have been responsible for the pneumothorax in many of these patients. Small pneumothoraces may be managed by radiographic observation, with or without needle aspiration, assuming the patient remains clinically stable. Tube thoracostomy is the best treatment, however, for larger pneumothoraces or pneumothorax in the patient receiving positive pressure mechanical ventilation or scheduled for major surgery. The physician must always be prepared for the possibility of tension pneumothorax and its adverse hemodynamic sequelae.

By far, the most common major late complication of central venous cannulation is *infection.* Bloodstream infections occur in approximately 5 percent of patients with standard central venous catheters, leading to an estimated 150,000 cases of catheter-related bacteremia or fungemia annually. [266] Given that the crude mortality of nosocomial bloodstream infections is nearly 35 percent, most simple efforts to reduce this complication appear to be both cost-effective and life saving. [266] [267] As previously noted, the starting point is meticulous attention to aseptic technique. [202] When more long-term central venous cannulation is anticipated, the subclavian site is preferred, because use of the jugular or femoral veins carries a higher risk of infection. [202] [266] Multilumen catheters carry a higher risk than single-lumen catheters, although the added clinical functionality of such catheters may mandate their use. [202] [268] Clearly, the type of catheter inserted influences the rate of catheter colonization and subsequent sepsis. Catheters are made from materials such as silicone, polyvinyl chloride, Teflon, and polyurethane. Furthermore, catheters of the same material may be manufactured differently, which influences their surfaces and the frequency of bacterial adherence to the surface. [269] One recent improvement in catheter design has been incorporation of an antimicrobial treatment onto the catheter surface. Combinations of either chlorhexidine and silver sulfadiazine or monocycline and rifampin have been shown to reduce the rates of catheter colonization and sepsis, although the latter treatment may be the more efficacious. [266] [267] Other effective catheter modifications include the use of a silver-impregnated subcutaneous cuff with catheters intended for long-term use. [212] Despite these improvements, several important issues pertaining to catheter-related infection remain controversial and unresolved. When patients require central venous catheterization for more than 3 to 4 days, some clinicians recommend catheter replacement at a new site, others suggest exchanging the catheter over a guide wire, and still others believe that catheters should not be changed unless there are signs of infection or other clinical indications. [202] [212] [268] [270] Clearly, the risks of infection must be weighed against the alternative risks of establishing a new site for central venous catheterization.

Many other adverse sequelae of central venous cannulation have been reported (see Table 30-4) . Although their incidence is not clearly known, most appear to be uncommon. They should be recognized, however, by all physicians performing these procedures, to limit the morbidity of central venous cannulation. Although some complications may be unavoidable, such as catheter-related infection in an immunocompromised host, many complications result from operator error. [121] [211] [271] [272] Several deserve special emphasis. *Cardiac tamponade* from perforation of the superior vena cava, right atrium, or right ventricle was the single most common fatal complication of central venous cannulation among 3,533 cases in the American Society of Anesthesiologists Closed Claims Project. [211] Most reports document the avoidable nature of this catastrophic event and highlight that patients are predisposed to this complication when central venous catheter tips are malpositioned within the right atrium, right ventricle, or abutting the wall of the superior vena cava. These observations emphasize that radiographic confirmation of proper catheter tip location is mandatory, regardless of whether the catheter is inserted from a central or peripheral site. In fact, many early reports of catheter-related cardiovascular perforation suggest that peripheral catheters may present unusually high risk for this complication, because arm abduction may cause the catheter tip to advance into a dangerous location within the heart. [207] [208] When cardiac tamponade is caused by catheter-induced cardiac perforation, symptoms develop suddenly, requiring the physician to have a high index of suspicion if severe hypotension occurs in any patient with a central venous catheter in place. Cardiac arrhythmias may provide an early clue to the intracardiac location of the catheter tip. [262] [273] Occasionally, both posteroanterior and lateral chest radio-graphs and injection of radiopaque contrast are required to locate the catheter tip precisely. [227] [274] The life-threatening nature of catheter-associated cardiac tamponade has been recognized for several years by the Food and Drug Administration and equipment manufacturers. [210] [211] Package inserts in central venous catheterization kits clearly and explicitly warn the user to avoid intracardiac catheter tip locations, except in the rare circumstance when this is needed, as for aspiration of venous air emboli.

Use of *guide wires, vessel dilators,* and *large-bore catheters* carries certain additional risks that mandate meticulous attention to technique. The proximal tip of the guide wire must remain under the physician's control at all times to avoid inserting the wire too far into the heart, thus causing arrhythmias or heart block [273] or potentially losing the guide wire within the circulation. [121] [275] By design, vessel dilators are stiffer than central venous catheters and may cause significant trauma if inserted forcefully or further than necessary to dilate the subcutaneous tissue track from skin to vein. [272] Large-bore introducer sheaths and multilumen catheters have become popular because of their clinical usefulness, yet their size may increase the risk of cannulation-associated trauma, hemorrhage from unrecognized line disconnections, and major *venous air embolism.* Not only may air be entrained during initial cannulation, [276] but improperly connected large-bore cannulas may pose an additional risk because of the large site for air entry directly into the central venous circulation. [229] [277] [278]

Unusual complications of central venous cannulation continue to be reported as new catheter modifications are designed. To reduce the risk of infection, catheters are being manufactured with an exterior antiseptic surface treatment containing silver sulfadiazine and chlorhexidine. Although more than 2.5 million of these catheters have been used in the United States without incident, [279] rare but severe anaphylactoid reactions have been reported in Japanese patients. [279] [280] A new double-lumen 15.5-French catheter has been designed for use in immunocompromised patients to provide long-term central venous access and an introducer

lumen to accommodate a standard pulmonary artery catheter for hemodynamic monitoring. It remains to be seen whether this type of extremely large catheter will create more problems than it solves. [281]

Although many complications of CVP monitoring relate to equipment misuse, the frequency of complications caused by data misinterpretation remains unknown. It is extremely likely, however, that clinicians misinterpret CVP measurements and have suboptimal understanding of CVP monitoring, just as has been demonstrated repeatedly for PAP monitoring by both physicians and nurses (see later discussion). Safe and effective use of CVP monitoring requires a detailed understanding of normal CVP waveforms and common pathologic changes in these measurements.

Central Venous Pressure Waveforms

Strictly speaking, CVP is the pressure at the junction of the vena cavae and the right atrium and reflects the driving force for filling the right atrium and ventricle. Because the large veins of the thorax, abdomen, and proximal extremities form a compliant reservoir for a sizable percentage of the total blood volume, CVP is highly dependent on intravascular blood volume and intrinsic vascular tone of these capacitance vessels. In other words, the CVP or right atrial pressure reflects the appropriateness of the blood volume to the capacity of the venous system. [282] In addition to providing a measure of the circulating blood volume, CVP reflects the functional capacity of the right ventricle. Based on the Frank-Starling mechanism, higher right heart filling pressures are required to maintain the ventricular stroke output when right ventricular contractility is impaired. Thus, in clinical practice, CVP monitoring is used for assessment of blood volume and right heart function.

CVP monitoring is performed using the same fluid-filled pressure tubing-transducer setup described earlier for direct arterial pressure monitoring (see the earlier section *Technical Aspects of Direct Blood Pressure Measurement*). Although a simple fluid-filled mechanical manometer may be used to estimate CVP, this method is not preferred for routine monitoring. First, manometric measurements are not as accurate as electronically transduced pressures and

TABLE 30-5 -- Central Venous Pressure Waveform Components

WAVEFORM COMPONENT	PHASE OF CARDIAC CYCLE	MECHANICAL EVENT
a wave	End-diastole	Atrial contraction
c wave	Early systole	Isovolumic ventricular contraction, tricuspid motion toward right atrium
v wave	Late systole	Systolic filling of atrium
h wave	Mid- to late diastole	Diastolic plateau
x descent	Mid-systole	Atrial relaxation, descent of the base, systolic collapse
y descent	Early diastole	Early ventricular filling, diastolic collapse

Figure 30-27 (Figure Not Available) Normal central venous pressure (CVP) waveform. The diastolic components (y descent, end-diastolic a wave) and the systolic components (c wave, x descent, end-systolic v wave) are all clearly delineated. A mid-diastolic plateau wave, the h wave, is also seen because heart rate is slow. Waveform identification is aided by timing the relation between individual waveform components and the electrocardiographic R wave, which is highlighted. Waveform timing using the arterial (ART) pressure trace is more confusing, owing to the relative delay in the systolic arterial pressure upstroke. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 2-5.)*

can only be measured intermittently, not displayed continuously. [283] [284] [285] Second, the use of an open manometer system may expose the patient to unnecessary risk of infection and venous air embolism. Finally, a wealth of information exists in the CVP waveform, which can be observed only by electronic transduction and display on a bedside monitor. [80]

The normal mechanical events of the cardiac cycle are responsible for the sequence of waves seen in a typical CVP trace. The CVP waveform consists of five phasic events, three peaks (a, c, v) and two descents (x, y) (Table 30-5 , Fig. 30-27) (Figure Not Available) . [286] [287] [288] The most prominent wave is the *a wave* of atrial contraction, which occurs at end-diastole following the ECG P wave. The a wave increases atrial pressure and provides the "atrial kick" to fill the right ventricle through the open tricuspid valve. Atrial pressure decreases following the a wave, as the atrium relaxes. This smooth decline in pressure is interrupted by the *c wave.* This wave is a transient increase in atrial pressure produced by isovolumic ventricular contraction, which closes the tricuspid valve and displaces it toward the atrium. The c wave always follows the ECG R wave, because it is generated by the beginning of ventricular systole. *

* The c wave observed in a jugular venous pressure trace may have a slightly more complex origin. This wave has been attributed to early systolic pressure transmission from the adjacent carotid artery and may be termed a *carotid impact wave.*[289] Because the jugular venous pressure also reflects right atrial pressure, however, this c wave likely represents both arterial (carotid impact) and venous (tricuspid motion) origins.

Atrial pressure continues its decline during ventricular systole, owing to continued atrial relaxation and changes in atrial geometry produced by ventricular contraction and ejection. This is the *x descent* or systolic collapse in atrial pressure. The x descent can be divided into two portions, x and x
, corresponding to the segments before and after the c wave. The last atrial pressure peak is the *v wave,* caused by venous filling of the atrium during late systole, while the tricuspid valve remains closed. The v wave usually peaks just after the ECG T wave. Atrial pressure then decreases, inscribing the *y descent* or diastolic collapse, as the tricuspid valve opens and blood flows from atrium to ventricle. (A final component of the CVP waveform, the *h wave,* occasionally appears as a pressure plateau in mid- to late diastole. The h wave is not normally seen unless the heart rate is slow and venous pressure is elevated. [289] [290]) In summary, the normal venous waveform components may be remembered as follows: the a wave results from atrial contraction; the c wave from tricuspid valve closure and isovolumic right ventricular contraction; and the v wave from ventricular ejection, which drives venous filling of the atrium.

Thus, in relation to the cardiac cycle and ventricular mechanical actions, the CVP waveform can be considered to have three systolic components (c wave, x descent, v wave) and two diastolic components (y descent, a wave). By recalling the mechanical actions that generate the pressure peaks and troughs, it is easy to identify these waveform components properly by aligning the CVP waveform and the ECG trace and using the ECG R wave to mark end-diastole and the onset of systole. When the radial artery pressure trace is used for CVP waveform timing instead of the ECG, confusion may arise because the arterial pressure upstroke occurs nearly 200 milliseconds after the ECG R wave (see Fig. 30-27) (Figure Not Available) . This normal physiologic delay reflects the times required for the spread of the electrical depolarization through the ventricle (
60 milliseconds), isovolumic left ventricular contraction (
60 milliseconds), transmission of aortic pressure rise to the radial artery (
50 milliseconds), and transmission of the radial artery pressure rise through fluid-filled tubing to the transducer (
10 milliseconds). [126] [145]

The normal CVP peaks have been designated systolic (c, v) or diastolic (a) according to the phase of the cardiac cycle in which the wave begins. However, one generally identifies these waves not by their onset or upstroke, but rather by the location of their peaks. For instance, the a wave generally begins and peaks in end-diastole, but the peak may appear delayed to coincide with the ECG R wave, especially in a patient with a short PR interval. In this instance, a and c waves merge, and this composite wave is termed an *a-c wave.* Designation of the CVP v wave as a systolic event may be even more confusing. Although the ascent of the v wave begins during late systole, the peak of the v wave occurs during isovolumic ventricular relaxation, immediately prior to atrio-ventricular valve opening and the y descent. Consequently, the most precise description would be that the v wave begins in late systole, but peaks during isovolumic ventricular relaxation, the earliest portion of diastole. For clinical purposes, it is simplest to consider the v wave to be a systolic wave, and most authors have adopted this approach. [286] [289]

Although three distinct CVP peaks (a, c, v) and two troughs (x, y) are discernible in the normal venous pressure trace, heart rate changes and conduction abnormalities alter this pattern. A short ECG PR interval causes fusion of a and c waves, and tachycardia reduces the length of diastole and the duration of the y descent, causing v and a waves to merge. In contrast, bradycardia causes each wave to become more distinct, with separate x and x
descents visible and a more prominent h wave. Although there are circumstances in which other pathologic waves may be evident in the CVP trace, one should resist the temptation to assign physiologic significance to each small pressure peak, as many will arise as artifacts of fluid-filled tubing-transducer monitoring systems. Instead, search for the expected waveform components, including those waveforms that are characteristic of the pathologic conditions suspected.

Various pathophysiologic conditions may be diagnosed or confirmed by examination of the CVP waveform. One of the most common applications is the rapid diagnosis of cardiac arrhythmias. [291] In *atrial fibrillation* (Fig. 30-28A) (Figure Not Available) , the a wave disappears and the c wave becomes more prominent, because atrial volume is greater at end-diastole and onset of systole, owing to the absence of effective atrial contraction. Occasionally, atrial fibrillation or flutter

waves may be seen in the CVP trace, when the ventricular rate is slow. *Isorhythmic atrioventricular dissociation* or *junctional (nodal) rhythm* (Fig. 30-28B) (Figure Not Available) alters the normal sequence of atrial contraction prior to ventricular contraction. Instead, atrial contraction now occurs during ventricular systole, when the tricuspid valve is closed, thereby inscribing a tall *cannon a wave* in the CVP waveform. Absence of normal atrioventricular synchrony during *ventricular pacing* (Fig. 30-28C) (Figure Not Available) can be identified in a similar fashion by searching for cannon waves in the venous pressure trace. In these instances, the CVP helps diagnosis the cause of arterial hypotension; loss of the normal end-diastolic atrial kick may not be as evident in the ECG trace as it is in the CVP waveform.

Right-sided valvular heart diseases alter the CVP waveform in different ways. [292] *Tricuspid regurgitation* (Fig. 30-29A) (Figure Not Available) produces abnormal systolic filling of the right atrium through the incompetent valve. A broad, tall systolic c-v wave is inscribed, which begins in early systole and obliterates the systolic x descent in atrial pressure. The CVP trace is said to be ventricularized, resembling right ventricular pressure. Note that this regurgitant wave differs in onset, duration, and magnitude from a normal CVP v wave caused by end-systolic atrial filling from the vena cavae. In patients with tricuspid regurgitation, right ventricular end-diastolic pressure is overestimated by the numeric display on the bedside monitor, which reports a single mean value for CVP. Instead, right ventricular end-diastolic pressure is estimated best by measuring the CVP value at the time of the ECG R wave, prior to the regurgitant systolic wave (see Fig. 30-29A) (Figure Not Available) . Unlike tricuspid regurgitation, *tricuspid stenosis* (Fig. 30-29B) (Figure Not Available) is a diastolic defect in atrial emptying and ventricular filling. Mean CVP is elevated, and a pressure gradient exists throughout diastole between right atrium and ventricle. The a wave is unusually prominent and the y descent is slurred, owing to the impaired diastolic egress of blood from the atrium. Other conditions that reduce right ventricular compliance, such as right ventricular ischemia, pulmonary hypertension, or pulmonic valve stenosis, may produce a prominent end-diastolic a wave in the CVP trace but do not attenuate the early diastolic y descent. CVP waveform morphology changes in other characteristic ways in the presence of pericardial diseases and right ventricular

Figure 30-28 (Figure Not Available) Central venous pressure (CVP) changes caused by cardiac arrhythmias. (A) Atrial fibrillation obliterates the a wave, increases the c wave and preserves the v wave and y descent. This arrhythmia also causes variation in the electrocardiographic (ECG) R-R interval and left ventricular stroke volume, which can be seen in the ECG and arterial (ART) pressure traces. (B) Isorhythmic atrioventricular dissociation. In contrast to the normal end-diastolic a wave in the CVP trace (left panel), an early systolic cannon wave is inscribed (*, right panel). Reduced ventricular filling accompanying this arrhythmia causes a decreased arterial blood pressure. (C) Ventricular pacing. Systolic cannon waves are evident in the CVP trace during ventricular pacing (left panel). Atrioventricular sequential pacing restores the normal venous waveform and increases arterial blood pressure (right panel). ART scale left, CVP scale right. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Figs. 14-1 , 14-5 (Figure Not Available) , and 14-16.) (Figure Not Available)*

Figure 30-29 (Figure Not Available) Central venous pressure (CVP) changes in tricuspid valve disease. (A) Tricuspid regurgitation increases CVP and the waveform displays a tall systolic c-v wave that obliterates the x descent. In this example, the a wave is not seen because of atrial fibrillation. Right ventricular enddiastolic pressure is estimated best at the time of the electrocardiographic R wave (arrows) and is lower than mean CVP. See text for greater detail. (B) Tricuspid stenosis also increases mean CVP, but the characteristic venous waveform is different from the one seen in tricuspid regurgitation. The diastolic y descent is attenuated and the end-diastolic a wave is prominent. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Figs. 17-3 (Figure Not Available) and 17-15.)*

infarction. These patterns are interpreted best in conjunction with PAP monitoring, which is discussed later.

Perhaps the most important application of CVP monitoring is to provide an estimate of the adequacy of the circulating blood volume and right ventricular preload. As noted earlier, for this purpose, transmural CVP is always the pressure of physiologic interest. In clinical practice, however, we measure and record pressures referenced to ambient atmospheric pressure. Consequently, accurate interpretation of CVP requires the physician to consider alterations in intrathoracic or juxtacardiac pressure that occur during the respiratory cycle. [160] [178] During spontaneous breathing

Figure 30-30 (Figure Not Available) Respiratory influences on the measurement of central venous pressure (CVP). (A) During spontaneous ventilation, onset of inspiration (arrows) causes a reduction in intrathoracic pressure, which is transmitted to both the CVP and the pulmonary artery pressure (PAP) waveforms. CVP should be recorded at end-expiration (mean CVP 14 mmHg). (B) During positive pressure ventilation, onset of inspiration (arrows) causes an increase in intrathoracic pressure. CVP is still recorded at end-expiration (mean CVP 8 mmHg). See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Figs. 16-1 (Figure Not Available) and 16-2.) (Figure Not Available)*

(Fig. 30-30A) (Figure Not Available) , inspiration causes a decrease in pleural and juxta-cardiac pressures, which is transmitted, in part, to the right atrium and lowers CVP. This same decrease in pleural pressure will influence other measured central vascular pressures in a similar fashion (see Fig. 30-30A) (Figure Not Available) . Note a subtle but critically important observation about the measurement of central vascular pressures. Although CVP measured relative to atmospheric pressure decreases during the inspiratory phase of spontaneous ventilation, transmural CVP, the difference between right atrial pressure and juxtacardiac pressure may actually increase slightly as more blood is drawn into the right atrium. The opposite pattern is observed during positive-pressure ventilation, in which inspiration increases intrathoracic pressure, raises the measured CVP, but decreases transmural CVP, because venous return is reduced by the elevated intrathoracic pressure. In clinical practice, transmural pressures are rarely measured, owing to difficulties in assessing juxtacardiac or intrathoracic pressure. Instead, *end-expiratory* values for cardiac filling pressures should be recorded in all patients, to provide the best estimate of transmural pressure. At the end of expiration, intrathoracic and juxtacardiac pressures approach atmospheric pressure, whether the patient is breathing spontaneously or receiving positive-pressure mechanical ventilation (Fig. 30-30B) (Figure Not Available) . Proper pressure values can be determined by visual inspection of the CVP waveform on a calibrated monitor screen or paper recording. Under most circumstances, the transmural CVP and the end-expiratory value for CVP will be close to one another. This facilitates comparison of CVP values (and other cardiac filling pressures) obtained from the same patient under varying patterns of ventilation, a common situation in anesthesia and critical care.

Not only can individual CVP waveforms provide unique diagnostic clues about the circulation, but trends in CVP during anesthesia and surgery also are useful in estimating fluid or blood loss and guiding replacement therapy. It is important to remember that there is a significant range for normal values and that small changes in CVP may reflect significant changes in the circulating blood volume and right ventricular preload. Additional useful information may be derived from examining how a fluid bolus simultaneously alters CVP and other variables of clinical interest, such as the blood pressure, urine output, and so forth.

PULMONARY ARTERY PRESSURE MONITORING

Swan, Ganz, and colleagues [293] introduced pulmonary artery catheterization for hemodynamic monitoring into clinical practice in 1970. In fact, many clinicians still refer to balloon-tipped, flow-directed pulmonary artery catheters (PAC) as Swan-Ganz catheters, in reference to the two cardiologists who originally popularized this diagnostic tool for management of patients with acute myocardial infarction. [293] [294] [295] [296] [297] These catheters allowed accurate measurement of important cardiovascular physiologic variables at the bedside, and their popularity soared over the next two decades as they were used in an increasing number of critically ill and surgical patients. By the middle 1990s, estimated annual PAC sales in the United States approached 2 million catheters, [298] [299] with an estimated cost associated with their use in excess of 2 billion dollars each year. [300]

Clearly, proper use of the PAC discloses a wide range of pertinent cardiovascular data that many clinicians, including experts in intensive care, cannot accurately predict from standard clinical signs and symptoms. [301] [302] [303] However, despite this evidence that PACs provide accurate cardiovascular measurements, it is not known, with any measure of certainty, whether PAC monitoring leads to improved patient outcome. [299] [300] [304] [305] [306] [307] [308] [309] [310] [311] Before considering this issue, we will review the physiologic basis for PAC monitoring, techniques for catheterization, complications associated with PAC use, and interpretation of normal and pathologic PAP waveforms. With these important concepts in mind, we will return to consider the PAC monitoring controversy, including the evidence for and against use of the catheter, as well as the current indications for this technique.

Physiologic Considerations: Prediction of Left Ventricular Filling Pressure

PAC is performed to measure hemodynamic variables in critical patients, including cardiac output, mixed venous oxygen saturation, and most importantly, pulmonary artery diastolic pressure (PADP) and PAWP. These pressure

Figure 30-31 (Figure Not Available) Pulmonary artery wedge pressure measurement creates a static column of blood connecting the catheter tip to a junction point where flow resumes in the pulmonary veins (PV) near the left atrium (LA). RA, right atrium; RV, right ventricle, PA, pulmonary artery; and LV, left ventricle. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 4-1.) (Figure Not Available)*

measurements are used to estimate left ventricular filling pressure and help guide fluid and vasoactive drug administration when clinical signs, symptoms, or other monitored variables are felt to be inadequate or unreliable. [299]

When a PAC floats to the wedge position, the inflated balloon at its tip isolates the distal pressure-monitoring orifice from upstream PAP. Blood flow ceases between the catheter tip and a junction point where pulmonary veins draining the occluded pulmonary vascular region join other veins in which blood still flows toward the left atrium (Fig. 30-31) (Figure Not Available) . A continuous static column of blood now connects the wedged PAC tip to this junction point in the pulmonary veins near the left atrium. Thus, wedging the PAC functionally extends the catheter tip to measure the pressure at the point at which blood flow resumes on the venous side of the pulmonary circuit. [312] Because resistance to flow in the large pulmonary veins is negligible, PAWP provides an accurate, indirect measurement of both pulmonary venous pressure and LAP. [131] [313]

PADP is used often as an alternative to the wedge pressure to estimate left ventricular filling pressure. Under normal circumstances, resistance to pulmonary blood flow is low, and the pressure in the pulmonary artery at end of diastole equilibrates with downstream pressure in the pulmonary veins and left atrium. [314] [315] [316] [317] From a monitoring standpoint, PADP has the added advantage of being available for continuous monitoring, in contrast to PAWP, which can be measured only intermittently when the PAC balloon is inflated.

For PADP or PAWP to be a valid estimate of left ventricular filling pressure, a continuous, static column of blood must exist between the tip of the wedged catheter and the draining pulmonary venous radicle. At the microcirculatory levels, this connecting channel consists of thin pulmonary capillaries, which are subject to extramural compressive forces exerted by surrounding alveoli. West et al [318] described a physiologic model of the pulmonary vasculature consisting of three zones that are based on the gravitationally determined relations between PAP, pulmonary venous pressure, and alveolar pressure. This lung zone model provides useful insights into conditions when the PAC may not provide accurate estimates of left ventricular filling pressures.

In lung physiologic zones 1 and 2, alveolar pressure can exceed pulmonary venous pressure (zone 2) or both PAP and pulmonary venous pressure (zone 1) (Fig. 30-32) (Figure Not Available) . A PAC positioned in these lung zones will be influenced by alveolar pressure and bear little relationship to the downstream pulmonary venous pressure or left ventricular filling pressure. Under these circumstances, alveolar or airway pressures are being monitored, rather than the intended vascular pressure in the left atrium or ventricle. Fortunately, in most clinical settings in which a PAC is used, patients are supine, which favors creation of zone 3 conditions. However, patients nursed in the lateral or semisitting position may have considerable nondependent portions of their lungs exhibit zone 2 behavior. In general, zones 1 and 2 become more extensive when LAP is low, when the PAC tip is located vertically above the left atrium, or when alveolar

Figure 30-32 (Figure Not Available) The pulmonary artery catheter tip must be wedged in lung Zone 3 to provide an accurate measure of pulmonary venous (P_v) or left atrial (LA) pressure. When alveolar pressure (P_A) rises above P_v in lung zone 2, or above pulmonary arterial pressure (P_a) in lung zone 1, wedge pressure will reflect alveolar pressure rather than intravascular pressure. RA, right atrium; RV, right ventricle; PA, pulmonary artery; and LV, left ventricle. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 6-10.)*

pressure is high. Catheters that are wedged outside zone 3 may be suspected when the normal phasic PAWP a and v waves are absent, when wedge pressure varies markedly with the respiratory cycle, and when mean wedge pressure exceeds PADP, because this should never occur unless tall a or v waves are present in the wedge-pressure trace [131] (see section on *Pulmonary Artery Pressure and Pulmonary Artery Wedge Pressure Waveforms*).

Pulmonary Artery Catheterization

PACs can be placed from any of the central venous cannulation sites described earlier, but the right internal jugular vein is preferred because it provides the most direct route to the right heart chambers and thereby usually leads to successful catheterization. [263] The procedure is conducted as already described for central venous cannulation, until the step where the venous catheter is to be inserted. At this point, a slightly larger skin nick is made to accommodate the large-bore (7.5-9.0 French) introducer sheath. This introducer has a hemostasis valve at its outer end, through which the PAC will be inserted, and a side-arm extension that allows

continuous central venous access for fluid and drug administration. A tapered-tip, stiff, dilator stylet is placed into the introducer sheath to facilitate passage of this large cannula over the guide wire from the skin, through the subcutaneous tissues, into the vein. Utmost care must be exercised when introducing this large dilator-cannula assembly, advancing it only to the depth required to enter the vein, then threading the introducer cannula completely into the vein over the guide wire and dilator. Finally, the guide wire and dilator are removed, the side-arm extension is secured to an intravenous infusion set using a Luer-lock connector, and the introducer sheath is sutured in place.

The standard PAC has a 7.0-, 7.5-, or 8.0-French circumference and is 110 cm in length, with these distances marked at 10-cm intervals. It contains four separate internal lumens. One leads to the distal port at the catheter tip and is used for PAP monitoring. The second leads to a proximal port, located approximately 30 cm from the catheter tip, and it is intended for CVP monitoring, as well as intravenous fluid and drug administration. The third lumen leads to a balloon near the catheter tip, and the fourth contains fine wires leading to a temperature thermistor, just proximal to the balloon. This thermistor is used to monitor pulmonary artery blood temperature as part of the thermodilution method for cardiac output monitoring (see later discussion).

The final steps in placing a PAC require the aid of a skilled assistant to help prepare the catheter and attach it properly to pressure monitoring transducers. The physician performing the catheterization removes the PAC from its package and inserts it through a sterile plastic sheath, being careful not to damage the balloon in this process. [319] This sheath or sleeve covers a length of the PAC residing outside the patient and thereby allows minor manipulations of PAC position during the monitoring period, while attempting to maintain catheter sterility. The assistant then attaches the distal (PAP) and proximal (CVP) ports to the standard pressure transducing system that will allow these waveforms to be displayed on the bedside monitor. These ports are flushed to ensure their proper function and to expel the air from these catheter lumina. [320] The balloon is inflated with the special syringe packaged with the PAC. This syringe is volume-limited to 1.5 mL, the standard volume used for balloon inflation. The balloon is tested by filling it with 1.5 mL of air to make certain that there are no leaks and that the balloon inflates symmetrically, without obstructing the opening of the distal lumen. [321]

The balloon should always be inflated with air, *not* liquid. The air-filled balloon at the tip of the catheter serves to carry the catheter forward with the blood flow through the right heart chambers and helps "float" the catheter to its proper position in the pulmonary artery, much like the spinnaker on a sailboat is driven by the trailing wind. Some authors have suggested that the balloon may be inflated with sterile saline to aid catheter passage when difficulties, such as severe tricuspid valve regurgitation, are present. [322] However, this is a fairly dangerous practice because saline, unlike air, is a noncompressible fluid, and using it to inflate the PAC balloon may increase the risk of pulmonary artery rupture. To reduce the risk of unintentional balloon inflation with liquid, the special balloon-inflation system should remain attached to the PAC at all times. [323]

A simple maneuver may now be performed to check for proper assembly and function of the PAC and monitoring system (Fig. 30-33) (Figure Not Available) . [324] [325] When the tip of the PAC is held near heart level, the recorded pressure should be 0 mm Hg, confirming that the transducer was correctly adjusted to the level of the heart at the beginning of the procedure. The catheter tip is then raised up straight to create a 30-cm tall vertical fluid column, which should produce a pressure of 22 mm Hg (equivalent to 30 cm H_2O), on the bedside monitor (see Fig. 30-33) (Figure Not Available) . This quick, simple step ensures that the pressure recorded from the distal lumen during PAC flotation is correct, because it checks the integrity of the entire monitoring system from the tip of the catheter to the waveform display on the screen.

The PAC is inserted through the hemostasis valve of the introducer to a depth of 20 cm, or approximately 5 cm beyond the tip of the introducer sheath. A characteristic CVP waveform must be identified to confirm that the PAC tip is in the vena cava or right atrium. The gentle curvature

Figure 30-33 (Figure Not Available) Bedside testing of the pulmonary artery catheter- pressure transducer system. With the tip of the catheter held at the level of the transducer and the heart, a pressure of 0 mm Hg is recorded. The catheter tip is raised to create a 30-cm vertical fluid column, and the resulting pressure display should equal 22 mm Hg (equivalent to 30 cm H_2O). See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 3-4.)*

Figure 30-34 (Figure Not Available) Characteristic waveforms recorded during passage of the pulmonary artery catheter. The right atrial pressure resembles a central venous pressure waveform and displays a, c, and v waves. Right ventricular pressure shows a higher systolic pressure than seen in the right atrium, although the end-diastolic pressures are equal in these two chambers. Pulmonary artery pressure shows a diastolic step-up compared with RVP. Note also that RVP increases during diastole, whereas pulmonary artery pressure decreases during diastole (shaded boxes). Pulmonary artery wedge pressure has a similar morphology to right atrial pressure, although the a-c and v waves appear later in the cardiac cycle relative to the electrocardiogram. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 3-1.)*

of the PAC should be oriented to point just leftward of the saggital plane (the 11-o'clock position as viewed from the patient's head). This orientation will facilitate catheter passage through the anteromedially located tricuspid valve. The balloon now is inflated, and the catheter is advanced into the right atrium, through the tricuspid valve into the right ventricle, through the pulmonic valve into the pulmonary artery, and finally into the wedge position. Characteristic waveforms from each of these positions confirm proper catheter passage and placement. These waveforms are later reviewed in detail (Fig. 30-34) (Figure Not Available) .

After PAWP is measured, the balloon is deflated, and the PAP waveform should reappear. During the monitoring period, wedge pressure may be obtained as needed by reinflating the balloon with 1.5 mL air, so that pulmonary blood flow can help float the catheter distally until pulmonary artery occlusion again occurs. The clinician must recognize that the PAC tip advances to a smaller pulmonary artery each time the balloon is inflated to measure PAWP. Similarly, the PAC should return to its monitoring position in the proximal pulmonary artery after the balloon is deflated. In some patients, the PAC may migrate distally even without balloon inflation. This problem is more common during cardiopulmonary bypass, owing to the repeated cardiac manipulations and temperature changes that alter the stiffness of the catheter. [326] Consequently, proper catheter position must be ensured throughout the monitoring period by observing the PAP waveform continuously. If a PAWP trace appears without balloon inflation, or during only partial balloon inflation, the balloon should be deflated and the catheter withdrawn several centimeters to reduce the risk of pulmonary vascular injury. If necessary, the PAC may be readvanced subsequently to achieve proper position and obtain the wedge pressure. Although the external protective sleeve covering the PAC is intended to maintain sterility during these minor adjustments in catheter position, the sleeve does not preclude contamination. Therefore, PACs should be manipulated only as necessary to maintain a proper safe location. [327]

Guidelines for Catheter Placement

From a right internal jugular vein puncture site, the right atrium should be reached when the PAC is inserted 20 to 25 cm, the right ventricle at 30 to 35 cm, the pulmonary artery at 40 to 45 cm, and the wedge position at 45 to 55 cm. When other vascular puncture sites are chosen for catheter placement, additional distance is required, typically an additional 5 to 10 cm from the left internal jugular and left and right external jugular veins, an additional 15 cm from the femoral veins, and an additional 30 to 35 cm from the antecubital veins. [325] These distances serve only as a guide. Waveform morphology must be verified from the monitor display, and catheter position must be confirmed with a chest radio-graph. The tip of the PAC should be within 2 cm of the cardiac silhouette on a standard anteroposterior chest film. [328]

Keeping in mind these typical distances aids proper waveform identification and helps avoid complications caused by unintended catheter loops and knots. If a right ventricular waveform is not observed after inserting the catheter 40 cm, coiling in the right atrium is likely. Similarly, if a pulmonary artery waveform is not observed after inserting the catheter 50 cm, coiling in the right ventricle has probably occurred. The balloon should be deflated, the catheter withdrawn to 20 cm, and then the PAC floating sequence is repeated.

Although the right internal jugular vein is the primary site for pulmonary artery catheterization, failure to achieve venous cannulation or other medical and surgical considerations may require use of alternative sites. For cardiac surgery, the left internal jugular vein is often the second choice because use of the subclavian veins poses a problem unique to this setting. After sternotomy and sternal retraction, a PAC inserted by the subclavian route may be compressed and kinked under the clavicle, making it impossible to withdraw or advance the catheter, should this be required during the course of surgery. [329]

Regardless of the intended surgical procedure, whenever one plans to insert a PAC through the left internal jugular, subclavian, and particularly the external jugular veins, the more tortuous course of these vessels may make it difficult to advance the large-bore introducer sheath fully into the vessel. This is not a problem, so long as the introducer cannula is withdrawn slightly to maintain a position in the vein that allows unimpeded intravenous infusion and free aspiration of venous blood. Often the introducer cannula needs to remain in this partially inserted position, while the PAC is introduced through its hemostasis valve. Owing to the more flexible, smaller tip of the PAC compared with that of the introducer, the PAC may advance easily and completely into the central vein and right atrium. The PAC balloon then

may be inflated and the procedure completed in the normal fashion. With the PAC in proper position, the introducer sheath usually can be guided fully into the central vein and sutured in place because the PAC has served, in essence, as a more effective "guide wire." Occasionally, the introducer sheath must remain partially or completely withdrawn to avoid acute angulation and kinking of the PAC as it leaves the sheath and enters the central vein. [329] [330] [331]

After successful venous cannulation, when attempts to advance the PAC to the right ventricle prove difficult, the physician should consider whether this results from abnormal venous anatomy. The most common abnormality of the systemic veins is *persistence of the left superior vena cava,* which is present in approximately 0.5 percent of the general population and 2 to 5 percent of patients with other forms of congenital heart disease. [332] [333] [334] [335] [336] The persistent left superior vena cava descends along the left mediastinum and empties into the coronary sinus, which is dilated as a consequence of the abnormal venous drainage pattern. Occasionally, the condition is recognized radiographically by an abnormal appearance of the left side of the mediastinum and cardiac border, or an abnormal pulsation of the left internal jugular vein. [335] [336] However, because there are no physiologic consequences of this abnormal venous anatomy, virtually all cases are asymptomatic and discovered incidentally at the time of attempted central venous or pulmonary artery catheterization. In patients with this anomaly, PAC placement may be difficult or impossible, owing to the tortuous course the catheter must follow from the vena cava, through the coronary sinus, to reach the right heart chambers. Because a normal right superior vena cava is present in most of these patients, the anomaly is recognized only when attempted PAC placement proceeds from a left-sided vein. More rarely, difficult PAC placement is encountered during attempted right-sided venous cannulation because the right superior vena cava is absent as well. In these cases, the right internal jugular vein joins the persistent left superior vena cava by a bridging innominate vein. A rare form of atrial septal defect, termed *unroofed coronary sinus,* may also be encountered in patients with these venous abnormalities. This congenital defect provides a site for coronary sinus-left atrial communication, with the potential for a PAC to enter the left atrium and systemic circulation through this defect. [336] With any of these venous anomalies, PAC advancement into the coronary sinus may disclose an unexpected pressure waveform, coronary sinus pressure. This waveform has characteristics of both the downstream right atrial pressure and an indirectly transmitted, dampened left ventricular pressure waveform. Its recognition requires that the physician have a clear appreciation for the expected waveforms encountered by the PAC as right heart catheterization proceeds.

A few additional points might aid successful positioning of the PAC. The air-filled balloon tends to float to nondependent regions as it passes through the heart into the pulmonary vasculature. Consequently, positioning a patient head down will aid flotation past the tricuspid valve, and tilting the patient onto the right side and placing the head up will aid flotation out of the right ventricle and may reduce the frequency of malignant ventricular arrhythmias during catheterization. [337] Owing to gravitational and anatomic factors, most catheters float to the right pulmonary artery. [338] Thus, to catheterize the left pulmonary artery selectively, the patient should be positioned with the right side down. [339] Deep inspiration during spontaneous ventilation will increase venous return and right ventricular output transiently. This may facilitate catheter flotation in a patient with low cardiac output. On occasion, a catheter may be floated to proper position when stiffened by injecting, through the distal lumen, 10 to 20 mL of the iced solution prepared for cardiac output measurement. Finally, a catheter that is initially difficult to place may be positioned easily when hemodynamic conditions change, as commonly occurs after induction of general anesthesia and initiation of positive-pressure ventilation.

Complications of Pulmonary Artery Catheterization and Pressure Monitoring

Use of PACs has been associated with various adverse effects. As in the case of CVP monitoring, PAC monitoring complications may be divided into: (1) those that occur during initial attempts to gain venous access, (2) those occurring during pulmonary artery catheterization, (3) those late complications associated with catheter residence in the body, and (4) those associated with misuse of equipment and misinterpretation of data. For the most part, problems during attempts to gain central venous access are similar for PAC or CVP monitoring (see Table 30-4) . However, catheterization of the right heart chambers beyond the cavoatrial junction may cause complications uniquely associated with PACs and rarely, if ever, seen with CVP monitoring alone (Table 30-6) .

Although many complications have been described over the past 25 years, their incidence is not clearly known because they are described, for the most part, in isolated case reports or small case series. [340] When all adverse effects are considered, including self-limited arrhythmias observed during catheter insertion, it appears that minor complications occur in more than 50 percent of patients. [299] [341] However, of much greater clinical relevance, major morbidity specifically associated with PAC use is uncommon. [342] In 1993, the American Society of Anesthesiologists Task Force on Pulmonary Artery Catheterization [299] reviewed 860 publications in the medical literature in an attempt to delineate the risks and benefits of PAC. This group discovered that the reported incidence of complications from PAC monitoring varied widely. Based on this literature review and their collective expert opinions, the task force suggested that serious complications due specifically to pulmonary artery catheterization occur in 0.1 to 0.5 percent of PAC-monitored surgical patients. [299] Two large prospective observational studies of more than 5,000 patients each provide good support for this contention. In 1984, Shah et al [263] reported use of PACs in 6,245 patients undergoing cardiac and noncardiac operations. [263] Quite remarkably, only 10 patients (0.16%) had serious complications resulting in morbidity and only 1 patient (0.016%) died as a result of pulmonary artery catheterization. More recently, a preliminary European report of PAC use in 5,306 patients undergoing cardiac operations confirms a similar low incidence of major morbidity, with injury

of the right ventricle or PA occurring in only 4 patients (0.07%). [343] Finally, only 1 of 2,000 adverse events reported in the Australian Incident Monitoring Study of 1993 involved use of a PAC, in contrast to 64 other adverse events involving access to the arterial or venous systems. [121] Although these large studies suggest that there is a low incidence of serious complications attributable to the use of PAC, the frequency of complications in a particular clinical setting or patient group remains unknown. However, clinicians who use PAC must be familiar with all the potential complications associated with catheter use in an attempt to avoid these problems, or at least recognize these problems early and treat them successfully.

Arrhythmias are the primary complication observed during pulmonary artery catheterization (PAC-PA catheter). In fact, minor atrial or ventricular arrhythmias are so common during PAC passage through the heart that most clinicians do not consider this a complication, but rather a confirmation that the PAC is traversing the cardiac chambers en route to the pulmonary artery. Shah et al [263] observed transient premature ventricular contractions in 68 percent and atrial dysrhythmias in 1.3 percent of their catheterized patients. Of greater clinical significance, *persistent ventricular arrhythmias* requiring treatment with lidocaine occurred in only 3.1 percent of patients, none of whom suffered prolonged hemodynamic instability. Although the balloon-tipped PAC is less arrhythmogenic when it strikes the endocardium than a standard intravenous catheter or transvenous pacing wire, [344] PACs have been reported to cause atrial fibrillation, ventricular tachycardia, and ventricular fibrillation. [337] [343] [344] [345] As rare as these arrhythmias may be, the physician must always consider them as a risk factor when placing a PAC. For example, in a patient with critical aortic stenosis scheduled for valve replacement, one may choose to withhold a PAC or to delay flotation of the catheter until the heart is exposed and cardiopulmonary bypass support is immediately available. Prophylactic use of IV lidocaine prior to pulmonary artery catheterization has not been shown to reduce consistently the incidence of ventricular arrhythmias, [346] [347] and most clinicians reserve this drug for treatment of sustained arrhythmias. When ventricular tachycardia or frequent ventricular premature beats occur during the catheterization procedure, the balloon should be deflated and the catheter withdrawn to the right atrium. This terminates the arrhythmia in nearly all cases, and the pulmonary artery may be catheterized using standard procedures once the arrhythmia has ceased.

A more difficult clinical question arises when hemodynamically significant arrhythmias develop later in the monitoring period, after the PAC has been in place for hours or days. Although it is unlikely that the PAC is responsible for these new arrhythmias, the position of the catheter tip should always be checked by observation of the pressure waveform and chest radiograph. A catheter tip that is malpositioned within the right ventricle is significantly more arrhythmogenic than a catheter tip, cushioned by the inflated balloon, that is floating through the heart during initial catheterization. Once proper PAC position is confirmed and other causes of ventricular arrhythmia, such as myocardial ischemia, are excluded, several clues may point toward the PAC as the cause of the rhythm disturbance. These include left bundle branch block morphology of the ventricular premature beats, their resistance to medical therapy, and their response to withdrawal of the catheter into the right atrium. [344]

As the PAC passes through the right ventricle and strikes the interventricular septum, transient *right bundle branch block* occurs in up to 5 percent of patients. [348] [349] [350] This complication presumably results from the minor trauma of catheter passage through the heart. It occurs less frequently with balloon-tipped catheters than with standard stiff cardiac catheters, which are known to cause right or left bundle branch block, depending on which ventricular chamber is catheterized. [349] [351] Right bundle branch block is of no real clinical consequence except in patients with preexisting left bundle branch block, in whom *complete heart block* may be precipitated. [350] Despite this theoretical concern, complete heart block from pulmonary artery catheterization is uncommon. Shah et al [263] catheterized 113 patients with preexisting left bundle branch block with only one patient developing complete heart block (0.9%). In a different population of 47 high-risk patients with left bundle branch block, many of whom had acute myocardial infarction or heart failure, Morris et al [348] employed 82 PACs without a single episode of complete heart block during the catheterization or for 24 hours thereafter. Thus, prophylactic placement of a transvenous ventricular pacing wire is not necessary in patients with preexisting left bundle branch block who require PAC monitoring. Instead, transcutaneous pacing equipment, an external pulse generator, and a temporary transvenous pacing wire or pacing PAC (see later discussion) should be readily available to treat severe bradycardia. It is important for the anesthesiologist to recognize that onset of heart block from pulmonary artery catheterization may be delayed and only fully manifest following administration of anesthetic drugs. For example, incomplete right bundle branch block following PAC insertion has been reported to progress to complete right bundle branch block and bradycardia following induction of anesthesia. [350] Thus, the anesthesiologist must be prepared to treat this complication whenever it arises.

Various *mechanical problems* with PACs or introducer sheaths have been reported, and a physician who is familiar with these potential problems should be able to

avoid most of them. In the setting of cardiac surgery, PACs may become entrapped by sutures placed in the heart or by the cannulas used for these operations. [263] [352] [353] [354] [355] [356] Sternal retraction during cardiac surgery poses another mechanical problem with PACs, particularly when they are inserted through the external jugular or subclavian routes. The PAC may kink as it exits the introducer sheath and makes an acute angle between the sheath and vessel wall. [329] [330] [331] This problem may be resolved by withdrawing the introducer sheath slightly or limiting the amount of surgical retraction. These mechanical difficulties may be recognized by a damped appearance of the monitored pressure traces or by difficulty infusing fluid or withdrawing blood through one of the catheter lumens. [263] They serve to remind the anesthesiologist and heart surgeon that the PAC should be checked for free movement during the surgical procedure and following any cardiac repair in which sutures have been placed near the course of the PAC. Although gross structural defects in PAC should be recognized by inspection prior to catheter insertion, more subtle manufacturing problems may escape

detection. [319] [320] Some of these, such as interluminal communications between the PAP, CVP, and balloon inflation lumens, may be suspected only when information derived from the catheters is inconsistent with other clinical data. [321] [357]

PACs may become entangled with other cardiac structures or catheters or dislodge temporary transvenous pacing wires. Knotting of PACs has also been reported. [358] [359] Knots or kinks in the catheter should be suspected if there is any difficulty withdrawing a PAC, and the diagnosis may be confirmed by chest radiography. Knots may be untied *in vivo* by radiologists using intravascular snares and fluoroscopic guidance. [360] If the knot has already been drawn tight, removal under direct surgical exposure of the venous cannulation site may be required. [361] These problems are more likely when the PAC is inserted an excessive distance leading to looping or coiling of the catheter within the cardiac chambers. Prevention is the best treatment.

Like any prosthetic intravascular device, PACs may serve as a nidus for intravascular *thrombosis.* [362] Although the incidence of thromboembolic complications is increased in patients who require PAC monitoring for longer periods of time, thrombi have been noted to be attached to a PAC within 1 to 2 hours of their insertion. [363] [364] When drugs such as aprotinin and epsilon aminocaproic acid are used to reduce perioperative bleeding, the risk of thrombus formation on the PAC may be even greater. [365] [366] Although external surface heparin bonding unquestionably has reduced thrombogenicity of PACs, [364] [367] it does not entirely remove this complication. [366] This predisposition to intravascular thrombosis in patients with PAC monitoring arises in part from the prosthetic catheter itself and in part from the subclinical endothelial injury produced by the catheter. Through autopsy examination of 32 patients who died with PACs in place, Connors et al [368] demonstrated that venous thrombi, fibrin strands, mural ecchymoses, or intimal petechiae were evident in 90 percent of patients. Rowley et al [369] performed autopsies on 55 previously catheterized patients and found that 53 percent had right-sided endocardial lesions. Although the general clinical implications of these autopsy findings are unclear, they serve as a warning of the potential risks of pulmonary artery catheterization.

Although minor venous thrombi [362] and pulmonary ischemic lesions [370] are fairly common in patients with PAC monitoring, major pulmonary embolism arising from use of a PAC is a rare occurrence. [371] Rather than thromboembolism, the most common cause of *pulmonary infarction* in patients with PACs is occlusion of pulmonary blood flow by a malpositioned catheter that occludes a branch of the pulmonary artery. [370] The radiographic hallmark of this condition is a wedge-shaped infiltrate radiating from the tip of a peripherally located PAC. This iatrogenic complication may be prevented by diligent monitoring of the PAP waveform recorded from the catheter tip, allowing early recognition of a catheter that migrated distally, became wedged within a small pulmonary artery, and obstructed distal blood flow.

PAC-related *infections* occur more commonly in patients who require monitoring for more than 3 days and those with preexisting sepsis. [372] Using sophisticated microbiologic techniques in 297 critically ill medical and surgical patients, Mermel et al [373] demonstrated a 22 percent incidence of local infection of the introducer sheath, but a low 0.7 percent incidence of bacteremia caused by the PAC. Although PACs may be colonized from multiple sources, the patient's skin is the most important source of organisms, and it is the introducer sheath, rather than the PAC itself, that is usually the infected device. In view of these findings, it is not surprising that scheduled changes of PACs do not reduce the risk of bloodstream infection, particularly when the catheter is changed over a guide wire through the original venipuncture site. [374] When clinical factors mandate changing the PAC, placement through a new vascular access site will reduce the risk of infection compared with guide wire- assisted exchange. However, cannulation at a new puncture site carries a greater risk of mechanical complications, and these risks and benefits must be balanced in each individual patient. [374]

The most serious infection related to PACs is *endocarditis.* The pulmonic and tricuspid valves are the most likely sites, but right atrial endocarditis has also been reported. [369] [375] Although these catastrophic infections appear to be rare, they represent part of the continuum of endocardial damage, thrombosis, and infection that has been documented to be associated with use of PACs. [369] Immunocompromised, debilitated, bacteremic patients may be at particular risk for these complications.

Perhaps the most life-threatening complication of pulmonary artery catheterization is one that is uncommon and often avoidable through meticulous attention to insertion and monitoring techniques. *Pulmonary artery rupture* occurs in approximately 0.02 to 0.2 percent of catheterized patients and appears to be a fatal complication in nearly 50 percent of cases. [263] [433] [376] [378] Although it may occur in a variety of monitoring situations, [379] many reported cases have involved patients undergoing heart surgery requiring cardiopulmonary bypass. [378] [380] Several patient factors common to this clinical setting have been proposed to increase the risk of this complication, including hypothermia, anticoagulation, advanced age, and pulmonary hypertension. [380] [381] [382] [383] Pulmonary hypertension may predispose patients to arterial injury during balloon inflation owing to the increased pressure gradient between the proximal PAP and the distal wedge pressure or because pulmonary hypertension distends the pulmonary vasculature and causes the PAC to wedge in a distal, less compliant vessel. Even though both factors may result in eccentric balloon inflation that tends to drive the exposed catheter tip into the vessel wall, [383] [384] experimental evidence that pulmonary hypertension increases risk of pulmonary artery rupture remains controversial. [382] [383]

Several mechanisms for pulmonary artery injury have been proposed and investigated. Hardy et al, [382] studying cadaveric specimens, determined that the pressure required to rupture the pulmonary artery of patients older than 60 years was well within the range of pressures normally exerted during balloon inflation, suggesting that a balloon forcefully inflated in a pulmonary artery smaller than the balloon diameter may rupture the vessel wall. Other proposed mechanisms for pulmonary artery rupture include chronic erosion by a catheter tip abutting the vessel wall or eccentric balloon inflation that forces the uncushioned catheter tip through the vessel wall. [381] [385] Regardless of the precise mechanism by which pulmonary arterial injury occurs in an individual patient, many case reports highlight

that this complication often results from suboptimal catheter insertion and monitoring techniques. These procedural errors include unnecessary catheter manipulation, excessive insertion distances predisposing to catheter tips located in distal small pulmonary arteries, unrecognized persistent wedge pressure, prolonged balloon inflation, or improper balloon inflation with liquid rather than air. [323] [378] [381] [384] [385] It is critical that the clinician recognize artifactual "overwedged" pressure recordings that indicate peripheral location of the PAC tip or impaction against the vessel wall and correct this problem immediately by withdrawing the catheter into the proximal pulmonary artery (see later discussion).

The hallmark of catheter-induced pulmonary artery rupture is hemoptysis, which may cause life-threatening exsanguination or hypoxemia. Less commonly, this complication presents as occult hypotension or respiratory compromise. If the visceral pleura fails to contain the bleeding, free rupture into the pleural space produces a large hemothorax. When time allows, a chest radiograph helps make the diagnosis by revealing the hemothorax or a new infiltrate near the tip of a distally positioned PAC. This infiltrate may be confused with catheter-related pulmonary infarction, but its pattern of resolution and other clinical signs and symptoms help distinguish these diagnoses. [377] In confusing cases, the diagnosis may be made by performing a wedge angiogram, in which radiopaque dye injected through the wedged PAC will extravasate into the pulmonary parenchyma to identify the site of arterial disruption. [381]

Treatment focuses on cardiorespiratory stabilization, maintaining adequate gas exchange, and arresting the hemorrhage. Specific therapeutic steps depend on the setting in which the complication occurs and may be quite different when pulmonary artery rupture is suspected in a debilitated patient in the intensive care unit compared with a relatively fit patient undergoing cardiopulmonary bypass. The first priority is ensuring adequate pulmonary ventilation and may require endobronchial intubation with either a single- or double-lumen endotracheal tube to allow selective unilateral lung ventilation and protect the unaffected lung. [386] Positive end-expiratory pressure (PEEP) applied to the affected lung may help control hemorrhage. [380] Anticoagulation, if present, should be reversed unless the patient must remain on cardiopulmonary bypass. Bronchoscopy is performed for tracheobroncheal toilet and to localize the site of bleeding. Other maneuvers may be performed at the bedside to provide temporary control of hemorrhage. A Fogarty catheter may be guided into the involved bronchus to tamponade the bleeding and prevent continued contamination of the uninvolved lung. [376] Management of the PAC itself in these circumstances is more controversial. Some authors recommend removing the catheter, [377] but others suggest leaving the PAC in place to monitor PAP and guide antihypertensive therapy targeted at lowering this pressure and reducing

bleeding. [378] Others have suggested that the PAC balloon may be carefully reinflated and the catheter floated into the involved pulmonary artery to occlude the bleeding arterial segment as a temporizing measure. [376]

Although these conservative medical treatments may be effective in many cases, some patients will require defini-tive surgical therapy, such as oversewing the involved pulmonary artery or resecting the involved segment, lobe, or lung. [376] [377] [380] [381] Patients who have this complication and are managed with conservative medical therapy alone are at risk for *pseudoaneurysm* formation and secondary hemorrhage. [376] [380] [384] [387] [388] Because of these delayed risks and the high mortality associated with rebleeding, some authors have recommended followup pulmonary arteriography and possible coil embolization or elective surgical resection in patients who were initially managed medically. [376] [380] [387] [389]

All the already described complications of PAC have been validated by published case reports or large case series, and the causal link between PAC use and these complications has been well established. A more insidious complication of PAC monitoring, and perhaps the most common serious adverse effect from the use of this technology is *misinterpretation of data,* leading to inappropriate, harmful therapy. [298] Although it is not clear what role this factor plays in creating complications in an individual patient, there is reason to believe that there are widespread knowledge deficits among practitioners who use PACs in clinical care. In 1990, Iberti et al [390] reported the results of a 31-question multiple-choice examination that tested knowledge of the PAC. The test was administered to 496 resident and staff physicians in medicine, surgery, and anesthesiology departments, who practiced in 13 North American medical centers. The authors found a poor overall level of knowledge of PACs, as evidenced by a mean test score of only 67 percent correct answers, and they concluded, "there is reason to be concerned about the effective use of the PAC." [390] Although higher scores were demonstrated by individuals with more training and more experience inserting and using catheter-derived information in patient management, none of these factors ensured a high level of knowledge. Similarly disappointing results were obtained subsequently when this examination was administered to 216 critical care nurses, [391] 535 European intensive care physicians, [392] and 1,095 members of the United States Society of Critical Care Medicine. [393] The authors of these reports seemed particularly concerned that wedge pressure measurement from a strip-chart recording was performed incorrectly by 30 to 50 percent of the clinicians reported in these studies. Other authors have also noted the large interobserver variability in interpretation of PAC pressure tracings. [394] These observations highlight the fact that effective use of PACs require a great deal of expertise and clinical experience, and even measuring the most fundamental PAC-derived variable, namely PAWP, may prove to be a complicated exercise. [395] [396] [397] With these issues in mind, normal and pathologic PAC waveforms are next reviewed, with an emphasis on the physiologic mechanisms that produce them.

Pulmonary Artery Pressure and Pulmonary Artery Wedge Pressure Waveforms

Normal Waveforms

As the flow-directed, balloon-tipped PAC is floated from a central vein to its proper position in the pulmonary artery, characteristic pressure waveforms are recorded (see Fig. 30-34) (Figure Not Available) . When the catheter tip reaches the superior vena

---

Figure 30-35 (Figure Not Available) Temporal relations between normal systemic arterial pressure (ART), pulmonary artery pressure (PAP), central venous pressure (CVP), and pulmonary artery wedge pressure (PAWP). Note that the PAWP a-c and v waves appear to occur later in the cardiac cycle compared with their counterparts on the right side of the heart seen in the CVP trace. ART pressure scale on the left; PAP, CVP, and PAWP pressure scales on the right. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 3-3.) (Figure Not Available)*

cava or right atrium, a CVP waveform should be observed, with its a, c, and v waves and low mean pressure value (see Table 30-1) . At this point, the PAC balloon is inflated, and the catheter is advanced until it crosses the tricuspid valve to record *right ventricular pressure.* This waveform is recognized by the sudden increase in systolic pressure, the wide pulse pressure, and the low diastolic pressure that approximates CVP. The PAC next enters the right ventricular outflow tract and floats across the pulmonic valve into the main pulmonary artery. Often, this passage is heralded by arrhythmias, especially premature ventricular beats, as the balloon-tipped catheter strikes the right ventricular infundibulum. *Pulmonary artery pressure* is characterized by the step-up in diastolic pressure recorded as the catheter crosses the pulmonic valve. In the absence of pulmonic valve stenosis, systolic PAP closely approximates right ventricular systolic pressure, but PADP generally exceeds right ventricular dia-stolic pressure. On occasion, it may be difficult to distinguish right ventricular pressure from PAP, particularly if only digital values for these pressures are reported. However, by examining the diastolic pressure contours, the distinction between right ventricular pressure and PAP becomes clear. PAP decreases steadily during diastole, as blood flows from the pulmonary artery toward the left atrium. In contrast, right ventricular pressure increases steadily during diastole as blood flows into the right ventricle through the open tricuspid valve (see Fig. 30-34) (Figure Not Available) . [325]

Under normal conditions, the PAP upstroke slightly precedes the radial artery pressure upstroke (Fig. 30-35) (Figure Not Available) . This reflects the longer duration of left ventricular isovolumic contraction, as well as the transmission time of the central aortic pressure upstroke to the downstream radial artery recording site. [145] Although the PAP upstroke precedes the radial artery pressure upstroke by 50 milliseconds, peak PAP precedes peak radial artery pressure by only 10 milliseconds. [398] As a practical matter, PAP and systemic arterial pressure contours appear to overlap on the bedside monitor, with these pressures rising, peaking, and falling at approximately the same points in time (see Fig. 30-35) (Figure Not Available) . [325] Understanding these temporal relations is critically important if one is to properly interpret abnormal PAP and PAWP waveforms, particularly when tall v waves are present in these traces (see later discussion).

The PAC, with balloon inflated, finally reaches the wedge position. As noted above, the PAWP is an indirect measurement of pulmonary venous pressure and LAP and should therefore resemble these pressure waveforms. Consequently, the PAWP waveform may be identified as a venous pressure trace that displays characteristic a and v waves and x and y descents. However, owing to the pulmonary vascular bed interposed between the PAC tip and left atrium, PAWP is a delayed representation of LAP. [313] [399] On average, 160 milliseconds are required for the LAP pulse to traverse the pulmonary veins, capillaries, arterioles, and arteries. As a consequence of this delay, the wedge-pressure a wave appears to follow the ECG R wave in early ventricular systole (see Fig. 30-35) (Figure Not Available) . However, the a wave is an end-diastolic pressure event, produced by left atrial contraction. This time delay in phasic wedge pressure waves must be appreciated for proper waveform interpretation.

Not only is PAWP a delayed representation of LAP, but it is also a damped reflection of phasic atrial pressure waves. The amount of damping is variable, but when LAP waves are prominent, the pressure peaks may be significantly underestimated and the pressure nadirs significantly overestimated by the wedge trace (Fig. 30-36) (Figure Not Available) . Even though the PAWP waveform will always appear to be a damped, delayed version of LAP, the mean pressure recorded from these two sites should be similar under most circumstances. [287]

To recognize prominent a or v waves in the PAWP trace, it is not always necessary to inflate the PAC balloon and obtain wedge position (Fig. 30-37) (Figure Not Available) . Because the wedge pressure records LAP waves transmitted in retrograde fashion from the left atrium, these waves will normally sum with the antegrade PAP waves produced by right ventricular ejection. The PAP trace thus becomes a composite wave, reflecting both retrograde and antegrade components. Consequently, tall left atrial a and v waves distort the normal PAP contour,

---

Figure 30-36 (Figure Not Available) Pulmonary artery wedge pressure (PAWP) is a damped, delayed reflection of left atrial pressure (LAP). The tall regurgitant v waves (v) caused by severe mitral regurgitation are seen clearly in the LAP trace but appear delayed and smaller in magnitude in the PAWP trace. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 4-4.) (Figure Not Available)*

with the a wave inscribed at the onset of the systolic upstroke and the v wave distorting the dicrotic notch (see Fig. 30-37) (Figure Not Available) . [313] [400] Once these waves are identified by observing the wedge pressure and comparing it with the PAP trace, it is convenient, and perhaps more prudent, to follow the wedge-pressure a and v waves in the PAP trace, without repeatedly inflating the balloon to measure wedge pressure. However, marked changes in PAP values or wave morphology should initiate balloon inflation and wedge-pressure measurement, because artifacts occasionally mimic these observations (see later discussion).

In summary, PAWP measured with a balloon-tipped PAC provides a delayed, damped estimate of LAP, by measuring the pressure where flow resumes at a pulmonary venous junction point near the left atrium. Mean PAWP will always be lower than mean PAP; otherwise, blood would not flow in an antegrade direction.

The PAWP waveform should display small a and v waves just as the LAP waveform, and these phasic components should be identifiable if the pressure

Figure 30-37 (Figure Not Available) Tall left atrial pressure (LAP) a and v waves transmitted in a retrograde direction through the pulmonary vasculature distort the antegrade pulmonary artery pressure (PAP) waveform. The LAP a wave distorts the systolic upstroke, and the v wave distorts the dicrotic notch. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 4-10.) (Figure Not Available)*

trace is displayed with sufficient gain and resolution on the monitor screen.

Left Atrial Pressure, Pulmonary Artery Wedge Pressure, and Pulmonary Capillary Pressure

Because of its method of placement, direct *left arterial pressure* (*LAP)* monitoring is usually restricted to patients undergoing cardiac surgery. The most common technique for monitoring LAP involves catheterization of the left atrium with a thin catheter introduced through the right superior pulmonary vein and secured with a purse-string suture. The catheter is brought out through the skin beneath the xiphoid process and attached to a closed pressure monitoring tubing-transducer system. Because LAP monitoring is discontinued in the postoperative period simply by withdrawing the left atrial catheter through the skin, transseptal methods for LAP monitoring during surgery have been proposed to reduce the risk of bleeding following catheter removal. [213] [401] [402] LAP measurement has also been performed for diagnostic cardiac catheterization by a retrograde arterial approach, transseptal venous catheterization, and even percutaneous direct left atrial puncture from a right paravertebral insertion site. [403]

LAP monitoring is less widely practiced today than in the past, largely because it has been supplanted by PAC monitoring. This has occurred, no doubt, because the PAC simultaneously provides an estimation of left ventricular filling pressure as well as additional useful monitoring information, including CVP and cardiac output. Although some authors have shown modest discrepancies between the LAP and PAWP in the period immediately following cardiopulmonary bypass, [404] the PAWP generally provides an excellent estimate of LAP for cardiac surgical patients in the postoperative period. [316] [404] [405] Furthermore, the pathophysiologic conditions that alter the relationships among the PADP, PAWP, and LAP have been well described and should be recognized by the physician to avoid misinterpretation of the data provided by these monitors (see later discussion).

Direct LAP monitoring continues to be particularly useful in pediatric patients undergoing complex congenital heart surgery, because of the difficulties using some of the standard percutaneous techniques in this patient population. Gold et al [406] reported use of more than 6,000 transthoracic left atrial and right atrial pressure monitoring catheters, with complications from LAP monitoring occurring in only 0.68 percent of 2,393 left atrial catheters. [407] However, the physician must recognize that direct access to the left heart chambers always carries the risk of air and particulate embolization to the systemic circulation. LAP monitoring therefore requires close attention to proper management by the entire team of caregivers to ensure that line patency is maintained and flushing is performed with care. The most common complications of LAP monitoring actually result from catheter removal. Because of the risk of bleeding from the cardiac site of catheter entry, the left atrial catheter must be removed before mediastinal chest drains. When the catheter cannot be withdrawn through the skin, surgical reexploration is needed to remove the retained

catheter. Other rare complications of LAP monitoring include entrapment of the catheter in mechanical aortic or mitral valve prostheses, [406] [408] fistula formation between the right superior pulmonary vein and the right mainstem bronchus, [406] and unrecognized retained catheter fragments that serve as a source of systemic embolization. [409]

Normal LAP waveforms resemble CVP or right atrial pressure waveforms, although there are few subtle morphologic distinctions. Because atrial depolarization originates in the sinoatrial node located at the junction of the superior vena cava and the right atrium, the right-sided a wave appears slightly earlier than the left-sided a wave (Fig. 30-38) (Figure Not Available) . Although the a wave is the most prominent pressure peak in a normal CVP trace, the v wave is often taller than the a wave in a normal LAP waveform. These observations suggest that right atrial contraction is generally more forceful than left atrial contraction, and that the left atrium is less distensible than the right atrium during passive systolic filling. [145] Finally, the interval between right atrial contraction and right ventricular contraction is longer by approximately 40 milliseconds than the interval between left atrial contraction and left ventricular contraction. [145] Consequently, a and c waves are seen more often as separate waves in a right atrial pressure trace than in a LAP trace. In normal LAP waveforms, the a and c waves merge into a composite a-c wave, although most clinicians simply describe this pressure peak as the a wave. Similarly, the PAWP waveform generally displays only a and v waves, because the PAWP c wave is obscured further by the transpulmonary damping effect of the lung vasculature.

The terms PAWP and pulmonary artery occlusion pressure (PAOP) are used interchangeably and refer to the same measurement obtained from the tip of a PAC following balloon inflation and flotation to the wedged position. As already discussed, PAWP and PAOP are used as indirect estimates of mean LAP. In contrast, the hydrostatic pressure in the pulmonary capillaries is a different pressure that must exceed LAP to maintain antegrade blood flow through the lungs. This pulmonary capillary pressure must not be confused with PAWP or LAP, nor should these terms be used interchangeably. [410] Continued use of the phrase "pulmonary capillary wedge pressure" to mean PAWP or PAOP has perpetuated misconceptions about these measurements.

Figure 30-38 (Figure Not Available) Normal temporal relations between the electrocardiographic, central venous pressure (CVP), and left atrial pressure (LAP) traces. The LAP and CVP waveforms have nearly identical morphologies, although the CVP a wave slightly precedes the LAP a wave. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 2-9.)*

Although the magnitude of the difference between pulmonary capillary pressure and PAWP is generally small, it can increase markedly when resistance to flow in the pulmonary veins is elevated. In most situations, the major component of pulmonary vascular resistance occurs at the precapillary, pulmonary arteriolar level. However, rare conditions like pulmonary veno-occlusive disease may cause a marked increase in postcapillary resistance to flow within the pulmonary veins. A similar situation arises in other conditions that disproportionately increase pulmonary venous resistance, such as central nervous system injury, acute lung injury, hypovolemic shock, endotoxemia, and norepinephrine infusion. [410] [411] Under these conditions, measurement of PAWP will underestimate pulmonary capillary pressure substantially and thereby underestimate the risk of hydrostatic pulmonary edema. Although pulmonary capillary pressure may be measured at the bedside by analyzing the decay in PAP following PAC balloon inflation, these techniques have not been adopted widely in clinical practice. [412] [413] [414] [415] [416] [417] To avoid confusion, the phrase "pulmonary capillary wedge pressure" should be abandoned because it is imprecise and misleading. [410]

Abnormal Waveforms

PAC catheter monitoring is subject to the same technical artifacts inherent in all invasive pressure monitoring techniques, as well as some additional problems unique to this method. [385] [418] [419] [420] Because the PAC is longer than other intravascular catheters, greater attention must be paid to ensure that the lumens are free from clot or air bubbles that will distort the pressure waveforms. In addition, the PAC passes through the heart and is subject to pressure recording artifacts resulting from cardiac-induced catheter motion. These artifactual pressure spikes may be distinguished from the underlying physiologic pressure waveform by their unique morphology and timing.

The most common prominent pressure spike artifact observed in a PAC trace is seen immediately following the ECG R wave at the onset of systole (Fig. 30-39) (Figure Not Available) . [418] [421] At this point in the cardiac cycle, tricuspid valve closure and right ventricular contraction and ejection set the PAC in motion and inscribe a spurious, nonphysiologic pressure wave. Note that this artifactual PAP wave occurs at the same time as the CVP c wave and may appear as an artifactual pressure trough, as well as artifactual pressure peak. If this artifactual trough pressure is detected inappropriately by the bedside monitor, it may be reported as a spuriously low value for PADP. Repositioning the PAC by advancing or withdrawing it a few centimeters often helps it assume a slightly different position in the heart and ameliorates this problem. [418]

Another common artifact in PAP measurement occurs when attempts to inflate the balloon cause the catheter tip to become obstructed and thus fail to measure intravascular pressure. This phenomenon is generally termed *overwedging* and usually is caused by distal catheter migration, with subsequent eccentric balloon inflation that forces the catheter tip against the pulmonary artery wall. Rather than recording intravascular pressure, the catheter now records the gradually rising pressure produced by the continuous flush system as it builds up pressure against the obstructed

Figure 30-39 (Figure Not Available) Artifactual pressure peaks and troughs in the pulmonary artery pressure (PAP) waveform caused by catheter motion. The correct value for pulmonary artery end-diastolic pressure is 8 mm Hg (A) although the monitor digital display erroneously reports the PAP as 28/0 mm Hg (B). See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 5-6.) (Figure Not Available)*

Figure 30-40 (Figure Not Available) Overwedging of the pulmonary artery (PA) catheter causes artifactual waveform recordings. The first two attempts to inflate the PA catheter balloon (first two arrows) produce a nonpulsatile increasing pressure caused by an occluded catheter tip. After the catheter is withdrawn slightly, balloon inflation allows proper wedge-pressure measurement (third arrow). Prior to the third attempt at balloon inflation, the PA pressure lumen is flushed. This restores the appropriate pulsatile detailed to the PA and wedge-pressure waveforms on the right side of the trace. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 5-7.) (Figure Not Available)*

distal opening. (Fig. 30-40) (Figure Not Available) Note that the overwedged pressure is devoid of pulsatile detail, much higher than PADP, and is continuously rising toward the flush pressure level. These observations all suggest that this cannot be an accurate measurement of PAWP.

As emphasized earlier, each PAC balloon inflation allows the catheter tip to migrate distally several centimeters to reach the wedge position. This flotation process generally occurs over several cardiac cycles. "Instant wedge pressure" occurring before full balloon inflation suggests that the PAC is located inappropriately in a smaller, distal branch of the pulmonary artery. The catheter should be withdrawn before overwedging results in vascular injury or pulmonary infarction. A distally positioned catheter may overwedge itself without balloon inflation. This must be recognized immediately by observing the waveform, and the PAC must be withdrawn until a normal PAP tracing is restored.

Pathophysiologic conditions involving the left-sided cardiac chambers or valves produce characteristic changes in the PAP or PAWP waveforms. [422] One of the most widely recognized abnormalities is the tall v wave of *mitral regurgitation* (Fig. 30-41) (Figure Not Available) . Unlike a normal wedge pressure v wave produced by late systolic pulmonary venous inflow, which fills the left atrium while the mitral valve is closed, the prominent v wave of mitral regurgitation begins in early systole and might be more precisely designated a regurgitant c-v wave. Mitral regurgitation causes fusion of c and v waves and obliteration of the systolic x descent, as the isovolumic phase of left ventricular systole is eliminated owing to the retrograde ejection of blood into the left atrium. [292] Because the prominent v wave of mitral regurgitation is generated during ventricular systole, measurement of mean PAWP will result in overestimation of left ventricular filling pressure, just as measurement of mean CVP in patients with severe tricuspid regurgitation will result in overestimation of right ventricular filling pressure (see Fig. 30-29) (Figure Not Available) . In patients with severe mitral regurgitation, left ventricular end-diastolic pressure (LVEDP) is estimated best by measuring PAWP prior to onset of the regurgitant v wave (Fig. 30-42 (Figure Not Available) ; see Fig. 30-41) (Figure Not Available) . Although mean wedge pressure exceeds LVEDP in

Figure 30-41 (Figure Not Available) Mitral regurgitation. A tall regurgitant v wave (v) is seen in the pulmonary artery wedge pressure (PAWP) trace and also may be noted in the unwedged pulmonary artery pressure (PAP) waveform (arrow). See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 17-5.)*

Figure 30-42 (Figure Not Available) Severe mitral regurgitation. A tall systolic v wave (v) is inscribed in the pulmonary artery wedge pressure (PAWP) trace and also distorts the pulmonary artery pressure (PAP) trace, giving it a bifid appearance. The electrocardiogram (ECG) is abnormal owing to ventricular pacing. Left ventricular end-diastolic pressure is estimated best by measuring PAWP at the time of the electrocardiographic R wave, prior to onset of the regurgitant v wave. Note that mean PAWP exceeds left ventricular enddiastolic pressure in this condition. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 17-11.)*

patients with mitral regurgitation, it remains a good approximation of mean LAP. Consequently, the regurgitant v wave contributes to left atrial hypertension and the subsequent risk of hydrostatic pulmonary edema.

When large v waves are present in the PAWP trace, it is critically important to recognize them and be able to distinguish the PAWP waveform from the unwedged PAP waveform. At first glance, a wedge trace with a tall systolic v wave resembles a typical unwedged PAP trace, but closer observation reveals a number of discriminating morphologic details. The PAP upstroke is steeper and slightly precedes the systemic arterial pressure upstroke, whereas a PAWP with a prominent v wave has a more gradual upstroke that begins after the radial artery pressure upstroke. Although the PAP peak occurs at about the same time as the systemic arterial pressure peak and the ECG T wave, the wedge pressure v wave reaches its peak later in the cardiac cycle, after the ECG T wave (see Figs. 30-41 (Figure Not Available) and 30-42) (Figure Not Available) . [292] [398] This so-called "rightward shift" in the PAP waveform should be recognized by careful scrutiny and comparison of the ECG, systemic arterial, pulmonary artery, and wedge pressure traces. Another feature that distinguishes PAP and PAWP traces in patients with severe mitral regurgitation is the unusual morphology of the PAP waveform itself. The prominent regurgitant v wave distorts the PAP waveform, giving it a bifid appearance in systole and obscuring the normal end-systolic dicrotic notch (see Figs. 30-41 (Figure Not Available) and 30-42) (Figure Not Available) . This is most evident in patients with the tallest wedge pressure v waves. [400] [423] By recognizing these subtle but important diagnostic details, a clinician may monitor the wedge pressure v wave by observing the unwedged PAP trace and obviate the need for repeated balloon inflation. Of greater importance, one should hope to avoid the disastrous situation in which a PAC migrates distally, becomes wedged unintentionally without balloon inflation, and the clinician, not recognizing the wedge tracing, attempts to inflate the balloon and thus causes pulmonary artery rupture.

Although some clinicians use the height of the PAWP v wave as an indicator of mitral regurgitation severity, this practice is fraught with problems and has some fundamental physiologic limitations. [292] [424] [425] [426] [427] [428] Because wedge pressure is a damped reflection of LAP, there may be some instances in which a prominent v wave is present in the LAP trace but is obscured in the wedge pressure trace. [429] More important, the PAWP v wave is a pressure surrogate for a volume event, namely regurgitant systolic flow, across the mitral valve. A closer look at left atrial pressure-volume relations helps to elucidate the apparently paradoxic coexistence of severe mitral regurgitation and a normal PAWP trace. [425] [430] Three factors determine whether mitral regurgitation produces a prominent v wave in the left atrial or wedge pressure traces: left atrial volume (often termed the patient's volume status), left atrial compliance, and volume of regurgitation (Fig. 30-43) (Figure Not Available) . Given that the left atrial pressure-volume relation is curvilinear, the same volume of regurgitation will result in a small increment in systolic pressure or a large increment in pressure, depending on the preexisting atrial volume at onset of systole. Similarly, the shape of the left atrial pressurevolume curve, which reflects atrial stiffness or compliance, will determine the height of the pressure wave for any given regurgitant volume. This may explain why patients with acute mitral regurgitation tend to have prominent PAWP v waves, in that they have smaller, stiffer left atria than

Figure 30-43 (Figure Not Available) V wave height as an indicator of mitral regurgitation severity. Left atrial pressure-volume curves describe the three factors that determine v wave height. (A) Influence of left atrial volume. For the same regurgitant volume (x), the left atrial v wave will be taller if baseline atrial volume is greater (point B versus point A) (B) Influence of left atrial compliance. For the same regurgitant volume (x), the left atrial v wave will be taller if baseline atrial compliance is reduced (point B versus point A). (C) Influence of regurgitant volume. Beginning at the same baseline left atrial volume (points A and B), if regurgitant volume increases (X versus x), the left atrial pressure v wave will increase (V versus v). See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 17-13.)*

patients with chronic valvular regurgitation. [426] [430] Although the total regurgitant volume of blood entering the left atrium will influence the height of v wave, this clearly is not the only determinant of v wave magnitude. Therefore, it is not surprising that wedge-pressure v waves are neither sensitive nor specific indicators of mitral regurgitation severity. [425] [426] [427] [428] Prominent PAWP v waves may exist in the absence of mitral regurgitation when LAP is elevated, which might occur when the left atrium is compressed, [431] and they also are seen commonly in patients with hypervolemia, congestive heart failure, and ventricular septal defect. [425] Note that the giant v waves seen in patients with ventricular septal defect have a different cause. They result from exaggerated antegrade systolic flow into the left atrium, caused by the left-to-right shunt, which increases pulmonary blood flow and systolic atrial filling through the pulmonary veins. [424]

In contrast to mitral regurgitation, which distorts the systolic portion of the PAWP waveform, *mitral stenosis* alters the morphology of the diastolic portions of this waveform. In this condition, the holodiastolic pressure gradient across the mitral valve results in an increased mean PAWP, a slurred early diastolic y descent, and a tall end-diastolic a wave. Similar hemodynamic abnormalities are seen in patients with left atrial myxoma or whenever there is obstruction to mitral flow. Diseases that increase left ventricular stiffness (e.g., left ventricular infarction, pericardial constriction, aortic stenosis, and systemic hypertension) produce changes in PAWP that resemble in part those seen in mitral stenosis. In these conditions, mean wedge pressure is increased and the trace displays a prominent a wave, but the y descent remains steep, because there is no obstruction to flow across the mitral valve during diastole. Because patients with advanced mitral stenosis often have coexisting atrial fibrillation, the prominent PAWP a wave will not be present in many of these cases, although the other hemodynamic features persist (Fig. 30-44) (Figure Not

Available) . [292]

Myocardial ischemia is accompanied by a number of physiologic abnormalities that are detectable with the PAC. Ischemia impairs or delays left ventricular relaxation and produces diastolic dysfunction. This pattern of ischemia is particularly characteristic of demand ischemia associated with tachycardia or induced by rapid atrial pacing. [183] [432] [433] [434] [435] [436] [437] Impaired ventricular relaxation results in a stiffer, less compliant left ventricle in diastole, causing LVEDP to rise. Not only does this, in turn, increase LAP and PAWP, but the morphology of these waveforms changes as well, with the phasic a and v wave components becoming more prominent as diastolic filling pressure increases. [435] [438] [439] [440] [441] [442] [443] [444] Although myocardial ischemia will often be detectable as a rise in PAP, (diastolic, mean, or even systolic pressure), these changes are generally less striking than the accompanying change in wedge pressure and the appearance of tall a and v waves in the PAWP trace (Fig. 30-45) (Figure Not Available) . In patients with left ventricular ischemia, the tall PAWP a wave is produced by end-dia-stolic atrial contraction into a stiff, incompletely relaxed left ventricle, and underscores the fact that the atrial kick provides a greater than normal contribution to ventricular filling under these conditions. [315] [442] [445] Although the hallmark of left ventricular diastolic dysfunction is an elevated LVEDP, this pressure elevation often coexists with a reduced left ventricular end-diastolic volume. [183] [433] The astute clinician must recognize that an elevated diastolic PAP

Figure 30-44 (Figure Not Available) Mitral stenosis. Mean pulmonary artery wedge pressure (PAWP) is increased (35 mm Hg), and the diastolic y descent is markedly attenuated. Compare the slope of the y descent in the PAWP trace with the y descent in the central venous pressure (CVP) trace. In addition, compare this PAWP y descent with the PAWP y descent in mitral regurgitation (see Figs. 30-41 (Figure Not Available) and 30-42) (Figure Not Available) . A waves are not seen in the PAWP or CVP traces owing to atrial fibrillation. Arterial blood pressure (ART). See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 17-19.)*

or wedge pressure in patients with myocardial ischemia may not indicate increased left ventricular preload.

Myocardial ischemia produces a characteristic pattern of left ventricular systolic dysfunction in addition to the dia-stolic abnormalities noted earlier. Systolic dysfunction is the hallmark of supply ischemia, caused by a sudden reduction or cessation of coronary blood flow to a region of the myo-cardium. [434] [446] With severe systolic dysfunction, changes in global left ventricular pump performance may be detected with hemodynamic monitoring. As ejection fraction falls and

Figure 30-45 (Figure Not Available) Myocardial ischemia. Pulmonary artery pressure (PAP) is relatively normal and mean pulmonary artery wedge pressure (PAWP) is only slightly elevated (15 mm Hg). However, PAWP morphology is markedly abnormal with tall a waves (21 mm Hg) resulting from the diastolic dysfunction seen in this condition. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 12-4.)*

left ventricular end-diastolic volume and LVEDP rise, hemodynamic monitoring will show systemic arterial hypotension and elevated diastolic PAP and wedge pressures. This hemodynamic pattern is uncommon during anesthesia and surgery and suggests severe systolic myocardial dysfunction. [447] [448] [449] A more common hemodynamic manifestation of myocardial ischemia occurs when left ventricular geometry is distorted or when the region of ischemic myocardium overlies a papillary muscle. [450] Acute mitral valve regurgitation may result, not because of any inherent abnormality of the mitral valve leaflets, but rather because of critical alterations in the supporting structures of the mitral valve, including the mitral annulus, chordae tendineae, papillary muscles, and underlying left ventricular myocardium. [450] [451] This form of mitral regurgitation is often termed "papillary muscle ischemia" or "functional mitral regurgitation." As noted earlier, PAC monitoring is particularly well suited to detect this event by revealing the onset of new regurgitant v waves in the PAWP or PAP traces (see Figs. 30-41 (Figure Not Available) and 30-42) (Figure Not Available) .

Whether the PAC should be used in all high-risk patients as a supplemental monitor for detection of myocardial ischemia remains debatable. [299] [452] [453] [454] [455] However, if physicians choose this form of monitoring, they should have a clear understanding of the mechanism by which ischemia alters PAP and PAWP, as well as an appreciation for the characteristic pressure waveform changes that will be produced. None of the current methods for detecting perioperative myocardial ischemia is perfectly sensitive or specific. Although patients with left ventricular ischemia are likely to have a higher mean PAWP than those without ischemia, these differences are small and may be difficult to detect clinically. [444] Furthermore, clear quantitative threshold values for mean wedge pressure or a and v wave peak pressures that are diagnostic of ischemic have not been identified, perhaps owing to the wide variation in these pressures in healthy individuals. [438] [439] [440] [441] [444] Consequently, the best approach is to integrate the PAC data with other monitored values and use changes in the PAWP or PAP as valuable parts of the diagnostic puzzle. [435] [456]

Right ventricular ischemia produces characteristic hemodynamic patterns that may be recognized with PAC monitoring. Just as left ventricular ischemia increases PAWP, right ventricular ischemia increases CVP and is one of the situations in which CVP may be higher than PAWP. In addition, CVP waveform morphology changes in a characteristic manner and displays a prominent a wave, resulting from right ventricular diastolic dysfunction, and a prominent v wave, resulting from ischemia-induced tricuspid regurgitation. [10] [287] [435] [457] [458] The CVP waveform in this condition is described as having an M or W configuration, referring to the tall a and v waves and steep x and y descents. [435] Severe pulmonary artery hypertension also may result in secondary right ventricular ischemia and dysfunction and increase CVP, but this condition is distinguished from primary right ventricular dysfunction because the PAP and pulmonary vascular resistance will be normal in the latter condition.

The CVP waveform in right ventricular infarction shares many morphologic features with that recorded from patients with restrictive cardiomyopathy or pericardial constriction, including elevated mean pressure, prominent a and v waves, and steep x and y descents. [458] [459] The pathophysiologic feature common to these conditions is impaired right ventricular diastolic compliance and is often termed "restrictive physiology." In *pericardial constriction,* this arises from the restraining effect of the diseased pericardium, whereas in restrictive cardiomyopathy and right ventricular infarction, diastolic dysfunction impairs ventricular relaxation and increases intrinsic ventricular stiffness. Pericardial constriction, also termed constrictive pericarditis or pericardial restriction, limits cardiac filling because of the rigid, often calcified pericardial shell. Impaired venous return decreases end-diastolic volume, stroke volume, and cardiac output. Despite reduced cardiac volumes, cardiac filling pressures are markedly elevated and equal in all four chambers of the heart at end-diastole (Fig. 30-46) (Figure Not Available) . Although PAC monitoring reveals this pressure equalization, the characteristic M or W configuration is more apparent in the CVP trace than in the PAWP trace, most likely because of the damping effect of the pulmonary vasculature on the left-sided filling pressure as recorded by the PAC. [156] [158] [287] [460] [461] [462]

Figure 30-46 (Figure Not Available) Pericardial constriction. This condition causes elevation and equalization of diastolic filling pressures in the pulmonary artery pressure (PAP), pulmonary artery wedge pressure (PAWP), and central venous pressure (CVP) traces. The CVP waveform reveals tall a and v waves with steep x and y descents and a mid-diastolic plateau wave (*) or h wave. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 18-1.) (Figure Not Available)*

Another hemodynamic hallmark of pericardial constriction is observed in the right and left ventricular pressure traces. These demonstrate rapid but short-lived early dia-stolic ventricular filling, which produces a diastolic "dip-and-plateau" pattern or "square root sign" (Fig. 30-47) (Figure Not Available) . [158] [463] In some cases, particularly when heart rate is slow, a similar waveform pattern may be noted in the CVP trace: a steep y descent (the diastolic dip) produced by rapid early diastolic flow from atrium to ventricle, followed by a mid-diastolic h wave (the plateau) from the interruption in flow imposed by the restrictive pericardial shell (see Figs. 30-46 (Figure Not Available) and 30-47) (Figure Not Available) .

