamic factors may account for up to 21 percent of perioperative strokes. [389] Neurologic complications due to carotid artery thrombosis may occur with an incidence as high as 3.3 percent and are associated with a high rate of major stroke or death, despite immediate operative intervention. [371] [390] [400] [401] [402] The reported incidence of intracerebral hemorrhage after carotid endarterectomy ranges from 0.4 to 2.0 percent. [399] Most intracerebral hemorrhages occur 1 to 5 days after the operation and are associated with significant morbidity and mortality. [403] [404]

Hypertension is common in the postoperative period after carotid endarterectomy. [330] [405] [406] Not surprisingly, patients with poorly controlled preoperative hypertension often have severe hypertension postoperatively. The causes are not well understood, but surgical denervation of the carotid sinus baroreceptors is contributory. [407] [408] Regional anesthesia is associated with less hypertension. [409] Other causes of postoperative hypertension, such as hypoxemia, hypercarbia, bladder distention, and pain, should be excluded and/or treated. Because neurologic and cardiac complications may be associated with postoperative hypertension, [330] [405] [410] [411] [412] [413] blood pressure should be aggressively controlled near preoperative values after surgery. Shortacting drugs are safest and most effective. Patients with persistent hypertension are ultimately converted to longeracting intravenous or oral agents before discharge from the intensive care unit.

Postoperative hyperperfusion syndrome is an abrupt increase in blood flow with loss of autoregulation in the surgically reperfused brain manifesting as headache, seizure, focal neurologic signs, brain edema, and possibly intracerebral hemorrhage. [411] Typically, this syndrome does not occur until several days after carotid endarterectomy. Patients with severe postoperative hypertension and severe preoperative internal carotid artery stenosis are at increased risk for developing this syndrome. [411] [412] [414]

Postoperative hypotension occurs almost as frequently as hypertension after carotid endarterectomy. [415] [416] Carotid sinus baroreceptor hypersensitivity or reactivation likely plays an important role. Postoperative hypotension may be more common after regional anesthesia. [372] [410] [415] [416] [417] To avoid cerebral and myocardial ischemia, hypotension should be corrected promptly. Cardiac output is frequently normal or elevated and systemic vascular resistance reduced in hypotensive patients after carotid endarterectomy. [415] Intensive surveillance for evidence of myocardial and cerebral ischemia and judicious use of fluids and vasopressors are recommended for postoperative hypotension. In most cases, hypotension resolves over a period of 12 to 24 hours.

Cranial and cervical nerve dysfunction after carotid endarterectomy is well documented in the literature. [418] [419] [420] [421] [422] [423] [424] Although most injuries are transient, permanent injuries can lead to significant disability. [418] Patients should be examined for injury to the recurrent laryngeal, superior laryngeal, hypoglossal, and marginal mandibular nerves shortly after extubation. Unilateral recurrent laryngeal nerve injury may result in ipsilateral true vocal cord paralysis in the paramedian position. Although most patients have hoarseness and an impaired cough mechanism, the injury is usually well tolerated. However, bilateral recurrent laryngeal nerve injury and resultant bilateral vocal cord paralysis can result in life-threatening upper airway obstruction. This situation must be anticipated in patients who have undergone previous contralateral carotid endarterectomy or neck surgery.

Carotid body denervation may occur after carotid endarterectomy as a result of surgical manipulation. Although rarely of clinical significance, unilateral loss of carotid body function may result in impaired ventilatory response to mild hypoxema. [425] Bilateral carotid endarterectomy is associated with loss of normal ventilatory and arterial pressure responses to acute hypoxia and increased resting partial pressure of arterial carbon dioxide. [426] In this situation, the central chemoreceptors are the primary sensors to maintain ventilation, and serious respiratory depression may result from opioid administration. [427] Fortunately, most patients require little more than acetaminophen or ketorolac for postoperative pain.

Wound hematoma probably occurs more frequently than is reported in the literature. Most cases are the result of venous oozing and require little more than external compression for 5 to 10 minutes. Expanding hematomas require prompt evaluation at the bedside and immediate evacuation if airway compromise is evident. Aggressive postoperative blood pressure control may help to reduce the incidence of hematoma.

We believe that all patients should be monitored in an intensive care setting for 16 to 24 hours after carotid endarterectomy because most events requiring intervention occur within this time frame. [428] [429] [430] Although some clinicians believe that intensive care monitoring is not routinely required, a significant number of patients do require such monitoring and intervention. [428] [431]

POSTOPERATIVE MANAGEMENT OF VASCULAR PATIENTS

Vascular surgery patients require special attention during the postoperative period because most cardiac complications occur postoperatively, and other problems may arise that require immediate attention. Conventional practice is to monitor all vascular surgery patients in an intensive care unit setting after surgery. Some centers have set up specialized vascular stepdown units, where lower-risk patients can be evaluated frequently by trained nursing staff. There are, however, no clinical trials to support this practice, and most centers admit all vascular surgery patients to the intensive care unit postoperatively.