Like pericardial constriction, *cardiac tamponade* impairs cardiac filling, but in the case of tamponade, a compressive pericardial fluid collection produces this effect. This results in a marked increase in CVP and a reduced cardiac diastolic volume, stroke volume, and cardiac output. Despite many similar hemodynamic features, tamponade and constriction may be distinguished by the different CVP waveforms seen in these two conditions. In tamponade, the venous pressure waveform appears more monophasic and is dominated by the systolic x pressure descent. The diastolic y pressure descent is attenuated or absent, because early diastolic flow from right atrium to right ventricle is impaired by the surrounding compressive pericardial fluid collection (Fig. 30-48) (Figure Not Available) . [156] [158] [287] [458] [460] [464] [465] [466] Clearly, other clinical and hemodynamic clues help distinguish these diagnoses, such as the presence of pulsus paradoxus, which is an almost invariable finding in cardiac tamponade (see Fig. 30-23) (Figure Not Available) . [467] CVP traces in pericardial constriction and cardiac tamponade thus have many similarities but also important distinguishing features. As a general rule, the CVP waveform in

Figure 30-47 (Figure Not Available) Pericardial constriction. The diastolic filling abnormality in this condition inscribes a "dip-and-plateau pattern" or "square root sign" in both the right ventricular (RV) and right atrial (RA) pressure traces. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 18-3.) (Figure Not Available)*

pericardial constriction has prominent x and y descents or a predominant y descent, whereas in cardiac tamponade, the venous pressure waveform shows attenuation

or obliteration of the y descent. Coexisting abnormalities such as tachycardia, arrhythmias, and atrial contractile failure may complicate interpretation of these waveforms. [460] [461] [462] [464] On occasion, localized pericardial constriction may simulate valvular stenosis, and hypovolemia may lower cardiac filling pressures to within the normal range and confound the diagnosis. [158] [461] [462] In some instances, patients may show features

Figure 30-48 (Figure Not Available) Cardiac tamponade. The central venous pressure waveform shows an increased mean pressure (16 mm Hg) and attenuation of the y descent. Compare with Figures 30-46 (Figure Not Available) and 30-47 (Figure Not Available) . See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 18-5.) (Figure Not Available)*

Figure 30-49 (Figure Not Available) Influence of positive pressure mechanical ventilation on pulmonary artery pressure. Pulmonary artery pressure should be measured at end expiration (#1, 15 mm Hg) in order to obviate the artifact caused by positive pressure inspiration (#2, 22 mm Hg). Compare with Figure 30-30 (Figure Not Available) . See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 16-3.) (Figure Not Available)*

of more than one condition, such as seen in patients with *effusive-constrictive pericarditis* who have constriction of the heart by the visceral pericardium in addition to a pericardial effusion that compresses the heart. [468]

Probably the single most important waveform abnormality or interpretive problem in PAC monitoring is discerning the correct pressure measurement in patients receiving positive pressure ventilation. When any PAP or PAWP recording is used to estimate ventricular preload, the physician must consider the confounding effects of changes in intrathoracic pressure that occur during the respiratory cycle. Just as in the case of CVP monitoring, transmural cardiac filling pressures are estimated best when end-expiratory pressure values are recorded. (See previous sections discussing *Cardiac Filling Pressure Monitoring; Physiologic Considerations: Diastolic Pressure-Volume Relations and Transmural Pressure,* and *Central Venous Pressure Waveforms.*) During positive pressure mechanical ventilation, inspiration increases PAP and PAWP. By measuring these pressures at end-expiration, the confounding effect of this inspiratory increase in intrathoracic pressure is obviated (Fig. 30-49) (Figure Not Available) . [160] Forceful inspiration during spontaneous ventilation has the opposite impact on measured PAP and PAWP, but again, measurement of these pressures at end-expiration eliminates this confounding factor (see Fig. 30-30) (Figure Not Available) . Bedside monitors are designed with algorithms that aim to identify and report the numeric values for endexpiratory pressures. [469] [470] [471] [472] Unfortunately, these are notoriously inaccurate. The most reliable method for measuring central vascular pressures at end-expiration is examination of the waveforms on a calibrated monitor screen or paper recording. [472] [473]

Use of Central Vascular Pressure to Estimate Left Ventricular Preload

It is clear that accurate, clinically meaningful interpretation of PAC-derived cardiac filling pressures requires a detailed understanding of the underlying physiologic principles and an awareness of the clinical conditions under which the measurements have been performed. By way of illustration, there are several different ways to interpret a PAWP measurement of 20 mm Hg (Fig. 30-50) (Figure Not Available) . This pressure is somewhat higher than the normal value, but depending on how this measured PAWP is interpreted, the therapeutic response that it generates may be quite different. These interpretations all depend on two factors, juxtacardiac pressure and ventricular compliance. The most common interpretation of a PAWP of 20 mm Hg assumes that the juxtacardiac pressure and ventricular compliance are normal and leads to the diagnosis of hypervolemia, with an increased left ventricular end-diastolic volume causing the increased PAWP. One arrives at a different interpretation of this PAWP if juxtacardiac pressure is increased for any reasons just reviewed, including cardiac tamponade, pericardial constriction, or positive pressure inspiration. Under these conditions, the same elevated PAWP may be associated with normal or reduced left ventricular end-diastolic volume. Finally, a PAWP of 20 mm Hg has a third interpretation if ventricular compliance is decreased, such as might occur with diastolic dysfunction from myocardial ischemia, hypertrophy, or cardiomyopathy. Under these conditions, as in the case of increased juxtacardiac pressure, left ventricular volume may be normal or reduced, despite elevated PAWP (see. Fig. 30-50) (Figure Not Available) .

Deciding whether any given central vascular pressure is ideal for a particular patient may be a clinical challenge. When the wedge pressure is extremely high or low, it is easy to recognize that this value must be adjusted to avoid pulmonary edema or improve cardiac output. However, things are rarely so clear-cut in critically ill patients, and the target value for optimal wedge pressure is uncertain and often decided empirically. Under these circumstances, a rapid *fluid challenge* may be a useful method to determine whether the PAWP is optimal for the patient in that setting. An intravenous bolus of crystalloid solution (250 mL) is given rapidly over 15 minutes, and the change in PAWP is measured, along with other pertinent hemodynamic variables. If the baseline wedge pressure is high or if a severe pulmonary capillary injury is present, a reduced volume may be used. Small increases in PAWP following the fluid challenge (e.g., less than 3 mm Hg) suggest that the ventricle is operating on the flat portion of its diastolic filling curve, whereas large increases in wedge pressure (e.g., 7 mm Hg or greater) suggest that the steep portion of the curve has been reached and that little further increase in stroke volume and cardiac output can be achieved without a substantial risk of producing hydrostatic pulmonary edema. [131] [177] [472]

As difficult as it may be to decide whether the PAWP is optimal for a particular patient, even greater uncertainty confronts the physician who uses CVP to determine whether cardiac preload is adequate or optimal. Clinicians

---

Figure 30-50 (Figure Not Available) Influence of juxtacardiac pressure and ventricular compliance on left ventricular (LV) preload. There are three interpretations of an increased transduced pulmonary artery wedge pressure (PAWP, 20 mm Hg). (A) Juxtacardiac pressure (-5 mm Hg) and LV compliance are normal, transmural PAWP is increased (25 mm Hg), and LV volume is increased. (B) Juxtacardiac pressure is increased (+10 mm Hg), LV compliance is normal, transmural PAWP is decreased (10 mm Hg), and LV volume is normal or decreased. (C) Juxtacardiac pressure is normal, LV compliance is decreased, transmural PAWP is increased (25 mm Hg), and LV volume is normal or decreased. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 15-8.)*

have recognized for years that in many patients, CVP may be misleading. [474] [475] [476] [477] It is now evident, however, that there are several anatomic and physiologic reasons to explain why this occurs. [178] The diastolic pressure-volume curves for the left and right ventricles are different even in healthy individuals, with the left ventricle being stiffer or less compliant. As a result, the issue is not whether there is a correlation between a change in CVP and PAWP, because in most cases, changes in CVP, PAWP, and PADP all occur in the same direction. [478] Instead, a more clinically relevant question might be whether small changes in CVP are clinically detectable, because they often coexist with larger changes in PAWP simply because the right and left ventricles have different dia-stolic pressure-volume curves. [479]

Use of CVP to estimate left ventricular preload is associated with additional interpretive problems, owing to the fact that the right and left ventricles share a common septal wall and are both surrounded by the pericardium. These confounding influences, termed *ventricular interdependence* and *pericardial constraint,* couple changes in right and left ventricular function, such that a primary change in right ventricular filling may produce a secondary change in left ventricular filling by altering its diastolic pressure-volume relation. [175] [177] [178] [185] [191] For example, acute pulmonary artery hypertension may increase right ventricular enddiastolic volume and pressure, shift the ventricular septum leftward, and increase LVEDP while decreasing left ven-tricular end-diastolic volume, owing to a shift in the left ventricular pressure-volume relation to a steeper, stiffer curve. Finally, numerous additional anatomic, physiologic, and pathophysiologic factors may alter the relationship between CVP and left ventricular preload (Fig. 30-51) (Figure Not Available) . [178] The further upstream from the left ventricle one records the "filling pressure," the greater the number of these factors that may conspire to alter the relation between the monitored pressure and left ventricular preload. In view of these considerations, it should be no surprise that reliance on CVP to estimate left ventricular preload is often misleading in critically ill patients. Furthermore, many of these factors may even alter the relation between pulmonary artery diastolic and wedge pressures as estimates for LVEDP, and these are considered later in this chapter.

Predicting Left Ventricular End-Diastolic Pressure

PAWP measurement has two somewhat distinct purposes. [480] First, knowledge of the pulmonary venous pressure provides an estimate of the hydrostatic pressure within the pulmonary capillaries, which is a major determinant of the vascular backpressure favoring formation of pulmonary edema. For this purpose, the *mean* PAWP averaged over the cardiac cycle is the pressure of interest. Note that wedge and capillary pressures are not identical, but in general, increases in wedge pressure lead to increases in capillary pressure. [411]

The second purpose for measuring left ventricular filling pressure is to estimate the preload of the left ventricle. In this instance, the *end-diastolic* wedge pressure following atrial contraction best predicts the end-diastolic filling pressure or preload of the left ventricle. [472] Measurement of LVEDP is performed at the Z-point,

identified on the left ventricular pressure trace as the point at which the slope of the ventricular pressure upstroke changes, approximately 50 milliseconds after the ECG Q wave, and generally coinciding with the ECG R wave (Fig. 30-52) (Figure Not Available) . [145] Most important, this is a phasic pressure point measured at end-diastole, not

Figure 30-51 (Figure Not Available) Anatomic and physiologic factors that influence the relations between various measures of left ventricular (LV) filling and true LV preload. The further upstream filling pressure is measured, the more confounding factors may influence the relation between this measurement and LV preload. RA, right atrium, RV, right ventricle, PA, pulmonary artery; LA, left atrium; CVP, central venous pressure; PADP, pulmonary artery diastolic pressure; PAWP, pulmonary artery wedge pressure; LAP, left atrial pressure; LVEDP, left ventricular end-diastolic pressure; and P-V, pressure-volume. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 15-5.) (Figure Not Available)*

a mean diastolic pressure in the left ventricle. Although PAWP is generally reported as mean pressure, an enddiastolic component of wedge pressure can be identified in its phasic pressure trace as well. In the presence of normal sinus rhythm, atrial contraction provides this end-diastolic mechanical event. Thus, measurement of the PAWP a wave pressure peak provides a more accurate estimate of LVEDP than that provided by mean PAWP (see Fig. 30-52) (Figure Not Available) . The important distinction is that average or mean wedge pressure estimates the hydrostatic pressure on the lungs, whereas the phasic or end-diastolic wedge pressure recorded after the a wave estimates LVEDP. Put more eloquently, "While the ventricular end diastolic pressure may be considered to be the hemodynamic 'stimulus' which determines the force of ventricular contraction, the mean atrial pressure may be considered the hemodynamic 'price' which the organism must pay for this stimulus to be provided." [481]

Pressure tracings from two patients, one with aortic stenosis and one with mitral regurgitation, help illustrate this point (Fig. 30-53) (Figure Not Available) . LVEDP is elevated (25 mm Hg) in both patients and well approximated by the left atrial (or wedge) pressure a wave peak. In both patients, this pressure provides the best single pressure estimate of left ventricular preload. Although both patients have the same LVEDP, mean left atrial (or wedge) pressure is much higher in the patient with mitral regurgitation (30 mm Hg) than in the patient with aortic stenosis (15 mm Hg). The patient with aortic stenosis produces an LVEDP of 25 mm Hg with a strong left atrial contraction, as evidenced by the tall left atrial a wave. This effective booster pump mechanism provides adequate LVEDP with a reasonable mean LAP that does not place the patient at risk for pulmonary edema. In contrast, the patient with mitral regurgitation has a very high mean LAP (30 mm Hg) caused by the tall regurgitant c-v wave. Clearly, mean PAWP is not always equal to the end-diastolic PAWP value, and the taller the pulsatile a and v wave components,

Figure 30-52 (Figure Not Available) Relationship between left atrial pressure (LAP) and left ventricular end-diastolic pressure (LVEDP). LVEDP is measured at the Z-point on the left ventricular pressure (LVP) trace, at the time of the electrocardiographic R wave. Mean LAP (9 mm Hg) underestimates LVEDP (15 mm Hg), but the LAP a wave pressure peak closely estimates LVEDP. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 6-1.)*

Figure 30-53 (Figure Not Available) Relationship between left atrial pressure (LAP) and left ventricular end-diastolic pressure (LVEDP) in aortic stenosis and mitral regurgitation. LVEDP is elevated in both conditions (25 mm Hg), but mean LAP (LAP-bar) remains low in aortic stenosis (15 mm Hg) but high in mitral regurgitation (30 mm Hg), owing to the regurgitant c-v wave inscribed during systole. LVP, left ventricular pressure. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 6-2.)*

the greater the discrepancy may be. This distinction is important and has been obscured in daily clinical practice by our emphasis on single numeric values for wedge pressure.

When a PAC is used in clinical practice, there are various situations in which the LVEDP is either underestimated or overestimated by the PAWP or PADP measurement (Tables 30-7 (Table Not Available) and 30-8) (Table Not Available) . [480] *Decreased left ventricular compliance* is the most common cause of underestimation of LVEDP. [482] Atrial contribution to left ventricular end-diastolic volume and LVEDP is normally less than 20 percent, but with dia-stolic dysfunction, this atrial contribution may approach 50 percent. [442] [445] Under these conditions, the PAWP a wave will be unusually prominent and will provide a close estimate for LVEDP, even though the mean wedge pressure underestimates LVEDP (see Fig. 30-45) (Figure Not Available) . [315] In patients with *aortic regurgitation,* abnormal diastolic left ventricular filling occurs from the aorta as soon as left ventricular pressure falls below aortic pressure and continues after left atrial contraction and closure of the mitral valve. Left ventricular diastolic pressure continues to rise until LVEDP is reached at the onset of mechanical systole, which reestablishes antegrade flow from left ventricle to aorta. Because mitral valve closure occurs prior to end-diastole, mean PAWP as well as the wedge-pressure a wave both underestimate LVEDP. [315] In the presence of *pulmonic regurgitation,* diastolic flow from the proximal pulmonary artery becomes bidirectional, antegrade into the left atrium, and retrograde into the right ventricle. When the right ventricular diastolic pressure is lower than LAP, pulmonary artery

diastolic flow seeks the lower pressure pathway toward the right ventricle, and PADP will underestimate PAWP, LAP, and LVEDP. [480] When pulmonary vascular resistance is normal, there is no pressure gradient across the pulmonary vascular bed at end of diastole, and PADP equilibrates with the downstream LAP. When right ventricular systole is delayed because of *right bundle branch block,* PAP continues to fall with the x or systolic descent in LAP. Under such conditions, PADP will underestimate LVEDP by as much as 7 mm Hg. [483]

A final condition that causes underestimation of LVEDP with the PAC is different from the pathophysiologic states noted earlier because, in this condition, the process of meas-uring PAWP alters circulation and produces a change in cardiac filling. Under normal conditions, inflation of the PAC balloon to measure PAWP interrupts antegrade blood flow through a small section of the lung and has no measurable effect on total pulmonary blood flow or left atrial filling. However, after *pneumonectomy,* and possibly other conditions that markedly reduce the pulmonary vascular bed, balloon inflation may occlude a significant portion of the remaining pulmonary vascular cross-sectional area. Mechanical obstruction of pulmonary blood flow results, causing increased CVP, and decreased LAP, cardiac output, and systemic blood pressure. [484] [485] Therefore, because the PAWP measurement itself obstructs pulmonary blood flow, the measured PAWP underestimates the LVEDP that existed prior to balloon inflation. This artifact should be suspected in the appropriate clinical setting, when a sudden reduction in systemic arterial pressure occurs coincident with PAC balloon inflation.

Respiratory influences on the PAP or PAWP traces are the most common cause of overestimation of LVEDP. In this regard, use of PEEP may pose a particular problem, because it may create zone 1 or zone 2 lung conditions and cause PAWP to be influenced by alveolar pressure. [486] Formulas have been derived to adjust for the effects of PEEP on wedge-pressure measurement. In general, mechanical ventilation with PEEP increases wedge pressure by an amount less than one-half the value of PEEP applied (i.e., 10 cm H_2O PEEP will raise wedge pressure less than 5 cm H_2O or 4 mm Hg). [131] [487] However, the ratio of chest wall compliance to lung compliance has a significant impact on the relation between the level of PEEP and its effect on PAWP, and simple mathematical methods to adjust for this effect are not entirely reliable. [131] [177] [488] [489] Alternative methods to correct for PEEP, such as measuring pleural pressure using an esophageal balloon, are cumbersome and not generally used. Prolonged discontinuation of PEEP before measuring wedge pressure is to be discouraged. Not only will circulatory dynamics change dramatically owing to rebound central hypervolemia caused by translocation of blood from the periphery, but respiratory gas exchange may deteriorate and be slow to recover. [131] As an alternative, Pinsky et al [489] found that transient airway disconnection for 2 to 3 seconds in patients receiving mechanical ventilation with PEEP

allowed measurement of nadir wedge pressure, which proved to be a better and safer way to estimate left ventricular filling pressure at higher levels of PEEP. When wedge pressure measurement did not change after abrupt airway disconnection, the on-PEEP wedge-pressure measurement accurately reflected left ventricular filling pressure. However, when wedge pressure decreased after airway disconnection, the nadir wedge pressure reached within 3 seconds provided a more accurate measurement. Fortunately, most patients who require high levels of PEEP may not manifest these artifactual wedge-pressure measurement problems. In patients with the adult respiratory distress syndrome, pulmonary artery wedge pressure closely estimates LVEDP at all levels of PEEP up to 20 cm H_2O owing to the relative microvascular protection from the effects of PEEP created by this condition. [490]

When the pulmonary vasculature is normal, pulmonary blood flow ceases at end-diastole, and PADP equals LAP. [491] However, if pulmonary vascular resistance increases, PAP equilibration with downstream pressure does not occur. Under these conditions, the pulmonary vascular bed begins to resemble the systemic vasculature, where a large pressure gradient between the systemic arterial pressure and the right atrial pressure persists at end-diastole. Therefore, in the presence of *pulmonary hypertension* caused by elevated pulmonary vascular resistance, PADP overestimates PAWP, LAP, and LVEDP (Fig. 30-54) (Figure Not Available) .

In contrast to the precapillary pulmonary vasoconstriction that exists in patients with pulmonary arterial hypertension, postcapillary obstruction to flow in the pulmonary veins may occur in the rare condition *pulmonary veno-occlusive disease.* Patients with this condition have normal LAP, but some disagreement exists as to whether these patients have normal or elevated PAWP. [131] [410] [492] [493] In part, these different observations may relate to whether the PAC has been wedged successfully, because the wedge position may be difficult to obtain in these patients or wedge pressure may be recorded from a vascular channel that is totally occluded. The most important factor, however, is whether the patient has predominantly small vein occlusion or large vein occlusion. Obstruction to flow in the small pulmonary veins narrows the static column of blood connecting the wedged PAC tip with the flowing column in the larger pulmonary veins. Given that the partial obstruction involves only the static column, wedge pressure will measure normal pulmonary venous and left atrial pressures because there is no pressure drop across the stenotic segment in the absence of flow. Conversely, large vein obstruction creates a gradient in the column of blood flowing from these veins toward the left atrium. In this instance, wedge pressure will detect an increased pulmonary venous pressure and overestimate LAP. [131] [410] [492] [493]

Figure 30-54 (Figure Not Available) Pulmonary hypertension. The increased gradient across the pulmonary vasculature causes pulmonary artery diastolic pressure to exceed pulmonary artery wedge pressure (PAWP). PAP, pulmonary artery pressure. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 6-11.)*

This model of pulmonary vein obstruction is consistent with the observations of Zidulka and Hakim, [312] who measured PAWP from both large and small pulmonary arteries. Other conditions may mimic the hemodynamic features of pulmonary veno-occlusive disease, including mediastinal fibrosis and intrathoracic or atrial tumors that obstruct pulmonary venous flow near the left atrium.

Mitral stenosis causes obstruction to blood flow from left atrium to left ventricle, and consequently, LAP will exceed left ventricular pressure throughout diastole. Furthermore, all upstream pressures recorded by the PAC will overestimate LVEDP owing to the valvular obstruction. [494] Because the pressure gradient across the mitral valve is directly related to the flow across it, PADP and PAWP will overestimate left ventricular filling pressures even more when transmitral flow is increased by tachycardia or elevated cardiac output.

LAP is increased in *mitral regurgitation* owing to the abnormal leakage of blood across the incompetent valve during systole, and LVEDP is better approximated by measuring wedge pressure prior to the onset of the regurgitant c-v wave (see Figs. 30-41 (Figure Not Available) and 30-42) (Figure Not Available) . [426] In contrast to the patient with mitral stenosis in whom LAP exceeds left ventricular pressure throughout diastole, the patient with mitral regurgitation has appropriate diastolic equilibration of atrial and ventricular pressures. The problem in mitral regurgitation is choosing the appropriate end-diastolic, pre-v wave pressure to use as an estimate for LVEDP. Mean PAWP will overestimate LVEDP in any patient whose PAWP has tall systolic v waves, including patients with *ventricular septal defect* and left ventricular failure. [424] [425]

When *tachycardia* develops, the duration of diastole is shortened, and there is less time for egress of blood from pulmonary vasculature to left atrium and from left atrium to left ventricle. [314] [481] [495] At both mitral valve and pulmonary vascular levels, pressure gradients develop as the duration of diastole progressively decreases during tachycardia. Consequently, PADP overestimates mean PAWP, which in turn overestimates LVEDP. Patients in atrial fibrillation will have more complete equilibration of PADP and LVEDP during longer R-R intervals. Consequently, these beats should be chosen to provide the best estimate of LVEDP.

In summary, there are many circumstances under which PAWP or PADP may underestimate or overestimate LVEDP. Some conditions are relatively common, whereas others are extremely rare, and often several conditions coexist, further complicating the measurement problem. For example, a patient with mitral stenosis resulting in pulmonary hypertension who develops tachycardia has three reasons for PADP to overestimate LVEDP. Major clinical errors would result if the high PADP is presumed to indicate increased left ventricular preload in this patient.

Pulmonary Artery Catheterization and Outcome: Controversies and Indications for Catheterization

Pulmonary artery catheterization has evoked more controversy than any other widely adopted cardiovascular monitoring practice, because it is an expensive, invasive technique that is widely used but still not rigorously proven to result in improved patient outcome. The PAC controversy has been fueled in part by strongly worded editorials, written by prominent physicians, debating whether PAC use should be suspended, pending better scientific proof of the efficacy of this monitoring practice. [300] [310] [496] [497] [498] [499] The titles of these editorials convey the emotional nature of these issues--"Death by pulmonary artery flow-directed catheter (editorial). Time for a Moratorium?"; [498] "Use and abuse of the balloon tip pulmonary artery (Swan Ganz) catheter: Are patients getting their money's worth?"; [500] and "Swan song for the Swan-Ganz catheter? The use of pulmonary artery catheters probably need re-evaluation--but they should not be banned." [310] Although some may take solace in the fact that similar controversies surround the use of other widely adopted, high-technology, clinical monitoring techniques, such as electronic fetal monitoring, [501] [502] [503] physicians who use PAC must remain well informed about the evidence for efficacy of this practice, because this evidence must guide selection of patients for PAC monitoring. [504]

In reviewing the scientific evidence for efficacy of PAC monitoring, one discovers many studies both supporting [505] [506] [507] [508] [509] [510] and refuting [304] [511] [512] [513] the benefits of this technique, but the small numbers of patients reported invariably limit the validity and applicability of these investigations. [299] Unfortunately, even larger studies currently available have had similar mixed results and marked limitations in study design. One observational study involving more than 1,000 general surgical patients reported lower perioperative mortality and reinfarction rates in patients monitored with PAC compared with historical controls, [514] but other large studies have not found a similar outcome benefit. One reason for these divergent results may be that these studies focused on different patient populations: patients with acute myocardial infarction, [515] [516] those undergoing cardiac surgery, [517] [518] and those critically ill with diverse medical and surgical diseases. [306] [309] Despite the large numbers of patients in some of these reports, many experts have questioned these studies because they were observational in design, rather than randomized controlled trials. [299] [308] [342] [519] Nonetheless, several of these studies have raised serious concerns among physicians because they suggested that the PAC was not only ineffective, but that patients who received PAC monitoring suffered increased morbidity and mortality compared with patients who did not receive such monitoring. [306] [515] [516]

Perhaps the most controversial of all these PAC outcome studies is the most recent, published in 1996, in which Connors et al [306] examined the association between PAC use during the first 24 hours of intensive care and subsequent survival. This prospective cohort study included 5,735 patients in 5 teaching hospitals, as part of a larger 9,000 patient study entitled "The study to understand prognoses and preferences for outcomes and risks of treatments (SUPPORT)." [520] [521] [522] [523] The patients in this study were desperately ill; entry into the study required a predicted 6-month mortality in excess of 50 percent. Patients who received PAC were judged to be sicker by every measurement analyzed, but the authors used case-matching analyses and applied a propensity score to adjust for these confounding medical covariates. To the extent that these statistical adjustments were successful, the results of the study were very worrisome. PAC-monitored patients had increased mortality, increased

lengths of hospital stay, and increased costs. Moreover, there was no subgroup of patients who appeared to benefit from PAC monitoring. The publication of this study was accompanied by a strongly worded editorial calling for a moratorium on PAC use or a randomized controlled trial to define its efficacy. [300]

The controversies surrounding PAC use have helped identify several key issues that remain unanswered but are intimately related to the basic question of PAC monitoring and patient outcome. These points may be summarized as follows:

1. There is tremendous variability in the level of skill and knowledge among clinicians who use PACs [390] [391] (see earlier discussion). Many experts believe that failure to control for this factor has been responsible for the poor performance of the PAC in most of the studies in the literature. [308] [311] [522] [524] Because previous studies have not provided an explicit description of how the PAC was used to guide care, the question of PAC efficacy remains uncertain. [299] [311]
2. Use of PAC varies widely between individual physicians, institutions, and different geographic locations. [309] [525] As in other parts of modern medicine, this begs the question whether PAC is overused in many settings or perhaps underused in others. Some have even raised the issue that PAC use has been driven in part by the variation in regionalmedical-care payment structures. [342]
3. Learning bias may be another important confounding factor. [311] [342] This is a well-recognized phenomenon in clinical medicine. In brief, it suggests that we now take better care of patients in general because we have learned such a great deal about cardiovascular pathophysiology and patterns of disease by using PACs that we now apply this knowledge effectively in the care of patients who do not have PAC monitoring.
4. Early use of PAC monitoring in the care of surgical patients, [526] [527] trauma patients, [509] or elderly patients who are at high risk [506] has been touted by some authors to be the real benefit of this procedure. The studies of Shoemaker et al [500] [526] [527] in particular have emphasized the importance of early monitoring and treatment to optimize tissue perfusion before irreversible organ damage occurs.
5. The role of PAC monitoring in improving patient outcome is inextricably tied to the therapies that it guides. As several authors have noted, "if there is no good treatment for the pathophysiologic state that is identified, there is no expectation of therapeutic benefit from the diagnostic procedure." [328] [342] This may be one of the key issues in our current conundrum, namely our inability to treat effectively many serious illnesses, like sepsis, even when the cardiovascular problems are clearly identified through PAC monitoring. In terms of PAC-guided therapies, one of the mostcontroversial is one in which the physician measures hemodynamic variables with the catheter, then attempts to increase oxygen delivery to some empiric goal. This treatment algorithm has been termed "maximizing oxygen delivery," "goal-oriented therapy," or "supraphysiologic goaldriven treatment." In essence, these therapies involve PAC monitoring to guide fluid and inotropic drug administration with various supranormal circulatory goals as end points: oxygen delivery greater than 600 mL/min/m ^{2} , oxygen consumption greater than 170 mL/min/m^2 , or cardiac index higher than 4.5 L/min/m^2 . Although some investigations have shown outcome benefit with this therapeutic approach, [510] [526] [528] others have shown either no effect of such therapy [529] or even increased mortality. [530] The questionable efficacy of this therapeutic approach has been cited as a significant reason why PAC monitoring has not proven effective. [306] [306] A complete consideration of this treatment strategy is beyond the scope of this discussion, but it remains an extremely controversial aspect of PAC monitoring. [531] [532] Although most experts agree that PACs allow more accurate titration of traditional therapy in critically ill patients, some of the most "aggressive" therapies that it guides remain unproven. [533]

In summary, the practice guidelines and consensus statements that have been generated over the past several years best summarize current indications for PAC monitoring. [299] [308] [534] [535] [536] The most recent of these practice guidelines is the Pulmonary Artery Consensus Conference, published in 1997. [308] [537] [538] [539] Conference participants addressed the question: Does management with the PAC improve patient outcomes in each of 21 different medical and surgical conditions? In 3 conditions, the answer was "no;" in 11, the answer was "uncertain;" and in 7, the answer was "yes." The panel further suggested that there was no basis for a moratorium on PAC use and that randomized controlled trials should be performed to resolve remaining questions regarding PAC effectiveness.

Randomized controlled trials of PAC monitoring remain very difficult to perform, owing to problems in gaining informed consent from critically ill patients, difficulties ensuring that physicians remain committed to trial guidelines, and obstacles encountered in patient selection bias and crossover from non-PAC monitoring to PAC monitoring. [513] [540] [541] [542] Although many believe that randomized clinical trials are the only way to resolve these issues, [299] [308] [524] [541] [542] [543] [544] [545] [546] [547] others believe that it would be better to spend our efforts improving the level of knowledge of PAC use, [298] or focusing on alternative technology like echocardiography. [342]

Rather than offer a long list of indications for PAC, a better approach to this clinical thought process is the one offered by the American Society of Anesthesiologists Task Force on Pulmonary Artery Catheterization. [299] Three factors must guide the physician's decision to employ PAC monitoring:

1. The patient is at high risk because of severe underlying cardiopulmonary disease.
2. The intended operation places the patient at risk because of the magnitude or extent of the procedure.
3. The environment or practice setting is propitious for PAC monitoring.

Many high-risk patients undergo low-risk operations that have little physiologic impact, and these individuals should not need PAC monitoring. One example would be the patient with advanced ischemic cardiomyopathy who needs cataract surgery under monitored anesthesia care. In contrast, a relatively low-risk patient undergoing a very high-risk procedure may benefit from PAC monitoring in the perioperative period. An example might be a patient with stable ischemic heart disease scheduled to undergo extensive abdominal cancer surgery. Finally, the third factor that

determines whether PAC monitoring is appropriate relates to the individual practice setting. [299] Clearly, all physicians and nurses using the PAC must have the requisite knowledge and skills to use it safely and effectively. However, there is something that, at the present time, still defies objective assessment. Keats [548] has termed this feature "the role of environment in the outcome of operation," by which he meant all the important unmeasurable aspects of each clinical setting, including, among other things, surgical skills and experience.

Additional Features of Pulmonary Artery Catheters

The popularity of PAC monitoring relates in large part to the fact that these catheters are multipurpose and provide a wide range of supplementary features for therapeutic and diagnostic applications. In addition to the standard lumens that allow measurement of PAP and CVP, catheters may have an additional venous infusion lumen, opening either 20 or 30 cm from the catheter tip. Special PACs are available that allow temporary endocardial pacing or intracardiac ECG recording. One such catheter has five small electrodes embedded in its outer wall, two located approximately 20 cm from the catheter tip, and three located approximately 30 cm from the catheter tip. Combinations of these electrodes allow bipolar endocardial ventricular, atrial, or atrioventricular pacing. [549] Other pacing PACs do not have the pacing electrodes permanently attached but instead have a special lumen that opens in the right ventricle, through which a thin bipolar wire may be introduced for endocardial ventricular pacing. [550] Another type of pacing PAC has special atrial and ventricular lumens that accommodate two separate wires to allow atrioventricular sequential pacing. [551] Although successful endocardial pacing is achieved in most patients with these catheters, reliable catheter positioning is more problematic than with standard PACs. Patient movement or PAC balloon inflation to measure PAWP may alter the position of the catheter or dislodge the wires within the heart and thereby interrupt pacing.

CARDIAC OUTPUT MONITORING

Aside from its pressure monitoring capabilities, undoubtedly the most important feature of the PAC is its ability to measure cardiac output using the thermodilution method. Cardiac output is the total blood flow generated by the heart, and in a normal adult at rest, it ranges from 4.0 to 6.5 L/min (see Table 30-2) . To the extent that the body regulates cardiac output to meet tissue metabolic requirements, measurement of cardiac output provides a global assessment of the circulation, including the neurohumoral influences on it. Cardiac output measurements are usually combined with other hemodynamic measurements (heart rate, arterial blood pressure, CVP, PAP, and PAWP) to allow calculation of additional important circulatory variables, such as systemic and pulmonary vascular resistance (see later discussion). Thus, the PAC provides a large fraction of the data that the critical care physician or anesthesiologist uses for comprehensive cardiovascular assessment.

Thermodilution Cardiac Output Monitoring

The *thermodilution* technique has become the *de facto* clinical standard for measuring cardiac output because of its ease of implementation and the long clinical experience using it in various settings. It is a variant of the *indicator dilution* method, in which a known amount of a substance is injected into the blood stream and its concentration change measured over time at a downstream site. As its name implies, the thermodilution method uses a thermal indicator, whereas other indicator dilution methods use various substances, such as indocyanine green dye. The fundamental physical basis for the indicator dilution method is given by the Stewart-Hamilton equation, named after the two investigators who were instrumental in the development of this technique. [552] [553]

The dye dilution method has not maintained widespread clinical popularity because it requires continuous withdrawal of arterial blood to plot the dye concentration curve, and the indicator, indocyanine green, can gradually build up with repeated injections. However, this method has been used to diagnose intracardiac shunts, by observing the altered shape of the dye dilution curve that is produced by the abnormal recirculation of dye under these conditions.

Two developments have had significant impact on the routine measurement of cardiac output in clinical practice. The first was the introduction of thermal indicators by Feg-ler, [554] and the second was the incorporation of a temperature measuring thermistor in the tip of a PAC. [555] [556] [557] Several unique features of the thermodilution cardiac output monitoring technique have led to its widespread popularity and rapid clinical acceptance. It can be performed quickly and repeatedly, the measurement does not require advanced diagnostic or technical skills, and it employs a nontoxic, nonaccumulating, and nonrecirculating indicator.

When a thermal indicator is used to measure cardiac output, the Stewart-Hamilton equation must be modified.

Blood temperature is measured continuously by the thermistor at the tip of the PAC and injectate temperature is measured by a second thermistor at the injectate port. [558] The computation constant (K) is provided in each PAC package insert, and it must be entered manually into the cardiac output computer prior to cardiac output measurement. This constant adjusts for the amount of thermal signal that will be introduced with each measurement, and it depends on the physical characteristics of the catheter (i.e., size and composition) and the intended injectate that will be used (i.e., specific heat, specific gravity, and volume). [557] The integral of temperature change over time is equal to the area under the thermodilution curve and is calculated electronically by the cardiac output computer.

To perform a thermodilution cardiac output measurement, a fixed volume of cold fluid is injected as a bolus into the proximal CVP lumen of the PAC, and the resulting change in the pulmonary artery blood temperature is recorded by the thermistor at the catheter tip. As in all other forms of cardiovascular monitoring, it is important to have a real-time display of the thermodilution curve resulting from each cardiac output measurement. [422] [529] This allows the clinician to discern artifacts that would invalidate the cardiac output measurement, such as unstable blood temperature or incomplete bolus injection. Usually a series of three cardiac output measurements performed in rapid succession are averaged to provide a more reliable result. [560] When carefully performed, thermodilution cardiac output measurements appear to provide results that are within 5 to 10 percent of other reference methods. [556] [561] [562] [563] Few complications are directly attributable to the technique itself, although tachyarrhythmias and bradyarrhythmias have been reported. [557] [564]

Several important technical issues must be considered to interpret thermodilution cardiac output measurements properly. The thermodilution technique measures right ventricular output and pulmonary artery blood flow. In the face of a large left-to-right or right-to-left shunt, right ventricular and left ventricular outputs will not be equal. The validity of the technique also requires that the thermal indicator be injected as a rapid bolus into the right atrium and that there is complete mixing of the indicator in the right ventricle, prior to its delivery to the pulmonary artery. These fundamental methodologic assumptions of the thermodilution technique are not valid in patients with right-sided valvular regurgitation. For example, patients with severe tricuspid regurgitation have recirculation of the thermal signal between the right atrium and right ventricle. The resulting thermodilution curves have an abnormally prolonged decay time, and the measured cardiac output may be inaccurate. [422] [565] [566] Unfortunately, there is no simple method to correct for this problem. In the presence of severe tricuspid regurgitation, cardiac output usually is underestimated by the thermodilution method, but it may be overestimated, depending on the severity of valvular regurgitation and the magnitude of the cardiac output. [567]

Other technical problems with thermodilution cardiac output measurement occur when the proximal CVP injectate port is not fully within the right atrium but rather contained within the introducer sheath. In this case, the thermal bolus will not be delivered properly and an abnormal cardiac output curve will be produced. [568] [569] This problem should be recognized when there is difficulty making the bolus injection in a patient whose PAC is inserted a relatively short distance: for instance, 40 cm. Similarly, a blood clot on the PAC that covers the thermistor at the tip may make temperature measurements inaccurate and produce spurious cardiac output values.

Because this measurement method is a thermal-based technique, there are many circumstances when an unrecognized change in blood temperature may alter the cardiac output measurement and cause it to be spuriously increased or decreased. In most patients, pulmonary artery blood temperature falls rapidly in the initial minutes following cardiopulmonary bypass. By progressively lowering the baseline blood temperature, these post-bypass temperature changes cause the

thermodilution method to underestimate significantly the true cardiac output at this time. [570] Other inaccuracies in thermodilution cardiac output measurement occur when pulmonary artery blood temperature changes because of rapid fluid infusion through a peripheral intravenous site, through the PAC introducer sheath, or through one of the proximal PAC ports. [571] [572] Either overestimation or underestimation of cardiac output occurs, depending on the timing of the additional fluid bolus.

The clinician can understand and predict all of these measurement artifacts by recalling the Stewart-Hamilton equation and recognizing that cardiac output is inversely proportional to the area under the thermodilution curve. Any factor that causes a factitious reduction in this area will result in an erroneous increase in measured cardiac output. For example, if the constant entered in the cardiac output computer was the value for a 10-mL injectate, but only a 5-mL injectate was used, the injected thermal indicator would be one-half the intended amount. As a result, the area under the thermodilution curve would be approximately one-half the expected value, and the computed cardiac output would overestimate the true cardiac output by a factor of two.

The choice of iced (0°C) or room temperature injectate has been examined in detail to determine the preferred method for accurate cardiac output measurement. Although the size of the thermal bolus signal is increased when an iced injectate is employed, this indicator is more time-consuming, expensive, and cumbersome to prepare, compared with a room temperature injectate. In addition, if the injection port thermistor becomes disconnected during use of iced injectate, the injectate temperature will be measured erroneously as room temperature, resulting in artifactually decreased cardiac output values because the $T_B - T_I$ term will be too small. Because several groups have demonstrated equivalent accuracy in cardiac output determinations when iced and room temperature injectates are compared, it appears that room temperature injectate is preferred for almost all clinical applications. [573] [574] However, an injectate volume of 10 mL should be used in all adults, because the measurements will be more accurate with this volume, compared with a smaller 3- or 5-mL volume. [574]

One of the more controversial issues in standard bolus thermodilution cardiac output monitoring is the proper timing of measurement in relation to the respiratory cycle,

particularly in patients receiving positive pressure mechanical ventilation. By the nature of its measurement and mathematical expression, cardiac output is reported as flow per minute, even though it is measured by a thermodilution curve that is generated over several seconds. The computer usually measures the first 60 to 70 percent of this curve, then extrapolates the remainder to the expected baseline. [571] Not surprisingly, the stroke output of the right ventricle varies considerably throughout the respiratory cycle, and measurements of right ventricular cardiac output will vary by as much as 50 percent, depending on the point during the respiratory cycle when the measurements are performed. [575] [576] Although reproducibility of consecutive measurements improves markedly when the bolus injections are synchronized to the same phase of the respiratory cycle, [577] true cardiac output is estimated better by making numerous injections throughout all phases of the respiratory cycle and then averaging the results. [576] Because the variation in pulmonary blood flow during respiration depends on many factors including the respiratory rate, tidal volume, airway pressure, and so forth, there is no simple way to know whether timing measurements at end-expiration will always provide the highest, lowest, or an intermediate value for cardiac output. [576] In the end, the clinician is faced with a tradeoff--accuracy versus reproducibility. [577] Recent studies with continuous cardiac output techniques highlight these issues and are discussed later.

Continuous Thermodilution Cardiac Output Monitoring

Over the past decade, new technologies were applied to PAC monitoring to allow nearly continuous cardiac output (CCO) monitoring using either hot [578] [579] [580] [581] [582] [583] or cold [584] thermal indicators. The hot thermal techniques are the ones more widely accepted in clinical practice. In brief, these methods involve the release of small quantities of heat from a 10-cm thermal filament incorporated into the right ventricular portion of a PAC. [581] [585] Commercially available CCO PACs use different proprietary algorithms to analyze the thermal signal measured by the thermistor at the tip of the catheter to arrive at an average cardiac output value. Typically, the displayed value for cardiac output is updated every 30 seconds and represents the average cardiac output over the previous 3 to 6 minutes. [586] Consequently, current thermal signal-based CCO methods should not really be considered continuous, real-time monitors, but rather techniques that provide continual, frequently updated cardiac output values.

In general, the CCO methods appear to have good agreement with standard bolus thermodilution cardiac output measurements or electromagnetic flow probe techniques. [579] [582] [583] [587] In a small, multicenter study, Mihm et al [579] found that CCO provided a clinically reliable measurement for a group of 47 intensive care unit patients. The device performed well in patients with a wide range of cardiac outputs (1.6-10.6 L/min) and core temperatures (33.2°C-39.8°C), and the method showed no deterioration in performance over the 72-hour monitoring period. In addition, CCO monitoring appears to be more reproducible or precise than standard bolus thermodilution techniques, although this may simply be a function of the fact that the continuous methods display a time-weighted, average cardiac output value, as opposed to a single instantaneous measurement. [578] [579] [588] [589]

Despite the fairly rapid clinical acceptance of the thermal CCO techniques, there are several issues that the user should appreciate. As already noted, CCO monitors have an inherent 5 to 15 minute delay in responding to abrupt changes in cardiac output, and the magnitude of this delay depends on the computer algorithm and measurement technique used in the monitor. [585] Although modifications of CCO algorithms to allow a more rapid response time have improved this aspect of monitor performance, acute changes in blood flow are still detected more slowly by CCO monitoring than by other methods, such as direct arterial pressure or mixed venous oximetry. [578] Claims that CCO monitoring provides the best early warning of important circulatory changes remain anecdotal at present. [590]

Because the thermal signal sensed by the CCO PAC is very small, sophisticated computer algorithms are needed to distinguish this signal from extraneous thermal noise. These same algorithms are employed to derive a displayed CCO value that represents a running, time-weighted average measured over the previous several minutes. Clearly, this CCO value will represent a cardiac output that is an average value recorded over the respiratory cycle. In contrast, bolus thermodilution cardiac output measurements will show quite different cardiac output values, depending on the phase of respiration during which they are recorded (see earlier discussion). Thus, the CCO-averaging algorithm obviates this physiologic effect that confounds bolus thermodilution cardiac output techniques. As a result, cardiac output measured by the CCO method may provide a more accurate measurement for patients receiving positive pressure mechanical ventilation. Although electronic smoothing or filtering is standard for all hemodynamic values displayed on the bedside monitor, such as heart rate (see Fig. 30-1) (Figure Not Available) , blood pressure, and so forth, the delay inherent in thermal CCO monitoring is much longer--minutes rather than seconds. In effect, the CCO technique involves a fundamental tradeoff between rapid response time and overall accuracy of measurement. The standards for these performance characteristics have not been defined, but must balance the response time against the stability of the displayed value and its immunity from thermal noise. [586]

In summary, the CCO PAC monitoring technique is growing in clinical popularity. It is more reproducible and precise than bolus thermodilution cardiac output measurement, but time delays inherent in the CCO technique require the clinician to rely on other monitored variables to detect acute circulatory changes. Because an external system for cold fluid injection is not required, the CCO technique requires less nursing time and may result in fewer measurement errors, less risk of fluid overload, and less risk of infection. This new method requires a significant warm-up time and may work poorly in an environment where there is a great deal of thermal noise, such as the cardiac operating room.

Fick Cardiac Output Measurement

The *Fick method* for cardiac output determination is a form of indicator dilution in which exogenous indicators are not required, but instead, transported oxygen serves this purpose. This method was first proposed in 1870 by the

German physiologist Adolph Fick, [591] who described a means to determine blood flow by measuring overall oxygen uptake and content in the blood. [592] The Fick equation relates cardiac output to oxygen consumption and blood oxygen content and is recognizable as a special form of the generalized indicator dilution equation:

And 10 converts deciliters to liters (dL = 100 mL)

The denominator of the Fick equation is the arteriovenous oxygen content difference.

This difference is calculated from the arterial and mixed venous oxygen contents.

In general, the contribution of dissolved oxygen is ignored in these calculations because it is small (0.003 × arterial or mixed venous partial pressure of oxygen).

To calculate cardiac output by the Fick method, arterial and mixed venous blood must be drawn for blood gas analysis. The latter requires pulmonary artery catheterization to collect a true mixed venous sample. In addition, oxygen consumption must be measured; traditionally, this required collecting the patient's exhaled air over several minutes with cumbersome equipment. In an attempt to simplify and automate the Fick technique, newer approaches have used pulse oximetry, pulmonary artery oximetry, and on-line respiratory gas analysis or indirect calorimetry to measure oxygen consumption. [593] [594] [595] Although clinicians sometimes estimate the Fick cardiac output by assuming a constant basal value for oxygen consumption of approximately 200 to 250 mL/min, this approach is likely to be inaccurate in critically ill patients. [559] Normal values for all of these variables are given in Table 30-2 .

/das/book/view/29494766/875/327.html

CONTINUOUS MIXED VENOUS OXIMETRY PULMONARY ARTERY CATHETERS

Although the formal Fick cardiac output method is not applied widely in clinical practice, the physiologic relations described by the Fick equation form the basis for another PAC-based monitoring technique termed continuous mixed venous oximetry. Rearrangement of the Fick equation reveals the four determinants of mixed venous oxygen saturation ($S_{v\text{--}O}$ 2):

To the extent that arterial oxygen saturation, oxygen consumption, and hemoglobin concentration remain stable, mixed venous oxygen saturation may be used as an indirect indicator of cardiac output. For example, when cardiac output falls, tissue oxygen extraction increases and the mixed venous blood will become more desaturated. However, as noted in this equation, mixed venous oxygen saturation also varies directly with arterial oxygen saturation and hemoglobin concentration and varies inversely with oxygen consumption. When any of these other variables change significantly, one cannot assume that a change in mixed venous oxygen saturation results solely from a change in cardiac output. Although these considerations may confound the use of mixed venous oxygen saturation as an indicator of cardiac output, monitoring this variable provides more comprehensive information about the balance of oxygen delivery and consumption by the body--not just cardiac output, but also the adequacy of cardiac output. [586]

Although mixed venous oxygen saturation may be determined by intermittent blood sampling from the pulmonary artery, a specially designed PAC can provide this information reliably and continuously. Fiberoptic bundles incorporated into the PAC determine the hemoglobin saturation in pulmonary artery blood based on the principles of reflectance oximetry. A special computer connected to this PAC displays mixed venous oxygen saturation continuously and allows standard thermodilution cardiac output measurements. Technical problems with continuous mixed venous oximetry are generally limited to improper PAC tip positioning or inaccurate calibration. [586] Multiwavelength fiberoptic technology and reflection intensity algorithms help to reduce wall artifacts caused by spurious reflections from a PAC thrombus or the pulmonary arterial walls. These catheters are calibrated at the bedside prior to use but may also be calibrated *in vivo* from a pulmonary artery blood gas sample if mixed venous saturation values are questionable. [596]

The continuous mixed venous oximetry PAC may be used to measure thermodilution cardiac output and arterial and mixed venous oxygen content values and thereby calculate oxygen consumption using a rearrangement of the Fick equation. However, values for oxygen consumption derived using these measurements generally underestimate direct oxygen consumption measured by mass spectrometry, metabolic

cart, or water-sealed spirometry. [531] Oxygen delivery also may be calculated from these PAC-derived values:

Many physicians have used these derived measures of oxygen consumption and oxygen delivery to guide treatment of critically ill patients. Unfortunately, as noted in the earlier discussions of pulmonary artery catheterization, this "goal-oriented therapy" has not been shown to result in improved patient outcomes in most instances. In summary, continuous mixed venous oximetry is an appealing, wellestablished technology, but these catheters are more ex-pensive than standard PAC, and clinical studies to date have not yet defined appropriate clinical indications for their use. [308] [513] [531] [586]

RIGHT VENTRICULAR EJECTION FRACTION PULMONARY ARTERY CATHETERS

Although cardiovascular monitoring has focused predominantly on left ventricular performance, in some instances, right ventricular dysfunction may be the more important factor limiting the circulation. [597] [598] [599] [600] Patient populations at increased risk for right ventricular dysfunction include those with chronic obstructive pulmonary disease, adult respiratory distress syndrome, pulmonary hypertension, and right ventricular ischemia and infarction. [458] [597] [598] [599] [600] [601]

Standard techniques are available for monitoring right ventricular performance in patients with acute myocardial infarction involving the right ventricle. Electrocardiographic monitoring using the V_4R lead has proved to be a sensitive and specific indicator of right ventricular ischemia and infarction. [602] [603] [604] PAC monitoring in patients with right ventricular infarction often reveals the characteristic hemodynamic patterns described earlier. [457] [458] [601] [605] However, accurate evaluation of right ventricular performance in patients with other causes of right ventricular dysfunction has proved more complicated. In patients with severe respiratory failure, the confounding effects of mechanical ventilation with high levels of PEEP have made interpretation of cardiac filling pressures difficult and, in some cases, misleading. [586] [606] [609]

In intraoperative and critical care environments, measurement of right ventricular ejection fraction (RVEF) with a specially designed PAC offers another method for evaluating right ventricular function. [610] This method uses a standard PAC equipped with a rapid response thermistor that detects and quantifies changes in pulmonary artery blood temperature with each heartbeat. [610] [611] The thermistor measures these small temperature changes following bolus administration of an iced or room temperature injectate, and the cardiac output computer determines the residual fraction of thermal signal following each heart beat and calculates the RVEF as 1 minus this average residual fraction. [611] Clearly, all factors that confound standard thermo-dilution cardiac output measurement will also interfere with accurate determination of RVEF. In addition, because the temperature changes measured by the RVEF PAC are small, beat-to-beat changes, the method will not work if the ECG R waves cannot be detected accurately, the R-R interval is short owing to tachycardia, or the cardiac rhythm is irregular. [586] Comparison of PAC-based RVEF measurements with angiographic or nuclear techniques has yielded mixed results in terms of accuracy, but this may reflect, in part, the absence of a widely accepted reference standard for this measurement. [611] [612] [613]

Intraoperative use of the RVEF PAC has focused primarily on detection of right ventricular dysfunction in patients with coronary artery disease undergoing surgical revascularization. Reduced RVEF has been noted following cardiopulmonary bypass, [614] particularly in patients with preexisting right coronary artery obstruction. [615] [616] Anecdotally, an acute reduction in RVEF from its normal value of approximately 40 percent may provide an early sign of right ventricular ischemia. [617] However, RVEF is an extremely loaddependent measurement of right ventricular performance, and the clinician must keep this fact in mind to interpret this measurement properly. [586] [607] [608]

Clinical use of the RVEF PAC appears to have found its greatest application to date in critically ill patients, especially in those with respiratory failure. [586] [607] [608] [609] [618] In these applications, the measurement of greatest interest has been the right ventricular end-diastolic volume (RVEDV), which is derived mathematically from RVEF:

Various authors have demonstrated that the RVEDV correlates better with cardiac output than standard preload measurements, such as CVP or PAWP. [586] [608] [609] These findings are not surprising given all the interpretive problems associated with cardiac filling pressure monitoring previously discussed. The better correlation between RVEDV and cardiac output may result, however, from the mathematical coupling of measurements, because both are derivatives of stroke volume determined with the PAC. [586] [609] Furthermore, as in the case of standard PAC monitoring, the benefit of RVEF PAC monitoring in terms of patient outcome remains unproven. [308]

PULMONARY ARTERY CATHETER-DERIVED HEMODYNAMIC VARIABLES

The cardiovascular system often is modeled as an electrical circuit, with the relationship between cardiac output, blood pressure, and resistance to flow related in a manner similar to Ohm's law. The electrical version of this relation is familiar as

The analogous formulas for determining systemic vascular resistance (SVR) and pulmonary vascular resistance (PVR)

rearrange Ohm's law and replace voltage with blood pressure and current with blood flow:

Multiplying by 80 corrects SVR and PVR values from Wood units (mm Hg/L/min) to standard metric units (dynesseccm^{-5}).

Normal values for SVR and PVR are given in Table 30-2 . Note that these calculations of systemic and pulmonary vascular resistance are based on a hydraulic fluid model that assumes continuous, laminar flow through a series of rigid pipes. [619] [620] These calculations also use atrial pressure as the downstream pressure for systemic or pulmonary flow, with CVP used for right atrial pressure in the SVR calculation and PAWP used for LAP in the PVR calculation. Alternative methods to calculate resistance ignore the effect of these downstream pressures. For the systemic circulation, total resistance may be calculated from MAP and cardiac output alone, and for the pulmonary circulation, total pulmonary resistance describes the ratio of mean pulmonary arterial pressure and cardiac output.

Clearly, all these resistance formulas oversimplify the behavior of the cardiovascular system. A more physiologic model of the systemic circulation considers the vasculature to be a series of collapsible vessels with intrinsic tone. This model, also called the *vascular waterfall,* describes a critical closing pressure in the downstream end of the circuit that exceeds right atrial pressure and serves to limit flow--an effective downstream pressure that is higher than the right atrial pressure used in the SVR formula. A detailed consideration of these issues is beyond the scope of this discussion and is available in other sources. [621] [622] The important issue for clinicians is that therapy focused on the fine adjustment of SVR may be very misleading and should be avoided.

Additional problems arise in considering the pulmonary vasculature and using PVR as a measure of resistance to flow across the lung. Pulmonary vasculature is more compliant than systemic vasculature, and marked increases in pulmonary blood flow may not produce any significant increase in PAP. In addition, flow usually ceases at end-diastole in the low resistance pulmonary circuit. [411] [623] Thus, changes in PVR may result from intrinsic alterations in pulmonary vascular tone (constriction or dilation), vascular recruitment, or rheologic changes. [620] [623] [624] For the pulmonary circuit, a better approach to evaluating the changes in pulmonary vascular resistance may be to examine the end-diastolic gradient between PADP and PAWP (see Fig. 30-54) (Figure Not Available) . [624] Alternatively, more complex calculations of impedance rather than resistance will better describe this property of the pulmonary circuit. [625]

Another set of common calculations derived from standard hemodynamic variables adjusts these measurements for the patient's body surface area (BSA) in an attempt to normalize these measurements for patients of different sizes. The BSA is generally determined from standard nomograms based on height and weight. The most commonly indexed variables are the cardiac index (CI = CO/BSA) and stroke volume index (SVI = SV/BSA), although the SVR and PVR are sometimes indexed as well (SVRI and PVRI). Note that indexed resistances are higher than nonindexed values, because the cardiac index term is in the denominator of these equations. The appropriate formulas are: SVRI = SVR × BSA and PVRI = PVR × BSA.

In theory, normalizing hemodynamic values through "indexing" should help clinicians determine appropriate normal physiologic ranges to help guide therapy. Unfortunately, there is little evidence that these additional calculations provide valid normalizing adjustments. BSA is a biometric measurement with an obscure relationship to blood flow, and it does not adjust for variations between individuals based on age, sex, body habitus, or metabolic rate. [626] Although it is important to be aware of a patient's size and medical history in interpreting and treating changes in any of the measured or calculated hemodynamic variables, it is not appropriate to target therapy solely at achieving normal indexed values.

ULTRASOUND-BASED METHODS OF CARDIAC OUTPUT MONITORING

The popularity and safety of diagnostic Doppler echocardiography in clinical medicine have driven the application of these techniques for measuring cardiac output. All of the ultrasound-based methods for cardiac output monitoring employ the Doppler principle. When ultrasound waves strike moving objects, these waves are reflected back to their source at a different frequency, termed the Doppler shift frequency, that is directly related to the velocity of the moving objects and the angle at which the ultrasound beam strikes these objects. For blood flow measurements, the red blood cells flowing through a major artery serve as the moving objects targeted by the ultrasound beam:

To measure blood flow velocity, the Doppler shift equation is rearranged to solve for velocity. In general, this method requires measurement only of the Doppler shift frequency, because the velocity of ultrasound in blood and the transmitted ultrasound frequency are known, and Costheta is assumed to equal 1 as long as the angle of insonation is small. This assumption requires that the ultrasound beam be oriented as much as possible in a direction that is parallel to the blood flow. For example, for angles less than 20 degrees, Costheta will be greater than 0.94, thereby introducing an error of less than 6 percent in the cardiac output calculation. Once the Doppler shift frequency is measured and blood flow velocity is calculated, stroke volume is derived as follows:

Finally, the cardiac output is derived from the product of the calculated stroke volume and heart rate.

Several different methods for measuring cardiac output use these basic principles of Doppler ultrasonography. Each technique employs slightly different equipment and meas-ures blood flow from a different site in the body. One method uses a Doppler probe mounted on the tip of an endotracheal tube to measure cardiac output using *transtracheal Doppler* insonation of aortic blood flow. [627] [628] The transtracheal Doppler method uses pulsed wave Doppler ultrasound to measure the flow velocity in the ascending aorta. In addition, the aortic cross-sectional area is determined by range-gating the Doppler signal in small 1-mm increments to measure aortic diameter and then calculate aortic cross-sectional area, assuming the aorta to be a circular vessel. [628] Although the method reportedly tracked directional changes in cardiac output accurately, it did not have wide clinical acceptance owing to problems with its implementation, including the requirement for tracheal intubation, a high failure rate, and marked operator-related dependency for success because of a difficult user interface and poor signal stability. [629] [630]

Another Doppler method uses a PAC equipped with three 1-mm ultrasound transducers mounted on the front and rear surfaces of the catheter tip. [631] [632] [633] The theoretical advantages of *Doppler PAC* cardiac output monitoring are that the technique determines a space-averaged measurement of blood flow velocity in the pulmonary artery and an instantaneous measurement of vessel diameter throughout the cardiac cycle. [633] [634] However, the modest accuracy of the technique and its requirement for pulmonary artery catheterization have limited wider clinical acceptance. The Doppler principle has also been applied to measure cutaneous blood flow by *laser Doppler velocimetry.* [635] Because this method detects only changes in skin blood flow rather than absolute cardiac output, its use is confined mainly to determining adequacy of graft tissue flow following microvascular anastomoses of major tissue flaps.

Other clinical methods to measure cardiac output using Doppler ultrasound have focused on less invasive approaches than the transtracheal or PAC techniques. Nearly 25 years ago, methods were developed to measure the blood flow velocity in the distal aortic arch with an ultrasound transducer applied to the suprasternal notch. [636] Further refinements of the technique used continuous wave Doppler to measure the systolic velocity integral and to estimate stroke volume in the ascending aorta. [637] By the 1980s, successful noninvasive measurement of cardiac output was reported in patients, using commercially available equipment to determine the velocities in the ascending aorta with continuous wave Doppler and the aortic cross-sectional area with A-mode pulsed echocardiography. [638] [639] [640] Although these *suprasternal Doppler* cardiac output techniques showed reasonable agreement with thermodilution methods, [638] [640] [641] they were relatively labor intensive, required a fair degree of experience and expertise, and could not be accomplished in a significant number of critically ill medical and surgical patients. [640] Because they provided only intermittent measurements at best, clinical acceptance of this method was limited.

The evolution of Doppler techniques into practical clinical monitoring tools required an ultrasound transducer that could be positioned and left in place for continuous monitoring without the need for repeated adjustments or time-consuming measurements by the physician. Such a transducer was incorporated into the tip of a standard esophageal stethoscope to allow continuous monitoring of cardiac output by interrogating the blood flow profile in the descending thoracic aorta. This technique, *esophageal Doppler* cardiac output monitoring, is the most widely applied method of noninvasive (or minimally invasive) cardiac output monitoring performed currently in surgical and critically ill patients. [642] In brief, the Doppler probe is inserted into the esophagus to a depth of approximately 35 cm from the incisors in a tracheally intubated patient. Probe position is adjusted to optimize the audible Doppler flow sound from the descending aorta. Because the esophagus and the descending aorta lie in close proximity and run essentially parallel to one another, the ultrasound transducer is mounted at a fixed angle that is known by the cardiac output computer and is used to correct the resulting Doppler shift frequency to provide an accurate velocity measurement (see earlier discussion).

The esophageal Doppler monitoring method interrogates blood flow in the descending thoracic aorta and therefore only measures a fraction of the total cardiac output. Consequently, the esophageal Doppler probe must be "calibrated" by some method. Most early investigators performed this initial calibration with a suprasternal Doppler measurement of cardiac output in the ascending aorta. [639] [643] [644] [645] [646] [647] In some instances, ascending aortic diameter was also measured using A-mode ultrasound, [639] [643] whereas later versions of these monitors employed a nomogram to estimate aortic diameter based on the patient's age, sex, height, and weight. [644] [645] [646] [647]

Early studies comparing cardiac outputs measured with the esophageal Doppler device to measurements using

other methods showed variable performance of the new technique. [648] [649] Although several investigators showed that the esophageal Doppler method accurately tracked changes in cardiac output measured by thermodilution, there were significant absolute differences in cardiac output between methods, with the Doppler technique both underestimating and overestimating simultaneous thermodilution values. [639] [644] Other investigations were less favorable, suggesting that the

esophageal Doppler method could not even be relied on as a trend monitor. [646] [647] [650] It appeared that the suprasternal Doppler measurements and the aortic diameter measurements were often in error and did not provide suitable initial calibration of the esophageal Doppler probe. Furthermore, these initial calibration methods were cumbersome, time consuming, and required significant operator expertise. [639] [646]

In recent years, the esophageal Doppler method for cardiac output monitoring has seen a certain amount of renewed enthusiasm, not so much as an accurate measure of absolute cardiac output, but as an indicator or estimate of systemic flow. [642] Singer et al [651] have popularized this technique in the United Kingdom, applying it to the care of critically ill patients and using newer features of the Doppler technique to discern additional hemodynamic information. [652] [653] [654] Improvements in instrument design have made it more informative to the clinician and much simpler to use. Current devices provide a clear visual display of the spectral Doppler waveform and calculate and display additional, albeit somewhat less conventional, hemodynamic variables. These derived variables include the peak blood flow velocity and acceleration and the heart rate-corrected flow time. Some studies have shown that these derived variables provide additional useful information about left ventricular preload, contractility, and systemic vascular resistance. [642] [651] [652] [653] [654] [655]

The newer esophageal Doppler monitoring devices are much simpler to operate because they do not require any of the ultrasound-based calibration procedures demanded by earlier devices. The emphasis in developing these devices has been more toward providing a continuous trend of cardiac output rather than an accurate continuous absolute measurement of blood flow. For this trending purpose, certain assumptions must still remain valid: the angle between the esophageal Doppler probe and the descending aorta is known and remains constant throughout the monitoring period; the aortic cross-sectional area remains constant throughout the monitoring period; and the fraction of cardiac output flowing down the descending aorta remains constant throughout the monitoring period. As could be predicted from all of these assumptions, newer esophageal Doppler monitors still do not provide cardiac output measurements that agree closely with thermodilution values. [656] [657]

The advantages and limitations of esophageal Doppler monitoring should be recognized to apply this method optimally in clinical practice. The technique is easy to use, minimally invasive, and inherently safe. This monitoring can be initiated rapidly, even in patients in whom pulmonary artery catheterization cannot be achieved or is contraindicated. [652] Esophageal Doppler monitoring provides a continuous, beat-to-beat waveform that is proportional to the left ventricular stroke volume. In addition, it derives other hemodynamic variables that may help guide clinical management. Limitations of the technique must also be appreciated by the physician to avoid pitfalls in data interpretation. First and foremost, as currently designed, the technique provides only an estimate of the true cardiac output. Furthermore, for changes in cardiac output to be properly detected, the previously mentioned assumptions must hold. It is not surprising that aortic cross-clamping and flow redistribution following cardiopulmonary bypass provide conditions when these assumptions are invalid. [639] [645] The esophageal Dop-pler technique cannot be used in non-tracheally intubated patients or in individuals with esophageal pathology, and the method is likely to be unreliable in patients with diseases of the aortic valve or thoracic aorta. Finally, like all ultrasound techniques, the acoustic window to acquire the Doppler signal may not be adequate in some individuals, thereby precluding use of this method.

The current clinical role for esophageal Doppler cardiac output monitoring is not to serve as a replacement for the PAC, but rather as an additional circulatory monitor in higher risk patients who do not warrant invasive monitoring. [642] [658] The popularity of this technique in the United Kingdom may reflect in part the much more restricted use of PACs in that country compared with use in the United States. [642] Preliminary studies have suggested that perioperative esophageal Doppler-guided volume resuscitation of moderate risk surgical patients reduces perioperative morbidity and shortens hospital stay. [659] [660] If these results can be duplicated in other settings and with larger groups of patients, this technique may find a role as a more routine monitor in patients who are at increased risk for perioperative circulatory complications.

NONPULMONARY ARTERY CATHETER-BASED CARDIAC OUTPUT AND PERFUSION MONITORING

An interest in studying cardiovascular function during space flight initially prompted investigations of impedance plethysmography as a noninvasive method of determining cardiac output. This technique of *bioimpedance* cardiac output monitoring was first described by Kubicek et al [661] and is based on changes in electrical impedance of the thoracic cavity occurring with ejection of blood during cardiac systole. [661] Their original formula relates these bioimpedance measurements to stroke volume:

Cardiac output is computed from the product of the derived stroke volume and heart rate. Over the years, this formula for deriving stroke volume has been modified based on refined models of the behavior of the thoracic resistivity. [642] [662] [663]

Various devices have been marketed commercially that measure cardiac output using the bioimpedance method. Each requires application of disposable electrodes to the skin surface along the sides of the neck and lateral aspect of the lower thorax. Impedance measurements are made by applying a continuous small electrical current across the chest. Patient height, weight, and gender are entered into the monitor by the operator to allow an accurate computation of the volume of the thoracic cavity. Bioimpedance cardiac output is computed for each cardiac cycle and continuously displayed as an average value over several heart beats.

Validation studies comparing the bioimpedance cardiac output measurement with other methods have produced inconsistent results. [642] [647] [648] [663] [664] [665] [666] [667] [668] [669] Although many studies suggest that the bioimpedence method is accurate in healthy volunteers, its reliability deteriorates in critically ill patients, including those with sepsis, increased lung water, aortic regurgitation, and electronic cardiac pacing. [663] [664] [669] Because the bioimpedance method is an indirect measure of cardiac output with a complex mathematical derivation, it is not surprising that this monitoring method has not proved to be as reliable as some other techniques. Despite recent claims of improved performance of newer devices with refined algorithms, [670] [671] bioimpedance cardiac out-put monitoring has not found broad clinical acceptance to date.

Other methods for cardiac output monitoring are available that do not require pulmonary artery catheterization. One such totally noninvasive technique is the *partial CO_2 rebreathing Fick technique.*[672] This method uses the change in CO_2 production and end-tidal CO_2 in response to a brief, sudden change in ventilation. A computer-controlled pneumatic valve intermittently increases dead space, thereby causing partial rebreathing of exhaled gases. Changes in CO_2 production and end-tidal CO_2 in response to the rebreathing are used to calculate cardiac output by a differential version of the Fick equation. The attractive features of this method are that it is entirely noninvasive, it can be performed every few minutes, and the brief episodes of rebreathing pose no substantial risk to most patients. [673] [674] [675] [676] As with all Fick-based techniques, the partial CO_2 rebreathing method does not account for pulmonary shunt. In effect, it measures pulmonary capillary blood flow as an indicator of total cardiac output and thus may require correction for this factor. [677] [678]

The *lithium dilution* technique is another cardiac output monitoring method that derives its fundamental basis from indicator dilution principles. [679] [680] [681] In brief, following a central venous bolus injection of a small dose of lithium chloride, an ion-selective electrode attached to a peripheral arterial catheter measures the lithium dilution curve, from which the cardiac output is derived. Preliminary investigations suggest that this is an accurate technique compared with standard thermodilution methods or electromagnetic flowmetry and may be even more precise than thermal indicator techniques. [682] [683] Although the lithium dilution method appears to be scientifically robust, it is not known how frequently small doses of lithium chloride (e.g., 0.15-0.6 mmol) may be injected in the typical clinical setting. Furthermore, the present method requires both central venous and arterial cannulation and thus carries all standard risks inherent in these invasive procedures.

Attempts to derive cardiac output from the systemic arterial pressure trace have met with limited success. These methods, generally termed *pulse contour* cardiac output, determine the cardiac output from computerized analysis of the aortic pressure waveform, [684] the radial artery pressure waveform, [685] or even a continuous noninvasive finger blood pressure waveform. [686] [687] In general, agreement between these methods and clinical standards, such as thermodilution cardiac output, have been poor, particularly when there are large changes in systemic vascular resistance. [684] This is not surprising in view of the complex nature of the morphology of the peripheral arterial pressure waveform.

The clinical role for these alternative methods of cardiac output monitoring remains in evolution. Advocates of flow monitoring argue that early preemptive therapy guided by these devices is more likely to improve patient outcome, compared with delayed therapy in critically ill patients who already have evidence of end-organ failure. [642] In the acute care setting, noninvasive cardiac output monitoring methods that are easily applied during surgery or on initial pres-entation to the emergency department or intensive care unit may have a unique role in providing a bridge to more comprehensive, invasive monitoring with a PAC. Inasmuch as several of these techniques have been found to be useful in detecting occult hypovolemia, [654] [660] other methods of detecting the adequacy of the circulating blood volume or end-organ perfusion have received attention recently.

The *double indicator dilution* method is one new technique for blood volume assessment at the bedside. It appears to provide measures of intravascular volume that may be superior to those of traditional preload measurements derived from pulmonary artery catheterization. [688] [689] *Pulse dye densitometry* is another new method that may provide a bedside indication of the circulating blood volume that was previously only measured with complex radioactive isotope techniques. This method involves the intravenous injection of indocyanine green dye, and its detection with a peripheral pulse dye densitometer that uses two-wavelength light absorption, similar to a pulse oximeter. [690] [691] [692] [693]

Other monitoring techniques aimed at detecting inadequate tissue perfusion have focused on the splanchnic circulation as a site that may provide an early indication of hypoperfusion. *Gastric tonometry* is a recently automated technique that allows measurement of gastric intramucosal P_{CO_2} and calculation of intramuscosal pH with a semicontinuous air tonometer. [694] [695] [696] Some investigations have already noted the superiority of this end-organ monitor as an indicator of the adequacy of tissue perfusion and a predictor of perioperative complications [659] [696] and death in critically ill patients. [697] Unfortunately, it is not known whether therapy directed at correcting such splanchnic hypoperfusion will confer clinical benefit. [698] [699] Newer cardiovascular monitoring techniques, such as measurement of circulating blood volume and gastric intramucosal pH, offer new variables for cardiovascular monitoring, that may augment or even supplant some current monitors.

AUTOMATED ANESTHESIA DATA MANAGEMENT SYSTEMS AND DATA RECORDERS

Use of numerous supplementary cardiac monitors in patients with cardiovascular disease results in the generation of huge amounts of data during the course of an anesthetic. One of the responsibilities of the anesthesiologist is to create a record that chronicles the anesthetic management and clinical course of the patient in the perioperative period. However, transcribing all data produced in complex, highly monitored cases can become a burdensome clerical task that can actually detract from patient care by diverting the anesthesiologist's attention. Use of automated data acquisition and anesthesia record-keeping devices addresses this problem. Obviously, the recording of hemodynamic data from monitors is only a part of the anesthetic record. Patient demographics, a history of operative events, fluid and anesthetic drug administration, and various text notes are all important additional components of this document. The automated device performs all of these functions efficiently, completely, and reliably, and thus can replace the traditional manual anesthesia record. [700]

Another significant and unique benefit of automated systems is the ability to collect anesthesia-related data in a unified format across all cases in an institution or in a number of linked institutions. Analysis of this database of comprehensive information allows efficient use of operating room resources, [701] facilitates quality assurance management, and offers valuable data for clinical research. The data from many centers can be merged to identify expected clinical outcomes across large patient populations and determine variances from the expected.

Use of computerized devices for intraoperative anesthesia data gathering purposes is not new, but only recently has there been a proliferation of commercially available devices. Implementation of an anesthesia information system is relatively easy and has high acceptance by clinicians, especially for complicated cases such as those involving cardiothoracic anesthesia. [700] In addition, the accuracy and precision of data recorded automatically are likely to be superior to the manually kept record. [702] [703]

The great advances made since the early 1980s in the power and miniaturization of microcomputers allow the recording system to perform with a suitable user interface. These computers are small, yet powerful enough to be designed as individual stand-alone units for each anesthetizing location, thus improving reliability and sustaining communication with larger systems over well-established hospital networks. Connection to a hospital network system provides an opportunity for remote printing of completed anesthesia records and downloading of vital data from other information systems. Another benefit of these systems is the opportunity for long-term data storage that allows future analysis. The potential value of such databases both within and among institutions is essentially limitless.

COAGULATION MONITORING

In contrast to hemodynamic monitoring, assessment of perioperative coagulation remains, at present, entirely an *ex vivo* process. Traditionally, coagulation monitoring in the surgical patient has focused on preoperative testing to identify patients at increased risk for perioperative bleeding and intraoperative monitoring of heparin therapy during cardiac and vascular surgery. More recently, availability of increasingly sensitive and specific point-of-care coagulation monitors has provided an opportunity to guide administration of blood components and hemostatic drugs more specifically, without the delays inherent in standard laboratory testing.

Monitoring heparin anticoagulation during cardiac and vascular surgery is widely recognized as essential for the safe performance of these operations. Heparin is a biopharmaceutical derived from bovine lung or porcine intestinal mucosa, composed of a heterogeneous mixture of compounds with diverse anticoagulant activities. [704] Consequently, variability of heparin activity and pharmacodynamic response are well documented. Various patient-specific factors also affect pharmacodynamic response to heparin, including age, intravascular volume, and plasma/membrane concentrations of antithrombin III, heparin cofactor II, platelet factor 4, and other heparin-binding proteins. [704] Not surprisingly, therefore, patients exhibit widely different anticoagulant responses to the same standard dose of heparin. [705] Finally, heparin anticoagulation monitoring must be performed if only to prevent the rare, but potentially lethal, complication resulting from a failure to administer heparin as intended prior to cardiopulmonary bypass or arterial clamping. [706]

The ideal test of perioperative coagulation would be simple to perform, accurate, reproducible, diagnostically specific, and cost-effective. Although no single monitoring device available to date has all these ideal operating characteristics, many provide useful information to guide patient management. Particularly when combinations of these devices are used, they provide valuable diagnostic insights into the mechanism of a patient's perioperative coagulopathy. The importance of integrated monitoring described earlier for hemodynamic assessment is equally applicable to coagulation monitoring.

Commercially available point-of-care coagulation monitors used in the perioperative setting may be divided into four categories:

1. Functional measures of coagulation or assays that measure the intrinsic ability of the blood to clot

    Activated coagulation time (ACT)

    Heparin management test (HMT)

    High-dose thrombin time (HiTT)

    Prothrombin time (PT)

    Activated partial thromboplastin time (aPTT)

2. Monitors of heparin concentration

    Protamine titration

    Ion-selective electrodes

3. Viscoelastic measures of coagulation

    Thromboelastogram (TEG)

    Sonoclot

4. Platelet function analyzers

Functional Measures of Coagulation

The ACT, described by Hattersley in 1966, [707] is a version of the Lee-White whole blood clotting time that is modified

to include an initiator for contact activation of the coagulation system. This activator, frequently diatomaceous earth, is used to accelerate clot formation and reduce the time to assay completion.

Hattersley's original assay required manual mixing of a blood sample with the contact activator followed by repeated visual assessment of the tube to determine time-to-visible-clot formation. More recent commercial ACT monitors simplify testing by automating clot detection. One of the more widely available ACT monitors employs a glass test tube that contains a small magnet at the bottom (Hemochron; International Technidyne, Inc., Edison, N.J.). After adding a sample of blood, the tube is placed into the analyzer, where a constant temperature of 37°C is maintained, and the tube is rotated slowly while the magnet maintains contact with a proximity detection switch. As fibrin clot forms, the magnet becomes enmeshed and is pulled away from the detection switch, thereby triggering an alarm and providing an end-time for the ACT measurement. Another ACT device uses a "plumb-bob" flag assembly that is raised and dropped repeatedly through the sample vial containing blood and contact activator (Hepcon and ACT II; Medtronic Blood Management, Parker, Colo.). As clot forms, the rate of descent of the flag through the blood slows, triggers an optical detector, and alarms to signify the end-time for the ACT.

Because each patient's baseline ACT measurement serves as a control for subsequent determinations, the method selected for ACT testing might appear to be unimportant. However, drugs used in the perioperative period, such as the antifibrinolytic drug aprotinin, may dramatically alter the times measured using different ACT monitoring systems. Aprotinin inhibits contact activation by celite (dia-tomaceous earth) [708] and produces an artifactual elevation of the celite ACT. If this interaction is not considered, an insufficient dose of heparin may be administered. Kaolin, an alternative contact activator, should be used to measure ACT in patients

receiving aprotinin, because it will bind the aprotinin and remove it from the plasma. [708] It is not clear whether excess concentrations of aprotinin will overwhelm the kaolin-binding capacity and thereby affect the kaolinactivated ACT.

The ACT in normal individuals is approximately 107 ± 13 sec (mean ± standard deviation). [707] However, the time at which a patient's "baseline" ACT is measured can influence the result. Following surgical incision, the baseline ACT decreases by more than two standard deviations in patients undergoing cardiac surgery, perhaps because of tissue factor release with tissue injury. [709] Heparin clearly prolongs the ACT, because this test measures the clotting potential of the intrinsic and common pathways of coagulation. In addition to ACT prolongation by heparin, a prolonged ACT signifies impaired ability of the blood sample to generate clot, for whatever reason. However, the ACT is relatively resistant to platelet dysfunction and is affected only by severe thrombocytopenia and platelet inhibitors such as prostacyclin or monoclonal antibodies directed against GPIIb/IIIa surface receptors. [710] [711] [712]

ACT testing is probably the most widely used perioperative coagulation monitor because of its simplicity, low-cost, and ability to monitor anticoagulation when large doses of heparin are used as required for cardiac surgical procedures. However, there are limitations associated with this method of monitoring. ACT is relatively insensitive to low concentrations of heparin, and ACT measurements are not particularly reproducible. [713] These deficiencies are especially important when ACT monitoring is used to verify hep-arin neutralization with protamine. ACT monitoring also may be influenced by phospholipid-bound microparticles extruded from the platelet surface during activation. These platelet microparticles artifactually shorten the ACT even in the presence of residual heparin. [714] In addition to artifactually low ACT values, high ACT values greater than 600 sec do not represent a linear dose-response relationship to high-dose heparin administration. [713] Furthermore, both hypothermia and hemodilution prolong the time to ACT clot formation. In some instances, these artifactual effects on measurement of the ACT may lead to false assumptions regarding the extent of anticoagulation. Reproducibility of the ACT may be improved by averaging duplicate ACT determinations. [715] In one study, ACT tubes containing either heparinase or protamine have been employed in conjunction with unmodified ACT tubes to improve the sensitivity for detecting low heparin concentrations that persist in the blood. [716]

The HMT (Cardiovascular Diagnostics, Inc., Raleigh, N.C.) offers promise as a solution to many problems associated with use of the ACT for monitoring during cardiac surgery. This method employs recent advances in dry reagent chemistry analysis of coagulation. It uses a microprocessor-controlled analyzer and disposable test cards to provide a rapid, reproducible measure of functional anticoagulation when large doses of heparin are employed. A reaction chamber within each test card contains paramagnetic iron oxide beads and the dry chemical reagents necessary to activate coagulation in the blood sample. [717] After a drop of blood is added to the card, capillary action draws a small portion of this blood sample into the reaction chamber. An oscillating magnetic field is applied to the solution of blood, chemical reactants, and beads. A light beam passed through the test chamber detects oscillations in the amplitude of transmitted light coincident with bead movement in the test chamber. As clot formation occurs, the beads become enmeshed within the clot, reducing the amplitude of light oscillations to trigger the end-time for the HMT measurement. The minute sample of blood drawn into the test chamber and the extreme sensitivity of the clot detection method used in this system minimize confounding effects from hypothermia and hemodilution. Preliminary evaluation of this monitor during cardiac surgery suggests that the HMT provides a more accurate and more reproducible measure of heparin activity than the ACT. [718] [719]

A third measure of heparin anticoagulation, also used primarily during cardiac surgery, is the HiTT (International Technidyne, Edison, N.J.). The HiTT assay contains high reagent concentrations of thrombin to cleave fibrinogen directly and generate a fibrin clot. In the presence of these excess thrombin concentrations, clot formation occurs independently of plasma coagulation factors other than fibrinogen. As a result, the HiTT is prolonged by heparin (or other thrombin inhibitors), extreme degrees of hypofibrinogenemia or dysfibrinogenemia, and high concentrations of fibrin split products. [720] [721] During most surgical procedures when heparin is being used, HiTT prolongation will correlate with the heparin anticoagulant effect. The major limitation to

more widespread use of the HiTT has been the limited shelf-life of the thrombin reagent, which must be mixed just prior to performing the assay.

Standard laboratory-based coagulation testing remains a common practice in patients with a preexisting coagulopathy and those scheduled to undergo surgical procedures commonly associated with postoperative coagulopathy, such as cardiac or hepatic surgery. Most often, the PT and aPTT are measured to provide baseline values for the patient, although the dose-response curves for these assays limit their usefulness when high-dose heparin anticoagulation is employed. As point-of-care coagulation monitors that measure the PT and aPTT become increasingly available, it is important to recognize that the test results from these monitors will not necessarily match the results reported by the hospital-based laboratory. These different methods of coagulation monitoring may differ from laboratory testing because reagent sensitivities vary considerably from manufacturer to manufacturer and from one lot of reagent to another. In addition, laboratory-based testing relies on plasma, as opposed to point-of-care monitors that use whole blood. [722] Indeed, some of the delay inherent in laboratory-based testing results from the time required to process the plasma sample from the patient's whole blood. Because values obtained with point-of-care monitors are unlikely to agree with laboratory-based testing, their successful use in clinical practice will often require that baseline measurement values be determined for each individual patient.

Heparin Concentration Measurement

Protamine titration is at present the most widely used method for determining heparin concentration in the perioperative setting. Protamine is a strongly basic polycationic protein, which directly inhibits heparin in a stoichiometric manner. In other words, 1 mg of protamine will inhibit 1 mg (approximately 100 units) of heparin. This reaction forms the basis for the protamine titration method of heparin concentration measurement. As increasing concentrations of protamine are added to a sample of heparin-containing blood, time-to-clot formation decreases until the point at which protamine concentration exceeds the heparin concentration in the blood sample, and then the time-to-clot formation increases. If a series of blood samples with incremental doses of protamine are analyzed, the sample in which the protamine and heparin concentrations are most closely matched will be the first one to generate clot. Thus, using protamine titration methodology, it is possible to estimate the heparin concentration present in a given sample of blood. [723] Assuming that the heparin-protamine titration curve of an individual patient remains constant throughout the operative period, it is possible to use the protamine titration method to estimate the dose of heparin required to achieve a desired plasma heparin concentration. In a similar manner, determination of heparin concentration at the conclusion of surgery allows a more precise estimate of the amount of protamine required to neutralize the circulating heparin. More precise administration of heparin and protamine may have a number of clinical advantages. Some investigations have suggested that thrombin activity during cardiopulmonary bypass may be reduced when stable heparin concentrations are maintained. [724] More effective thrombin inhibition during bypass should benefit patients by decreasing consumption of coagulation factors and thereby reducing postoperative bleeding. [725] Although protamine titration initially was performed manually, automated methods currently are available (Hepcon; Medtronic Blood Management, Parker, Colo.). These monitors employ cassettes of 4 to 6 vials containing protamine to perform the titration assay. Different measurement cassettes are chosen, depending on the expected range of heparin concentration.

Protamine titration methodology is relatively sensitive to low concentrations of heparin and is limited only by the range of protamine concentrations provided for testing. For this reason, protamine titration has proved particularly useful for verifying heparin neutralization following protamine administration. This method for determining heparin concentration is relatively resistant to the influences of hypothermia and hemodilution. Furthermore, heparin concentration monitoring by protamine titration is not altered during aprotinin therapy, in contrast to celite ACT measurements. The major limitation of heparin concentration monitoring is failure to assess functional coagulation or the intrinsic clotting potential of the blood. To use an extreme example, consider a patient with a homozygous deficiency for antithrombin III. Although functional measures of coagulation, such as the ACT, would clearly identify these patients by failure to achieve the desired prolongation of the ACT after heparin administration, measures of heparin concentration alone would demonstrate the expected blood heparin level but would fail to identify the lack of anticoagulant effect.

Preliminary reports have described another method for measuring heparin concentration in whole blood using electrochemical sensors. These heparin sensors use a polyvi-nylchloride membrane impregnated with triiododecylmethyl-ammonium chloride (TDMAC) to produce an electric potential in response to heparin, which correlates well with laboratory-based measures of heparin concentration. [726] The heparin sensor offers several advantages over protamine titration methods for determination of heparin concentration. First, the heparin sensor is not dependent on clot for-mation. This allows determination of heparin concentrations in patients with underlying coagulopathies as well as with blood samples containing anticoagulants in addition to heparin, such as citrate or ethylenediaminetetra-acetic acid (EDTA). In addition, the heparin sensor produces a linear response over a greater heparin concentration range than current protamine titration methods. Rather than reporting heparin concentration discontinuously, as necessitated by protamine titration cartridges, heparin concentrations de-termined with ion-selective membranes are reported over a continuous range. Despite the apparent advantages of these electrochemical sensors, their accuracy may be altered by high plasma concentrations of salicylate, nitrate, iodide, or bromide. [727] The clinical usefulness of these ion-selective electrodes awaits further development of these sensors into commercially applicable forms.

Viscoelastic Measures of Coagulation

Initially developed in the 1940s, viscoelastic measures of coagulation have undergone a resurgence in popularity

---

during the past decade. The unique aspect of viscoelastic measures lies in their ability to measure the entire spectrum of clot formation from early fibrin strand generation through clot retraction and eventual fibrinolysis. The Thromboelastograph (TEG) (Haemoscope; Morton Grove, Ill), developed by Hartert in 1948, [728] uses a small 0.35-mL blood sample placed into a disposable cuvette within the instrument. The cuvette is maintained at a temperature of 37°C and continuously rotates around an axis of approximately 5 degrees. A metal piston attached by a torsion wire to an electronic recorder is lowered into the blood within the cuvette. As clot formation occurs, the piston becomes enmeshed within the clot, and rotation of the cuvette is transferred to the piston and electronic recorder.

Although variables derived from the TEG tracing do not coincide directly with laboratory-based tests of coagulation, the TEG is capable of detecting characteristic abnormalities of clot formation and fibrinolysis. [729] Various parameters that describe characteristics of clot formation and lysis are inscribed by the TEG recorder. The *R* value (reaction time) measures time to initial clot formation (normal: 7.5-15 min). It is considered comparable to the whole blood clotting time and may be accelerated by adding celite to the TEG sample cuvette. The R value is prolonged by a deficiency of one or more plasma coagulation factors. Maximum amplitude *(MA)* provides a measure of clot strength and may be decreased by either qualitative or quantitative platelet dysfunction or decreased fibrinogen concentration. Normal MA is 50 to 60 mm. The *alpha angle* and *K* (BiKoatugulierung or coagulation) values measure the rate of clot formation and may be prolonged by any factor slowing clot generation, such as

Figure 30-55 (Figure Not Available) The functional components of the thromboelastograph consist of a rotating cuvette, a suspended piston attached to a torsion wire, and a recorder. As the blood sample clots, rotation of the curvette is transferred to the torsion wire and translated by the recorder as a characteristic tracing. Quantitative parameters derived from the thromboelastograph trace are the reaction time (R), BiKoatugulierung value or coagulation time (K), alpha angle (alpha), and maximum amplitude (MA). See text for greater detail. *(From Tuman K, Speiss B, McCarthy R et al: Effects of progressive blood loss on coagulation as measured by thromboelastography. Anesth Analg 66:856, 1987.)*

Figure 30-56 Characteristic thromboelastograph tracings.

plama coagulation factor deficiency or heparin anticoagulation (Figs. 30-55 (Figure Not Available) and 30-56) .

The Sonoclot (Sienco, Inc; Morrison, Colo.) provides an alternative viscoelastic measure of coagulation. Compared with TEG, the Sonoclot immerses a rapidly vibrating probe into a 0.4-mL sample of blood. As clot formation occurs, impedance to probe movement through the blood increases and generates an altered electrical signal and characteristic clot "signature." The Sonoclot may be used to derive the ACT as well as provide information regarding clot strength and clot lysis. [730]

Both the TEG and Sonoclot generate characteristic diagrams by translating the mechanical resistance encountered by the sensor as it moves through the clotting blood sample. Measurements derived from these diagrams have been related to more traditional measures of coagulation, such as the ACT. [731] In addition, abnormal patterns have been associated with deficiencies of coagulation factors and functional platelet abnormalities. [732] [733] One of the more common applications of the TEG analyzer is the real-time detection of excessive fibrinolysis during liver transplantation. The TEG also may be used to differentiate surgical bleeding from coagulopathy following cardiac surgery. [734] More widespread application of viscoelastic coagulation monitoring has been hindered by the lack of specificity associated with abnormal findings and the qualitative nature of assay interpretation. Recent computerization and automation of these instruments have improved the reproducibility of the measurements and have made the results more quantitative. However, additional investigations are required to define further the usefulness of viscoelastic coagulation monitoring in the perioperative setting.

Platelet Function Monitors

Despite tremendous advances in point-of-care monitoring of plasma coagulation, bedside assessment of platelet function has remained problematic. Although platelet function

---

influences many point-of-care coagulation monitoring methods currently in use, these platelet-mediated effects are often nonspecific and unpredictable. The ACT is influenced only by profound platelet dysfunction, [710] and whereas the TEG and Sonoclot are capable of detecting platelet abnormalities, their sensitivity and specificity are limited in terms of defining the platelet problem in the context of a complex perioperative coagulopathy. The standard method for identifying qualitative platelet dysfunction is laboratory-based optical aggregometry, performed with specific platelet agonists in platelet-rich plasma. Unfortunately, this form of testing is technically demanding and cannot be performed at the bedside. Furthermore, alteration of platelet function by the method of sample preparation may affect the results. [735] Flow cytometry, using fluorescent-labeled antibodies, provides a sensitive method for quantitating platelet activation and platelet surface receptor availability. A further advantage of this form of platelet function analysis is the ability to use whole blood, thereby eliminating the potential for blood sampling and processing artifacts. However, as with platelet aggregation studies, flow cytometry requires substantial technical expertise and laboratory-based support.

Several platelet function assays, specifically designed for use at the bedside, have entered clinical trials. The HemoSTATUS (Medtronic Blood Systems; Parker, Colo.) platelet function test exploits the ability of platelet-activating factor (PAF) to accelerate clot formation of a kaolin-activated ACT. HemoSTATUS testing is performed on the Medtronic HMS coagulation analyzer using a six-channel kaolin ACT cartridge preloaded with increasing concentrations of PAF. A clot ratio is determined for each individual patient assay based on the ratio of the PAF-accelerated ACT compared with the standard ACT. An individual patient's clot ratio is compared with a maximal clot ratio derived from normal volunteers and provides a measure of the patient's platelet function. In the presence of platelet dysfunction, higher concentrations of PAF are required to achieve a comparable PAF-activated ACT. When the HemoSTATUS monitor has been used following cardiac surgery, investigators have demonstrated a relationship between platelet function and postoperative bleeding. [736] Furthermore, maximal clot ratio as determined by the HemoSTATUS has been demonstrated to improve following administration of either DDAVP or platelet concentrates. However, other investigators have failed to corroborate these results, and thus, further investigations are needed. [737] [738]

Currently undergoing clinical trials, the Rapid Platelet Function Analyzer (RPFA; Accumetrix, San Diego, Calif.) is an automated turbidimetric whole blood assay of platelet function, which assesses the ability of activated platelets to bind fibrinogen-coated polystyrene beads. [739] On addition of the test blood sample, thrombin receptor activating peptide directly activates platelets within the sample, thereby stimulating the expression of GPIIb/IIIa platelet surface receptors. As activated platelets bind and aggregate fibrinogen-coated beads, light transmission through the sample increases and generates a measurable signal. Although the RPFA is simple to operate and provides a rapid bedside measure of platelet function, a baseline measurement is required for each patient to calculate the extent of subsequent changes in platelet function.

The PFA-100 (Platelet Function Analyzer; Dade International Inc; Miami, Fla.) is unique among both laboratory-based and point-of-care platelet function monitors. It incorporates high-shear conditions to simulate primary hemostasis following injury to a small vessel. Citratecontaining blood, added to a disposable test cartridge, is aspirated through a 200-mum capillary and then forced through a 150-mm aperture in a membrane containing collagen and either adenosine diphosphate or epinephrine. [740] Exposure of platelets within the blood sample to activating agents within the membrane under high-shear conditions stimulates platelet adherence and aggregation. As the platelet plug forms, blood flow through the aperture decreases and the time to aperture occlusion is displayed as the "closure time." Although clinical trials with this instrument remain in progress, preliminary findings have demonstrated that the PFA-100 detects both congenital and acquired disorders of platelet function with a high degree of sensitivity and specificity. [741] [742]

Advances in our understanding of hemostasis and thrombosis at the molecular level have contributed directly to recent biotechnologic innovations in the assessment of perioperative hemostasis. Further advances in point-of-care coagulation monitoring offer the opportunity for clinicians to make more informed decisions about

transfusion therapy and hemostatic drug administration to minimize bleeding in the perioperative setting.

Chapter 31 - Transesophageal Echocardiography *

Michael K. Cahalan

INTRODUCTION

In 1976, Dr. Leon Frazin and associates [1] published the results of studies using an esophageal M-mode transducer and thereby introduced the technique of transesophageal echocardiography (TEE). Subsequently, Matsumoto et al [2] used M-mode TEE to study left ventricular (LV) function during cardiovascular surgery, but M-mode echocardiography provides too limited a view of spatial relationships to be practical for intraoperative monitoring. In the early 1980s, Hanrath et al [3] introduced a two-dimensional (2-D), phased-array transducer mounted on the tip of a flexible gastroscope, and TEE's intraoperative potential became apparent. In the mid-1980s, color flow Doppler technology became commercially available, making it possible for TEE to provide not only high-resolution, real-time images of cardiac structure and function, but also simultaneous, superimposed maps of intracardiac blood flow. With these technical advances, TEE's role was ensured in the perioperative assessment of patients with a wide variety of cardiovascular diseases.

In this chapter, the perioperative applications of TEE most important for the anesthesiologist are emphasized. The tools and techniques for exploiting TEE are presented, including basic ultrasound modalities, probe operation, and techniques to diagnose the causes of common hemodynamic problems. TEE assessment of global and regional LV function is described in detail, because standard textbooks of echocardiography tend to ignore or gloss over such applications. TEE evaluation of valvular function and surgical repairs is well covered elsewhere, so it is given more limited coverage here. [4] [5] [6] [7] [8] [9] [10] [11] For the practitioner who plans extensive use of TEE, one or more of the standard texts on echocardiography should prove invaluable. [12] [13] [14]

ULTRASOUND IMAGING MODALITIES

Physical Principles

Echocardiography typically involves intermittent pulses of ultrasound waves with a frequency of 2.5 to 7.5 million cycles per second (MHz). Frequencies greater than 7.5 MHz are not routinely used in echocardiography because penetration of the sound waves into tissues is too limited (penetration is inversely related to frequency). Frequencies less than 2.5 MHz are not routinely used, because resolution of small objects is too limited (resolution is directly related to frequency). Ultrasound waves in the range of 2.5 to 7.5

* *Also see Appendix 1, Practice Guidelines for Perioperative Transesophageal Echocardiography*

MHz provide tissue penetration of 10 to 25 cm and resolve objects 1 mm or less in size. When ultrasound waves strike an interface of tissues of differing densities, such as the pericardium and the heart, a portion is reflected. The amount reflected depends on the difference in the tissue densities; that is, the greater the difference, the greater the portion reflected. For example, air in the LV reflects a much greater portion of the transmitted ultrasound than blood and is translated as a brighter signal on the display screen. Tissue is localized by the time a sound wave takes to bounce back to the transducer; that is, the longer a sound wave takes to bounce back, the greater is its distance from the transducer. (Sound is assumed to travel at 1,540 m/s in all tissues of the body at 37°C.) No ionizing radiation of any type is used in echocardiography, and no adverse effects of ultrasound have been demonstrated in humans.

M-Mode and Two-Dimensional Echocardiography

The first echocardiograms, "motion" or "M-mode" studies, were one-dimensional views of cardiac structures produced by single crystal transducers with the results traced on moving photosensitive paper. Today, M-mode echocardiography is used principally to view rapidly moving structures, such as valve leaflets, because M-mode transducers can produce up to 1,000 images per second (Fig. 31-1) (Figure Not Available) . However, M-mode images reveal only a small portion of the heart at one time, making orientation and interpretation of spatial relationships difficult.

Figure 31-1 (Figure Not Available) An M-mode transesophageal echocardiogram of a normal aortic valve. For reference, a single frame (stop action) of the two-dimensional cross-section is shown at the top right of the figure. The dotted vertical line through the two-dimensional echocardiogram depicts the single line of sampling provided by the M-mode echocardiogram over time (the horizontal axis for the lower two-thirds of the figure). The electrocardiogram defines systole and diastole. Note in the middle of the M-mode image the three tilted rectangles connected by the slightly undulating line. These rectangles and lines are formed by the motion of the leaflets of the aortic valve as they open and close during the cardiac cycles shown. From top to bottom in this M-mode echocardiogram, the structures indicated by the white lines are the posterior wall of the left atrium (just under the electrocardiogram), the posterior wall of the aortic annulus, the aortic valve (as already described), the anterior wall of the aortic annulus, a pulmonary artery catheter, and the myocardium of the right ventricular outflow tract. *(From Cahalan [21])*

Figure 31-2 (Figure Not Available) A short-axis two-dimensional cross-section of a normal aortic valve (AV). This basal two-dimensional short-axis view reveals the morphology of the three cusps of this normal valve. LA, left atrium; RA, right atrium; RVOT, right ventricular outflow tract; TV, tricuspid valve. *(From Cahalan [21])*

By using multiple crystals (linear or phased-array transducers) or by rapidly moving a single crystal (mechanical transducer), multiple views can be obtained and collated into a 2-D image. Although 2-D techniques produce only about 30 images per second, definition in two dimensions provides an enormous advantage in recognizing anatomic and pathologic landmarks (Fig. 31-2) (Figure Not Available) . Images are displayed in "real time" on a monitor screen and are recorded on videotape or digital format for later review. By altering the position or angle of the ultrasound beam, the operator produces multiple cross-sectional (tomographic) images revealing the external and internal anatomy and function of the heart and great vessels.

Pulsed-Wave Doppler

By measuring the Doppler shift, modern ultrasonographs quantify blood flow velocities. The Doppler shift is the shift in frequency of a wave when the source of the wave is moving (in this case, the wave reflected by moving red cells). When pulses of sound are used (pulsed-wave or PW Doppler), the operator defines a small area (termed "sample volume") anywhere in the 2-D sector scan, and the ultrasonograph automatically converts the Doppler data in that sample volume to a display of the real-time blood flow velocities (Fig. 31-3) (Figure Not Available) . Thus, PW Doppler defines blood flow velocities and their location within the heart and great vessels.

However, two important limitations apply. First, the Doppler shift is proportional to the cosine of the angle theta between the ultrasound beam and the direction of the blood cells. Thus, if the cells are moving directly parallel to the ultrasound beam, the angle is zero and the cosine of zero is one, providing a true estimate of blood flow velocity. At all other angles, the cosine is less than one, resulting in less Doppler shift and an underestimation of flow velocity. Clinically,

Figure 31-3 (Figure Not Available) Pulsed-wave Doppler echocardiogram of the main pulmonary artery (MPA). At the top of the echocardiogram is a still-frame image of the two-dimensional cross-section used to position the Doppler sample volume (white sphere). On the bottom two-thirds of the echocardiogram is the display in white of the instantaneous blood flow velocities (vertical axis) versus time (horizontal axis) occurring in that sample volume. The electro-cardiogram (ECG) is shown for timing purposes. The horizontal line through the base of the Doppler tracing is the baseline (zero flow) for the flow velocities. Flow velocities above this line are positive (i.e., toward the transducer) to a maximum of 68 cm/s. Flow below the line is negative (i.e., away from the transducer) to a maximum of -14 cm/s. *(From Cahalan [21])*

angles of less than 15 degrees (the cosine is almost one) are insignificant to velocity estimation, whereas angles exceeding 20 degrees markedly attenuate the Doppler shift, necessitating caution in interpreting such data. This relationship is best stated in the Doppler equation:

where V is the velocity to be measured, F_d is the Doppler shift in ultrasound frequency measured by the ultrasound machine, C is the speed of sound in tissue (a constant), and F_0 is the frequency of the transducer. Second, the maximum velocity of blood flow that can be unambiguously measured is inherently limited ("Nyquist limit"). The Nyquist limit is determined by the pulse repetition frequency, which, in turn, depends directly on the depth of the ultrasound scan and inversely on the ultrasound frequency. If the Nyquist limit is exceeded, sudden apparent flow reversal ("aliasing") will be depicted (Fig. 31-4) (Figure Not Available) . "Aliasing" is

analogous to the sudden apparent reversal of direction in stagecoach wheels visible in old Westerns when the velocity of the wheel spokes exceeds the frame rate of the movie camera. Typically, aliasing of PW Doppler occurs at blood flow velocities of 0.4 to 0.6 m/s. Normal flow within the heart may reach 1.4 m/s, and pathologic flows may be up to 6 m/s. To measure these velocities, continuous-wave (CW) Doppler is needed.

Continuous-Wave Doppler

CW Doppler uses two separate crystals: one to emit ultrasound continuously and one to receive it continuously. CW Doppler is basically PW Doppler with an infinite pulse repetition frequency that eliminates the problem of aliasing (Fig. 31-5) (Figure Not Available) . However, this infinite pulse repetition rate allows insufficient time for the first pulse to return to the transducer before the next is emitted. Consequently, the ultrasonograph cannot determine which pulse of sound was frequency shifted and, therefore, cannot precisely define the location of the moving target. Nonetheless, the maximum velocity can prove to be vital information: by simplification of the Bernoulli equation, Hatle et al [15] and Holen et al [16] proved that the peak gradient across a stenotic valve equals $4V^2$, where V is the velocity determined by CW Doppler in meters per second. Thus, CW Doppler defines higher blood flow velocities than PW, but, unlike the latter, CW Doppler cannot precisely define the location of the velocities.

Color Doppler

Point-by-point determination of blood flow velocities often is too time-consuming and does not reveal the instantaneous distribution of flow velocities within the cross-sectional image that is required for many diagnostic decisions. Color Doppler imaging was developed for this purpose: to permit sampling of the Doppler shift simultaneously in many areas of the sector scan. In color Doppler, a form of PW Doppler, a color code is used to depict flow toward (red) and away (blue) from the transducer; lighter and darker shades of red and blue, respectively, denote relatively faster and slower velocities. Continuous color maps of flow are superimposed on gray-scale cross-sectional echocardiograms. However, color Doppler generally is a semiquantitative technique and, like PW Doppler, will alias (color reversal) when the Nyquist limit is exceeded. Two aliasing patterns are easily recognized: the first is "normal" aliasing in which the area of apparent flow reversal forms one or more broad, relatively homogenous color surfaces (Color Plate 31-1).

Figure 31-4 (Figure Not Available) Pulsed-wave Doppler echocardiogram with aliasing at the high-velocity point. Pulsed-wave Doppler measurement of blood flow velocities in a mitral valve (MV) orifice during four cardiac cycles is shown. At the top of the figure is a still-frame image of the two-dimensional cross-section used to position the Doppler sample volume (white sphere). On the bottom two-thirds of the figure is the display in white of the instantaneous blood flow velocities (vertical axis) versus time (horizontal axis) occurring in that sample volume. The electrocardiogram is shown for timing purposes. The horizontal line through the base of the Doppler tracing is the baseline (zero flow) for the flow velocities. Flow velocities above the line are positive (i.e., toward the transducer) to a maximum of 183 cm/s. Flow velocities below the line are negative (i.e., away from the transducer) to a maximum of -77 cm/s. This tracing documents significant mitral regurgitation (the positive systolic velocities), but it does not measure the peak velocity of regurgitant flow because it is beyond the Nyquist limit--the systolic velocities off the top of the scale are said to alias, that is, they go off scale and wrap around into the domain of negative velocities. LA, left atrium; LV, left ventricle. *(From Cahalan [21])*

Blood flow velocities within a normal heart (0.6-1.4 m/s) often produce this type of aliasing because they exceed the Nyquist limit for color Doppler (0.4-0.6 m/s). The second type of aliasing results from disturbed or turbulent flow within the heart (e.g., mitral regurgitation) and is not normal (Color Plate 31-2). When the ultrasonograph detects two different velocities within the same small sample volume (from disturbed flow), it displays a mixture or mosaic of colors. These mosaics often form jet-like configurations and are commonly called "color jets." Because color Doppler presents the spatial relationships between structure and blood flow, it greatly enhances the recognition of valvular abnormalities and intracardiac shunts.

EQUIPMENT DESIGN AND OPERATION

Probes

The simplest TEE probe has one phased-array transducer with 64 piezoelectric elements. The transducer is about 40 mm long, 13 mm wide, and 11 mm thick; operates at 5 or 7.5 MHz; and is mounted on the tip of a 9-mm-diameter gastroscope. The ultrasound beam is oriented at right angles to the gastroscope to produce transverse imaging planes of the heart. As with standard gastroscopes, two rotary knobs ("wheels") control the movement of the tip of the scope. One of the wheels flexes and retroflexes the transducer (i.e., moves the transducer toward and away from the heart). The other wheel angulates the transducer rightward and leftward.

Biplane transducers incorporate a second transducer mounted immediately proximal and at right angles to the first to add a longitudinal imaging plane. These probes have a significantly longer inflexible tip than single-transducer probes, but this feature rarely prevents esophageal passage in the unconscious patient.

Multiplane transducers use a single transducer mounted on a rotating device that allows the transducer to spin on its axis from 0 to 180 degrees within the tip of the gastroscope (transducer housing). Because cardiac structures and blood flow are not always aligned precisely with the transverse or longitudinal plane, this design has significantly refined imaging capability. Although a few millimeters wider and thicker than single-plane transducers, multiplane probes are easily passed through the esophagus of the unconscious patient.

By reducing the number of crystals and by further miniaturizing transducers, manufacturers have produced single-plane and biplane transducers small enough (6 to 7-mmdiameter gastroscopes) for use in infants and neonates (Fig. 31-6) (Figure Not Available) .

Figure 31-5 (Figure Not Available) Continuous-wave Doppler measures high-velocity flows without aliasing. Continuous-wave Doppler measurement of blood flow velocities in a mitral valve orifice during four cardiac cycles is shown. At the top of the figure is a still-frame image of the two-dimensional cross-section used to position the Doppler sample cursor (diagonal white line). On the bottom two-thirds of the figure is the display in white of all the instantaneous blood flow velocities (vertical axis) versus time (horizontal axis) occurring anywhere along that cursor. The electrocardiogram (ECG) is shown for timing purposes. The horizontal line through the base of the Doppler tracing is the baseline (zero flow) for the flow velocities. Flow velocities above the line are positive (i.e., toward the transducer) to a maximum of 753 cm/s. Flow velocities below the line are negative (i.e., away from the transducer) to a maximum of -316 cm/s. This tracing documents significant mitral regurgitation (the positive systolic velocities) with a peak blood flow velocity of approximately 5 m/s (each white dot on the vertical axis equals 100 cm/s or 1 m/s). LA, left atrium; LV, left ventricle. *(From Cahalan [21])*

Figure 31-6 (Figure Not Available) Four transesophageal echocardiography probes are compared. From left to right, the probes are single plane, pediatric single plane, multiplane, and biplane. The probe tips are viewed in their maximum dimension. *(From Cahalan [21])*

Ultrasonographs

Ultrasonographs contain high-powered computers capable of initiating the ultrasound signal and processing the returning data. A series of electronic transforms (some guarded commercial secrets) produces the real-time images displayed on the video screen. All ultrasonographs share common technical aspects including gain, depth, and Doppler controls. However, the differences in technical aspects among manufacturers and even among models from the same manufacturer are sufficiently great to prevent the formulation of any universal operating instructions. Fortunately, detailed instructions for each model are available in the operator's manual supplied with each ultrasonograph. Alternatively, cardiac sonographers are often excellent sources of instruction in the operation of these machines.

BASIC EXAMINATION TECHNIQUE AND CROSS-SECTIONS

Overview

Unless specific diagnostic questions require the assistance of a cardiologist, anesthesiologists usually perform intraoperative TEE. Because of time constraints and relatively narrow

TABLE 31-1 -- The Four Basic Transverse Cross-Sections [a]

(Not Available)

From Cahalan [21]

[a] The four basic transverse-plane cross-sections are listed along with the depth from the incisors at which they are most commonly found, their anatomic level, the transducer angle for optimal viewing in most patients (multiplane probes only), and their principal use

diagnostic goals, the anesthesiologist performs a more limited examination than often described in the cardiology literature. [17] [18] [19] [20] However, an absolute minimum of four cross-sections should be attempted even when only a single-plane transducer is available (Table 31-1) (Table Not Available) . Without these cross-sections, common cardiac pathologic features may be missed, and correct interpretation of subsequent hemodynamic alterations may be impossible. Therefore, a standardized intraoperative examination is recommended as the foundation for monitoring and for detailed diagnostic imaging when indicated.

Probe Introduction

Once the patient is anesthetized and the trachea is securely intubated, the contents of the patient's stomach are suctioned. Gentle massage of the left upper quadrant of the abdomen during suctioning may help to remove air that otherwise can degrade imaging. Then the patient's neck is extended, and the well-lubricated TEE probe is introduced into the midline of the hypopharynx with the transducer side facing anteriorly. Usually, with minimal force, the probe will pass blindly into the esophagus, especially if the patient's neck is extended. If the probe does not pass blindly, a laryngoscope is used to lift the larynx anteriorly, and the probe is placed into the patient's esophagus under direct vision. During transducer insertion or withdrawal, the controls of the gastroscope must be in the neutral or relaxed position to allow the transducer to follow the natural course of the esophagus, thereby potentially minimizing the risk of injury.

Basic Transverse Plane Examination

With the transducer at 28 to 32 cm (measured at the upper incisors), the basal short-axis cross-section of the aortic valve is easily obtained by turning the shaft of the gastroscope and adjusting its depth in the esophagus until the transducer is directly behind the aortic valve (see Fig. 31-2 (Figure Not Available) ; Color Plate 31-3). "Basal" specifies the position of the transducer behind the base of the heart. This cross-section is ideal for detection of aortic valve abnormalities, including aortic stenosis. With a single or biplane probe, the best view of the aortic valve is obtained by using the appropriate wheel of the gastroscope to angulate the tip of the probe leftward 15 to 30 degrees. This angulation better aligns the transverse imaging plane with the annulus of the aortic valve, thereby achieving a true short-axis cross-section. With a multiplane transducer, angulation of the tip of the gastroscope is unnecessary. Instead, the transducer can be rotated 15 to 30 degrees within the tip of the gastroscope to accomplish the same effect.

Advancing the transducer 3 to 5 mm from this position, turning it slightly leftward (by rotating the shaft of the gastroscope) and retroflexing it (with the appropriate wheel of the gastroscope) to direct the ultrasound beam downward (10-30 degrees caudally) provides a view of the LV outflow tract (the "five-chamber" cross-section): left atrium and ventricle, right atrium and ventricle, and LV outflow tract (Fig. 31-7 (Figure Not Available) ; Color Plate 31-4). With color Doppler, this cross-section permits detection of mitral stenosis, mitral regurgitation, and aortic insufficiency. When examining valves and other three-dimensional (3-D) structures with 2-D imaging and Doppler techniques, the operator must use multiple, closely spaced 2-D "slices" of the 3-D structures to be certain that localized abnormalities have not been missed. Fortunately, this is easily accomplished with the mitral valve and LV outflow tract: after the five-chamber cross-section has

Figure 31-7 (Figure Not Available) Five-chamber echocardiogram. This image was obtained with a multiplane transducer positioned at 0 degrees as indicated by the semicircular icon positioned to the right of the sector scan. This cross-section is commonly called the five-chamber view because all four cardiac chambers and the left ventricular outflow tract (LVOT) can be seen. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. *(From Cahalan [21])*

been achieved, the operator relaxes the retroflexion of the gastroscope, centers the mitral valve in the sector scan, and slowly withdraws and then advances the transducer until the entire mitral valve surface has been sliced like a loaf of bread. This slicing procedure is first performed with 2-D imaging and then with color Doppler. Thereafter, the operator centers the LV outflow tract in the sector scan and repeats the 2-D and color Doppler examinations.

Advancing the transducer 3 to 5 mm deeper into the esophagus below the level at which the five-chamber cross-section was achieved and again retroflexing it to direct the ultrasound beam 10 to 30 degrees caudally provides the four-chamber cross-section (Fig. 31-8 (Figure Not Available) ; Color Plate 31-5). This cross-section is best for evaluation of relative LV and right ventricular size and function. A normal right ventricle appears smaller than the LV (intracavitary area roughly two-thirds of the LV cavity area) because it is crescent shaped and partially wrapped around the LV. With color Doppler, this cross-section permits detection of tricuspid stenosis and regurgitation.

Finally, advancing the transducer 2 to 7 cm further and then flexing it anteriorly 20 to 40 degrees reveals the short-axis cross-section of the LV at the level of the papillary muscles (Fig. 31-9 (Figure Not Available) ; Color Plate 31-6). This short-axis cross-section is ideal for monitoring LV filling and ejection, because all major coronary arteries supply myocardium viewed in this cross-section, changes in preload cause greater changes in the LV short-axis than in the long-axis dimension, and movement of the probe from this cross-section is readily apparent because of the prominent landmarks the papillary muscles provide.

Figure 31-8 (Figure Not Available) Four-chamber echocardiogram. Because this cross-section, like the five-chamber cross-section, rarely reveals the apex of the left ventricle (LV), estimates of filling

and ejection derived from these cross-sections usually underestimate LV end-diastolic volume and overestimate ejection fraction. However, the relative size and function of the two ventricles are apparent in the four-chamber cross-section, and, as a result, this cross-section is often the best for detection of right ventricular (RV) dysfunction. Although RV function appears normal in this image, the leftward bulging of the intra-atrial septum is abnormal and suggests high right-sided pressures. LA, left atrium; RA, right atrium. *(From Cahalan [21])*

Figure 31-9 (Figure Not Available) Midpapillary short-axis echocardiogram. This echocardiogram was obtained with a single-plane probe. ALPM, anterior lateral papillary muscle; IVS, intraventricular septum; LV, left ventricle; PMPM, posterior medial papillary muscle. *(From Cahalan [21])*

Biplane and Multiplane Examination

Five additional, longitudinal cross-sections are added to the basic examination when using a biplane or multiplane probe--three basal cross-sections at the aortic valve level, one midesophageal cross-section at the mitral valve level, and one transgastric cross-section at the mid-LV level (Table 31-2) (Table Not Available) . Thus, the basic biplane or multiplane examination requires nine cross-sections. To appreciate the relationship between transverse and longitudinal cross-sections requires some 3-D conceptualization. At the aortic valve level, transverse plane, short-axis cross-section, one needs to imagine the ascending aorta coming out of the page and the LV outflow tract behind it (see Fig. 31-2 (Figure Not Available) and Color Plate 31-3). When the imaging plane is reoriented from transverse to longitudinal (accomplished by switching to the second transducer in a biplane system or rotating the transducer to 90 degrees in a multiplane system), the heart appears to have rotated 90 degrees so that the ascending aorta is positioned on the right side of the image and the LV outflow tract is on the left (Fig. 31-10 (Figure Not Available) ; Color Plate 31-7). This cross-section (longitudinal plane, ascending aorta) is excellent for detection of ascending aortic abnormalities, including aortic dissections. With a biplane probe, the best view of the ascending aorta is obtained by using the appropriate wheel of the gastroscope to angulate the transducer leftward 20 to 30 degrees. With a multiplane transducer, the best view of the ascending aorta is achieved at 110 to 120 degrees of transducer rotation.

Next, the gastroscope is turned to the right until the longitudinal imaging plane reveals a long-axis cross-section of the superior vena cava and right atrium, an optimal cross-section for locating central venous catheters and sinus venous atrial septal defects (Fig. 31-11 (Figure Not Available) ; Color Plate 31-8). With a biplane probe, the best view of the superior vena cava is obtained by using the appropriate wheel of the gastroscope to angulate the transducer leftward 20 to 30 degrees. With a multiplane transducer, this cross-section is best achieved at 110 to 120 degrees of transducer rotation.

TABLE 31-2 -- Longitudinal Imaging Planes[a]

(Not Available)

From Cahalan [21]

[a] The five basic longitudinal-plane cross-sections are listed along with the depth from the incisors at which they are most commonly found, their anatomic level, the transducer angle for optimal viewing in most patients (multiplane probes only), and their principal use.

Then the gastroscope is turned to the left past the view of the ascending aorta until the longitudinal imaging plane reveals the right ventricular outflow tract and pulmonary artery (Fig. 31-12 (Figure Not Available) ; Color Plate 31-9 (Figure Not Available)). This cross-section is ideal for guiding pulmonary artery catheterization and for detecting pulmonary valvular disorders and some ventricular septal defects. With a biplane probe, the best view of the right ventricular outflow tract and pulmonary artery is obtained by using the appropriate wheel of the gastroscope to angulate the transducer rightward 10 to 30 degrees. With a multiplane transducer, this cross-section is best achieved at 60 to 80 degrees of transducer rotation.

The next longitudinal cross-section is obtained with the transducer at the mid esophageal level (i.e., behind the mitral valve). The operator positions the transducer for either the transverse plane, four-chamber, or five-chamber cross-section (whichever affords the best view of the LV) (see Figs. 31-7 (Figure Not Available) and 31-8; (Figure Not Available) Color Plates 31-4 (Figure Not Available) and 31-5 (Figure Not Available)). Then, one imagines the anterior wall of the LV coming out of the page and the inferior wall behind it. When the imaging

Figure 31-10 (Figure Not Available) Ascending aorta (AsAo) long-axis echocardiogram. This image was obtained with a multiplane transducer rotated to 120 degrees (as indicated by the semicircular icon positioned to the right of the sector scan) to align the ultrasound beam optimally with the ascending aorta. This degree of optimal alignment can usually be attained with a biplane probe as well by angulating the tip of the probe leftward. LA, left atrium; LV, left ventricle; LVOT, LV outflow tract; MV, mitral valve; RVOT, right ventricular outflow tract. *(From Cahalan [21])*

Figure 31-11 (Figure Not Available) Superior vena cava long-axis echocardiogram. This image was obtained with a multiplane transducer rotated to 110 degrees (as indicated by the semicircular icon positioned to the right of the sector scan) to align the ultrasound beam optimally with the superior vena cava. This degree of optimal alignment can usually be attained with a biplane probe as well by angulating the tip of the probe leftward. LA, left atrium; RA right atrium; SVC, superior vena cava. *(From Cahalan [21])*

plane is reoriented from transverse to longitudinal, the heart appears to have rotated 90 degrees, placing the LV anterior wall on the right side of the image and the inferior wall on the left (two-chamber cross-section) (Fig. 31-13 (Figure Not Available) ; Color Plate 31-10 (Figure Not Available)). Often, this cross-section provides the best TEE image of the LV apex. With a biplane probe, the view of the apex is optimized by using the appropriate wheel of the gastroscope to angulate the transducer leftward 10 to 20 degrees. With a multiplane transducer, this view is optimized at 110 to 120 degrees of transducer rotation. Because the LV apex is the furthest cardiac structure from the TEE transducer, it is rarely visualized in sufficient resolution to exclude the presence of a thrombus.

The last longitudinal cross-section in the standard examination is obtained with the transducer in the transgastric position (i.e., mid-LV level). The operator positions the transducer for the transverse plane, midpapillary short-axis cross-section and imagines the mitral valve and left atrium in front of the page and the LV apex behind it (see Fig. 31-9 (Figure Not Available) and Color Plate 31-6 (Figure Not Available)). When the imaging plane is reoriented

Figure 31-12 (Figure Not Available) Right ventricular outflow tract (RVOT) echocardiogram. This image was obtained with a multiplane transducer rotated to 80 degrees (as indicated by the semicircular icon positioned to the right of the sector scan) to align the ultrasound beam optimally with the RVOT and main pulmonary artery (MPA). This degree of optimal alignment can usually be attained with a biplane probe as well by angulating the tip of the probe rightward. AV, aortic valve; LA, left atrium; PV, pulmonary vein; TV, tricuspid valve. *(From Cahalan [21])*

from transverse to longitudinal, the heart appears to have rotated 90 degrees, and the mitral valve and left atrium appear on the right side of the image and part of the LV apex on the left (Fig. 31-14 (Figure Not Available) ; Color Plate 31-11 (Figure Not Available)). This midpapillary long-axis cross-section shows less of the apex than the two-chamber cross-section, but it does not require repositioning of the probe from its usual monitoring position in the midpapillary short-axis cross-section (where changes in LV filling and ejection are most easily detected). Moreover, the midpapillary long-axis cross-section may reveal basal and sometimes apical segmental dysfunction missed if only the midpapillary short axis is monitored.

Although the basic TEE examination outlined earlier reveals most of the essential information available from TEE,

Figure 31-13 (Figure Not Available) Two-chamber echocardiogram. This image was obtained with a multiplane transducer rotated to 90 degrees (as indicated by the semicircular icon positioned to the right of the sector scan). Note the left atrial appendage (LAA). It overhangs the anterior wall of the left ventricle (LV). The other ventricular wall seen in this cross-section is the inferior wall. LA, left atrium; MV, mitral valve. *(From Cahalan [21])*

Figure 31-14 (Figure Not Available) Midpapillary long-axis echocardiogram. This image was obtained with a biplane probe. Part of the left ventricular inferior (top of image) and anterior (opposite wall) walls are seen. The apex is not seen. The posterior medial papillary muscle (PMPM) gives rise to the chordae tendineae supporting the anterior leaflet of the mitral valve (MV). Between the posterior leaflet and the anterior ventricular wall, the left ventricular outflow tract is particularly well seen in this patient. Often it is not seen in this cross-section, but it can be well evaluated in other cross-sections such as the five-chamber view. The anterior lateral papillary muscle is not seen in this patient, because it lies posterior to the midline of this ventricle. In fact, in this cross-section, both papillary muscles are usually not seen, because they are usually not located exactly opposite each other on the anterior and inferior ventricular walls. LA, left atrium; LV, left ventricle. *(From Cahalan*

[21])

additional cross-sections often are required to resolve specific questions. For example, withdrawing the transverse plane transducer approximately 2 to 3 cm above the aortic valve level reveals the main pulmonary artery and its bifurcation. At this level, pulmonary artery flow is almost directly parallel to the ultrasound beam, permitting Doppler estimates of true blood flow velocity for evaluation of pulmonic stenosis or regurgitation and for calculation of cardiac output (see later). Midway between this cross-section and the aortic valve short-axis cross-section, the entrance of the left superior pulmonary vein can be imaged by rotating the probe approximately 45 degrees to the left. PW Doppler measurements of blood flow velocities in this vein provide estimates of left atrial filling pressure or of the severity of mitral regurgitation (see later). Rotation of the probe further leftward reveals the descending aorta. By insertion and withdrawal of the probe from this position, the descending aorta and parts of the transverse arch can be imaged using both transverse and longitudinal transducer orientations. The presence and extent of dissection, atheroma, and thrombi in the descending aorta can be evaluated reliably. The last of the most commonly useful additional crosssections is achieved by advancing the transversely oriented transducer well into the patient's stomach and then flexing the tip of the gastroscope to its maximum extent. If the probe is well into the stomach, maximum flexion will require very little force on the wheel of the gastroscope. Then the operator gently withdraws the probe until feeling resistance at the gastroesophageal junction, where an inverted five-chamber cross-section is achieved (deep gastric five-chamber).

In this cross-section, the ultrasound beam is parallel to the blood flow through the LV outflow tract and aortic valve facilitating Doppler estimation of cardiac output or of the degree of aortic stenosis (see later). Further details on TEE cross-sections can be found in standard echocardiography texts or multimedia CD-ROM. [11] [12] [13] [14] [21]

Essential Precautions

TEE poses very little risk if it is properly performed. Although anesthesiologists are highly skilled in instrumentation of the airway and esophagus, some special precautions need to be observed to minimize the chances of injury caused by TEE. First, if the history and physical examination suggest esophageal disease, the potential benefits of TEE must clearly outweigh the apparent risks, or TEE should be abandoned. Second, the TEE probe should be inspected prior to each use, and if defects are detected (i.e., cracks in the transducer housing or shaft of the gastroscope), the probe must not be used, but instead sent for repairs. Each manufacturer supplies maintenance and service recommendations that should be incorporated into the departmental quality assurance program. Third, when the TEE probe is advanced or withdrawn in the patient's esophagus, the control wheels of the gastroscope should be in their neutral positions and left unrestrained. These wheels have locking devices that must be unlocked during probe movements. Fourth, if the probe meets resistance in the esophagus, it should not be forced to advance further. Rarely, repositioning of an abdominal or thoracic retractor relieves the resistance. Otherwise, the operator should suspect esophageal disease and should abandon the TEE examination. Alternatively, esophagoscopy can be performed to determine the safety of persisting in efforts to pass the TEE probe. Last, when the TEE probe is to remain in one position for an extended period, the ultrasound energy (transmitting power of the transducer) and mechanical deflection of the probe tip (i.e., flexion, retroflexion, and angulation) should be minimized. Ideally, the wheels of the gastroscope should not be locked for extended periods, in order to prevent extremes of mechanical deflections from inadvertently persisting.

HEMODYNAMIC DETERMINATIONS

Preload

TEE provides high-resolution images that depict the extent of LV filling. For instance, in 30 patients scheduled for cardiac surgery, Cheung et al [22] removed 15 percent of each patient's blood volume (in 6 equal aliquots) prior to cardiopulmonary bypass while monitoring the midpapillary short-axis cross-section with TEE. A significant decrease in LV end-diastolic area was detected after removal of the first aliquot (2.5% of the estimated blood volume or about 200 mL). With subsequent aliquots, end-diastolic area decreased linearly (0.3 cm^2 /1.0% of blood volume removed), such that, after removal of all 6 aliquots, the end-diastolic area had decreased by 27 percent in patients with normal LV function and by 21 percent in patients with depressed LV function. Although the pulmonary artery occlusion pressure and central venous pressure also declined during the study, the correlation with end-diastolic area was very weak or nonexistent, indicating marked differences in LV compliance.

In settings in which LV compliance changes, TEE may be the only practical method to assess preload adequately. For instance, Harpole et al [23] studied patients undergoing resection of abdominal aortic aneurysm in whom intraoperative echocardiograms, pulmonary artery pressures, and first-pass radionuclide data were recorded simultaneously. The correlation between echocardiographic and radionuclide estimates of preload and ejection was excellent. Virtually no correlation was found between estimates from either of these techniques and pulmonary artery pressures. Thus, TEE, but not pulmonary artery catheterization, provides a direct, quantitative method to assess changes in LV preload in patients with changing LV compliance.

However, absolute measurement of LV volumes is more difficult with TEE, because TEE rarely reveals the true apex of the LV. Without this landmark, the LV long-axis dimension must be empirically assigned, or foreshortened estimates must be accepted. For instance, Smith et al [24] studied 36 patients undergoing LV angiography and TEE. These investigators used the LV long-axis dimension measured in the 4-chamber cross-section. Although they found good correlation between the estimates of LV volumes from angiography and TEE, TEE consistently underestimated absolute volumes, because it underestimated the long-axis dimension. Use of the longitudinal plane, 2-chamber cross-section should improve TEE estimates of the LV long-axis dimension and thereby should improve absolute estimates of LV volumes, but, to date, no study has definitely proven this assertion.

Hypotension

When a sudden, severe change in hemodynamics occurs, qualitative estimates of LV filling and ejection serve as the practical guide for administration of fluids and inotropes. With some ultrasonographs, computer technology converts the echocardiographic images from one cardiac cycle into digital code and then plays this cycle repetitively to allow side-by-side comparison with other cardiac cycles captured at other times during surgery. With this technology, an experienced observer consistently can detect decreases in preload before they result in greater than a 10 percent decrease in blood pressure. [25] This technology also facilitates qualitative assessment of changes in LV ejection and prompts differential diagnosis of the cause of hypotension. For example, severe hypovolemia is easily recognized as a marked decrease in LV end-diastolic area with a marked increase in LV ejection fraction, and LV failure is seen as a marked increase in LV end-diastolic area and marked decrease in LV ejection fraction. During hypotension, arterial vasodilatation, aortic regurgitation, mitral regurgitation, and ventricular septal defect can manifest the same LV filling and ejection pattern at the midpapillary short-axis cross-section: adequate LV end-diastolic filling area with increased LV ejection fraction. Fortunately, distinguishing among these causes of hypotension is not difficult using other cross-sections and color Doppler (see subsequent sections). Table 31-3 (Table Not Available) summarizes the most

TABLE 31-3 -- Origin of Hypotension[a]

(Not Available)

From Cahalan [21]

[a] Obviously, other problems can cause hypotension, but the ones listed here include the most common occurring in the operating room. Two important caveats need to be mentioned. First, low systemic vascular resistance and hypovolemia sometimes occur simultaneously (for instance, in sepsis), and until hypovolemia is treated, low systemic vascular resistance will not be apparent. Second, one cannot assume that just because the papillary muscles meet during systole (i.e., LV cavity obliteration) the patient is hypovolemic. This finding can occur in either low systemic vascular resistance or hypovolemia. To make this differential diagnosis correctly, one must determine whether diastolic filling is adequate.

common causes of hypotension and their echocardiographic characteristics at the midpapillary short-axis cross-section.

Consider two dramatic examples of the value of TEE in hypotensive patients. First, Reichert et al [26] used TEE in 60 consecutive patients with severe, persistent hypotension following cardiac surgery. In one-half of these patients, TEE demonstrated that the presumed cause of the hypotension was incorrect. Indeed, in 5 patients, unnecessary reoperations were prevented because TEE correctly revealed that tamponade was not present despite hemodynamic data suggesting it. Second, Heidenreich et al [27] compared transthoracic echocardiography and TEE in 61 consecutive patients who experienced more than 1 hour of severe hypotension during their care in a combined surgical and medical intensive care unit. The echocardiographic results were immediately revealed to the attending physician, who determined whether any change in therapy was indicated. Based on these results, the cause of each patient's hypotension was classified as nonventricular (i.e., valvular or pericardial), ventricular (i.e., failure), or noncardiac (i.e., hypovolemia or low systemic vascular resistance). Transthoracic echocardiography and TEE were diagnostically adequate in 36 and 97 percent of the patients, respectively. When nonventricular conditions were diagnosed as the cause of the hypotension, patient survival (81%) was almost twice as likely as when ventricular (41%) or noncardiac causes (44%) were revealed. Moreover, TEE revealed clinically significant new findings missed by transthoracic echocardiography in 28 percent of patients leading to surgery in 20 percent of the patients. These two prospective studies and other retrospective studies confirm the diagnostic and prognostic value of TEE in patients with severe, persistent hypotension. [26] [27] [28] [29]

Cardiac Output

Real-time images of LV filling and ejection permit qualitative, immediate assessment of marked changes in cardiac output. However, with PW and CW Doppler, TEE can quantify cardiac output. A Doppler measurement of blood flow velocity is combined with a 2-D measurement of cross-sectional area:

Cardiac output = VTI × CSA × costheta × heart rate

where VTI is the velocity time integral (the area under the Doppler-derived velocity versus time curve per systole), CSA is the cross-sectional area through which the velocity passes, and costheta is the cosine of the angle between the ultrasound beam and the blood flow (usually the angle is assumed to be zero degrees so that this factor equals unity and can be disregarded). Initial studies of flow in the main pulmonary artery and across the mitral valve compared with thermodilution-derived estimates yielded somewhat disappointing results. [30] Subsequent comparisons, when patients with tricuspid regurgitation were excluded (tricuspid regurgitation confounds thermodilution measurements), when CW Doppler was used from a deep gastric five-chamber cross-section, and when multiplane or biplane capabilities were exploited, suggest that TEE should have a bias of near zero and limits of agreement of less than 1 L/min for measurement of cardiac output. [31] [32] [33] [34]

Left Ventricular Filling Pressure

Surprisingly, TEE provides practical ways to estimate LV filling pressure. Placing the Doppler cursor at the junction of the left atrium and the left superior pulmonary vein, Kuecherer et al [35] demonstrated that a systolic fraction of flow of less than 55 percent was a specific and sensitive sign of left atrial pressure greater than 15 mm Hg. This sign is easily detected as predominance of flow during diastole [36] (Figs. 31-15 (Figure Not Available) and 31-16) (Figure Not Available) . Significant mitral regurgitation, the presence of nonsinus rhythm, and extremes of cardiac output affect pulmonary venous flow and therefore limit this application of TEE. [37] Alternative methods have been described that obviate these limitations. [38] [39] Accordingly, TEE cannot estimate left atrial pressure precisely, but it can reliably identify clinically significant elevations.

Left Ventricular Contractility

Measuring LV contractility is much more difficult. The LV fractional area change measured at the midpapillary short-axis cross-section is a reasonable approximation of LV ejection fraction, but the ejection fraction is clearly afterload dependent and should be viewed cautiously as an index of overall ventricular performance. However, LV ejection fraction is an excellent predictor of survival in patients with coronary artery disease and is widely used in the perioperative assessment of high-risk patients.

Left Ventricular Afterload

TEE provides a better estimate of LV afterload, endsystolic wall stress (which incorporates LV systolic dimension, pressure, and wall thickness) than is possible with other intraoperative monitors. Moreover, TEE-determined wall stress and intraoperative myocardial ischemia are strongly associated. In a study of patients undergoing carotid endarterectomy, systolic blood pressure and heart rate were maintained at ward level in all patients using phenylephrine

---

Figure 31-15 (Figure Not Available) Normal pulmonary venous flow pattern. Pulsed-wave Doppler measurement of normal blood flow velocities in the left upper pulmonary vein (LUPV) is shown. At the top of the figure is a still-frame image of the two-dimensional cross-section used to position the Doppler sample volume (white sphere). On the bottom two-thirds of the figure is the display in white of the instantaneous blood flow velocities (vertical axis) versus time (horizontal axis) occurring in that sample volume. The electrocardiogram (ECG) is shown for timing purposes. The horizontal line through the base of the Doppler tracing is the baseline (zero flow) for the flow velocities. Flow velocities above the line are positive (i.e., toward the transducer) to a maximum of 69 cm/s. Flow below the line is negative (i.e., away from the transducer) to a maximum of -32 cm/s. In this patient with normal left atrial pressure, systolic predominance of flow is evident; that is, more flow enters the atrium during the period of ventricular systole than during ventricular diastole, as evidenced by the greater peak and average flow velocities during systole than during diastole. LA, left atrium. *(From Cahalan [21])*

in one group and "light" anesthesia in the other. [40] Endsystolic wall stress was 40 percent greater and the incidence of ischemia was 2.5-fold higher in the phenylephrine group (because of LV distention and wall thinning), findings indicating the importance of afterload as a determinant of oxygen demand and myocardial ischemia.

DETECTION OF MYOCARDIAL ISCHEMIA

Intraoperative Transesophageal Echocardiography Versus Electrocardiography

Since Tennant and Wiggers [41] first described the association of segmental wall-motion abnormalities (SWMA) and ischemia, many other investigators have demonstrated that ischemic segments of human and animal heart do not exhibit normal inward wall motion or thickening during systole (Chs. 32 and 49) . During acute myocardial ischemia, SWMA precede and may occur in the absence of electrocardiographic (ECG) changes. [42] [43] [44] [45] In 50 patients undergoing coronary artery or major vascular surgery, echocardiographic and 7-lead ECG (3 limb leads, 3 augmented leads, and V_5) studies revealed new intraoperative SWMA diagnostic of myocardial ischemia (marked decrement in LV segmental motion and thickening) in 24 patients, compared with ischemia-indicative ST-segment changes (>0.1 mV deviation) in only 6 patients. [45] SWMA occurred minutes before the ECG change in 3 of these 6 patients, and no ST-segment change occurred before or without new SWMA. Similarly, 3 of 50 patients who sustained intraoperative myocardial infarctions developed SWMA that persisted until the end of surgery in the corresponding area of myocardium, but only 1 of 3 had ischemic ST-segment changes. Four of 5 patients with double-vessel disease developed SWMA in regions of myocardium supplied by the diseased coronary arteries, not in the "risk-free" myocardium. Of 10 study patients without coronary disease, none had ST-segment changes or SWMA. Subsequent studies in similar patients confirmed these results. [46] [47]

However, in noncardiac surgical patients at risk for coronary artery disease, investigators comparing TEE, 2-lead Holter monitoring, and 12-lead continuous ECG monitoring found that 2-lead Holter monitoring detected almost twice as many episodes of ischemia as the 12-lead ECG or TEE. [48] The apparently superior sensitivity of 2-lead Holter monitoring likely is due to differences between the TEE and ECG protocols and the patient population; that is, the 2-lead Holter and 12-lead ECG were monitored continuously, whereas TEE was evaluated only intermittently, and TEE images were analyzed by review of videotape recordings, not by the more reliable technique of cine loop analysis. Additionally, only about one-half of these patients had proven coronary artery disease, a factor critical in interpreting the results, because as the prevalence of a disease decreases

Figure 31-16 (Figure Not Available) High left atrial (LA) pressure produces diastolic predominance in the pulmonary venous flow pattern. Pulsed-wave Doppler measurement of blood flow velocities in the left upper pulmonary vein (LUPV) in a patient with abnormally high LA pressure is shown. At the top of the figure is a still-frame image of the two-dimensional cross-section used to position the Doppler sample volume (white sphere). On the bottom two-thirds of the figure is the display in white of the instantaneous blood flow velocities (vertical axis) versus time (horizontal axis) occurring in that sample volume. The electrocardiogram (ECG) is shown for timing purposes. The horizontal line through the base of the Doppler tracing is the baseline (zero flow) for the flow velocities. Flow velocities above the line are positive (i.e., toward the transducer) to a maximum of 80 cm/s. Flow below the line is negative (i.e., away from the transducer) to a maximum of -44 cm/s. In this patient with abnormally high LA pressure, diastolic predominance of flow is evident; that is, more flow enters the atrium during the period of ventricular diastole than during ventricular systole as evidenced by the greater peak and average flow velocities during diastole than during systole. The negative flow velocities are due to atrial contraction pushing blood back into the pulmonary vein. *(From Cahalan [21])*

in a population, the risk of false-positive findings increases. For example, 2-lead Holter monitoring reveals ST-segment changes diagnostic of ischemia in 7 percent of healthy young adults and in 26 percent of healthy young adults given digitalis. [49] [50] Thirteen percent of patients in the study just described were receiving digitalis.

Limitations of Transesophageal Echocardiography for Ischemia Detection

Even when an area of myocardium is clearly in view, segmental contraction can be difficult to evaluate if the entire heart rotates or translates markedly during systole or if discoordinated contraction results from bundle branch block or ventricular pacing. Consequently, a valid system for SWMA assessment first must compensate for global motion of the heart (typically by using a "floating" frame of reference), then evaluate both regional endocardial motion and myocardial thickening. A worsening of segmental wall motion and wall thickening (in the absence of similar global changes) of at least two classes (Table 31-4) (Table Not Available) is required to make the diagnosis of ischemia; less pronounced changes are not interpreted consistently, even by experts.

Interpretation of septal motion is the most problematic because septal motion is often confounded by discoordinated contraction patterns. However, a simple rule applies: when the septum is viable and nonischemic, it thickens appreciably during systole, although its inward motion may begin slightly before or after inward motion of the other ventricular segments. Thus, new SWMA can be detected

TABLE 31-4 -- Classes of Segmental Wall Motion and Thickening [a]

(Not Available)

From Cahalan [21]

[a] Assessment of segmental wall motion is subjective, but this grading system helps to limit the variability among readers by defining categories of inward endocardial motion and myocardial thickening. "Change in radius" refers to the percentage of change during systole in the radius from the endocardium to the imaginary center of the left ventricle. Because normal myocardial thickening is 2 to 5 mm and inward endocardial motion is 5 to 10 mm, thickening is more difficult to assess than endocardial motion. Nevertheless, thickening is the more reliable guide to myocardial function, because it is unaffected by variables that confound assessment of endocardial motion: translational motion of the heart, conduction abnormalities, and ventricular pacing. In the absence of these variables, endocardial motion usually is an adequate indicator of the function of the underlying myocardium.

during bundle branch block, ventricular pacing, and marked global movements of the heart, but not by assessment of endocardial motion alone.

Owing to biologic differences in healthy patients, not all hearts contract normally, and not all parts of the same heart contract to the same degree. [51] Consequently, not all SWMA are indicative of myocardial ischemia. For example, myocardial infarction and myocarditis can cause SWMA. However, an acute decrease or cessation of segmental contraction, such as new intraoperative SWMA, is almost always due to myocardial ischemia. The few exceptions to this rule are noted in the next few paragraphs.

One exception to this rule is myocardial stunning, or prolonged, postischemic ventricular dysfunction. [52] When ischemia has been prolonged, full restoration of blood flow may occur minutes to hours before return of normal segmental contraction. Does a new SWMA detected immediately after bypass represent inadequate revascularization and ongoing ischemia, or is it stunned myocardium from inadequate cooling during bypass? Differentiating this cause is important: inadequate revascularization may require placement of additional grafts, whereas stunned myocardium requires only supportive measures until its function returns.

Echocardiographic contrast agents can delineate myocardial blood flow, [53] but, to date, they have not been proven to do so reliably in stunned myocardium. Fortunately, stress echocardiography may be an alternative approach: moderate to high doses (
40 mug/kg) of dobutamine may improve segmental function in chronically stunned but not infarcted myocardium. [54] [55] [56] Intraoperative studies confirming these findings in acutely stunned myocardium are needed. In the meantime, when stunned myocardium is suspected following cardiopulmonary bypass, graft status should be reevaluated, and segmental myocardial function should be closely monitored for signs of improvement. If worsening occurs, if graft status is questionable, or if the patient's hemodynamic status is tenuous, additional revascularization should be considered.

Acute SWMA also may be due to unmasking areas of scarring by changes in LV afterload; that is, a marked increase in blood pressure may retard contraction more in an already damaged segment of myocardium than in a normal segment. However, this is an unlikely explanation for the acute SWMA reported in intraoperative studies to date. First, most new SWMA have occurred in segments of myocardium with normal contraction at baseline (after induction of anesthesia). Second, only marked changes in segmental contraction are judged indicative of ischemia. It is difficult to imagine that a sudden increase in afterload would cause one segment to cease or nearly cease contracting in the absence of changes in the other segments. Buffington and Coyle and others [57] [58] used an animal model to test the effects of extreme increases in afterload and demonstrated changes so minimal that they are unlikely to be detected with TEE. Third, with one exception (see next paragraph), there is no consistent correlation between hemodynamics and new SWMA.

The one exception was noted by Seeberger et al [59] during an experimental intraoperative stress-testing protocol. They observed new SWMA during marked preload reduction resulting from rapid atrial pacing in patients with baseline SWMA (presumably from prior infarction). Although some of the new SWMA induced in this protocol were due to myocardial ischemia (they had associated ST-segment changes and/or they persisted briefly after restoration of normal preload), others appeared not to be due to ischemia (no ST-segment changes and immediate resolution with restoration of preload). In a follow-up study using rapid phlebotomy, these investigators confirmed that sudden preload reduction can induce acute, nonischemic SWMA in patients with existing SWMA. [60] Thus, when a new SWMA is suspected and preload is markedly reduced, restoration of preload should be attempted prior to definitive assessment of segmental function.

DETECTION OF CARDIOVASCULAR DISORDERS

Aortic Pathology

Unlike most other sophisticated diagnostic tests, TEE can be performed rapidly at the patient's bedside or during surgery (Ch. 49) . As a result, TEE may be the diagnostic test of choice in patients with suspected aortic injury or aortic dissection. In 160 consecutive victims of blunt chest trauma, TEE correctly identified aortic injury in 14 patients and suggested it in 2 others, while producing no false-positive diagnoses. [61] In contrast, aortography required more time and produced one false-positive and four false-negative diagnoses. Moreover, TEE reliably differentiates two distinct patterns of injury: subadventitial disruptions, which require emergency surgery; and intimal tears, which do not. [62] However, TEE's diagnostic value in this clinical setting may depend on the operator or the patient population. [63] [64] [65]

For the detection of aortic dissection, TEE has proven superior to aortography and computed tomography. [66] [67] Although marginally less specific than magnetic resonance imaging for some dissections (those originating in the aortic arch), TEE requires less time and expense. [68] In patients with aortic dissection, delays in treatment can be fatal. However, TEE does not consistently image the origins of the innominate and left carotid arteries. Because of this limitation, TEE has only a 60 percent sensitivity for detection of arch vessel involvement in dissection, compared with 94 percent sensitivity for spiral computed tomography. [69]

In 130 patients older than 65 years who were undergoing coronary artery bypass grafting, TEE detection of protruding atheroma of the ascending aorta proved the only independent predictor of stroke--not age, previous stroke, carotid bruit, transient ischemic attacks, or surgical palpation of the ascending aorta. [70] In a related study, TEE detected protruding atheroma of the ascending aorta in ten patients scheduled for cardiopulmonary bypass: three of the six patients undergoing customary cardiopulmonary bypass sustained strokes, in contrast to none of the remaining four patients in whom surgical management was altered to circulatory arrest and aortic debridement. [71] Less aggressive approaches to this problem include alteration of the cannulation site to avoid "sand blasting" of the atheroma and raising the patient's blood pressure (50-90 mm Hg) during cardiopulmonary bypass to supply better collateral flow should cerebral embolus occur. [72] [73] Although one study indicated that TEE is not as sensitive as epiaortic scanning for detection

of atheromas of the aortic arch, it is an excellent screening tool: if TEE reveals no significant atheromas in the ascending or descending aorta, none are likely to be present in the aortic arch. [74] [75] Moreover, TEE-detected atheromatous disease of the descending aorta is a better predictor of significant coronary artery disease than conventional risk factors. [76]

Valvular Pathology

Intraoperatively, TEE commonly refines the preoperative diagnosis and reveals new findings with major implications. In 5 of 182 patients scheduled for coronary artery surgery, intraoperative TEE detected unsuspected mitral regurgitation so severe that it required unscheduled mitral valve repair. [77] Conversely, TEE performed before cardiopulmonary bypass revealed so little mitral valve dysfunction that mitral repair was omitted in 22 of 51 patients scheduled for combined coronary artery and mitral valve surgery. However, detailed assessment of valvular function can be very challenging, even for the most experienced echocardiographers. Nevertheless, with a modest degree of training, severe abnormalities are recognized readily with the help of color Doppler (see later). Comprehensive coverage of this topic is included in standard textbooks of echocardiography. [12] [13] [14] [78] [79] [80]

The degree of aortic stenosis is easily appreciated in the transverse plane, aortic valve short-axis cross-section in which the extent of leaflet opening sometimes can be directly measured with planimetry. [81] [82] [83] Multiplane TEE provides marginally more accurate assessment of anatomy and valve area than single-plane TEE, because with multiplane TEE the ultrasound beam can be more precisely aligned with the short axis of the aortic annulus than can be done with single-plane TEE, [84] but both reliably detect severe stenosis. [85] [86] Doppler studies in this cross-section reveal turbulence above the valve and in the sinuses of Valsalva, but they cannot quantify severity because blood flow is perpendicular to the ultrasound beam. In contrast, the transgastric five-chamber cross-section allows excellent alignment of the beam with blood flow for determination of the gradient across the valve [87] (Fig. 31-17) (Figure Not Available) . Additional information on the morphology of the aortic valve can be garnered from the longitudinal plane, ascending aorta cross-section.

Even modest degrees of aortic regurgitation can be clinically significant during cardiac surgery, producing LV distention during cardiopulmonary bypass and diminishing the effectiveness of antegrade cardioplegia. [88] With color Doppler, aortic regurgitation is easily recognized using the transverse plane, five-chamber cross-section (Table 31-5) (Table Not Available) . Mild regurgitation is characterized by a narrow-based, diastolic color jet (<2 mm at its origin in the valve) that occupies less than one-third of the cross-sectional area of the LV

Figure 31-17 (Figure Not Available) Continuous-wave Doppler estimation of aortic valve (AV) gradient. Continuous-wave Doppler measurement of blood flow velocities immediately above the AV during seven cardiac cycles is shown. At the top of the figure is a still-frame image of the two-dimensional cross-section used to position the Doppler sample cursor (diagonal white line). On the bottom two-thirds of the figure is the display in white of the instantaneous blood flow velocities (vertical axis) versus time (horizontal axis) occurring anywhere along that cursor. The electrocardiogram is shown for timing purposes, and the gray horizontal line running through the Doppler tracing is the baseline (zero flow) for the flow velocities. With this Doppler alignment, all flow velocities are negative (i.e., away from the transducer). The Doppler scale has been set to a maximum of -629 cm/s, and this tracing documents significant aortic stenosis: a peak blood flow velocity of approximately 4 m/s (each white dot on the vertical axis equals 100 cm/s or 1 m/s) corresponding to a peak gradient across the AV of 64 mm Hg. LV, left ventricle. *(From Cahalan [21])*

TABLE 31-5 -- Simplified Grading Criteria for Aortic Insufficiency [a]

(Not Available)

From Cahalan [21]

[a] Diastolic jet width is assessed with color Doppler in the five-chamber view at the closure point of the aortic valve (the origin of the regurgitant jet). The transducer should be repositioned until the origin of the jet is clearly imaged. Failure to image the origin of the jet may lead to overestimation of its severity. Diastolic jet area is assessed with color Doppler in the five-chamber view. % of LVOT is the percentage of the LVOT occupied by the plume of the color jet (the area of turbulent flow depicted by the mosaic of color pixels). This parameter is markedly affected by aortic diastolic pressure. Failure to adjust color or two-dimensional gains correctly may lead to underestimation or overestimation of the severity of the regurgitation. Color gain should be set just below the level that results in random color sparkle, and two-dimensional gains should be set at the minimum levels allowing adequate visualization of cardiac structures. Diastolic jet depth is assessed with color Doppler in the 5-chamber view. The length of penetration of the jet from the LVOT into the LV is estimated in centimeters. This parameter is also markedly affected by aortic diastolic pressure and gain settings.

outflow tract and extends minimally into the LV (1-2 cm). Moderate regurgitation is a broader-based, diastolic color jet (3-5 mm) occupying less than two-thirds of the cross-sectional area of the LV outflow tract and extending moderately into the LV (3-5 cm). Severe regurgitation is a broad-based, diastolic color jet (>5 mm) occupying all the LV outflow tract and extending well into the LV (Color Plate 31-12 (Figure Not Available)). If the LV outflow tract is not visible in the five-chamber view because of an intervening mitral prosthesis, the longitudinal cross-section of the ascending aorta or the transgastric five-chamber cross-section may be excellent alternative views for the evaluation of aortic regurgitation.

The presence and severity of mitral stenosis are easily determined with TEE using the transverse plane, four- or five-chamber cross-sections and the longitudinal plane, two-chamber and midpapillary long-axis cross-sections. 2-D imaging reveals thickened leaflets that dome toward the LV and open poorly. Color Doppler reveals laminar flow acceleration into the stenotic orifice and a turbulent jet emerging into the ventricle (Color Plate 31-13 (Figure Not Available)). PW and CW Doppler traces display a characteristic flow pattern with increased peak and mean velocities (Fig. 31-18) (Figure Not Available) . Although mathematical evaluation of these traces is the most precise method to

Figure 31-18 (Figure Not Available) Continuous-wave Doppler evaluation of mitral stenosis. Continuous-wave Doppler measurement of blood flow velocities through a stenotic mitral valve is shown. At the top of the figure is a still-frame image of the four-chamber cross-section used to position the Doppler cursor. On the bottom two-thirds of the figure is the display in white of the instantaneous blood flow velocities (vertical axis) versus time (horizontal axis) occurring anywhere along that cursor. The electrocardiogram (ECG) is shown for timing purposes. The horizontal line through the base of the Doppler tracing is the baseline (zero flow) for the flow velocities. Velocities displayed above the baseline are positive and represent flow toward the transducer. These velocities are due to mitral regurgitation and are so high they exceed the scale used in this example. Velocities displayed below the baseline are negative and represent flow away from the transducer. These velocities are due to severe mitral stenosis and average about 2 m/s indicating a gradient across the mitral valve of 16 mm Hg. Also note how slowly the flow velocity decreases after the peak of the E wave (indicated in the figure by "Slope"). The pressure half-time can be calculated from this slope and is markedly increased in the presence of severe mitral stenosis. *(From Cahalan [21])*

assess the severity of mitral stenosis, [15] [16] [89] no mathematics is required to recognize severe mitral stenosis. In addition to the signs noted earlier, severe mitral stenosis always causes marked left atrial enlargement and left atrial spontaneous contrast. Spontaneous contrast is a swirling, smoke-like appearance of 1- to 2-mm densities not due to exogenously administered contrast agents, but to aggregation of red cells in areas of low flow. Whenever left atrial enlargement and spontaneous contrast are noted, thrombus in the left atrium and, in particular, in the left atrial appendage should be suspected and excluded. [90] [91] [92] [93] [94]

The presence and severity of mitral regurgitation are evaluated from the same cross-sections used for evaluation of mitral stenosis and with the same grading strategy used for aortic regurgitation (Table 31-6) (Table Not Available) . Mild regurgitation is characterized by a narrow-based, systolic color jet (<2 mm at its origin in the valve) that occupies less than 25 percent of the left atrial cross-sectional area and extends less than half of the distance to the posterior wall of the left atrium. Moderate regurgitation is a broader-based, systolic color jet (3-5 mm at its origin in the valve) occupying less than 50 percent of the left atrial cross-sectional area and extending 50 to 90 percent of the distance to the posterior wall of the left atrium. Severe regurgitation is a broad-based, systolic color jet (>5 mm) occupying most of the left atrium and extending into the pulmonary veins and left atrial appendage [95] [96] [97] [98] (Fig. 31-19) (Figure Not Available) .

TABLE 31-6 -- Simplified Grading Criteria for Mitral Regurgitation [a]

(Not Available)

From Cahalan [21]

[a] Systolic jet width is assessed with color Doppler in the five- or four-chamber view at the closure point of the mitral valve (the origin of the regurgitant jet). The transducer should be repositioned until the origin of the jet is clearly imaged. Failure to image the origin of the jet may lead to overestimation of its severity. Systolic jet area is assessed with color Doppler in the five- or four-chamber view. $\%LA_a$ is the percentage of the LA_a occupied by the plume of the color jet (the area of turbulent flow depicted by the mosaic of color pixels). This parameter is markedly affected by left ventricular systolic pressure. Failure to adjust color or two-dimensional gains correctly may lead to underestimation or overestimation. Color gain should be set just below the level that results in random color sparkle, and two-dimensional gains should be set at the minimum levels allowing adequate visualization of cardiac structures. Systolic jet depth is assessed with color Doppler in the five- or four-chamber view. $\%LA_d$ is the depth of the penetration of the jet into the LA expressed as a percentage of the distance from the mitral annulus to the posterior wall of the left atrium. This parameter is also markedly affected by left ventricular systolic pressure. In severe mitral regurgitation, the regurgitant jet may extend into one or more pulmonary veins and may cause transient reversal of pulmonary venous blood flow.

Figure 31-19 (Figure Not Available) Pulmonary vein flow reversal and severe mitral regurgitation. Pulsed-wave Doppler measurement of blood flow velocities in the left upper pulmonary vein (LUPV) is shown. At the top of the figure is a still-frame image of the two-dimensional cross-section used to position the Doppler sampling volume (white circle). On the bottom two-thirds of the figure is the display of the instantaneous blood flow velocities (vertical axis) versus time (horizontal axis) occurring in the LUPV. The electrocardiogram (ECG) is shown for timing purposes, and the horizontal line running through the Doppler tracing is the baseline (zero flow) for the flow velocities. Velocities displayed above the baseline are positive and represent flow toward the transducer (in this case, into the left atrium [LA]). Velocities displayed below the baseline are negative and represent flow away from the transducer (in this case, into the LUPV). This Doppler tracing documents systolic flow reversal (normally it is positive, that is, toward the LA in systole) and confirms the presence of severe mitral regurgitation. *(From Cahalan [21])*

Figure 31-20 (Figure Not Available) Severe mitral regurgitation with wall-hugging jet. This honed-down five-chamber echocardiogram reveals severe mitral regurgitation. The long color jet (depicted in gray in this image) has a fairly broad base and an eccentric direction indicating severe mitral regurgitation. Wall-hugging jets such as this one have a small cross-sectional area because much of their energy is absorbed by the wall of the atrium. The mechanism of the regurgitation is apparent: the anterior leaflet (on the left side of the video screen) is prolapsing, allowing blood to escape beneath it and to jet over the surface of the posterior leaflet into the left atrium (LA). LV, left ventricle; MV, mitral valve. *(From Cahalan [21])*

Eccentrically directed jets of mitral regurgitation that hug the wall of the atrium generally are associated with more severe valvular regurgitation than their cross-sectional area may suggest [99] (Fig. 31-20) (Figure Not Available) . Moreover, eccentrically directed jets usually point away from the defective leaflet (i.e., laterally directed jets usually are associated with anterior leaflet defects, and medially directed jets are associated with posterior leaflet defects). [100]

The general guidelines listed earlier are widely used, but at least 20 more criteria have been described for assessment of mitral regurgitation. [101] Most important, the degree of regurgitation may be exquisitely dependent on LV loading conditions and papillary muscle perfusion. For practical purposes, quantitative measures of the regurgitant orifice area, for example, calculations based on the theory of proximal isovelocity surface area (PISA) are rarely used in most operating rooms, because they are too time-consuming and require meticulous technique. [102] Fortunately, simply using the width of the base of the regurgitant jet (as described earlier) may be more accurate in estimating mitral regurgitation severity and may be less susceptible to alterations in loading conditions than other more complicated methods. [103] [104] Pulmonary and tricuspid valve disorders are assessed in a fashion analogous to that just described for the aortic and mitral valves.

ASSESSMENT OF SURGICAL REPAIRS

Adults

TEE has profoundly affected valvular heart surgery (Chs. 49 and 50) . It provides the surgical team with a definitive evaluation of valvular function immediately before and after the surgical intervention, thereby allowing surgery to be revised if necessary and flawed repairs to be corrected before leaving the operating room. Morbidity and mortality are reduced if the patient leaves the operating room with the most appropriate and properly functioning repair. In a study of 154 patients undergoing valve surgery at Duke University in Durham, North Carolina, [105] TEE detected new findings that changed the surgical plan prior to cardiopulmonary bypass in 29 patients (19%). The most common new finding of major importance was detection of unsuspected valvular insufficiency in seven patients (5%) resulting in unscheduled surgery of the affected valves. Other findings with major surgical implications included unsuspected left atrial thrombi (three patients), unsuspected atrial septal defects (two patients), and unsuspected ascending aortic dissection (one patient). In one other patient, TEE revealed adequate mitral function, and the scheduled mitral operation was canceled. Following cardiopulmonary bypass, TEE documented unsatisfactory repairs in ten patients (6%) resulting in immediate further surgery. Although six of these patients had abnormal V waves or elevated pulmonary capillary wedge pressures, four patients had normal hemodynamics, and their defective repair was detected only by TEE. At the conclusion of surgery, TEE revealed adequate valvular function in 123 patients (80%): 18 of these patients (15%) suffered a major postoperative complication, and 6 died (5%). In contrast, TEE revealed moderate valve dysfunction in seven (5%) patients: six of these patients suffered major complications (86%), and three died (50%).

In a similar study at the Mayo Clinic in Rochester, Minnesota, [106] TEE detected 3+ mitral regurgitation after the first attempt at mitral valve repair in 11 (8%) of 143 patients and severe systolic anterior motion of the mitral leaflet in 13 (9%) patients. This motion of the mitral leaflet refers to an abnormal, septally directed motion of the anterior mitral leaflet during systole (best seen in the 5-chamber cross-section) which partially opens the mitral valve and obstructs the LV outflow tract. TEE verified that the systolic anterior motion resolved with restoration of normal hemodynamics in 8 of these 13 patients, without surgical intervention. Although traditional methods of assessing mitral valve function during surgery may detect some failed repairs, [107] they are not highly reliable and do not reveal the mechanism of failure, a key factor in the decision to repeat the repair or replace the valve. [108] [109] [110]

TEE may change the course of coronary artery surgery. In a study of 88 patients deemed to be at high risk for perioperative complications, Savage et al [111] reported that TEE had a major effect on anesthetic management in 51 percent of patients and on surgical management in 33 percent of patients including revised or unplanned coronary grafts in 15 percent of the patients and unplanned valve procedures in 20 percent. In this high-risk study group, the incidence of myocardial infarction (1.2%) and death (1.2%) was less than in a comparable group of patients in whom TEE was not used (3.8 and 3.5%, respectively). This difference did not reach statistical significance. In infants and children, TEE reliably detects congenital heart defects including residual defects that require immediate reoperation. [112] [113] [114]

COMPLICATIONS

Most of the reported complications of TEE have occurred in outpatients and have been associated with the stress response that awake or minimally sedated patients experience while swallowing the probe. However, a low incidence of oral and pharyngeal injuries (0.1-0.3%) has been reported, [115] but in other studies, the incidence of postoperative gastrointestinal complaints did not differ significantly from that in comparable patients who had not undergone TEE. [116] [117] [118] One early report described two patients who suffered temporary unilateral vocal cord paralysis after TEE monitoring during "sitting" craniotomies. [119] Both patients were positioned with nearly full neck flexion, likely resulting in injury to the recurrent laryngeal nerve when the larynx, endotracheal tube, and shaft of the gastroscope were compressed between the chin and vertebral column. Subsequent, uncontrolled studies reported a 0.1 to 12 percent incidence of transient hoarseness after TEE. [116]

Serious pharyngeal or esophageal injury following TEE has been reported, but it is rare. [120] [121] [122] [123] [124] [125] [126] [127] Among 10,218 patients (European multicenter study) undergoing TEE (primarily outpatients), esophageal perforation occurred in 1 patient, who subsequently died; autopsy revealed a malignant tumor invading the esophagus. [128] Although bacteremia during TEE is uncommon, [129] [130] endocarditis has been reported in outpatients. [131] [132] Endocarditis from intraoperative TEE has not been reported, and the risk is probably near zero because antibiotics are usually administered. In infants, even an appropriate-sized TEE probe may occasionally obstruct the airway distal to the endotracheal tube or may compress the descending aorta. [133] [143] In our experience in neonates, TEE may be associated with inadvertent extubation.

INDICATIONS

In 4 to 33 percent of patients undergoing cardiac surgery, information provided by TEE has a major effect on surgical management. [71] [77] [105] [106] [109] [111] [112] [135] [136] [137] [138] [139] Because the patients who will benefit from TEE cannot be reliably identified prior to cardiac surgery, because TEE is an exceedingly low-risk procedure, and because surgical complications and reoperations potentially avoidable with TEE are extremely expensive, TEE is likely to be quite cost-effective for cardiac surgical programs to employ routinely. [114] [140] Some types of minimally invasive cardiac surgery cannot be performed without it. [141]

In other patient populations, the indications for TEE are less clear. In patients with thoracic trauma or suspected aortic dissection, TEE may be the diagnostic test of choice prior to surgery because TEE is diagnostically reliable and faster than alternative techniques. [62] [66] [67] [68] [142] [143] [144] If a pulmonary artery catheter is planned principally for intraoperative monitoring, TEE should be considered as a potentially more informative and lower-risk alternative. Whenever marked intraoperative hemodynamic changes are anticipated in patients unlikely to tolerate such changes, TEE should be considered. In persistently hypotensive patients and those with low output syndromes who fail to respond to initial therapy, TEE should be used--the presumed diagnosis may be wrong. In one study, TEE corrected erroneous diagnoses (based on standard hemodynamic measurements) in one-half of patients with persistent hypotension following cardiac surgery. [26] TEE also should be considered for monitoring neurosurgical patients at special risk for air embolism, because TEE is more sensitive than alternative monitors for detection of intravascular air and readily reveals paradoxic transit of air. [145] Finally, TEE should be considered whenever it is likely to reveal information that will alter care significantly and comparable information cannot be obtained with less costly or less invasive procedures.

The perioperative guidelines for TEE published by the American Society of Anesthesiologists and the Society of Cardiovascular Anesthesiologists Task Force go beyond the foregoing recommendations by delineating three categories of TEE applications. [146] Category I applications are supported by the strongest evidence, are frequently useful in improving outcome, and are often indicated depending on individual circumstances. Examples of category I applications include TEE in patients undergoing valvular heart surgery and in patients with persistent, severe hypotension of unknown origin. Category II applications are supported by weaker evidence, may be useful in improving outcome, and may be indicated depending on individual circumstances. Examples of category II applications include monitoring hemodynamics and detection of myocardial ischemia in high-risk patients. Category III applications are supported by little evidence and are infrequently useful in improving outcome. The indications for category III applications are uncertain. Examples of category III applications include assessment of myocardial perfusion (contrast echocardiography) and detection of embolic events during orthopedic surgery.

Three important caveats apply to these guidelines. First, these guidelines are for anesthesiologists who practice TEE, not for all anesthesiologists. Second, these guidelines do not state that TEE must be used in any clinical setting, because they recognize that variations in medical needs, resources, and expertise may dictate better alternatives. Third, these guidelines state that deviations from them are expected, and the individual anesthesiologist should have great latitude in determining when TEE is appropriate for a particular patient. Expert opinion was used in the formulation of the guidelines, but only when objective evidence was lacking, and never as the sole reason for classifying an application as category I. In addition, the Task Force report defines two levels of TEE training and practice: a basic level in which TEE is used for indications that lie within the customary practice of anesthesiology (i.e., assessment of ventricular filling and function); and an advanced level in which TEE is utilized to its full perioperative diagnostic potential (i.e., evaluation of surgical repairs and other complex diagnostic applications). Cognitive and technical skills required to achieve these levels are delineated, but no arbitrary number of cases is specified. These guidelines are intended for anesthesiologists who practice TEE and not for others who use alternative diagnostic techniques. Moreover, these guidelines should prove more applicable and appropriate for anesthesiology than guidelines published by other specialties. [147]

Figure 31- (Figure Not Available) **Color Plate 31-1.** "Normal" color Doppler aliasing. In this five-chamber echocardiogram, "normal" color Doppler aliasing is seen because laminar flow of blood through the mitral valve and into the left ventricle (LV) exceeds the Nyquist limit (68 cm/s in this example--see color reference icon at upper right of figure) resulting in reversal of the color coding of flow direction. Notice that this color reversal occurs across fairly broad, regular areas, and not in a random or point-by-point fashion, as occurs with turbulent flows (always abnormal). In this example, follow the blue flow from high in the left atrium (LA) as it accelerates into the mitral orifice and notice how color Doppler depicts the increasing flow velocities: the blue color becomes lighter and lighter until the Nyquist limit is reached. Then, color reversal occurs with light blue becoming yellow. Just at that reversal point, the velocity equals the Nyquist limit, in this example 68 cm/s. Subsequent reversals may occur at that limit or at multiples of that limit. RA, right atrium; RV, right ventricle. (From Cahalan [21])

Figure 31- (Figure Not Available) **Color Plate 31-2.** Color Doppler aliasing depicting turbulent flow. In this five-chamber echocardiogram, color Doppler reveals aliasing due to severe mitral regurgitation: a broad-based systolic color jet emanating from the mitral valve and extending far into the left atrium (LA). This jet is composed of a mosaic of colors mixed in a seemingly random, point-by-point fashion, because the jet results from the turbulent flow of mitral regurgitation. Turbulence is never normal in the heart, and thus mosaic jets such as the one shown here are highly valuable diagnostic signs of underlying pathology. LV, left ventricle; LVOT, LV outflow tract. (From Cahalan [21])

Figure 31- (Figure Not Available) **Color Plate 31-3.** Transversely oriented ultrasound beam directed through the aortic valve. The left side of this illustration depicts the spatial relationships between the probe, ultrasound beam, and anatomic structures when the beam is directed to produce the short-axis cross-section of the aortic valve. Chapter 32 - Electrocardiography

Zaharia Hillel
Daniel M. Thys

INTRODUCTION

The intraoperative use of the electrocardiogram (ECG) has markedly developed over the past several decades. [1] Originally, this monitor was used during anesthesia for the detection of arrhythmias in high-risk patients. [2] At that time, standard limb lead II was displayed, because its electrical axis parallels the electrical axis of the heart and the P wave is usually easily observed. In recent years, the importance of ECG as a standard monitor has been recognized, and its use during the conduct of any anesthetic regimen is now recommended. [3] Beyond the usefulness of ECG for the recognition of intraoperative arrhythmias, one of the major indications for ECG monitoring is the intraoperative diagnosis of myocardial ischemia. [4] Despite widespread attempts at prevention, coronary artery disease continues to be a major health problem in the United States. Patients undergoing different types of surgical procedures have significant coronary artery disease, and in these patients, the ECG should be used to identify myocardial ischemia as well as to recognize arrhythmias. With many patients now coming to surgery with pacemakers in place, the ECG also enables the physician to follow the function of the device during the surgical procedure. Since the first utilization of the ECG during anesthesia, the technology available to the anesthesiologist has become considerably more sophisticated. The aim of this chapter is to familiarize the reader with some of the newer developments in the use and interpretation of the ECG.

NORMAL ELECTRICAL ACTIVITY

P Wave

A complete ECG cycle, intervals, and segments are shown in Figure 32-1 . Under normal circumstances, the sinoatrial (SA) node has the most rapid spontaneous depolarization rate and is therefore the dominant cardiac pacemaker (Table 32-1) . From the SA node, the impulse spreads through the right and left atria. Specialized tracts conduct the impulse to the atrioventricular (AV) node, but they are not essential. The three selective inputs to the AV node are (1) the right superior "fast" pathway, (2) the right superior "slow" pathway, and (3) a left-sided, less well-characterized pathway. On the ECG, depolarization of the atria is represented by the P wave. The initial depolarization involves primarily the right atrium and occurs predominantly in an anterior, inferior, and leftward direction. Subsequently, it proceeds to the left atrium, located in a more posterior position.

P- R Interval

Once the depolarization has reached the AV node, a delay is observed. The delay permits contraction of the atria and supplemental filling of the ventricular chambers. On the ECG, it is represented by the P-R interval.

QRS Complex

After passage through the AV node, the electrical impulse is conducted along the ventricular conduction pathways

Figure 32-1 A single normal ECG cycle with waves, segments, and intervals identified.

consisting of the common bundle of His, the left and right bundle branches, the distal bundle branches, and the Pur-kinje fibers. The QRS complex represents the progress of the depolarization wave through this conduction system. After terminal depolarization, the ECG should normally return to baseline.

ST Segment and T Wave

Repolarization of the ventricles begins at the end of the QRS complex and consists of the ST segment and T wave. Whereas ventricular depolarization occurs along established conduction pathways, ventricular repolarization is a prolonged process that occurs independently in every cell. The T wave represents the uncanceled potential differences of ventricular repolarization. The junction of the QRS and the ST segment is called the J junction. The T wave is sometimes followed by a small U wave, the origin of which is unclear. An inverted U wave has been associated with several clinically significant conditions, such as hypertension, coronary artery disease, valvular heart disease, and certain metabolic disorders. There may be an association between exercise- or rest-related U-wave inversion and significant stenosis of the left anterior descending artery or the left main coronary artery.

TABLE 32-1 -- Spontaneous Electrical Activity of Cardiac Tissues

TISSUE	INTRINSIC DEPOLARIZATION RATE (BEATS/MIN)
Sinoatrial node	>60
Atrioventricular node	40-60
Purkinje fibers	<40

Figure 32-2 (Figure Not Available) Einthoven triangle. *(From Thys and Kaplan [1])*

LEAD SYSTEMS

Standard Limb and Precordial Leads

The small electric currents produced by the electrical activity of the heart spread throughout the body, which behaves as a volume conductor, allowing the surface ECG to be recorded at any site. The standard leads are bipolar leads, because they measure differences in potential between pairs of electrodes. The electrodes are placed on the right arm, the left arm, and the left leg. The leads are formed by the imaginary lines connecting the electrodes, and the polarities correspond to the conventions of the Einthoven triangle (Fig. 32-2) (Figure Not Available) . They are labeled leads I, II, and III. If the 3 electrodes of the standard leads are connected through resistances of 5,000 ohms each, a common central terminal with zero potential is obtained. When this common electrode is used with another exploring electrode, the potential difference between them represents the actual potential (Fig. 32-3) (Figure Not Available) . On a standard 12-lead ECG, 3 unipolar limb

Figure 32-3 (Figure Not Available) Unipolar limb lead circuit (VR). *(From Thys and Kaplan [1])*

Figure 32-4 (Figure Not Available) Goldberger modification to the unipolar lead aVR. *(From Thys and Kaplan [1])*

leads are usually recorded: aVR, aVL, and aVF. The "a" indicates that they are augmented limb leads and were obtained using the Goldberger modification (Fig. 32-4) (Figure Not Available) . In this modification, the resistors are removed from the circuit, and the exploring electrode is disconnected from the central terminal. This modification produces larger ECG deflections.

Additional information on the heart's electrical activity is obtained by placing electrodes closer to the heart or around the thorax. In the precordial lead system, the neutral electrode is formed by the standard leads, and an exploring electrode is placed on the chest wall. The ECG is normally recorded with the exploring electrode in one, or more, of six precordial positions. They are indicated by the letter V, followed by a numeral from 1 to 6 indicating the location of the electrode on the chest wall (Fig. 32-5) (Figure Not Available) .

ECG Monitoring Systems

Three-Electrode System

As the name implies, the three-electrode system uses only three electrodes to record the ECG. In such a system, the ECG is observed along one bipolar lead between two of the electrodes while the third electrode serves as a ground. A selector switch allows the user to alter the designation of the electrodes. Three ECG leads can be examined in sequence without changing the location of the electrodes. Although the three-electrode system has the advantage of simplicity, its use is limited in myocardial ischemia because it provides a narrow picture of myocardial electrical activity.