Myocardial ischemia and cardiac morbidity occur most frequently in the postoperative period. Patients should be carefully monitored for signs and symptoms of ischemia, but up to 90 percent of these episodes are asymp-tomatic. [59] [90] [93] [95] [432] [433] The determinants of myocardial oxygen supply and demand should be optimized for all patients (see Fig. 51-3 (Figure Not Available)) to prevent ischemia before it develops. Dysrhythmias may be secondary to ischemia or to sympathectomy associated with regional anesthesia.

Besides myocardial ischemia and cardiac morbidity, other problems include coagulopathy, either from residual heparin or dilutional coagulopathy after massive transfusion. Even in the absence of coagulopathy, bleeding through fresh vascular anastomoses may occur when significant postoperative hypertension is untreated. Hypovolemia occurs following aortic surgery as a result of significant third-space fluid losses and bleeding. Hypovolemia may lead to hypotension and hypoperfusion of the coronary arteries and/or lower-extremity vascular grafts. Graft occlusion in the lower extremities occurs in 3 to 10 percent of patients [54] [304] [305] after lower-extremity or aortic surgery and should be recognized immediately and surgically corrected. Lowerextremity pulses should be checked at hourly intervals. Some patients require administration of heparin or dextran to prevent thrombosis when the surgical repair is questionable or when patients have diffuse atherosclerotic disease.

Residual hypothermia in the early postoperative period is associated with an increased incidence of myocardial ischemia and cardiac morbidity; therefore, body temperature should be carefully monitored and controlled in all vascular surgery patients. In a prospective randomized trial, the relative risk of early postoperative cardiac morbidity was reduced by 55 percent when normothermia was maintained by use of a forced-air warming system (Fig. 51-14) (Figure Not Available) . [219] In the early postoperative period, vascular surgery patients have a twofold to threefold greater incidence of myocardial ischemia when core temperature is less than 35°C. [220] Even mild hypothermia of
35°C is associated with a 200 to 700 percent increase in norepinephrine levels, [216] [434] generalized vasoconstriction, [435] and increased blood pressure in postoperative patients. [216] Shivering occurs, which increases total body oxygen consumption, but only by about 40 percent in the typical elderly vascular patient. [215]

It is important to control the stress response in the postoperative period. This includes preventing the potential triggers for myocardial ischemia (pain, anemia, hypothermia, hemodynamic extremes, and ventilatory insufficiency). In mechanically ventilated patients, the weaning period is especially stressful, and myocardial ischemia occurs frequently during this time. [436] Careful sedation and expeditious weaning are desirable. When possible, extubation in the operating room is less stressful and is preferable for carotid and lower-extremity vascular surgery patients. For more invasive surgical procedures (TAA and abdominal aortic aneurysm), postoperative mechanical ventilation is usually necessary.

Figure 51-14 (Figure Not Available) (A) Incidence of postoperative cardiac morbidity in patients who were actively warmed with a forced-air system (normothermic) and those who received no warming (hypothermic). Morbid cardiac events (unstable angina, myocardial infarction, or cardiac arrest) occurred more frequently in the hypothermic patients ($P = .03$). Ventricular tachycardia and combined electrocardiographic or morbid events also occurred more frequently in the hypothermic patients ($P = .04$ and $P = .001$, respectively). *(Adapted from Frank et al [219])* (B) Incidence of myocardial ischemia following lower extremity vascular surgery by core temperature on admission to the intensive care unit, anesthetic technique, and age. Patients below 35°C had a two- to threefold greater incidence of ischemia. Patients older than 65 years of age had a twofold greater incidence of ischemia. *(Adapted from Frank et al [220])*

Vascular surgery continues to challenge the anesthesiologist, given the significant physiologic stress superimposed on a relatively elderly patient population with a high incidence of coexisting disease. Clinical studies provide insight into the preoperative assessment and optimization of cardiac risk, the implications of anesthetic technique, and the diagnosis, prevention, and treatment of myocardial ischemia in vascular surgery patients. These studies have improved our ability to care for the vascular surgery patient with reduced morbidity and better overall outcome.

Chapter 52 - Neurosurgical Anesthesia

John C. Drummond
Piyush M. Patel

INTRODUCTION

This chapter provides management guidelines for common situations in neurosurgical anesthesia (Table 52-1) . It begins with a review of issues that arise in connection with many procedures. Procedure-specific discussions follow. This chapter assumes familiarity with the cerebral physiology and effects of anesthetics as described in Chapter 19 . Neurologic monitoring is described in Chapter 35 . Carotid endarterectomy is discussed in Chapter 51 .