Modified Three-Electrode System

Numerous modifications of the standard bipolar limb lead system have been developed. Some of these are displayed in Figure 32-6 (Figure Not Available) . They are used in an attempt to maximize P-wave height for the diagnosis of atrial arrhythmias or to increase

Figure 32-5 (Figure Not Available) Anatomic location of the precordial unipolar leads V_1-V_6. *(From Thys and Kaplan [1])*

the sensitivity of the ECG for the detection of anterior myocardial ischemia. In clinical studies, these modified three-electrode systems have been shown to be as sensitive as or more sensitive than the standard V_5 lead system for the intraoperative diagnosis of ischemia. [5]

Central Subclavicular Lead

The central subclavicular (CS_5) lead is particularly well suited for the detection of anterior myocardial wall isch-emia. The right arm (RA) electrode is placed under the right clavicle, the left arm (LA) electrode is placed in the V_5 position, and the left leg electrode is in its usual position to serve as a ground. Lead I is selected for detection of anterior wall ischemia, and lead II can be selected for monitoring inferior wall ischemia or for the detection of arrhythmias. If a unipolar precordial electrode is unavailable, this CS_5 bipolar lead is the best and easiest alternative to a true V_5 lead for monitoring myocardial ischemia.

Central Back Lead

The central back (CB_5) lead is good for the detection of ischemia and supraventricular arrhythmias as demonstrated in a study comparing CB_5 and V_5 in patients with closed and open chests. [6] The P wave was 90 percent larger than in lead V_5, whereas a good correlation between ventricular deflections of CB_5 and V_5 leads was noted. CB_5 is obtained by placing the RA electrode over the center of the right scapula and the LA electrode in the V_5 position. The lead selector switch should be on lead I. The CB_5 lead may be useful in patients with ischemic heart disease, who are susceptible to the development of arrhythmias during the perioperative period.

Figure 32-6 (Figure Not Available) Modified bipolar standard limb lead system: MCL_1, CS_5, CM_5, CB_5, CC_5. *(From Thys and Kaplan [1])*

When modified bipolar limb leads are used, monitoring personnel should be aware that in certain aspects these leads differ significantly from true unipolar precordial leads. The modified precordial leads usually show a greater R-wave amplitude than standard precordial leads, and this feature can result in amplification of the ST-segment response.

The criteria for diagnosing myocardial ischemia (see later) may therefore need to be adjusted when modified bipolar leads are used. It has been shown during exercise stress testing that normalization of the degree of ST-segment depression to the height of the R wave increases the sensitivity and specificity of ECG for the

recognition of myocardial ischemia. [7] In an intraoperative study, Mark et al [8] noted that during cardiac surgery, placement of a Canadian sternal retractor was associated with a reduction in V_5 R-wave amplitude from 15 ± 1 to 10 ± 1 mm. Simultaneously, V_5 S-wave amplitude and absolute ST-segment deviation were reduced from 3.5 ± 0.4 to 1.7 ± 0.3 mm and from 0.50 ± 0.04 to 0.39 ± 0.05 mm, respectively (Table 32-2) (Table Not Available) . Mark et al concluded that their results support the proposal

TABLE 32-2 -- Electrocardiographic Changes During Sternal Retractor Placement in 83 Patients

(Not Available)

(Modified from Mark et al [8])

that inclusion of an R-wave gain factor may improve perioperative ECG monitoring.

Five-Electrode System

The use of five electrodes allows the recording of the six standard limb leads (I, II, III, aVR, aVL, aVF), as well as one precordial unipolar lead. Generally, the unipolar lead is placed in the V_5 position, along the anterior axillary line in the fifth intercostal space (Fig. 32-7) (Figure Not Available) . With the addition of only two electrodes to the ECG system, up to seven different leads can be monitored simultaneously. This allows one to monitor several areas of the myocardium for ischemia or to establish a differential diagnosis between atrial and ventricular arrhythmias.

In 1976, Kaplan and King [9] suggested monitoring lead V_5 as the best choice for the detection of intraoperative isch-emia. Using a single lead, London et al [10] demonstrated that, in high-risk patients undergoing noncardiac surgery, the greatest sensitivity was obtained with lead V_5 (75%), followed by lead V_4 (61%). Combining leads V_4 and V_5 increased the sensitivity to 90 percent, whereas with the standard lead II and V_5 combination, the sensitivity was only 80 percent. London and colleagues also suggested that if three leads (II, V_4 , and V_5) could be examined simultaneously, the sensitivity would rise to 98 percent. Most modern ECG monitors, however, do not readily allow the simultaneous display of more than one precordial lead. Some investigators have also suggested that the monitoring of a right-sided precordial lead (V_{4R}) may be of benefit in patients with occlusive disease of the right coronary artery. [11]

Great individual variability in the placement of precordial leads is a problem that has been recognized. In an attempt to reduce the error, Herman et al [12] studied a device that facilitates precordial lead placement. ECG obtained after device-guided electrode placement showed variations with those obtained without it in 60 percent of patients. Significant Q-wave appearance/disappearance and/or significant

Figure 32-7 (Figure Not Available) Multiple lead ECG system consisting of four extremity electrodes and the V_5 lead. RA = right arm, LA = left arm, RL = right leg, LL = left leg. *(From Narang and Thys [3])*

ST-segment elevation/depression occurred in 19 percent of patients.

Invasive Electrocardiographic Monitoring

The electrical potentials of the heart can be measured not only from a surface ECG but also from body cavities adjacent to the heart (esophagus or trachea) or from within the heart itself.

Esophageal ECG

The concept of esophageal ECG is not new; numerous studies have demonstrated the usefulness of this approach in the diagnosis of complicated arrhythmias. The esophageal electrodes are incorporated into an esophageal stethoscope and are welded to conventional ECG wires (Fig. 32-8) (Figure Not Available) . A prominent P wave is usually displayed in the presence of atrial depolarization, and its relation to the ventricular electrical activity can be examined (Fig. 32-9) (Figure Not Available) . To observe a bipolar esophageal ECG, the electrodes are connected to the right and left arm terminals and lead I is selected on the monitor.

Figure 32-8 (Figure Not Available) The Cardioesophagoscope. The esophageal leads are made of plastic. The ECG wires are connected to the right and left arms, with lead I selected on the ECG monitor. *(From Narang and Thys [3])*

Figure 32-9 (Figure Not Available) Enhanced detection of atrial electrical activity using the esophageal ECG (EsECG). EsECG demonstrates arrhythmia progression from normal sinus rhythm (NSR), with one premature contraction (PAC), to atrial flutter (A flutter) and atrial fibrillation (A fibrillation). Lack of information about atrial activity from lead V_5 made definitive diagnosis impossible. *(From Thys and Kaplan [1])*

In a study of 20 cardiac patients, 100 percent of atrial arrhythmias were correctly diagnosed with the esophageal lead (using intracavitary ECG as the standard), whereas lead II led to a correct diagnosis in 54 percent of the cases and V_5 in 42 percent of cases (Table 32-3) (Table Not Available) . [13] Additionally, the esophageal ECG may be helpful in the detection of posterior wall ischemia because of its proximity to the posterior aspect of the left ventricle (Fig. 32-10) (Figure Not Available) . To minimize the risk of esophageal burn injury, an electrocautery protection filter capable of filtering radiofrequencies greater than 20 kHz should be inserted between the ECG cable and the esophageal lead.

Several investigators have described devices that allow both ECG recording from the esophagus and pacing of the heart using the same device. [14] Esophageal electrodes have been found particularly useful in patients with emphysema or in critically ill patients in whom satisfactory surface ECG cannot be obtained. [15] [16]

Intracardiac ECG

For many years, long saline-filled central venous catheters have been used to record intracardiac ECG. More recently, Chatterjee et al [17] described the use of a modified balloon-tipped flotation catheter for recording intracavitary ECG (Fig. 32-11) (Figure Not Available) . The multipurpose pulmonary artery catheter that is currently available has all the features of a standard pulmonary artery catheter. In addition, three atrial and two ventricular electrodes have been incorporated into the catheter. These electrodes permit recording of intracavitary ECG and the establishment of atrial or AV pacing. The diagnostic capabilities with this catheter are great because atrial, ventricular, or AV nodal arrhythmias and conduction blocks can be demonstrated. The large voltages obtained from the intracardiac electrodes are relatively insensitive to electrocautery interference, thus making them useful for intraaortic balloon pump triggering. [18] Other pulmonary artery catheters have ventricular and atrial ports that allow passage of pacing wires. These catheters can also be used for diagnostic purposes, as well as for therapeutic interventions (pacing).

Endotracheal ECG

The endotracheal ECG allows monitoring of the ECG when it is impractical or impossible to monitor the surface ECG. The endotracheal ECG consists of a standard endotracheal tube in which two electrodes have been embedded (Fig. 32-12) (Figure Not Available) . This device may be most useful in pediatric patients for the diagnosis of atrial arrhythmias. [19] The same safety precautions as for esophageal ECG (see earlier) should be followed.

Intracoronary ECG

The clinical use, during angioplasty, of a coronary guide wire for the recording of intracoronary ECG was first reported during 1985. [20] The major advantage was perceived to be a greater detection of acute ischemia than with surface ECG.

TABLE 32-3 -- Comparison of Esophageal and Standard Electrocardiography for Correct Arrhythmia Diagnosis in 20 Patients

(Not Available)

(Modified from Kates et al [13])

Figure 32-10 (Figure Not Available) Tracing of EsECG, II, and V_5 showing posterior ischemia. *(From Kates et al [13])*

In a study of 300 consecutive patients, intracoronary ECG detected ST-segment changes in 83 percent of lesions, versus 67 percent on surface ECG. [21] Maeda et al [22] noted a more rapid shortening of the Q-T interval with intracoronary ECG than with surface ECG after angioplasty balloon inflation.

DISPLAY, RECORDING, AND INTERPRETATION

The American Heart Association (AHA) has published instrumentation and practice standards for ECG monitoring in special care units. [23] They consist of performance standards, performance requirements, and disclosure requirements. Some of the recommendations include that monitors be able simultaneously to display and to analyze multiple leads and that users be informed of minimally acceptable accuracy in a standardized manner. Many of the principles detailed in these standards are also applicable to intraoperative monitoring.

Basic Requirements

The function of the ECG monitor is to detect, amplify, display, and record the ECG signal. The ECG is usually displayed on an oscilloscope. Several monitors now offer nonfade storage oscilloscopes to facilitate wave recognition. All ECG monitors for use in patients with cardiac disease should also have paper recording capabilities. The recorder is needed to make accurate diagnoses of complex arrhythmias, as well as to allow careful analysis of all the ECG waveforms. In addition, the recorder allows one to differentiate real ECG changes from artifacts.

Oscilloscope Displays

Most modern oscilloscopes are high-resolution monochrome or color monitors, similar to those used in computer technology. They frequently allow considerable flexibility in screen configuration, including waveform positions, colors, and sweep speeds. The norm in modern technology is to display three ECG channels simultaneously. These usually consist of two limb leads and one unipolar precordial lead. In addition to the waveforms, average heart rates and optional arrhythmia and ST-segment information are displayed in alphanumeric format (see later).

Standard ECG Recordings

The ECG is normally recorded on special paper consisting of grids of horizontal and vertical lines. Distances between vertical lines represent time intervals, whereas distances between horizontal lines represent voltages. The

Figure 32-11 (Figure Not Available) The multipurpose pacing pulmonary artery catheter. Three atrial and two ventricular electrodes can be seen. *(From Narang and Thys [5])*

Figure 32-12 (Figure Not Available) Diagram of tracheal tube ECG system. *(From Narang and Thys [5])*

lines are 1 mm apart, with every fifth line intensified. The speed of the paper is standardized to 25 mm/s. Therefore, on the horizontal axis, 1 mm represents 0.04 second and 0.5 cm represents 0.20 second. On the vertical axis, 10 mm represents 1 mV. On every recording, a 1-cm (1-mV) calibration mark should indicate that the ECG is appropriately calibrated. The user should follow the manufacturer's recommended calibration procedure for each monitoring episode. Strip chart recorders that are part of an ECG monitoring system should meet all the standards of time base accuracy, frequency response, linearity, and so forth, proposed for conventional ECG recording systems. [24] [25]

Artifacts

The Patient

The electrical signal generated by the heart and monitored by the ECG is very weak, amounting to only 0.5 to 2 mV at the skin surface. It is therefore imperative that the skin be prepared optimally, to avoid signal loss at the skin-electrode interface. Hair should be removed from the electrode sites with scissors and shavers. The skin should be cleaned with alcohol and should be free of any dirt. It is best to abrade the skin lightly to remove part of the stratum corneum, which can be a source of high resistance to the measured voltages. To avoid the problem of muscle artifact, electrodes should be placed over bony prominences, whenever possible. Muscle movement, in the form of shivering, can produce significant ECG artifact.

Electrodes and Leads

Loose electrodes and broken leads may produce a variety of artifacts that may stimulate arrhythmias, Q waves, or inverted T waves. Pregelled disposable silver/silver chloride electrodes are generally used in the operating room. The technical standards for such electrodes have been published by the American Association for the Advancement of Medical Instrumentation. [26] It is important that all the electrodes be moist, uniform, and not out of date. Needle electrodes should be avoided because of the risk of thermal injury. Some ECG monitors have built-in cable testers that enable a lead to be tested by connecting the cable's distal end into the monitor. A high resistance causes a large voltage drop, indicating that the lead is faulty. The main source of artifact from ECG leads is loss of the integrity of the lead insulation. This subsequently leads to pickup of other electric fields in the operating room, such as the 60-Hz alternating current (AC) from lights and also currents from the electrocautery device. Any damaged ECG lead should be discarded for this reason. Lead movement can also lead to artifact.

Operating Room Environment

Many pieces of equipment found in the operating room emit electric fields that can interfere with the ECG: 60-Hz power lines for lights, electrosurgical equipment, cardiopulmonary equipment, and defibrillator discharges. Most of this interference can be minimized by proper shielding of the cables and leads of the ECG, although the interference created by the electrosurgical equipment cannot be reliably filtered without distortion of the ECG. Electrocautery is the most important source of interference on the ECG in the operating room; it usually completely obliterates the ECG tracing. Analysis of the electrocautery has identified three component frequencies. The radiofrequency between 800 and 2,000 kHz comprises most of the interference, coupled with 60-Hz AC frequency and 0.1- to 10-Hz low-frequency noise from intermittent contact of the electrosurgical unit with the patient's tissues. Preamplifiers may be modified to suppress radiofrequency interference, but these filter circuits are still not widely available in the operating room.

Other causes of ECG artifacts in the operating room environment have been reported. Intraoperative monitoring of somatosensory-evoked potentials has been known to simulate pacemaker spikes. [27] They are caused by incorporation in certain monitors of a "pacer enhancement circuit." This problem can be eliminated by disabling the circuit. Artifactual spikes have been noted to coincide with the drip rate in the drip chamber of a warming unit. [28] The spikes were probably related to the generation of static electricity from water droplets. The use of an automated percutaneous lumbar diskectomy nucleotome has been reported to simulate

supraventricular tachycardia (SVT), related to a mechanical interference. [29]

Monitoring System

All ECG monitors use filters to narrow the bandwidth in an attempt to reduce environmental artifacts. The highfrequency filters reduce distortions from muscle movement, 60-Hz electrical current, and electromagnetic interference from other electrical equipment. [30] The low-frequency filters ensure a more stable baseline by reducing respiratory

---

and body movement artifacts, as well as those resulting from poor electrode contact. The AHA recommends that a flat frequency response be obtained at a bandwidth of 0.05 to 100 Hz. [25] The 100-Hz high-frequency limit ensures that tracings are of sufficient fidelity to assess QRS morphology and to evaluate rapid rhythms such as atrial flutter accurately. The low-frequency limit of 0.05 Hz allows accurate representation of slower events such as P-wave and T-wave morphology and ST-segment excursion. Most modern ECG monitors allow the operator a choice among several bandwidths. The actual filter frequencies tend to vary among manufacturers. One manufacturer (Hewlett Packard, Andover, Mass) allows a choice among a "diagnostic mode" with a bandwidth of 0.05 to 130 Hz for adults and 0.5 to 130 Hz for neonates, a "monitoring mode" with a bandwidth of 0.5 to 40 Hz for adults and 0.5 to 60 Hz for neonates, and a "filter mode" with a bandwidth of 0.5 to 20 Hz. The importance of bandwidth selection on the detection of perioperative myocardial ischemia was evaluated by Slogoff et al. [31] These investigators simultaneously used five ECG systems: a Spacelabs (Redmond, Wash) Alpha 14 model series 3200 Cardule with bandwidths of 0.05 to 125 Hz or 0.5 to 30 Hz, a Marquette Electronics (Milwaukee, Wisc) MAC II ECG with 0.05 to 40 Hz or 0.05 to 100 Hz, and a Del Mar (Cincinatti, Ohio) Holter recorder at 0.1 to 100 Hz. The ST-segment positions with the three systems using the lower filter limit (0.05 Hz) recommended by the AHA were similar, whereas on the Spacelabs (0.5 to 30 Hz), they were consistently more negative. The ST-segment displacement on the Holter recorder was consistently less negative and less positive. In at least one automatic ST-segment analysis system (Hewlett Packard, Andover, Mass), the lower frequency filter (0.05 Hz) is automatically activated when the ST analyzer is in use.

INDICATIONS

Diagnosis of Arrhythmias

Arrhythmias are common during surgery, and their causes are numerous. Using continuous electromagnetic tape recordings, Bertrand et al [32] reported an 84 percent incidence of supraventricular and ventricular arrhythmias in 100 patients during surgery. These arrhythmias were most common during endotracheal intubation or extubation and occurred more frequently in patients with preexisting cardiac disease (60% versus 37%). In a study of patients undergoing cardiac surgery, Angelini et al [33] reported that in 29 of 50 patients (58%) having valve surgery and in 35 of 78 patients (45%) undergoing coronary revascularization, significant postoperative arrhythmias developed. There are several major factors contributing to the development of perioperative arrhythmias:

1. *General anesthetics:* Halogenated hydrocarbons, such as halothane or enflurane, produce arrhythmias, probably by a reentrant mechanism. [34] Halothane also sensitizes the myocardium to endogenous and exogenous catecholamines. Drugs that block the reuptake of norepinephrine, such as cocaine and ketamine, can facilitate the development of epinephrine-induced arrhythmias (Ch. 3).
2. *Local anesthetics:* Regional anesthesia by central neuraxial blockade, the goal of spinal or epidural anesthesia, may be associated with a profound albeit transient pharmacologic sympathectomy. This phenomenon may cause parasympathetic nervous system dominance leading to bradyarrhythmias from mild to very severe. This is especially true when the blockade extends to very high thoracic levels (Ch. 39).
3. *Abnormal arterial blood gases or electrolytes:* Edwards et al [35] showed that hyperventilation to a Pa CO_2 of 30 or 20 mm Hg lowered a normal serum potassium to 3.64 or 3.12 mEq/L, respectively. If serum potassium and total body potassium start at low levels, it is possible to decrease the serum potassium to the 2-mEq/L range by hyperventilation and thus precipitate severe cardiac arrhythmias. Alterations of blood gases or electrolytes may lead to arrhythmias either by producing reentrant mechanisms or by altering phase 4 depolarization of conduction fibers. Electrolyte disturbances associated with cardiopulmonary bypass can also lead to intraoperative arrhythmias (Ch. 38) .
4. *Endotracheal intubation:* This maneuver may be the most common cause of arrhythmias during surgery and is often associated with hemodynamic disturbances (Ch. 39) .
5. *Reflexes:* Vagal stimulation may produce sinus bradycardia and may allow ventricular escape mechanisms to occur. It may also produce AV block or even asystole. In vascular surgery, these reflexes may be related to traction on the peritoneum or to direct pressure on the vagus nerve during carotid surgery (Ch. 51) . During jugular vein cannulation, stimulation of the carotid sinus may occur due to pressure from fingers and can lead to bradyarrhythmias. Specific reflexes, such as the oculocardiac reflex, can produce severe bradycardia or asystole.
6. *Central nervous system stimulation and dysfunction of the autonomic nervous system:* Many ECG abnormalities can occur in patients with intracranial disease, especially subarachnoid hemorrhage. These abnormalities include changes in Q-T intervals, development of Q waves, ST-segment changes, and the occurrence of U waves (Ch. 52) . [36] The mechanism of these arrhythmias appears to be related to changes in autonomic nervous system tone.
7. *Preexisting cardiac disease:* Angelini et al [33] showed that patients with known cardiac disease have a much higher incidence of arrhythmias during anesthesia than do patients without known disease.
8. *Central venous cannulation:* The insertion of catheters or wires into the central circulation often leads to arrhythmias (Ch. 30).
9. *Surgical manipulation of the cardiac structures:* Arrhythmias are often noted during insertion of atrial sutures or placement of venous bypass cannulas (Chs. 49 and 50) .
10. *Location of surgery:* Dental surgery is often associated with arrhythmias, because profound stimulation of both sympathetic and parasympathetic nervous systems often occurs. [37] Junctional rhythms are often seen and may be due to stimulation of the autonomic nervous system via the fifth cranial nerve.

Once an arrhythmia is recognized, it is important to determine whether it produces a hemodynamic disturbance, what type of treatment is required, and how urgently therapy should be instituted. Treatment should be initiated promptly if the arrhythmia results in marked hemodynamic

---

impairment. Additionally, treatment should be instituted if the arrhythmia is a precursor of a more severe arrhythmia (e.g., frequent multifocal ventricular premature beats [VPB] with R-on-T phenomenon can lead to ventricular fibrillation), or the arrhythmia may be detrimental to the patient's underlying cardiac disease (e.g., tachycardia in a patient with mitral stenosis). For the detection of rhythm disturbances, the standard limb lead II is preferred because it usually displays large P waves.

Treatment of Arrhythmias

The diagnosis and treatment of arrhythmias can be simplified by using the following six questions as a checklist when looking at an ECG display and attempting to decide whether treatment is necessary:

1. What is the heart rate?
2. Is the rhythm regular?
3. Is there one P wave for each QRS complex?
4. Is the QRS complex normal?
5. Is the rhythm dangerous?
6. Does the rhythm require treatment?

Following are some common intraoperative arrhythmias to which the six questions should be applied.

Sinus Bradycardia

The pacemaker site is in the sinus node, but the rate is slower than normal. Etiologic factors include drug effects, acute inferior myocardial infarction, hypoxia, vagal stimulation, and high sympathetic blockade. Sinus bradycardia accounts for 11 percent of intraoperative arrhythmias:

1. *Heart rate:* 40 to 60 beats/min. In patients on chronic beta blocker therapy, it is defined as a heart rate of less than 50 beats/min.
2. *Rhythm:* The rhythm is regular, except for occasional escape beats from other pacemaker sites.
3. *P*: *QRS:* There is 1:1 relationship between the P waves and the QRS complexes.
4. *QRS complex:* Normal.
5. *Significance:* Heart rates lower than 40 beats/min are poorly tolerated even in healthy patients and should be evaluated on the basis of their effect on cardiac output. Treatment is recommended if hypotension, ventricular arrhythmias, or signs of poor peripheral perfusion are observed. Sinus bradycardia may be part of the sick sinus syndrome in which sinus node dysfunction can precipitate bradycardias, heart block, tachyarrhythmias, or alternating bradytachyarrhythmias [38]

(Fig. 32-13) (Figure Not Available) .

6. *Treatment:* Usually none is necessary, but a progression from atropine (0.5-1.0 mg intravenous [IV] bolus, repeated every 3-5 min up to 0.04 mg/kg or approximately 3.0 mg total dose for the average 75-kg male), to ephedrine (5-25 mg IV bolus), dopamine (5-20 mug/kg/min IV infusion), epinephrine (1-10 mug/min IV infusion), or isoproterenol (1-4 mug/min IV infusion) to temporary transcutaneous pacing or transvenous pacemaker insertion may be necessary for severe or refractory sinus bradycardia.

Sinus Tachycardia

The pacemaker site is in the sinus node, but the rate is faster than normal. Sinus tachycardia is the most commonly occurring arrhythmia in the perioperative period. It occurs with such frequency that it is not included in most incidence studies. Common causes include pain, inadequate anesthesia, hypovolemia, fever, hypoxia, hypercarbia, heart failure, and drug effects. [4]

1. *Heart rate:* The rate is faster than 100 beats/min in the adult patient and can go up to 170 beats/min, which may be seen during a severe episode of hyperpyrexia.
2. *Rhythm:* Regular.
3. *P*: *QRS:* 1:1.
4. *QRS complex:* Normal. There may be associated ST-segment depression with severe increases in heart rate and resulting myocardial ischemia.
5. *Significance:* Prolonged tachycardias in patients with underlying heart disease can precipitate congestive heart failure owing to the increased myocardial work required. The tachycardia decreases coronary perfusion time, which can cause secondary ST-T-wave changes and can precipitate angina pectoris in patients with coronary artery disease. A major diagnostic problem is encountered when the heart rate is 150 beats/min, because this is a common rate for sinus tachycardia, paroxysmal atrial tachycardia (PAT), or atrial flutter with a 2:1 block. These three arrhythmias can

sometimes be separated by the use of carotid sinus massage, intravenous administration of edrophonium, or atrial or esophageal ECG leads to identify the P waves on the ECG more accurately.

6. *Treatment:* The underlying disorder should be treated. If necessary, while determining the cause, esmolol or propranolol should be used in patients with ischemic heart disease who develop ST-segment changes, to prevent further myocardial ischemia.

Figure 32-13 (Figure Not Available) Sick sinus syndrome. *(From Marriott [81])*

Sinus Arrhythmia

The pacemaker impulse arises from the SA node, but the arrhythmia is manifested by alternating periods of slower and faster heart rates. The P-R interval is normal, as is the QRS complex. Most commonly, but not invariably, the rate increases with inspiration and decreases with expiration. This arrhythmia occurs more often in children than in adults. [4]

1. *Heart rate:* 60 to 100 beats/min.
2. *Rhythm:* Irregular.
3. *P*: *QRS:* 1:1.
4. *QRS complex:* Normal.
5. *Significance:* Normal finding.
6. *Treatment:* None.

Atrial Premature Beats

An ectopic pacemaker site in either the left or the right atrium initiates the atrial premature beat (APB). The shape of the P wave is different from the usual SA node P wave and may be inverted. The P-R interval may be shorter or longer than normal, depending on the site of the ectopic focus and on the refractoriness of the AV nodal pathway. The APB spreads not only through the AV node and ventricular conduction system, but also in retrograde fashion reaches the SA node, thus resetting the sinus pacemaker. The interval from the APB to the next sinus beat is therefore a normal sinus cycle (i.e., no compensatory pause). The absence of a compensatory pause is an important distinguishing feature between APB and VPB. Occasionally, APB may find part of the ventricular conduction system refractory. In that case, they travel down an aberrant pathway and create an abnormal QRS complex. They are then called APB with aberrant ventricular conduction and can easily be confused with VPB. Because the recovery period of the right ventricular conduction system outlasts that of the left, the most common form of aberration appears as a right bundle branch block (RBBB). Helpful points in separating APB with aberrant ventricular conduction from VPB include (1) the presence of a preceding P wave, usually abnormally shaped, (2) an RBBB configuration of the QRS complex, (3) the presence of an rsR
ventricular complex in V_1 , and (4) the finding that the initial vector forces are identical to the preceding beat but are usually the opposite with a VPB. Other characteristics of APB are as follows:

1. *Heart rate:* Variable, depending on the frequency of APB.
2. *Rhythm:* Irregular.
3. *P*: *QRS:* Usually 1:1. The P waves have various shapes and may even be lost in the QRS or T waves. Occasionally, the P wave is so early as to find the ventricle refractory, and a nonconducted beat occurs.
4. *QRS complex:* Usually normal unless there is ventricular aberration.
5. *Significance:* In one study, APB represented 10 percent of all intraoperative arrhythmias. They have little clinical significance, but frequent APB may lead to other more serious supraventricular arrhythmias or may be a sign of digitalis intoxication.
6. *Treatment:* Rarely necessary, but digitalis, beta blockers, or verapamil may be considered if hemodynamic function is impaired.

Paroxysmal Supraventricular Tachycardia

Paroxysmal SVT (PSVT) is characterized by a rapid regular rhythm usually with a narrow QRS complex and lacking the normal SA node P wave. The inclusion of tachycardias involving the AV node (Fig. 32-14) (Figure Not Available) allows for their useful classification as due to reentry in the AV node, apparent or concealed accessory AV pathways, or, less often, SA node reentry (Table 32-4) (Table Not Available) . Ectopic atrial or ectopic nodal tachycardias are also among the less frequent SVT. Inappropriate or persistent sinus tachycardia is another variant. PSVT rhythms are usually abrupt in both onset and termination. PSVT is easily distinguished from rapid atrial fibrillation, which is an irregular rhythm, or rapid atrial flutter, which has flutter waves.

1. *Heart rate:* 130 to 270 beats/min.
2. *Rhythm:* Usually regular unless the impulse originates from multiple atrial foci.
3. *P*: *QRS:* There is a 1:1 relationship, although the P wave may often be hidden in the QRS complex or T wave.
4. *QRS complex:* Generally normal, but ST-T changes indicative of ischemia may be noted. Aberration of ventricular conduction may occur, complicating the differential diagnosis with ventricular tachycardia. SVT may also be confused with sinus tachycardia, atrial flutter, and atrial fibrillation. In differentiating these rhythms, carotid sinus massage or edrophonium (5-10 mg IV) traditionally was used. More recently, adenosine, 6 to 12 mg by IV bolus, has been used to slow the rate by transiently enhancing the normal degree of AV block or terminate the arrhythmia. [39] Esophageal ECG leads may also be helpful to better define atrial activity. [40]

5. *Significance:* PSVT can be seen in 5 percent of normal young adults and in patients with Wolff-Parkinson-White syndrome or other preexcitation syndromes. During anesthesia, PSVT accounts for up to 2.5 percent of all arrhythmias, and the arrhythmia has been associated with intrinsic heart disease, systemic illness, thyrotoxicosis, digitalis toxicity, pulmonary embolism, and pregnancy. When a patient is under anesthesia, PSVT can be precipitated by changes in the autonomic nervous system tone, by drug effects, or by intravascular volume shifts and can produce severe hemodynamic deterioration. At times, the PSVT may

be associated with AV block, owing to the fast atrial rate and slow AV conduction. PSVT with 2:1 block represents digitalis intoxication in many patients.

6. *Treatment:* This arrhythmia often must be treated because of its rapid rate and associated poor hemodynamic function. Several steps can be taken to treat this arrhythmia:
   a. Vagal maneuvers such as carotid sinus massage, which should only be applied to one side. [41] [42] [43]
   b. Adenosine, which is the drug of choice: 6-mg rapid IV bolus, preferably via an antecubital or more central vein. If no response is elicited, second and third doses of 12 to 18 mg adenosine may be administered by rapid IV bolus. [44]
   c. Verapamil (2.5-10 mg IV), which terminates AV nodal reentry successfully in about 90 percent of cases (was the drug of choice and is now second choice). [45]
   d. Esmolol (1-mg/kg bolus and 50-200-g/kg/min infusion), which has been shown effective. [46]
   e. Propranolol, in 0.5-mg IV bolus doses.
   f. Edrophonium, in 5- to 10-mg IV bolus doses. [47]
   g. Phenylephrine (100-mug IV bolus) if the patient is hypotensive. [47]
   h. Intravenous digitalization with one of the short-acting digitalis preparations: ouabain (0.25-0.5 mg IV) or digoxin (0.5-1.0 mg IV). [48]
   i. Rapid overdrive pacing, in an effort to capture the ectopic focus. [49]
   j. Synchronized cardioversion with incremental doses of energy of 100, 200, 300, and 360 J, preferably after light sedative premedication with a benzodiazepine. [50]
   k. Procainamide, in addition to cardioversion or antitachycardia pacing. Procainamide may be useful to treat SVT when antegrade conduction across an accessory AV path is the suspected mechanism.

TABLE 32-4 -- Classification of Supraventricular Tachycardia

(Not Available)

(From Marriott [81])

Figure 32-14 (Figure Not Available) Diagrammatic representation of various mechanisms of supraventricular tachycardia. S-AN = sinus node, BP = bypass tract, A-VN = A-V node. *(Modified from Marriott [81])*

Electrode catheter ablation using radiofrequency energy has evolved as the definitive, long-term treatment for most persistent AV reentrant or focal atrial SVT. [51]

Atrial Flutter

Atrial flutter most commonly represents a macro-reentrant arrhythmia that circulates in a specific manner in the right atrium (counterclockwise rotation as viewed in the angiographic left anterior oblique view). Because it is associated with very fast heart rates, it is usually accompanied by AV block. Classic sawtooth flutter waves (F waves) are usually present. The characteristics of atrial flutter are as follows:

1. *Heart rate:* The atrial heart rate is 250 to 350 beats/min with a ventricular rate of about 150 beats/min (2:1 or 3:1 AV conduction block).

2. *Rhythm:* The atrial rhythm is regular. The ventricular rhythm may be regular if a fixed AV block is present or irregular if a variable block exists.
3. *P*: *QRS:* Usually, there is a 2:1 block with an atrial rate of 300 beats/min and a ventricular rate of 150 beats/min, but it may vary between 2:1 and 8:1. F waves are best seen in leads V_1 , II, and the esophageal lead.
4. *QRS complex:* Normal. T waves are lost in the F waves.
5. *Significance:* It usually indicates the presence of severe heart disease. It is seen with increased incidence in patients with coronary artery disease, mitral valve disease, pulmonary embolism, hyperthyroidism, cardiac trauma, cancers of the heart, and myocarditis.
6. *Treatment:* The initial treatment should be control of the ventricular response rate with agents that slow AV node conduction:
   a. Beta blockers such as IV esmolol, 1-mg/kg IV bolus (or propranolol).
   b. Calcium channel blockers such as verapamil, 5 to 10 mg IV (or diltiazem). [52]
   If the ventricular response is excessively rapid and/or secondary hemodynamic instability is present:
   c. Synchronized direct current (DC) cardioversion starting with a relatively high energy of 100 J and gradually increasing to 360 J is indicated. [53]
   d. The class III antiarrhythmic agent ibutilide (Corvert, 1 mg in 10 mL saline or D_5W, infused IV slowly over 10 min) has been documented to convert atrial flutter to sinus rhythm in a majority of patients with relatively new-onset atrial flutter. [54] This may be repeated once, [55] and although it is highly effective, life-threatening torsades de pointes (see later) may occur hours after ibutilide administration, thus making 4- to 8-hour monitoring after treatment highly desirable.
   e. Procainamide (5-10-mg/kg IV loading dose infused no faster than 0.5 mg/kg/min) may rarely be used in attempt to restore sinus rhythm after the ventricular response has been adequately controlled. [56]
   f. Rapid atrial pacing from within the atrium enhanced by ibutilide or procainamide also effectively terminates atrial flutter. [57]

Atrial Fibrillation

Atrial fibrillation is an excessively rapid and irregular atrial focus with no P waves appearing on the ECG, but, instead, a fine fibrillatory activity called f waves. This is the most irregular rhythm: it is called irregularly irregular and may be associated with a pulse deficit. The characteristics are as follows:

1. *Heart rate:* The atrial rate is 350 to 500 beats/min, and the ventricular rate is 60 to 170 beats/min.
2. *Rhythm:* Irregularly irregular.
3. *P*: *QRS:* The P wave is absent and is replaced by f waves or no obvious atrial activity at all.
4. *QRS complex:* Normal.
5. *Significance:* The causes of atrial fibrillation are similar to those of atrial flutter. This rhythm is often associated with significant cardiac disease; however, idiopathic, lone paroxysmal atrial fibrillation has become increasingly recognized. The clinical significance and treatment of atrial fibrillation are also similar to those of atrial flutter, except for two important considerations. The loss of an atrial "kick" secondary to inefficient contraction of the atria may reduce ventricular filling and may significantly compromise cardiac output. In addition, after 24 hours, atrial fibrillation may be associated with the development of atrial thrombi, with resultant pulmonary and systemic embolization.
6. *Treatment*
   a. *Acute atrial fibrillation:* Treatment of acute atrial fi-brillation is very similar to that for atrial flutter. More attention should be focused on ventricular response, especially with the administration of IV diltiazem or esmolol. Ibutilide may restore sinus rhythm, but it is less effective than in the treatment of flutter. [54] [55] Synchronized DC cardioversion should be relied on in patients with pronounced hemodynamic instability. However, if fibrillation is present for longer than 48 hours, attempts to restore sinus rhythm may be associated with a heightened risk of embolization. In this setting, in a patient with normal coagulation function, adequate anticoagulation for 3 to 4 weeks should be considered prior to attempting to restore sinus rhythm.
   b. *Long-term therapy:* Long-term therapy of atrial fibrillation varies and depends on factors such as whether the arrhythmia is constant or paroxysmal, the nature of the underlying heart disease, and the state of ventricular function or hemodynamic stability/reserve. In the older individual or in the setting of specific risk factors (e.g., hypertension, diabetes mellitus, severe left-ventricular systolic dysfunction), anticoagulation with warfarin should be strongly considered. When control of ventricular response is difficult with standard agents (e.g., beta blockers, calcium channel blockers, digitalis), electrode catheter ablation of the AV junction and permanent pacemaker insertion have seen increased use. These are definitive, curative, not merely rate-control procedures. In the absence of coronary artery disease or significant left-ventricular systolic dysfunction, class 1c antiarrhythmic agents (flecainide or propafenone) have become the agents of choice. [58] Use of class 1a drugs (quinidine, procainamide, disopyramide) has sharply diminished because of concerns about their significant proarrhythmic function, as well as their systemic and organ side effects. Off-label use of antiarrhythmic drugs that block repolarizing potassium currents (e.g., sotalol [59] and amiodarone [60] [61] has gained popularity for the suppression of atrial fibrillation in individuals with significant structural heart disease; however, controlled trials that document efficacy are still lacking.

Junctional Rhythms

The AV node itself shows no intrinsic phase 4 depolarization. Therefore, cells in the node cannot act as pacemakers. Ectopic activity, however, may be initiated from sites just above and below the AV node. It makes sense to consider these arrhythmias as AV junctional in nature. The resultant P wave is abnormal and, depending on the position of the ectopic pacemaker, may be very close to, buried in, or following the QRS complex. Depending on the rate of fire of the ectopic pacemaker, the resultant rhythm is nodal premature,

---

nodal quadrigeminy, trigeminy, or bigeminy, nodal rhythm, or nodal tachycardia.

1. *Heart rate:* Variable, 40 to 180 beats/min (nodal bradycardia to junctional tachycardia).
2. *Rhythm:* Regular.
3. *P*: *QRS:* 1:1 but, there are three varieties:
   a. *High-nodal rhythm:* The impulse reaches the atrium before the ventricle; therefore, the P wave precedes the QRS but has a shortened P-R interval (0.1 s).
   b. *Mid-nodal rhythm:* The impulse reaches the atrium and the ventricle at the same time. The P wave is lost in the QRS.
   c. *Low-nodal rhythm:* The impulse reaches the ventricle first and then the atrium, so that the P wave follows the QRS complex.
4. *QRS complex:* Normal, unless altered by the P wave.
5. *Significance:* Junctional rhythms are common in patients under anesthesia (20%) especially with halogenated anesthetic agents. The junctional rhythms frequently decrease blood pressure and cardiac output by about 15 percent, but they can decrease it up to 30 percent in patients with heart disease. [62]
6. *Treatment:* Usually, no treatment is required, and the rhythm reverts spontaneously. If hypotension and poor perfusion are associated with the rhythm, treatment is indicated. Atropine, ephedrine, or isoproterenol can be used in an effort to increase the activity of the SA node so it will take over as the pacemaker. A small dose of succinylcholine (10 mg IV) may revert a nodal rhythm to a sinus rhythm during anesthesia with halothane or enflurane. This probably works as a result of the effect of succinylcholine as a sympathetic ganglionic stimulator. In some cases, propran-olol may correct the rhythm disturbance if it is due to sympathetic stimulation. Dual-chamber electrical pacing at a rate faster than a slow nodal rhythm is another option. For a comparative description of different physical methods to terminate junctional tachycardia, the reader is referred to a review. [63]

Ventricular Premature Beats

VPBs result from ectopic pacemaker activity arising below the AV junction. The VPB originates in and spreads through the myocardium or ventricular conducting system, resulting in a wide (>0.12-s), bizarre QRS complex. The ST segment usually slopes in the direction opposite to that of the main deflection of the QRS complex. There is no P wave associated with a VPB, but retrograde depolarization of the atria or blocked sinus beats may obscure the diagnosis.

The most important entity in the differential diagnosis is APB with aberrant ventricular conduction. The distinction should be made whenever possible.

Although an APB normally reaches the SA node and resets the sinus rhythm, such an occurrence is rare when the ectopic pacemaker is in the ventricle. Therefore, a VPB often blocks the next depolarization from the SA node, but the following sinus beat occurs on time. The result is a compensatory pause, consisting of the interval from the VPB to the expected normal QRS, which is blocked at the AV node, plus a normal sinus interval.

VPBs are common during anesthesia, accounting for 15 percent of observed arrhythmias. They are much more common in anesthetized patients with preexisting cardiac disease. Other than heart disease, known etiologic factors include electrolyte and blood gas abnormalities, drug interactions, brain-stem stimulation, and trauma to the heart.

1. *Heart rate:* Depends on the underlying sinus rate and frequency of the VPBs.
2. *Rhythm:* Irregular.
3. *P*: *QRS:* No P wave with the VPB.
4. *QRS complex:* Wide and bizarre with a width of more than 0.12 second. If it is of an RBBB nature, prominent R forces are present in V_1. If left bundle branch block (LBBB) in appearance, notching of the S wave and less acute downslopes are common.
5. *Significance:* The new onset of VPBs must be considered life-threatening because, in certain clinical situations, the arrhythmia may progress to ventricular tachycardia or fibrillation. These situations include coronary artery insufficiency, myocardial infarction, digitalis toxicity with hypokalemia, and hypoxemia. VPBs are more likely to lead to fibrillation if they are multiple, multifocal, or bigeminal, occur near the vulnerable period of the preceding ventricular repolarization (the so-called R-on-T phenomenon), [64] or appear in short-long-short coupling sequences.
6. *Treatment:* The first step is to correct any underlying abnormalities such as decreased serum potassium or low arterial oxygen tension. If the arrhythmia is of hemodynamic significance or if it is believed to be a harbinger of worse arrhythmias, lidocaine is usually the treatment of choice, with an initial bolus dose of 1.5 mg/kg. Recurrent VPBs can be treated with a lidocaine infusion of 1 to 4 mg/min; additional therapy can be supplied with esmolol, propranolol, procainamide, quinidine, disopyramide, atropine, verapamil, or overdrive pacing.

Ventricular Tachycardia

The presence of three or more sequential VPBs defines ventricular tachycardia. Diagnostic criteria include the presence of fusion beats, capture beats, and AV dissociation. The specific morphologic appearance of the QRS complex may also be helpful in distinguishing ventricular tachycardia from other arrhythmias. The characteristics of ventricular tachycardia are as follows:

1. *Heart rate:* 100 to 200 beats/min.
2. *Rhythm:* Usually regular, but may be irregular if the ventricular tachycardia is paroxysmal.
3. *P*: *QRS:* No fixed relationship, because ventricular tachycardia is a form of AV dissociation in which the P waves can be seen marching through the QRS complex.
4. *QRS complex:* Wide, more than 0.12 second in width, with similar morphologic criteria in lead V_1 as for VPB.
5. *Significance:* Acute onset is life-threatening and requires immediate treatment.
6. *Treatment:* Lidocaine IV bolus followed by infusion is indicated, and immediate cardioversion may also be needed. Recurrent episodes may require therapy with procainamide, amiodarone, bretylium, or any of the drugs used in the treatment

---

of VPB. IV amiodarone has been shown to be as effective as bretylium. [65] Amiodarone is administered as one or more doses of 150 mg IV in 100 mL saline or D_5 W over 10 minutes followed by an IV infusion of 1 mg/min for 6 hours and 0.5 mg/min thereafter. Although amiodarone is associated with substantially less hypotension compared with bretylium, hypotension and bradycardia are its main side effects. Its pharmacologic effects persist for more than 45 days.

Ventricular Fibrillation

Ventricular fibrillation is an irregular rhythm resulting either from a rapid discharge of impulses from one or more ventricular foci or from multiple wandering reentrant circuits in the ventricles. The ventricular contractions are erratic and are represented on the ECG by bizarre patterns of various sizes and configurations. P waves are not seen. Important causes of the arrhythmia include myocardial isch-emia, hypoxia, hypothermia, electric shock, electrolyte imbalance, and drug effects. The characteristics are as follows:

1. *Heart rate:* Rapid and grossly disorganized.

2. *Rhythm:* Totally irregular.
3. *P*: *QRS:* None seen.
4. *QRS complex:* Not present.
5. *Significance:* There is no effective cardiac output, and life must be sustained by artificial means, such as external cardiac massage.
6. *Treatment:* Cardiopulmonary resuscitation must be initiated immediately, and then defibrillation must be performed as rapidly as possible. Asynchronous external defi-brillation should be performed with a DC defibrillator, using 200 to 400 J. In extreme situations, the use of two defibrillators in tandem across the chest, one applied in the anteroposterior direction and the second applied in the left midaxillary to right midaxillary direction, has been suggested. The two devices are discharged simultaneously to increase the likelihood of successful defibrillation. Animal studies have failed to demonstrate the superiority of dual-pathway simultaneous shocks over single-pathway shock. [66] Early administration of repeated doses of 1 mg of magnesium sulfate may facilitate defibrillation. Supportive pharmacologic therapy may include lidocaine, amiodarone, bretylium, procainamide, phenytoin, or esmolol. In some instances, epinephrine is used to coarsen the fibrillation in an attempt to defibrillate the patient. Torsades de pointes, which may mimic ventricular fibrillation or ventricular tachycardia, is a life-threatening arrhythmia that occurs in the presence of disturbed repolarization (hence its association with prolonged Q-T intervals). [67] Discontinuation of drugs that predispose to Q-T-interval prolongation and correction of electrolyte abnormalities are essential in the treatment of torsades de pointes. Acute therapy may include defibrillation, IV magnesium sulfate, IV isoproterenol, overdrive pacing, and IV amiodarone. [68]

Diagnosis of Ischemia

Perioperative myocardial ischemia is predictive of adverse cardiac outcomes [69] (Chs. 30 and 49) . Factors that predispose to the development of perioperative ischemia include the presence of preexisting coronary artery disease and perioperative events that affect the myocardial oxygen balance. Perioperative clinical studies have found a high incidence of ECG evidence of ischemia (20-80%) in patients with coronary artery disease who are undergoing cardiac or noncardiac surgery. [70] [71] The incidence of perioperative myocardial infarction in patients with coronary artery disease with or without previous coronary artery bypass grafting (CABG) has been studied. [72] Most patients without prior CABG in whom perioperative infarction developed had three-vessel disease. The infarction rate in the CABG group was very low, supporting the protective effect of prior CABG before noncardiac surgery. In the anesthetized patient, the detection of ischemia by ECG becomes even more important because the hallmark symptom, angina, is not available.

It has also become evident that a significant number of patients suffer from asymptomatic or "silent ischemia." [73] Silent ischemia is manifested by characteristic ECG signs of ischemia in the absence of angina and is not necessarily associated with changes in hemodynamics or heart rate. Among patients with chronic stable angina who have ST-segment depression during exercise, ambulatory ECG monitoring during daily life identifies transient ambulant ischemic episodes in approximately 40 to 50 percent of patients. In these patients, silent ischemic episodes account for about 75 percent of all ambulant ischemic episodes. [74]

The ECG changes occurring during myocardial ischemia are often characteristic and are detected with careful ECG monitoring. Although the ECG criteria for ischemia were established in patients undergoing exercise stress testing, they may also be applied to anesthetized patients (Table 32-5) . These criteria are (1) horizontal or downsloping ST-segment depression of 0.1 mV, (2) ST-segment elevation of 0.1 mV in a non-Q-wave lead, and (3) slowly upsloping ST-segment depression of 0.2 mV (all measured from 60 to 80 ms after the J point) [75] (Fig. 32-15) (Figure Not Available) . Okin et al [76] studied the relation of the time after the J point at which ST depression is measured to the magnitude of ST-segment depression during peak exercise. These investigators found that a positive exercise ECG (0.1 mV or more of additional horizontal or downsloping ST depression at end-exercise) had a specificity of 96 percent for coronary artery disease when ST-segment depression was measured at either the J point or J + 60 milliseconds. There was no difference in sensitivity of ECG criteria at the J point or at J + 60 ms. However, at J + 60 milliseconds there were significant differences in ST-segment depression at peak exercise among healthy persons, patients with clinical angina, and patients with documented coronary artery disease.

It is commonly believed that monitoring for intraoperative myocardial ischemia is unnecessary in neonates.

TABLE 32-5 -- Electrocardiographic Criteria for Ischemia in Anesthetized Patients

Upsloping ST segment: 2-mm depression, 80 ms after J point
Horizontal ST segment: 1-mm depression, 60-80 ms after J point
Downsloping ST segment: >1 mm from top of curve to PQ junction
ST elevation
T-wave inversion

Figure 32-15 (Figure Not Available) Assessment of ST-segment abnormality in the diagnosis of ischemia. *(From Ellestad [97])*

Whereas ECG lead systems for adults are concerned with the detection of ischemia as well as arrhythmias, neonatal ECG monitoring has focused on arrhythmia recognition alone. Results of some studies, however, suggest that the neonatal heart is more susceptible to ischemia than the adult heart. [77] These studies have demonstrated the importance of calibrated ECG monitoring in neonates with congenital heart disease (Ch. 50) .

Although ST-segment analysis provides sensitive information about myocardial ischemia, it should, nonetheless, be remembered that in about 10 percent of patients, underlying ECG abnormalities hinder the analysis. Such abnormalities include hypokalemia, digitalis administration, LBBB, Wolff-Parkinson-White syndrome, left ventricular hypertrophy with strain, and acute pericarditis (Fig. 32-16) (Figure Not Available) . In these patients, other diagnostic modalities, such as transesophageal echocardiography, should be considered.

Diagnosis of Conduction Defects

Conduction defects can be observed during surgery. They can result from the passage of the pulmonary artery catheter through the right ventricle, or they can be a manifestation of myocardial ischemia. Because high-grade (second- and third-degree AV blocks) conduction defects often have deleterious effects on hemodynamic performance, their intraoperative recognition is important.

Three types of conduction system blocks are possible: SA block, AV heart block, and intraventricular conduction block (Table 32-6) (Table Not Available) . His bundle ECG has greatly improved the understanding of conduction through the heart. [78] In SA block, the block occurs at the sinus node. Because atrial excitation is not initiated, P waves are not found on the ECG. The next

Figure 32-16 (Figure Not Available) Digitalis effect on ST segments and T waves (ectopic atrial rhythm, 2:1 AV block, type 1 second degree AV block, left ventricular hypertrophy with strain). *(From Marriott [81])*

beat can be a normal sinus beat, a nodal escape beat, or a ventricular escape beat.

The second type of heart block is an AV heart block, or AV block, which may be either incomplete or complete. [79] First- and second-degree AV blocks are usually considered incomplete, whereas a third-degree AV block is considered to be complete heart block. First-degree AV block is often found in healthy hearts, but it is also associated with coronary artery disease or digitalis administration. It is characterized by a P-R interval longer than 0.21 second. All atrial impulses progress through the AV node to the Purkinje system. This form of heart block ordinarily requires no treatment (Fig. 32-17) (Figure Not Available) . Second-degree AV block is associated with the conduction of some, but not all, of the atrial impulses to the AV node and into the Purkinje system. It is further subdivided into two specific types. [80] Mobitz type 1, or Wenckebach, block is characterized by progressive lengthening of

TABLE 32-6 -- Conduction Defects

(Not Available)

(From Thys and Kaplan [1])

the P-R interval until an impulse is not conducted and the beat is dropped (Fig. 32-18) (Figure Not Available) . This form of block is relatively benign and often reversible and does not require a pacemaker. It may be caused by digitalis toxicity or myocardial infarction and is usually transient. Mobitz type 1 block reflects disease of the AV node. The other form of second-degree heart block is Mobitz type 2 block, which may reflect disease of the bundle of His and Purkinje tissues, especially when the QRS complex is broad. In this, the less common and more serious form of second-degree heart block, dropped beats occur without any progressive lengthening of the P-R interval (Fig. 32-19). (Figure Not Available) This type of block has a serious prognosis, because it frequently progresses to complete heart block and may require pacemaker insertion prior to major surgical procedures. Third-degree AV block, also called complete heart block, occurs when all electrical activity from the atria fails to progress into the Purkinje system. The atrial and ventricular contractions have no relationship with each other, although each chamber contracts regularly. The ventricular rate is approximately 40 beats/min. The QRS complex may be normal if the pacemaker site is in the AV node, but it is usually widened to longer than 0.12 second when the pacemaker site is located in the ventricle (Fig. 32-20). (Figure Not Available) The heart rate is usually too slow to maintain adequate cardiac output, and syncope or Adams-Stokes syndrome may occur, as well as heart failure. These patients usually require insertion of a transvenous endocardial or epicardial pacemaker to increase their heart rate and cardiac output. The third type of block is an intraventricular conduction disturbance, which is usually classified as LBBB, RBBB, or hemiblock. LBBB is the most serious of these conduction disturbances. Impulses reach the ventricles exclusively through the right bundle branch, hence the wide QRS complex of more than 0.12 second and a wide-notched R wave in leads I, aVL, and V_6 (Fig. 32-21) (Figure Not Available) . The most important leads to study in bundle branch blocks are I, V_1 , and V_6 . The pattern of LBBB in V_6 is similar to that of left ventricular hypertrophy, but exaggerated. An LBBB pattern is always associated with significant cardiac disease. In an RBBB, the QRS complex exceeds 0.11 second and leads V_1 to V_3 have broad rSR
complexes, whereas leads I and V_6 have wide S waves (Fig. 32-22) (Figure Not Available) . RBBB may be of no clinical significance, as opposed to LBBB. However, it is frequently associated with chronic lung disease or atrial septal defects.

Hemiblock is a term used when one of two divisions of the left bundle is blocked, because if both divisions are blocked, complete LBBB exists. Even though hemiblocks are a form of intraventricular block, the QRS complex is not prolonged. Marriott's [81] criteria for left anterior hemiblock are as follows (Fig. 32-23) (Figure Not Available) : (1) left axis deviation (usually -60 degrees); (2) small Q in leads I and aVL and small R in leads II, III, and aVF; (3) a normal QRS duration; (4) a late intrinsicoid deflection in lead aVL (0.045 s); and (5) an increased QRS voltage in limb leads. By contrast, the criteria for a left posterior hemiblock are as follows (Fig. 32-24): (Figure Not Available) (1) right axis deviation (usually +120 degrees); (2) small R in leads I and aVL and small Q in leads II, III, and aVF; (3) a normal QRS duration; (4) a late intrinsicoid deflection in lead aVF (>0.045 s); (5) an increased QRS voltage in limb leads; and (6) no evidence of right ventricular hypertrophy. The hemiblocks can occur by themselves but are often associated with an RBBB to form a bilateral bundle branch block. Patients with an RBBB and a left anterior hemiblock (Fig. 32-25) (Figure Not Available) progress to complete heart block only 10 percent of the time, whereas patients with RBBB and a left posterior hemiblock (Fig. 32-26) (Figure Not Available) often do proceed to complete heart block.

Figure 32-17 (Figure Not Available) First-degree AV block is diagnosed by the presence of a P-R interval onger than 0.21 second. *(From Thys and Kaplan [1])*

Figure 32-18 (Figure Not Available) Mobitz type 1 (or Wenckebach) is diagnosed by the progressive lengthening of the P-R interval until an impulse is not conducted and a dropped beat occurs. *(From Thys and Kaplan [1])*

Trifascicular blocks are usually said to consist of one of the foregoing bilateral bundle branch blocks (i.e., RBBB plus a left fascicular block) in addition to a prolonged PR interval (Fig. 32-27) (Figure Not Available) . Bundle of His ECGs are necessary to determine whether the AV conduction disturbance is, in fact, localized in the AV node or whether it is distal, possibly representing an incomplete fascicular block in the last remaining fascicle.

AUTOMATIC RECORDING

Holter monitoring has been used by a number of anesthesiologists to document the perioperative incidence of arrhythmias and ischemia. In Holter monitoring, ECG information from one or two bipolar leads is recorded by a miniature magnetic tape recorder. Up to 48 hours of ECG signals can be collected. Subsequently, the tape is processed by a playback system, and the ECG signals are analyzed. On most modern systems, the playback unit includes a dedicated computer for rapid analysis of the data and automatic recognition of arrhythmias.

A significant early obstacle to the widespread use of conventional Holter monitoring in the perioperative period was the delayed, retrospective analysis and interpretation. This limitation was overcome by real-time Holter monitors. They record specific ECG segments for later playback, as well as analyze the rhythm and ST segment in real time and alert the user to acute perturbations. [82] A report on validation testing of the SEER real-time digital Holter device (Marquette Electronics, Milwaukee, Wisc) found it highly accurate in detecting ST-segment deviations. [83] These results were obtained with digitally simulated ECG data, and accuracy in the clinical setting remains yet to be validated. A different device, the Q-Med (Q-Med, Inc, Clark, NJ), is a small, continuous ECG recording device that has been used in patients undergoing cardiac and noncardiac surgery. [84] [85] The device not only records the ECG signals, but also it performs an automatic analysis of the ECG tracing and sounds an alarm when ischemic changes are recognized. Abnormal events are selectively stored and are subsequently retrievable. In spite of significant technical progress, however, Holter monitoring continues to be limited primarily to clinical investigations.

COMPUTER-ASSISTED INTERPRETATION

Computer programs for the interpretation of ECG are now widely used. In a large study, the ECG of 1,200 adult patients with known clinical conditions were interpreted by cardiologists and by nine different computer programs. [86] The results demonstrated that, in some cases, computer interpretations

of ECG were correct and cardiologists were incorrect when their diagnoses were tested against the clinical evidence. The opposite was twice as likely when the average computer program and the average cardiologist were compared. The computer programs with the best performance were almost as accurate as the best cardiologists in classifying the ECG of patients in seven common diagnostic groups. The study did not the test the computers' abilities, however, in two critical areas: acute myocardial ischemia and arrhythmia recognition. Modern monitoring equipment is highly computerized, and most of the physiologic information is manipulated, analyzed, and stored in the digital format. An early step in data collection therefore involves the conversion of analogue signals (time-variable voltages or amplitudes) into digital format with an analogue-to-digital converter. Once in the digital format, the physiologic information can readily be

subjected to a variety of analyses. In ECG, the most common analyses, besides rate calculations, are related to arrhythmia recognition and the detection of myocardial ischemia.

Arrhythmias

There is little doubt that, during prolonged visual observation of the ECG on the oscilloscope, certain arrhythmias go undetected. This was clearly demonstrated by Romhilt et al, [87] who showed that coronary care unit nurses failed to detect serious ventricular arrhythmias in 84 percent of their patients. Computers have therefore been designed for the automatic detection of arrhythmias in an attempt to increase the detection of abnormal rhythms. Using an early preproc-essing algorithm called AZTEC, a computer accurately detected 78 percent of ventricular ectopic beats. It measured QRS width, offset, amplitude, and area to classify complexes into morphologic families. [88] In a prospective evaluation of such a system, it was found that the computer accurately detected 95.4 percent of VPB, but only 82.4 percent of supraventricular premature beats.

Other systems have depended on QRS recognition and cross-correlation with stored QRS complexes. [89] In cross-correlation, each detected QRS complex is compared with a list of previously detected complexes. If a complex does not correlate better than 0.9 with a previously stored complex, it is considered to have a new configuration and is added to the list (Fig. 32-28) (Figure Not Available) . Certain points of the complex, such as the P-R interval and ST segment, are stored as a template for future comparison. Whenever a new complex matches an existing template, it is averaged into that template, so that each template represents a running average of all complexes of a particular configuration. [90] Each template is defined as normal, abnormal, or questionable according to previously defined criteria. The AHA has published several parameters that need to be tested to permit a meaningful understanding of a system's values and limitations and to permit reasonable comparison among systems. [25]

Figure 32-24 (Figure Not Available) Left posterior hemiblock in association with biatrial enlargement and nonspecific ST- and T-wave abnormalities. *(From Thys and Kaplan [1])*

Myocardial Ischemia

One method of detecting intraoperative myocardial ischemia is automated ST-segment monitoring. [91] Several computer programs for on-line detection of ischemia and

Figure 32-25 (Figure Not Available) Right bundle branch block in association with left anterior hemiblock. Note the RsR pattern in V_1 and the wide S in the lateral leads. The axis of the initial QRS vector is -88 degrees. *(From Thys and Kaplan [1])*

analysis of ST segments are available commercially. Each manufacturer uses different analysis techniques, and not all the algorithms are in the public domain. In one system (Marquette Electronics, Milwaukee, Wisc), an ST learning phase begins by looking at the first 16 beats, in all leads, for the dominant normal or paced shape. The shapes are correlated using a selected number of points on each of the active valid lead waveforms. An algorithm looks for leads in the fail or artifact mode to determine the number of valid leads used in the analysis. The algorithm also makes all leads positive to enable totaling the sum of the points on the valid

Figure 32-26 (Figure Not Available) Right bundle branch block with left posterior hemiblock. Note the wide S in the lateral leads and the rR pattern in V_1 . The axis of the initial QRS vector is +166 degrees. *(From Thys and Kaplan [1])*

Figure 32-27 (Figure Not Available) Trifascicular block. The P-R interval is 232 milliseconds, and a right bundle branch block is noted. The axis of the QRS vector is -85 degrees, indicating a left anterior hemiblock. *(From Thys and Kaplan [1])*

leads. This sum is used in determining a peak or fiducial point. The fiducial point is used as a point of reference on the QRS. A template is formed from selected points around the fiducial point for each ECG lead. As each beat is analyzed, its template is compared with templates of previous beats. If the templates correlate within 75 percent of a previously stored shape, it is deemed a match and is classified as an existing shape. If there is no match, it becomes a new

Figure 32-28 (Figure Not Available) Computerized "template" of the underlying normal QRS complex (X) and an ectopic complex termed a "test beat" (Y). Beat Y is matched to beat X by the computer during the region of comparison by cross-correlation algorithms. *(Modified from Morganroth [90])*

shape. On the 17th beat, the dominant normal QRS shape or paced shape is determined. The algorithm then searches for an additional 16 beats that correlate with the dominant template. With the 18th beat, a process called incremental averaging is initiated. The incremental averaging is a method of tracking positive or negative changes occurring on the waveform. These changes are tracked for each of the valid leads. The changes may be physiologic, such as ST-segment changes resulting from ischemia or related to artifact caused by high-frequency noise. The tracking of the changes is achieved by only allowing a 0.1-mm adjustment, either positive or negative, from the prior shape of each beat. On the 32nd beat, the product of the incrementally averaged templates become the learned ST templates. Until ST is relearned, all changes in the QRS shape are tracked against this learned template. The isoelectric point and ST points are determined during the learning phase and are based on the width of the QRS shape. The isoelectric point is placed 40 milliseconds prior to the onset of the QRS and the ST point is placed 60 milliseconds past the offset of the QRS measurement. The isoelectric point provides the point of reference for determining the ST-segment measurement. The technique of incremental averaging is well suited to a continuous input with slow changes. It, however, links the speed at which changes occur in the template to the heart rate. [92]

This system was evaluated in the intraoperative setting in patients undergoing cardiac surgery. [93] The device monitored three selected leads and displayed the absolute values of the ST segment as a line. Upward deflection of the trend line indicated worsening ischemia, whereas a downward trend reflected a return of the ST segment toward the isoelectric line. It was concluded that once the device was clinically accepted, the awareness for ischemic changes was heightened among the participating anesthesiologists and therapeutic interventions were more rapidly instituted, possibly leading to improved outcome.

A second ST-segment analysis system (Hewlett Packard, Andover, Mass) differs from the foregoing in several ways. A period of 15 seconds is analyzed first, and the ST displacement is determined on the basis of five "good" beats. These displacements are ranked, and the median value is determined. This technique eliminates the influence of occasional VPBs and ensures that a representative beat is selected. The objective of this procedure is to obtain a representative beat, rather than an average template. The measurement point for the ST segment can be selected as the R wave + 108 milliseconds (default) or the J point + 60 or 80 milliseconds. ST values and representative complexes are stored at 1-minute resolution for the most recent 30-minute trend and at 5-minute resolution for the preceding 7.5-hour trend.

In a third system (Spacelabs, Redmond, Wash), a composite ST-segment waveform is developed every 30 seconds and is compared with a reference tracing acquired during an initial learning period. The isoelectric and ST-segment points can be manually adjusted to any location on the ECG tracing, or they may be automatically set to predetermined values. Using selective ST-segment displacement on seven different types of digitally simulated ECGs, London and Ahlstrom [94] "bench tested" a version of a Spacelabs automated ST-analysis device, the PC2 Bedside monitor. The device performed very well with five of the

---

simulated ECGs, but it had some difficulty with two because of improper placement of the isoelectric point. Visual confirmation of ST-segment analyzer results was therefore advised.

The relative merits and shortcomings of the different ST-segment analysis systems in the clinical setting have not been fully elucidated. The ability of two automated ST-segment analysis systems to detect myocardial ischemia during noncardiac surgery was compared with 8-lead printed ECG and transesophageal echocardiography as reference standards. [95] In this study of 44 patients, the automated ST-analysis systems showed only fair agreement with transesophageal echocardiography or ECG in detecting ischemia. A different, brief cautionary report mentions a case in which automated ST-segment monitoring falsely signaled the presence of intraoperative ischemia. [96]

CONCLUSIONS

The ECG should be monitored in all patients undergoing anesthesia. Although it does not provide information on the mechanical function of the heart, it permits detection of electrical disturbances that can profoundly affect this function. Today, with the judicious use of selected lead combinations, most arrhythmias and ischemic events can be precisely diagnosed in the intraoperative setting. This diagnostic activity is time consuming, however, and there is considerable evidence that many intraoperative ECG changes go undetected. There is little doubt that future technologic developments will facilitate the intraoperative recognition of ECG disturbances and, one hopes, will lead to better patient outcome.

ACKNOWLEDGMENT

The authors acknowledge the contribution of Professor JA Kaplan to this chapter, as well as his continuing inspiration.

Chapter 33 - Respiratory Monitoring

Richard E. Moon
Enrico M. Camporesi

/das/book/view/29494766/875/359.html

INTRODUCTION

The Oxford English Dictionary defines a monitor as "something that reminds or gives warning." [1] Another defini-tion is "an instrument used to measure continuously or at intervals a condition that must be kept within prescribed limits." [2] If the discussion of monitors were to be confined to the latter definition, perhaps only self-contained instruments (e.g., pulse oximeters) should be discussed in this chapter; however, a wider view is more appropriate. For example, intermittent, although not necessarily at fixed intervals, analysis of arterial blood gases is often an important monitor of a patient's condition and can be considered as a "monitor." We discuss respiratory physiology as it applies to assessment of patient well-being and the appropriate measures that may be obtained either continuously or intermittently.

There is general agreement that patient safety has been enhanced by the development of technologies that permit accurate physiologic monitoring; basic studies to elucidate the causes of mishaps, including incident monitoring; educational efforts by national patient safety organizations such as the Anesthesia Patient Safety Foundation and the Australian Patient Safety Foundation; and the promulga-tion of monitoring standards that have become widely accepted. Eichhorn et al [3] outlined minimal recommended standards for patient monitoring during anesthesia at hos-pitals within the Harvard Medical School system, com-monly referred to as the "Harvard Standards." In addition to monitors of cardiovascular function and patient temperature, these authors suggested that mandatory respiratory monitors include methods of continuous monitoring of patient ventilation (including a breathing system disconnection monitor) and a monitor of oxygen concentration within the patient breathing system. A strong recommendation was made for monitoring end-tidal CO_2 concentrations. Since then, the American Society of Anesthesiologists has also promulgated basic monitoring standards. [4] *

Figure 33-1 (Figure Not Available) Oxygen transport cascade. A schematic view of the steps in oxygen transport from the atmosphere to the site of utilization in the mitochondrion is shown here. Approximate P_{O_2} values are shown for each step in the cascade, and factors determining those partial pressures are shown within the square brackets. There is a distribution of tissue P_{O_2} values depending on local capillary blood flow, tissue oxygen consumption, and diffusion distances. Mitochondrial P_{O_2} values are depicted as a range because reported levels vary widely. *(Adapted from Nunn. [286]) Reprinted by permission of Butterworth Heinemann, a division of Reed Educational & Professional Publishing Ltd.*

Included in the ASA standards are a requirement for measurement of both inspired oxygen concentration and quantitative assessment of blood oxygenation, such as pulse oximetry. Adequate illumination and exposure of the patient are necessary to assess color. Adequacy of ventilation must be continually evaluated, and quantitative monitoring of carbon dioxide or volume of expired gas is strongly encouraged. When an endotracheal tube is inserted, correct placement of the tube must be verified by clinical assessment and by identification of carbon dioxide in the expired gas. Continual end-tidal carbon dioxide analysis shall be performed from the time of endotracheal tube placement until extubation or initiation of transport to a postoperative care location, using a quantitative method such as capnography. During mechanical ventilation a device capable of detecting airway disconnects shall be in continuous use. *Continual* is defined as *repeated regularly and frequently in steady rapid succession; continuous* is defined as *prolonged without any interruption at any time.*

The limited ability of human organ systems to function anaerobically dictates a transport system that can maintain O_2 delivery to peripheral tissues. The monitoring of one component of this system, the cardiovascular system, is discussed in Chapter 30 . This chapter discusses the other component, the respiratory system, and the appropriate monitoring necessary to detect malfunction in its gas exchange function.

GAS EXCHANGE

The major function of the lung is gas exchange: addition of O_2 to blood and the elimination of CO_2 from blood (Ch. 15) . Because of the close relationship between the partial pressure of CO_2 in blood (P_{CO_2}) and arterial (and hence tissue) pH, it is important to ensure that arterial CO_2 remain within an appropriate physiologic range. Adequate O_2 delivery must also be maintained. Figure 33-1 (Figure Not Available) shows the O_2 cascade from atmospheric gas to the intracellular site of utilization. Assessment of the adequacy of this delivery system may theoretically be made at any step of the cascade. For example, common clinical practice dictates that arterial O_2 content (Pa_{O_2}) should be sufficient. It is common practice to attempt to maintain arterial hemoglobin Hb-O_2 saturation (Sa_{O_2}) above 90 percent. This level is reasonable for two reasons. First, clinical experience supports the notion that maintenance of hemoglobin at 90 percent saturation with O_2 in the presence of adequate cardiac output will provide sufficient O_2 delivery to the tissues. Second, because the Hb-O_2 dissociation curve becomes abruptly steeper at O_2 saturation levels below 90 percent, further decreases in Pa_{O_2} may result in sharp diminution of O_2 content and, hence, O_2 delivery. In addition to Sa_{O_2}, however, O_2 delivery is a function of blood flow and Hb concentration. A target value for Sa_{O_2} of 90 percent or greater should not become a sacrosanct standard for all conditions. Acute altitude hypoxia with Sa_{O_2} values at 80 to 89 percent is well tolerated by normal individuals, even during exercise, at least for periods of several hours, with no evidence of permanent sequelae. [5] [6] [7] It is conceivable that individuals with acute anemia may not tolerate hypoxia as well because of the enhanced reduction in arterial O_2 content.

Alveolar Gases

Before attempting to understand respiratory gas exchange monitoring it is imperative to understand the basis of gas exchange physiology. The lung consists of a heterogeneous collection of gas exchange units (alveoli), with a range of O_2 and CO_2 gas tensions. It is therefore erroneous to speak of "the" alveolar P_{O_2} or P_{CO_2}; however, the concept of a homogeneous lung, in which all alveoli have the same gas tensions, is a useful one. The alveolar partial pressures calculated by using such a model may be thought of as averages for the O_2 and CO_2 partial pressures in the real (nonhomogeneous) lung. The following equations exemplify alveolar P_{O_2} and P_{CO_2} (P_{AO_2} and P_{ACO_2}), or alveolar gas equations.

where V_{CO_2} = CO_2 production rate; V_{O_2} = O_2 consumption rate; V_A = alveolar ventilation rate; k = constant; F_{IO_2} = fractional inspired O_2 concentration; P_{IO_2} = inspired P_{O_2} after humidification = (P barometric - PH_2O) · F_{IO_2}; and R = respiratory quotient = V_{CO_2}/V_{O_2} (usually 0.8).

The equation for P_{ACO_2} is a function of only two variables. In clinical medicine, V_{CO_2} is relatively constant, and P_{ACO_2} is mainly a function of alveolar ventilation V_A, to which it is inversely proportional.

Because

where V_E = respiratory minute ventilation; and V_D = dead-space ventilation, and because alveolar ventilation is usually a constant fraction of minute ventilation:

The alveolar gas equation for CO_2 may be rewritten as

where c is a constant derived from k and k
.

This approximation may not hold if CO_2 production is substantially elevated, for example, during a major motor seizure, shivering, or fever. CO_2 may decrease as a result of general anesthesia or hypothermia. It is altered by approximately 7 percent for each degree (Celsius) change in body temperature, and in the young has been observed to increase up to 3-fold during violent shivering, [8] although in elderly patients (>60 years) the observed increase is only about one-third. [9]

The alveolar gas equation for O_2 (Equation 2) can be used to delineate the following major factors that result in low P_{AO_2}:

1. Low P_{IO_2} (decreased barometric pressure [altitude] or breathing a gas mixture with inspired O_2 fraction [F_{IO_2}] less than 0.21)
2. Elevated P_{ACO_2} (either due to hypoventilation or increased CO_2 production)
3. Reduced respiratory quotient (R); this is usually a minor effect because the physiologic range of R is on the order of 0.7 to 1.2, the latter seen during metabolic acidosis or excessive feeding

Figure 33-2 CO_2 content of arterial blood as a function of P_{CO_2}. For a given P_{CO_2} deoxygenated blood has a higher CO_2 content than oxygenated blood (Haldane effect). Unlike the Hb-O_2 saturation curve, the CO_2 content curve has no plateau and in the clinically useful range can be approximated by a straight line. *(Data from Christiensen et al [289])*

Arterial Blood Gases

The variables that determine alveolar gas tension have been described. The following additional factors also determine the gas tensions in arterial blood:

1. Ventilation/perfusion (V_A/Q) mismatching
2. Right-to-left shunting
3. Diffusion nonequilibrium

To understand fully the role of V_A/Q in determining arterial gas tensions, it is necessary to discard the homogeneous lung model and consider a model with multiple parallel units of gas exchange and blood flow, in which the resulting arterial gas tension is determined by the mixing of different proportions of blood from each gas exchange unit. The gas tensions in each unit depend upon the regional ventilation, perfusion, and diffusion.

Gas exchange units with low or zero V_A/Q ratios have low end-capillary P_{O_2}. The O_2-blood dissociation curve has a plateau at the point at which Hb is fully saturated (see Fig. 33-9), and there is a maximum to which gas exchange units with normal ventilation and perfusion can raise their end-capillary O_2 content. Arterial oxygen content (and hence P_{O_2}) is a flow-weighted average of all gas exchange units. Therefore, under usual conditions, V_A/Q mismatching always results in arterial hypoxemia.*

The effect of V_A/Q mismatching on Pa_{CO_2} is often erroneously assumed to be negligible because Pa_{CO_2} usually can be maintained within the normal range even in the face of severe pulmonary pathology. However, the reason this occurs is that the CO_2-blood dissociation curve (Fig. 33-2) is a

* The only circumstance in which V_A/Q mismatch results in an increase in arterial P_{O_2} is during uptake of nitrous oxide.

Figure 33-3 (Figure Not Available) Arterial P_{O_2} as a function of F_{IO_2} and shunt fraction (Q_S/Q_T). Assumptions are shown on the upper left. The presence of shunt decreases arterial P_{O_2} for a given F_{IO_2}. As Q_S/Q_T increases, supplemental O_2 has progressively less effect on arterial P_{O_2}. *(Modified from Lawler and Nunn [291])*

monotonically increasing one. Moreover, the degree to which Pc_{CO_2} can be increased by units with abnormal V_A/Q is relatively small. The venoarterial P_{CO_2} difference is usually only 5 mm Hg under resting conditions and rarely exceeds 10 mm Hg. Therefore, it is usually possible for lung units with low P_{CO_2} (and hence Pc_{CO_2}) to "compensate" for units with high P_{CO_2}, producing a normal Pa_{CO_2} even in the face of significant V_A/Q abnormality. Although V_A/Q mismatching affects CO_2 exchange to the same degree as it does O_2 exchange, this is often not reflected in the blood gases because, as pointed out previously, compensatory hyperventilation can maintain Pa_{CO_2} within the normal range.

Right-to-left shunting is a special case of V_A/Q mismatch, with a V_A/Q ratio of zero. Blood flowing through a right-to-left shunt, whether intrapulmonary or intracardiac, will have gas tensions equal to mixed venous values. The net effect on arterial P_{O_2} and P_{CO_2} depends on the magnitude of the shunt (Fig. 33-3) (Figure Not Available) and the mixed venous and pulmonary capillary gas tensions. Because a major determinant of mixed venous P_{O_2} (and to a lesser extent mixed venous P_{CO_2}) is cardiac output (Q), changes in Q may modify the degree to which arterial P_{O_2} is determined by pulmonary gas exchange (Fig. 33-4).

Diffusion nonequilibrium is the situation that would exist if the gas tensions in the pulmonary capillary erythrocyte (Pc_{O_2}, Pc_{CO_2}) are not equal to the alveolar gas tensions. This situation can occur under two physiologic conditions: (1) increased pulmonary blood flow such that the erythrocyte does not have sufficient time in the alveolar capillary to enable gas tensions to reach equilibrium, or (2) a thickening of the alveolar-capillary membrane such that the rate of diffusion of gas from alveolus to capillary or vice versa is slowed. For CO_2 diffusion, nonequilibrium would result in arterial P_{CO_2} (Pa_{CO_2}) higher than P_{ACO_2}. For O_2 it would mean that Pa_{O_2} would be less than P_{AO_2}. In practice, there has never been any evidence for failure of diffusion equilibrium of CO_2. Despite much discussion of O_2 diffusion nonequilibrium, it probably rarely exists in clinical medicine. There is evidence for its existence during moderate exercise in patients with interstitial fibrosis and during severe exercise in normal individuals, particularly at high altitudes. [5] In anesthesia or critical care, O_2 diffusion nonequilibrium would probably occur only under very unusual circumstances

Figure 33-4 Effect of cardiac output on P_{O_2}. (A) Arterial and mixed venous O_2 tension and content are shown at a cardiac output of 5 L/min. Assuming a constant V_{O_2}, it can be seen that an increase in cardiac output to 8 L/min (B) will increase the Pa_{O_2} from 78 to 85 mm Hg. The reason for this is that at higher cardiac output Sv_{O_2} increases. The resulting increase in O_2 content of the shunted blood (here assumed to be 10% of cardiac output) then raises arterial O_2 content and hence Pa_{O_2}. P_{O_2} is in mm Hg; O_2 content is in mL/dL.

(e.g., a septic patient with high cardiac output breathing air at the top of Pike's Peak--altitude 4,301 m, barometric pressure 444 mm Hg).

It follows that the most likely causes of low Pa_{O_2} are low inspired P_{O_2}, hypoventilation, and V_A/Q mismatching, including right-to-left shunt (effect modulated by mixed venous P_{O_2}).

A common measurement used to assess the adequacy of pulmonary gas exchange is the A-a gradient:

Calculation of the A-a gradient takes into account any degree of hypoventilation or low inspired P_{O_2} such that an abnormally high A-a gradient reflects either V_A/Q mismatch (more specifically, low V_A/Q units) or shunt. The normal value for a child or young adult is less than 10 mm Hg. The A-a gradient has been related to age in years [10] according to the following formula:

There is considerable scatter of the data around the mean values predicted by this relationship, with individual values for the A-a gradient exceeding 30 mm Hg. The A-a gradient also increases with abnormalities of pulmonary gas exchange. The utility of the A-a gradient may be demonstrated by an example. The interpretation of the following arterial blood gases in an unconscious individual in an emergency room (breathing room air) may be aided by calculating the A-a gradient:

Assuming that barometric pressure equals 760 mm Hg, body temperature is 37°C (therefore P_{H_2O} = 47 mm Hg), and R equals 0.8 (in this case using Equation 2), then P_{AO_2} equals 59 mm Hg. Therefore, the A-a gradient equals 9 mm Hg (59 - 50), a normal value. Because the impairment of arterial oxygenation is associated with a normal A-a gradient, there is no intrinsic abnormality of pulmonary gas exchange. The diagnosis is most likely central respiratory depression.

One problem with the clinical use of the A-a gradient is that the normal value is highly dependent on inspired O_2 concentration. As F_{IO_2} increases, the A-a gradient becomes larger. In a normal individual breathing 100 percent O_2, the A-a gradient can exceed 70 mmHg; therefore, the interpretation of the A-a gradient in a patient breathing supplemental O_2 can be difficult. A more useful parameter is the a/A ratio (Pa_{O_2}/P_{AO_2}). Empirically, the a/A ratio was shown by Gilbert and Keighley [11] to be relatively invariant with F_{IO_2}. This observation of constant a/A ratio is also valid in a hyperbaric chamber up to an ambient pressure of 3 atm abs (Ch. 67). The normal a/A ratio is 0.85; lower values indicate impaired pulmonary gas exchange.

If mixed venous blood is available for analysis, a solution can be found for a simplified but clinically useful compartmental model of the lung. This three-compartment model assumes the following division of gas exchange units within the lung:

1. A compartment with V_A/Q = 1 (optimal matching of ventilation and perfusion).
2. A compartment with V_A/Q = 0 (shunt compartment).
3. A compartment with V_A/Q =
   (dead space compartment).

Shunt fraction (venous admixture) is the proportion of total blood flow perfusing the shunt compartment and can be calculated from the following equation:

where Q_S = shunt blood flow; and Q_T = cardiac output. Cc
O_2, CaO_2, CvO_2 = O_2 content in end-capillary, arterial and mixed venous blood, respectively.

CaO_2 and CvO_2 can be calculated directly. Cc
O_2 must be calculated from P_{AO_2} and the Hb-O_2 dissociation curve.

O_2 content is in mL/dL; P_{O_2} is in mm Hg; Hb concentration is in g/dL.

If P_{AO_2} is sufficiently high that end-capillary blood has Hb-O_2 saturation close to 100 percent, then by dividing numerator and denominator by the O_2 capacity (i.e., O_2 content at 100 percent saturation), Equation 8 can be rewritten as the following approximation:

Q_S/Q_T calculated using either equation (i.e., using oxygen as the "marker gas") includes units of low V_A/Q in addition to pure shunt. Breathing 100 percent O_2, however, eliminates the contribution of low V_A/Q units to Q_S/Q_T because any lung unit with nonzero V_A/Q will fully saturate with O_2 the capillary blood perfusing it. Some clinicians measure blood gases in patients breathing 100 percent O_2 in order to estimate the shunt. Unfortunately, the measurement is complicated by the fact that 100 percent O_2 breathing results in the progressive development of resorption atelectasis and a parallel increase in shunt. [12]

Whereas normal a/A ratio and hence Pa_{O_2} must imply the absence of low V_A/Q ratios or shunt, a normal Pa_{CO_2} does not. Regional hypercapnia may occur in pulmonary capillaries perfusing lung units that are relatively underventilated. A unit may be underventilated because of local airway obstruction or because of a high proportion of underperfused or nonperfused units (dead space) that consume a disproportionate amount of total ventilation. In either case, Pa_{CO_2} can be restored to normal by increasing total ventilation. V_A/Q abnormalities that affect pulmonary CO_2 exchange may not be detectable simply by inspection of the arterial blood gases. A method of assessing the most likely type of abnormality to affect CO_2 exchange is to determine physiologic dead space (V_D) using the Bohr equation:

where P_{ECO_2} = mixed expired P_{CO_2}; and V_T = tidal volume.

Frequently it is assumed that P_{ACO_2} = Pa_{CO_2} (Enghoff modification). To measure P_{ECO_2}, expired gas must be analyzed in a mixing box, or a bag must be used to collect several expired breaths. The dead space calculated using this equation includes anatomic and physiologic dead space as well as external dead space such as in the breathing circuit. Dead space can also be measured on a breath-by-breath basis if a volume capnogram is used. Dead space measured using this formula (total physiologic dead space) includes airway dead space (anatomic or series dead space) and alveolar dead space (intrapulmonary or parallel dead space).

Mixed expired gas analysis is often not clinically available, but an assessment of dead space ventilation may be made by examining the relationship between minute ventilation (V_E) and Pa_{CO_2}. V_E is continuously displayed by modern ventilators and can also be measured in spontaneously breathing individuals by using a spirometer. Assuming normal V_{CO_2}, the following equation describes an empirical relationship [13]:

where W = body weight (kg).

In other words, if V_E (L/min) multiplied by Pa_{CO_2} (mm Hg) exceeds eight times body weight (kg), an increase in dead space exists, indicating that to maintain a normal Pa_{CO_2}, higher than usual ventilation is required. This product may also be elevated by increased CO_2 production (shivering, fever, or metabolic acidosis).

Using the respiratory gases to assess pulmonary gas exchange has some drawbacks. First, the relationship between partial pressure and gas content is nonlinear for both O_2 and CO_2. Alterations in cardiac output, hemoglobin concentration (resulting in altered venous blood gas tensions), or inspired gas composition may lead to different calculated values of Q_S/Q_T or V_D/V_T even if actual V_A/Q ratios in the lung are unchanged. [14] Second, changes in O_2 or CO_2 exchange can only provide information on a limited portion of the spectrum of V_A/Q ratios. Furthermore, an increase in calculated Q_S/Q_T (Equation 8) cannot distinguish between a shift to lower

V A/Q ratios and an increase in true shunt.

In a more sophisticated technique described by Wagner et al, [12] [15] a dilute mixture of several "inert" (not metabolically active) tracer gases is infused intravenously. The ratio of partial pressures Pc
/Pv or P A/Pv at a gas exchange unit is described by the following equation

where Pc
, Pv, P A = partial pressures of the gas in end-capillary blood, venous blood, and alveolar gas, respectively; lambda = blood/gas partition coefficient of the gas; and V A/Q = ventilation/perfusion ratio of the gas exchange unit.

In this technique (multiple inert gas elimination, MIG), the six gases generally used are sulfur hexafluoride, ethane, cyclopropane, enflurane, diethyl ether, and acetone, spanning a range of lambda around 70,000. Each gas provides information about a particular region in the spectrum of V A/Q, permitting a multi-compartment model to be calculated. The MIG method has been used to demonstrate the development of both V A/Q mismatching and shunt during general anesthesia. [16] Figure 33-5 (Figure Not Available) demonstrates the use of MIG to calculate a 50 compartment model of V A/Q. Using this model, shunt fraction assessed by using MIG has been correlated with atelectatic areas in dependent lung regions visible on chest computed tomography (CT) scan (see Fig. 33-5) (Figure Not Available) . [17] [18] MIG has been used to demonstrate improved V A/Q matching during continuous axial rotation in patients with acute lung injury. [19] Although this technique cannot yet be used as an on-line monitor, future development of rapid, inexpensive gas analyzers could conceivably allow continuous monitoring of V A/Q using this principle.

MEASUREMENT OF BLOOD GAS TENSIONS

The most straightforward method of ascertaining Pa O_2 is to measure it directly from a blood sample (Ch. 38) , usually by using a Clark electrode, which incorporates platinum and reference electrodes in an electrolyte bath. When a negative polarizing voltage is applied to the platinum electrode, O_2 molecules in solution are reduced by electrons from the electrode. The electrons from the cathode react as follows:

Each molecule of O_2 is reduced to two hydroxyl ions by four electrons. In the Clark electrode, the electrolyte solution is separated from the fluid being measured (e.g., blood) by a thin O_2 permeable membrane. The current generated is proportional to P O_2 within the sample. When CO_2 is equilibrated with an aqueous solution the concentration of carbonic acid is proportional to the P CO_2 .

P CO_2 electrodes work by measuring the change in pH induced when blood equilibrates with a potassium chloride/sodium bicarbonate solution. [20]

The history of the development of blood gas analysis has been described in Severinghaus and Astrup, [21] and that of oxygen monitoring in general by Severinghaus. [22] An excellent treatment of the electrochemistry and mathematics of blood gas electrodes can be found in Cobbold. [23]

To obviate the need to withdraw blood samples for P O_2 analysis, intra-arterial P O_2 monitors are being developed. Initial attempts to use a Clark-type electrode were confounded by problems of drift and blood coagulation, problems that have largely been overcome. A fiberoptic technique has also been used, based on the property of O_2 to absorb energy from excited electrons in a fluorescent dye. Incident light is used to elevate electrons in the dye to a higher energy state. These excited electrons may then return to a lower energy level, emitting a photon in the process. Molecular O_2 , by absorbing the energy, inhibits the photon emission. This process, fluorescence quenching, is related to the P O_2 . [24]

In situations in which arterial puncture cannot be achieved or may be technically difficult (for example, in

Figure 33-5 (Figure Not Available) Effect of anesthesia on pulmonary atelectasis and gas exchange. (A) CT scan through the chest of an awake patient. Adjacent to it is the distribution of ventilation (open circles) and perfusion (solid circles) in a 50-compartment lung model, determined by using the multiple inert gas method. A unimodal distribution is shown for the awake individual with a shunt-fraction ($\dot{Q}_S/\dot{Q}_T$) of 0.8 percent. (B) After a period of general anesthesia with positive-pressure ventilation, crescent-shaped areas of increased tissue density (arrows) appear in posterior lung regions. Corresponding to these changes are a widening of both V_A and Q distributions and an increase in $\dot{Q}_S/\dot{Q}_T$ to 7.4 percent. (C) The same individual after the application of 10 cm H_2O PEEP. Very little change is observed in the areas of atelectasis, and V_A/Q matching is further worsened, with the development of a bimodal ventilation distribution and a further increase in $\dot{Q}_S/\dot{Q}_T$ to 11.1 percent. These changes are accompanied by a drop in Pa O_2 from 162 to 137 mmHg. *(From Tokics et al [17])*

neonates), capillary P O_2 may approximate the arterial value. This is particularly true if the sampling site (e.g., heel) is prewarmed, causing an abundance of local blood flow relative to local tissue O_2 consumption. Although capillary P O_2 tends to be significantly lower than the arterial value, capillary O_2 saturation approximates arterial O_2 saturation (Sa O_2) (capillary value is usually slightly lower) because of the shallow slope of the upper part of the Hb-O_2 dissociation curve.

Temperature Correction of Blood Gases

Conventionally, blood gas electrode temperature is maintained at 37°C in most hospital laboratories. Rarely is a patient's body temperature exactly 37°C. Obtaining a blood gas sample at any other temperature and then either warming or cooling the sample to 37°C will cause a change in the blood gas tensions inside the syringe. Heating a sample of blood causes decreased gas solubility in plasma as well as reduced O_2 affinity for hemoglobin. Therefore, if a syringe of blood is gas-tight and no bubbles are present, heating of the syringe will elevate blood gas tension. The reverse is true for cooling a blood sample. Therefore, P O_2 (and P CO_2) values obtained from a hypothermic patient will be artifactually elevated. Several algorithms exist for temperature correction, such that the true partial pressure, predictive of physical and chemical activity at the tissue, can be calculated (Table 33-1) . The algorithms approved by the National Committee for Clinical Laboratory Standards [25] and most commonly used in clinical instruments sold in the United States are indicated in Table 33-1 .

The application of this equation for P O_2 is shown in Figure 33-6 (Figure Not Available) . The P O_2 derived from a 37°C electrode is overestimated if the patient is hypothermic and underestimated if the patient is febrile. At high P O_2 values (>400 mm Hg) the effect is small because hemoglobin is fully saturated in this region. At P O_2 values below 100 mm Hg, however, the degree of overestimation may be severe. For example, at a patient temperature of 30°C and a P O_2 below 80 mm Hg, the

TABLE 33-1 -- Algorithms for Correction to Body Temperature of Blood Gas Tensions Measured at 37°C
Data from a collective review by Ashwood et al [275] and Siggaard-Andersen et al [276]

[a]

[a] NCCLS-approved standard [25]

true P O_2 is overestimated by about 60 percent unless temperature correction is applied.

Presently available evidence indicates that, during hypothermia, corrected arterial pH should be maintained in the alkalotic range (i.e., maintain uncorrected pH close to 7.4 (Ch. 38) . In contradistinction, the analysis presented previously suggests that P O_2 values should be corrected for temperature. [26]

Figure 33-6 (Figure Not Available) Temperature correction of blood P O_2 : percentage error of P O_2 measurement at various body temperatures, with blood gas electrode at 37°C. If patient temperature is 20°C, a P O_2 measurement performed at 37°C would overestimate the true value by more than 200 percent. The curves demonstrate that the percentage of error is greater for venous values (P O_2 < 100 mm Hg) than for arterial measurements (P O_2 > 300 mm Hg). *(From Camporesi and Moon [26])*

Artifactual Effects on Gas Tension Measurement

Handling of arterial blood samples for measurement in a laboratory removed from the patient is important to maintain stability of gas tensions. Gas bubbles in the syringe will allow diffusion of O_2 and CO_2 between the blood sample and the bubbles, usually lowering the values in the blood. This is particularly true for O_2 at high P O_2 values because in this region, O_2 is less soluble in blood than is CO_2 . Removal of all air bubbles before capping the syringe and placing it in ice water can maintain stability of blood gas samples for several hours. Erythrocytes do not contain mitochondria, and therefore, do not consume oxygen. Both leukocytes and platelets do contain mitochondria, and in the presence of extreme leukocytosis or thrombocytosis, significant O_2 consumption by the blood sample may occur. [27] This may be suspected when P O_2 values are inexplicably low in the presence of high leukocyte or platelet counts. Inhibition of cellular O_2 consumption may be accomplished by adding to the sample sodium fluoride [28] (available in evacuated tubes used for collection of blood for glucose measurement) or cyanide.

TRANSCUTANEOUS GAS TENSION MEASUREMENT

In areas of the skin where local blood flow exceeds the amount required for local O_2 consumption, as mentioned previously, capillary P_{O_2} may approximate Pa_{O_2}, which may be particularly true if the local area is warmed. This principle has been exploited by manufacturers of transcutaneous P_{O_2} (P_{TCO_2}) measuring devices, which usually consist of a small electrode that is attached with adhesive to the skin. The skin is locally warmed to 40 or 41°C. O_2 from capillaries diffuses through the intact skin into a Clark-type electrode that measures P_{O_2} directly. This value usually correlates well with Pa_{O_2}; however, in the presence of peripheral vasoconstriction [29] or with thick (adult) skin, the measurement may be erroneous. A reduction in cardiac output tends to result in an artifactual decrease in P_{TCO_2} because of the ensuing cutaneous hypoxia. Peripheral vascular disease also reduces P_{TCO_2}, and the technique has been demonstrated to predict the success or failure of wound healing. [30]

Transcutaneous gas monitoring is particularly useful in infants, in whom local skin blood flow tends to be high and in whom repeated withdrawals of arterial blood may cause anemia. These instruments require frequent calibration. Furthermore, the time constant of measurement is relatively long, and a sudden decrease in Pa_{O_2} may not be detectable quickly enough so that a therapeutic response can be made. Also, skin burns have sometimes resulted from prolonged application of these devices.

Using a miniaturized Clark electrode embedded in a polymethylmethacrylate eyepiece, transconjunctival P_{O_2} monitoring devices are well tolerated and provide a P_{O_2} reading that is approximately half the arterial P_{O_2}. [31] Although it is highly correlated with Pa_{O_2} in hemodynamically stable patients, it is significantly affected by degree of hydration. [32] [33]

P_{TCCO_2} monitoring devices are also available, [34] although because of the ease with which end-tidal P_{CO_2} can be measured, particularly in intubated patients, P_{TCCO_2} measurement has been less popular. Because the changes in transcutaneous gas tensions that occur during apnea are relatively slow to monitor for airway disconnects, other techniques are preferable.

MEASUREMENT OF OXYGEN SATURATION

Several species of Hb may exist in blood: oxyhemoglobin (O_2Hb), deoxygenated Hb (HHb), carboxyhemoglobin (COHb), and methemoglobin (MetHb). To avoid ambiguity, the following definitions have been proposed [35]:

S_{O_2} is most commonly reported as a percentage obtained by multiplying the value obtained from Equations 17 and 18 by 100.

Measurement of Sa_{O_2} is an alternative method to PO_2 of assessing arterial blood oxygenation. The fact that absorption and reflectance spectra of Hb are affected by its oxygenation allows for convenient optical methods of measurement. The traditional method for monitoring Sa_{O_2} is to observe the skin and mucous membranes for cyanosis (Ch. 28) . In 1947 a systematic comparison of the clinical detection of a cyanosis by medical staff and blood O_2 saturation measurement with an ear oximeter in normal volunteers demonstrated the poor accuracy of cyanosis as an indicator of hypoxemia. [36] In this study a total of 7,204 observations of skin and mucous membrane color were made in normal volunteers breathing air or hypoxic gas over a measured Sa_{O_2} range of 71 to 100 percent. False-positive diagnosis of cyanosis was common; cyanosis was diagnosed in 37 percent of 4,587 observations despite a measured Sa_{O_2} of 91 to 100 percent. On the other hand, in 1,723 observations of hypoxic volunteers with a measured Sa_{O_2} between 71 and 80 percent, normal color was said to be present 12 percent of the time. Lundsgaard and Van Slyke [37] had suggested that in order for cyanosis to be detectable, 5 g/dL of deoxygenated Hb must be present in the arterial blood, although Stadie [38] found that cyanosis could be detected at lower arterial concentrations of deoxygenated Hb (Fig. 33-7) . If the threshold for visual detection of cyanosis is assumed to be at an arterial concentration of desaturated blood = 5 g/dL, then at a total Hb concentration of 16 g/dL cyanosis would not occur until Sa_{O_2} decreased to less than 70 percent. At a total Hb concentration of 10 g/dL, cyanosis would only occur when Sa_{O_2} reached 50 percent. The evident inaccuracy and uncertainty inherent in attempts to assess oxygenation by visual inspection have led to highly successful quantitative methods.

CO-Oximetry

Simultaneous measurement of several Hb species with different absorption spectra can be accomplished by using

Figure 33-7 Quantity of deoxygenated Hb in arterial blood as a function of degree of cyanosis. Although traditionally it has been assumed that 5 g/dL of deoxygenated hemoglobin is required for the detection of cyanosis, mild cyanosis can clearly be observed at lower values. *(Data plotted from Stadie [38])*

multi-wavelength absorption with at least one wavelength for each component Hb. [39] This principle has been incorporated into clinical instruments capable of measurement of a blood sample in a cuvette within 1 to 2 minutes. Commonly available devices measure Hb, O_2Hb, COHb, and MetHb and, except when the patient has been administered a dye (e.g., methylene blue [40] [41]) they are susceptible to few artifacts.

Transcutaneous Oximetry

The fact that different hemoglobin species, particularly Hb and oxyhemoglobin (OHb) have different absorption spectra suggests the possibility of using absorption of light *in vivo* to calculate arterial Hb-O_2 saturation (Sa_{O_2}). A dual-wavelength system can be used to estimate Sa_{O_2} if the following conditions are met: (1) the light is transilluminating arterial blood, (2) there are no significant quantities of other hemoglobin species, for example, methemoglobin (MetHb) or carboxyhemoglobin (COHb), and (3) the absorption of light by tissue is negligible.

The first condition may be met, for example, by transilluminating the earlobe if the tissue is kept warm. Under these circumstances the ratio of blood flow to tissue O_2 consumption is relatively high and the capillary blood is predominantly arterial. The second condition is met under most clinical circumstances, in which the total of other Hb species is usually less than 5 percent of the total. The third condition can be ensured by appropriate choice of wavelength.

Dual-wavelength oximeters became available in the 1940s, but because of their rather cumbersome size and the need to calibrate them for each individual patient, they never attained widespread use. An eight-wavelength ear oximeter was produced by Hewlett-Packard, [42] in which active heating of the earlobe by the sensor maintained a high proportion of arterial blood in the capillary bed.

Principles of Pulse Oximetry

One of the major objections to the use of ear oximeters is that one can never be totally sure that the earlobe contains predominantly arterial blood because this instrument has no means of differentiating between arterial and venous hemoglobin. The pulse oximeter is able to make this differentiation by assuming that the pulsatile portion of the signal is entirely arterial blood. This assumption is almost always true except under unusual clinical circumstances, such as when there are prominent venous pulsations as in tricuspid regurgitation. [43]

The principle of pulse oximetry is shown schematically in Figure 33-8 (Figure Not Available) . The light passing through tissue is absorbed by tissue, as well as by venous and arterial blood. The ratio S is calculated at two wavelengths of light, usually around 660 nm and 940 nm.

where AC_{660} , AC_{940} = pulsatile components of absorbance at 660 and 940 nm wavelengths; and DC_{660} , DC_{940} = corresponding steady-state components.

S is then empirically related to O_2 saturation and incorporated into the design of the instrument. It has been proposed that the assessment of Sa_{O_2} by pulse oximetry be abbreviated as Sp_{O_2} . [35]

In practice, pulse oximeters use two light-emitting diodes (LED) and one photo diode as transmitting and sensing transducers, usually placed on opposite sides of a digit. The two LEDs are activated alternately. The ratio S is calculated electronically; from it Sp_{O_2} is derived by an internally stored algorithm. Although in principle the light absorbance technology for monitoring oxyhemoglobin (O_2Hb) saturation has been in existence for almost 50 years, the use of the pulse principle has increased substantially the reliability of such monitors and resulted in their widespread use.

Figure 33-8 (Figure Not Available) Principle of pulse oximetry. Light passing through tissue containing blood is absorbed by tissue as well as arterial, capillary, and venous blood. Usually only the arterial blood is pulsatile, however. Light absorption may therefore be split into a pulsatile component (AC) and a constant or nonpulsatile component (DC). Hb-O_2 saturation may be obtained by application of equation (19) in text. *(From Tremper and Barker [86])*

To assess arterial oxygenation in instances in which it is impossible to provide a transmission path, reflectance oximetry has been exploited. Probes have been developed to monitor fetal oxygenation during labor, [44] [45] [46] and an esophageal probe has been used for monitoring Sp_{O_2} in situations when extremities are unavailable or have a pulse of insufficient amplitude. [47]

One drawback of oximetry is that it is rather insensitive to large changes in arterial P_{O_2} at the high end of the Hb-O_2 dissociation curve, where large changes in P_{O_2} are associated with small changes in Sp_{O_2} . Another problem with it is that because only two wavelengths are used, only two species of Hb can be resolved (assumed to be oxyhemoglobin and reduced hemoglobin). Depending on their absorption spectrum, significant quantities of other Hb species may not be readily detected (see later). Other disadvantages of pulse oximetry include inability to obtain a signal of sufficient amplitude during hypothermia or low cardiac output, interference by electrocautery and a variety of artifacts described later. Finally, as a monitor of the adequacy of ventilation and because Sp_{O_2} is only minimally affected by P_{CO_2} (via the Bohr effect), pulse oximetry may fail to warn when circumstances permit an open airway and availability of 100 percent inspired O_2 . [48]

Use of Pulse Oximetry

Although oximetry has been available since the 1940s, the development of pulse oximetry triggered its wide acceptance because of the latter's reliability and convenience. Pulse oximetry has become a standard component of anesthesia monitoring, and it has also gained wide acceptance in postanesthesia care units and ICUs, as well as for patients undergoing a variety of diagnostic procedures such as gastrointestinal endoscopy. The wide application of pulse oximetry attests to the clinical utility of this major advance in monitoring.

Intraoperative Monitoring

In a trial in which 20,802 patients scheduled for surgery were randomly assigned to receive monitoring with pulse oximetry or not, hypoxemia was detected during anesthesia 20 times and hypoventilation 3 times as frequently in the pulse oximetry group. [49] [50] These differences persisted in the postanesthesia care unit, and in addition bronchospasm, atelectasis, and bradycardia were detected more frequently in the group monitored with oximetry. There were no differences, however, between groups in the incidence of cardiovascular, neurologic, or infectious complications or death. One might incorrectly conclude that the use of pulse oximetry has made no measurable improvement in the practice of anesthesia. In the closely monitored setting of the operating room, however, the incidence of catastrophic events attributable to undetected hypoxemia is predictably low. It is likely that pulse oximetry can detect and possibly avoid some catastrophic perioperative complications, but a trial likely to have sufficient statistical power to demonstrate such an outcome difference would be impossibly large. On the basis of favorable clinical experience with this technology, pulse oximetry will undoubtedly remain a standard monitoring technique during anesthesia. [51]

Postoperative Monitoring

Bierman et al [52] reported that the use of pulse oximetry may reduce the number of arterial blood gas analyses by approximately 50 percent in a group of patients followed through their ICU course after elective cardiac surgery (Ch. 68) . In addition, several clinically unrecognized hypoxemic episodes were detected in the group of patients monitored with pulse oximetry. In 1985 Catley et al [53] continuously monitored patients in the early postoperative period and observed frequent episodes of arterial desaturation. Since then there have been numerous studies in which continuous recording of pulse oximetry was used to monitor patients for up to several days after surgery. [54] [55] [56] [57] [58] [59] [60] [61] [62] [63] [64] [65] [66] [67] [68] However, a significant number of the low readings can be due to motion artifact, the elimination of which requires appropriate methodology. [69]

These studies indicate that significant desaturation (Sp_{O_2} , 80-85%) is relatively common. Desaturation also occurs in some patients prior to surgery, [60] [61] [63] [64] and there is evidence that the existence of preoperative hypoxemic episodes may predict desaturation postoperatively. Hypoxemia is often correlated with peak effects of analgesia, and supplemental O_2 administration appears to be effective in prevention. [58] [65]

Desaturation is often correlated with an increase in heart rate [57] [59] and electrocardiographic (ECG) evidence of myocardial ischemia. [59] [62] Rosenberg and Kehlet [67] also observed that patients who experienced postoperative desaturation tended to have lower scores on cognitive tests.

The demonstration of hypoxemic episodes by continuous pulse oximetry and the evidence suggesting that they may cause important central nervous system and cardiovascular morbidity points to other clinical situations in which similar studies are warranted. For example, studies in pregnant experimental animals have shown that moderate reduction in inspired P_{O_2} of the mother can cause significant reduction in umbilical artery and venous P_{O_2} , alteration of fetal heart rate, and reduced fetal O_2 consumption. [70] [71] [72] [73] Therefore, postoperative hypoxemic episodes in pregnant women might be detrimental to the fetus. However, in a human study in which 10% inspired O_2 was administered for 10 minutes to women in the third trimester of pregnancy there was no measurable change in baseline fetal heart rate, heart rate variability, or Doppler velocimetry in the umbilical or middle cerebral arteries, [74] despite Sp_{O_2} values as low as 80 percent. These observations suggest that during short-term periods of maternal hypoxemia in humans, compensation mechanisms such as increased uterine blood flow prevent significant fetal hypoxia.

Errors in Pulse Oximetry

Because pulse oximeters are dual-wavelength devices, the presence of Hb species other than Hb and O_2Hb must result in erroneous readings.

Carboxyhemoglobin

The effect of carboxyhemoglobin may be discerned by examining its absorption spectrum. At 920 nm, COHb has an

extremely low absorbance and does not contribute to total absorbance. At 660 nm, however, COHb has an absorbance very similar to that of O_2Hb; therefore, Sp_{O_2} will be falsely high. This effect has been measured in a canine study in which the actual pulse oximeter reading of Nellcor and Ohmeda pulse oximeters was approximated by the following formula [75] :

where Sp O_2 * = pulse oximeter reading.

A falsely high pulse oximeter reading occurs in the presence of COHb. In that study, when COHb was 50 percent, Sp O_2 was approximately 95 percent. In human cases of carbon monoxide poisoning, a similar error has been observed. [76] [77] [78] [79] [80] In 30 patients with COHb levels ranging from 25.2 to 54 percent (mean 36.9%) Hampson [80] observed that each percent increase in COHb resulted in only a 1 percent decrease in Sp O_2 reading.

Methemoglobin

Methemoglobin (MetHb) has a larger absorbance than either of the two major species of Hb at 940 nm but simulates Hb at 660 nm. Therefore, at high Sa O_2 levels (>85%) the reading underestimates the true value; at low Sa O_2 levels (<85%) the value is falsely high. [81] [82] In the presence of high MetHb concentrations, the measured Sa O_2 approaches 85 percent, independently of the actual arterial oxygenation.

Other Toxic Alterations in Hemoglobin

Sulfhemoglobin, which can form after exposure to certain drugs and chemicals, and cyanmethemoglobin, a product of the pharmacologic induction of methemoglobinemia for treatment of cyanide poisoning, are nonfunctional hemoglobins. Although sufhemoglobinemia is known to produce errors in CO-oximetry, [83] [84] [85] usually with a false reading of methemoglobin, the effects of these species on pulse oximetry has not been reported.

Structural Hemoglobinopathies

In neonates there is a large proportion of hemoglobin F. Because hemoglobin F has almost the same absorption spectrum as hemoglobin A, it has almost no measurable effect on Sp O_2 . [86]

Sp O_2 has been reported to be accurate in patients with hemoglobin S disease when Sa O_2 determined by this method was compared with Sa O_2 obtained by using *in vitro* oximetry, [87] [88] [89] although it is possible that the presence of Hb S produces a similar artifact in both types of instrument. During sickle cell crisis it has been reported that Sp O_2 overestimates Sa O_2 measured by CO-oximetry [90] by an average of 6.9 percent. Patients with sickle cell disease have a rightward shift of the Hb-O_2 dissociation curve (increased P_{50}), and therefore at any given Pa O_2 value, the Sp O_2 is lower than the normal Hb-O_2 dissociation curve would predict.

Jay and Renzi [91] reported pulse oximetry in a patient with hemoglobin H anemia. They reported that two different pulse oximeters read 93 and 95 percent (artifactually high), respectively, in a patient who had a hematocrit of 9 percent; however, they did not report independent measurements of Sa O_2 with which to compare the pulse oximeter readings.

Hemoglobin Koln, an unstable hemoglobin, has been associated with an artifactual reduction of 8 to 10 percent in Sp O_2 reading. [92] [93]

Artificial hemoglobin solutions, such as diaspirin-cross-linked hemoglobin [94] and bovine polymerized hemoglobin (oxygen carrier 201), [95] [96] have no apparent effect on Sp O_2 , at least after infusion of relatively low doses and under normoxic conditions (Ch. 45) .

Hemoglobin Concentration

At normal oxygenation levels in humans, over a range of hemoglobin levels from 2.3 to 8.7 g/dL, Sp O_2 accurately reflects Sa O_2 . [97] During hypoxia, however, Sp O_2 tends to underestimate Sa O_2 to a degree that increases linearly as Hb concentration falls. In a study by Severinghaus and Koh, [98] at an actual Sa O_2 of 53 percent and an Hb concentration of 8.2 g/dL, the average measured Sp O_2 was approximately 15 percent low, of which 8 percent was attributed to anemia (the remaining error was due to oximeter measurement errors unrelated to Hb concentration).

Polycythemia has no apparent effect upon pulse oximeter reading. In studies of children with cyanotic congenital heart disease, many of whom were polycythemic, there was no systematic error in Sa O_2 reading that could be attributed to high Hb concentration. [99] [100]

Dyes

Clinically used dyes may also have an effect on pulse oximetry. Methylene blue results in a severe decrease in measured Sp O_2 . [101] [102] [103] [104] [105] Its administration can also cause alterations in cardiac output (an increase, then a decrease). Therefore, in the presence of V_A/Q mismatch, this may result in a transient increase and then a decrease in actual Sa O_2 . The presence of high concentrations of methylene blue in blood can also alter CO-oximeter readings such that an artifactual decrease in measured O_2 saturation may result. Quantitative information, however, is lacking.

Indocyanine green causes less artifactual decrease than methylene blue, [102] and a still smaller decrease is noted with indigo carmine. [102] [106] Fluorescein injection has no measurable effect. [102] [106]

Isosulfan blue (sulfan blue, Patent blue V), a dye used to visualize lymphatic vessels for surgical procedures, has a peak absorption at 640 nm [107] and increased absorbance at 660 nm. Its administration has been associated with prolonged artifactual reduction in Sp O_2 . [108] [109] [110] It tends to affect CO-oximetry by producing an artifactual increase in methemoglobin and a negative carboxyhemoglobin reading. This phenomenon is not observed with subcutaneous injection of up to 100 mg into adults.

Nail Polish and Other Nail Pigments

Effects of nail polish have also been measured. Blue nail polish, with absorbance near 660 nm, has the greatest effect on Sp O_2 reading, an artifactual decrease. Other colors have smaller effects. [111] Red henna, a pigment used for hand and nail decoration in some tropical countries, has no significant effect on Sp O_2 , although black henna can block enough light to prevent a satisfactory reading. [112]

Bilirubin

High levels of bilirubin have no significant effect on pulse oximeter readings, [113] [114] although older types of ear oximeters may measure a falsely low value. [42] In the presence of jaundice, multi-wavelength laboratory oximeters may also register a falsely low Sa O_2 and a falsely high COHb and MetHb. [115] [116]

Skin Pigment

Deeply pigmented skin can result in inability to pick up arterial pulsations by a pulse oximeter. Small errors in Sp O_2 readings from black individuals have been reported by some investigators, with others finding no significant effect. [106]

Tape

Four varieties of transparent tape have been shown not to alter Sp O_2 measurements between 85 and 100 percent [117] ; however, smeared adhesive caused by

reusing a disposable oximeter probe has been reported to cause falsely low Sp o_2 readings. [118]

Low Oxygen Saturation

There are obvious practical difficulties associated with *in vivo* calibration of pulse oximeters in humans at low Sa o_2 . Using normal volunteers and direct measurement of Sa o_2 in arterial blood, Severinghaus et al [119] compared the results of Sp o_2 obtained from a variety of pulse oximeters during brief periods of profound hypoxemia. The mean nadir of arterial Hb-O_2 saturation was 56 percent. Within the pulse oximeters tested at that time, there was considerable variation. At 75 percent Sa o_2 the bias (systematic error) was scattered uniformly around zero, with individual units either overestimating or underestimating the true Sa o_2 by as much as 7 percent. Below 60 percent Sa o_2 most units underestimated the actual Sa o_2 (false low measurement).

Other

Ambient light, particularly fluorescent light, can falsely elevate Sp o_2 reading, [120] [121] which occurs especially if the flicker frequency of the light is close to a harmonic of the diode switching frequency. Poor contact of the sensor with the skin can result in direct "optical shunting" of light from source to detector, either directly or by reflection from the skin, resulting in a falsely low Sp o_2 reading. [122] Reduced blood flow to the extremity results in a diminished signal and can cause inability to obtain an Sp o_2 reading [123] or a falsely low reading, [123] [124] possibly in part due to greater fractional tissue consumption of arterial oxygen. This results in a lower saturation in the pulsatile blood component that is measured. There may be a slight reduction (approximately 1%) in measured Sp o_2 during the reactive hyperemia that occurs after ischemia in the arms. [125] The authors hypothesized that venous pulsations may have been responsible for the decrease.

Vasoconstriction or hypotension can cause loss of Sp o_2 signal. Topical application of nitroglycerin ointment has been used to restore the signal, although this can worsen hypotension. Digital block is often successful. Topical application of Emla cream (lidocaine 2.5%, prilocaine 2.5%, Astra Pharmaceuticals, Westborough, Mass) to the earlobe covered by an occlusive plastic dressing for 30 minutes has been reported to facilitate a reliable signal. [126]

The reported errors in pulse oximetry are summarized in Table 33-2 . Pulse oximetry has been well reviewed by Alexander et al, [127] Kelleher, [106] Tremper and Barker, [86] Severinghaus and Kelleher, [121] and Wahr et al. [128]

MIXED VENOUS OXYGEN MONITORING

Mixed venous O_2 saturation (Sv $_{O_2}$) is affected by several factors:

where [Hb] = hemoglobin concentration (g/dL); 13.9 = constant (O_2 combining power of Hb [mL/10 g]); and Q= cardiac output.

Low Sa $_{O_2}$ or low cardiac output, low [Hb], or elevated V $_{O_2}$ may result in a decrease in Sv $_{O_2}$. All these conditions could produce impairment of O_2 delivery to the tissues. Therefore, this single measurement (Sv $_{O_2}$) may be uniquely helpful in detecting any condition that might result in impaired tissue oxygenation. Sv $_{O_2}$ can be monitored by intermittent measurement of blood withdrawn through a pulmonary artery catheter or may be continuously monitored by using a pulmonary artery catheter equipped with fiberoptic bundles. These catheters have two fiberoptic bundles carrying an incident light beam and a reflected light beam. Using the fact that the reflected spectrum of Hb is dependent on the degree of oxygenation, the appropriate calculations can be performed by the instrument and a continuous display of Sv $_{O_2}$ provided. Low Sv $_{O_2}$ (usually < 60%) may sensitively reflect an abnormality of one or more of the factors on the right-hand side of Equation 21. Several factors may artifactually elevate Sv $_{O_2}$, however. These include wedging of the catheter and mitral regurgitation (which tend to bring the catheter tip into contact with arterialized blood), as well as sepsis and left-to-right shunts (either intracardiac or peripheral).

Monitoring of P $_{vO_2}$ instead of Sv $_{O_2}$ requires additional considerations. Although Sv $_{O_2}$ is a function of four variables (Equation 21), other factors acting on the Hb-O_2 binding curve may alter P $_{vO_2}$ independently. In Figure 33-9 a normal

TABLE 33-2 -- Artifacts in Pulse Oximetry

FACTOR	EFFECT	REFERENCES
TOXIC ALTERATIONS IN HEMOGLOBIN		
Carboxyhemoglobin (COHb)	Slight reduction in Sp $_{O_2}$ reading (i.e. overestimates fraction of Hb available for O_2 transport)	[76] [77] [78] [79] [80]
Cyanmethemoglobin	Not reported	
Methemoglobin (MetHb)	At high levels of MetHb, Sp $_{O_2}$ approaches 85%, independent of actual Sa $_{O_2}$.	[81] [82]
Sulfhemoglobin	Not reported (affects CO-oximetry by producing a falsely high reading of MetHb [83] [84] [85]).	
STRUCTURAL HEMOGLOBINOPATHIES		
Hemoglobin F	No significant effect	[86]
Hemoglobin H	No significant effect (i.e., overestimates fraction of Hb available for O_2 transport)	[91]
Hemoglobin Koln	Artifactual reduction in Sp $_{O_2}$ of 8-10%	[92] [93]
Hemoglobin S	No significant effect	
HEMOGLOBIN REPLACEMENT SOLUTIONS		
Diaspirin cross-linked Hb	No significant effect	[94]
Bovine polymerized Hb (oxygen carrier-201)	No significant effect	[95] [96]
DYES		
Fluorescein	No significant effect	[102] [106]
Indigo carmine	Transient decrease	
Indocyanine green	Transient decrease	[102] [106]
Isosulfan blue (Patent Blue V)	No significant effect at low dose; prolonged decrease at high dose.	[108] [109] [110]
Methylene blue	Transient, marked decrease in Sp $_{O_2}$, lasting up to several minutes. Possible secondary effects due to effects on hemodynamics (see text)	[101] [102] [103] [104] [105]
HEMOGLOBIN CONCENTRATION		
Anemia	If Sa $_{O_2}$ normal: no effect. During hypoxemia, at Hb values less than 14.5 g/dL: progressive underestimation of actual Sa $_{O_2}$	[97] [98]
Polycythemia	No significant effect	[99] [100]
OTHER		
Ambient light interference	Bright light, particularly if flicker frequency is close to a harmonic of light-emitting diode switching frequency, can falsely elevate Sp $_{O_2}$ reading.	[120] [121]
Arterial O_2 saturation	Dependent on manufacturer. During hypoxemia Sp $_{O_2}$ tends to be artifactually low.	[119] [268] [277] [278]
Blood flow	Reduced amplitude of pulsations can cause difficulty in obtaining a reading and a falsely low reading.	[123] [124]

Henna	Red henna: no effect; black henna: may block light sufficiently to preclude measurement.	[112]
Jaundice	No effect. Multi-wavelength laboratory oximeters may register a falsely low Sa O_2 and a falsely high COHb and MetHb. [115] [116]	[113] [114]
Motion	Movement, especially shivering, may depress Sp O_2 reading.	[121]
Nail polish	Slight decrease in Sp O_2 reading; greatest effect is with blue nail polish.	[111]
Sensor contact	"Optical shunting" of light from source to detector either directly or by reflection from skin results in falsely low Sp O_2 reading.	[122]
Skin pigmentation	Small errors or no significant effect reported. Deep pigmentation can result in reduced signal.	[106]
Tape	Transparent tape between sensor and skin has little effect. Falsely low Sp O_2 has been reported when smeared adhesive is in the optical path.	[117] [118]
Vasodilatation	Slight decrease	[125]
Venous pulsation (e.g., tricuspid insufficiency)	Artifactual decrease in Sp O_2	[43]

curve is shown adjacent to curves depicting both increased and decreased Hb-O_2 affinity. For the same Sa O_2 and Sv O_2 (and hence arteriovenous O_2 content difference) substantially different values for P vO_2 will occur under the three conditions. Correct interpretation of P vO_2 values must depend on the position of the Hb-O_2 dissociation curve, as dictated by pH, P CO_2, body temperature, and erythrocyte 2,3-diphosphoglycerate (DPG) concentration.

Sv O_2 measurement has been carried one step further by Rasanen et al, [129] who have used this instrument (to measure Sv O_2) and a pulse oximeter (to measure Sa O_2) to calculate shunt fraction continuously according to Equation 10.

Rasanen et al demonstrated that continuous reading of Q_S/Q_T using this principle could be used as a guide to providing an optimum level of continuous positive airway pressure (CPAP) in a group of patients whose tracheas were intubated and in whom lowest Q_S/Q_T was desired. [129] The authors found that the on-line method was cost-effective and concluded that CPAP therapy could be accurately titrated in the majority of patients with acute respiratory failure by using this method to calculate shunt fraction.

TISSUE OXYGENATION

Arterial oxygenation as an indicator of respiratory function may be controversial because an acceptable arterial O_2 content may not necessarily be associated with adequate tissue

Figure 33-9 Hb-O_2 saturation curves. Dotted lines indicate common arterial and venous values: Sa O_2 = 90 percent and Sv O_2 = 70 percent. The middle curve (A_0 , V_0) represents the relationship with pH 7.40, body temperature 37°C. The right-hand curve (A_1 , V_1) would occur if pH were 7.20 or T = 41°C. The left-hand curve (A_2 , V_2) represents the relationship when T = 33°C. Increased levels of any of the four factors shown (temperature, $[H^+]$, erythrocyte 2,3-diphosphoglycerate, P CO_2) will decrease Hb-O_2 affinity (rightward shift); decreased levels will raise Hb-O_2 affinity (leftward shift). The same arterial and venous Hb-O_2 saturation under different conditions can therefore result in a wide range of arterial and venous gas tension values.

oxygenation because of abnormalities of blood flow. A more appropriate monitor of oxygen delivery would in fact measure tissue oxygenation. Tissue P O_2 electrodes have been designed and implemented but have associated problems of sampling bias and tissue destruction. In addition, because of heterogeneity of local tissue blood flow and O_2 consumption, there exists a distribution of tissue P O_2 values, rather than a single value as in blood P O_2 . Nevertheless, changes in tissue oxygenation have been demonstrated under varying clinical conditions (Fig. 33-10) (Figure Not Available) . [130]

Another approach is the noninvasive monitoring of O_2 saturation of blood within the tissue, which can be accomplished by transilluminating the tissue with at least two appropriately chosen wavelengths of light. [131] Light within the near infrared band (wavelengths 650-1100 nm) can penetrate tissue reasonably well. Incident light is applied to the scalp, where it enters the tissue; a small proportion is scattered by the tissue and returned to the analyzer via a fiberoptic bundle. Instruments capable of monitoring blood O_2 saturation *in vivo* within brain tissue have been commercially available for some years. Measured saturation within the illuminated volume includes arterial, capillary, and venous blood but is heavily weighted toward venous values, [132] which under normal circumstances reflect adequacy of tissue oxygenation. [133]

Reduction of O_2 to water occurs at the terminal end of the cytochrome chain, and therefore, monitoring of the cytochrome redox state is more likely to provide a better estimate of O_2 availability at the cellular level than currently available clinical monitoring parameters. By using a similar technique with four wavelengths, it is possible to obtain information about the state of oxygenation of intracellular chromophores, including myoglobin and cytochrome a,a $_3$. [134] [135] This technology has been used to monitor intracellular changes in muscle and brain because of respiratory acidosis in anesthetized cats [132] (Fig. 33-11) (Figure Not Available) , in canine hearts

Figure 33-10 (Figure Not Available) Changes in muscle P O_2 during dopamine infusion. Displayed values represent the mean of seven septic patients treated in an intensive care unit. Dopamine infusion results in an increase in tissue P O_2 of about 12 mm Hg after 100 minutes. *(From Kersting et al [130])*

during and after coronary occlusion, [136] in human forearm ischemia, [137] and in human brain during hypoxia [138] and cardiopulmonary bypass. [139]

EXPIRED GAS ANALYSIS

Mass Spectrometry

Mass spectrometers are devices that measure concentrations of gases largely on the basis of their molecular weight. Gas samples are passed through an ionizer, typically an electron beam, which strips the individual molecules of one or more electrons, giving them a positive charge. The ionizing beam also splits some molecules, creating molecular fragments. After ionization the gas mixture to be measured is accelerated through a magnetic field. In the sector type the ionized gas molecules are passed through magnetic and electric fields at right angles to each other. The paths of the ions become curved by the action of these two fields, in a manner dependent upon the charge/mass ratio. Detectors placed at specific locations allow individual gas concentrations to be measured proportionally to the counts per minute. The quadrupole type of mass spectrometer uses both radio frequency and constant electric fields to force ions of a fixed charge/mass ratio to pass through selectors into a detector, usually a photomultiplier tube. After ionization the gas molecules can then be accelerated by an electric field toward a target after first being focused into a narrow beam. On the way to the target the ion beam passes through an arrangement of rods, the quadrupole. The quadrupole's electrostatic field is changed in a stepwise fashion so only

Figure 33-11 (Figure Not Available) Change in cytochrome a,a $_3$ redox level in brain and muscle of anesthetized cat as a function of arterial P $_{CO_2}$ determined with a three-wavelength differential spectrophotometer. Near-infrared light (wavelengths 775, 815, and 904 nm) was applied to the skin overlying hindlimb muscles and the intact skull via fiberoptic bundles. Transmitted light from the muscles and reflected light (at approximately 60 degrees to the incident beam) from the brain was collected via a second fiberoptic bundle. Processing of the signals allowed independent assessment of cytochrome a,a$_3$ redox level. Changes in density are shown as mean ± SEM. Arterial P $_{O_2}$ was between 100 and 125 mm Hg. The cerebral vasodilation accompanying hypercapnia resulted in increased oxidation of cytochrome a,a $_3$, indicating greater oxygen availability to mitochondria in the brain. In skeletal muscle there was a simultaneous change in cytochrome a,a $_3$ redox state consistent with reduced oxygen availability. This technique may eventually allow continuous monitoring of tissue oxygenation in patients under anesthesia or in the intensive care unit. *(From Hampson and Piantadosi. [132] With permission from Elsevier Science.)*

ions of a single charge/mass ratio may reach the target area (Fig. 33-12) (Figure Not Available) . The rate at which ions hit the target is proportional to the concentration of that particular gas in the original mixture. The electrostatic field settings appropriate for a given charge/mass ratio are alternated in order to measure in turn each of the gases of interest in the mixture (multiplexing). These instruments are reliable and relatively rugged, with delay time typically on the order of 100 to 200 ms.

The ability of the mass spectrometer to measure individually different concentrations of gases depends upon charge/mass ratio. Because most of the ions created by the ionizer are singly charged (missing a single electron), the most important variable is the molecular weight. Two different molecules of the same molecular weight (for example, CO_2 and N_2O) are not ordinarily distinguishable by a mass spectrometer using the principles outlined. In order to surmount this difficulty, empirical algorithms that distinguish particular pairs of molecules by analyzing molecular fragments created by the ionizing beam have been designed.

Because mass spectrometers have traditionally been large and expensive instruments, the original implementation of their use in anesthesia placed them in a remote location. Samples were conveyed to the instrument from a large number of operating rooms, and analysis was performed on a time-sharing basis. [140] This time-sharing approach increased the delay time because of the necessary length of tubing necessary between the patient and the instrument. Another disadvantage was that each patient could only be analyzed for a fraction of the total time available. Presently, a number of portable instruments are available for individual operating room use. These instruments typically can measure CO_2 , O_2 , N_2 , Ar, N_2O, and volatile anesthetic agents simultaneously.

Raman Gas Analysis

When a photon from a light source collides with a molecule of gas, it may be re-emitted (scattered light) with no loss of energy (Rayleigh scattering). Alternatively, there may be absorption of some of the kinetic energy from the photon, resulting in the scattered photon's having a lower energy level and hence longer wavelength (Raman scattering). In Raman scattering the degree of energy absorption by a

Figure 33-12 (Figure Not Available) Quadrupole mass spectrometer. The gas sample passes through the ionization chamber and focusing electrode. Ions then pass through the quadrupole. Rapid changes in the applied electric fields cause all ions except those with the chosen charge to mass ratio to hit the sides of the instrument. Only the ions of interest will strike the target and be detected. *(Modified from Datex-Ohmeda [292])*

molecule from incident photons depends upon molecular weight and structure; therefore, spectral analysis of the scattered light may be used to measure simultaneously the individual concentrations of a mixture of gases. The light source is usually an argon laser with a wavelength of 488 nm. Samples of gas are conducted through a cell, and the scattered light is passed through a spectrometer. The peaks are then detected with a photomultiplier tube. Anesthetic gases and respiratory gases can be simultaneously measured. [141] A clinical instrument based upon the Raman principle has been tested on patients undergoing general anesthesia with accuracy comparable to a mass spectrometer. [142]

Infrared Absorption

In the infrared absorption method an infrared light beam is projected through the gas sample and the intensity of the transmitted light is measured. CO_2 absorbs light with a characteristic peak at a wavelength close to 4,300 nm. Several other molecules, such as anesthetic gases (especially nitrous oxide), water vapor, carbon monoxide, and O_2 also absorb light in this area of the spectrum, interfering with CO_2 measurement, especially if the incident light composition includes wavelengths other than those in a very narrow region around the CO_2 absorption peak. In practical use, the fixed geometry of the gas-sampling cell, a narrow-band infrared light source, and compensating electronic circuits can often automatically correct for interference by other gases.

Colorimetric CO_2 Analysis

Colorimetric detectors make use of the fact that CO_2 forms acidic solutions in water. Paper impregnated with an aqueous solution of a pH sensitive dye (e.g., metacresol purple) can be maintained inside a hydrophobic filter. When CO_2 -containing gas comes into contact with the test paper, the pH drops, and the indicator changes color. Disposable devices can be manufactured to analyze CO_2 semiquantitatively (e.g., Easy Cap, manufactured by Nellcor Puritan Bennett, Pleasanton,

Calif) and used to confirm tracheal intubation in the field. [143]

Polarographic Analysis

Because in the Clark electrode the electrolyte solution is contained within a gas permeable membrane, the electrode can be used for P_{O_2} measurement in gaseous oxygen mixtures. This method is commonly used for on-line gas analysis in anesthesia or intensive care ventilator circuits.

Paramagnetic Analysis

Oxygen has the property of *paramagnetism,* which means it is attracted toward a magnetic field. Several types of instruments have been designed to use this property of O_2 to measure the P_{O_2} in a mixture of gases (Fig. 33-13) (Figure Not Available) .

Figure 33-13 (Figure Not Available) Paramagnetic oxygen analyzer. Two sealed spheres filled with nitrogen are suspended in a magnetic field. N_2 is slightly diamagnetic, and the resting position of the beam is such that the spheres are displaced away from the strongest portion of the field. If the surrounding gas contains oxygen, the spheres are pushed further out of the field by the relatively paramagnetic oxygen. The magnitude of the torque is related to the paramagnetism of the gas mixture and is proportional to the P_{O_2} . Movement of the dumbbell is detected by photocells, and a feedback current is applied to the coil encircling the spheres, returning the dumbbell to the zero position. The restoring current, and hence the output voltage, are proportional to the P_{O_2} . *(Courtesy of Servomex Co., Norwood, Mass.)*

Nitric Oxide (NO) Analysis

Nitric oxide (Ch. 72) has been administered therapeutically in concentrations of 1 to 100 parts per million (ppm) as a pulmonary vasodilator. Continuous monitoring of the inhaled concentration can be accomplished using relatively inexpensive but specific and stable electrochemical detectors. [144] [145] Recently, there has been interest in monitoring endogenously produced NO in exhaled gas. [146] Analysis of exhaled NO waveforms, in which end-tidal NO concentrations are typically on the order of 1 to 100 parts per billion (ppb), can only be satisfactorily performed using mass spectrometry or rapid response chemiluminescence analyzers, [147] which typically have a resolution of 0.1 ppb or less. Gaseous chemiluminescence analyzers usually rely upon the chemical reaction of NO with ozone (O_3) to produce nitrogen dioxide (NO_2). Some NO_2 molecules are produced in an excited state (NO_2*). [148] When NO_2* then spontaneously reverts to its ground state, a photon is emitted. This emitted chemiluminescence signal, which has a wavelength at maximum intensity of approximately 1,200 nm, can be detected using a photomultiplier. NO_2 in the original gas sample reacts slowly with O_3 , even if it is present in high concentration. Chemiluminescence analyzers measure NO_2 concentration by first converting it to NO in a high temperature reactor chamber.

WAVEFORM ANALYSIS OF EXPIRED RESPIRATORY GASES

Capnography, the measurement of CO_2 in expired gases, has evolved in the last few years into a commonly used procedure. Whereas a variety of techniques can be used for CO_2 measurement (mass spectrometry, Raman analysis), the majority of capnographs rely on infrared absorption. [149] Use of this technique can reliably and quantitatively provide vital respiratory monitoring information in the operating room and in all critical care areas.

End-tidal P_{O_2} (PET_{O_2}) may be used as an estimate of P_{AO_2} and hence Pa_{O_2}. End-tidal CO_2 (PET_{CO_2}) analysis has achieved a high degree of popularity, which has not occurred for P_{O_2} monitoring because of unpredictable variability of the A-a gradient. In normal individuals this gradient may be less than 10 mm Hg; however, in patients with severe V_A/Q mismatching, the gradient may be substantially increased. Furthermore, the A-a gradient is increased at high-inspired O_2 concentration even with normal lungs. Therefore, PET_{O_2} almost always overestimates Pa_{O_2}. For example, the PET_{O_2} of a dead person being ventilated with 100 percent O_2 would be approximately 700 mm Hg (P barometric - P_{H_2O})! An example of a continuous tracing of expired P_{O_2} in an anesthetized patient is shown in Figure 33-14.

According to the gas sampling technique, infrared CO_2 monitors can be separated into two categories: sidestream monitors, which draw a continuous sample of the gas from the respiratory circuit into the measuring cell, and mainstream monitors, which directly straddle the airway with a reading cell placed at the attachment between respiratory circuit and endotracheal tube or breathing mask. The key difference in use between the two types of capnographs depends

Figure 33-14 Simultaneous measurement of expired P_{CO_2} and P_{O_2}. These tracings were obtained with Pa_{O_2} = 153 mm Hg and Pa_{CO_2} = 32 mm Hg. Whereas PET_{CO_2} is close to Pa_{CO_2}, PET_{O_2} substantially overestimates the arterial value.

on details of practical importance and on the type and duration of the monitoring environment.

Sidestream Capnographs

An important concept is that sidestream capnographs depend crucially on a sampling flow that continuously aspirates from the "side" of the main respiratory gas flow a fixed amount of gas. The rate of gas sampling can usually be adjusted from 50 to 500 mL per minute and at times up to 2 L per minute. This continuous bias flow can be the source of significant methodologic error. If the sampling flow ever exceeds the expired gas flow, contamination from the fresh gas flow source will occur. The sampling gas pump, flow regulator, sampling system (including the connector to the sampling port), and water trap or water separator constitute multiple sites for gas leak or breakage. Additionally, depending upon the size and length of the sampling tube and the rate of gas flow, a certain delay in gas detection is introduced (CO_2 flight time), which can amount to several seconds when the sampling rate is low and the sampling dead space is high (e.g., long tubes). After measurement in the gas cell, the sampled gas can be exhausted into the atmosphere or retrieved and reinjected through a second tube into the breathing circuit to restore breathing circuit volume. This variable may be of great importance in closed-circuit and precise metabolic gas volume measurements. The analytic core of the instrument, the infrared measuring cell, must be carefully protected so that liquids and particulate matter do not enter it and cause erroneous readings of CO_2 because of their high infrared absorbance. The major problem is caused by water vapor, which is invariably present in expired air (at 37°C) with a saturated vapor pressure of 47 mm Hg. This condenses at lower (room) temperature on sampling tube walls. In critical care settings and often in the operating room, the inspired gas is kept warm and humid during long cases. This increases the load on water separation systems applied to capnographs. Water traps and filters have been

designed to protect the measuring chamber. Several clever designs have been tested, but all work best when cleaned and maintained periodically.

Monitoring of end-tidal carbon dioxide concentration ($E_{t\,CO_2}$) in the spontaneously breathing patient whose trachea is not intubated requires some improvisation. Nasotracheal cannulas connected to a sidestream monitor usually provide a usable waveform but frequently become obstructed with saliva or mucus and are uncomfortable. A convenient method to obviate this problem is to thread an intravenous catheter into the common lumen of a pair of nasal O_2 cannulas so that the tip lies midway between the two nasal prongs. The extension tube normally connected to the O_2 source is tied off, and the intravenous catheter is then connected to a sidestream capnometer. [150] A commercially available version allows O_2 administration while $E_{t\,CO_2}$ is continuously monitored (Divided Canula, Salter Labs, Arvin, Calif).

Mainstream Capnometers

In a mainstream capnometer, with the measuring head placed in close proximity to the endotracheal tube, the measuring chamber is usually heated to about 40°C to prevent water condensation on the chamber window. The heating sensing head must be kept away from direct contact with the patient's skin; it is relatively heavy and must be supported to prevent endotracheal tube kinking. In addition, the sensor's window must be kept clean of mucus and particles to prevent false reading; calibration may be problematic. Despite all these problems, the response time is faster: no gas is subtracted from the breathing circuit, no sampling pumps or other suction devices add complexities to the mechanical system, and there is no uncertainty caused by the rate of gas sampling.

Capnographs must be calibrated periodically, at different intervals in various models but usually at least daily. Equipment drift is most often due to accumulation of saliva or other extraneous materials accumulating in the light path of the analyzer. Calibration can usually be performed by periodic use of calibrated gases. Mainstream capnometers are often equipped with calibration sample cells sealed with mixtures of CO_2 and N_2. In some instruments, room air is sampled in the mainstream cuvette to "zero" the CO_2 level automatically.

A useful analysis range varies from 0 to 10 percent (76 mm Hg) for $E_{t\,CO_2}$ to an extended range up to 100 mm Hg, which may be useful in rare cases of hypoventilation or malignant hyperthermia. The inspired CO_2 range must include 0 and extend up to 15 mm Hg for cases in which rebreathing must be detected and peak values determined.

Time Delays and Other Errors

A capnogram is produced by the sequential analysis of inspired and expired gas, either flowing by the mainstream window, which is usually positioned just proximal to the endotracheal tube or breathing mask, or sampled from a sidestream sampling site connected to the breathing circuit. In the case of sidestream sampling, a definite time delay is introduced by the length and volume of the tubing carrying the sampled gas to the detector. This holds equally true for a capnogram produced by an

infrared sensing device, a respiratory mass spectrometer, or other gas-sensing devices based on a different principle. This delay time caused by the transfer of the sampled gas into the reading cell can be minimized by using high-flow rates for the sampling flow and narrow, short tubing assemblies compatible with the position of the equipment with respect to the patient breathing circuit. Once the sampled gas reaches the sensing cell, an additional delay is introduced by the rise time of the instrument. The rise time is a characteristic delay induced by the exponential response to a square front of changing gas concentration, in which CO_2 concentration changes instantaneously from zero to a new steady-state level ($CO_{2\,SS}$). This can be described by the following exponential equation:

where S = signal at time t; e = base of natural logarithms
2.718); and tau = time constant.

When t = tau (one time constant), it is possible to calculate that S = 0.63 · I. This is frequently used to measure the response of the circuitry. It is often presented in clinical instruments as a different fraction of the response, such as the 10 to 90 percent response time (
2 tau).

If we assume, for argument's sake only, a square-wave capnogram is the most difficult for an instrument to follow, and a time constant of 100 ms (a frequent value for a clinical instrument), it is usually theoretically possible to follow respiratory profiles of CO_2 within 5 percent of the real value (accuracy better than 5 percent) up to respiratory rates of 100 breaths per minute. In practice, most clinical capnographs display this accuracy up to 60 breaths per minute. [149] A shared mass-spectrometer, with the usually longer sampling line used in the share configuration, may display significant inaccuracy at respiratory rates around 40 breaths per minute. [151] The relative duration of inspiration and expiration (I/E ratio) can also affect the accuracy of the recording instrument. Standardized respiratory cycle profiles have been used to compare the most commonly employed clinical instruments. [152]

When quantitative results are expected from sidestream capnographs, the solubility of CO_2 in the tubing materials used must be taken into account: polyethylene and Teflon tubing are much more permeable to CO_2 than is nylon. The composition of sampling lines has been shown to significantly affect mass spectrometry readings for CO_2 . [153] Whereas radial diffusion of CO_2 out of the sampling line is mainly affected by the tubing material and the length of exposure of the sample inside the tubing (related to the flow rate of sampling), axial diffusion across the fronts of CO_2 -rich boluses traveling along sampling lines can also smear both the upstrokes and the downstrokes of waveforms. This type of diffusion has a significant effect on the interpretation of $E_{t\,CO_2}$ at higher respiratory frequencies.

The Capnographic Waveform

Time Capnogram

The most commonly used display mode is P_{CO_2} versus time.

Traditionally, several phases are distinguished in the capnograph trace. During inspiration and the first portion of

Figure 33-15 Time and volume capnographs. (Left): Expired P_{CO_2} versus time (standard time capnogram). The waveform is conventionally subdivided into phases. During phase I exhaled gas from the large airways has $P_{CO_2} = 0$. Phase II is the transition between airway and alveolar gas. Phase III (alveolar plateau) is normally flat, but in the presence of V_A/Q mismatching has a positive slope. The down slope of the capnogram at the onset of inspiration is usually referred to as phase IV; however, there is sometimes a terminal increase in slope associated with the onset of airway closure (dashed line, labeled phase IV
in the figure. This corresponds to the terminal upstroke seen in single inert gas washout curves, referred to in that setting as phase IV. [293] The P_{CO_2} value at the end of exhalation is referred to as the end-tidal P_{CO_2} (PET_{CO_2}). Also shown are exhaled gas flow rate and volume. (Right): Volume capnogram. In this form of the capnogram, exhaled P_{CO_2} is plotted versus exhaled volume. Mixed expired P_{CO_2} can be measured for each breath, as the area under the capnogram. Total physiologic dead space ($V_{D\,PHYS}$) can be measured, therefore, using arterial P_{CO_2} and Equation 11 (Bohr equation, assuming $P_{ACO_2} = Pa_{CO_2}$). Line AC is drawn tangent to the terminal portion of the alveolar plateau. Vertical line BE is constructed such that the two shaded areas (EFG and BCG) are equal in area. FE represents anatomic dead space ($V_{D\,ANAT}$), [294] which includes not only the volume in the trachea and large airways but also any volume within a breathing circuit in which exhaled gas is rebreathed, such as the endotracheal tube, passive humidification device, or Y-piece. Alveolar dead space ($V_{D\,ALV}$) can therefore be calculated as the difference between $V_{D\,PHYS}$ and $V_{D\,ANAT}$. [295] Because the area of trapezoid BCDE is equal to the volume of CO_2 exhaled per breath, mean (or average) alveolar P_{CO_2} is the value at the midpoint of segment BC (point M). [295]

expiration during which dead space gas is exhaled, there is no CO_2 (phase I). As expiration continues, a short phase of the capnograph is recognized (phase II), with a rapid upstroke toward the alveolar plateau, representing the rising front of CO_2 (Fig. 33-15 left). The boundary of this front can be smeared by a variety of causes but most notably by uneven mixing of the alveolar CO_2 bolus in the airways. Phase III, also called the alveolar plateau, represents the constant or slowly upsloping part of the capnogram.

In the time capnogram the alveolar plateau lasts for the greater part of the trace (Fig. 33-16A1) , although the expiratory flow is highest at the beginning of the expiration and tapers off in exponential fashion during the last third of expiratory time. Most of the exhaled volume of a passive expiration,

Figure 33-16 Examples of capnograph waveforms. (A1) A normal tracing. (A2) An increased slope of phase III, usually representing uneven gas mixing within the lung. (B1) Spontaneous ventilation with added dead space demonstrated by nonzero-inspired P_{CO_2} . After removal of dead space (B2), inspired P_{CO_2} decreases to zero, and the upstroke and downstroke of the waveforms become sharper because of reduced mixing. (C1) Rapid oscillations of expired P_{CO_2} due to cardiac action, producing "mini-breaths." (C2) Bifid waveform in patient undergoing elective surgery after unilateral lung transplantation for emphysema. The initial upstroke represents gas from the normal (transplanted) lung. This is followed by gas exhaled from the remaining (emphysematous) lung, which has a steep slope of its individual alveolar plateau (phase III).

therefore, exits the trachea (and the tracheal tube or the anesthetic mask) during the first half of exhalation time.

Several effects are responsible for the frequent appearance of the gentle upslope observed in the alveolar plateau. Most can be traced to uneven emptying of different alveolar regions with different time constants and varying V_A/Q ratios. An additional important cause is that the alveolar gas that is sampled later in expiration is, in fact, richer in CO_2 than the early fraction because CO_2 excretion from pulmonary capillaries into the alveoli continues at a nearly constant rate during expiration, but CO_2 molecules are diluted into a lung volume made progressively smaller by the exhalation process. Slow exhalation, as during an acute asthmatic attack or in patients with chronic obstructive pulmonary disease (COPD), with reduced lung recoil, usually induces a steeper alveolar plateau (see Fig. 33-16A2) . Phase III reaches a peak, usually attained only during the final phase of exhalation, and is called the end-tidal partial pressure of CO_2 (PET_{CO_2}). PET_{CO_2} in the normal individual is usually 2 to 3 mm Hg lower than Pa_{CO_2} . Chronic pulmonary disease and acute disturbances in V_A/Q usually widen this difference to several millimeters of mercury. Occasionally $PETCO_2$ may exceed $PaCO_2$. [154] [155] [156] [157] Other than calibration error, the most common cause is slow respiratory rate or high mixed venous P_{CO_2} . In these situations the cyclic variations in alveolar P_{CO_2} (which oscillates between arterial and mixed venous values) may be relatively large, causing the PET_{CO_2} to rise above the arterial value.

When patients are anesthetized in the lateral position (Ch. 26) uneven ventilation of the dependent lung and lesser perfusion of the nondependent lung increase the range of alveolar gas disparity and hence the upslope of the alveolar plateau. This can be verified by alternating sampling sites between the two lungs when ventilating a patient in the lateral position with separate endobronchial tubes.

Sometimes, when expiration is prolonged and progresses to a lung volume below closing capacity, expired CO_2 concentration may rise sharply at the end of the alveolar plateau, in a fashion analogous to that of N_2 concentration after washout with 100 percent O_2. [158] One possible reason for this is that if lung units subtended by airways predisposed to closure, at least in the spontaneously breathing patient, contain alveolar gas with lower P_{CO_2}, closure of these airways would allow a greater proportion of CO_2-rich gas to reach the upper airway, producing the sharp upswing in CO_2 concentration. An alternative hypothesis is that during the course of expiration, well-ventilated lung units have a progressive, nonlinear, upsloping increase in P_{CO_2}, whereas that of poorly ventilated (closure prone) units increases in a linear fashion. Therefore, when airway closure occurs, the rate of rise in well-ventilated units predominates, and slope of the capnogram abruptly increases. [159] Using the terminology of the single breath washout curve, this portion of the capnogram is occasionally referred to as phase IV (see Fig. 33-15 left).

The last segment of a capnograph is represented by the beginning of inspiration, when the CO_2 concentration rapidly decreases toward the inspired value (most commonly referred to as Phase IV). The capnogram value during inspiration represents the concentration of CO_2 in the inspirate and is dependent mostly on the breathing circuit used and inspiratory flow and fresh gas flow values. Rebreathing of dead space volume is often the cause of an inspired level above baseline (see Fig. 33-16B1), but this can be promptly corrected by removing the dead space (see Fig. 33-16B2). Exhaustion of the CO_2 absorber may also result in elevated inspired P_{CO_2}. The sampling flow rate of sidestream monitors must be taken into account when interpreting many features of the capnogram profile. Usually, sampling flow rates vary, and they can be set between 50 and 400 mL per minute, with an average optimal value for an adult patient of about 200 mL per minute. As soon as the respiratory gas flows decrease below the sidestream gas sampling rate, the characteristics of the sampling vary: Instead of sampling a portion of the mainstream flow, the equipment contributes significantly to bulk flow out of the respiratory circuit, which is important in the pediatric setting, during low-flow anesthesia, and when interpreting capnograms obtained during very low respiratory rates. For example, during a prolonged expiration or an end-expiratory pause, while the gas flow exiting the trachea approaches zero, the sampling of the monitor may aspirate gas alternately from the trachea and the inspiratory limb. A profile that illustrates this effect is shown in Figure 33-15C1 ; it is called *cardiogenic oscillation,* referring to the cause of the alteration. Synchronous changes in pulmonary blood flow during slow expiration and mechanical agitation of different lung regions induced by cardiac activity and pulmonary blood flow contribute to the creation of ripples, often observed in a repetitive pattern during the alveolar plateau in synchrony with the heartbeat. The usual interpretation of cardiogenic oscillatory ripples is mechanical agitation of deep lung regions that expel CO_2-rich gas in synchrony with the heartbeat. Waveforms caused by cardiogenic oscillation are more pronounced when sampling of gas is obtained from deeper tracheal and bronchial areas. Such fluctuations are often smoothed over when the sampling port is more distal to the airways or when lung volume is increased by application of positive end-expiratory pressure (PEEP) (see Fig. 33-16C2) .

Inspection of the whole curve rather than measurement only of peak expired and peak inhalation values, which may be reported digitally, improves the scope and interpretation of the trace. When a capnographic trace is displayed so that all characteristics of the various stages of the waveform are visible, on a rapidly scrolling oscilloscope or on fast-moving paper, it is possible to recognize several features that may be of diagnostic value. When capnograms are plotted on slow-moving paper or trends of only inspired and $E_{t\,CO_2}$ values are produced, it is still possible to recognize important clinical information regarding rising or falling concentrations of both inspired and expired CO_2. Examples of capnograph waveforms are shown in Figure 33-16 .

Normal end-expiratory CO_2 partial pressure ranges between 35 and 45 mm Hg. An increase above this level (hypercapnia) must be interpreted in the light of additional information because it depends on a variety of factors: (1) increased CO_2 production, as during an acute attack of malignant hyperpyrexia or developing fever, (2) depression of the respiratory center, with concomitant reduction of total ventilation and elevation of $E_{t\,CO_2}$, and (3) reduction of effective ventilation induced by partial paralysis, neurologic disease, high spinal anesthesia, weakened respiratory muscle, or respiratory disease.

If ventilation is controlled, inadequate mechanical ventilation must be the first interpretation of increased $E_{t\,CO_2}$. If an increasing trend in $E_{t\,CO_2}$ is observed while total ventilation remains constant, it is essential to verify the patient's temperature to exclude the diagnosis of hyperpyrexia. Additional frequently observed causes of transient increases in $E_{t\,CO_2}$ are release of tourniquets with reperfusion of isch-emic areas, release of aortic clamps, intravenous administration of bicarbonate (Fig. 33-17) , insufflation of CO_2 into the peritoneal cavity as during laparoscopy, and acute defects in mechanical ventilation systems.

Abnormally low end-tidal values (below 35 mm Hg) most often reflect hyperventilation but may also be caused by increased dead space with normal Pa_{CO_2}. For example, alveolar gas emanating from a lung region with no blood flow (and hence no local CO_2 transfer) dilutes exhaled gas and decreases PET_{CO_2} relative to Pa_{CO_2}. Hypocapnia may also be artifactually induced by high sampling rate of the sidestream monitor in the face of an elevated fresh gas flow rate. In addition, low $E_{t\,CO_2}$ may reflect decreased V_{CO_2} ($E_{t\,CO_2}$ during cardiac arrest may equal zero).

Similarly, areas of lung that are perfused but unventilated (e.g., in atelectasis), due to shunting of mixed venous blood, will have high regional Pa_{CO_2} and hence high arterial minus end-tidal CO_2 (Pa_{CO_2} - PET_{CO_2}), which has been used as a criterion for optimizing PEEP in ventilated patients. [160] Increasing levels of PEEP would be expected to resolve atelectasis and decrease Pa_{CO_2} - PET_{CO_2} in these areas. In normal areas, overdistension will impair perfusion and therefore increase regional $PaCO_2$ - $E_{t\,CO_2}$. Optimum PEEP can be defined as when a balance is reached.

Irregularities in the alveolar plateau are often observed when mechanical factors acutely alter the pattern of alveolar emptying, such as when the arm of a surgeon compresses the chest at midexpiration. A cleft or a dip may indicate a spontaneous breath of small tidal volume, able to move just a small bolus of inspired gas past the sampling site. This has been often interpreted as indicating activation of respiratory

Figure 33-17 The effect of sodium bicarbonate administration on $E_{T\,CO_2}$. A continuous tracing of $E_{T\,CO_2}$ is shown as a function of time. Intravenous administration of 50 mEq followed by 30 mEq of $NaHCO_3$ results in an abrupt increase in expired CO_2 due to neutralization of bicarbonate by hydrogen ion.

centers by a patient recovering from anesthesia or activation of respiration induced by sudden increasing stimulation in the surgical field. It may also indicate inadequate inspiratory power during switching from mechanical to spontaneous ventilation and can be the first sign of the need for reversal of neuromuscular blockade; however, it may indicate just the opposite, the need for increased total ventilation to induce apnea in the patient. The dip in the plateau of the capnogram must be interpreted with care, therefore, depending on the surgical stage, the drug exposure history of the patient, and the anesthetic plan.

The main use of the capnographic signal in anesthesia is the immediate verification of tracheal intubation beyond doubt by the immediate and continuous presence of metabolic CO_2 in the expired gas. Esophageal intubation may produce one or a few breaths containing CO_2 during expiration, but the concentration of this gas in exhalations from the stomach cavity rapidly decreases to zero. In this fashion, the continuous appearance of expired CO_2 is rapidly being adopted as a criterion for correct tracheal intubation.

Another major use of this signal has been to determine the correct ventilatory needs (minute ventilation) during controlled ventilation. This use is easily extended to continuous monitoring of spontaneous ventilation and to monitoring of appropriate ventilation during titration of anesthetic agents that depress ventilation. In partial rebreathing circuits and in low-flow anesthesia, capnometry facilitates the adjustment of fresh gas flow, which is a major determinant of CO_2 levels insofar as it may increase minute ventilation. The shape of a partial rebreathing capnogram may vary greatly, depending on the ventilatory frequency and tidal volume. In all these utilization modes, the sensing head of the capnograph or the site of gas sampling is best kept close to the tracheal tube, connected with the minimal dead space assembly. In this mode, for instance, it is easy to reveal disconnection of the breathing system or inappropriate functioning of mechanical ventilators. Partial rebreathing circuit systems include a CO_2 absorber, whose exhaustion is manifested by hypercarbia. Clinical signs of hypercarbia may be only slowly recognized, whereas increase in inspired CO_2 is immediately observable with a capnograph. Rapid alterations in $E_{t\,CO_2}$ can be recognized within a single exhalation. In a different

setting, capnography has been used on the exhaust side of a cardiopulmonary bypass oxygenator to track CO_2 excretion at different body temperatures.

Volume Capnogram

If exhaled volume and P_{CO_2} are measured simultaneously, exhaled P_{CO_2} can be displayed versus exhaled gas volume (see Fig. 33-15 right). Volume capnography has several advantages over time capnography. First, the CO_2 signal can be integrated to obtain the volume of CO_2 exhaled per breath, thus obtaining an on-line, breath-by-breath measurement of V_{CO_2}. Second, significant changes in the morphology of the expired waveform can be detected in the volume capnogram (e.g., secondary to PEEP) that are not seen in the traditional time capnogram. [161]

Third, dead space can be partitioned into components of interest. Total physiologic dead space ($V_{D\,PHYS}$) can therefore be measured, using arterial P_{CO_2} and Equation 11

(Bohr equation, assuming $P_{ACO_2} = Pa_{CO_2}$). Anatomic dead space ($V_{D\,ANAT}$, including gas volume within a breathing circuit in which exhaled gas is rebreathed, such as the endotracheal tube, passive humidification device, or Y-piece) can be calculated directly from the volume capnogram (see Fig. 33-15) . Alveolar dead space ($V_{D\,ALV}$) is the difference between $V_{D\,PHYS}$ and $V_{D\,ANAT}$, and is related to the difference between alveolar and arterial P_{CO_2}, according to Equation 23. [295]

Normally, one can estimate alveolar P_{CO_2} using PET CO_2 obtained from the time capnogram as a measure of P_{ACO_2}. When the alveolar plateau has a significant slope, however, PET CO_2 can exceed Pa_{CO_2} [154] [155] [156] [157] , and average alveolar P_{CO_2} ($P_{AE}CO_2$; see Fig. 33-15) obtained from the volume capnogram may be a more appropriate measure. [161]

Effect of Water Vapor

Because water vapor is often the major source of error, several "water trap" devices or heated suction tubes are used to deliver moisture-free gas to the reading cell.

The effect of gas temperature is as follows. Assume body temperature is 37°C and Pa_{CO_2} = PET CO_2 = 40 mm Hg. If the sampling tube and detector are maintained at a temperature above 37°C, there will be no condensation or "rain out" of water, and the measured P_{CO_2} will be 40 mm Hg. On the other hand, if the expired gas is allowed to cool to room temperature (say 20°C), water will condense in the tubing and the new water vapor pressure (P_{H_2O}) will decrease to the saturated P_{H_2O} at room temperature. If a drying agent is used in the sample line, P_{H_2O} will drop to zero. In either case, the measured P_{CO_2} will change, as shown in Table 33-3 .

TABLE 33-3 -- Effect of Water Condensation or Gas Sample Drying on End-Tidal CO_2 Measurement at Sea Level and 15,000 Ft Altitude [a]

	MOUTH	CELL (20°C)	CELL (ACTIVE DRYING)
Sea level (P_B 760 mm Hg)			
PH_2O	47.0	17.5	0
$ETFCO_2$	0.053	0.055	0.056
$ETPCO_2$	40.0	41.7	42.6
15,000 ft altitude (P_B = 429 mm Hg)			
PH_2O	47.0	17.5	0
$ETFCO_2$	0.093	0.100	0.105
$E_{T\,CO_2}$	40.0	43.1	44.9

Abbreviations: P_B , barometric pressure; PH_2O, water vapor pressure; $ETFCO_2$, end-tidal fractional concentration of CO_2 ; $E_{T\,CO_2}$, end-tidal CO_2 pressure

[a] Since barometric pressure remains constant throughout the system, the removal of water vapor either partially (tubing and cell at room temperature) or completely (active drying) will elevate the fractional concentration and hence the partial pressure of remaining gases. The magnitude of the effect is greater at high altitude, where PH_2O is a larger fraction of barometric pressure. Note that the fractional concentration of CO_2 in end-tidal gas is considerably higher at 15,000 ft than at sea level despite a constant $E_{T\,CO_2}$.

OXYGEN AND CARBON DIOXIDE EXCHANGE MONITORING

The most direct method of measuring oxygen uptake (V_{O_2}) and CO_2 elimination (V_{CO_2}) is by analysis of inspired and expired gas concentrations. If one can measure the minute volume along with inspired and expired O_2 and CO_2 concentrations, V_{CO_2} can be calculated by the following equation:

where V_E, V_I = expired and inspired respiratory minute volumes, respectively; and F_{ECO_2}, F_{ICO_2} = mixed expired and inspired CO_2 concentrations, respectively.

Because the quantities of oxygen consumed and carbon dioxide eliminated are rarely exactly equal, V_E and V_I differ slightly. Because F_{ICO_2} is usually zero, Equation 24 can be simplified:

Similarly, an equation can be written for the calculation of oxygen consumption:

In practice, it is difficult to measure minute ventilation with the necessary degree of accuracy to be able to distinguish small differences between V_I and V_E. Because exchange of inert gas (i.e., gas in the breathing mixture that is neither CO_2 nor O_2) generally equals zero, V_I can be calculated as follows:

where

Therefore, Equation 26 can be rewritten as

V_{O_2} measurement using this equation becomes progressively less accurate as inspired O_2 fraction is increased above 50 percent. At high F_{IO_2} values, because F_I inert becomes small, errors in the measurement of F_I inert result in correspondingly large errors in V_{O_2}. At $F_{IO_2} = 1$, this equation breaks down completely.

Open-circuit measurement of V_{O_2} and V_{CO_2} under anesthesia using this method has been described by Viale et al. [162] Self-contained analyzers have been designed. [163] [164] These instruments have proved to be extremely satisfactory for gas exchange monitoring in patients in the critical care environment. One practical problem with systems incorporating a zirconium oxide O_2 sensor is extreme sensitivity to

small concentrations of fluorinated anesthetic gases, which may cause severe malfunction.

Another method of measuring O_2 consumption is to monitor the arteriovenous O_2 content difference and multiply by cardiac output:

where CaO_2, CvO_2 = arterial and mixed venous O_2 contents, respectively (mL/L); and Q_T = cardiac output.

Blood O_2 content may be calculated using Equation 9 (note: when using Equation 31, the O_2 content values calculated using Equation 9 must be multiplied by 10 to obtain the VO_2 in the correct units).

This method of calculation of V_{O_2} (reversed Fick technique) is reasonably satisfactory for clinical purposes, although it becomes less accurate in the setting of high

cardiac output and low arteriovenous O_2 content differences. It tends to underestimate the V_{O_2} measured directly, as described previously, by 30 to 60 mL per minute. [165] [166] [167] This difference has been attributed to pulmonary O_2 consumption, which is not measured by the reversed Fick method. Direct measurement is closer to the reversed Fick technique when continuous thermodilution cardiac output is used, suggesting that a bias in thermodilution cardiac output measurement may also be partly responsible for the difference. [168]

RESPIRATORY CENTER DRIVE

Measurement of the respiratory drive (Ch. 15) is particularly important in assessment of the effects of anesthetics on the respiratory system and in particular in the process of weaning patients from mechanical ventilation. Of the various causes of respiratory failure, including pulmonary mechanical abnormalities and impairment of respiratory gas exchange, depressed ventilatory drive is probably the most common cause of failure to wean immediately after general anesthesia. Experimentally, the drive to breathe has been measured as the ventilatory output (minute ventilation, V_E) as a function of varying levels of elevated Pa CO_2 or decreased levels of Pa O_2. Formal assessment of respiratory drive in the traditional manner is difficult to obtain in the clinical environment, and various measures of neural respiratory center output have been sought.

Partitioning the respiratory waveform into inspiratory and expiratory components can provide further information. Mean inspiratory flow (tidal volume/inspiratory time) is an index of respiratory drive. [169] It is possible, however, for a patient to have a high respiratory drive but not be able to translate that drive into respiratory output because of impaired ventilatory mechanics.

A low ventilation rate is considered to be a reasonably accurate indicator of respiratory depression caused by anesthetic agents, particularly narcotics. Although parenteral narcotics usually produce a slowing of ventilation rate, there are pitfalls in the reliance on bradypnea as a sign of respiratory depression. Camporesi et al [170] demonstrated that the predominant mode of ventilatory depression in normal volunteers given epidural morphine was a reduction in tidal volume, with little change in respiratory rate. Rawal and Wattwil [171] showed in both normal volunteers and postoperative cholecystectomy patients no change or increase in ventilation rate after epidural morphine despite a significant reduction in minute ventilation. Sandler and Chovaz [172] monitored six patients receiving epidural morphine after elective thoractomy. Two of the six experienced periods of apnea that were not preceded by slow respirations. Ready et al [173] described four cases of marked respiratory depression after epidural morphine. All had Pa CO_2 values of 63 mm Hg or higher; one patient developed a Pa CO_2 of 95 mm Hg. Respiratory rates in all four patients were 8 per minute or faster. The patient with a Pa CO_2 of 95 mmHg had a respiratory rate of 12 per minute. Clearly, bradypnea does not predict apnea, and severe respiratory depression can exist in patients with acceptable respiratory rates.

A more sophisticated measure is the maximum negative inspiratory airway pressure obtained 100 ms after a temporary occlusion of the airway (P_{100} or $P_{0.1}$) in a spontaneously breathing patient. Periodic transient airway occlusion that occurs in this way is not appreciably noticed by the patient. Furthermore, chemosensitivity, determined in volunteers by CO_2 responsiveness, is not significantly affected by intermittent (every 30 seconds) P_{100} maneuvers. [174] The normal value for P_{100} during resting ventilation is 1 to 2 cm H_2O. P_{100} is a useful index of respiratory drive, requiring no voluntary effort on the part of the subject and being minimally affected by changes in respiratory mechanics. The technique is well described by Milic-Emili et al. [175] Under anesthesia, P_{100} is depressed [176]; however, the effect of anesthesia is highly dependent upon Pa CO_2 so that P_{100} at high Pa CO_2 is actually increased, even under anesthesia. Conceivably one could use P_{100} as a guide to the discontinuation of mechanical ventilation after general anesthesia. In acute respiratory failure due to other causes, P_{100} is generally elevated; Herrera et al [177] and Sassoon et al [178] observed values of P_{100} above 6 cm H_2O and 4.2 cm H_2O, respectively, during T-tube trials to be correlated to lack of success in weaning. Montgomery et al [179] found a similar relationship but reported a better prediction of weaning successes using the P_{100} response after breathing of 3 percent CO_2 (P_{100} H). The mean P_{100} H/P_{100} ratio was 2.04 in seven successful weaning attempts and 1.17 in seven failures.

PULMONARY AND CHEST WALL MECHANICAL FUNCTION

Principles of Gas Flow Measurement

Monitoring of inspiratory and expiratory flow can be useful for a variety of reasons. First, measures of resistance (discussed later) require both pressure and flow measurement. Second, flow may be integrated to provide a monitor of inspired or expired volume. Several types of flow meter exist. Possibly the most commonly used flow meter in anesthesia is the rotameter, in which gas flow imparts movement to a series of vanes connected to a wheel. The Wright spirometer integrates this movement, providing the user with a measure of volume. The Fleisch pneumotachograph consists of a bundle of small-diameter tubes in parallel. Flow within these capillary tubes is laminar, and pressure drop is therefore

linearly related to gas flow. [180] Screen-type pneumotachographs work by measurement of the pressure drop across a mesh screen. These devices are usually smaller and lighter than Fleisch-type pneumotachographs; however, they are inherently nonlinear. Moreover, their practical implementation is often limited by their tendency to collect moisture and debris, which changes their operating characteristics. Modern mechanical ventilators often incorporate vortex-type pneumotachographs, which work by measurement of interruptions in an ultrasonic beam placed across a tube in which struts disrupt the laminar flow, resulting in vortices. [180] Ultrasonic flow meters measure the speed of ultrasonic waves propagated parallel to the direction of flow. [181] Hot-wire anemometers consist of electrically heated wires placed in the gas stream, which tend to cool the wire and change the electric conductivity. Flow is measured by the amount of additional electric current generated by a feedback circuit that is necessary to maintain the wire at constant temperature. These devices characteristically have an extremely high frequency response, but their behavior is highly dependent on gas temperature and contamination of the gas stream with mucus and water droplets. [180]

Respiratory Output

The mechanical output of the respiratory system may be assessed by measuring respiratory muscle activity and resulting gas flow.

The electric activity of the diaphragm, the most important inspiratory muscle, has been measured in adults with needle electrodes inserted into the eighth or ninth intercostal spaces in the midaxillary line [182] and in neonates with surface electrodes applied subcostally at the nipple line. [183] Diaphragmatic electromyograms (EMGs) can be obtained in this manner in neonates but in adults is frequently contaminated by the simultaneous electric activity of the overlying intercostals. A cleaner diaphragmatic EMG signal may be obtained by using an esophageal electrode. [184] Electric gating of the much larger electrocardiographic (ECG) signal may allow relatively pure diaphragmatic EMG signals to be recorded. [185] Fatiguing muscle tends to produce EMG potentials at lower frequencies, allowing diaphragmatic fatigue in a variety of situations to be diagnosed by frequency analysis of the signal obtained in this way. [184] Mechanical activity of the diaphragm cannot be assessed directly; however, because of its shape (approximately hemiellipsoidal) contraction of the diaphragm must result in a transdiaphragmatic pressure. Esophageal and gastric pressure simultaneously measured may be used to calculate transdiaphragmatic pressure. A nasogastric tube with esophageal and gastric balloons is specifically manufactured for this purpose (Bicore Monitoring Systems, Irvine, Calif). Transdiaphragmatic pressure measurement has been used to assess diaphragmatic function [186] and loss of diaphragmatic contraction demonstrated in the early postoperative period after upper abdominal surgery. [187] Loss of transdiaphragmatic pressure generation implies lack of diaphragmatic contraction (Fig. 33-18) (Figure Not Available) . [188]

Diaphragm motion can be assessed somewhat more indirectly by observing or monitoring thoracic and abdominal movements during inspiration. The normal outward movement of both chest and abdomen during inspiration is replaced by paradoxic inward movement of the abdomen in the presence of diaphragmatic inaction, [189] which may be due to phrenic nerve paresis or diaphragmatic fatigue. [190] [191] External movement of the thorax and abdomen can be monitored in this way by using magnetometers, which can monitor anteroposterior and lateral thoracic and abdominal dimensions [189] [192] or strain gauge displacement transducers. [193] Another method uses two coils of wire that encircle the torso at the thorax and abdomen. The selfinductances of the coils change in proportion to the encircled areas and can be calibrated to provide continuous monitoring of ventilation. [194] Unfortunately, these methods are rather sensitive to changes in posture or body position [195] and cannot be used during surgery on the thorax or abdomen.

The final mechanical output of the respiratory system (gas flow) can be assessed by monitoring minute ventilation directly or monitoring its components, ventilation rate, and tidal volume.

Monitoring of breath sounds provides a low-cost, high-reliability, semiquantitative measure of gas flow into and out of the lung. Continuous monitoring of breath sounds using an earpiece connected to a precordial or esophageal stethoscope allows immediate detection of breathing circuit disconnection in mechanically ventilated patients. It facilitates early detection of decreased tidal volume, changes in respiration rate, and endotracheal tube cuff leaks. It also provides qualitative data that may indicate changes in pulmonary mechanics. Wheezes (rhonchi) are produced when gas flow and

Figure 33-18 (Figure Not Available) Examples of transdiaphragmatic pressure monitoring. (A) Simultaneous esophageal and gastric pressure waveforms during tidal breathing in the normal individual. Negative esophageal (and hence pleural) pressure swings are accompanied by positive gastric pressure waves, indicating the development of transdiaphragmatic pressure during inspiration. (B) The same waveforms in a patient with phrenic nerve palsy (and hence absent diaphragmatic contraction). Negative intrathoracic pressure swings (arrows) are accompanied by gastric pressure swings in the same direction. Intrathoracic pressure changes are therefore being directly transmitted through a passive diaphragm. These changes can also be observed in the early postoperative period in patients who have had upper abdominal surgery. *(From Brown et al [185])*

airways interact so that airway walls become apposed. Oscillation of the airways between open and nearly closed causes airway vibration, which results in sound production detected as wheezing. Wheezes may occur when airway diameter is narrowed as a result of smooth muscle contraction (bronchospasm), mucosal thickening or edema, buildup of secretions, extrinsic compression, or an endobronchial mass such as a tumor or foreign body. Although severe generalized airways obstruction may occur without wheezing, for example, in emphysema, the presence of wheezes correlates with reversibility of airways obstruction. [196] Crackles (rales) are discontinuous sounds produced by the sudden opening of small airways during inspiration. These are indicative of airway closure and subsequent reopening, which may occur in interstitial fibrosis or in any situation resulting in premature closure of small airways (pneumonia, pulmonary edema, low lung volumes). In patients with large amounts of airway secretions, particularly in the large airways, coarse crackles may also be caused by gas bubbling through airway secretions. The origin of lung sounds has been reviewed. [197] [198] [199]

Minute ventilation and tidal volume are easy to measure directly in patients whose tracheas are intubated, and these parameters are routinely measured by modern mechanical ventilators. In the patient whose trachea is not intubated, however, these parameters can only be obtained somewhat inaccurately by monitoring external dimensions of the thorax and abdomen either "clinically" by direct observation or by using one of the techniques noted. Subjective assessment in particular is

extremely inaccurate, [200] commonly with overestimation of tidal volume by up to 60 percent. Alternatively, V_E can be monitored directly by using a head tent. [201] These methods are difficult to apply for routine clinical use. Therefore, measurement of ventilation rate remains the mainstay of respiratory output monitoring. Mechanical measures of gas flow, such as these, provide combined assessments of both respiratory drive and mechanical function of the respiratory system. In the presence of relatively normal thoracic mechanics, however, respiratory gas movement is considered to be a reasonable monitor of respiratory output.

Measurement of Respiratory Mechanics

Principles

Mechanical properties of the respiratory system include the passive mechanical properties of resistance, elastance, and inertance, in addition to the motor properties of the muscles of respiration (Ch. 24) . Resistance (R), in pulmonary mechanical terms, is the increment in pressure (DeltaP) applied to the system divided by the increment in flow or rate of change of volume (DeltaV):

Normal resistance is 1.5 $cm/H_2O.L^{-1}.s$, but under anesthesia it may be as high as 9 $cm/H_2O.L^{-1}.s$. Most of the resistance of the respiratory system is due to the flow resistance of the major conducting airways. A small portion of the resistance is due to the tissue viscosity.

Conductance (G) is the reciprocal of resistance:

Elastance (E) is the applied pressure divided by the resulting static change in volume:

A more commonly used variable is compliance (C), the reciprocal of elastance:

A commonly used unit for compliance is $mL/cm\ H_2O$. Because the lung and chest wall are mechanically in series,

where C_{TH}, C_L and C_{CW} are the thoracic, lung, and chest- wall compliances, respectively.

Inertance (I) is the applied pressure divided by the gas acceleration or the second derivative of volume with respect to time:

Inertance is analogous to the mass of tissue and gas within the lung. Normal thoracic inertance is .02 to .04 $cmH_2O.L^{-1}.s^2$. Ordinarily, because acceleration of gas flow and mass of gas and tissue are low, inertance plays a minor part in the mechanical behavior of the respiratory system. Under conditions of high-frequency ventilation or high-inspired gas density (e.g., in deep diving), however, inertance may play a major role in determining gas flow.

Practical Measurement of Passive Respiratory Mechanical Properties

Estimates of compliance and resistance in the respiratory system may be obtained by inspection of the airway pressure-volume (or time) relationships. Thoracic compliance may be obtained by inflating the lungs with known increments of volume and measuring the static pressure at each point. Under normal circumstances, the lung and chest wall have approximately equal compliance of approximately 200 mL/cmH_2O^{-1} , resulting in a total thoracic compliance of 100 $mL/cm\ H_2O^{-1}$. Individual measurements of chest wall and lung components of the total respiratory compliance cannot be made without some estimate of pleural pressure. Conventionally, pleural pressure is measured by inserting a pressure-monitoring balloon within the esophagus. Unfortunately,

in the supine patient the weight of the mediastinum results in a falsely high estimate of pleural pressure when using this technique. Direct pleural pressure measurement must therefore be obtained to measure lung and chest wall compliance accurately in this position. A noninvasive method of pleural pressure measurement, using a flat loop of Teflon-insulated wire attached to the skin of the suprasternal fossa, has been described. [202] The skin movement that accompanies changes in intrapleural pressure is transduced by the coil of wire by continuous measurement of its self-inductance. Measurements of pulmonary compliance using this technique correlated well with similar measurements using an esophageal balloon to estimate intrapleural pressure. The technique is time-consuming, however, and measurements cannot be obtained in some individuals.