RECURRENT ISSUES IN NEUROANESTHESIA

There are several basic elements of neurosurgical/neuroanesthetic management that are recurrent and that should be discussed and agreed on with the surgical team at the outset of every neurosurgical procedure. The list varies with the procedure and may include the following: the intended surgical position and requisite positioning aids; the intentions with respect to the use of steroids, diuretics, anticonvulsants, and antibiotics; the surgeon's perception of the "tightness" of the intracranial space and of the remaining intracranial compliance reserve; the appropriate objectives for management of blood pressure, CO_2 tension, and body temperature; the anticipated blood loss; the intended use of neurophysiologic monitoring (which may impose constraints on the use of anesthetic agents and/or on the use of muscle relaxants), and, occasionally, the perceived risk of air embolization. The considerations driving the decisions made about these issues are presented in the following subsections. One additional recurrent issue, brain protection, is discussed briefly in the second part of this chapter and in detail in Chapter 19 .

Intracranial Pressure Control/Brain Relaxation

The necessity to prevent increases in intracranial pressure (ICP) or to reduce an ICP that is already elevated is recurrent in neuroanesthesia. When the cranium is closed, the objective is to maintain an adequate cerebral perfusion pressure (CPP) (CPP = mean arterial pressure [MAP] - ICP) and/or to prevent herniation of brain tissue between intracranial compartments or through the foramen magnum (Fig. 52-1) (Figure Not Available) . When the cranium is open, the issue may be one of providing relaxation of the intracranial contents to facilitate surgical access or, in extreme circumstances, to reverse the process of brain herniation through a craniotomy (see Fig. 52-1) (Figure Not Available) . The principles that apply are similar whether the cranium is open or closed.

The various clinical indicators of increased ICP include headache (particularly a postural headache that awakens the patient at night), nausea and vomiting, blurred vision, somnolence, and papilledema. Suggestive findings on a computed tomography (CT) scan include midline shift, obliteration of the basal cisterns, loss of sulci, ventricular effacement (or enlarged ventricles in the event of hydrocephalus), and edema. Edema appears on a CT scan as a region of hypodensity. The basal cisterns appear as a black (fluid) halo around the upper end of the brain stem. They include the interpeduncular cistern, which lies between the

TABLE 52-1 -- Abbreviations

AVM	Arteriovenous malformation
BBB	Blood-brain barrier
CBF	Cerebral blood flow
CBFV	Cerebral blood flow velocity
CBV	Cerebral blood volume
CMR	Cerebral metabolic rate
CMRg	Cerebral metabolic rate for glucose
CMR_{O_2}	Cerebral metabolic rate for oxygen
CNS	Central nervous system
CPP	Cerebral perfusion pressure
CSF	Cerebrospinal fluid
CSFP	Cerebrospinal fluid pressure
CVR	Cerebral vascular resistance
EEG	Electroencephalogram
GCS	Glasgow coma scale
ICP	Intracranial pressure
l-CBF	Local cerebral blood flow
l-CMR	Local cerebral metabolic rate
LLA	Lower limit of autoregulation
MAP	Mean arterial pressure
NO	Nitric oxide
N_2O	Nitrous oxide
PET	Positron emission tomography
r-CBF	Regional cerebral blood flow
Sjv_{O_2}	Jugular venous oxygen saturation
TCD	Transcranial Doppler
TEE	Transesophageal echocardiography
VAE	Venous air embolism

Figure 52-1 (Figure Not Available) Schematic representation of various herniation pathways: (1) subfalcine, (2) uncal (transtentorial), (3) cerebellar, and (4) transcalvarial. *(From Fishman [243])*

two cerebral peduncles, the quadrigeminal cistern, which overlies the four colliculi, and the ambient cisterns, which lie lateral to the cerebral peduncles.

Figure 52-2 presents the pressure-volume relationship of the intracranial space. The plateau phase occurring at low volumes reveals that the intracranial space is not completely closed, and there is some compensatory latitude. Compensation is accomplished principally by the translocation of

Figure 52-2 The intracranial pressure-volume relationship. The horizontal portion of the curve indicates that there is initially some latitude for compensation in the face of an expanding intracranial lesion. That compensation is accomplished largely by displacement of cerebrospinal fluid (CSF) and venous blood from intracranial to extracranial spaces. Once the compensatory latitudes are exhausted, small volume increments result in large increases in intracranial pressure, with the associated hazards of either herniation or decreased cerebral perfusion pressure (CPP) resulting in ischemia.

cerebrospinal fluid (CSF) and venous blood to the spinal CSF space and to extracranial veins, respectively. Ultimately, when the compensatory potential is exhausted, even tiny increments in the volume of the intracranial contents can result in substantial ICP increases. These increases have the potential to result in either herniation of brain tissue from one compartment to another (or into the surgical field) (see Fig. 52-1) (Figure Not Available) , with resultant mechanical injury to brain tissue, or reduction in perfusion pressure with a concomitant ischemic injury.