Thoracic compliance can be estimated on a breath-by-breath basis by monitoring the inspiratory pressure-time curve. If a constant tidal volume is being used to ventilate a patient, the thoracic compliance will be inversely related to the inspiratory pressure. It is important that the pressure used to calculate thoracic compliance be at end inspiration (plateau pressure) because during the period of inspiratory gas flow there is an additional component of pressure due to airways resistance. The changes in peak airway pressure (related to both airways resistance and thoracic compliance) and the plateau pressure (related only to compliance) may quickly identify pulmonary mechanical abnormalities in ventilated patients (Fig. 33-19) . An empirically defined measurement, tidal volume divided by peak inspiratory pressure change, is defined as dynamic compliance (Cdyn):

where V_T = tidal volume; P_{pk} = peak airway pressure; PEEP = positive end-expiratory pressure; and the normal value is 40 to 80 $mL/cm\ H_2O$.

Static compliance (Cstat) can be calculated by measuring the "plateau" pressure and using the following equation:

The normal value is 50 to 100 mL/cm H_2O.

In order to make these compliance calculations, the end-expiratory pressure (if any) must be subtracted from the peak pressure or plateau pressure. The PEEP value can usually be read directly from the airway pressure monitor at end-expiration. However, when insufficient expiratory time prevents complete emptying of the lungs, significant end-expiratory elevation of alveolar pressure that is not detected at the airway pressure monitor (auto-PEEP) may occur. [203] [204] Auto-PEEP is most likely to exist when elevation of airway resistance or compliance causes prolongation of expiratory time or when high ventilation rates are required. [203] Auto-PEEP can result in decreased cardiac output, hypotension, and electromechanical dissociation in mechanically ventilated patients. It also affects compliance measurements. Detection of auto-PEEP can be accomplished by occluding the exhalation port of the ventilator while delaying the onset of the next ventilator breath. Alveolar pressure will then equilibrate with the ventilator circuit, and auto-PEEP can be read on the airway pressure monitor (Fig. 33-20) (Figure Not Available) . During this temporary occlusion maneuver, it is important to prevent supplementary gas flow (e.g., fresh gas flow) from entering the circuit and falsely elevating the auto-PEEP value.

An increase in static compliance may be caused by atelectasis, pulmonary edema, pneumothorax, external compression

Figure 33-19 Examples of airway pressure waveforms. Airway pressure is plotted versus time. Decreased static thoracic compliance results in an increase in *plateau* pressure; increases in airway resistance cause increased *peak* airway pressure and hence decreased dynamic compliance. (See text for details.)

Figure 33-20 (Figure Not Available) Auto-PEEP. Severe airway obstruction may result in high alveolar gas pressure at end expiration, which can exert the same effect on hemodynamics as externally applied PEEP. This is not usually detectable unless the expiratory port of the ventilator circuit is occluded. Auto-PEEP may then be read directly from the airway pressure monitor. *(Modified from Pepe and Marini [203])*

of the chest (e.g., intra-abdominal hemorrhage or in the operating room, abdominal packing, or the surgeon's leaning on the torso), or accumulation of pleural fluid. Increases in dynamic compliance may be caused by elevated airways resistance (e.g., due to bronchospasm, mucus accumulation) or obstruction or kinking of the endotracheal tube.

It is important to realize that in parallel with the patient's thoracic compliance are the internal compliances of the breathing circuit and any associated humidification or gas warming systems. Circuit compliance may be as high as 10 mL/cm H_2O and must be accounted for if an accurate measurement of thoracic compliance is required.

During spontaneous breathing decreased thoracic compliance places an additional load on the patient's respiratory muscles. Thoracic compliance less than 25 mL/cm H_2O is unlikely to result in successful weaning from mechanical ventilation. [205]

Thoracic resistance (Rth) can be measured in the intubated patient by oscillating the airway with a sinusoidal or randomly varying flow with simultaneous measurement of flow and pressure. Significant increases in Rth have been observed in anesthetized patients after reversal of neuromuscular blockade with edrophonium 0.43 mg/kg. [206] An indirect estimate of airways resistance may also be obtained by monitoring the flow-time or volume-time relationship of a passive exhalation after manual inflation of a lung. [207] If a constant thoracic compliance is assumed, the time constant of exhalation is related to airways resistance.

A commercially available instrument (Datex-Ohmeda, Tewksbury, Mass) is capable of providing continuous displays

Figure 33-21 (Figure Not Available) Intraoperative spirometry (Side Stream Spirometry, Datex Medical Instrumentation, Tewksbury, Mass). Labels have been added for clarification. (A) Volume-pressure loop. Peak (Ppk) and plateau (Pplat) inspiratory pressures are shown. The slopes of the solid and dashed lines represent dynamic compliance (C_{dyn}) and static compliance (C_{stat}), respectively. (B) Flow-volume loop from the same breath as in Fig. A. Inspiratory flow is primarily regulated by the ventilator and therefore in the midportion of inspiration is relatively constant. Expiratory flow is determined by passive emptying of the lungs, which in turn is dependent upon recoil pressure and airways resistance, resulting in a different configuration of the expiratory portion of the loop. The expiratory loop is most sensitive to changes in airways resistance; increased expiratory flow resistance results in a flattening of the expiratory curve (see Fig. 33-22D) (Figure Not Available) . *(Patient record courtesy of Dr. R. Sladen)*

of inspired volume versus airways pressure and flow versus inspired volume (Figs. 33-21 (Figure Not Available) and 33-22). (Figure Not Available) [208] This instrument has been used to monitor changes in pulmonary compliance due to intraoperative pulmonary edema, [208] during laparoscopic instillation of gas into the peritoneal cavity, [209] and to detect malpositioning of double-lumen endotracheal tubes. [210]

APNEA MONITORING

Most of the principles of apnea monitoring have already been discussed. In practice, the appropriateness of a particular apnea monitor depends on the situation in which it is to be used. For example, a head canopy monitor of ventilation [201]

Figure 33-22 (Figure Not Available) Pressure-volume loops (A, C) and flow-volume loops (B, D) recorded during two-lung ventilation (1) and one-lung ventilation (2). (A, B) Double-lumen tube placed correctly; (C, D) double-lumen tube malpositioned. Ventilator settings were identical (tidal volume 10 mL/kg, rate 10-12 breaths/min) during all recordings. When changing from double- to single-lung ventilation, compliance is reduced (A) and expiratory airways resistance slightly increased (flattening of the expiratory flow-volume curve (B). Malpositioning of the tube resulted in increased flow resistance and reduced compliance to a significantly greater degree than when the tube was correctly positioned. The flattening of the expiratory portion of the flow-volume curve is most evident in Fig. D. *(From Bardoczky [210])*

may be appropriate in an ICU but is entirely inappropriate for use at home in a young child. Apnea monitors are usually based on one of three general principles: detection of gas flow, chest-wall movement, and gas exchange (monitors of either Pa CO_2 or Sa O_2). Guyatt et al [211] described a method in which a pressure transducer was connected to a nasal O_2 cannula. Periodic fluctuations of around 1 cm H_2O because of cyclical respiratory flow were observed during nose breathing. Respiratory rates could easily be obtained with this technique even when O_2 was flowing through the cannula. Direct monitoring of ventilation can be obtained easily in a patient whose trachea is intubated. Use of a rigid air-tight canopy that encases the subject's head with a neck seal has been described by Sorkin et al. [201] The canopy is continuously flushed with fresh gas. The subject's respiration produces a net flow in and out of the canopy, which is unaffected by the fresh gas flow. The system could comfortably be worn while either awake or asleep. Another method of airflow detection was described by Werthammer et al [212] ; in it an acoustic monitor encapsulated in silicone rubber was taped 0.25 cm inside a nostril. Eight premature infants were continuously monitored for 1 to 2 hours; 26 episodes of apnea lasting 15 seconds or more were detected and confirmed by direct observation. An impedance monitor detected only seven of these episodes. Hok et al [213] have described an acoustic method that was demonstrated to detect hypoventilation and apnea with greater sensitivity than pulse oximetry. An extremely unobtrusive method is to use a tiny, rapid response hygrometer taped close to a nostril. This type of sensor can monitor respiratory rates at least up to 60 per minute as effectively as capnometry, in either infants or adults. [214]

Chest-wall movement may be detected in several ways. One method is inductive plethysmography (e.g., Respitrace and Respigraph [Non-Invasive Monitoring Systems, Miami, Fla]). [194] The abdomen and thorax are each encircled by a coil, in which respiratory movements are detected as changes in the self-inductance. A more commonly used approach is transthoracic impedance, a technique that is commonly implemented in commercially available ECG monitors. In this method, a small alternating current (typically 100 microamps) at around 100 kHz is passed through a pair of ECG leads, allowing transthoracic electrical impedance to be continuously measured by a change in the induced 100 kHz voltage. Low-frequency changes in respiratory impedance can easily be demodulated from the signal. [69] [212] EMG of the respiratory muscles can also be used to monitor respiration, [183] although it is more difficult because of contamination of the EMG signal with a much higher voltage ECG potential. Another monitor of chest-wall movement makes use of a detector placed under the bed mattress (RE-134 Apnea/Respiration Monitor, Electronics Monitors, Inc., Euless, Tex). This monitor detects changes in the patient's center of gravity that occur because of respiration. Algorithms

are used to exclude ballistocardiographic artifacts that may otherwise be interpreted as respiratory movements. The main disadvantage of patient movement monitors is that they may fail to detect obstructive apnea, in which ventilatory effort or movement can occur without gas flow.

Because apnea per se may not result in any physiologic abnormality, a measure of its possible adverse effects (hypoxia or hypercapnia) may be preferable. Continuous measurement of E_tCO_2 , although easy in an intubated patient, is more difficult in a patient whose trachea is not intubated because of discomfort from the catheter placement and clogging with mucus and saliva. This problem frequently accompanies direct placement of a cannula into the nasopharynx. Some improvements may be obtained if a catheter is placed inside a nasal airway. A more satisfactory solution is to use specially designed nasal cannulas in which one prong is used to sample exhaled gas and the other can be used to deliver oxygen.

Another approach is to use O_2 saturation. George et al [215] compared arterial desaturation with manually detected events using a variety of monitors, including chin EMG, airflow measurement, and respiratory movement measured by inductance plethysmography. Apnea was defined as cessation of respiration for more than 10 seconds. Nine overnight records from six patients with sleep apnea were analyzed and compared with Sa O_2 measurement using an ear oximeter. Decreases in Sa O_2 of more than 3 percent from baseline were considered significant. Using this criterion only 1.32 percent of 4,008 apneic episodes were undetected. Catley et al [53] used ear oximetry and respiratory inductive plethysmography to monitor patients postoperatively and demonstrated that morphine analgesia, compared with regional analgesia with local anesthetic, was associated with a high incidence of hypoxemia and associated obstructive apnea, central apnea, paradoxic breathing, and slow respiratory rate.

Given the proven reliability of pulse oximetry, it would seem that this method, perhaps in association with capnography, may provide an excellent method of apnea monitoring. Principles of apnea monitoring have been reviewed in detail by Sackner and Krieger. [216]

LUNG WATER

The frequent occurrence of pulmonary edema in clinical medicine has led to a variety of techniques for the early detection of increased lung water. Bedside estimation of lung water would be clinically useful. A variety of techniques exist presently.

Chest Radiography

The most commonly used technique clinically is the standard chest radiograph, in which signs of pulmonary edema are well described. An animal study demonstrated that approximately a 35 percent increase in extravascular lung water is required for the diagnosis of "definite pulmonary edema." The absence of radiographic evidence of pulmonary edema, however, virtually rules out significant increases in lung water. [217]

Computed tomography (CT) of the lung may provide more detailed information about regional lung density changes that correlate with localized edema. [218] As in plain radiography, the changes seen on CT are not specific. Moreover, the radiation dose is higher and the cost is significantly greater than for plain radiography.

Compton scattering has also been used for lung water measurement. Rather than using the attenuation of transmitted x-ray photons as the monitor, the Compton technique measures photons scattered at 90 degrees to the incident beam. As lung water increases, the number of scattered photons increases. A portable instrument based on this technology has been described, [219] and the technique has been used in humans to compare physiologic and radiographic effects of intravenous saline infusion. [220]

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has significant theoretical advantages over radiographic techniques. Clinical devices operate by measurement of protons in water, with no interference from other molecules. [221] [222] It requires no radiation and it has resolution at least as good as that of CT scanning. Disadvantages are cost and long image acquisition time. Extravascular water cannot be distinguished from intravascular water, although the blood contained in large vessels can be subtracted.

Positron Emission Tomography

Positron emission tomography (PET) can be used to provide tomographic images of the lung by use of radioactive tracers. [223] Intravenous administration of radioactive tracer (^{15} O-labeled water) provides a marker for lung water. Extravascular water can be separated from total water by subtracting the intravascular signal for ^{15} O-labeled carbon monoxide administered by inhalation. An advantage is the ability to examine lung water by lung region. Disadvantages include high cost and the necessity for an on-site cyclotron to produce the necessary short-lived isotopes.

Double Indicator Dilution

Injection of an ice-cold indocyanine green dye solution into the pulmonary artery and simultaneous thermal and green dye densitometry by constant withdrawal of blood from the femoral artery constitute another technique for measurement of lung water. [224] Green dye passes undisturbed through the lung, whereas heat diffuses into the bolus, tending to warm it to a degree that is dependent upon the thermal mass within the lung (primarily lung water). Using this technique in human organ donors, the thermal dye technique consistently overestimated gravimetric measurement of extravascular lung water postmortem. [225] The error is probably due to warming of the bolus by the heart and blood vessels and to differences in the time constants of the thermal and green dye detectors. Use of a thermal indicator alone has been shown to have approximately the same sensitivity as double dilution. [226]

A method has been described in which heat is replaced as the diffusible indicator by heavy water (deuterium oxide,

---

D_2O), which can be assayed in arterial blood by infrared absorption. After an aqueous mixture of indocyanine green dye and heavy water is injected into a central vein, continuous withdrawal of arterial blood through an optical cell allows for simultaneous measurement of D_2O and green dye. Thus, time constant errors, which occur with thermal dilution, are eliminated. This technique has been used in animals to assay lung water in experimentally produced pulmonary edema [227] and in humans during general anesthesia for abdominal surgery [228] and during hemodialysis. [229] Direct comparisons with gravimetric determination of lung water in experimental animals reveal that this method tends to underestimate lung water. Possible reasons include a slow diffusion constant for D_2O into lung water and inaccessibility of some lung water to the pulmonary vascular bed. [230] All indicator dilution techniques depend on physical contiguity of the lung water to the pulmonary vessels; nonperfused areas of edema are not measured.

Multiple Gas Technique

Inhalation of a mixture of an insoluble gas (e.g., helium) with a gas that is soluble in water (e.g., acetylene) allows another method of lung water estimation. [231] [232] In one application of this method a mixture of gases is rebreathed. The rate of disappearance of the soluble gas is related to lung water and pulmonary blood flow. Corrections can be made for blood flow by adding to the gas mixture carbon monoxide (which is highly soluble in blood but has low solubility in extravascular lung water not containing hemoglobin). This method is noninvasive and relatively inexpensive. Like thermal measurement of lung water, however, the method of gas dilution measures only lung water that is accessible to the airways.

Impedance Plethysmography

Electric impedance of the chest is inversely related to the amount of lung water. Four band-shaped electrodes are applied. One pair of excitation electrodes (placed at the neck and lower thorax) is used to pass an alternating current of approximately 0.5 mA longitudinally through the thorax. Two inner electrodes (at the base of the neck and at the diaphragm, cephalad to the lower excitation electrode) detect the induced voltage, which is proportional to the thoracic electric impedance (Z). Increases in air volume or intrathoracic fluid accumulation cause a decrease in impedance. Absolute water measurement cannot be obtained; however, patients can each serve as their own controls. Moreover, the technique is sensitive to changes in any intrathoracic water. Van De Water et al [233] have reported an experience using this technique in over 200 patients. In cases in which a decrease in intrathoracic water could be observed (radiographic clearance of pulmonary edema, thoracentesis, and pericardiocentesis), the expected increase in Z occurred.

None of these methods has attained routine clinical use, although the value of lung water measurements has been demonstrated by a number of studies, for example

measurement of the effect on lung water of perioperative administration of crystalloid versus colloid to patients undergoing aortic surgery. [234] Future developments will undoubtedly result in clinical applicability for lung water measurement.

MONITORING HIGH-FREQUENCY VENTILATION

High-frequency ventilation (Ch. 72) has been variously defined but in general represents mechanical ventilation at high rates (usually 160 breaths/min). Several means of ventilating in this manner have been used experimentally and clinically. The use of conventional positive-pressure ventilators at high rates and small tidal volumes is called high-frequency positive pressure ventilation (HFPV). Tidal volumes are usually on the order of 3 to 4 mL/kg body weight, with a frequency of 60 to 100 per minute. The use of an oscillator, providing both positive and negative pressure fluctuations (e.g., a loudspeaker), is called high-frequency oscillatory ventilation (HFOV). Higher frequencies, upward of 3,000 per minute, have been used with this modality. A "bias flow" of fresh gas at the level of the oscillator provides the source of the respiratory gas and washes out CO_2. Injection of a high-velocity pulse of gas into the airway through a narrow cannula, entraining with it fresh gas, is termed *high-frequency jet ventilation* (HFJV).

In all of these forms of high-frequency ventilation, instantaneous gas flows and pressure fluctuations cannot usually be monitored with conventional transducers. Because the system is basically open, a portion of the gas flow directed into the airway may leak out and not participate in intrapulmonary gas exchange. High-frequency ventilatory fluctuations generated by these ventilators may also in part do nothing more than compress and decompress the compliance of the ventilatory circuit and large conducting airways. Conventional mechanical monitoring is therefore difficult. Furthermore, capnography is difficult to apply because dilution of expired gas may render end-tidal measurements, even assuming a high-fidelity, high-frequency capnograph, artificially low.

Monitoring of patients receiving high-frequency ventilation requires the ability to monitor O_2 and CO_2 exchange, as well as mechanical safety, including airway disconnection and obstruction. Hoskyns et al [235] measured tidal volumes in 0.8- to 1.9-kg infants ventilated at 2 to 25 Hz using an external respiratory jacket. A side port of the jacket was used to monitor pressure changes, which correlated linearly with tidal volume.

Whereas patient oxygenation can readily be monitored with pulse oximetry, there is no reliable noninvasive monitor of CO_2 exchange. One way of monitoring CO_2 is to measure the mean waste gas CO_2 concentration by placing a capnograph in the expired circuit. If any condition that interferes with CO_2 exchange develops, the mean expired CO_2 decreases. Although this method provides a fairly gross measure of adequacy of CO_2 exchange, the expired CO_2 concentration is highly dependent upon fresh gas flow rate. A more satisfactory monitor might multiply fresh gas flow by expired CO_2 fraction to obtain V_{CO_2}. Changes in CO_2 could then reflect a mechanical problem with the ventilator. Unfortunately, there are other factors that may alter V_{CO_2}, such as anesthesia or hypothermia. One cannot obtain a measure of

P_{ACO_2} or Pa_{CO_2} by this method. The most commonly used currently available method is to interject a conventional breath periodically in order to measure $E_{t\,CO_2}$. Capnometry can be used to measure $E_{t\,CO_2}$ during HFJV without such a maneuver, provided that gas is sampled from a port situated at the tip of the endotracheal tube. [236]

Monitoring of airway pressure is extremely important in high-frequency ventilation. HFJV, in particular, uses high pressures and gas flows. Expiratory port occlusion can therefore result in extremely high airway pressures. Commonly, gas pressures are measured on both sides of the jet valve (drive pressure and jet pressure), along with an independent pressure measurement in the airway (Fig. 33-23). An automated feedback loop is required to interrupt the jet ventilation by closing the solenoid valve in the event of excessively high pressures either in the airway or on the jet side of the valve. Low pressures can be used as indications of airway disconnection or ventilator malfunction.

In addition to safety concerns, airway pressure in a number of studies has been shown to correlate with gas exchange efficiency during HFJV. [237] Increasing peak airway pressures result in lower Pa_{CO_2}. A superior indicator of Pa_{CO_2} is actually the difference between peak airway pressure and end-expiratory airway pressure. [238] There is no unique relationship, however, and the actual Pa_{CO_2} obtained for a given patient depends on properties of the lung. Position of the monitoring transducer may be critical because proximal airway pressures may be artifactually low. [238]

Jet ventilation for prolonged periods of time ideally should be performed on patients with the ability to monitor arterial blood gases directly. Periodic measurement of Pa_{CO_2} may provide greater assurance of adequate pulmonary gas exchange than simple reliance on noninvasive measures.

Figure 33-23 High-frequency jet ventilation. The jet is created when a high-pressure air-O_2 supply is rapidly modulated by the solenoid valve. Fresh inspired gas is from a low-pressure source, typically an anesthesia circuit. Drive pressure (P_D) and jet pressure (P_J) are customarily monitored in order to detect solenoid or jet malfunction. An independent monitor of airway pressure (P_{AW}), which will reliably detect overpressurization of the airway, circuit disconnection, or ventilator malfunction, should also be available.

WEANING FROM MECHANICAL VENTILATION AND TRACHEAL EXTUBATION

Mechanical ventilation may be instituted for a variety of reasons, including impaired respiratory drive, increased mechanical load, impaired respiratory motor function, and impaired pulmonary gas exchange. Endotracheal intubation is usually performed to facilitate mechanical ventilation but may also be instituted for maintenance of a patent upper airway, to enable suctioning of secretions, bronchoscopy, and to provide airway protection. Liberation of a patient from mechanical ventilation and successful extubation may be separate clinical issues.

When considering the challenge of weaning from mechanical ventilation (Ch. 72) it is useful to examine the reason for its initiation. The most common reason for mechanical ventilation during and after anesthesia is impaired respiratory drive; however, components of increased mechanical load and impaired neuromuscular function may contribute to an abnormally low ventilatory function. Patients with severe COPD usually are mechanically ventilated because of transient increases in mechanical load superimposed upon a chronic increase in airways resistance. Impaired respiratory drive and abnormal respiratory muscle mechanics may also play a role, however. Abnormal arterial oxygenation may exist despite what would appear to be adequate ventilatory effort. Therefore, ventilatory support may be required mainly to support arterial oxygenation or CO_2 elimination. Assessment of the patient with regard to possible discontinuation of mechanical ventilation may vary somewhat, depending on the reason for mechanical ventilatory support. Weaning ventilatory support from a patient whose only reason for mechanical ventilation is residual anesthesia is generally straightforward. A different approach is often required for a patient who has had prolonged ventilatory support for chronic respiratory disease. [239] After surgery, patients may have components of both impaired respiratory drive (residual anesthesia) and abnormal pulmonary mechanics (stiff lungs because edema or surgical trauma to respiratory muscles). Some criteria that have been used are shown in Table 33-4 . The most commonly used weaning criteria have included a vital capacity not below 10 mL/kg, maximum inspiratory pressure (MIP) not above 25 cm/H_2O, respiratory rate not above 20 per minute and V_E not above 10 to 20 L per minute in the face of normal Pa_{CO_2} . Arterial oxygenation should also be maintained with an inspired O_2 concentration not above 50 percent, with 5 cm/H_2O or less of PEEP.

The success or failure of a weaning criterion often depends upon the clinical situation. Many of the criteria that were originally derived from patients being weaned from mechanical ventilation in the postoperative period are not applicable to patients who have been ventilator-dependent for several days or weeks, in whom respiratory muscle atrophy, malnutrition, and peripheral neuropathy have often supervened. In the latter situation it is unlikely that a single weaning criterion will be adequate to predict success.

Frequently, a trial of spontaneous ventilation is instituted (T-tube trial). T-tube trials often result in reduced functional residual capacity, which may further add to an increased respiratory

TABLE 33-4 -- Possible Criteria for Ventilator Weaning

TEST	CRITERION FOR WEANING
MECHANICAL FUNCTION	
Vital capacity (FVC)	>10-15 mL/kg
FEV_1	>10 mL/kg
Tidal volume (V_T)	>5 mL/kg
Maximum inspiratory pressure (MIP)	<-20 cm H_2O
Maximum voluntary ventilation (MVV)	>2 times resting V_E
Respiratory rate (V_F)	>25/min
Respiratory minute volume (V_E)	<10 L/min
V_F/V_T	<100 bpm/l
$V_F/(V_T/kg)$ [a]	<11 bpm/mL/kg
Thoracic compliance	
Static	33 mL/cm H_2O
Dynamic	22 mL/cm H_2O
Work of breathing	
Per minute	1.6 kg · m/min
Per L/min V_E	0.14 kg · m/min
$(0.75V_T/C\ dyn) \cdot (T_I/T_{TOT})/(MIP)$ [b]	<0.15
Functional residual capacity (FRC)	>50% predicted
GAS EXCHANGE FUNCTION	
A-a gradient (F_{IO_2} = 1.0)	<350 mm Hg
Pa_{O_2}/P_{AO_2} ratio	0.35
Shunt fraction (Q_S/Q_T)	<0.2
Dead space/tidal volume ratio (V_D/V_T)	<0.6

Minute ventilation (V_E) with normal Pa CO_2	<180 mL · kg^{-1} · min^{-1}
Respiratory quotient (R)	<0.9
Pa O_2 /F IO_2	>200
RESPIRATORY DRIVE	
P_{100}	<6 cm H_2O
P_{100} /MIP	<0.09
OTHER	
Urine output	500 mL/6 h
Arterial pH	>7.30
Gastric intramural pHi during pressure support trial	>7.30 or a change <0.09
[C dyn · MIP · (Pa O_2 /P AO_2)]/V F[c]	13 mL/bpm
[(C dyn/kg) · MIP · (Pa O_2 /P AO_2)]/V F[a]	0.1 mL/kg per bpm

Abbreviations: C dyn, dynamic thoracic compliance; T_I, inspiratory time; T_{TOT}, respiratory cycle length; bpm, breaths per minute

Data from [3] [176] [179] [239] [240] [241] [242] [244] [280] [281] [282] [283] [284] [285] [286] [287]

[a] Pediatric use [279]

[b] Inspiratory effort quotient (IEQ). If intrinsic PEEP (PEEPi) present, IEQ = (PEEPi + 0.75V_T/C dyn) · (T_I/T_{TOT})/(MIP · PEEPi) [280]

[c] CROP index (compliance, rate, oxygenation, pressure) [242]

load after extubation. Therefore, some clinicians advocate extubation while the patient is being supported with intermittent mandatory ventilation. For example, Gorback and Kantor [240] evaluated general surgical patients postoperatively for extubation when the synchronized intermittent mandatory ventilation (SIMV) rate was 4 per minute, Pa O_2 was not below 60 mm Hg with F IO_2 not above 0.4, PEEP was not above 5 cm H_2O, and no inotropic support was required. The investigators then proceeded to extubate patients if they matched three of the following five criteria: maximum inspiratory pressure 30 cm H_2O or less, arterial pH 7.30 or more, respiratory rate 30 per minute or more (including IMV breaths), vital capacity 10 mL/kg or more, and tidal volume 5 mL/kg or more. These criteria were used for 120 consecutive extubations; only 1 of the 120 patients required reintubation.

The individual approach used depends on the clinical situation. Whereas the approach suggested previously may be successful in patients mechanically ventilated after general surgical procedures, other criteria may be required after prolonged ventilation for respiratory failure due to pulmonary or neuromuscular disease. Indeed, a combination of measures that will assess respiratory mechanical function as well as gas exchange is generally implemented. Excellent reviews of weaning criteria and techniques have been published by Tobin and Yang, [241] Yang and Tobin, [242] Goldstone and Moxham, [243] Esteban, [244] and Mancebo. [245]

TRACHEAL EXTUBATION AFTER COMPROMISE OF AIRWAY

Protection of the airway with potential encroachment by hemorrhage, edema, infection, or tumor using an endotracheal tube (Ch. 39) often engenders uncertainty at the time of extubation. Airway patency after extubation may not be ensured, and sudden loss of airway may occur. Reintubation may then be difficult or impossible.

Useful measures that can be taken at the time of extubation include the following: inspection of the upper airway, either directly or with a fiberoptic instrument to detect residual swelling of the oropharynx or nasopharynx, or occlusion of the endotracheal tube with cuff deflated. If the patient is able to breathe around the tube in this way, it is less likely that critical airway compromise will occur after extubation. It is possible that if the endotracheal tube is large with respect to the patient's airway, the patient may not be able to breathe around it even in the presence of a normal airway. Replacement of the tube with a smaller one may be accomplished over a rigid introducer, which allows abrupt loss of the airway to be treated immediately with reinsertion. A nasogastric tube with the bulbous end cut off may be used, but a more rigid plastic introducer is preferable. Alternatively, a fiberoptic bronchoscope may be introduced into the endotracheal tube. If the patient is able to breathe after removal of the tube from the larynx and lower pharynx, direct inspection of the airway may be accomplished during removal of the fiberoptic instrument.

These measures should be undertaken while someone with the necessary skills to perform an emergency tracheotomy is available. Before removal of the endotracheal tube, the patient should be preoxygenated with 100 percent O_2, providing a margin of safety in the event of loss of airway patency.

TRANSPORTATION OF THE PATIENT

Movement of the patient between various critical care units (operating room, ICU, or postanesthesia care unit) or between the ICU and diagnostic radiology presents special problems (Ch. 66) . Planning for such a move should include preparing for a worst-case scenario. Movement of the patient from the operating room to the postanesthesia care unit may engender problems of hypoxemia, loss of airway, hemodynamic instability or vomiting, and aspiration. After an uncomplicated anesthetic, the most likely untoward event is arterial hypoxemia and loss of airway. Because the patient is at risk for hypoxemia due to a variety of causes, including hypoventilation, atelectasis, impaired V_A/Q matching, residual second gas effect (N_2O), shivering, and resulting decrease in mixed venous P_{O_2} and airway obstruction, it would appear safest to transport the patient with supplemental O_2 unless the distance between operating room and postanesthesia care unit is short. Respiration can be continuously monitored using one of the following: a tightly fitting mask and observing movements of a breathing bag, a hand held under the chin to feel exhalations, a precordial stethoscope or, if the patient is still intubated, an esophageal stethoscope. Patients at higher risk of hypoxemia during transport include children, patients with baseline gas exchange abnormality, and obese individuals. Particularly in these types of patients relatively rapid desaturation may occur, even if the patient has been ventilated with 100 percent O_2 immediately before transport. [246] [247] Continuous monitoring of Sp_{O_2} is an additional option.

A worst-case scenario for a patient undergoing transportation over a long distance, particularly in an elevator, would include accidental extubation or inability to ventilate. Therefore, in addition to the monitoring techniques described, long-distance transportation within the hospital should always occur with the ability to provide emergency positive-pressure ventilation and emergency endotracheal intubation. Several manufacturers produce portable pulse oximeters, which can be very useful in this setting.

EPIDURAL AND INTRATHECAL OPIATES

A large number of clinical reports suggest that spinal (epidural or intrathecal) opiate administration may provide prolonged superior analgesia after surgery as compared with parenteral administration in the traditional fashion (Ch. 69) . Moreover, clinical investigation suggested that respiratory function, particularly after upper abdominal surgery, [248] may be improved with epidural administration of morphine, compared with intravenous administration. However, early reports of delayed respiratory depression after epidural and intrathecal morphine administration have led to tremendous scrutiny of the respiratory depressant effect of narcotics given by this route. [249] Several detailed clinical investigations of blood gases, ventilation, and respiratory drive have shown acceptable degrees of depression after spinal narcotic administration. However, assessment of the mean response in small numbers of individuals may not predict the likelihood of an extreme response, which may occur infrequently. Few large-scale surveys are available. Rawal et al [250] reported on a survey in 1984 of 93 departments of anesthesia in Sweden, in which approximately 12,000 patients received epidural narcotics perioperatively, and 1,000 patients received intrathecal narcotics. The vast majority of these patients received morphine; 0.04 percent of patients showed clinical signs of ventilatory depression within 1 hour of epidural morphine injection, and 0.09 percent demonstrated delayed ventilatory depression. Delayed ventilatory depression occurred in 0.36 percent of patients who received intrathecal morphine, which occurred within 7 to 9 hours after injection. Stuart-Taylor et al [251] reported that 7 of 800 patients receiving epidural diamorphine experienced respiratory depression to less than 10 breaths per minute. Ready et al [252] reported that 2 of 1,106 consecutive patients treated with epidural morphine after surgery required medication for respiratory depression. Scherer et al [253] reported that 1 of 1,071 patients receiving thoracic epidural buprenorphine experienced respiratory depression. Lubenow [254] reported six incidents of respiratory depression in 5,172 patients receiving epidural narcotics. All patients with ventilatory depression were successfully treated, and there were no deaths from this complication.

Respiratory depression and consequent hypoxemia is not confined to patients who have received epidural narcotics. Periodic desaturation has also been reported after intravenous or intramuscular opiate administration. [53] [54] [59] [60] [63] [64] [66] [67] [255] [256] [257] [258] [259] Reeder [63] reported that one patient after abdominal vascular surgery experienced 229 episodes of desaturation to Sp O_2 less than 70%, representing 43 percent of the third postoperative night. Etches [260] reported eight cases of serious respiratory depression out of approximately 1,600 patients who had received intravenous opioids via patient-controlled infusion pumps.

Some studies have compared traditional and epidural routes of administration. Wheatley et al [60] reported that hypoxemia occurred in patients receiving narcotics intravenously and intramuscularly as well as via the epidural route, although most commonly in the latter. Jayr et al [261] observed that 13 percent of patients receiving a subcutaneous 2.5-mg-per-hour infusion of morphine after abdominal surgery experienced at least one episode of arterial desaturation (Sp O_2 below 85%) during the first postoperative night; only 6 percent of patients receiving an epidural infusion of morphine and bupivacaine experienced similar desaturation. Small series reported by other investigators suggest that mild desaturation is equally likely with either technique. [56] [262] [263] In the study of Pan and James 1 of 15 patients in the epidural group, who had earlier received 37.5 mg of promethazine for nausea and vomiting, required naloxone treatment for somnolence and hypoxemia. [263] Brose and Cohen [55] observed that episodes of desaturation (Sp O_2 < 85%) were more frequent in patients who received epidural narcotics compared with intravenous narcotics but not different from those who received narcotics intramuscularly. A randomized, controlled study of PCA versus epidural infusion of bupivacaine in 60 patients who had undergone major abdominal surgery for cancer indicated that mild decreases in Sp O_2 (85-89%) were more common in patients receiving epidural analgesia, but there was no difference between groups in frequency of Sp O_2 in the range 80 to 84 percent. [264]

These observations suggest that narcotic administration via the epidural or intravenous route carries a similar risk of mild or moderate episodic hypoxemia. Notwithstanding the hypothesis that these phenomenona produce morbidity, [67] [259] [265] [266] [267] the clinical significance of such episodes presently, if any, must be considered unproven. Temporal association of transient hypoxemia with clinical events such as myocardial ischemia and confusion does not prove causation. Normal volunteers can be safely exposed to repetitive periods of hypoxemia (Sa O_2 as low as 40%) for 30 to 45 seconds. [119] [268] Although there is evidence that exposure to extreme hypoxia (mean lowest Sa O_2 68%) for prolonged periods can cause minor psychomotor deficits, [269] there is little evidence that exposure to moderate altitude hypoxia for hours (for example astronomers commuting daily from sea level to the Mauna Kea observatories at barometric pressure = 468 mmHg; mean arterial P O_2 = 39.7 mm Hg, P CO_2 = 27.7 mm Hg[7]) or even days results in permanent sequelae. [7] [270] [271] Therefore, in terms of assessing the risks of various forms of postoperative analgesia, mild postoperative reduction in Sp O_2 is only a surrogate end point, which may not reflect the risk of the most feared complication: major respiratory depression resulting in respiratory arrest or death.

Earlier reports recommended the routine use of apnea monitoring on patients given spinal narcotics, but apnea monitors are often associated with false alarms and are frequently ignored. Furthermore, significant respiratory depression can occur with a normal respiratory rate. [170] [171] [173] Significant respiratory depression is almost invariably associated with sedation, however. Thus, a periodic check of mental status may be more sensitive than mechanical monitors in detecting clinical respiratory depression and is an essential component of monitoring patients who have received epidural narcotics.

Several years of clinical experience with epidural opiates has suggested that monitoring beyond clinical assessment is not necessary, particularly in low-risk patients [173] [251] [252] [253] [254] [272] [273] and has led to the implementation of less stringent policies in most institutions. [274] Standards of care after epidural opioid administration in the United States are illustrated by a survey of 197 institutions, including teaching and community hospitals, published by Muir et al. [273] Patients are monitored in a general care ward after opioid administration via a thoracic epidural catheter in 88.6 percent of institutions and after lumbar administration in 96.8 percent. Pulse oximetry and electronic apnea monitoring are each routinely utilized in 28 percent of institutions after thoracic opioid administration, and in 27 percent and 5 percent, respectively, after lumbar administration. The frequency with which respiration rate and sedation are monitored is shown in Table 33-5 .

There is a fairly widespread consensus that, in addition to regular monitoring of respiration rate and level of sedation, monitoring equipment and resuscitative drugs should be readily available. Naloxone and a syringe with which to administer it should be stored at the bedside. Dosage adjustment or more intensive monitoring may be suitable for individuals with cardiorespiratory disease or other risk factors

TABLE 33-5 -- Frequency of Respiratory Rate and Sedation Monitoring following Epidural Narcotic Analgesia in a Survey of 197 Institutions

FREQUENCY	THORACIC		LUMBAR

TABLE 33-6 -- Factors Predisposing to the Development of Respiratory Depression Following Epidural Opioids

(Not Available)

From Etches et al [245]

for respiratory depression (Table 33-6) (Table Not Available) . Because delayed respiratory depression can occur particularly after morphine administration, it is prudent to continue the monitoring algorithm for several hours after the final dose has been administered.

In conclusion, the widespread clinical use of epidural narcotics, particularly morphine, suggests that this technique is safe for most patients without the need for monitoring beyond simple clinical observation.

Chapter 34 - Renal Function Monitoring

Solomon Aronson

INTRODUCTION

Renal dysfunction remains a serious complication during the perioperative period in critically ill patients undergoing major surgery. The onset of acute perioperative renal failure portends a poor prognosis not solely from the loss of renal function but also from associated life-threatening complications, including sepsis, gastrointestinal hemorrhage, and central nervous system dysfunction. In high-risk patients undergoing high-risk surgery, the mortality rate from perioperative acute renal failure (ARF) has changed little during the past 3 decades. [1] [2] [3] [4] [5] [6] The reported mortality from ARF, once diagnosed, remains between 20 and 90 percent. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] Perioperative renal failure continues to account for half of all patients requiring acute dialysis. [12] Perhaps one reason for our inability to prevent renal failure is a shift in medical populations to older and more critically ill patients. An unfortunate consequence of the use of sophisticated support mechanisms and a willingness to expend considerable resources is that critically ill patients now survive high-risk surgery that was previously not offered, only to die later of ARF. The persistently high incidence of perioperative renal failure observed may also be due to our inability to adequately monitor renal function changes and to predict the onset of ARF in the operative and critical care setting.

An understanding of how to interpret information derived from monitoring presumes an understanding of terms used to describe the observations made. In the case of renal function monitoring, these assumptions may not always be warranted. Perioperative renal failure, for example, has been defined clinically as the need for postoperative dialysis or, in some cases, as a postoperative serum creatinine level exceeding a predetermined preoperative value (e.g., an increase of 0.5 mg/dL or of 50% or more). In one review, no two studies of 26 defined ARF the same way. [13] The overall reported frequency of ARF among all patients admitted to the hospital is 1 percent [14] and may increase to 2 to 5 percent [4] [15] during hospitalization; however, there is no universally accepted standard for detecting renal insufficiency or failure. Reporting on the cause, incidence, and management of renal dysfunction also varies greatly because of wide variations in the definition of terms used to describe degrees of renal dysfunction in the literature. It is not surprising, therefore, that an estimated 5 percent of the general population has renal disease (however defined) that is severe enough to adversely affect surgical outcome. [16]

Several mechanisms involving a renal tubule, a tubulointerstitial process, and a reduction in filtering capacity of the glomerulus have been implicated in renal dysfunction. Prerenal causes are responsible for most cases of perioperative ARF. Since the second World War, it has become clear that ARF can result from decreased renal blood flow from a myriad of causes. Prerenal azotemia accounts for 70 percent of general community-acquired ARF [14] [15] and for more than 90 percent of perioperative ARF. [13] [17] Typically, an early compensatory phase of normal renal adaptation (e.g. pre- prerenal failure) progresses to become decompensatory as prerenal failure ensues. [18] ARF may simply be characterized as an abrupt decline in renal function at this transitional stage. Depending on preexisting reserve capacity, this stage may persist from a period of hours to days. At this point, the key decline in renal function is sufficient to result in retention of nitrogenous end products of metabolism and cessation of fluid and electrolyte homeostasis. These events are not reversible by modifying nonrenal factors and are difficult to predict. Prerenal azotemia and tubular ischemic injury represent extreme examples of the same problem (i.e., insufficient renal blood flow). When prerenal azotemia progresses

to renal failure, the terms acute tubular necrosis, vasomotor nephropathy, and ischemic tubular injury are often used interchangeably in the literature.

Although most causes of ischemic renal failure are reversible, after a critical point of prolonged severe ischemia, necrosis may be irreversible. [19] In patients with inadequate renal blood flow, this irreversible injury is commonly caused by the added risk of drugs that alter the intrarenal distribution of blood flow by abnormal hemodynamics or by preexisting disease (Chs. 51 , 53 , and 55). [20] These predisposing variables, as well as the onset and pathogenesis of perioperative renal failure, are often difficult to determine, however, because direct assessment of renal hemodynamics and renal tubular function is typically not possible. Therefore, renal function must often be indirectly assessed. An understanding of normal renal physiology and of the pathophysiology of ARF is thus critical. Furthermore, because perioperative treatment strategies depend on differentiating normal from abnormal renal function, understanding the limitations of commonly used renal function monitoring techniques is also important.

THE BASIS OF RENAL FUNCTION MONITORING

In general, the renal response to any specific condition or insult is primarily determined by associated physiologic and hemodynamic conditions prevailing at the time (Ch. 18). In patients with renal disease, the challenge of optimal perioperative management is demanding because recognition of subtle change is difficult. As our understanding of renal disease evolves, traditional answers have turned into new questions. In the past decade, we have gained great insight into intrarenal actions of intrinsically produced substances and extrinsically administered agents. Overall, however, renal failure symptoms typically are not detected until less than 40 percent of normal functioning nephrons remain, and uremic symptoms occur when less than 5 percent of normal functioning nephrons remain. [18]

The three general functions of the kidneys are (1) to excrete potentially toxic metabolic end products, (2) to regulate water and tonicity, and (3) to produce hormones. The kidney excretes a majority of the waste products metabolized from dietary intake, chiefly urea formed from ammonia released in protein metabolism, creatinine from muscle metabolism, and uric acid from purine metabolism. Serum creatinine levels and blood urea nitrogen (BUN) levels are used to measure the efficiency of metabolic waste removal. The levels of these end products rise slightly with increased dietary intake or increased catabolism. With normal renal function, an increase in concentration of waste products in blood results in rapid excretion of the increased load. The waste products are filtered in the glomeruli and tend to remain in the tubular fluid because they cannot permeate the nephron wall. In contrast, more than 98 percent of the filtered water and solute is reabsorbed back into the body. Some degradation products, like uric acid, are reabsorbed in the proximal tubule, secreted back into the tubule fluid, and then eliminated in urine. Cells and proteins with molecular masses greater than 70,000 daltons do not cross the glomerular capillary wall. However, smaller proteins, peptides, amino acids, and glucose are filtered to a variable degree. The proximal tubule reabsorbs these substances, thus minimizing their loss in urine. Other substances that cannot be filtered are excreted primarily by active secretion into the tubular fluid (Fig. 34-1) . Thus, the kidney is able to clear metabolic waste from the blood efficiently while conserving cells, proteins, and nutrients. When the glomerular membrane is damaged, red blood cells and large amounts of protein may enter the filtrate and later appear in urine.

The kidney regulates extracellular volume (approximately one-third of total body water) primarily by manipulating sodium to maintain normal tonicity. The body senses intravascular volume losses through receptors in the left atrium, the afferent arteriole of the kidney, and the carotid sinus. Increased sympathetic neural tone to the kidney, decreased sodium delivery to the macula densa of the distal convoluted tubule, or reduced perfusion pressure stimulates renin release. The renin-angiotensin-aldosterone system then acts to conserve sodium and water (Figs. 34-2 , 34-3). Normally, daily sodium intake is excreted in the urine (150 mEq/d). With changes in water intake, sodium excretion in urine changes to maintain normal extracellular volume. The homeostatic range for the sodium intake/urinary excretion balance is great: less than 1 to more than 1,000 mEq/d. Urinary excretion of sodium begins with filtration. The tubules then reabsorb almost all (99%) of the filtered sodium. Seventy percent is reabsorbed in the proximal tubule, 20 percent in the thick ascending limb of the loop of Henle and distal convoluted tubule, and 9 percent in the collecting ducts. The mechanisms regulating the urine excretion of sodium include systemic changes in circulating volume, causing decreased filtration and consequently decreased filtered sodium load. Less circulating volume also decreases levels of atrial natriuretic factor and increases aldosterone levels.

The second part of the tonicity function that the kidney serves is maintaining osmolarity within normal limits through regulation of water excretion. Reduced water intake with continued urinary water excretion leads to a rise in plasma osmolarity, and vice versa. The major effector in the regulation of water excretion is the antidiuretic hormone (ADH) vasopressin. Vasopressin is secreted into the peripheral plasma by the posterior pituitary gland. The kidney is capable of wide variations in water excretion (urine flow) in

Figure 34-1 The glomerular permeability (e.g., filtration to plasma ratio) is represented on the Y axis compared to the molecular weight of the filtered substance represented on the X axis. *(Data from Renkin and Robinson [14])*

Figure 34-2 Renin released into the circulation interacts with angiotensinogen to cleave off the decapeptide angiotensin I; through converting enzymatic activity this becomes the active octapeptide angiotensin II. Angiotensin II is a potent vasopressor and has a direct effect on the adrenals to stimulate aldosterone. By its vasoconstrictive action angiotensin II increases salt retention.

response to changing levels of vasopressin in the peripheral plasma. Water excretion can be 100-fold lower in extreme antidiuresis (high vasopressin) than in extreme diuresis. These changes are achieved without substantial changes in steady-state rate of total solute excretion (osmolar excretion). This ability depends on the kidneys' ability to concentrate or dilute the urine. Water output from the kidneys of a 70-kg person normally ranges from 500 mL to 12 L/d. The kidney maintains a normal range of urinary concentrations and volumes first by producing a large amount of dilute fluid in the loop of Henle and the distal convoluted tubule. When the fluid passes through the highly concentrated solutes in the medulla in the presence of ADH, most of the water is reabsorbed. In the absence of ADH, only about half the water is reabsorbed. An acute (transient) effect of altered levels of circulating vasopressin (or ADH) or solute excretion is different from a steady-state response. When vasopressin is begun in water-loaded rats, an almost immediate decrease in water excretion occurs, and the excretion rates eventually return to control levels (consistent with steady-state behavior).

Figure 34-3 Mechanism for renal sodium and volume regulation. ANF, atrial natriuretic factor; GFR, glomerular filtration rate; C.O., cardiac output; B.P., blood pressure; NaCl, sodium chloride.

Such transient behavior is observed not only in response to altered levels of circulating vasopressin but also following induction of anesthesia.

The medullary concentration of solutes is high (1,400 mOsm/L) because (1) the ascending limb of the loop of Henle actively reabsorbs sodium and chloride without water into the medullary interstitium, and (2) large amounts of urea enter the inner medulla from the collecting tubule. The cortical and outer medullary collecting tubules are sites of passive water reabsorption that are impermeable to urea. Urea becomes concentrated in the collecting ducts of the inner medulla, which are permeable to urea moving passively down its concentration gradient. The high concentrations of sodium, chloride, and urea are not washed out of the medulla because medullary blood flow is low and the configuration of the capillaries of the vasa recta permits a countercurrent exchange. Of the 140 to 180 L/d of fluid filtered at glomeruli, approximately 70 percent (100 L/d) is reabsorbed isosmotically in the proximal tubule, and 15 percent (20 L/d) is reabsorbed passively in the medulla in

the descending loop of Henle. The remaining 15 percent (20 L/d) of highly concentrated tubular fluid reaches the papillary tip of the loop of Henle. As the fluid ascends the loop of Henle, sodium is reabsorbed (passively in the medulla and actively in the thick ascending limb in the outer medulla and cortex). Tubular fluid thus becomes hypotonic to plasma. Sodium reabsorption without water continues in the distal tubule. The collecting ducts may receive tubular fluid with concentrations below 100 mOsm/L. Tubular permeability to water increases or decreases, depending on the amount of ADH present, and may vary from 8 to 20 L, with subsequent urine volumes varying from 0.5 to 12 L/d in the normal 70-kg person.

The kidney functions as an endocrine gland in the renin-angiotensin system. Renin is secreted into the body by the granular cells of the juxtaglomerular apparatus of the kidney. Once in the blood stream, renin catalyzes the splitting of angiotensin I from angiotensinogen, which is secreted from the liver and is always present in the plasma in high concentrations. The kidneys also secrete renal erythropoietic factor, which is involved in the control of erythrocyte production by the bone marrow. In response to decreased oxygen delivery to the kidney, renal erythropoietic factor is secreted and acts enzymatically in the plasma on a globulin secreted by the liver to form erythropoietin, which then acts to stimulate the bone marrow to increase its production of erythrocytes. The kidneys produce the active form of vitamin D and are linked to calcium metabolism; during times of prolonged fasting, the kidneys synthesize glucose from amino acids and other precursors and thus have the potential to be gluconeogenic organs.

Physiology of Urine Formation

Urine formation is dependent on a number of factors: hydraulic and oncotic pressures within the glomerular capillary, local and systemic neurohumoral influences, and an intact kidney-ureter-bladder feedback loop (Ch. 18). The formation of urine begins with glomerular ultrafiltration and progresses to selective tubular reabsorption and tubular secretion. General anesthesia and surgery influence renal function primarily by affecting filtration and reabsorp-tion. [21] [22] [23] [24] [25] All anesthetic agents, whether volatile or intravenous, have the potential to alter renal function by altering blood pressure and cardiac output so that renal blood flow is redistributed. This redistribution is accompanied by sodium and water conservation and decreased urine formation. Commonly used premedications can also influence urine output. [26] Narcotics and barbiturates, for example, can produce a small decrease in glomerular filtration rate (GFR) and, consequently, urine volume.

Regional anesthesia above level T4 reduces sympathetic tone to the kidney and makes renal blood flow and filtration directly dependent on perfusion pressure during sympathectomy. [27] Renal function and urine formation during regional anesthesia depend on the overall sum of the different homeostatic responses evoked, not just the sympathectomy. The combined effect of multiple factors, such as level of the block, preservation of autoregulatory mechanisms to preserve renal blood flow, circulating catecholamines, reninangiotensin, ADH, steroids, and prostaglandins, all determine the degree of urine formation.

Anesthetic drugs may increase or decrease catecholamines, alter renal vascular resistance, depress myocardium, and decrease renal blood flow, or they may have a direct nephrotoxic effect on renal tubular function. Surgery in general, aortic cross-clamping and declamping in particular; trauma; and stress also may indirectly influence urine formation by changing myocardial function, sympathetic activity, neuronal or hormonal activity (e.g., renin and angiotensin production), intravascular volume, or systemic vascular resistance. [28] [29] [30]

Starling Forces

Glomerular filtration is governed by the equation

where GFR is the glomerular filtration rate or the rate at which fluid is filtered through the glomerular capillaries into the Bowman capsule, K_f is the glomerular filtration coefficient or the factor that considers the permeability and surface area of the glomerular basement membrane, P_{GC} is the glomerular capillary pressure, P_{BC} is the pressure in the Bowman capsule, and P_{PO} is the plasma oncotic pressure.

The last three factors represent the Starling forces that govern the hydrostatic forces through the glomerular membrane. Acute changes in GFR, and consequently in urine formation, are commonly caused by changes in glomerular capillary pressure. For example, events that reduce plasma flow rates reduce the hydraulic pressure of glomerular capillaries and favor decreased ultrafiltration, whereas events that increase plasma flow rate have the opposite effect. Theoretically, the effects of varying concentrations of plasma proteins may influence urine formation and GFR. As the concentration of proteins in plasma decreases, the oncotic pressure and the oncotic force opposing ultrafiltration also decrease. Conversely, a rise in oncotic pressure reduces the rate of glomerular filtration. This effect is most likely offset by the oncotic force of plasma proteins (albumin), which enables adequate intravascular volume to be maintained. The

precise role in preserving renal function of oncotic pressure versus maintenance of adequate renal blood flow or other variables influencing glomerular filtration has never been studied. It is interesting to note, however, that in one reported series, patients resuscitated with albumin after massive transfusion had more renal dysfunction than those resuscitated with saline. [31]

Neurohumoral Influences

Because the tubules and the collecting ducts of the kidney reabsorb almost 99 percent of the filtered solute, the daily filtration volume (approximately 180 L) greatly exceeds the typical daily urinary volume of 1 to 2 L. To clear nitrogenous wastes daily, 400 to 500 mL of urine is required. The countercurrent multiplier system in the loop of Henle is a critical component of the kidney's ability to excrete or conserve salt and water. Sodium and water reabsorption depend on the hypertonicity of the medullary interstitium, which is dependent on the maintenance of normal renal blood flow. The major hormonal influences determining conservation or loss of filtered sodium and water are aldosterone, ADH, atrial natriuretic factor, and the renal prostaglandins.

High concentrations of aldosterone stimulate reabsorption of sodium and water, primarily in the distal tubule and the collecting ducts. Aldosterone is produced by the adrenal cortex in response to the feedback from the renin-angiotensinaldosterone system, simplified as follows: reduced delivery of sodium to the macula densa causes release of renin from the granular cells of the juxtaglomerular apparatus. Renin, in turn, catalyzes the release of angiotensin I from angiotensinogen. Angiotensin I is then transformed to angiotensin II in the lungs, catalyzed by angiotensin-converting enzyme. Finally, angiotensin II stimulates the production of aldosterone.

Antidiuretic hormone acts primarily on the collecting ducts to increase water reabsorption. ADH is released from the posterior pituitary gland in response to increased blood osmolarity, which stimulates osmoreceptors in the hypothalamus. ADH is inhibited by stimulation of atrial baroreceptors or increased atrial volume. [32] ADH release is also influenced by stress and increased partial pressure of arterial carbon dioxide. [33] A high level of ADH thus results in the excretion of small volumes of concentrated urine.

Atrial natriuretic peptide causes systemic vasodilation and promotes renal excretion of sodium and water by increasing glomerular filtration. [34] Atrial natriuretic peptide is secreted by the cardiac atria and other organs in response to increased intravascular volume. It decreases systemic blood pressure by relaxing vascular smooth muscle, reducing sympathetic stimulation, and inhibiting the renin-angiotensin-aldosterone system.

The kidney also synthesizes prostaglandins, which regulate the influence of other hormones. During hemodynamic instability and increased adrenergic stimulation, for example, prostaglandin E_2 decreases the vasoconstrictive effect of angiotensin II on the afferent arterioles and preserves renal blood flow. Inhibition of prostaglandin synthesis during normal states of hydration, renal perfusion, and sodium balance does not affect renal function. When the kidney is confronted with a vasoconstricted state, such as hypotension and hypovolemia, however, the presence of renal prostaglandins is essential for preserving adequate renal blood flow. Patients taking nonsteroidal anti-inflammatory drugs are at risk during conditions of impaired circulatory status because these agents inhibit cyclooxygenase activity, an important enzyme in the prostaglandin synthesis pathway, thereby rendering the kidney (afferent arteriole) susceptible to the systemic vasoconstrictive effect of angiotensin II and other catecholamines normally secreted to preserve intravascular volume and perfusion pressure.

Ureteral Peristalsis

Ureteral peristalsis influences urine formation. Interaction between the urinary bladder, the kidney, and the ureters regulates urine production by the kidney and urine transport to the bladder by the ureter. [35] During general anesthesia, ureteral peristalsis may influence the rate of urine output measured with a Foley catheter. Young et al [36] demonstrated in an experimental model of ureteral peristalsis that general anesthesia decreases the rate of ureteral contractility (Fig. 34-4) (Figure Not Available) . Normally, ureteral peristalsis originates with electrical activity at pacemaker sites located in the proximal portion of the urinary collecting system. The electrical activity is then propagated, giving rise to the mechanical event peristalsis and ureteral contraction, which propels the bolus of urine distally. Basal peristalsis within the ureter is influenced by pressures within the renal pelvis, the ureter, and the ureteral-vesical junction. The autonomic nervous system also plays an important role in ureteral function and consequently in urine formation. [37] Cholinergic agonists generally increase the frequency and the force of ureteral contraction. Agents that act primarily on adrenergic receptors tend to stimulate ureteral activity, whereas agents that primarily activate adrenergic receptors tend to inhibit ureteral activity. Histamine stimulates ureteral activity. In a variety of preparations, morphine has been reported to increase ureteral tone. Infections within the urinary tract may impair urine transport. In humans, irregular peristaltic contractions have been recorded with retroperitoneal inflammation secondary to appendicitis, regional enteritis, ulcerative colitis, and peritonitis. [38] Clinically, the response of the ureter to pathologic conditions seems to vary with age. More marked degrees of ureteral dilation are observed in the neonate and the young child than in the adult. [39] Aging brings both a decrease in the effectiveness of beta-adrenergic agonists to relax the ureter and a progressive increase in smooth muscle cell mass, producing the overall effect of no apparent change in the ureteral contractile process in the geriatric patient.

Monitoring of Glomerular Filtration Rate

Structure of the Glomerulus

In general, the GFR is determined by the rate of glomerular plasma flow (as it influences ultrafiltration pressure), systemic oncotic pressure, glomerular hydraulic pressure

Figure 34-4 (Figure Not Available) Effect of general anesthesia on the rate of ureteral contractility. *(From Young et al [36])*

differences, and an ultrafiltration coefficient. The ultrafiltration coefficient is the product of glomerular capillary hydraulic permeability and total surface area available for filtration. The filtration rate across a capillary bed is therefore the product of surface area, pressure gradients, and permeability. In the glomerulus, the capillaries are configured in tufts, which increases their surface area. Hydrostatic pressures are normally maintained higher in glomerular capillaries than in other capillary beds by a delicate balance of preglomerular and postglomerular vascular tone in arterioles. The permeability of the glomerular capillary wall is equal for substances with molecular masses up to 5,000 to 6,000 daltons and falls to almost zero at 60,000 to 70,000 daltons. [40] Thus, metabolic wastes and essential nutrients are filtered freely, and larger proteins, such as albumin and immunoglobulin G, are filtered in trace amounts, if at all. The glomerulopathic process in diabetes, [41] for example, most likely derives from all of the factors that cause sustained increase in glomerular pressure and flow. Hyperglycemia induces a state of extracellular fluid volume expansion, structural hypertrophy of the kidney, and altered glucoregulatory and vasoregulatory hormone action. These hemodynamic consequences of hyperglycemia lead to renal vasodilation and increased plasma flow rate. The increase of plasma flow in turn causes increased glomerular transcapillary flux of plasma proteins. The elevation in glomerular flow (pressure) also alters the permeability and selectivity of the glomerular basement membrane, resulting in increased protein filtration. The increased transglomerular flux of plasma proteins leads to their accumulation in the mesangium, which serves further as a stimulus to proliferate glomerulosclerosis.

Inulin Clearance

GFR, the rate at which plasma water is filtered across the glomerulus, is an important index of renal function. Because the tubule reabsorbs most of the water filtered through the glomerulus, urine volume cannot be used to measure GFR. For measurement, a substance is required that is filtered through the glomerulus at the same rate as water and is excreted in the urine (i.e., neither reabsorbed or secreted). The amount of such a substance filtered is then equal to the amount eliminated in the urine and can be determined from the product of the substance's concentration in plasma and the amount of plasma water filtered.

Inulin, an exogenous polysaccharide with a molecular mass of 5,200 daltons, is an ideal substance to measure GFR because it is filtered freely in the glomerulus, is not reabsorbed or secreted, and is excreted in the urine. Since its introduction into clinical practice in 1934, inulin clearance has been considered the standard for measurement of GFR. [42] To assess inulin clearance, one administers a priming dose of inulin intravenously, followed by a continuous infusion calculated to maintain constant blood concentrations. After an equilibration period (generally 1 hour), clearance measurements are obtained. Urine is collected (typically with a Foley catheter), and venous blood samples are obtained at the

midpoint of each clearance period. The longer the clearance period, the less likely the introduction of error from incomplete voiding. The standard formula for calculation of clearance is as follows:

where U_I and P_I are the urine and plasma concentrations of inulin, C_I is its clearance, and V is the urine flow rate.

Creatinine Clearance

In clinical practice, the endogenous substance creatinine is used to measure clearance. Creatinine (molecular mass 133 daltons) is a smaller substance than inulin and is produced from muscle metabolism. Creatinine is not an ideal substance for measuring clearance, because a small amount is secreted under normal conditions. Although creatinine clearance may exceed inulin clearance, the clearance of endogenous creatinine approximates that of inulin and has proved an excellent measure of GFR. [43] The creatinine to inulin clearance ratio is almost identical in normal infants, children, and adults. In subjects with moderate-to-severe renal insufficiency, however, the creatinine to inulin clearance ratio is increased. [44] Increased secretion and clearance of creatinine in patients with renal insufficiency may result in overestimates of true GFR. Urea (molecular mass 60 daltons), on the other hand, cannot be used to estimate GFR because under normal conditions, it is filtered and reabsorbed. More importantly, urea clearance changes with the state of hydration; for example, under conditions of dehydration, urea clearance would be significantly less than inulin clearance.

UNDERSTANDING CHANGES IN PERIOPERATIVE RENAL FUNCTION

The precise mechanisms heralding the transition from compensated preserved renal function to uncompensated renal failure during the perioperative period remain poorly understood, in part because the methods used to assess renal function changes are insensitive and nonspecific. All anesthetic techniques and perioperative events that decrease blood pressure and cardiac output have the potential to alter renal function because of blood flow redistribution within the kidney and decreased glomerular filtration.

Effects of Regional Anesthesia

Regional anesthetics and the kidneys interact in a complex manner that varies according to the underlying cardiovascular, renal, fluid, and electrolyte status of the patient (Ch. 42). [45] The combined effect of multiple factors (e.g., catecholamines, renin-angiotensin, ADH, steroids, prosta-glandin) determines the consequences for renal function. The effect of sympathetic blockade depends on the level of the block and the presence of underlying disease. In a patient with global systolic ventricular dysfunction or dilated cardiomyopathy, regional anesthesia may exert the beneficial effects of an afterload-reducing and preload-reducing agent. However, the same anesthesia in a patient with hypovolemia may exacerbate hypotension and decrease renal perfusion. Thus, the interactions between regional anesthesia and renal function are different in patients with different underlying disease. In patients with ischemic heart disease, regional anesthesia may exacerbate regional myocardial dysfunction through vasodilation, hypotension, and decreased coronary perfusion pressure [46] and may thereby decrease renal perfusion.

Recall that spinal cord segments T4 through L1 contribute to the sympathetic innervation of the renal vasculature, which is innervated via sympathetic fibers from the celiac and renal plexus. [27] [47] Therefore, as long as flow is maintained and perfusion pressure does not fall below the autoregulatory range during spinal and epidural anesthesia, there will be little change in GFR or renal vascular resistance. Sulerman et al [48] demonstrated in healthy volunteers that renal blood flow is unchanged during epidural anesthesia with a T6 sensory block. In their study, mean arterial pressure remained above 70 mm Hg and never decreased below 6 percent of the baseline level. The sympathetic innervation of the kidney affects multiple aspects of renal function, including hemodynamics, electrolyte and water reabsorption, and renin secretion. [45] Urine volume and free water clearance may decrease during spinal anesthesia as a result of increased ADH secretion. Increased renal sympathomimetic activity decreases renal blood flow through alpha-adrenergic mediation and increases renin release via beta-adrenergic innervation directly or by interaction with the renal tubular macula densa and the baroreceptor reflex mechanism. [49]

Effects of Inhaled Anesthetics

There is a well-recognized renal nephrotoxic effect of the older fluorinated inhalation anesthetics that is attributed to serum inorganic fluoride concentration (Chs. 4 and 6). Increased levels of serum inorganic fluoride caused polyuric renal insufficiency. [50] Methoxyflurane, which is no longer used clinically, and enflurane, when used for prolonged periods (9.6 MAC hours), cause an increase in serum inorganic fluoride. [50] [51] [52] After enflurane anesthesia, maximal urinary osmolality decreases in response to vasopressin for 5 days. These changes are of little consequence in patients with normal renal function. However, in patients with preexisting renal dysfunction, enflurane may cause further renal deterioration.

Sevoflurane appears to act as does enflurane with regard to the generation of inorganic fluoride (F-) as a result of metabolism. [53] [54] [55] [56] Sevoflurane undergoes approximately 5 percent metabolism, and the primary metabolites are fluoride and hexafluoroisopropanol. Once formed, hexafluoroisopropanol is conjugated in the liver with glucuronic acid and excreted. The oxidative defluorination of sevoflurane in the liver causes liberation of free fluoride ions. Concerns that sevoflurane might have the potential (as does methoxyflurane) to impair the ability of the kidneys to concentrate urine have been raised. [54] Earlier research had indicated that renal dysfunction from methoxyflurane was likely

---

to occur when dose or duration of administration resulted in serum fluoride concentrations that exceeded 50 muM/L. [51] This presumed threshold for toxicity has been extrapolated for other halogenated anesthetic agents, including enflurane and sevoflurane. However, because sevoflurane is defluorinated by the cytochrome P-450 enzyme system, renal defluorination of sevoflurane is not clinically significant. In American Society of Anesthesiologists class I and II patients, it was shown that serum fluoride levels averaged 36.6±4.3 muM/L after 9 MAC hours of sevoflurane anesthesia. [53] [57] These fluoride levels peaked 2 hours after the end of anesthesia and decreased by 50 percent within 8 hours. The rapid decline of plasma fluoride was attributed to the insolubility and rapid pulmonary elimination of sevoflurane. Desmopressin was used to test urine concentrating ability before anesthesia and on days 1 and 5 after 9.5 MAC hours of sevoflurane and enflurane anesthesia. [57] Mean plasma fluoride levels were approximately twice as high in volunteers receiving sevoflurane than in those receiving enflurane, and 43 percent of volunteers receiving sevoflurane had plasma fluoride levels that exceeded 50 muM/L. Despite these results, the kidneys of the volunteers receiving sevoflurane were not impaired in their ability to concentrate urine, whereas 20 percent of volunteers receiving enflurane had transient concentrating deficits on day 1. The investigators postulated that intrarenal production of fluoride ion was a more important factor in the pathogenesis of nephrotoxicity than the association between plasma fluoride levels and nephrotoxicity. [56] The intrarenal metabolism of methoxyflurane is 4-fold greater than the intrarenal metabolism of sevoflurane.

All inhaled anesthetic agents interact with carbon dioxide absorbents to produce toxic compounds. A controversy has arisen concerning the relationship between sevoflurane, nephrotoxicity, and compound A. In circuit systems under conditions of high temperature and low flow rates, carbon dioxide absorbents degrade sevoflurane, resulting in detectable concentrations of vinyl ether compound A (fluoromethyl-2,2-difluoro-1-{trifluoromethyl} vinyl ether). These degradation products are conjugated in the liver with glutathione. Cysteine conjugates formed in the bile ducts and kidney by the conjugates are metabolized in the kidney by an enzyme (cysteine-conjugate beta-lyase) to form end products that result in renal injury, which is characterized by diuresis, glycosuria, proteinuria, and elevated serum BUN and creatinine levels. The renal injury in experimental rat models was a function of the concentration and the duration of exposure of compound A. [58] The threshold for injury was exposure to compound A at 50 to 114 parts per million (ppm) for 3 hours while the lethal dose of compound A, from which 50 percent of rats died, was 331 ppm over 3 hours; 203 ppm over 6 hours; or 127 ppm over 12 hours. [59] It has been proposed that the disparity between the results in humans and those in rats is due to differences in the metabolic pathway of compound A in the species. Of the four recognized metabolic pathways for compound A, three do not involve renal beta-lyase and do not result in organ toxicity. Humans have a 10-fold to 30-fold relative absence of the renal beta-lyase enzyme pathway compared with rats, which may account for the apparent absence of renal injury from sevoflurane in humans. One study [60] evaluated the safety of low-flow sevoflurane anesthesia compared with low-flow isoflurane anesthesia in patients scheduled to have prolonged surgery (i.e., >6 hours). The average MAC hours in the sevoflurane group and in the isoflurane group were similar. The soda lime temperature averaged 45±1.6°C. The average compound A concentration in the sevoflurane group was 20±7 ppm. Markers of renal injury, including BUN, creatinine, *N*-acetyl-beta- D-glucosaminidase (NAG), and alanine aminopeptidase were increased similarly in all groups during the prolonged exposure to the volatile anesthetics.

Eger et al [61] evaluated the highest concentrations of compound A possible during anesthesia (mean arterial pressure, 56 mm Hg) with sevoflurane in human volunteers. Fresh carbon dioxide absorbent was used and sevoflurane was given (without nitrous oxide) at 1.25 MAC, while esophageal temperature was maintained at 37°C. Volunteers were exposed to the anesthetic gas for 8 hours. In that study, compound A levels approached 50 ppm in the inspired limb of the breathing circuit, and the volunteers were asked to bring in 24-hour urine collections for 3 consecutive days after the anesthetic exposure. In most subjects, there were transient

elevations of urinary protein, albumin, glucose, alpha- glutathione S-transferase , and pi-glutathione S-transferase. No such increases were observed after a similar exposure to desflurane.

Subsequently, [62] another study evaluating the safety and efficacy of sevoflurane versus isoflurane in patients during conditions of flow of less than 2 L/min was conducted. In that study, patients from multiple institutions undergoing elective surgery lasting from 2 to 8 hours were evaluated. Fresh Baralyme was used for all cases, and nitrous oxide was not permitted. The use of sevoflurane averaged 1 MAC hour. No differences were found in urine albumin, glucose, protein, or osmolality between treatment groups. Moreover, within the sevoflurane group, there were no significant correlations between compound A levels and BUN, creatinine or urinary excretion of protein, glucose, NAG, proximal tubule alpha-GST, or distal tubule pi-GST. [62]

Effects of Hemodynamic Changes

Both prerenal and renal factors can cause or lead to ischemic renal dysfunction. There appears to be an early phase of renal adaptation or pre-prerenal failure to the decreased delivery of blood to the glomerulus. [18] When these compensatory mechanisms become decompensatory, prerenal failure ensues. Renal clearance is determined by the delivery of waste products to the kidney (renal blood flow) and by the kidney's ability to extract them (GFR).

A variety of experimental models have been devised to simulate hemodynamically mediated human ARF. [63] [64] [65] [66] In these models, renal blood flow is commonly interrupted mechanically or pharmacologically. A reduction of flow by more than 50 percent is the rule during the initial phase of the experiment. After transient but total renal ischemia for 40 to 60 minutes in a dog, rat, or rabbit, a lesion appears whose clinical manifestations, laboratory features, and pathologic features closely resemble those in humans with ARF. [35] During the established phase, GFR is disproportionately depressed, compared with a moderate decline in renal blood flow. Micropuncture studies *in vivo* and perfusion of isolated

renal tubules *in vitro* have revealed that the ensuing oliguria can be attributed to reduced GFR, sequestration of tubule fluid within obstructed tubules, and backleak of tubule fluid across necrotic epithelium into the interstitium. [66] The maintenance of adequate blood supply to the kidneys therefore is critical; however, determining what constitutes adequate blood supply (oxygen) is difficult. The exact role and the timing of changes in renal blood flow in the initiation and the maintenance of ARF continue to be studied.

A number of theories have been proposed to explain the pathogenesis of hemodynamically mediated ARF. Although a reduction in renal blood blow is clearly the initiating cause (Fig. 34-5) (Figure Not Available) , [67] [68] the occurrence of ARF after hypotension is unpredictable. The precise circumstances precipitating a change from an underperfused healthy kidney to a damaged organ are difficult to define. Even with decreased delivery of blood to the glomerulus, a series of compensatory mechanisms may still preserve renal filtration function (Fig. 34-6) (Figure Not Available) . [18] Salt and water are retained to restore intravascular volume and fractional tubular reabsorption. The distribution of cardiac output to the kidneys is also regulated. At a given level of cardiac output, intrarenal factors affect the ratio of renal to systemic vascular resistance, thereby influencing the percentage of cardiac output received by the kidneys. Another critical component in the intrinsic modulation of renal filtration function is the regulation of filtration fraction. At the glomerular capillary, plasma is separated into a protein-free ultrafiltrate and a nonfiltered portion. Normally, the filtration fraction (the relationship of GFR to renal plasma flow) is about 0.2. Initially, filtration fraction is maintained by efferent arteriolar constriction. Unabated, the mechanisms that influence efferent arteriolar vasoconstriction ultimately may influence afferent arteriolar vasoconstriction. The resulting decrease in filtration fraction is the hallmark of postischemic ARF. [18] Ischemic tubular damage may be exacerbated further by an imbalance between oxygen supply and demand. Most vulnerable to the imbalance are the thick ascending tubular cells of the loop of Henle in the medulla. [68] [69] [70] [71]

Figure 34-5 (Figure Not Available) Schematic representation of the mechanisms that initiate and maintain decreased glomerular filtration seen in experimental-induced acute renal failure. Intrarenal distribution of blood flow as well as total renal blood flow can be assessed with radioactive gases or radiolabeled microspheres. Microsphere, xenon washout, and angiographic techniques have shown that outer cortical blood flow decreases in ischemic models of ARF. [72] [73] [74] Because 85 to 90 percent of renal blood flow is distributed to cortical glomeruli, the finding of cortical pallor and redistribution of renal blood flow away from the cortex means that redistribution may be responsible for the functional lesions of ARF. In some cases, the return of perfusion to the cortex has correlated with a return of renal function. [73] The theory that intrarenal distribution of blood flow away from the outer cortex to the inner medulla decreases oxygen supply while increased tubular reabsorption of solute increases oxygen demand is further supported by studies of renal energetics during ARF. [75] [76] When biochemical changes were monitored in the hypotensive rat kidney with phosphorus 31 nuclear magnetic resonance imaging, [77] oli-guria preceded decreases in cellular adenosine triphosphate and tissue acidosis. It has been postulated that a decrease in GFR and, consequently, energy requirement for tubular reabsorption may be a mechanism by which the kidney reduces energy demands before energy supply is critically limited. Both increased demand and decreased supply are precipitated during states of inadequate perfusion, such as those resulting from depleted intravascular volume, maldistribution of systemic flow away from the renal vascular bed, cardiogenic shock, and destructive vascular conditions.

PREOPERATIVE EVALUATION OF RENAL FUNCTION

The greater the magnitude and duration of the surgical insult and the number of acute and chronic risk factors, the greater the likelihood of perioperative renal compromise and the need for preoperative identification of renal function (Chs. 23 and 25). In patients with inadequate blood flow, injury is commonly caused by the added risk of drugs, by abnormal hemodynamics, or by preexisting disease. [20] Acute risk factors, such as volume depletion, aminoglycoside use, radiocontrast dye exposure, use of nonsteroidal anti-inflammatory drugs, septic shock, and pigmenturia, augment the risk of ARF rather than induce it. It appears that the combined interaction of these multiple acute risk factors is central in the pathogenesis of ARF (Table 34-1) . [15] Patients with preexisting renal insufficiency, for example, are especially prone to develop ARF as a result of cardiovascular surgery. Patients with diabetes mellitus and renal insufficiency are especially vulnerable to radiocontrast agents. A review of the literature suggests that the most critical determinants of postoperative renal function are preoperative renal function, maintenance of appropriate intravascular volume, and normal myocardial function.13 Acute elevations of BUN and serum creatinine levels occur in approximately 5 percent of all hospital admissions and in up to 20 percent of intensive care patients.16 The incidence increases directly with the severity of trauma and the degree of injury or disease.

Under normal physiologic conditions, homeostasis may be maintained despite substantially reduced renal function. Impaired functional reserve capacity becomes evident only when operative stress imposes severe demands on renal function; therefore, a comprehensive evaluation of renal function reserve should be sought before surgery. In addition to intrinsic renal disease, several extrinsic variables influence the outcome of renal function tests: intracellular and extracellular volume, cardiovascular function, and neuroendocrine factors. [78] [79] [80] Advanced age also markedly decreases renal function reserve. GFR, normally about 125 mL/min in a young adult, decreases to about 80 mL/min at 60 years of age and to 60 mL/min at 80 years. Although not necessarily

the primary cause for end-stage renal disease, hypertension in up to 85 percent of patients with renal failure is a major risk factor for the high cardiovascular morbidity that occurs. [81] In addition to its contribution to renal failure in hypertensive nephrosclerosis, secondary to essential hypertension and hyperfiltration in diabetic nephropathy, hypertension also contributes to the loss of renal function associated with aging. Mild hypertensive disease that is associated with renal disease therefore implies that renal disease may be primary. Reliable evaluation requires not only a knowledge of various renal function tests but also an awareness of their diagnostic limitations. For appropriate management, ischemic causes (prerenal azotemia) should ideally be distinguished from those factors that maintain the intrinsic state of renal failure (acute tubular necrosis). Prerenal azotemia and acute tubular necrosis, however, may not necessarily be mutually exclusive.

Unfortunately, there is no simple, inexpensive test that adequately quantifies renal function. The readily available tests fail to accurately reflect the status of the kidneys in a large percentage of patients, especially the elderly, the malnourished, and the dehydrated. Commonly obtained tests of renal function are urinalysis, BUN determination, serum creatinine determination, and creatinine clearance.

Urinalysis provides qualitative information that must be interpreted cautiously. Hematuria (more than one to two red blood cells per high-power field in a concentrated sediment) suggests glomerular disease or, in a trauma patient, injury to the kidneys or the lower urinary tract. A urine test result that is positive for blood in the absence of red blood cells suggests the presence of free hemoglobin or myoglobin in the urine. Pyuria (more than four white blood cells per high-power field) suggests urinary tract infection. Although urine may normally contain hyaline and granular casts, cellular casts represent a pathologic condition. Red blood cell casts suggest interstitial nephritis, including pyelonephritis. Urinary pH, although difficult to interpret on a spot urine sample, may assist in the diagnosis of some acid-base disturbances. The pH of urine tends to be more acidic when factors that initiate failure are prerenal rather than postrenal. The presence of proteinuria on a routine dipstick examination may be "normal" or it may suggest severe renal disease. In a concentrated urine sample, trace or 1+ proteinuria is a nonspecific finding, whereas 3+ or 4+ proteinuria suggests glomerular disease. The existence of glucosuria without hyperglycemia indicates proximal tubular damage. Lysozymuria, the increase of the enzymatic protein lysozyme in urine, occurs if serum level is elevated above the normal renal threshold (45 mg/mL) or when renal tubular function is impaired. [82] Normal urinary lysozyme level is less than 1.9 mg/mL, with a level greater than 5 mg/mL regarded as evidence for significant renal tubular damage. Elevated serum levels of lysozyme may be a consequence of renal failure as well as a marker for it. Because white blood cells have a high concentration of lysozyme, urinary tract infections may also lead to elevated serum levels.

Both BUN and serum creatinine levels offer rapid but inexact estimates of creatinine clearance. The incidence and severity of ARF usually is greater when preoperative serum creatinine level is greater than 2 mg/dL [4] ; however, an isolated serum creatinine measurement is an unreliable indicator

Figure 34-7 The inverse logarithmic relationship between serum creatinine concentration (Y axis) and glomerular filtration rate (X axis). Note that serum creatinine is not markedly increased until

there is a reduction in glomerular filtration rate to about one-fourth of normal (120 to 30).

of GFR when renal function is changing. There is an inverse logarithmic relationship between GFR and serum creatinine concentration (Fig. 34-7) . Decreasing the rate by half results in twice the serum creatinine level. For example, a patient with a preoperative serum creatinine level of 0.6 mg/dL whose filtration rate was reduced by half (after a large preoperative contrast dye load) would have a serum creatinine of 1.2 mg/dL, still in the normal range. Therefore, a single serum creatinine measurement is not a very sensitive test for preoperative renal function reserve. However, it is relatively specific and useful in considering significant renal disease; that is, it would be rare for someone who is not emaciated to have a creatinine level of 1.5 mg/dL and to have a creatinine clearance of less than 40 mL/min. The actual measurement of creatinine clearance constitutes the best overall indicator of GFR. In one study, more than half of 131 critically ill patients had normal urine output, BUN level, and serum creatinine level but reduced creatinine clearance. Creatinine clearance was the best predictor of mortality in these patients compared with the other measures of renal function. [83] Although serum creatinine level may be a more reliable measure of glomerular function than is BUN level, the simultaneous determination of BUN and serum creatinine levels offers a more complete evaluation of renal function than either determination alone. Ordinarily, the BUN-to-serum creatinine ratio is approximately 10; that is, if the BUN level is approximately 10 times as great as the serum creatinine level, one may conclude that the measurements are probably correct. Conversely, if the ratio deviates significantly from 10, one should consider the nonrenal factors influencing BUN level, or serum creatinine level, or both. All three measurements (BUN, serum creatinine level, and creatinine clearance) require careful interpretation.

DIRECT AND INDIRECT MONITORS OF RENAL FUNCTION

Means for direct, on-line evaluation of renal function are limited. We can monitor indirectly, however, the several factors that may contribute to the failure of compensatory mechanisms supporting renal function perioperatively. To maintain the normal excretory functions of the kidney (filtration,

TABLE 34-2 -- Direct and Indirect Monitors of Renal Function

reabsorption, and secretion), adequate perfusion is essential. Among obstructive causes that may initiate ARF, an occluded or kinked urinary catheter can cause perioperative oliguria and must be eliminated as a source of obstruction. Toxic causes precipitated by antibiotics (aminoglycosides, amphotericin B) and radiocontrast agents also may be responsible for the development of ARF. For example, with aminoglycosides, nephrotoxicity is poorly correlated with either kidney tissue or plasma levels of the drug but is markedly augmented by concomitant volume depletion or liver cirrhosis. [15] Similarly, ARF loosely correlates with the amount of radiocontrast material injected unless the patient has preexisting diabetic nephropathy or low cardiac output syndrome. Thus, the vigilance of the anesthesiologist is the first monitor required for preserving renal function.

Unlike the nephrologist, who can evaluate a patient's renal function under stable conditions over long periods, an anesthesiologist caring for hemodynamically unstable patients in the operating room is unable to use standard tests of renal function, such as creatinine clearance. The anesthesiologist must rely on indirect variables, such as urine volume, to assess renal perfusion. Unfortunately, urine output may not reliably reflect glomerular filtration and renal function under intraoperative conditions. Toward the ideal goal of monitoring renal perfusion directly, we have monitors to ensure adequate intravascular volume (preload) and adequate cardiac performance or systemic perfusion. Serum chemistries and urinary indices may enable the assessment of adequate distribution of cardiac output to the kidneys themselves. However, only direct assessment of renal blood flow (and its regional distribution) can tell us whether a kidney is adequately perfused. Evidence of local renal tissue metabolism ensures that oxygen use is adequate. The combination of blood flow (oxygen delivery) and oxygen utilization should reflect normal function (Table 34-2) .

Intravascular Volume

Central Venous Pressure Versus Pulmonary Capillary Wedge Pressure

Monitoring techniques to ensure adequate intravascular volume should be selected after a consideration of the physiologic condition of the patient in each specific situation (Ch. 30). Epidemiologic studies have shown that renal failure commonly develops when dehydration acts in synergy with other chronic conditions. Diabetes mellitus and volume depletion together, for example, increase the chance of developing ARF 100-fold. [15] Monitoring central venous pressure to assess adequate preload is contingent on normal

left and right ventricular function; normal pulmonary vascular resistance; and normal mitral, pulmonary, and tricuspid valve function. Monitoring pulmonary artery pressure or pulmonary capillary wedge pressure to assess preload assumes normal left ventricular compliance, normal mitral valve function, and normal airway pressure.

Left Atrial Pressure

Directly measuring left atrial pressure may offer insights for understanding the kidney pressure-flow relationship because left atrial hypotension has been shown to be a powerful stimulus for renal vasoconstriction. [84] Despite similar reductions in cardiac output and arterial blood pressure, renal blood flow appears to decrease much less during experimental conditions of cardiogenic shock, in which left atrial pressures are increased, compared with conditions of hemorrhagic shock, in which left atrial pressures are decreased. [84] It is postulated that when a decrease in cardiac output is accompanied by left atrial hypotension, reduction in systemic arterial pressure is followed by the normal response of renal vasoconstriction. The left atrial receptors are connected to the renal circulation by atrial natriuretic peptide, a hormone secreted by the cardiac atria in response to intravascular volume expansion. [85] Atrial natriuretic hormone acts on the arterial and venous systems, the adrenals, and the kidneys to reduce intravascular volume and decrease blood pressure. [34] Within the kidney, the hormone increases hydraulic pressure in the glomerular capillaries via afferent arteriolar dilation and efferent arteriolar vasoconstriction. Atrial natriuretic peptide reduces blood pressure by relaxing smooth muscle and reducing sympathetic vascular stimulation. It also inhibits renin and aldosterone secretion, thus producing renal vasodilation, natriuresis, and diuresis. [34] [86]

Left Ventricular End-Diastolic Area

Although the most direct way to clinically monitor for adequate intravascular volume or preload may be during surgery by assessment of the left ventricular end-diastolic area with echocardiography, [87] [88] the most practical method is by obtaining preoperative history and physical examination and by maintaining changes in systemic blood pressure to changing conditions. An awake patient may be observed for orthostatic changes in blood pressure, whereas an anesthetized patient may be observed for paradoxical arterial pulse changes with positive-pressure inspiration. [89] The clinician must decide which modality will most accurately reflect intravascular volume for a patient in a particular situation.

Cardiopulmonary Function

The next step in the logical sequence of renal function monitoring is the assessment of adequate cardiac function through determination of systemic perfusion, pulse oximetry, acid-base assessment, cardiac output monitoring, or left ventricular fractional area of change as a surrogate for ejection fraction (Chs. 16 and 30). [90]

Systemic Perfusion and Acid-Base Balance

Severe arterial hypoxemia to a partial pressure of arterial oxygen (Pa O_2) value of less than 40 mm Hg is associated with decreased renal blood flow and renal vasoconstriction. [91] [92] There is no consensus on the mechanism that underlies the antidiuresis response to hypoxia. It appears that systemic hypoxia can produce antidiuresis and antinatriuresis independent of renal nerve innervation. [93] Capnometry may be a useful monitor because hypercarbia has been associated with decreased renal blood flow in patients requiring mechanical ventilation. [94]

Cardiac Output

The electrocardiogram is essential not only to detect the depolarization-repolarization changes consistent with the electrolyte abnormalities of renal dysfunction but also to monitor for normal rate and rhythm. The synchronized atrial kick preceding ventricular contraction may contribute significantly to cardiac output in the patient with a noncompliant left ventricle. The clinician can assess cardiac function by using the thermodilution technique for measuring cardiac output with the pulmonary artery catheter and can assess global and regional myocardial function with echocardiography.

Perfusion Pressure

Stone and Stahl [95] studied the effect of renal hemorrhage in otherwise healthy patients and concluded that a decrease in mean perfusion pressure from 80 to 60 mm Hg reduced renal blood flow about 30 percent without an autoregulatory response of the renal vasculature. Others have suggested that renal blood flow decreases precipitously when mean blood pressure drops below 80 mm Hg, [35] a theory that has not been adequately tested in patients under general anesthesia with cardiac output maintained. In chronically hypertensive patients with altered vascular autoregulation, the minimum perfusion pressure may be higher. The lowest level of acceptable perfusion pressure during cardiopulmonary bypass remains a subject for debate. It has been suggested that low renal perfusion during extracorporeal circulation may be a cause of renal failure because of the physiologic alterations, such as hypotension, inherent in the technique. [96] In a study by Yao et al, [97] mean arterial pressure during cardiopulmonary bypass was maintained with vasoactive drugs at 80 to 100 mm Hg in one group of patients and at 50 to 60 mm Hg in another group during moderate hypothermic conditions. It was found that renal circulation was maintained as long as mean arterial pressure was maintained above 50 mm Hg. Other studies challenge evidence that demonstrates decreased perfusion pressure as a cause of renal failure. [98] [99] Because renal function in the perioperative period is influenced by a number of hemodynamic and hormonal factors, attempting to generalize an optimal perfusion pressure for every patient is difficult.

The decision to use an arterial line, a pulmonary artery catheter, or transesophageal echocardiography should depend

on the patient's functional cardiac reserve status, the extent of the proposed surgical insult, and the capabilities of the anesthesiologist, the perioperative team, and the hospital. Differentiation between hypovolemic hypotension and cardiogenic hypotension, for example, is critical if one is to properly tailor management and prevent exacerbation of renal ischemia. The best way to prevent intraoperative renal ischemia is to maintain renal blood flow. Although maintaining adequate cardiac output is necessary for maintaining adequate renal blood flow, it may not guarantee adequate flow. Monitoring with invasive devices, such as pulmonary artery catheters, arterial cannulas, and transesophageal echocardiography, has never been demonstrated to reduce the incidence of ARF.

Distribution of Cardiac Output to the Kidneys

Although the kidneys constitute less than 0.5 percent of body mass, they receive 20 to 25 percent of the total cardiac output in the normal adult. The distribution of cardiac output to the kidneys may be influenced by a number of factors, including hypovolemia, activation of the sympathetic nervous system or the renin-angiotensin system, extrinsically administered vasopressors and vasodilators, and local neurohumoral factors.

The fraction of cardiac output perfusing the kidneys depends on the ratio of renal vascular resistance to systemic vascular resistance. [18] In general, the response to renal hypoperfusion involves three major regulatory mechanisms that support renal function: (1) afferent arteriolar dilation increases the proportion of cardiac output that perfuses the kidney; (2) efferent arteriolar resistance increases the filtration fraction; and (3) hormonal and neural responses improve renal perfusion by increasing intravascular volume, thereby indirectly increasing cardiac output. The afferent arterioles react to reductions in perfusion pressure by relaxing their smooth muscle elements to decrease renal vascular resistance. This property represents a relaxation response or myogenic reflex to reduced transmural pressure across the arteriolar wall. The kidney also possesses a tubuloglomerular feedback system, which is designed to maintain the homeostasis of salt and water excretion. Decreased solute delivery to the macula densa in the cortical portion of the thick ascending loop of Henle results in relaxation of the juxtaposed afferent arteriolar smooth muscle cells, thus improving glomerular perfusion and filtration.

The kidney produces vasodilator prostaglandins to counteract the effects of systemic vasoconstrictor hormones such as angiotensin II. [100] In a state of low cardiac output when systemic blood pressure is preserved by the action of systemic vasopressors, renal blood flow is not depressed because the effect of the vasopressors is blunted within the kidney.

A selective increase in efferent arteriolar resistance decreases glomerular plasma flow, thereby preserving GFR. Glomerular filtration is augmented because capillary pressure upstream from the site of vasoconstriction tends to rise. This mechanism enables the kidney to offer high organ vascular resistance to contribute to the maintenance of systemic blood pressure without compromising its function of filtration. Studies using specific inhibitors of angiotensin II have shown that efferent arteriolar resistance is due largely to the action of angiotensin II. [101] At low concentrations, norepinephrine has a vasoconstricting effect on efferent arterioles, indicating that the adrenergic system may also be important for maintaining the renal compensatory response. [102]

There is abundant evidence to support the notion that reductions in cardiac output are accompanied by the release of vasopressin and by increased activity of the sympathetic nervous system and the renin-angiotensin-aldosterone system. These regulatory mechanisms to preserve renal blood flow conserve salt and water. The control of blood delivery to the kidney, the fraction of plasma filtered, and the amount of volume returned to the systemic circulation are determined by regulatory mechanisms within the kidney that attempt to preserve filtration function during compromised circulation. These compensatory mechanisms, however, have limits. Excessive vasoconstrictive forces may eventually induce a decrease in filtration function. This shift from compensation to decompensation may be exacerbated by pharmacologic interventions. Thus, oliguria is both a symptom of ARF and a consequence of the normal compensatory mechanisms to prevent it. Differentiating between the two is critical for outcome and therapeutic strategies.

Clinical investigators have expended considerable effort to evaluate laboratory tests of serum and urinary indexes that attempt to differentiate the cause of oliguric states, to predict outcome, and to direct therapy for the prevention of ARF. Unfortunately, none of the tests is sensitive or specific enough to predict which patients will and which will not respond to therapy. Among the tests commonly obtained are urine volume, urine specific gravity, urine osmolality, serum creatinine level, serum GFR level, urine/plasma creatinine ratio, urine/plasma urea ratio, urine sodium level, fractional excretion of sodium, free rate clearance, and creatinine clearance.

Urine Volume

Monitoring urinary output as a sign of the adequacy of renal perfusion is easy and is based on the assumption that patients with diminished renal perfusion excrete a low volume of concentrated urine. Urinary flow rate is, however, an indirect parameter of renal function because many nonrenal factors may directly and profoundly affect urine output. Oliguria (anuria) during hypotensive anesthesia on one hand and polyuria on the other make it obvious that low urine output does not specifically reflect inadequate renal perfusion and that normal urine output does not guarantee a normally functioning kidney. The presence of urine flow (regardless of the amount) indicates that there is blood flow to the kidney, because without perfusion, glomerular filtration and generation of urine cease. The level of nitrogenous wastes in the blood depends on systemic production and renal clearance. Renal clearance depends on renal blood flow and glomerular filtration. The kidney concentrates the ultrafiltrate so that at maximal concentration, 400 to 500 mL of urine is required to clear the daily obligatory nitrogenous wastes. [103] Traditionally, inadequate urinary volume, or oli-guria, is defined as urinary output of less than 0.5 mL/kg/h.

Multiple studies, however, have shown no correlation between urine volume and histologic evidence of acute tubular necrosis, GFR, creatinine clearance, or changes

from preoperative to postoperative levels of BUN and creatinine levels in patients with burn injury, [104] trauma, [105] [106] or shock status, or those undergoing cardiovascular surgery. [107] [108] [109] Moreover, measurement of mean and lowest hourly urinary output during aortic vascular surgery has not been predictive of postoperative renal insufficiency. [107]

Oliguria may reflect a variety of factors independent of GFR, and a normal hourly urine output does not rule out renal failure. Among these factors is tubular excretion of solute and water, which is determined by local and systemic levels of renin, aldosterone, and ADH. In the operating room, patients are often hemodynamically unstable; decreased blood volume or cardiac output, fluctuating hormone levels (aldosterone, renin, ADH), nervous system reflexes, and increased catecholamine concentrations, added to the effects of general anesthesia, can alter GFR. The data do not support oliguria as a reliable sign of pending renal dysfunction. [103] [104] [105] [106] [107] [108] [109]

Urine Indexes and Serum Chemistries

Urine Specific Gravity

The specific gravity of urine is also easy to measure. In this test, the mass of 1 mL of urine is compared to the mass of 1 mL of distilled water to reflect renal concentrating ability. With poor perfusion or prerenal azotemia, urine specific gravity should be 1.030, reflecting the kidney's conservation of sodium and water. With acute tubular necrosis, the loss of concentrating ability moves urine specific gravity toward 1.010. Because urine specific gravity is a measure of mass and the renal concentrating system responds to osmolality, [110] [111] many substances and conditions can change the specific gravity of urine. The factors that make the test nonspecific appear in Table 34-3 . For example, in patients of advanced age, distal renal tubular function is often impaired, whereas proximal tubular function is spared. The ability of their kidneys to concentrate urine after water deprivation is impaired in these patients, making urine specific gravity an unreliable test. Because the pathophysiology of acute tubular necrosis often reveals significant heterogeneity

of tubular damage and the value of urine specific gravity depends on the extent of that damage, the test is unreliable unless the significance of the tubular damage has previously been assessed.

Urine Osmolality

Osmolality is a measure of the number of osmotically active particles in solution in the solvent phase. It is one of the major forces that move fluid throughout the body, especially in the kidney. Theoretically, then, urine osmolality is physiologically superior to urine specific gravity as a test of renal function; however, the same substances and conditions that render urine specific gravity a nonspecific test can also affect the reliability of urine osmolality (see Table 34-3) . Since the late 1940s, physicians have recognized the inability of the kidneys to produce concentrated urine during acute tubular necrosis and have used as a guideline urine osmolality of greater than 500 mOsm/kg H_2O to identify prerenal azotemia and urine osmolality of less than 350 mOsm/kg H_2O to indicate acute tubular necrosis. Indeed, a defective urinary concentrating mechanism tends to be one of the most consistent and lasting tubular defects of ARF.

The sensitivity and specificity of urine osmolality as a test for predicting or distinguishing acute tubular necrosis from prerenal azotemia are clinically inadequate. [109] [112] [113] [114] [115] [116] [117] With greater than 500 mOsm, the positive predictive value for diagnosing prerenal azotemia ranges from 60 to 100 percent. With less than 350 mOsm, the positive predictive value for diagnosing acute tubular necrosis ranges from 69 to 95 percent. Thus, the measure of urine osmolality appears to be helpful at extreme values but is, unfortunately, a nonspecific test most of the time.

Serum Creatinine and Blood Urea Nitrogen

The relationship between serum creatinine and BUN levels to GFR seems to make the determination of either one an ideal indicator of filtration rate. However, there are two important points to remember about elevations of serum creatinine and BUN levels: they are late signs of renal dysfunction because GFR must often be reduced as much as 75 percent before elevations reach abnormal levels, [118] and many nonrenal variables affect serum creatinine and BUN levels (Table 34-4) . A product of protein metabolism, BUN level is increased by high protein intake, blood in the gastrointestinal tract, and accelerated catabolism (e.g., as occurs in traumatized or septic patients). The normal range is 8 to 20 mg/dL. Because urea is synthesized in the liver, hepatic dysfunction decreases urea production and therefore BUN concentration. Most important, BUN concentration fails a key criterion as a reliable estimate of GFR. Although urea is freely filtered at the glomerulus, it is reabsorbed to a large and variable extent. The reabsorption of urea is greater, approximately 60 percent of the filtered load, when urinary flow is low; only about 40 percent is reabsorbed when flow is high.

Creatinine, a product of skeletal muscle protein catabolism, is produced at a lower rate in elderly than in young adults and in women than in men. Consequently, serum creatinine

levels may fail to accurately reflect the magnitude of nephron loss. Because creatinine production is proportional to muscle mass, many chronically ill, wasted, elderly patients have serum creatinine values in the normal range, despite reduced renal concentrating ability and GFR. Conversely, many critically ill patients at risk for developing ARF may have high metabolic rates secondary to hyperalimentation, sepsis, or posttraumatic states. Higher metabolic rates mean higher nitrogenous waste production requiring greater-than-average renal blood flow and urine flow rates to maintain normal serum creatinine concentration. Postoperative serial serum creatinine measurements are predictive of renal dysfunction in only 33 percent of cases following noncardiac surgery [16] and are equally unreliable following cardiovascular surgery. [118] It was believed that combining BUN and serum creatinine levels would provide more reliable information than either alone: if ratios of BUN to serum creatinine exceeded 20:1: for example, dehydration was suspected. However, the same factors that render the individual tests nonspecific and insensitive remain true when their ratios are considered.

Urine/Plasma Creatinine

The urine/plasma creatinine index was first introduced in 1950 by Bull et al [119] as a method of evaluating patients with acute tubular necrosis. It was determined retrospectively that patients whose urine/plasma creatinine levels rose above 10 after having been below 10 were no longer at serious risk for "uncontrolled mineral and water loss." Thus, this index was introduced primarily as a prognostic aid and not as a diagnostic one.

The sensitivity and specificity of the urine/plasma creatinine index are unfortunately clinically unreliable for diagnosing acute tubular necrosis and prerenal azotemia. [120] Miller et al [113] concluded that the index was not useful, except in extreme situations, because of significant overlap between groups. Espinel and Gregory [114] prospectively studied 87 patients (61 with acute tubular necrosis or pre-renal azotemia) and concluded that urine/plasma creatinine ratio may be a useful indicator of acute tubular necrosis if the ratio is less than 10 and that it may be an indicator of prerenal azotemia if the ratio is less than 40. However, significant overlap in values was noted for 33 percent of patients.

Urine/Plasma Urea

In 1959, Perlmutter et al [121] proposed that the ratio between urine and serum urea nitrogen levels would differentiate prerenal azotemia from acute tubular necrosis. These investigators proposed that a ratio of greater than 14 is associated with transient oliguria and that a ratio of less than 10 is associated with acute tubular necrosis. In 1965, Eliahou and Bata [112] reported that the urine/blood urea ratio may not be useful for diagnosis in all cases. Subsequently, Chisholm et al [122] confirmed that the urine/plasma urea ratio was often misleading in the diagnosis of uremia.

Urea production is not constant and is affected by many nonrenal variables (see Table 34-4) . [123] These variables include sudden increases or decreases in protein intake, states of increased protein catabolism (trauma, infections, hyperthermia, or steroid therapy), gastrointestinal bleeding, and liver dysfunction. Because urea levels can vary tremendously independent of renal function, it is not surprising that knowing the urine/plasma urea ratio does not make it possible to differentiate between prerenal azotemia and acute tubular necrosis.

Urinary Sodium

With decreasing perfusion, the normally functioning kidney conserves sodium and water. The factors affecting this phenomenon are numerous and include heterogenicity of nephrons, secretion of aldosterone, secretion of ADH, diuretic therapy, saline content of intravenous infusion solutions, sympathetic neural tone, and sodium-avid states (congestive heart failure, cirrhosis). It is traditionally accepted that a urinary sodium level of less than 20 mEq suggests prerenal azotemia and a level of greater than 40 mEq, acute tubular necrosis.

The reported sensitivity and specificity of urinary sodium levels for diagnosis of acute tubular necrosis and prerenal azotemia suggest that the levels can be used for diagnosis of approximately half of the patients with acute tubular necrosis. [109] [113] [114] [115] [119] [124] [125] Considering the complex physiology of sodium homeostasis, it is not surprising that levels of urinary sodium are unreliable indicators of prerenal azotemia or acute tubular necrosis. The test is nonspecific because a significant overlap exists between the diagnostic categories, and urinary sodium measurement tends to correlate more with volume and type of resuscitation fluid than with renal function. [106]

Fractional Excretion of Sodium

The fractional excretion of sodium was first described by Espinel [124] and represents the fraction of sodium excreted of that filtered. Handa and Morrin [120] had previously described the renal failure ratio, which is also derived from the excreted fraction of filtered sodium. The only difference between the two is that in determining renal failure ratio, it is assumed that plasma sodium level is controlled within fairly

narrow limits and is constant. The fractional excretion of sodium (FeNa) is calculated as follows:

where P_{cr} is plasma creatinine, P_{Na} is plasma sodium, U_{cr} is urinary creatinine, and U_{Na} is urinary sodium, and all variables are easy to obtain.

At first investigators had reported that the fractional excretion of sodium clearly differentiated prerenal azotemia from acute tubular necrosis. [113] [114] [115] [124] Subsequently, case reports have demonstrated that the fractional excretion of sodium is a nonspecific indicator and is not as sensitive as initially believed. [124] [125] [126] [127] [128] [129] [130] Brown [126] suggested that the fractional excretion of sodium was diagnostic of acute tubular necrosis but was of little or no value for the early prediction of renal failure. Brosius and Lau [127] showed that early determinations of the fractional excretion of sodium were more apt to be misleading than later determinations, indicating that the measurement is unlikely to be helpful in the early diagnosis of acute tubular necrosis. Shin et al [105] concluded that knowing the fractional excretion of sodium was useful only when oliguria was already present. A sodium excretion value of less than 1 versus greater than 1 percent enables differentiation between prerenal azotemia and acute tubular necrosis in most cases. However, because this indicator is usually noted later in the course of renal disease than are changes in creatinine or free water clearance, the fractional excretion of sodium is less beneficial for predicting imminent renal failure. [131] [132]

Free Water Clearance

Free water clearance is a measure of the kidney's ability to dilute or concentrate urine as necessary to maintain homeostasis. It is determined by the following equation:

where UV is urine volume, U_{osm} is urinary osmolality, and P_{osm} is plasma osmolality.

After an initial retrospective analysis, Jones and Weil [133] prospectively assessed the sensitivity of free water clearance and concluded that serial measurements predicted the patients who would experience progressive renal dysfunction. [109] In a prospective study, however, Rosenberg et al [106] found no significant correlation between renal function and free water clearance in 69 patients with trauma or sepsis. After studying 38 patients in an intensive care unit, Baek et al [134] concluded that

the diagnosis of ARF was evident 1 to 3 days sooner with free water clearance than with other clinical and laboratory diagnostic criteria (creatinine clearance was not measured). These investigators recommended that sequential measurements of free water clearance could be used as an early indicator of pending ARF. A free water clearance of -15 to +15 mL/h is a sign of incipient renal dysfunction. The normal range for free water clearance is -25 to -20 mL/h. After retrospectively reviewing the records of 675 trauma victims, Shin et al [135] concluded that free water clearance alone was not sufficient for the early detection of renal dysfunction. They suggested that the combination of free water clearance greater than 20 mL/h and creatinine clearance less than 25 mL/min predicted a high-risk group. When they prospectively monitored free water clearance in patients after surgery, [105] they concluded that this measure was not as sensitive as creatinine clearance for predicting ARF in trauma patients. The same substances and conditions that decrease the usefulness of urine osmolality for indicating renal failure can similarly decrease the usefulness of free water clearance (see Table 34-3) . [136]

Creatinine Clearance

Creatinine clearance measures the ability of the glomeruli to filter creatinine from the plasma and approximates the rate of glomerular filtration. Measurements of creatinine clearance are most useful to quantify renal reserve. Creatinine clearance often is estimated in the stable patient by use of the following equation:

where wt is weight in kilograms. However, that estimate is subject to the same limitations as the measurement of serum creatinine. Precise measurements of creatinine clearance require collection of timed urine samples, by use of the following formula:

where U is the urinary concentration of creatinine (mg/dL), V is the volume of urine (mL/min), and P is the plasma concentration (mg/dL).

When Shin et al [135] retrospectively reviewed the records of 26 patients who had acute tubular necrosis, they concluded that the diagnosis was likely to be made in patients who had both a creatinine clearance of less than 25 mL/min and a free water clearance of greater than 15 mL/h. In a follow-up study of 40 trauma patients who underwent surgery, Shin et al [105] concluded that creatinine clearance of less than 25 mL/min alone permitted the early detection of renal dysfunction in patients with the potential for development of renal failure, and free water clearance was not as sensitive.

The major limitation in the determination of creatinine clearance is the necessity of collecting urine accurately. Although reasonable correlation between 2-hour and 24-hour creatinine clearance (R=0.85) has been reported in intensive care patients (Fig. 34-8) (Figure Not Available) , [137] [138] it remains true that the longer the urine collection period, the more accurate the calculation of creatinine clearance. Changing hydration of the patient invalidates short-term determinations of GFR, as does failure to record urine volume accurately. The error in calculation of creatinine clearance can vary from 10 to 27 percent, depending on the accuracy of urine collection, [139] body weight, surface area, and normal day-to-day variation. Another significant drawback is that for the patient with ARF, a test that requires 24-hour urine collection is often impractical. Nevertheless, it appears that creatinine clearance

Figure 34-8 (Figure Not Available) Correlation between the 2-hour creatinine clearance (CC02) and the 22-hour creatinine clearance (CC22) *(From Sladen et al [137])*

is the most efficient test available to assess glomerular filtration.

Biochemical Markers of Renal Function

The kidney contains many different cell types with its primary roles concerned with glomerular filtration, tubular reabsorption and secretion, and concentration of metabolites. Although complex, the kidney may be able to respond to disease in only a limited number of ways at the cellular level. Noninvasive tests have been developed that reflect the morphologic, functional, and biochemical regional specialization.

NAG is a widely used urinary enzyme assay for the assessment of renal disease and the detection of nephrotoxicity. Unlike a number of unstable enzymes excreted into the urine, NAG remains suitable for clinical diagnosis of renal disease. An increase in NAG activity in urine is a sensitive test for renal tubular damage. [140] Its molecular mass precludes filtration by the glomerulus and it is also the most active glycosidase found in the proximal tubule lysosomes. The value of NAG as a diagnostic test is further enhanced by its presence in a number of isoenzyme forms. The relative amount of each isoenzyme varies at different stages of renal disease.

A number of analytical methods are available for the determination of urinary NAG, including fluorometric, colorimetric, spectrophotometric, and dipstick tests. Each of these methods is tedious and is associated with limitations that prevent widespread clinical adaptation. Low levels of NAG are excreted by normal individuals; therefore, assay procedures must be sensitive enough to overcome the endogenous inhibitor urea. [141] Another variable to overcome is variation from urine collection that occurs over time. Factoring the enzyme activity with creatinine concentration over the same urine flow collection period is a reasonable approach for this latter problem. [142] In general, sensitivity and reproducibility of the fluorometric method, when it is performed correctly, is excellent; however, the equipment necessary is not commonly available in laboratories.

The colorimetric technique overcomes the limitations of the fluorometric technique, by the incorporation of a calibrant for easy interlaboratory comparison and access in most clinical chemistry laboratories with modification for use with spectrophotometric analysis. [143] The latest development is a dipstick method (RENAG, Boehringer-Mannheim) for detection of NAG in the urine. [144] The NAG strip incorporates a biochemical derivative that releases a blue-violet color on hydrolysis. The test requires up to 30 minutes after the addition of reagents; however, problems can arise if the sample is contaminated with blood or bilirubin. Besides pigmented material in urine, a concentrated urine specimen that is high in urea also renders the test inaccurate.

Perhaps the most interesting discovery regarding urinary NAG for detection of renal disease is that there appears to be isoenzyme specificity for various types of pathology. [145] NAG is the most active lysosomal hydrolase and is normally found in tissues as two major forms: A and B. These major forms differ in their subunit composition. Traditionally, the main clinical interest in these isoenzymes had been their use in the detection of two autosomal recessive disorders, Tay-Sachs disease and Sandhoff disease. In 1970, Price et al [146] reported that the B form increased in a urinary pattern of NAG following surgical trauma. Since that time, it has been

appreciated that the relative amount of the B form increased (i.e., the ratio of A to B forms decreased) compared with urine in the normal population. The development of automated methods for separation of NAG isoenzymes allows the pattern of excretion to be compared in various disease states (Table 34-5) (Table Not Available) . Of interest to the anesthesiologist is that evidence suggests that following major surgery, the percentage of an intermediate form (I) increases in the urine. [147] Smaller increases in the I form were also observed in rejection of renal transplants. Rejection was more strongly associated with a decrease in the A/B ratio in a cohort of renal transplant patients. No change in the isoenzyme profile was found in stable transplant patients, whereas reversible rejection was characterized by an increase in the intermediate form and a decrease in the relative amount of the A form present. When a patient did not respond to treatment, both the I and the B forms were elevated, but the A form decreased. [148]

In addition, different nephrotoxic drugs or conditions appear to produce characteristic urinary isoenzyme profiles. There is elevation of the B and I forms following administration of aminoglycosides, for example. Total urinary and serum NAG activity also has been reported to increase in diabetic patients. Overall, NAG activity in the urine reflects the activity of the disease or severity of the damage. Serial monitoring is therefore most useful because trending is the most appropriate method to

interpret the results. The lack of sensitive, simple, inexpensive and efficient methods is the limiting factor for widespread clinical use. Another urinary enzyme, clusterin, may prove to be more specific than NAG [149] for nephrotoxicity caused by aminoglycoside use while remaining equally sensitive.

A number of other urinary constituents have been identified to detect cytotoxic and abnormal processes in specific regions of the kidney (Table 34-6) (Table Not Available) . alpha-Glutathione S-transferase is found principally in the proximal convoluted tubules, and pi-glutathione S-transferase is found principally in the distal convoluted tubule. beta$_2$ -Microglobulin is a subunit of the class 1 antigen of the major histocompatibility complex and is structurally homologous to immunoglobulins. [150] Its mass is 11,600, it is freely filtered from plasma by the renal glomerulus, and more than 99.9 percent is reabsorbed in the proximal tubule. beta $_2$ -Microglobulin is measured by radioimmunoassay and immunodiffusion techniques. [151] Its secretion in urine is a sensitive indicator of tubular damage or disease. Limitations to its use include its unstable nature in urine of pH 5.5 or below, thereby precluding

From Baines [189]

its use when concomitant urinary tract infection or pyuria is present. There is also a temperature lability of its degradation by proteolysis, and its measurement requires a sophisticated laboratory that precludes widespread clinical use. Alanine aminopeptidase excretion has been identified as a specific marker for proximal tubular brush border dysfunction, as has gamma-glutamyl transpeptidase excretion. In general, a concern for these sensitive markers of renal function is the lack of essential gold standardization for discriminating disease process from normal variant. The enhanced excretion of biochemical markers, tubular enzymes, or antigens might be the consequence of an exfoliated damaged tubular cell, an increased turnover of tubular cells, or some other metabolic disturbance. The biologic variability of the sensitive analytes in response to physiologic stress is large compared with anticipated changes observed in early disease. Therefore, the signals of early irreversible disease may not always be distinguished from the noise of biologic variability, and their use should be applied with appropriate caution.

Renal Blood Flow

Normally, the kidneys receive 1,000 to 1,250 mL/min of blood in the average adult. This amount far exceeds that needed to provide the kidney's intrinsic oxygen requirement but ensures optimal clearance of all wastes and drugs. Essentially, all blood passes through glomeruli, and about 10 percent of renal blood flow is filtered (a GFR of 125 mL/min in the normal adult). The basal normal blood flow is 3 to 5 mL/min/g of tissue, greater than in most other organs (i.e., seven to eight times as much as basal coronary blood flow and 400 times as much as skeletal muscle blood flow). This average primarily reflects blood flow in the cortical glomeruli because perfusion to the inner medulla and papilla is only about one-tenth of total flow.

The vascular structure of the renal cortex is complex, and intracortical blood flow may not be evenly distributed (Fig. 34-9) (Figure Not Available) . [152] The renal artery enters the kidney at the hilum, where it divides into five interlobar arteries, each an end artery. At the junction of the renal medulla and cortex, the interlobar branches divide into arcuate arteries, which

Figure 34-9 (Figure Not Available) Diagram demonstrating the complex vascular and tubule organization of the kidney. The pattern of glomeruli (G) arising from afferent arterioles (AA) is demonstrated in the left-hand portion of the figure. Proximal convoluted tubules (PCT) are perfused by a peritubular capillary network derived from efferent vessels (EV). Loops of Henle are grouped together with collecting ducts (CD). Only thin limbs of Henle extend with collecting ducts to the papillary tip. These are accompanied by vasa recta extending from the cores of the vascular bundles. C, cortex; OM, outer medulla; IM, inner medulla. *(From Beeuwkes and Bonventre [186])*

course at right angles to the interlobar arteries. The interlobular arteries arise at right angles to the arcuate arteries and penetrate through the renal cortex. The afferent arterioles, which arise from the interlobular arteries, divide within the cortical tissue to form the glomerular capillary network. The capillaries then reunite to form the efferent arterioles. The subsequent course of the efferent arterioles varies, depending on whether they are located superficially in the cortex or are situated in the juxtamedullary cortex. Superficial efferent arterioles feed a plexus of peritubular venous capillary vessels. These vessels supply the proximal and distal tubules and portions of the loops of Henle and the collecting ducts before joining the interlobular veins and returning to the inferior vena cava through the arcuate, interlobar, and renal veins. Juxtamedullary efferent arterioles also supply the venous capillary network and give rise to the vasa recta, small-diameter vessels that penetrate deep into the medulla. These vessels provide most of the oxygen supply to the loop of Henle and join together to form the arcuate veins. The juxtaglomerular apparatus is between the afferent and efferent arterioles and the macula densa, a specialized group of cells in the distal convoluted tubule.

Because the renal cortex contains most of the glomeruli and depends on oxidative metabolism for energy, ischemic hypoxia injures the renal cortical structures, particularly the pars recta of the proximal tubules. As ischemia persists, the supply of glucose and substrates continues to decrease; glycogen is consumed, and the medulla, which depends to a greater extent on glycolysis for its energy sources, becomes more adversely affected. Interruption of blood flow to kidneys for more than 30 to 60 minutes results in ARF and irreversible cell damage. Early cell changes are reversible, such as the swelling of cell organelles, especially in the mitochondria. As ischemia progresses, lack of adenosine triphosphate interferes with the sodium pump mechanism, water and sodium accumulate in the endoplasmic reticulum of tubular cells, and the cells begin to swell. In experimental models of ARF, the following pathologic changes occur: (1) swelling of tubular epithelial cells leads to formation of bullae, which protrude into the tubular lumen distal to the cell; (2) necrosis of tubular cells results in abnormal membrane permeability; (3) structural changes in the glomerular epithelium may decrease glomerular filtration; and (4) constriction of intrarenal arteries and arterioles may further reduce glomerular blood flow.

The time of onset for tubular damage in experimental models of ARF is usually within 25 minutes of ischemia as the microvilli of the proximal tubular cell brush borders begin to change. Within an hour, they slough off into the tubular lumen, and membrane bullae protrude into the straight portion of the proximal tubule. After a few hours, intratubular pressure rises, and tubular fluid backflows passively. Within 24 hours, obstructing casts appear in the distal tubular lumen. Even if renal blood flow is completely restored after 60 to 120 minutes of ischemia, GFR may not immediately improve. [64]

In ischemia-induced ARF, lesions are unevenly distributed among nephrons, probably reflecting variability in blood flow. In contrast, in nephrotoxin-induced failure, the necrosis of proximal tubular cells obstructs the tubular lumen with cast-like material, and lesions are more evenly distributed among all nephrons. [153] After restoration of blood flow, intrarenal vascular resistance is high because of cell swelling and ischemic damage, and flow is as much as 50 percent below control values. [154] Renal hypoperfusion in the setting of a toxic insult may act in synergy to increase the risk of ARF. As blood flow becomes inadequate to support glomerular filtration, urine flow ceases, and toxic substances accumulate in the urine and renal parenchyma. Other factors contributing to increase the risk of renal failure include the interference of certain drugs (e.g., nonsteroidal antiinflammatory drugs) with autoregulation and preservation of blood flow to strategic regions of the kidney, drug-induced membrane damage, or mitochondrial uncoupling causing an insufficient utilization of oxygen. Finally, toxic substances

and oxygen deprivation (because of low blood flow) produce depletion of adenosine triphosphate (aminoglycosides).

Distribution

Renal function reflects, and is reflected by, regional nephron heterogenicity and changes in regional renal blood flow. The vascular pattern of the kidney is complex, and the distribution of renal blood flow is nonhomogeneous (see Fig. 34-9) (Figure Not Available) . In the clinical setting of hypotension, the kidney appears to have a distinct susceptibility to injury. The reason for this susceptibility is not readily apparent, because renal blood flow is normally high and oxygen supply exceeds by far

the requirements for oxygen utilization. This overall balance, however, may conceal regional hypoxia, predominately in the outer medulla.

The interest in renal blood flow as a predictor of renal function was first stimulated in 1947, when Trueta et al [155] introduced the concept of cortical ischemia and attributed the pathogenesis of ARF to increased blood flow through the medulla. Supporting evidence for this view has since been confirmed by many investigators who measured renal blood flow distribution with various methods. [156] [157] [158] [159] [160] [161] Monitoring regional renal blood flow patterns may help us understand the physiology of renal salt and water excretion and the comparative pharmacologic effects on the "redistribution" of blood flow within the cortex. Perhaps nephrons in the outer cortex are "salt losers," and those in the inner cortex, the "salt retainers." If this is true, salt-retaining states should occur with the selective reduction of renal blood flow to the superficial cortex, and these states may or may not be accompanied by a rise in renal blood flow to the deep cortex. [30] [161]

Because oliguria most commonly results from reduced cardiac output secondary to hypovolemia, it is essential to understand how hypovolemia affects distribution of renal blood flow. Activation of the sympathetic nervous system and possibly the renin-angiotensin system reduces renal blood flow and GFR. Despite well-maintained arterial blood pressure, blood flow may decrease to one-third its normal level. Constriction of afferent arterioles becomes sufficient to reduce the hydrostatic pressure in glomerular capillaries to levels inadequate for maintenance of normal filtration. Thus, oliguria is initially caused by a decrease in filtration rate from reduced renal blood flow. This condition occurs before the metabolic function of the kidney itself becomes inadequate. As renal blood flow continues to decrease, arteriolar vasoconstriction leads to ischemia and morphologic damage.

Renal arteriographic and xenon washout studies in patients with ARF have shown selected profound reduction in renal blood flow. [157] [159] [160] Arteriography revealed severe attenuation of the intrarenal arterial tree, inability to visualize cortical vessels, absence of a normal cortical nephrogram, and striking reduction in the velocity of contrast dye as it passed through the kidney. These same patients had no bleeding from the cortex during open renal biopsy. Also, xenon washout studies show that the usual rapid transit of xenon through the cortex (indicating cortical perfusion) in the normal kidney is absent in acute oliguria. Renal cortical perfusion at one-third its normal level, involving constriction of the afferent arterioles, is a condition that is more than sufficient to stop renal functioning.

Assessment

The understanding that distribution of renal blood flow is nonhomogeneous, the recognition of nephron structure and functional heterogenicity, and the suggestion that changes in the zonal distribution of renal blood flow affect renal salt and water homeostasis have led investigators to focus on developing new techniques to measure intrarenal blood flow. [161] Methods to measure distribution of renal blood flow in humans include the extraction para-aminohippurate, indicator dilution, radiolabeled tracers, Doppler ultrasonography, and external gas washout techniques. The risks and limitations associated with these techniques limit their usefulness.

Any nontoxic substance cleared by the kidney and not metabolized may be used to measure renal blood flow by application of the Fick principle, whereby renal plasma flow is calculated as follows:

where U is urinary concentration, V is urine flow rate, A is arterial plasma concentration, and RV is renal venous plasma concentration. Renal blood flow is then calculated from the formula

The volume of plasma from which the kidney can extract and excrete a specific substance in a given time is, by definition, the renal clearance of the substance. If a substance is completely eliminated from the plasma in one pass through the renal circulation, is filtered at the glomerulus, is not synthesized or destroyed, and is physiologically inert, then it would be ideal for measuring renal plasma flow. Paraaminohippurate is a substance that almost meets these criteria. The practical advantage of measuring the extraction of para-aminohippurate is that its renal extraction is approximately 90 percent in humans after one passage. Measurement of renal blood flow is based on the assumption that cortical extraction is 100 percent and that extraction in the medulla is zero percent; therefore, it has been assumed that the nonextracted fraction (10 %) should reflect the fraction of blood flowing through the medulla. There is, however, experimental evidence that cortical extraction is not 100 percent, [162] casting doubt on the accuracy of intrarenal blood flow assessment with extraction techniques. Other limitations of the extraction technique include the requirement for a high rate of urine flow, a steady state for 15 to 30 minutes, and the sampling of systemic arterial and renal venous blood.

Indocyanine green, which is bound to albumin in plasma, has been used in the indicator dilution method with densi-tometry. The indicator dilution method necessitates catheterization of a renal artery and vein. Although attempts have been made to measure renocortical (fast) and medullar (slow) blood flows separately from dye dilution curves, no convincing results have been produced. [163] Measurement of

renal blood flow by a continuous thermodilution technique, which requires renal venous cannulation and continuous injection of normal saline, has been proposed. [164] Measurements have correlated with calculated renal blood flows derived from clearance techniques in patients after cardiac catheterization; however, only total renal blood flow is measured with the thermodilution technique.

External krypton 85 and xenon 133 clearance techniques estimate local blood flow per gram of tissue from local gas clearance. [157] The gas washout technique requires selective catheterization of the renal artery and is usually performed in conjunction with arteriography. The renal artery also may be punctured intraoperatively for injection. After intra-arterial injection, the gas diffuses rapidly into the renal tissue, theoretically equilibrating in tissue and blood. The renal washout curve is then assessed by external counting (Fig. 34-10) (Figure Not Available) . The reliability of washout methods has been questioned, and absolute flow rates cannot be determined with this method. In anuric subjects, various causes for unreliability of the method may be suspected. For example, the disappearance rate of the gas decreases when kidney volume increases, and kidney volume typically increases during ARF. The partition coefficient of 133 Xe may be less than 1.0 when the water content of the kidney is increased, as in ARF. If equilibrium of gas between tissue and capillaries is not achieved, actual flow rates may be underestimated. Hemodynamics must remain constant during washout curve recordings. The analysis is further complicated by the problem of resolving "external" summation curves into appropriate components representing flow through anatomic regions of the kidney. Theoretically, the desaturation curve after rapid injection of the radioactive isotope (recorded with a gamma counter placed over the kidney) is a summation of different desaturation curves. Each of the component curves represents a different region of the kidney, thereby allowing flow rate per gram of tissue and relative volume of each region to be calculated. [165] [166] What remains to be shown, however, is whether these calculated components really correspond to well-defined anatomic regions in the kidney. Until now, little evidence supports such a conclusion, beyond agreement that the first rapid washout component curve corresponds to flow in the renal cortex. The limitations of the gas washout method should be kept in mind when clinical measurements are made; another limitation of this gas washout technique occurs because areas without perfusion cannot be demonstrated. The component representing an ischemic area is fused with components corresponding to regions that are normally perfused at a slow rate. This procedure results in lack of detection of renal infarctions or segmental ischemic zones if the surrounding unaffected tissue is perfused normally.

Qualitative and semiquantitative evaluation of renal perfusion can be obtained with a gamma camera recording of the transit of a radiopharmaceutical tracer through the kidney.

Figure 34-10 (Figure Not Available) Analysis of an externally monitored radioactive krypton washout curve for the kidney in a dog. (Note the logarithmic vertical scale.) The rapid component (component I) represents cortical blood flow. Half-times for each component together with estimated flow rates and compartment sizes are shown in the table above the plotted curves. *(From Thorburn et al [165])*

Qualitative evaluation of renal perfusion consists of the visual assessment of the serial images. Quantitative evaluation consists of the comparative evaluation of the first transit of tracer from the aorta (or iliac-renal artery) to the kidney. Among the problems and limitations associated with the renogram is movement of the radiopharmaceutical (injected intravenously as a bolus) before it reaches the kidney, necessitating that the pharmacokinetic model contain all the possible exchange compartments between the kidney and the plasma for accurate analysis of the tissue radioactivity curve. The presence of low urine flow rates, dilated pelvic caliceal cavities, or severely reduced renal function may also cause difficulties for test interpretation. In general, the information that can be derived from the renogram includes renal clearance (as a fraction of the radioisotope to blood volume) and comparative blood flow of the two kidneys relative to each other. [167] Because the results obtained are comparative, lesions are revealed only when they have asymmetric distribution.

The development of duplex ultrasound has enabled the evaluation of changes in renovascular resistance and intrarenal blood flow in patients. The technique is noninvasive and may be repeated as often as required. Typically, an interlobar artery is selected for evaluation for these reasons: the anatomic course and relations of the vessel allow easy recognition on subsequent serial scans in the same patient; the vessel is large enough to assume laminar flow throughout its length; and the angle of the ultrasound beam can generally be minimized to assume maximum Doppler frequency shift. Renal vascular resistance can be assessed by the pulsatility index. [168] The lower the pulsatile index, the less the resistance to flow. The value is derived by dividing the difference between systolic maximum height and dia-stolic minimum height of the waveform by its mean height (Fig. 34-11) (Figure Not Available) . Change in flow velocity can be assessed from change in mean frequency shift. The frequency shift is proportional to the mean velocity of blood flow within the vessel multiplied by the cosine of the angle between the ultrasound beam and the direction of flow. The angle is assumed to be close to zero. With this method, only blood flow velocity in large interlobar arteries and resistance can be assessed. The duplex Doppler ultrasound technique may provide a unique opportunity to demonstrate the effects of drugs on the renal vasculature as well as to predict the onset of pending renal failure or transplanted kidney rejection. Overall, this technique should provide an opportunity for measuring relative changes in large vessel flow velocity but not in absolute renal blood flow.

Contrast ultrasonography is a clinical diagnostic tool for assessing tissue perfusion with contrast agents, typically nontoxic solutions containing gaseous microbubbles, which reflect the ultrasonic beam emitted by an echo transducer. [169] Contrast ultrasonography has been used to image renal blood flow. [170] [171] The microbubbles produced by ultrasonic cavitation (sonication) are smaller than red blood cells and, in passing with them through the microcapillary vascular bed, reflect an echo beam to permit direct ultrasonic imaging of tissue perfusion (Fig. 34-12) (Figure Not Available) . Sonicated microbubbles have been shown to exhibit intracavitary velocities comparable to those of red blood cells, as observed by Doppler. Numerous investigators have postulated that by controlling the size and stability of the microbubbles, quantitative measurements could be accomplished. With contrast ultrasonography, absolute blood flow and volume *in vitro* can be calculated; with contrast ultrasound and a mathematical model based on indicator dye-dilution theory, cortical blood flow in the canine kidney has been assessed. [171] Modest correlations have been found between calculated renal blood flow assessed by contrast ultrasonography and flow assessed with an electromagnetic flow probe. The pharmacologic effects of fenoldopam and dopamine on distribution of blood flow in the renal cortex also have been

Figure 34-11 (Figure Not Available) Renal duplex scan showing sample volume superimposed over B-scan image in typical normal velocity flow pattern, from the main renal artery at the hilum. vS, systolic velocity; vd, diastolic velocity; theta, angle of incidence between transmitted ultrasound signal and received ultrasound signal.

assessed with contrast ultrasonography. [172] With anticipated improvements in the sensitivity of commercial ultrasound imaging devices and in the stability of contrast agents, contrast ultrasound may allow absolute quantitation of renal blood flow in an intraoperative setting for the early recognition of ARF. Clinical trials are under way to test the safety and efficacy of commercially prepared ultrasound contrast agents for assessing renal perfusion patterns in surgical patients.

Utilization of Renal Blood Flow

Although the kidneys receive nearly a quarter of the cardiac output and extract relatively little oxygen, there is a marked discrepancy between cortical and medullary blood flow and oxygen delivery and consumption. The apparent overabundance of blood flow to the cortex is designed to maximize flow-dependent functions, such as glomerular filtration and tubular reabsorption. In the medulla, blood flow and oxygen supply are restricted by a tubulovascular anatomy specifically designed for urinary concentration. Hypoxic perfusion of an isolated kidney preparation has demonstrated that the cells of the thick ascending limb of the loop of Henle in the medulla are extremely vulnerable to hypoxic damage. [69] This damage is patchy and is most evident in tubules farthest from a vessel. The selective vulnerability of the cells in the thick ascending loop of Henle is thought to result from their high oxygen consumption. Blood flow is approximately 90 to 95 percent to the cortex, compared with 5 to 10 percent to the medulla. Average blood flow is 5.0 mL/g/min and 0.03 mL/g/min for the cortex and medulla, respectively, and the oxygen extraction ratio (i.e., oxygen consumption over oxygen delivery) is 0.18 and 0.79 for the cortex and medulla, respectively. Normally, the partial pressure of oxygen is about 50 mm Hg in the cortex and 8 to 15 mm Hg in the medulla, making the thick ascending loop of Henle most vulnerable to tissue hypoxia. Severe hypoxia may therefore easily develop in the medulla if total renal blood flow is inadequate.

The initial response to decreased renal blood flow is an increase in sodium absorption in the ascending loop of Henle, which increases oxygen demand in the regions most vulnerable to decreased oxygen delivery. Ischemic renal damage may reflect hypoxic injury deep in the medulla to the metabolically active cells of the ascending loop of Henle. The normal response to systemic hypoperfusion is active sodium and water reabsorption, a metabolic response that demands oxygen at the time of greatest hypoxic vulnerability. To compensate, sympathoadrenal mechanisms cause cortical vasoconstriction and oliguria, which redistributes blood flow away from the outer cortex to the inner cortex and medulla. Another compensatory mechanism, increased sodium delivery to the macula densa, results in afferent arteriolar constriction. With afferent arteriolar vasoconstriction, glomerular filtration decreases, after which solute reabsorption in the loop of Henle and oxygen consumption are reduced. In a hypoperfused kidney preparation, oxygen-enriched perfusion reduced cellular damage, hypoxic perfusion increased it, and complete cessation of perfusion (glomerular filtration zero, preventing ultrafiltration) was associated with less cellular injury than hypoxic

perfusion. [68] Thus, the severity of cellular injury appears related to the degree of imbalance between cellular oxygen supply and demand. Afferent arteriolar vasoconstriction may be a normal protective response to acute tubular injury. By reducing ultrafiltration, further energy expenditure by already ischemic medullary tubular cells is prevented, even at the cost of retaining nitrogenous waste.

Theoretically, therapeutic intervention designed to prevent renal insufficiency should be focused on preserving renal blood flow and oxygen delivery. Continuous monitoring of urinary oxygen tension has been examined as a method for assessing renal function during the perioperative period. [173] [174] [175] Urinary oxygen tension (Pu_{O_2}) decreases with clinical shock and dehydration. It has been demonstrated that Pu_{O_2} decreased when renal blood flow decreased and/or when Pa_{O_2} decreased and that Pu_{O_2} increased when Pa_{O_2} increased. Changes in Pu_{O_2}, however, are relatively insensitive to oxygen content compared with changes in Pa_{O_2}. Because urinary oxygen tension is dependent on renal perfusion and renal oxygenation, it may be a useful tool for predicting renal cell injury, yet it is not now clinically practical to measure Pu_{O_2}. Urine samples obtained from bladder catheters provide artificially high Pu_{O_2} values because samples are easily contaminated with oxygen present in room air. Another problem with measuring urinary oxygen tension or saturation is that bladder measurements may be different from ureteral measurements. Ureteral measurements also may not reflect accurately the regional use of oxygen in the renal cortex versus the renal medulla or the renal pelvis. Thus, interpreting the physiologic significance of changes in urine oxygen tension or saturation requires knowledge of where the oxygen comes from and its relationship to other physiologic variables.

Regional Oxygen Supply and Demand in the Kidney

Total renal blood flow to the kidney is extremely high when compared with its weight and arteriovenous oxygen difference. Greater than 90 percent of the blood flow is directed to the outer cortex, and relatively little goes to the renal medulla. There appears to be a physiologically important reason for the paucity of blood flow and, consequently, the oxygenation in the medulla. [176] The tubules carrying blood to the medulla are arranged in a "hairpin loop" pattern to allow a countercurrent exchange of solute between the ascending and the descending limbs of the hairpin loop. In this way, urine in the tubule becomes highly concentrated. The osmotic gradient in the deeper portions of the medulla requires active transport of sodium in the thick ascending loop of Henle and limited blood flow through the medullary vessels to prevent washout of the solutes in those deeper tubules. To maintain this concentration gradient in the thick ascending limb, high energy demand (active

sodium transport) must be coupled with low oxygen delivery. The ambient partial pressure of oxygen in the medulla ranges from 10 to 15 mm Hg. The high metabolic requirement of the thick ascending loop of Henle in a hypoxic environment makes it especially vulnerable to injury associated with an imbalance in oxygen supply and demand. [177] [178] [179]

Influence of Renal Blood Flow on Glomerular Filtration Rate

Decreased renal perfusion initiates a series of systemic and renal compensatory responses that act to preserve ultrafiltration. [35] At this stage, glomerular filtration and renal blood flow are maintained by increased distribution of cardiac output to the kidney, selective afferent vasodilation and efferent vasoconstriction, and increased sodium and water conservation. If these protective mechanisms fail, the response progresses from compensation to decompensation and renal blood flow decreases. Then, a positive feedback loop is stimulated, heralded by afferent arteriolar vasoconstriction that decreases capillary hydrostatic pressure and ultrafiltration.

Cortical and medullary nephrons have a unique relationship to their respective vascular bundles in the kidney: cortical nephrons have their thick ascending limbs far from vascular bundles, and medullary nephrons have their thick ascending limbs adjacent to vascular bundles. During hypoxia, the cortical nephrons suffer the most. [180] When renal blood flow is compromised, blood flow and glomerular filtration in the superficial outer cortical nephrons decline first. Corticomedullary redistribution of renal blood flow protects the vulnerable medullary oxygen balance. Decreased glomerular filtration during compromised flow appears to be protective because decreased urine delivery to the tubules requires less reabsorptive work of them and prevents further imbalance of oxygen supply and demand. Medullary hypoxia can be modulated by a variety of pharmacologic or physiologic maneuvers. Reduction of tubular work load by furosemide (Lasix) administration is effective in preventing medullary hypoxic cellular injury. [176] [181] In addition to maneuvers that reduce tubular transport or glomerular filtration, adenosine [182] and nitric oxide [183] have been proposed as pharmacologic options that can modify medullary hypoxia.

MONITORING RENAL FUNCTION DURING RENAL TRANSPLANT SURGERY

During renal transplant surgery (Ch. 55), maintaining renal perfusion is the obvious goal when the "donor" kidney is removed. If the donor is brain dead, every effort should be focused on augmenting oxygen supply and reducing oxygen consumption. Supportive means, such as maintaining intravascular volume (even blood administration) and cardiac performance with inotropic agents if needed, should be considered. Theoretically, reduction in medullary thick ascending loop tubular transport (an energy-consuming and oxygen-consuming mechanism) may be inhibited before removal of the kidneys; however, improved renal function after transplantation remains to be demonstrated. Methods for tubular preservation by decreasing sodium transport in the thick ascending loop of Henle include administration of diuretics, hemodilution, and complete cessation of renal blood flow via renal artery clamping, which effectively prevents ultrafiltration. [181]

The number of patients receiving kidney transplants as therapy for end-stage renal disease should continue to increase

---

because transplantation both is cost effective and improves quality of life when compared with dialysis. Unavailability of donor organs is often the limiting variable when transplantation is considered. Other than incurable disease (e.g., human immunodeficiency virus positivity or disseminated malignancy) or active infection, there may be no absolute contraindications for transplantation. A patient's systemic disease and ability to tolerate the operative procedure, both of which can be influenced by the anesthesiologist, are relative contraindications for transplantation. When patients are monitored during renal transplant surgery, venous and arterial access should be used cautiously because they may be limited when shunts or fistula sites are required. Monitoring for arrhythmias with an electrocardiogram is also useful. Electrolyte disturbances that may require treatment as a result of renal dysfunction may thus be detected.

Posttransplant delayed function (the need for more than one hemodialysis treatment during the first week after transplant) is associated with significantly worse morbidity and mortality in transplant patients than is immediate function. [184] One measure that facilitates immediate function is intraoperative fluid and drug management. Segmental renal perfusion following transplantation and augmentation of blood flow after drug administration can be safely assessed with intraoperative contrast echocardiography [170] during renal transplant surgery. The technique offers promise for monitoring regional renal blood flow changes following hemodynamic or pharmacologic perturbations during surgery. Aggressive intraoperative blood volume expansion (central venous pressure, 15 to 18 mm Hg) has improved function after cadaver renal transplantation. The decision to monitor intravascular volume and tolerance for blood volume expansion during transplantation with a central venous catheter, pulmonary artery catheter, or transesophageal echocardiography depends on a patient's cardiac reserve function.

SUMMARY

In patients with real or potential renal dysfunction, the perioperative management continues to be challenging. The causes of perioperative ARF vary but typically have a common mechanism of insufficient renal blood flow delivery, or acute tubular necrosis, or both.

As our understanding of renal function continues to evolve, traditional answers turn into new questions. The introduction of new agents and the reexploration of old techniques and their respective influence and reliance on renal function should become clearer with advances in renal function monitoring. That this information will modify the prognosis of renal dysfunction remains untested at this time, however. Meanwhile, we are limited to relying on indirect variables of renal function that may or may not bear a reliable relationship to GFR and renal blood flow, and therefore renal function, during the perioperative period.

Chapter 35 - Neurologic Monitoring

Susan Black
Michael E. Mahla
Roy F. Cucchiara

INTRODUCTION

The evaluation of neurologic signs was one of the earliest scientific approaches to judging the effects of anesthetics on the brain. In the 1940s Guedel proposed the use of pupillary signs as a guide to determining the depth of anesthesia. As the patient passes through the stages of anesthesia, the pupils change from normal when awake to dilated during the excitement phase of stage II. In early stage III the pupils constrict secondary to the loss of cortical inhibitory effects on the Edinger-Westphal nucleus. In deeper planes of stage III the pupils progressively dilate as paralysis of the fibers of the pupiloconstrictor muscles ensues.

Modern anesthetic techniques usually combine inhaled anesthetics with intravenously administered drugs or supplemental drugs (e.g., opioids); therefore, eye signs are no longer as helpful in determining anesthetic depth as they once were. The development of modern electronics and microprocessors has made possible the rapid evaluation of electrical data from the body to permit nearly real-time evaluation of nervous system function.

This chapter focuses on monitoring the intact nervous system using electronic instruments, examines some of the electroneurophysiologic and pathologic changes that occur acutely in the operating room, and shows how these signals are altered by commonly used anesthetics.

MONITORING MODALITIES

The technology that is most available in sophisticated operating rooms today is the electroencephalogram (EEG), evoked potentials (EP), and electromyogram (EMG). The EEG is used to help identify pathologic brain findings, define clinical problems, and predict outcome of brain insults. These uses are the result of correlation of pattern recognition with clinical states of over nearly half a century of experience. The encephalographer can accurately identify consciousness, unconsciousness, epilepsy, sleep, and coma. The correlation between EEG pattern and anesthetic depth is less clear, perhaps because of the variety and types of drugs used in anesthesia and the subtle loss of awareness. The electrode records activity from the brain tissue nearest to it, and all areas of the brain do not respond identically to the same anesthetic drug level. Precise assessment of anesthetic depth by EEG is possible with certain specific drugs at specific levels of anesthesia. The steps in the continuum from awake to deeply anesthetized are not all equally clear, but some general patterns are described. Computer advances have made possible high-speed mathematic manipulation of the EEG signal to present it in a more readable fashion. Interpretation of the raw EEG is still largely dependent on the experience of the reader.

Evoked potentials are measurements of electrical potential changes that pass along stimulated nervous tissue. The voltages generated in this process are quite small and are obscured by the higher voltages produced by the EEG. Repeated sampling and sophisticated electronic summation and averaging techniques are needed to extract the evoked potential signal from the background EEG.

Sensory evoked potentials are by far the most common type of evoked potentials monitored intraoperatively. During the last decade much research has been carried out regarding the use of intraoperative motor evoked potentials; however, motor evoked potentials are used routinely only in a very few centers currently. There are three basic types of sensory evoked potentials: somatosensory (SSEP), auditory (BAEP), and visual (VEP). The SSEP is used to assess a peripheral nerve to central nervous system pathway. The BAEP is a measure of conduction along cranial nerve VIII, through brain-stem structures, and out to the cortex. The VEP utilizes stimulation of the light receptors of the retina to evaluate pathways from the optic nerve to the occipital cortex.

THE STANDARD EEG

The Signal

The technical goal of the EEG is to provide a clear signal free of electrical noise and permit anatomic localization of the various signals generated. The recording electrode impedance should be about 5 kOmega to permit clear EEG signals in the 10- to 50-muV range. As electrode impedance increases, the signal to noise ratio decreases, which permits the background electrical "noise" to obscure the EEG signal. Impedance is kept low by using silver electrodes with electrolyte gel between the scalp and electrode and holding the electrode tightly to the scalp with colloidin. When wick electrodes are applied directly to the brain surface, impedance is decreased by saturation of the wick with an electrolyte solution.

The recording montage permits anatomic localization of the signal. The standard EEG montage is the 10-20 system (Fig. 35-1) (Figure Not Available) . This system is a symmetric array of scalp electrodes 10 percent of the circumferential distance above the inion and external auditory meatus and 20 percent of the circumferential distance apart. Twenty recording electrodes are used with one or more reference electrodes placed outside the recording field. This set-up permits the encephalographer to select a pair of electrodes with a discrete anatomic location from which to record. The standard is a 16-channel recording. [1]

Recordings of electrical activity of the brain may be made directly from microelectrodes to measure activity from an individual unit or from larger electrodes to record from the brain surface or from the scalp. The conventional EEG is recorded from the scalp; the recording from the surface of the brain is the electrocorticogram (ECoG). The generators of these waveforms are not clearly defined, although the patterns have been well described and correlated with clinical and pathologic conditions.

The EEG signal contains three basic parameters: amplitude, frequency, and time. Amplitude is the electrical height of the wave in V. Frequency can be thought of simply as the number of times per second the wave crosses the zero voltage line. Time is the duration of the sampling of the signal; this is continuous and is real time in the standard EEG but is a sample epoch in the processed EEG.

The Normal EEG

The patterns seen on the EEG vary somewhat among individuals but are consistent enough to allow for accurate recognition. The usual base frequency in the awake patient is the beta range (>13 Hz). This high-frequency and usually low-amplitude signal is common from the alert attentive brain. With the action of closing the eyes, the tracing immediately adds signals from the alpha range (8-13 Hz) with a slightly higher amplitude (Fig. 35-2) (Figure Not Available) . This range is usually used as a reference signal during anesthesia. When events that lead the brain to produce higher frequencies occur, the EEG is described as "activated," and when slower frequencies are produced (theta at 4-7 Hz and delta at 4 Hz) the EEG is "depressed." The sleep EEG may contain all of these frequencies at various times. The slower frequencies occur during deep natural sleep with sleep spindles (Fig. 35-3) (Figure Not Available) , but during light sleep (rapid eye movement [REM] sleep) the EEG becomes activated and the eye muscle EMG appears on the EEG.

General characteristics of the normal EEG are that it is symmetric, the patterns are predictable, spike waveforms are absent, and it cannot be used to predict normal brain function.

The Abnormal EEG

General characteristics of the "abnormal" EEG are asymmetry and patterns of amplitude and frequency that are not predictable or expected in the usual recording. These reflect either anatomic or metabolic alteration in the underlying brain. Regional asymmetry can be seen with tumor, epilepsy, and cerebral infarction. Epilepsy may be recognized by high-voltage spike waves, whereas cerebral infarction may appear as a low voltage and low frequency pattern, as compared to the rest of the brain tracing. Global distortions of the EEG are not asymmetric because there is no normal side with which to compare the tracing. Identifying "abnormality" in global EEG patterns that deviate from normal is very important in the clinical situation. Epilepsy, hypoxia, and anesthetic effects are examples.

PROCESSED EEG

The interpretation of the standard written EEG record is both a science and an art. The waveforms are the data base for the interpretation; qualitative overall impression of the record is the experience. Both are important in arriving at a diagnosis. Until recent years the latter approach was dominant simply because the waveforms could not be described mathematically in a time frame that would make such a data base of any use. Mainframe computers then began to convert the analogue signal of the EEG to a digital signal and

---

Figure 35-1 (Figure Not Available) International 10-20 system of electrode placement for recording EEG as well as SEP. *(From Hughes [1])*

mathematically manipulate the data. The process was complex, expensive, and still had little relevance to the clinician. Early techniques took 1 hour to digitize and analyze 1 second of EEG data. The hardware capability of computers has exploded during the past decade and has caught up with the mathematic potential available in analysis of complex waveforms. Real-time on-line processing that previously required mainframe computer capability began to appear as the EEG processor "black box" developed.

A number of assumptions must be made when moving to the processed EEG. First, as the processed EEG signal becomes more electronically remote (more processed), there is a point where it will be increasingly difficult or even impossible to relate what we know about the raw EEG data to

Figure 35-2 (Figure Not Available) The loss and return of alpha-activity as the eyes open and close can be seen. The large spikes are muscle artifact. *(By permission of the Mayo Foundation)*

Figure 35-3 (Figure Not Available) Characteristic "sleep spindles" in normal sleep are shown in the center. *(By permission of the Mayo Foundation)*

comprehension of the processed signal; this is true of many of the processed EEG displays utilized today. Increasingly, clinicians with no experience in interpreting raw EEG data are utilizing processed EEG with little ability to understand how it relates to the original raw data. Second, the standard 16-channel EEG montage provides more information than can be consistently utilized in processed EEG and more than is needed for routine intraoperative use. Third, because the processed EEG is derived from the raw EEG, it will not contain information that is not in the original signal. Derivations of the original signal may include computational displays and algorithms, but the data base can only be the original signal. Fourth, some of the diagnostic changes will be unilateral and some bilateral. Display of the activity of both hemispheres is necessary to delineate unilateral from bilateral changes. An appropriate number of leads is needed. The gold standard for EEG analysis is the continuous visual inspection of a 16- to 20-channel ink-on-paper EEG by an experienced electroencephalographer. [2] [3]

Devices

There are specific frequency and amplitude ranges that seem to be important in the EEG under anesthesia. The simplest way to remove artifact and accentuate the waves of interest is to use a system of filters and amplifiers so that frequencies above 20 Hz are filtered out, and waves between 4 and 10 Hz are selectively amplified. There are two basic forms of EEG processing utilized currently: power analysis and bispectral analysis. Power analysis utilizes Fourier transformation to convert the raw EEG signal into its component sine waves of an identifiable frequency and amplitude. The raw EEG data, which is a plot of amplitude over time can then be converted to plot amplitude of EEG activity at each frequency at a given point in time. Many commercially available processed EEG machines display power that is amplitude squared as function of frequency. These monitors may then display the data in two general forms, either compressed spectral array (CSA) or density spectral array (DSA). In CSA, frequency is displayed along the x axis and power along the y axis with height of the waveform equal to the power at that frequency. Time is displayed along the z axis with the tracings overlapping each other, with the most recent in front (Fig. 35-4) (Figure Not Available) . DSA displays frequency along the x axis, time along the y axis, and power is reflected by the density of the dot at each frequency. Each display format provides the same data, and choice depends simply on the preference of the user. Many changes that occur under anesthesia are reflected as changes in amplitude, frequency, or both. These changes can be clearly seen in these displays if adequate and appropriate channels are monitored. Power analysis has been utilized clinically for many years as a diagnostic tool during procedures with risk for intraoperative cerebral ischemia such as carotid endarterectomy and cardiopulmonary bypass. Power analysis has proven to be a sensitive and reliable monitor in the hands of experienced operators utilizing an adequate number of channels. In addition, parameters obtained from power analysis have been investigated as monitors for depth of anesthesia. [4] This application has not yet found widespread use.

On the other hand, bispectral analysis also takes into account the phase relationships between the individual components of the raw EEG signal. The phase relationships are not included in power analysis. Bispectral analysis is a more recent modality and, currently, the primary use is as a monitor of anesthetic depth. Although the bispectral analysis may also yield components indicative of cerebral pathologic states developing

Figure 35-4 (Figure Not Available) Diagram of technique used to generate compressed spectral array. Example below shows compressed spectra of the alpha-rhythm from a normal subject. *(From Stockard and Bickford [27])*

---

intraoperatively, such as cerebral ischemia, monitors utilizing this technology in a diagnostic mode are not available. [5]

Data Acquisition Period

An important consideration in the processed EEG is the element of time. The standard EEG is continuous in real time. The processed EEG usually obtains its data over a given time period (epoch), processes the data, and then displays them. There is a relationship between epoch length and spectral resolution. If an infinite epoch length is chosen, the waveform can be described precisely. If a short length is selected, three main factors mitigate against mathematic precision: the epoch sampled may not be representative of the overall activity, the nature of the data window becomes increasingly important, and there may be insufficient data points for Fourier transformation. This issue, as related to the intraoperative EEG for anesthetic depth, has been studied by Levy. [6] A longer epoch may produce less epoch-to-epoch variability and allow more precise description of frequency and power; however, the longer epoch increases the delay before new information is processed and displayed, thereby reducing the amount of information available for clinical decision making. In studying EEG epochs of 2 to 32 seconds, Levy

concluded that 2-second epochs are appropriate during general anesthesia. Burst suppression is an exception, however, because of the possibility of sampling primarily during burst or suppression periods. This shortcoming is not a major one because this pattern is easily identified on raw EEG and is expected with use of barbiturates in anesthesia.

ANESTHESIA AND THE EEG

With the advent of the then "high-tech" EEG in 1950, Courtin et al [7] sought to monitor the brain and devise a servo-controlled system that could adjust the anesthetic concentration administered on the basis of the EEG pattern. It was an ingenious idea, but despite descriptions of the EEG during anesthesia, knowledge and technology were not adequate at that time. In addition, because all anesthetic drugs do not produce exactly the same changes in EEG pattern as anesthesia deepens, generic correlation of the EEG with depth of anesthesia remains an elusive goal. One of the major reasons that EEG is difficult to use for assessing anesthetic depth is that most modern anesthetics utilize many different classes of drugs for premedication, induction, and maintenance of anesthesia, all of which have significant EEG effects. In addition, other intraoperative factors may affect the EEG (Table 35-1) , further adding to the difficulty of interpreting the EEG.

In recent years much research has been directed at developing a processed EEG parameter that is indicative of depth of anesthesia. These processed parameters fall into two broad categories: parameters derived from power analysis of the raw EEG data and parameters derived from bispectral analysis of the EEG. Power analysis processes data from the raw EEG related to frequency and amplitude

TABLE 35-1 -- Nonanesthetic Factors Affecting the EEG During Anesthesia

SURGICAL FACTORS	PATHOPHYSIOLOGIC FACTORS
Cardiopulmonary bypass	Hypoxemia
Occlusion of major cerebral vessel (carotid endarterectomy, aneurysm clipping)	Hypotension Hypothermia Hypercarbia and hypocarbia
	Untoward events
	Brain death

of the waveforms over time but does not consider phase relationships between the component waves. Bispectral analysis is a somewhat more complex process that includes phase relationship data. Processed parameters from power analysis investigated as indicators for depth of anesthesia include Spectral Edge Frequency 95% (SEF95), which is the frequency below which 95% of the EEG activity falls; Median Frequency (frequency at the midpoint of the power spectrum); and Relative Delta Power (percent of the EEG power in the delta band). Some authors have had success in utilizing one or more of these parameters to predict depth of anesthesia. [4] Other authors have found that although these parameters change with changes in depth of anesthesia, they were not consistently predictive of depth of anesthesia as assessed by response to stimuli or return of consciousness during emergence from anesthesia. [8] [9] In particular it has been noted that these parameters are very dependent on the type of anesthetic agent or combination of agents utilized. Whereas one parameter might correlate well with a primarily volatile anesthetic technique, it might perform less consistently during a narcotic-based anesthetic.

Most recently, encouraging results have been obtained using the bispectral index (BIS) to monitor anesthetic depth (Ch. 29) . The bispectral index is a processed parameter derived from multiple features generated by bispectral analysis of the EEG. Through clinical trials, features of the bispectral analysis that were predictive of response to stimuli under the effects of a variety of anesthetic agents were identified. These features were combined to a multivariate index using discriminant analysis. [5] [10] Once the BIS was developed, it was further tested and refined to improve the predictive ability. [10] The BIS is displayed as a numeric value from 0 to 100 and can be trended over time. Many clinical trials have investigated the ability of BIS to monitor anesthetic depth and predict response to stimuli. Trials have been directed at determining values of BIS predictive of loss of consciousness, loss of recall, and prevention of movement in response to surgical stimulation. The BIS value indicative of a certain level of consciousness varies somewhat between different anesthetic techniques [10] ; however, the ability of the BIS to predict loss of consciousness and lack of recall during sedation has been consistently demonstrated by a number of authors using a variety of drugs and drug combinations. [4] [10] On the other hand, the ability of BIS to predict hemodynamic response to surgical stimulation or movement in response to surgical stimulation has been less consistently demonstrated and may be more dependent on the anesthetic technique. [11] [12] These results

Figure 35-5 BIS tracings from an awake craniotomy with intraoperative cortical mapping. Propofol infusion was titrated against BIS value to provide adequate sedation during the operative procedure. Termination of the propofol infusion during the cortical mapping is followed by a prompt increase in BIS value and recovery of the patient to fully alert.

have suggested to some that the anesthetic state involves at least two different components. One is a reflection of hypnosis and consists of loss of consciousness and recall; BIS is indicative of this state. However, the obtundation of response to noxious stimuli is less well predicted by BIS. [10] BIS monitoring of level of sedation during an awake craniotomy with cortical mapping is shown in Figure 35-5 .

Anesthetic drugs affect both the frequency and amplitude of EEG waveforms. Although each drug class and each specific drug has some specific, dose-related EEG effects (Table 35-2) , some generalizations (basic anesthesia-related EEG pattern) are possible. Subanesthetic doses of both intravenous and inhaled anesthetics usually produce an increase in frontal beta activity and abolish the alpha activity normally seen in the occipital leads in the awake, relaxed patient with the eyes closed. As the patient actually goes to sleep with general anesthesia, the brain waves become larger in amplitude and slower in frequency. In addition, under general anesthesia, the alpha EEG frequencies are primarily seen in the frontal EEG leads rather than in the occipital leads. Further increases in the dose of the inhalation or intravenous agent produce further slowing of the EEG, and some agents have the capability to totally suppress EEG activity (see Table 35-2) . Other agents never produce burst suppression or an isoelectric EEG, despite increasing dose either because they are incapable of suppressing the EEG (e.g., opioids) or because cardiovascular toxicity of the drug (e.g., halothane) prevents administration of a large enough dose.

Intravenous Anesthetic Drugs

Barbiturates, Propofol, and Etomidate

Despite widely varying potencies and durations of action, all of these drugs produce similar EEG patterns (Fig. 35-6 (Figure Not Available) shows EEG effects of thiopental). These drugs all follow the basic anesthesia-related EEG pattern described previously with initial EEG activation (see Fig. 35-6 (Figure Not Available) A), followed by dose-related depression. As the patient loses consciousness, characteristic frontal spindles are seen (see Fig. 35-6 (Figure Not Available) B), which are

replaced by polymorphic 1- to 3-Hz activity (see Fig. 35-6 (Figure Not Available) C) as the drug is further administered. Increases in dose result in lengthening periods of suppression interspersed with periods of activity (burst suppression). With a very high dose, EEG silence results. All these drugs have been reported to cause epileptiform activity in humans, but epileptiform activity is clinically significant only following methohexital and etomidate.

Ketamine

Ketamine does not follow the basic anesthesia-related EEG pattern. Anesthesia with ketamine is characterized by frontally dominant rhythmic theta activity with increased amplitude. Increased doses produce intermittent polymorphic delta activity of very large amplitude interspersed with

TABLE 35-2 -- Anesthetic Drugs and the EEG

DRUG	EFFECT ON EEG FREQUENCY	EFFECT ON EEG AMPLITUDE	BURST SUPPRESSION?
Isoflurane			Yes, >1.5 MAC
Subanesthetic	Loss of alpha, frontal beta		
Anesthetic	Frontal 4-8 Hz activity		
Increasing dose >1.5 MAC	Diffuse theta and delta burst suppression silence	0	
Desflurane	Similar to equi-MAC dose of isoflurane	Similar to equi-MAC dose of isoflurane	Yes, >1.2 MAC
Sevoflurane	Similar to equi-MAC dose of isoflurane	Similar to equi-MAC dose of isoflurane	Yes, >1.2 MAC
Nitrous oxide (alone)	Frontal fast oscillatory activity (>30 Hz)	, especially with inspired concentration >50%	No
Enflurane			Yes, >1.5 MAC
Subanesthetic	Loss of alpha, frontal beta		
Anesthetic	Frontal 7-12 Hz activity		
Increasing dose >1.5 MAC	Spikes/spike and slow waves burst suppression; hypocapnia seizures		
Halothane			Not seen in clinically useful dosage range
Low dose	Frontal 10-20 Hz activity		
Moderate dose	Frontal 10-15 Hz activity		
Increasing dose >1.5 MAC	Diffuse theta, slowing with increasing dose		
Barbiturates			Yes, with high doses
Low dose	Fast frontal beta-activity	Slight	
Moderate dose	Frontal alpha-frequency spindles		
Increasing high dose	Diffuse delta burst suppression silence	0	
Etomidate			Yes, with high doses
Low dose	Fast frontal beta-activity		
Moderate dose	Frontal alpha-frequency		
Increasing high dose	Diffuse delta burst suppression silence	0	
Propofol			Yes, with high doses
Low dose	Loss of alpha, frontal beta		
Moderate dose	Frontal delta, waxing/waning alpha		
Increasing high dose	Diffuse delta burst suppression silence	0	
Ketamine			No
Low dose	Loss of alpha, variability		
Moderate dose	Frontal rhythmic theta		
High dose	Polymorphic delta, some beta	(beta is low amplitude)	
Benzodiazepines			No

Low dose	Loss of alpha, increased frontal beta-activity		
High dose	Frontally dominant delta and theta		
Opiates			No
Low dose	Loss of beta, alpha slows		
Moderate dose	Diffuse theta, some delta		
High dose	delta, often synchronized		

delta-<4 Hz frequency; theta-4-7 Hz frequency; alpha-8-13 Hz frequency; beta->13 Hz frequency; MAC-minimum alveolar concentration

low-amplitude beta activity. [13] Electrocortical silence cannot be produced with ketamine. EEG activity may be very disorganized and variable at all doses. Recovery of EEG activity even after a single bolus dose of ketamine is relatively slow compared to barbiturates. There is no information available about the relationship between emergence reactions following ketamine and the EEG. Ketamine has also been associated with increased epileptiform activity. [13]

Benzodiazepines

Despite varying potencies and durations of actions, benzodiazepines also follow the basic anesthesia-related EEG pattern. As a class, however, these drugs are incapable of producing burst suppression or an isoelectric EEG.

Opioids

Opioids do not, as a class, follow the basic anesthesiarelated EEG pattern. In general, opioids produce a doserelated decrease in frequency and increase in amplitude of the EEG. If further doses of opiates are not given, alpha and beta activity will eventually return. The rapidity of return depends on the initial dose and on the drug. Remifentanil is associated with the most rapid return to normal. [14] Complete suppression of the EEG cannot be obtained with the opioids.

Figure 35-6 (Figure Not Available) EEG effects of intravenous administration of thiopental in humans. (A) Rapid activity; (B) barbiturate spindles; (C) slow waves; (D) burst suppression. *(From Clark and Rosner [138])*

Epileptiform activity occurs both in humans and in animals receiving large to supraclinical doses of opioids. For example, sharp wave activity is relatively common after induction of anesthesia with fentanyl with 20 percent of patients showing this phenomenon after 30 mug/kg, 60 percent at 50 mug/kg, 58 percent at 60 mug/kg, and 80 percent at 70 mug/kg. This activity is mainly noted in the frontotemporal region. [15]

Inhaled Anesthetics

Nitrous Oxide

Used alone, nitrous oxide causes a decrease in amplitude and frequency of the dominant alpha rhythm. With the onset of analgesia and depressed consciousness, frontally dominant fast oscillatory activity (>30 Hz) is frequently seen. [16] This activity may persist to some extent for up to 50 minutes after discontinuation of nitrous oxide. When nitrous oxide is used in combination with other agents, it increases the depth of anesthesia that would be associated with the agent alone, both clinically and with respect to the EEG pattern seen.

Isoflurane, Sevoflurane, Enflurane, Halothane, and Desflurane

Potent inhaled anesthetics follow the basic anesthesiarelated EEG pattern. Isoflurane causes a slowing of the EEG activity that increases with increasing depth of anesthesia. Isoflurane begins to produce periods of EEG suppression at 1.5 minimum alveolar concentration (MAC), which become longer with increasing dose until electrical silence is produced at 2 to 2.5 MAC. At times, an isolated spike wave can be seen during intersuppression activity at 1.5 to 2.0 MAC isoflurane. [17] Sevoflurane causes similar dose-dependent EEG effects as does isoflurane with equi-MAC concentrations of sevoflurane and isoflurane, causing similar EEG changes. [18] Epileptiform activity has not been

induced by administration of sevoflurane in patients without epilepsy; however, seizure activity on EEG, but not clinical seizure activity, has been reported in pediatric patients with a history of epilepsy during induction of anesthesia with sevoflurane. [19] The enflurane pattern is similar to that of isoflurane except that epileptiform activity is considerably more prominent. At 2 to 3 MAC, burst suppression is seen, but virtually all intersuppression activity consists of large spike and wave discharges. Hyperventilation with these high concentrations of enflurane increases the length of suppression, decreases the duration of bursts but increases the amplitude and main frequency component of the intersuppression activity. Frank EEG seizures may also occur that produce the same cerebral metabolic effects as pentylenetet-razol, a known convulsant. Halothane follows a pattern similar to that of isoflurane, but the greater degrees of EEG suppression seen with isoflurane are not seen with halothane until dosages associated with profound cardiovascular depression (3-4 MAC) are used. Desflurane produces EEG changes similar in nature to equi-MAC concentrations of isoflurane. In limited clinical studies, there has been no evidence of epileptiform activity with desflurane, despite hyperventilation and 1.6 MAC dosage. [20] Clinical studies have demonstrated that the EEG effects of inhalational anesthetic agents are influenced by age and baseline EEG characteristics. Older patients and those with EEG slowing at baseline were more sensitive to the EEG effects of isoflurane and desflurane. Similar changes were noted but at lower anesthetic concentrations. [21]

SURGERY AND THE EEG

Although EEG has not yet seen widespread use as a measure of depth of anesthesia, it has found much greater success as a monitor of the adequacy of cerebral blood flow, especially during carotid endarterectomy. Because anesthetic drugs do affect the EEG (see Table 35-2) , and many of these EEG changes may mimic EEG changes associated with inadequate cerebral blood flow, some guidelines about anesthetic management during EEG monitoring for cerebral ischemia might be helpful (Table 35-3) .

Cardiopulmonary Bypass

In humans there are always several circumstances that occur with the institution of cardiopulmonary bypass (CPB)

TABLE 35-3 -- Anesthetic Guidelines for Intraoperative Monitoring for Ischemia

1. No changes in anesthetic technique should be made during critical periods of monitoring (e.g., induced hypotension, carotid clamping, or aneurysm clipping).
2. Specifically avoid major changes in anesthetic gas levels or boluses of opiates, barbiturates, or benzodiazepines near times of increased ischemic risk.
3. If drugs must be given that create extreme EEG showing or an isoelectric pattern, it is sometimes possible to monitor SSEPs, which may remain relatively unaffected.

(Ch. 49) . For example, the level of anesthesia may be altered by CPB, alterations in arterial carbon dioxide tension and blood pressure may occur, and hemodilution with hypothermic perfusate may be used. These possible outcomes make it difficult to isolate the effects of CPB, brain perfusion, and anesthetic level on EEG. Profound EEG changes occur, sometimes asymmetrically, and interpretation is difficult at best. Levy has tried to distinguish the effects of hypothermia from other events occurring at the institution of bypass. [22] Assessment of anesthetic level during narcotic-based anesthesia suggests a shift to lower frequencies with production of an anesthetic state without recall. [23] Much work remains to be done in utilization of the processed EEG to provide information for clinical management of patients during CPB.

Carotid Endarterectomy

Of all the uses of the processed EEG, those events that are linked to a known event at a specific time and are unilateral, involving a large part of the hemisphere, are the easiest to interpret. These are the fortunate circumstances that are present when monitoring the brain of a patient undergoing carotid endarterectomy (Ch. 51) . The primary reason to monitor the brain during carotid endarterectomy is to acquire data to use as a basis for therapeutic intervention (e.g., placement of a shunt). We may fortuitously see changes in the processed EEG when a shunt becomes kinked or displaced or when cerebral emboli occur during dissection of the plaque, during hypotension, or even after the repair should a patient suffer intracerebral hemorrhage. But these are uncommon events. The main thrust of brain monitoring in carotid procedures is to aid in identifying the patient who needs a shunt. The concept of selective shunting is not agreed upon by all surgeons. Some never place a shunt and claim results that are nearly flawless. Others always place a shunt with similar results. If the processed EEG is not utilized to provide information for selective shunting, its usefulness is drastically reduced. If the processed EEG is to be used as a guide for shunting, then it must accurately identify those patients who are made critically ischemic by temporary unilateral occlusion of their carotid system.

Two issues impact the efficacy and reliability of processed EEG as a monitor for cerebral ischemia during carotid endarterectomy. First, what are the minimum number of channels (or areas of the brain) to be monitored? The 16-channel unprocessed EEG is clearly a reliable and sensitive monitor for intraoperative cerebral ischemia during carotid endarterectomy. In a series of over 2,000 patients monitored with 16-channel EEG at the Mayo Clinic, there were no false-negatives. [24] In other words, no patient had undetected intraoperative cerebral injury; however, 16-channel EEG monitored by a dedicated technician is not possible in the majority of operating rooms. Therefore, processed EEG using fewer than 16 channels is utilized much more commonly. Clinical experience as well as clinical investigations suggest that the minimum number of channels for adequate sensitivity and specificity are four channels (two per side). When a limited number of channels was compared to 16-channel EEG monitoring, 100 percent sensitivity and specificity were obtained utilizing 2 channels per hemisphere,

Figure 35-7 (Figure Not Available) This Lifescan printout was obtained approximately 3 minutes after occlusion (XC) of the left carotid artery. It shows attenuation of activity on the left with occlusion. The EEG showed a similar change. The rCBF with occlusion was 9 mL/100 g/min. *(From Spackman et al [26])*

provided those channels monitored the middle cerebral artery territory. These results were obtained with the combination of a frontoparietal channel with a frontotemporal channel. [25] The second issue is the experience level of the observer monitoring the processed EEG. Is a dedicated, experienced technician or electroencephalographer needed? In a study addressing this question, the 16-channel unprocessed EEG monitored by a dedicated technician was compared to a processed EEG reviewed by three anesthesiologists of differing levels of experience with processed EEG. Fifty patients undergoing carotid endarterectomy were studied to compare the processed EEG to the full 16-channel EEG and regional cerebral blood flow measurements as indicators of cerebral ischemia. [26] The three anesthesiologists interpreted the tracings without knowledge of the case. They were presented only with the written trace with an indication of the point at which the carotid was clamped (Fig. 35-7) (Figure Not Available) . The accuracy of interpretation hinges on the false-negative result. If a false-negative finding is read, the surgeon might fail to shunt an ischemic patient. A false-positive result is less of a problem because that patient is not ischemic but is given a shunt anyway.

The predictive value of the anesthesiologist being correct in interpreting the trace as unchanged after clamping was 91 to 98 percent, which indicates that the device can be used by relatively novice interpreters with fair accuracy to determine the presence of cerebral ischemia at the time of carotid occlusion. In this study, the review by the anesthesiologist was not carried out during the course of the procedure but rather "off line." As such it does not address the issue of whether an anesthesiologist providing the intraoperative anesthetic management of the patient can provide adequate monitoring of the processed EEG simultaneously.

Surgery for Epileptic Foci

It has long been recognized that seizures can begin with a focus of electrical synchrony that spreads to include the remainder of the cortex. Localization of such a focus at the operating table is an important part of present-day surgery for drug-resistant seizures. This localization is performed by electrocorticography in either the awake patient or by provocation during general anesthesia. At some centers, the electrocorticography leads are placed in the awake patient, and mapping is done in the EEG laboratory. The patient then returns another day for resection of the excitable focus under either local or general anesthesia. The anesthetic level is minimized, and a provocative technique such as hyperventilation or small-dose barbiturate administration can be employed to trigger the focus so as to aid in its localization. If the cortex is excessively depressed pharmacologically, seizure activity cannot be provoked. Intraoperative seizure mapping requires the involvement of

an electroencephalographer familiar with this technique. Rarely would an anesthesiologist possess the expertise required for intraoperative seizure focus localization.

/das/book/view/29494766/875/395.html

PATHOPHYSIOLOGIC EFFECTS ON THE EEG

Hypoxia

"Slowing" of the EEG during hypoxia is a nonspecific global effect. Fast frequencies are lost, and low frequencies dominate. Eventually, the EEG is abolished as cerebral metabolic activity is severely reduced, depending upon the severity of the hypoxic event.

Hypotension

Significant levels of hypotension seem to be needed to cause the earliest of central nervous system (CNS) signs, as measured by discrimination tests such as the flicker-fusion test. This test examines the flicker rate at which the observer

Figure 35-8 (Figure Not Available) Changes in the compressed spectral array during hypotension. *(From Stockard and Bickford [27])*

perceives the light to be continuous. In the early days of deliberate hypotension this test was part of the preoperative evaluation to judge how far the pressure could be reduced for operation. Clear signs of confusion and inability to concentrate or respond properly to simple commands must represent very low levels of cerebral perfusion when caused by hypotension because the cerebral vasculature is maximally dilated at that time. The EEG changes associated with even this level of hypotension are not dramatic, although they are clear by comparison with a previously active recording. Herein lies the problem with using the processed EEG to determine whether the level of hypotension has resulted in brain ischemia. The changes on processed EEG are not very pronounced and are bilateral. Such changes can be detected, but when the hypotension is induced slowly the changes are gradual and harder to read. Changes associated with acute hypotension as caused by sudden arrhythmia and are easier to read. A tracing of the effect of hypotension on the compressed spectral array is shown in Figure 35-8 (Figure Not Available) . [27] In our opinion, EEG changes due to hypotension really do represent cerebral ischemia of a significant degree and should be considered an important finding.

Hypothermia

During cooling on CPB, the total power and peak power frequency of the high-frequency band were highly correlated with temperature using Fourier analysis and spectral edge data; however, there was significant variability between subjects, especially during cooling. [27] Complete EEG suppression usually develops at 15 to 18°C.

Hypercarbia and Hypocarbia

Hyperventilation is known to activate excitable seizure foci. Hypoventilation with accumulation of carbon dioxide has subtle effects similar to increasing end-tidal tension of the volatile anesthesia. [28]

Untoward Events

One of the suggested reasons for monitoring the brain is to enable us to detect "untoward events" during anesthesia, which suggests that there are CNS insults that, if detected early, could be rapidly reversed or treated to prevent permanent injury. We have already considered hypoxia, hypotension, and cerebral ischemia caused by carotid artery occlusion. What "untoward event" may have occurred when a patient awakens from general anesthesia with an unexpected neurologic deficit? Most such problems are caused by peripheral nerve injuries and with a sufficiently detailed neurologic examination can be identified as such. It is unlikely that any routine brain monitor is going to help identify such injuries. Although SSEPs measured from the distribution of the nerve at risk might very well do so, this level of monitoring is not routine and would probably be used only when one expects a nerve injury to occur.

We had an opportunity to describe three patients who demonstrated an unexpected focal neurologic deficit on emergence from anesthesia. [29] On the basis of what we know about the processed EEG, we can speculate on whether it would have been useful in these cases. An older man with chronic atrial fibrillation underwent percutaneous ultrasonic lithotripsy under general anesthesia. He awakened slowly and was found to have right hemiplegia and aphasia. The diagnosis was thromboembolism of cardiac origin to the distribution of middle cerebral artery. This intraoperative event probably would have been detected on the processed EEG because it would have been acute and unilateral. Recent studies utilizing fibrinolytic agents (tissue plasminogen activator) within 3 hours of onset of thromboembolic strokes have demonstrated improvements in outcome. Delay of treatment beyond 3 hours is associated with increasing complications. [30] Use of this treatment in the immediate postoperative period has not been studied and could be expected to be associated with increased bleeding complications. Therefore, as yet it is unclear whether diagnosing the intraoperative event in this patient would have resulted in a therapeutic intervention. Another patient was a middle-aged woman undergoing vaginal hysterectomy also under general anesthesia. She was lethargic in the recovery room for some time before it was realized that she was hemiplegic. She had suffered an intracerebral bleed intraoperatively. Again the processed EEG would be expected to show a fairly definitive picture in this kind of case because the changes would be hemispheric and rather acute. That information might have raised the level of suspicion and could have led to earlier diagnosis. Treatment consisted of evacuation of the hematoma. The sooner this therapy could be implemented the better the result expected. Perhaps

this patient's residual deficit would have been reduced if such monitoring had been used. Finally, a young woman was undergoing laparoscopic tubal ligation. During the procedure she had multifocal ventricular ectopy and elevated airway pressures. She entered the recovery room unusually lethargic, and hemiplegia was noted shortly thereafter. She probably sustained paradoxical carbon dioxide embolism to her coronary and cerebral circulation. This type of global cerebral event probably would not be evident on the processed EEG because even though it is acute, the changes would have to be very dramatic to be noticed because they would be bilateral. These cases occurred in a surgical case load of nearly 60,000 general anesthetics. Similar series of rare catastrophic intraoperative neurologic events have been reported from other centers. [31] The routine use of the processed EEG could have been expected to contribute rarely to the overall care of this patient group. It is for the reader to decide whether this information applies to his or her practice.

Brain Death

The clinical diagnosis of brain death (Ch. 76) is made when there is demonstration of the absence of all cerebral and brain stem function (Table 35-4) (Table Not

Available) . Various clinical tests have been devised to diagnose brain death (Table 35-5) (Table Not Available) . Apnea testing is accepted as an essential component of the evaluation; however, electrocerebral silence on the EEG, when not confounded by the presence of high-dose barbiturates, metabolic encephalopathy, or very young age, supports the diagnosis of brain death. [32] [33]

INTRAOPERATIVE MONITORING OF SENSORY EVOKED POTENTIALS

Intraoperative monitoring of sensory evoked potential (SEP) has gained increasing popularity over the last several years because it provides the ability to monitor the functional integrity of sensory pathways in the anesthetized patient undergoing surgical procedures placing these pathways at risk. EPs are electrical manifestations of the CNS response to external stimuli. SEPs are recorded by stimulating a peripheral sensory nerve and recording the resulting electrical potential at various sites along the sensory pathway to the cerebral cortex. Because of the very low amplitude of EP (0.1-20 muV), it is not possible to distinguish them from background brain wave activity and artifacts in the routine EEG. To extract the EP from the background EEG activity, computer signal averaging or summation is used. With this technique the electrical activity, both evoked and spontaneous, after a repetitive sensory stimulus is averaged. The SEP occurs at a constant time after the sensory stimulus; the spontaneous brain activity (the EEG) occurs at random intervals after the sensory stimulus. The sum of the nonrandom evoked response increases directly with the number of responses added. The sum of the random EEG activity increases by the square root of the number of samples obtained. The averaged response of two electrical activities, SEP and spontaneous EEG, increases at different rates, and the SEP is revealed above the spontaneous electrical activity of the brain. [34] The resolution of the EPs increases as the square root of the responses recorded.

SEPs are of two general types determined by the distance of the recording electrode from the neural generator of the evoked response. EPs recorded from electrodes close to the neural generators (within approximately 3-4 cm in the average adult) are termed near-field potentials. [35] Near-field potentials are transmitted to the recording electrode by propagated conduction along a discrete length of nerve, [36] and the morphology is directly affected by electrode location. [35] Far-field potentials are recorded from electrodes located a greater distance from the neural generator and are conducted to the recording electrode through a volume conductor (brain, cerebrospinal fluid, and membranes). As a result, it is more difficult to locate the source of the active tissue (the current spreads diffusely throughout the conducting medium), and the electrode position has little effect on the morphology of the recorded EP. [35] [36] As the distance between the recording electrode and the neural generator increases, the recorded SEP becomes smaller and slower. More signals have to be averaged to record far-field potentials (up to several thousand) than near-field potentials (as few as 50 to 100). [35] [36] EPs are also defined as cortical or subcortical (which arise from the spinal cord and brain stem). With EPs recorded from scalp electrodes (standard 10-20 system for EEG) (see Fig. 35-1) (Figure Not Available) , cortical evoked responses are near-field potentials, and brain-stem responses are far-field potentials.

In evaluating EPs, the latency and amplitude of the generated waveforms are measured. Deflections below the baseline are labeled positive (P) and those above the baseline negative (N). Standard identification of waveforms is by letter designating the direction of the deflection followed by

a number representing the latency of that waveform (e.g., N14). Because amplitude and latency change with recording circumstances, normal values must be established for each neurologic monitoring laboratory and differ somewhat from values recorded in other labs. SEPs utilized for diagnostic evaluation of patients with suspected neurologic abnormalities as well as those monitored intraoperatively are SSEPs, brain-stem auditory evoked potentials (BAEPs), and visual evoked potentials (VEPs). For all these modalities, recording electrodes are placed on the scalp, using the same standard 10-20 system as for recording the EEG.

Intraoperative changes in EPs, such as decreased amplitude, increased latency, or complete loss of the waveform, are considered to be indications of surgical trespass or ischemia, or they may reflect systemic changes. When these changes are detected and considered to be significant, the anesthesiologist or surgeon can make changes to relieve or lessen the insult to the monitored pathway. Interventions by the anesthesiologist are directed at improving perfusion to the nervous tissue at risk and include increasing arterial blood pressure, especially if induced hypotension is used or if the patient's pressure has fallen to below the preoperative level; transfusion if significant anemia is present; volume expansion; and normalization of arterial blood gas tensions if indicated. Alterations in EPs may warn the surgeon of direct injury of nervous tissue in the operative field often due to retractor pressure or ischemia caused by compromise of blood supply either through placement of vascular clips or cross-clamps or due to distortion of the vasculature (i.e. during correction of scoliosis, or with use of retractors). Appropriate changes in the operative procedure may result in avoidance or lessening of postoperative neurologic dysfunction. Tolerance limits for degree of change in EPs or duration of complete loss of waveform before permanent neurologic dysfunction occurs are not clearly defined. Many centers utilizing intraoperative SEP monitoring define decreases in amplitude of 50 percent or more from baseline associated with a prolongation in latency as clinically significant SEP changes, in need of intervention or explanation. In practice, often any SEP changes associated with a surgical event are considered clinically significant. Changes in SEP that do not progress to complete loss of the waveform are less likely to indicate a new postoperative neurologic deficit. Complete loss of the SEP waveform intraoperatively without recovery is highly likely to be associated with a new deficit. If the SEP recovers either spontaneously or by interventions intraoperatively, the likelihood of neurologic injury depends on the procedure and the duration of the SEP loss. Some studies suggest that loss of the SEP waveform for less than 15 minutes is associated with no new permanent neurologic deficit, whereas complete loss for longer periods is highly likely to reflect permanent neurologic injury. [37]

The operating room is a "hostile" environment for recording SEP. Because these potentials are very small in amplitude, electrical noise, which is quite common in most operating rooms, will often interfere with recording of good quality EPs. "Biologic noise" such as the cardiac electrical activity (ECG) and muscle movement (EMG activity) may obscure the desired evoked response. To successfully record SEP in the operating room environment, these sources of noise must be recognized and the appropriate action taken to allow recording of the desired evoked response (i.e., unnecessary electrical equipment unplugged, and small doses of muscle relaxant given to minimize EMG). A number of physiologic changes as well as drugs administered intraoperatively can result in changes in the SEP unrelated to potential injury to nervous tissue. These factors must be recognized, minimized if possible, and included in the differential diagnosis as changes in SEP are detected intraoperatively. One of the most important principles of recording SEP intraoperatively is that reproducible, reliable tracings must be obtained at baseline prior to any intervention likely to cause changes in the evoked response. If good quality tracing with identifiable waveforms cannot be recorded and reproduced at baseline, then SEP monitoring will be of little use in monitoring integrity of the CNS intraoperatively. If significant variability exists or waveforms are difficult to identify, then it will not be possible intraoperatively to distinguish SEP changes that are clinically significant from the preexisting variability of waveforms.

SOMATOSENSORY EVOKED POTENTIALS

SSEPs are recorded after stimulation of a peripheral sensory nerve, usually with electrical stimulation via a surface electrode on the skin or fine needle electrodes. A square wave stimulus of 0.2- to 2-ms duration is delivered to the peripheral nerve, and the intensity is adjusted to produce a minimal muscle contraction. Increasing the stimulus intensity beyond the sum of the motor and sensory threshold does not influence the amplitude or latency of the recorded EP. [28] Rate of stimulation varies from 1 to 2 Hz. [35] The common sites of stimulation include median nerve at the wrist, common peroneal nerve at the knee, and posterior tibial nerve at the ankle. [38] The tongue, trigeminal nerve, pudendal nerve, and ulnar nerve have also been studied. [38]

SSEPs consist of both short- and long-latency EPs. The short-latency SSEPs are the EPs most commonly studied intraoperatively because they are less influenced by factors that may vary during the perioperative period, such as anesthetic depth. The pathways involved in the generation of short-latency SSEPs include large-fiber sensory nerves with their cell bodies in the dorsal root ganglia and central processes traveling rostrally in the ipsilateral posterior column of the spinal cord synapsing in the dorsal column nuclei at the cervicomedullary junction (first-order fibers), second-order fibers crossing and traveling to the contralateral thalamus via the medial lemniscus, and third-order fibers from the thalamus to the frontoparietal sensorimotor cortex. [26] Primary cortical evoked responses result from the earliest electrical activity generated by the cortical neurons and are thought to arise from the postcentral sulcus parietal neurons. The secondary cortical potentials (longer-latency) are thought to arise in the association cortex, are less stable, have greater variability of waveform than primary cortical responses, [36] and habituate rapidly on repetitive stimulation. [35] Nonspecific cortical responses occur widely across the frontal and temporal cortex regardless of the sensory stimulation, show marked habituation with repetitive stimulation, but are enhanced when the stimulation is meaningful or when the subject concentrates. [35] Cortical EPs other than the primary cortical response

TABLE 35-6 -- Generators of SSEPs After Median Nerve Stimulation

PEAK	GENERATORS
N9 (EP)	Brachial plexus
N11	Posterior columns or spinal roots
N13/P13	Dorsal column nuclei
N14,15	Brain stem or thalamus
N19/P22	Parietal sensory cortex

are not recorded intraoperatively because they are severely altered by general anesthesia or are extremely difficult to record in the operating room environment. [35]

For recording SSEPs after upper limb stimulation, recording electrodes are placed at the Erb point above the clavicle overlying the brachial plexus, at the posterior midline of the neck at the second cervical vertebra (over the gracile and cuneate nuclei), and on the scalp overlying the sensory (parietal) cortex contralateral to the stimulated limb. For recording EPs after lower limb stimulation, electrodes are placed over the lower lumbar spine. [38] Intraoperatively, cortical SSEPs may also be recorded from electrodes placed directly on the cerebral cortex and subcortical potentials with electrodes placed invasively into bone, ligament, or the epidural space in the operative site. [35] Purported generators for short-latency SSEPs are listed in Table 35-6 and Figure 35-9 (Figure Not Available) . [35] [38] After lower-limb stimulation, absolute latencies are increased because of the greater distance the

Figure 35-9 (Figure Not Available) Short-latency SEPs produced by stimulation of the median nerve at the wrist. *(From Chiappa and Ropper [38])*

stimulation must travel along the peripheral sensory nerve. The first cortical response occurs at approximately 27 ms after stimulation. Interpeak latencies are also evaluated to assess specific conduction times such as N9 to N14 conduction time, reflecting transmission in the proximal brachial plexus, the cervical roots, and the dorsal columns; the N14 to N19 conduction represents pure central conduction time between the dorsal column nuclei and the primary sensory cortex. [39]

Intraoperative recording of SSEPs has been used to assess the functional integrity of the sensory pathways during operative procedures that place these pathways at risk as a result of surgical trespass either along the course of the peripheral nerve, within the spinal canal, or in the brain or when there is potential for compromise of the vascular supply to the sensory pathways. SSEP monitoring has also been used to assess the integrity of adjacent structures that are more difficult to monitor directly, such as the motor tracts. Intraoperative SSEP monitoring has been described for a wide variety of procedures, including correction of scoliosis with instrumentation [40] [41] ; spinal cord decompression and stabilization after acute spinal cord injury [42] [43] ; spinal fusion [44] ; brachial plexus exploration after injury to the plexus [45] ; resection of spinal cord tumor, cyst, or vascular lesion [46] ; correction of cervical spondylosis [46] ; resection of fourth ventricular cyst [46] ; release of a tethered cord [46] ; resection of intracranial vascular lesions involving the sensory cortex [46] ; clipping of intracranial aneurysms [37] ; carotid endarterectomy [47] ; resection of thalamic tumor [48] ; surgical correction after thoracic spine fracture [49] ; abdominal and thoracic aortic aneurysm repair [28] ; and repair of coarctation of the aorta. [50] Intraoperative monitoring of SSEPs has been used most extensively in patients undergoing surgical procedures involving the spinal column or spinal cord, or both. Extensive experience has been gained in patients who have decompressive laminectomies or who have undergone corrective procedures for scoliosis. Intraoperative changes in SSEPs have been noted in 2.5 to 65 percent of patients undergoing surgical procedures on the spine or spinal cord. [41] [44] [49] [51] When these changes are promptly reversed either spontaneously or with interventions by the surgeon or anesthesiologist (such as lessening the degree of spine straightening in scoliosis surgery or increasing arterial blood pressure), the patients most often have preserved neurologic function postoperatively. When these changes persisted, however, the patients most often awakened with worsened neurologic deficit. Both false-negative and false-positive results have been reported with SSEP monitoring during spine surgery. Patients with intact SSEPs throughout the procedure have awakened with a new significant neurologic deficit. On the other hand, patients with significant changes in intraoperative SSEPs have suffered no change in neurologic function postoperatively. [51] Overall, the reliability of adequate SSEP monitoring to predict the postoperative somatic sensory function has been reported to be excellent. [35] [46] [49] However, because the motor tracts are not monitored and the blood supply to the dorsal columns of the somatosensory tracts monitored is primarily from the poste- rior spinal arteries and that to the motor tracts is primarily from the anterior spinal artery, it is possible for a significant motor deficit to develop postoperatively in patients with intact SSEPs throughout the operative course. Indeed, such

events have been reported. [42] [52] In operations on the spine and after acute spinal cord injury the sensory and motor changes usually follow closely [35] ; however, in patients suffering neurologic dysfunction after thoracic aortic aneurysm repair, frequently proprioception is intact when motor and other sensory functions are impaired. This result occurred in 32 percent of patients with neurologic injury after aortic aneurysm repair in one series. [53] Clearly, intraoperative SSEP monitoring in

these patients carries a significant risk for false-negative results. In addition, significant difficulties in intraoperative recording of SSEPs have been reported. Technically inadequate intraoperative SSEP recordings are reported to occur in 0 to 41 percent of patients monitored. [46] [48] [49] [54] These difficulties arise from the electrically hostile environment of the operating room, a high incidence of artifact, abnormal preoperative SSEPs in patients with abnormal neurologic function, inaccessible electrodes during the operative procedure, and sensitivity of the EP, especially the cortical components, to factors that may fluctuate in the intraoperative period, such as temperature, blood gas tensions, anesthetic depth, and blood pressure. Indeed, one author found the SSEPs to be the most difficult of SEPs to monitor intraoperatively. [49] In order for SSEP monitoring to benefit a patient, the neurologic pathway monitored must be potentially at risk during the procedure, and if SSEP changes occur, an option for intervention must exist. If both of these are not true, then monitoring is likely to offer little benefit to the patient. To optimize conditions for SSEP monitoring, the anesthesiologist should choose an anesthetic technique that does not markedly depress the SSEP and the anesthetic depth and physiologic state of the patient should remain as constant as possible during periods of potential surgical injury to the monitored pathway. In addition, reliable tracings should be obtained before any intervention.

Evaluation of central conduction time during SSEP monitoring has also been used in acute settings other than the perioperative period. Prolongation of central conduction in comatose patients has been associated with a worse long-term prognosis. [55] Prolongation of central conduction time in patients after subarachnoid hemorrhage is associated with transient neurologic deficits and precedes the development of these deficits. The changes in central conduction time are likely related to cerebral ischemia. [56]

BRAIN-STEM AUDITORY EVOKED POTENTIALS

BAEPs are recorded by delivering clicks repeatedly to one ear. Stimulus intensity is usually set at 60 to 70 dB above the patient's click-hearing threshold. The duration of the click is approximately 100 sec and the frequency 10 Hz. Use of different click polarity (the direction of the initial movement of the tympanic membrane) to cause either rarefaction or condensation produces different waveforms, amplitudes, and latencies. BAEP may be recorded with one or the other click polarity but not both usually. Intraoperatively, clicks of alternating polarity may be used to decrease stimulus artifact, but the waveforms produced are an average of those produced by either one alone. Rate and intensity of stimulus delivery affect the BAEP. [35] [57] Monaural stimulation is used because responses from a normal ear stimulated simultaneously obscure any abnormal responses from the contralateral ear. The stimuli are delivered by acoustically shielded headphones when not used in the operation room. Intraoperatively, inserted earphones on molded earpieces are used. Although they admit more extraneous noise, they do not interfere with access to the surgical field and are preferable for intraoperative monitoring. [35] [57] Recording electrodes are placed on the lobe of the stimulated ear and on the top of the head (vertex). [57] White noise is delivered to the contralateral ear. Five hundred to 2,000 repetitions are required on average because BAEPs recorded from the scalp are far-field potentials. [35] [57]

Peaks in recordings of BAEP are labeled I through VII, and the purported neural generators for these peaks are shown in Figure 35-10 . As with SSEP, amplitude, absolute latencies, and interpeak latencies are evaluated to assess integrity of the auditory system, localize the functional defect, and assess peripheral and central conduction times. Because waves VI and VII are inconsistent, they are not routinely studied, [57] and most papers reporting use of BAEP in the operating room use waves up to wave V. [58] [59] [60]

BAEPs have been monitored intraoperatively during procedures involving or near the auditory pathway as well as in posterior fossa procedures when brain-stem function might be compromised. Cases in which BAEPs are commonly monitored include microvascular decompression of cranial nerves (especially V and VII), resection of acoustic neuroma, posterior fossa exploration for vascular or neoplastic lesions, clipping of basilar artery aneurysm, and section of nerve VIII for intractable tinnitus. [46] [58] [59] During microvascular decompression of the facial nerve in patients with hemifacial spasm, hearing loss has been reported in up to 15 percent of cases, and this incidence can be greatly decreased with BAEP monitoring. [61] [62] Intraoperative changes noted included transient or permanent latency increases on the operative side, obliteration of waveform distal to the operative site that was either transient or permanent, and, rarely, obliteration of BAEP contralateral to the operative side. [48] [49] [58] [59] These changes were associated with a variety of perioperative events, including section of nerve VIII (deliberate or unintentional); retraction of nerve VIII, cerebellum, or brain stem; operative manipulation of nerve VIII; hypotension and hypocarbia; drilling around the internal auditory canal; irrigation of nerve VIII; severe cerebellar edema; and positioning of the head for retromastoid cra-niotomy (Table 35-7) . [48] [58] [59] Patients with transient or persistent increases in latency or decreases in amplitude can be expected to have unchanged or only slight worsening of hearing postoperatively. Patients with complete but reversible loss of BAEP will also have unchanged or mild worsening of hearing postoperatively. Patients with complete irreversible loss of BAEP will most likely have complete or near complete loss of hearing in the ipsilateral ear postoperatively. [46] [48] [49] [59] One series had a single false-positive result. One patient had complete loss of BAEP with intact hearing postoperatively. [48] False-negative results are extremely rare. In one series, BAEPs were monitored in a patient undergoing resection of a meningioma in the lateral ventricle and were unchanged intraoperatively and postoperatively; however, this patient did not regain consciousness postoperatively. [49] This case illustrates the lack of cortical

Figure 35-10 Schematic of auditory neural pathway. The BAEP is initiated by stimulation of the cochlea with a broadband click stimulus given via an ear insert in the external auditory canal. Neural generators of the BAEP peaks are shown.

function monitoring with intraoperative monitoring of BAEP through wave V. Acoustic neuroma resection and posterior fossa craniotomy for microvascular decompression of the V and VII nerves are the most common cases in which BAEPs are monitored. Changes observed are commonly increased in I-V interpeak latency and loss of amplitude of wave V. These changes are usually due to intraoperative stretch of the VIII nerve by retractor placement during cerebellar retraction. Such changes are usually reversed with repositioning of the retractor. Complete loss of wave V may be caused by injury of the VIII nerve in the operative field. During acoustic neuroma resection, occasionally waves I-V are lost. Generally, this is due to interruption of the cochlear blood supply and is associated with complete deafness in the affected side. [63] BAEPs are considered the easiest of the SEPs to monitor intraoperatively and are least

TABLE 35-7 -- Correlation Between BAEP Changes and Associated Clinical Events

BAEP CHANGE	ASSOCIATED EVENTS
Transient latency increase	Drilling, irrigation, retraction, surgical irritation, hypocarbia and hypotension, positioning
Persistent latency increases	Retraction or pressure on auditory tract
Transient loss of EP	Retraction, pressure, surgical dissection
Permanent loss of ipsilateral EP	Surgical interruption of auditory pathway or interruption of cochlear blood supply
Loss of contralateral EP	Cerebellar edema

sensitive to changes in perioperative variables. Ability to record technically adequate BAEP has been reported in 90 to 100 percent of cases in which monitoring was attempted. [46] [48] [58] [59] Preoperative deafness on the operative side eliminates the possibility of recording intraoperative BAEPs. Preservation of BAEP intraoperatively indicates preserved hearing postoperatively, and persistent changes indicate significant risk of injury.

VISUAL EVOKED POTENTIALS

VEPs are recorded after monocular stimulation with recording electrodes over the occipital, parietal, and central scalp. [59] Shift reversal of a checkerboard pattern with constant luminance is the preferred stimulus because the generated EPs have a narrower range of normal variation and are more sensitive to conduction defects. However, it is currently not possible to deliver this type of stimulation intraoperatively. Instead flash stimulation with a change in luminance is utilized. The stimuli are produced by light-emitting diodes placed in a goggle over a closed lid. The flash rate is 1 to 3 Hz with a duration of 3 to 5 ms. The sample time is 250 to 500 ms, and 64 to 128 samples are averaged per recording. [35] [48] [49] [57] For some operative procedures, such as operations on the anterior cranial fossa, the goggles interfere with approach to the operative field. Light-emitting diodes mounted on a contact lens have been used in these situations. [46] VEPs are cortical EPs, which vary with the type of stimulus, part of the retina stimulated, degree of pupil dilation, and patient's attention level. [35] Two positive peaks at approximately 100 and 200 ms are observed (Fig. 35-11) (Figure Not Available) . [35]

Figure 35-11 (Figure Not Available) Pattern-shift VEPs. *(From Chiappa and Ropper [57])*

Intraoperative VEP monitoring has been advocated for procedures placing the visual system at risk, especially for those in the area of the optic chiasm. Procedures in which VEP monitoring has been used include resection of pituitary tumors, craniopharyngioma, optic glioma, orbital pseudotumor, occipital arteriovenous malformation, meningioma impinging on the optic chiasm, chondrosarcoma of the sphenoid wing, drainage of pituitary abscess, clipping of internal carotid artery and basilar artery aneurysms, surgical correction of CSF rhinorrhea, and treatment of orbital fracture. [46] [48] [49] Changes in EP latency and amplitude were used to guide operative manipulations or to indicate adequate systemic blood pressure in patients in whom induced hypotension was being used. [35] [49] Satisfactory intraoperative recordings can be recorded in 88 to 100 percent of patients. [46] [48] [49] However, intraoperative variability unrelated to changes in neurologic function may be as high as 68 to 81 percent. [48] [49] In addition, in one large series there was a relatively high incidence of both false-positive and false-negative results. Thirteen percent of patients with intraoperative loss of VEPs had unchanged vision postoperatively, and 7 percent had intact VEPs with significant visual defects. [49] VEPs are sensitive to a number of factors that cannot be controlled intraoperatively, such as luminance because the flash must pass through the closed eyelid; pupil size and direction; and attention to the stimulus. In addition, improved systems to deliver the stimulus intraoperatively have to be developed. [49] In the opinion of the author of one of the largest series of patients studied with intraoperative VEP monitoring with current techniques, VEPs cannot be reliably interpreted intraoperatively. [49] VEPs have enjoyed the least popularity of all forms of intraoperative EP monitoring.

Pharmacologic Factors Influencing Sensory Evoked Potentials

There are multiple drugs used in the perioperative period that can influence the intraoperative monitoring of SEPs (Table 35-8) . Different classes of drugs have differing effects. In addition, the sensitivity of evoked responses to drug effects varies with the sensory modality monitored. In general, VEPs are the most sensitive, and BAEPs are the most resistant to drug effects. In addition, early waves (brain-stem) are less affected by drugs than are late potentials (cortical).

The volatile anesthetics isoflurane, sevoflurane, desflurane, enflurane, and halothane have similar effects in differing degrees on the SEPs. As with most drugs, VEPs are the most sensitive to the effects of volatile anesthetics, and the BAEPs are the most resistant to anesthetic-induced changes. The spinal and subcortical waves are less affected than the cortical potentials. [64] [65] [66]

The effects of the currently used volatile agents on SSEPs are dose-dependent increases in latency and conduction times and a decrease in amplitude. [64] [65] [66] [67] [68] The relative effects of different volatile agents on SSEPs are somewhat controversial: Some evidence suggests that halothane has a greater

TABLE 35-8 -- Drug Effects on Sensory and Motor Evoked Potentials

impact on SSEPs than either isoflurane or enflurane [66] other evidence supports a greater effect by enflurane and isoflurane than halothane. [64] Both desflurane and sevoflurane appear to have qualitatively and quantitatively similar effects of SEPs as isoflurane. [69] [70] Up to 0.5 to 1 MAC isoflurane in the presence of nitrous oxide is compatible with adequate monitoring of cortical SSEPs (Fig. 35-12) (Figure Not Available) . [64] [68] Preservation of the ability to monitor cortical SSEPs has been reported with similar levels (0.5-1 MAC) of both halothane and enflurane in nitrous oxide [64] [68] (Figs. 35-13 (Figure Not Available) . and 35-14 (Figure Not Available))

The volatile anesthetics result in increases in latency of BAEPs without affecting the amplitude. [68] [71] [72] [73] However, volatile anesthetics cause both increases in latency and decreases in amplitude in the early cortical responses after auditory stimulation. [72] Adequate monitoring of BAEPs is possible with the volatile anesthetics in concentrations up to

Figure 35-13 (Figure Not Available) Representative SSEP cortical responses (C-3, or C-4-FPz) at various MAC levels of enflurane. *(From Peterson et al [64])*

and exceeding 1 MAC (with and without nitrous oxide) (Figs. 35-15 (Figure Not Available) and 35-16 (Figure Not Available)). [68] [71] [72] [73] [74]

Use of the volatile agents during monitoring of VEPs results in dose-dependent increases in latency with or without changes in amplitude. [68] [75] [76] [77] [78] Isoflurane results in dose-dependent increases in latency and decreases in amplitude up to 1.8 percent in 100 percent oxygen, at which time the waveform is lost. [68] [75] Enflurane in the absence of hypocarbia also leads to decrease in amplitude. [75] Halothane causes

Figure 35-15 (Figure Not Available) Influence of isoflurane alone on BAEP in a typical subject. Latency of peaks III and IV to V increased at 1.0 percent but stabilized with increasing anesthetic depth. *(From Manninen et al [71])*

increases in latency without changes in amplitude (Fig. 35-17) (Figure Not Available) . [76] [77]

Although volatile anesthetics cause significant changes in the waveforms of sensory evoked potential, it is possible to provide adequate monitoring intraoperatively in the presence of volatile anesthetics. Doses of agents causing obliteration of the response to be monitored must be prevented. Equally important, anesthetic concentration should not be changed during the critical periods of intraoperative monitoring, those in which surgical interventions are most likely to result in damage to neurologic tissue and changes in the SEPs. Because the volatile anesthetic-induced changes in SEPs are dose-dependent, increasing anesthetic depth at a crucial point in the operative procedure can result in confusing changes in the SEPs that may be due to either the anesthetic or the surgical procedure. The appropriate intervention is then difficult to determine.

As with the volatile anesthetics, nitrous oxide causes differing effects on the SEPs depending on the sensory system monitored. It causes decreases in amplitude without changes in latency in SSEPs when used alone or when added to a narcotic-based or volatile anesthetic. [64] [65] [79] Addition of 50 percent nitrous oxide to a fentanyl-based anesthetic results in greater decreases in amplitude than administration

Figure 35-17 (Figure Not Available) Waveforms of visual evoked responses from one patient elicited when awake and anesthetized at three end-expired levels of halothane. Four separate tracings obtained during each condition have been superimposed. *(From Uhl et al [76])*

of up to 1 percent isoflurane or enflurane, especially in patients with abnormal preoperative SSEPs. [65] The addition of nitrous oxide to a maintenance volatile anesthetic during the monitoring of BAEPs causes no further change. [71] Likewise use of nitrous oxide alone causes no change in BAEPs. [79] Use of nitrous oxide alone results in an increase in latency and a decrease in amplitude in VEPs, but when it is added to a volatile anesthetic technique it causes no further changes in VEPs. [75] [79]

The effects of barbiturates on EPs have been studied both in animal models and in humans. Increasing doses of thiopental in patients result in progressive dose-dependent increases in latency, decreases in amplitude in median nerve SSEPs, and progressive increases in latency in BAEPs. The changes in SSEPs are more pronounced than are the changes in BAEPs, and changes in later waveforms exceeded those in the earlier waveforms. This finding is consistent with the theories that barbiturates affect synaptic transmission more than axonal conduction, that the early waveforms in SEPs are to axonal transmission, and that later waves are dependent on multisynaptic pathways. At doses of thiopental far in excess of

those producing an isoelectric EEG, adequate monitoring of SSEPs and BAEPs was preserved. [80] The effects of pentobarbital in cats have also been evaluated. The effects on SSEPs and BAEPs observed are similar to those of thiopental in humans. Increases in latency of both BAEPs and SSEPs were seen. The waveforms were never obliterated even at doses above those causing complete suppression of spontaneous EEG activity. VEPs were more sensitive in that at low doses all except the earliest waveforms were obliterated. The early potentials persisted with increases in latency even to very high pentobarbital doses. [81] Similar increases in latency and decreases in amplitude of both spinal and cortical SSEPs were seen in humans with thiamylal sodium. [82] Preserved ability to monitor SSEPs in head-injured patients receiving therapeutic thiopental infusions has been demonstrated. [83] Adequate perioperative monitoring of SEPs is possible even in the presence of high-dose barbiturate therapy as long as the effects of the drug (increased latency with or without decreased amplitude) are considered.

After both bolus administration and intravenous infusions etomidate causes increases in latency of all waves and prolongation of central conduction time in SSEPs as well as increases in amplitude of the cortical waves but slight decreases in amplitude of cervical potentials. [84] This effect may be due to an alteration in the balance of inhibitory and excitatory influences or an increase in the irritability of the CNS. The effects seem to be present in the cortex but not in the spinal cord. [85] Etomidate infusions have been used to enhance SSEP recording in patients when it was not possible to obtain reproducible responses at the beginning of intraoperative

monitoring because of the patients' pathology. The infusions provided adequate monitoring and detection of intraoperative events leading to compromise of the spinal cord. [85] The effects of etomidate on BAEPs are dose-dependent increases in latency and decreases in amplitude. [86]

Droperidol in premedicant doses has been demonstrated to have varying effects on SSEPs. In most patients, decreases in amplitude were noted as well as loss of late waves. However, in a few patients increases in amplitude were noted. In all patients, conduction time was prolonged. [87] The benzodiazepines also can cause changes in SEPs. [88] [89] Diazepam causes increases in latency and decreases in amplitude of SSEPs, increases in latency in the cortical response after auditory stimulation, and no change in BAEPs. [88] [89] Midazolam causes decreases in amplitude without changes in latency of SSEPs. [84] Phenothiazines, diphenylhydantoin, phenobarbital, and ethosuximide in therapeutic doses do not result in consistent changes in BAEPs. [90] Acute alcohol ingestion results in dose-dependent increases in latency and decreases in amplitude in VEPs in healthy patients. [91]

In general, opioids cause dose-dependent increases in latency and decreases in amplitude of SSEPs. Fentanyl causes dose-dependent increases in latency of all waves, with the cortical or late waves affected more than earlier waves. It also causes a decrease in amplitude. The amplitude changes are more variable than the latency increases. [92] [93] Even at large doses of fentanyl (up to 60 mug/kg) reproducible SSEPs can be recorded. [93] Morphine causes similar dosedependent changes in SSEPs to fentanyl. [92] Meperidine causes increases in latency but may also result in increases in amplitude of SSEPs. [94] Even in relatively high doses, opioids can be used in patients requiring intraoperative SSEP monitoring without impairment of ability to monitor neurologic function adequately. However, opioid-induced changes must be taken into account when evaluating the recordings. Large intravenous bolus administration of opioids should be avoided at times of potential surgical compromise to neurologic function to prevent confusing the interpretation of SEP changes if they develop. BAEPs were resistant to doses of fentanyl up to 50 g/kg with no changes observed in absolute latency, interpeak latency, or amplitude. [95]

Physiologic Factors Influencing Sensory Evoked Potentials

A number of physiologic variables, including systemic blood pressure, temperature, and blood gas tensions can influence SEP recordings. With decreases in mean arterial blood pressure to below levels of cerebral autoregulation due to either blood loss or vasoactive agents, progressive changes in SEPs have been noted. SSEP changes observed are progressive decreases in amplitude until loss of the waveform with no changes in latency. [96] [97] BAEPs are relatively resistant to even profound levels of hypotension (mean arterial pressure of 20 mm Hg in dogs). [96] Cortical (synaptic) function appears to be more sensitive to ischemia than spinal cord transmission. [97] Rapid decreases in blood pressure to levels above the lower limit of autoregulation have also been associated with transient SSEP changes of decreased amplitude that resolve after several minutes of continued hypotension at the same level. [98] Reversible SSEP changes at systemic pressures within the normal range have been observed in patients undergoing Harrington rod placement after spinal distraction. These changes resolved with increases of systemic blood pressure to slightly above the patient's normal pressure, suggesting that the combination of surgical manipulation with levels of hypotension generally considered "safe" could result in spinal cord ischemia. [99] Changes in temperature also affect SEPs. Hypothermia causes increases in latency and decreases in amplitude with loss of the waves at 25 to 27°C in VEPs, [100] increases in latency, and alterations in morphology of BAEPs with late waves more affected than early ones. [101] Hyperthermia also alters SEPs, with increases in temperature leading to decreases in amplitude in SSEPs and loss of EPs at 42°C during induced hyperthermia. [102] Changes in arterial blood gas tensions have been reported to alter SEPs, probably in relation to changes in blood flow or oxygen delivery to neural structures. [103] [104] SSEP changes (decreased amplitude) resulting from hypoxia have been reported. [104] Isovolemic hemodilution results in progressive increases in latency of SSEPs and VEPs that become significant at hematocrits below 15 percent. Changes in amplitude were variable until very low hematocrits (<7%) were reached when amplitude of all waveforms decreased. [105]

MONITORING OF MOTOR TRACTS AND NERVES

Intraoperative monitoring of cranial and peripheral motor nerves is used in a number of operative procedures to allow

early detection of surgical trespass of the nerve and to assess level of nerve function intraoperatively. Intraoperative electromyographic monitoring of motor nerve function can include evaluation of three types of motor nerve and muscle activity. Neurotonic discharges are recorded from fine wires placed in muscles innervated by the motor nerve and are spontaneous bursts of activity resulting from operative stimulation of the nerve by either irrigating fluids or operative instruments. [106] Occurrence of neurotonic discharges warns the surgeon of the presence of the nerve within the operative area and can help prevent unintentional damage to the nerve during the procedure. Density and frequency of neurotonic discharges are correlated with degree of postoperative nerve dysfunction. [107] Compound muscle action potential (CMAP) is the muscle activity recorded from either fine wires within muscles innervated by the motor nerve or surface electrodes over the muscle after direct stimulation of the nerve within the operative field by the surgeon using a hand-held stimulating electrode. Stimulation of the nerve proximal to the operative area or tumor can be used to assess functional integrity of the nerve. [106] Nerve action potential (NAP) is recorded after direct stimulation of the nerve either within or outside the operative field, and a recording of the summated activity of the axons within the operative field is made. NAP monitoring allows for localization of slowing or block of nerve impulse conduction within the operative field. [106]

Intraoperative monitoring of facial nerve function has been used in patients undergoing surgical procedures placing the facial nerve at risk, such as acoustic neuroma resection, microvascular decompression for hemifacial spasm, resection of cerebellopontine angle meningiomas, removal of temporal bone neoplasms and cerebellar hemangioblastoma, and surgical treatment of glomus tympanicum and traumatic facial nerve paralysis. [106] [108] Much of the experience with intraoperative facial nerve monitoring is during acoustic neuroma resection. Improved preservation of facial nerve function after acoustic neuroma resection by intraoperative facial nerve EMG monitoring has been demonstrated, especially in patients with medium- to large-size tumors. [107] The National Institutes of Health consensus conference on acoustic neuroma therapy has recommended that facial nerve monitoring be used in patients undergoing resection of acoustic neuroma, based on the clinical experience and research indicating that its use results in improved neurologic outcome.

In patients with hemifacial spasm, two abnormal responses are seen during EMG monitoring: autoexcitation and lateral spread response. Autoexcitation refers to late responses lasting 50 to 100 ms that follow the normal motor response to facial nerve stimulation. Electrical stimulation of one branch of the facial nerve results in muscle response not only in the muscle innervated by that branch but also in those innervated by other branches of the facial nerve; this is termed the lateral spread response. Both of these responses are abnormal and have been demonstrated to disappear intraoperatively when the facial nerve is adequately decompressed. During microvascular decompression for hemifacial spasm, intraoperative monitoring of the facial nerve provides both warning of surgical encroachment on the nerve and information on the adequacy of the operative procedure to relieve the patient's symptoms intraoperatively. [109]

Intraoperative monitoring of the motor component of other cranial nerves has been performed. EMG monitoring of the trigeminal nerve can be accomplished with wires placed in the temporalis or masseter muscles or surface electrodes over these muscles. Cranial nerve V monitoring has been used during nerve section for tic douloureux to ensure preservation of the motor branch of the trigeminal nerve. It is also used in conjunction with facial nerve monitoring during resection of large posterior fossa lesions. [106] The spinal accessory nerve can be monitored with recording electrodes in the trapezius or sternocleidomastoid muscles, for example, during resection of large meningiomas, glomus jugular tumors, and neck carcinomas. [106] EMG monitoring of the hypoglossal nerve with electrodes in the tongue has been infrequently used for large posterior fossa lesions and clivus tumors. [106] Although EMG monitoring of the eye muscles can be performed, it is rarely used.

Monitoring of peripheral motor nerves has been performed in a number of operative procedures by placing wire electrodes in the muscles innervated by nerves that may traverse the operative area. EMG monitoring can warn the surgeon of unexpected surgical trespass of the nerve, help locate a nerve within the field, and localize the level of conduction block or delay. EMG of peripheral nerves has been used in patients undergoing spine surgery to decrease the risk of nerve root injury during the procedure because radiculopathies have been reported to occur after these procedures. [106] Monitoring of peripheral nerves has also been performed in patients undergoing nerve plexus or single-nerve explorations to locate areas of injury and assess axonal continuity to help guide the operative procedure. [106]

In patients undergoing EMG monitoring of cranial or peripheral motor nerves, anesthetic management is not influenced, except that muscle relaxants should be avoided or limited during the period of monitoring. Although the most common approach is to avoid neuromuscular blocking agents completely during the period of monitoring, adequate monitoring of the facial nerve is possible during partial neuromuscular blockade (decrease of the CMAP by 50%). This level of blockade is associated with clinical weakness [110] however, the most commonly used monitors of neuromuscular paralysis are not adequate to accurately monitor this level of relaxation. The trials in which partial neuromuscular paralysis were utilized are small-, and large-scale trials evaluating outcome have not been performed. As a result, most neuroanesthesiologists continue to recommend avoidance of neuromuscular blocking agents. In patients undergoing selective dorsal rhizotomy for relief of spasticity, the EMG is monitored to determine which rootlets to section. These patients have abnormal muscle responses, and in some volatile anesthetics and nitrous oxide may impair the ability to monitor adequately, and narcotics tend to have less impact on the ability to monitor. [111] [112]

MOTOR EVOKED POTENTIALS

Monitoring of the integrity of the motor tracts within the spinal cord is a technique with great potential benefit. Loss of motor function during spinal or vascular surgery without loss of sensory function or change in SSEPs can occur. SSEPs monitor the ascending proprioception fibers of the

fasciculus gracilis and cuneatus in the dorsal columns of the spinal cord, which differ in blood supply from the lateral corticospinal tracks in the anterior columns of the spinal cord where the descending motor tracks are located. Trans-cranial stimulation of the motor tract with monitoring of nerve impulse in the spinal cord and peripheral nerve as well as muscle response has been performed (motor evoked potential [MEP]) and loss of motor transmission without loss of SSEP demonstrated. [113] This technique has potential applications in spinal surgery in which transmission across the operative field can be assessed as well as in aortic surgery with the potential for impairment of the blood supply to the anterior cord. To monitor muscle function, neuromuscular blocking agents should be avoided. However, these agents can be used if only nerve transmission in the cord or peripheral nerves is monitored.

MEP monitoring was developed specifically to assess function of motor pathways and overcome one of the limitations of SEP monitoring. There are many variants of MEP monitoring. The first method involves transcranial stimulation, either electrical or magnetic. For electrical stimulation, electrodes placed on the scalp overlying the motor cortex are used to activate the motor cortex and produce the MEP. For magnetic stimulation, a powerful magnetic stimulator is placed on the scalp over the motor cortex. Brief repetitive applications of a strong magnetic field induce current in the motor cortex and produce an MEP. These transcranial stimulating methods may also activate surrounding cortical structures as well as subcortical white matter pathways (both sensory and motor). Distal antidromic propagation of the transcranially applied stimulus is blocked by synapses in all of the ascending sensory pathways. The stimulus is propagated easily orthodromically via descending motor pathways. The evoked responses may be recorded over the spinal cord, the peripheral nerve, and the muscle itself. In order to enhance the MEP, these responses may be averaged in the same manner as sensory EPs, but averaging is often unnecessary. A third method of producing the MEP involves electrical stimulation of the spinal cord itself above the area of the cord at risk during surgery. Responses are recorded over the distal spinal cord, peripheral nerve, and muscle.

This monitoring modality, while promising in some aspects, has many problems associated with it that remain to be resolved. The exact pathways and generators involved with MEP production have not been completely determined, and intraoperative experience with MEPs is relatively limited. Multiple anecdotal reports suggest that MEP monitoring during surgery on the spine or its blood supply may be very useful, but whether this monitor can be used to guide management and predict postoperative neurologic function in a large series of patients is unclear. [114] [115] [116] [117] For example, it is hoped that MEPs would be able to better predict postoperative motor function than SEPs following occlusion of the blood supply to the spinal cord during operations on the thoracic aorta. Two studies suggest that MEPs may not be as effective as hoped. The first study recorded MEPs from the lumbar spinal cord in dogs produced by transcranial electrical stimulation. [115] Elmore et al [118] found that these spinally recorded potentials did not accurately predict postoperative motor function. A second study recorded MEPs at both the spinal cord and peripheral nerve level in dogs produced by transcranial electrical stimulation. [119] Reuter et al [119] also found that the spinally recorded responses were inaccurate in predicting motor function postoperatively. The peripheral nerve responses disappeared in all animals and were not present 24 hours later regardless of whether the animal could move its lower extremities. These studies suggest that the spinally recorded MEP is likely representing a response generated by the descending corticospinal tract. This white matter pathway is relatively resistant to ischemia when compared to the more metabolically active anterior horn cells (gray matter). Recovery of this white matter-generated MEP response could occur following reperfusion of the cord while the gray matter might not recover. Responses recorded from the peripheral nerve would reflect postsynaptic anterior horn cell function, but lower extremity ischemia occurring following aortic cross-clamping often precludes recording this or the response from muscles during surgery. Much more experimental and clinical work is needed before MEP monitoring becomes widely accepted.

Effects of anesthetics are surprisingly profound, particularly on MEP recordings from muscle produced by either transcranial electrical or especially magnetic stimulation (see Table 35-8) . [111] [120] [121] [122] [123] [124] Anesthetic effects on MEP responses recorded at spinal levels appear to be much less profound. Anesthetic effects on MEPs produced by spinal stimulation are also relatively minor. When responses are recorded from muscle, neuromuscular blocking agents should be avoided or monitored quantitatively, maintaining T1 at or greater than 30 percent of control values. [116] [120] Otherwise, muscle relaxants are desirable because they will reduce gross muscle movement produced by MEP stimulation and facilitate the surgical procedure. There are only limited data regarding short- or long-term safety of either magnetic or electrical transcranial stimulation of the cortex. Although some centers have had consistent success utilizing transcranial MEP monitoring, its use is not widespread and should be considered promising but experimental.

TRANSCRANIAL DOPPLER MONITORING

An easy to apply, direct noninvasive measurement of cerebral blood flow (CBF) is the transcranial Doppler (TCD). The TCD is a diagnostic tool that has found application as a monitor in the operating room relatively recently. [124] The TCD uses sound waves to measure the velocity of blood flowing in the basal arteries of the brain. Sound waves are transmitted through the relatively thin temporal bone (Fig. 35-18) . When these sound waves come in contact with blood, they are reflected off the red blood cells back through the brain and skull to a detector. The velocity of the sound waves reflected back to the surface will be changed because the blood cells themselves are in motion either toward or away from the sound wave detector. This phenomenon is known as the Doppler shift and is directly related to the velocity and flow direction of the blood cells. The velocity of the blood cells will be faster during systole and slower during diastole. The blood in the center of the lumen will move faster than the blood near the vessel wall. Thus, a spectrum

Figure 35-18 Schematic of TCD. Sound waves are transmitted through the relatively thin temporal bone and reflected from red blood cells moving in the basal arteries of the brain.

of flow velocities is produced. This spectrum resembles the shape of the waveform produced by the pulse oximeter or an arterial pressure transducer (Fig. 35-19A) . TCD flow velocity measurements are most commonly and easily made in the middle cerebral artery (MCAv) but may also be measured in other arteries, including the anterior cerebral, anterior communicating, posterior cerebral, posterior communicating, and basilar arteries.

Two assumptions must be made in order for TCDmeasured blood flow velocity to have a direct relationship to CBF. First, flow and flow velocity will only be directly related if the diameter of the artery where the flow velocity is measured and the measurement angle of the Doppler probe remain constant. Second, CBF in the basal arteries of the brain must be directly related to cortical CBF. Neither of these assumptions has been scientifically proven. The TCD has not been validated in a large series of intraoperative cases against either established monitors of cerebral flow such as the EEG or against direct cortical CBF measurements.

The major reported intraoperative use of the TCD involves testing adequacy of CBF, while the carotid is cross-clamped during carotid endarterectomy. Studies comparing measured CBF with MCAv have not shown a good correlation between the two measurements. [125] In addition, the period of carotid cross-clamping is only a relatively small portion of the time that the patient with carotid disease is at risk for ischemia, and most strokes occur at other times during or after surgery. Few data are available about the nature and degree of acceptable TCD changes during the remainder of the operation. Normal variations in blood flow velocities during surgery in patients without cerebrovascular disease appear to be large (Pashayan AG and Mahla ME, unpublished data). With increasing clinical experience with TCD during carotid endarterectomy, it has become one of the accepted monitors of CBF during carotid surgery.

TCD is also used during CPB to detect air or particulate emboli during cannulation, during bypass, when weaning from bypass, and during decannulation. [126] TCD can detect

Figure 35-19 (A) Normal TCD tracing from the middle cerebral artery at a depth of 55 mm. (B) TCD tracing from a patient with cerebral vasospasm. Note very high flow velocities beyond the ability of the machine to quantify. (C) TCD pattern from middle cerebral artery in brain death. Note brief systolic inflow of blood followed by flow reversal in diastole.

these emboli quite easily. Several small clinical studies have suggested that TCD monitoring is useful in identifying portions of the procedure with highest risk for microemboli, allowing potential for alterations in the procedure to decrease

microembolic events. In addition, the number of microemboli has been suggested to be predictive of postoperative neurologic dysfunction; however, the majority of these studies are relatively small and the clinical utility is still undefined. [127] [128] Ease of application and interpretation of the characteristic spectra produced by emboli make this a very attractive monitor for cardiac surgery.

TCD has been used in the ICU to document both the presence and severity of cerebral vasospasm following subarachnoid hemorrhage. As the major cerebral arteries narrow, flow velocity within the lumen must increase if blood flow is to be maintained (Fig. 35-19B). Mean flow velocities over 120 cm per second seem to correlate well to angiographic vasospasm. [129] [130]

The TCD has also been used in the intensive care unit as an aid to the diagnosis of brain death. Studies have demonstrated a characteristic blood flow velocity pattern in patients who are clinically brain dead [131] (Fig. 35-19C) . TCD studies are easily performed at the bedside and can be used to determine whether definitive studies documenting brain death (which may require transporting the patient) need to be performed. Further studies documenting the sensitivity and specificity of this test in the diagnosis of brain death are needed before this test can be used as a sole criterion for brain death.

JUGULAR BULB VENOUS OXYGEN SATURATION

Jugular bulb venous oxygen saturation (SjvO2) can be measured by placing a fiberoptic catheter via the internal jugular vein retrograde into the jugular bulb. It is a measure of the global balance between oxygen supply and demand. In most clinical studies, SjvO2 measurements of below 50 percent have been considered to be indicative of cerebral ischemia. Because it is a measure of global cerebral oxygenation, focal areas of cerebral ischemia may go undetected. SjvO2 monitoring has been used most extensively in the intensive care unit to monitor patients with severe head injury. In addition, its use to guide intraoperative treatment has been described during carotid endarterectomy, crani-otomy for neoplasms and vascular anomalies, and car-diopulmonary bypass procedures. [132] [133] [134] [135] [136] [137] Although it is used routinely in some neurosurgical centers, it has not yet gained widespread clinical acceptance as a routine monitor of neurologic well-being during procedures placing the CNS at risk.

SUMMARY

Regardless of the type of intraoperative neurologic monitor, several principles must be true in order for the utilization of neurologic monitoring to provide potential benefit to the patient. First, the pathway at risk during the surgical procedure must be amenable to monitoring. Second, if evidence of injury to the pathway is detected, there must be some intervention possible. If changes in the neurologic monitor are detected and no intervention is made, then although the monitor may be of prognostic value, it does not have the potential to benefit the patient by avoiding neurologic injury. Third, the monitor must provide reliable and reproducible data. If the data have a high degree of variability in the absence of clinical interventions, then their utility for detecting clinically significant events is limited.

TABLE 35-9 -- Current Practice in Neurologic Monitoring

PROCEDURE	MONITORS	CURRENT PRACTICE
Carotid endarterectomy	Awake patient/neurologic exam EEG SSEP TCD	NIH recommends use of one of the available monitors
Scoliosis surgery	SSEP Wake-up test	Monitoring recommended
Acoustic neuroma	Facial nerve monitor BAEP	VIIth nerve monitoring recommended; BAEP shows some clinical evidence of improved outcome
Intracranial aneurysm clipping	SSEP EEG	Used routinely in some centers; limited clinical data on outcome
Vth nerve decompression	BAEP	Used in some centers
VIIth nerve decompression	BAEP	Data from small series shows improved hearing preservation
Supratentorial mass lesions	SSEP	Used in some centers in selected high risk procedures
Infratentorial mass lesions	BAEP/SSEP	BAEP to detect retractor-related VIII nerve injury, SSEP in rare, high-risk lesions adjacent to ascending sensory pathways
Decompression of spinal stenosis	SSEP	Used in some centers in high-risk procedures (more often cervical)
Spinal cord trauma	SSEP	Used in some centers in high-risk procedures
Cardiopulmonary bypass	EEG TCD SjvO2	Used routinely in some centers, actively studied, but no outcome data as of yet
Aortic coarctation	SSEP	Used routinely in a few centers
Aortic aneurysm repair	SSEP	Used routinely in a few centers

In this chapter, we have discussed the current clinically utilized intraoperative neurologic monitors. Ideally, clinical studies would provide outcome data on the efficacy of a neurologic monitor in a given procedure to improve neurologic outcome. Unfortunately, although there is a wealth of clinical experience with many monitoring modalities, there is little in the way of randomized prospective studies evaluating the efficacy of neurologic monitoring. Based on clinical experience with neurologic monitoring as well as nonrandomized clinical studies in which neurologic monitoring is utilized and generally compared to historical controls, practice patterns for use of neurologic monitoring have developed. In certain procedures, neurologic monitoring is recommended and used by the majority of centers; it is used almost routinely in some centers but not in others, and there is no clear evidence that it should be recommended for all. Finally, there are procedures in which monitoring is used selectively for patients believed to be at higher-than-usual risk for intraoperative neurologic injury. Table 35-9 provides a summary of current clinical practice.

Chapter 36 - Neuromuscular Monitoring

Jorgen Viby-Mogensen

INTRODUCTION

In 1958, Christie and Churchill-Davidson [1] described how nerve stimulators could be used to assess neuromuscular function objectively during anesthesia. For many years, however, only a few anesthesiologists used nerve stimulators routinely. Instead, the degree of neuromuscular block during and after anesthesia was evaluated with clinical criteria alone. Nevertheless, I believe that the interest in monitoring neuromuscular function during anesthesia has been growing over the past few years: New short- and intermediate-acting nondepolarizing neuromuscular blocking drugs have become available and awareness of the problems of postoperative residual neuromuscular blockade has been increasing. [2] [3]

In awake patients, muscle power can be evaluated through tests of voluntary muscle strength, but during anesthesia and recovery from anesthesia this is not possible. Instead, the clinician uses clinical tests to assess muscle power directly and to estimate neuromuscular function indirectly (muscle tone, the feel of the anesthesia bag, an indirect measure of pulmonary compliance, tidal volume, and inspiratory force). All of these tests, however, are influenced by factors other than the degree of neuromuscular blockade. Therefore, whenever more precise information regarding the status of neuromuscular functioning is desired, the response of muscle to nerve stimulation should be assessed. This procedure also takes into account the considerable variation in individual response to muscle relaxants. [4]

This chapter reviews the basic principles of peripheral nerve stimulation, the requirements for effective use of nerve stimulators, and the clinical conditions warranting their use. It also describes the response to nerve stimulation during depolarizing (phase I and phase II) and nondepolarizing neuromuscular blocks. Finally, the chapter discusses methods of evaluating evoked neuromuscular responses both with and without the availability of recording equipment.

PRINCIPLES OF PERIPHERAL NERVE STIMULATION

Neuromuscular function is monitored by evaluating the muscular response of muscle to supramaximal electrical stimulation of a peripheral motor nerve. The reaction of a single muscle fiber to a stimulus follows an all-or-none pattern. By contrast, the response of the whole muscle depends on the number of muscle fibers activated. If a nerve is stimulated with sufficient intensity, all muscle fibers supplied by the nerve will react, and the maximum response will be triggered. After administration of a neuromuscular blocking drug, the response of the muscle decreases in parallel with the number of fibers blocked. The reduction, in response during constant stimulation, reflects the degree of neuromuscular blockade.

For the preceding principles to be in effect, the stimulus must be truly maximal throughout the period of monitoring;

---

therefore, the electrical stimulus applied is usually at least 20 to 25 percent above that necessary for a maximal response. For this reason, the stimulus is said to be supramaximal; however, supramaximal stimulation hurts, which is not a concern during anesthesia, but during recovery the patient may be awake enough to experience the discomfort of nerve stimulation. Therefore, some researchers advocate stimulation with submaximal current during recovery. Although several investigations indicate that testing of neuromuscular function can be reliably performed postoperatively using submaximal stimulation, [5] [6] [7] the accuracy of the monitoring is unacceptable at low current. [8] As a result, supramaximal stimulation should be used when possible. The character of the waveform produced by the electrical impulse and the length of the stimulus are also important. [9] The impulse should be monophasic and rectangular (i.e., it should be a square wave) because a biphasic pulse may cause a burst of action potentials in the nerve (repetitive firing), increasing the response to the stimulation. The optimal pulse duration is 0.2 to 0.3 ms. A pulse exceeding 0.5 ms may stimulate the muscle directly or cause repetitive firing.

PATTERNS OF NERVE STIMULATION

Traditionally, evaluation of neuromuscular function has used three patterns of electrical stimulation: single-twitch, train-of-four (TOF), and tetanic nerve stimulation. Two newer modes are also available: post-tetanic count (PTC) stimulation and double-burst stimulation (DBS).

Single-Twitch Stimulation

In the single-twitch mode of stimulation, single supramaximal electrical stimuli are applied to a peripheral motor nerve at frequencies ranging from 1.0 Hz (once every second) to 0.1 (once every 10 seconds) (Fig. 36-1) (Figure Not Available) . The response to single-twitch stimulation depends on the frequency with which the individual stimuli are applied. If the rate of delivery is increased to more than 0.15 Hz, the evoked response will gradually decrease and settle at a lower level. [10] As a result, a frequency of 0.1 Hz is generally used. Because 1-Hz stimulation shortens the time necessary to determine supramaximal stimulation, this frequency is sometimes employed during induction of anesthesia; however, the apparent time of onset and length of neuromuscular blockade depend on the pattern and duration of stimulation. Therefore, results obtained using 1-Hz single-twitch stimulation cannot be compared with results obtained by using, for instance, 0.1-Hz single-twitch stimulation or TOF stimulation. [11]

Train-of-Four Stimulation

In TOF nerve stimulation, introduced by Ali et al [12] during the early 1970s, four supramaximal stimuli are given every 0.5 seconds (2 Hz) (Fig. 36-2) (Figure Not Available) . When used continuously, each set (train) of stimuli normally is repeated every 10th to 12th second. Each stimulus in the train causes the muscle to contract, and "fade" in the response provides the

Figure 36-1 (Figure Not Available) Pattern of electrical stimulation and evoked muscle responses to single-twitch nerve stimulation (at frequencies of 0.1 to 1.0 Hz) after injection of nondepolarizing *(Non-dep)* and depolarizing *(Dep)* neuromuscular blocking drugs *(arrows).* Note that except for the difference in time factors, no differences in the strength of the evoked responses exist between the two types of block. *(From Viby-Mogensen J [10C])*

basis for evaluation. That is, dividing the amplitude of the fourth response by the amplitude of the first response provides the TOF ratio. In the control response (the response obtained before administration of muscle relaxant), all four responses are ideally the same: The TOF ratio is 1.0. During a partial nondepolarizing block, the ratio decreases ("fades") and is inversely proportional to the degree of blockade. During a partial depolarizing block, no fade occurs in the TOF response; ideally, the TOF ratio is approximately 1.0. Fade in the TOF response after injection of succinylcholine signifies the development of a phase II block (discussed later in the *Depolarizing Neuromuscular Blockade* section).

The advantages of TOF stimulation are greatest during nondepolarizing blockade, as the degree of block can be

Figure 36-2 (Figure Not Available) Pattern of electrical stimulation and evoked muscle responses to TOF nerve stimulation before and after injection of nondepolarizing *(Non-dep)* and depolarizing *(Dep)* neuromuscular blocking drugs *(arrows). (From Viby-Mogensen J [10C])*

read directly from the TOF response, even though a preoperative value is lacking. [13] [14] [15] In addition, TOF stimulation has some advantages over tetanic stimulation: It is less painful and, unlike tetanic stimulation, generally does not affect the degree of neuromuscular blockade. However, onset and recovery of neuromuscular blockade after succinylcholine and atracurium were different with 0.08-Hz single-twitch stimulation and TOF stimulation. Although statistically significant, these differences were too small to be clinically important. [11] Also, it has been found that increasing periods of control TOF stimulations before injection of a nondepolarizing muscle relaxant may decrease the onset time and increase the duration of clinical relaxation. [16] [17]

Tetanic Stimulation

Tetanic stimulation consists of very rapid (e.g., 30-, 50-, or 100-Hz) delivery of electrical stimuli. The most commonly used pattern in clinical practice is 50-Hz stimulation given for 5 seconds, although some investigators have advocated the use of 50-, 100-, and even 200-Hz stimulation for 1 second. [18] During normal neuromuscular transmission and a pure depolarizing block, the muscle response to 50-Hz tetanic stimulation for 5 seconds is sustained. During a nondepolarizing block and a phase II block after succinylcholine, the response will not be sustained (i.e., fade occurs) (Fig. 36-3) (Figure Not Available) .

Figure 36-3 (Figure Not Available) Pattern of stimulation and evoked muscle responses to tetanic (50-Hz) nerve stimulation for 5 seconds (Te) and post-tetanic stimulation (1.0-Hz) twitch. Stimulation was applied before injection of neuromuscular blocking drugs and during moderate nondepolarizing and depolarizing blocks. Note fade in the response to tetanic stimulation, plus post-tetanic facilitation of transmission during nondepolarizing blockade. During depolarizing blockade, the tetanic response is well sustained and no post-tetanic facilitation of transmission occurs. *(From Viby-Mogensen J [10C])*

Fade in response to tetanic stimulation is normally considered a presynaptic event, and the traditional explanation is that at the start of tetanic stimulation, large amounts of acetylcholine are released from immediately available stores in the nerve terminal. As these stores become depleted, the rate of acetylcholine release decreases until equilibrium between mobilization and synthesis of acetylcholine is achieved. Despite this equilibrium, the muscle response caused by tetanic stimulation of the nerve at, for example, 50 Hz, is maintained (given normal neuromuscular transmission) simply because the release of acetylcholine is many times greater than the amount necessary to evoke a response. When the "margin of safety" of the postsynaptic membrane (i.e., the number of free cholinergic receptors) is reduced by a nondepolarizing neuromuscular blocking agent, the decrease in release of acetylcholine during tetanic stimulation produces "fade." [19] In addition to blocking the postsynaptic receptors, nondepolarizing neuromuscular blocking drugs may also impair the mobilization of acetylcholine within the nerve terminal. This effect may contribute to the fade in the response to tetanic (and TOF) stimulation. The degree of fade depends primarily on the degree of neuromuscular blockade. Fade also depends on the frequency (Hz) and the length (seconds) of stimulation and on how often tetanic stimuli are applied. Unless these variables are kept constant, results from different studies using tetanic stimulation cannot be compared.

During partial nondepolarizing blockade, tetanic nerve stimulation is followed by a post-tetanic increase in twitch tension (i.e., post-tetanic facilitation of transmission [PTF]) (see Fig. 36-3) (Figure Not Available) . This event occurs because the increase in mobilization and synthesis of acetylcholine caused by tetanic stimulation continues for some time after discontinuation of stimulation. The degree and duration of PTF depend on the degree of neuromuscular blockade, with PTF usually disappearing within 60 seconds of tetanic stimulation. PTF is evident in electromyographic (EMG), acceleromyographic, and mechanical recordings during a partial nondepolarizing neuromuscular blockade. By contrast, post-tetanic twitch potentiation, which sometimes occurs in mechanical recordings before any neuromuscular blocking drug has been given, is a muscular phenomenon that is not accompanied by an increase in the compound muscle action potential. [20] [21]

Tetanic stimulation has several disadvantages. It is very painful and therefore normally not acceptable to the unanesthetized patient. Furthermore, especially in the late phase of neuromuscular recovery, tetanic stimulations may produce a lasting antagonism of neuromuscular blockade in the stimulated muscle, such that the response of the tested site may no longer be representative of other muscle groups. [22] [23]

Traditionally, tetanic stimulation has been used to evaluate residual neuromuscular blockade. Except in connection with the technique of post-tetanic count, however, tetanic stimulation has very little place in everyday clinical anesthesia. If the response to nerve stimulation is recorded, all the information required can be obtained from the response to TOF nerve stimulation. By contrast, if the response to nerve stimulation is evaluated only by feel [24] or by eye (VibyMogensen et al, unpublished observation), even experienced observers are unable to judge the response of tetanic

stimulation with sufficient certainty to exclude residual neuromuscular blockade.

Post-Tetanic Count Stimulation

Injection of a nondepolarizing neuromuscular blocking drug in a dose sufficient to ensure smooth tracheal intubation causes intense neuromuscular blockade of the peripheral muscles. Because no response to TOF and single-twitch stimulation occurs under these conditions, those modes of stimulation cannot be used to determine the degree of blockade. It is possible, however, to quantify intense neuromuscular blockade of the peripheral muscles by applying tetanic stimulation (50 Hz for 5 sec) and observing the post-tetanic response to single-twitch stimulation given at 1 Hz starting 3 seconds after the end of tetanic stimulation. [25] During very intense blockade, there is no response to either tetanic or post-tetanic stimulation (Fig. 36-4) . However, when the very intense neuromuscular blockade dissipates and before the first response to TOF stimulation reappears, the first response to post-tetanic twitch stimulation occurs. For example, after injection of pancuronium (0.1 mg/kg) for tracheal intubation, the response to post-tetanic twitch stimulation appears approximately 37 minutes before the first reaction to TOF stimulation. [25] The corresponding figures for atracurium (0.5 mg/kg) and vecuronium (0.1 mg/kg) vary from 7 to 8 minutes. [26] [27] As the intense block dissipates, more and more responses to post-tetanic twitch stimulation appear. For a given neuromuscular blocking drug, the time until return of the first response to TOF stimulation is related to the number of post-tetanic twitch responses present at a given time (the post-tetanic count) (Fig. 36-5) (Figure Not Available) .

The main application of the PTC method is in evaluating the degree of neuromuscular blockade when there is no reaction to single twitch or TOF nerve stimulation, as may be the case after injection of a large dose of a nondepolarizing neuromuscular

Figure 36-4 Pattern of electrical stimulation and evoked muscle responses to TOF nerve stimulation, 50 Hz tetanic nerve stimulation for 5 seconds (TE), and 1.0 Hz post-tetanic twitch stimulation (PTS) during four different levels of nondepolarizing neuromuscular blockade. During very intense blockade of the peripheral muscles (A), no response to any of the forms of stimulation occurs. During less pronounced blockade (B and C), there is still no response to stimulation, but post-tetanic facilitation of transmission is present. During surgical block (D), the first response to TOF appears and post-tetanic facilitation increases further. The post-tetanic count (see text) is 1 during intense block (B), 3 during less intense block (C), and 8 during surgical block (D).

Figure 36-5 (Figure Not Available) Relationship between time to the first reaction to TOF nerve stimulation and the number of post-tetanic twitches (i.e., the post-tetanic count) during intense blockade caused by pancuronium, atracurium, and vecuronium. Mean curves and 95 percent prediction regions are shown. *(From Viby-Mogensen J [10C])*

blocking drug. However, PTC can also be used whenever sudden movements must be eliminated (e.g., during ophthalmic surgery). The necessary level of block of the adductor pollicis muscle to ensure paralysis of the diaphragm depends on the type of anesthesia and, in the intensive care unit (ICU), on the level of sedation. [28] [29] To ensure elimination

Figure 36-6 (Figure Not Available) Relationship between the rate of muscle response to stimulation of the tracheal carina and the degree of neuromuscular blockade of peripheral muscles, as evaluated by using post-tetanic count. The subjects were 25 patients anesthetized with thiopental, nitrous oxide, and fentanyl who were given vecuronium (0.1 mg/kg) for tracheal intubation. For comparison, the first response to TOF stimulation usually occurs when PTC is approximately 10 (range, 6 to 16). The carina was stimulated with a soft sterile rubber suction catheter introduced via the endotracheal tube. The total response consisted of mild responses plus severe response. A mild response was said to occur if stimulation of the carina induced only slight bucking that did not interfere with surgery. A severe response was said to occur if stimulation elicited bucking that interfered with surgery and required intervention. Elimination of severe responses requires an intense neuromuscular blockade; PTC must be less than 2 to 3, and elimination of all reactions requires that PTC be 0. *(From Fernando PUE et al. [26] Copyright 1987, Munksgaard International Publishers, Ltd. Copenhagen, Denmark)*

of any bucking or coughing in response to tracheobronchial stimulation, neuromuscular blockade of the peripheral muscles must be so intense that no response to post-tetanic twitch stimulation can be elicited (PTC-0) (Fig. 36-6) (Figure Not Available) . [28]

The response to PTC stimulation depends primarily on the degree of neuromuscular blockade. It also depends on the frequency and duration of tetanic stimulation, the length of time between the end of tetanic stimulation and the first post-tetanic stimulus, the frequency of the single-twitch stimulation, and also (probably) the length of single-twitch stimulation before tetanic stimulation. When the PTC method is used, these variables should therefore be kept constant. Also, because of possible antagonism of neuromuscular blockade in the hand, tetanic stimulation should not be given more often than every 6 minutes. [30] If the hand muscles undergo antagonism of neuromuscular blockade while the rest of the body is still paralyzed, the hand muscles are no longer useful for monitoring.

Double-Burst Stimulation

DBS was developed with the specific aim of allowing manual (tactile) detection of small amounts of residual neuromuscular blockade under clinical conditions. [31] During recovery from neuromuscular blockade, the degree of residual block can be evaluated from recorded responses to TOF nerve stimulation. Without recording equipment, however, it is not possible by visual or tactile means to evaluate the TOF response with certainty to exclude shallow degrees of residual neuromuscular blockade. [32] With DBS (as opposed to TOF stimulation), it is easier to "feel" fade in the response. [33]

DBS consists of two short bursts of 50-Hz tetanic stimulation separated by 750 ms. The duration of each square wave impulse in the burst is 0.2 ms (Fig. 36-7) . Although the number of impulses in each burst can vary, initial studies indicate that DBS with three impulses in each of the two tetanic bursts ($DBS_{3,3}$) is suitable for clinical use. Studies are currently evaluating the suitability of other types of DBS. [34] [35] [36]

Figure 36-7 Pattern of electrical stimulation and evoked muscle responses to TOF nerve stimulation and double-burst nerve stimulation (i.e., three impulses in each of two tetanic bursts, $DBS_{3,3}$) before injection of muscle relaxants (control) and during recovery from nondepolarizing neuromuscular blockade. TOF ratio = the amplitude of the fourth response to TOF divided by the amplitude of the first response. $DBS_{3,3}$ ratio = the amplitude of the second response to $DBS_{3,3}$ divided by the amplitude of the first response. (See text for further explanation.)

Figure 36-8 Fade detectable by feel in the response to TOF and double-burst stimulation ($DBS_{3,3}$) in relation to the true TOF ratio, as measured mechanically. The axis indicates the percentage of instances in which fade can be felt at a given true TOF ratio. [32] [33] A TOF ratio of 0.70 to 0.75 is normally taken to reflect adequate recovery of neuromuscular function, [86] so that ideally fade should be felt in all patients with a TOF ratio below 0.7 and in no patients with a ratio above 0.7 (the "ideal curve"). (This figure was based on an idea originating with N. Ueda, Kurume University, Japan).

In nonparalyzed muscle, the response to $DBS_{3,3}$ is two short muscle contractions of equal strength. In the partly paralyzed muscle, the second response is weaker

than the first (i.e., the response fades) (see Fig. 36-7) . Measured mechanically, the TOF ratio correlates closely with the $DBS_{3,3}$ ratio. During recovery and immediately after surgery, tactile evaluation of the response to $DBS_{3,3}$ is superior to tactile evaluation of the response to TOF stimulation. [33] [37] [38] However, as appears from Figure 36-8 , absence of fade in the manually evaluated response to $DBS_{3,3}$ does not exclude residual neuromuscular blockade. [39]

THE NERVE STIMULATOR

Although many nerve stimulators are commercially available, not all meet the basic requirements for clinical use. The stimulus should produce a monophasic and rectangular waveform, and the length of the pulse should not exceed 0.2 to 0.3 ms. Stimulation at a constant current is preferable to stimulation at a constant voltage because current is the determinant of nerve stimulation. Also, for safety reasons, the nerve stimulator should be battery operated, include a battery check, and be able to generate 60 to 70 mA, but not more than 80 mA. Many commercially available stimulators can deliver only 25 to 50 mA and a constant current only when skin resistance ranges from 0 to 2.5 k. This deficiency is a disadvantage; during cooling, skin resistance may increase to approximately 5 k, which may cause the current delivered to the nerve to fall below the supramaximal level, leading to a decrease in the response to stimulation. As a result, the anesthesiologist may misjudge the degree of neuromuscular blockade. Ideally, the nerve stimulator should have a built-in warning system or a current level display that alerts the user when the current selected is not delivered to the nerve.

The ideal nerve stimulator should have other features as well. The polarity of the electrodes should be indicated. Also, the apparatus should be capable of delivering the following modes of stimulation: TOF (as both a single train and in a repetitive mode, with TOF stimulation being given every 10-20 sec); single-twitch stimulations at 0.1 and 1.0 Hz; and tetanic stimulation at 50 Hz. In addition, the stimulator should have a built-in time constant system to facilitate post-tetanic count. Tetanic stimulus should last 5 seconds and be followed 3 seconds later by the first post-tetanic stimulus. At least one DBS mode should be available, preferably DBS $_{3,3}$. Single-twitch stimulation at 1 Hz is useful during initiation of monitoring because it shortens the time necessary to determine supramaximal stimulation. Most investigators agree that there is no need for tetanus at 100 or 200 Hz because 50-Hz tetanic stimulation stresses neuromuscular function to the same extent as does a maximal voluntary effort. [40] Furthermore, in contrast to 100- and 200-Hz stimulation, 50-Hz tetanic stim-ulation does not cause fatigue (fade) in nonparalyzed muscle. [20] [21]

THE STIMULATING ELECTRODES

Electrical impulses are transmitted from stimulator to nerve by means of surface or needle electrodes, the former being the more commonly used in clinical anesthesia. Two basic types of surface electrodes exist: rubber electrodes and disposable pregelled silver or silver chloride electrodes. Both types can be used equally well, provided the actual conducting area is small, approximately 7 to 8 mm in diameter. Otherwise, the current produced in the underlying nerve may not be adequate. Rubber electrodes should not be allowed to become old because impedance of the electrodes increases with time. The skin should always be cleansed properly and preferably rubbed with an abrasive before application of the electrodes. When a supramaximal response cannot be obtained by using surface electrodes, needle electrodes should be used. Although specially coated needle electrodes are commercially available, ordinary steel injection needles can be used as well. The needles should be placed subcutaneously but never in a nerve.

SITES OF NERVE STIMULATION AND DIFFERENT MUSCLE RESPONSES

In principle, any superficially located peripheral motor nerve may be stimulated. In clinical anesthesia, the ulnar nerve is the most popular site; the median, the posterior tibial, common peroneal, and facial nerves are also sometimes used. For stimulation of the ulnar nerve, the electrodes are best applied at the volar side of the wrist (Fig. 36-9) (Figure Not Available) . The distal electrode should be placed about 1 cm proximal to the point at which the proximal flexion crease of the wrist crosses the radial side of the tendon to the flexor carpi ulnaris muscle. The proximal electrode preferably should be placed 2 to 5 cm proximal to the distal electrode. With this placement of the electrodes, electrical stimulation normally elicits only finger flexion and thumb adduction. If the one electrode is placed over the ulnar groove at the elbow, thumb adduction is often pronounced because of stimulation of the flexor carpi ulnaris muscle. When this latter placement of electrodes (sometimes preferred in small children) is used, the active negative electrode should be at the wrist to ensure a maximal response. [41] [42] Polarity of the electrodes is less crucial when both electrodes are close to each other at the volar side of the wrist; however, placement of the negative electrode distally normally elicits the greatest neuromuscular response. [43] When the temporal branch of the facial nerve is stimulated, the negative electrode should be placed over the nerve, and the positive electrode should be placed somewhere else over the forehead.

Because different muscle groups have different sensitivities to neuromuscular blocking agents, [44] results obtained for one muscle cannot be extrapolated automatically to other muscles. The diaphragm is among the most resistant of all muscles to both depolarizing [45] and nondepolarizing [46] neuromuscular blocking drugs. In general, the diaphragm requires 1.4 to 2.0 times as much muscle relaxant as the adductor pollicis muscle for an identical degree of blockade (Fig. 36-10) (Figure Not Available) . [46] Also of clinical significance are the facts that onset time is normally shorter for the diaphragm than for

Figure 36-9 (Figure Not Available) Evaluation of neuromuscular blockade by feeling the response of the thumb to stimulation of the ulnar nerve. *(Courtesy of Organon Teknika, Boxtel, Holland).*

Figure 36-10 (Figure Not Available) Mean cumulative dose-response curve for pancuronium in two muscles shows that the diaphragm requires approximately twice as much pancuronium as does the adductor pollicis muscle for the same amount of neuromuscular blockade. The depression in muscle response to the first stimulus in TOF nerve stimulation (probit scale) was plotted against dose (log scale). Force of contraction of the adductor pollicis was measured on a force-displacement transducer; response of the diaphragm was measured electromyographically. *(From Donati F [46])*

the adductor pollicis muscle and that the diaphragm recovers from paralysis more quickly than do the peripheral muscles (Fig. 36-11) (Figure Not Available) . [47] Less resistant than the diaphragm are the other respiratory muscles, as well as the larynx and the orbicularis oculi muscle. [48] [49] [50] [51] Most sensitive are the abdominal muscles, the peripheral muscles of the limbs, the geniohyoid muscle, the masseter, and the upper airway muscles. [52] [53] [54] [55] [56] From a practical clinical point of view, it is worth noting that (1) the orbicularis oculi response to facial nerve stimulation reflects the extent of neuromuscular blockade of the diaphragm better than does the response of the adductor pollicis to ulnar nerve stimulation, [38] and (2) the upper airway muscles seem to be more sensitive than peripheral muscles, at least to pancuronium. [53] [54] Although three recent investigations using acceleromyography have indicated small differences in the response to TOF nerve stimulation in the arm (adductor pollicis muscle) and the leg (flexor hallucis brevis muscle), these differences are probably of little clinical significance. [58] [59] [60]

The precise source of these differences is unknown. Possible causes may be differences in the margin of safety of the neuromuscular junction of different muscle groups, fiber composition, innervation ratio (number of neuromuscular junctions), blood flow, and muscle temperature.

In assessing neuromuscular function, the use of a relatively sensitive muscle such as the adductor pollicis of the hand has both disadvantages and advantages. Obviously, during surgery it is a disadvantage that even total elimination

Figure 36-11 (Figure Not Available) Evolution of twitch height (mean ± SD) of the diaphragm *(closed circles)* and of the adductor pollicis muscle (open circles) in 10 anesthetized patients after administration of atracurium 0.6 mg/kg. *(From Pansard J-L [47])*

of the response to single-twitch and TOF stimulation does not exclude the possibility of movement of the diaphragm, such as hiccuping and coughing. With the introduction of PTC, however, which allows for evaluation of the very intense blockade necessary to ensure total paralysis of the diaphragm, this problem has diminished. On the positive side, the chance of overdosing the patient decreases if the response of a relatively sensitive muscle is used as a guide to the administration of muscle relaxants during surgery. Also, during recovery, when the adductor pollicis has recovered sufficiently, it can be assumed that no residual neuromuscular blockade exists in the diaphragm.

RECORDING OF EVOKED RESPONSES

The choice of recording method is a practical decision. Three methods are available: measurement of evoked mechanical responses (mechanomyography), measurement of evoked electrical responses (EMG), and measurement of acceleration of the muscle response.

Mechanomyography

A requirement for correct and reproducible measurements of evoked tension is that the muscle contraction be isometric. In clinical anesthesia, this condition is most easily achieved by measuring thumb movement after application of a resting tension of 200 to 300 g (a preload) to the thumb. When the ulnar nerve is stimulated, the thumb (the adductor pollicis muscle) acts on a force-displacement transducer. The force of contraction is then converted into an electrical signal, which is amplified, displayed, and recorded. The arm and hand should be fixed rigidly, and care should be taken to prevent overloading of the transducer. [20] Also, the transducer should be placed in correct relationship to the thumb (i.e., the thumb should always apply tension precisely along the length of the transducer). It is important to remember that the response to nerve stimulation depends on the frequency with which the individual stimuli are applied and that the time used to achieve a stable control response may influence the subsequent determination of onset time and duration of block. [16] [17] [61] [62] Generally, the reaction to supramaximal stimulation increases during the first 8 to 12 minutes after commencement of the stimulation. Therefore, in clinical studies, control measurements (before injection of muscle relaxant) should not be made before the response has stabilized for 8 to 12 minutes or a 2-second or 5-second 50-Hz tetanic stimulation has been given. [62] Even then, twitch response often recovers to 110 to 150 percent of the control response after paralysis with succinylcholine. This increase in response, thought to be caused by a change in the contractile response of the muscle, normally disappears within 15 to 25 minutes.

Although numerous methods for mechanical recording of evoked mechanical responses exist, [15] [63] [64] not all meet the criteria outlined.

Electromyography

Evoked EMG records the compound action potentials produced by stimulation of a peripheral nerve. The compound action potential is a high-speed event that for many years could only be picked up by means of a preamplifier and a storage oscilloscope. Modern neuromuscular transmission analyzers are able to make on-line electronic analyses and graphic presentations of the EMG response.

The evoked EMG response is most often obtained from muscles innervated by the ulnar or the median nerves. Stimulating electrodes are applied as in force measurements. Although both surface and needle electrodes may be used for recording, no advantage is obtained by using the latter. Most often, the evoked EMG is obtained from the thenar or hypothenar eminence of the hand or from the first dorsal interosseous muscle of the hand, preferably with the active electrode over the motor point of the muscle (Fig. 36-12) (Figure Not Available) . The signal picked up by the analyzer is processed by an amplifier, a rectifier, and an electronic integrator. The results are displayed either as a percentage of control or as a TOF ratio.

Evoked electrical and mechanical responses represent different physiologic events. Evoked EMG records changes

in electrical activity of one or more muscles, whereas evoked mechanomyography records changes associated with excitation-contraction coupling and the contraction of the muscle as well. For these reasons, the results obtained with these methods may differ. [65] [66] [67] Although evoked EMG responses generally correlate well with evoked mechanical responses, [68] marked differences may occur, especially in the response to succinylcholine and in the TOF ratio during recovery from a nondepolarizing block. [65] [66] [67] [68]

So far, only one study has correlated the evoked EMG response with clinical criteria of adequate recovery of neuromuscular function. [68] This study compared clinical recovery from atracurium-induced blockade with TOF ratios meas-ured simultaneously by evoked electrical and mechanical responses. These two types of evoked responses were very similar in their relationship to clinical recovery. More studies are needed to correlate the evoked EMG responses with clinical criteria of surgical relaxation and adequacy of recovery from neuromuscular blockade.

In theory, recording of evoked EMG has several advantages over recording of evoked mechanical responses. Equipment for measuring evoked EMG responses is easier to set up, the response reflects only those factors influencing neuromuscular transmission, and the response can be obtained from muscles not accessible to mechanical recording. However, evoked EMG does entail some difficulties. Although good recordings are possible in most patients, results are not always reliable. For one thing, improper placement of electrodes may result in inadequate pickup of the compound EMG signal. If the neuromuscular transmission analyzer does not allow observation of the actual waveform of the compound EMG, determining the optimal placement of the electrodes is difficult. Another source of unreliable results may be that fixation of the hand with a preload on the thumb may be more important than generally appreciated, [68] [69] as changes in the position of the electrodes in relationship to the muscle may affect the EMG response. In addition, direct muscle stimulation sometimes occurs. If muscles close to the stimulating electrodes are stimulated directly, the recording electrodes may pick up an electrical signal even though neuromuscular transmission is completely blocked. Another difficulty is that the EMG response often does not return to control value. Whether this situation is the result of technical problems, inadequate fixation of the hand or changes in temperature is unknown (Fig. 36-13) (Figure Not Available) . Finally, the evoked EMG response is very sensitive

Figure 36-13 (Figure Not Available) Evoked electromyographic printout from a Relaxograph. Initially, single-twitch stimulation was given at 0.1 Hz, and vecuronium (70 mug/kg) was given intravenously for tracheal intubation. After approximately 5 minutes, the mode of stimulation was changed to TOF stimulation every 60 seconds. At a twitch height (first twitch in TOF response) of approximately 30 percent of control (marker 1), 1 mg of vecuronium was given intravenously. At marker 2, 1 mg of neostigmine was given intravenously, preceded by 2 mg of glycopyrrolate. The printout also illustrates the common problem of failure of the electromyographic response to return to control level. *(Courtesy of Datex-Ohmeda, Helsinki, Finland).*

to electrical interference, such as that caused by diathermy.

Acceleromyography

The technique of acceleromyography is based on Newton's second law: force equals mass times acceleration. [70] If mass is constant, acceleration is directly proportional to force. Accordingly, after nerve stimulation, one can measure not only the evoked force but also the acceleration of the thumb.

Acceleromyography uses a piezoelectric ceramic wafer with electrodes on both sides (Fig. 36-14) . Exposure of the electrode to a force generates an electrical voltage proportional to the acceleration of the thumb in response to nerve stimulation. When the accelerometer is fixed to the thumb and the ulnar nerve is stimulated, an electrical signal is produced whenever the thumb moves. This signal is then analyzed in a specially designed analyzer [71] or perhaps displayed on a recording system. At least three detached monitors based on measurement of acceleration are commercially available: The TOF-Guard, the TOF-Watch (both from Organon Teknika, Boxtel, Holland), and the ParaGraph Neuromuscular Blockade Monitor (Vital Signs Inc., Totowa, NJ). Furthermore, a unit, the Neuromuscular Transmission Module, M-NMT, based on the same principle, is part of the Datex AS/3 monitoring system (Datex-Ohmeda, Helsinki, Finland).

Acceleromyography is a simple method of analyzing neuromuscular function, both in the operating room and in the intensive care unit. [72] [73] One requirement is that the muscle be able to move freely. During a nondepolarizing neuromuscular blockade, good correlation exists between the TOF ratio measured by this method and TOF ratio measured with

Figure 36-14 TOF-Watch (Organon Teknika, Boxtel, Holland). This neuromuscular transmission monitor is based on measurement of acceleration using a piezo-electric transducer. [46] [47] Note the transducer fastened to the thumb and the stimulating electrodes. At the display of the TOF-Watch, note the TOF ratio given in percentage.

a force-displacement transducer [70] [71] [74] or using electromyography. [75] Also, the precision of acceleromyography seems to be comparable to that of mechanical measurements. [76]

Some questions still exist, however, regarding the use of this method of measurement that was primarily introduced for clinical use. [70] [71] The control TOF ratio is consistently higher than when measured using a force-displacement transducer. Therefore, measurements made with an accelerometer for scientific purposes are not directly comparable with results obtained with a force-displacement transducer [77] [78] [79] or with electromyography. [75]

For further information on recording evoked responses, the reader is referred to guidelines for Good Clinical Research Practice in pharmacodynamic studies of neuromuscular blocking agents, published in *Acta Anaesthesiologica Scandinavica* 40:59-74, 1996. [61]

EVALUATION OF RECORDED EVOKED RESPONSES

Nerve stimulation in clinical anesthesia is usually synonymous with TOF nerve stimulation. Therefore, the recorded response to this form of stimulation is used to explain how to evaluate the degree of neuromuscular blockade during clinical anesthesia.

Nondepolarizing Neuromuscular Blockade

After injection of a nondepolarizing neuromuscular blocking drug in a dose sufficient for smooth tracheal intubation, TOF recording demonstrates three phases or levels

---

Figure 36-15 (Figure Not Available) Diagram of the changes in response to TOF nerve stimulation during nondepolarizing neuromuscular blockade. *(From Viby-Mogensen J [101])*

of neuromuscular blockade: intense blockade, moderate or surgical blockade, and recovery (Fig. 36-15) (Figure Not Available) .

Intense Neuromuscular Blockade

Intense neuromuscular blockade occurs within 3 to 6 minutes of injection of an intubating dose of a nondepolarizing muscle relaxant, depending on the drug and the dose given. This phase is also called the "period of no response" because no response to TOF or single-twitch stimulation occurs. The length of this period varies, again depending primarily on the duration of action of the muscle relaxant and the dose given. The sensitivity of the patient to the drug also affects the period of no response. Although during this phase, it is not possible to determine exactly how long intense neuromuscular blockade will last, correlation does exist between PTC and time to reappearance of the first response to TOF stimulation (see Fig. 36-5) (Figure Not Available) .

Moderate or Surgical Blockade

Moderate or surgical blockade begins when the first response to TOF stimulation appears. This phase is characterized by a gradual return of the four responses to TOF stimulation. Furthermore, good correlation exists between the degree of neuromuscular blockade and the number of responses to TOF stimulation. When only one response is detectable, the degree of neuromuscular blockade (the depression in twitch tension) is 90 to 95 percent. When the fourth response reappears, neuromuscular blockade is usually 60 to 85 percent. [14] [80] [81] The presence of one or two responses in the TOF pattern normally indicates sufficient relaxation for most surgical procedures. During light anesthesia, however, patients may move, buck, or cough. Therefore, when elimination of sudden movements is crucial, a more intense block (or a deeper level of anesthesia) may be necessary. The more intense block can then be evaluated by using the post-tetanic count (see Fig. 36-6) (Figure Not Available) .

Antagonism of neuromuscular blockade should normally not be attempted when blockade is intense because reversal will often be inadequate, regardless of the dose of antagonist administered. [82] Also, after the administration of large doses of muscle relaxants, reversal of the block to clinically normal activity is not always possible if only one response in the TOF is present. In general, antagonism should not be initiated before at least two, or preferably three, responses in the TOF are observed.

Recovery

The return of the fourth response in the TOF heralds the recovery phase. During neuromuscular recovery, a reasonably good correlation exists between the actual TOF ratio and clinical observations, but the relationship between TOF ratio and signs and symptoms of residual blockade varies greatly among patients. [83] When the TOF ratio is 0.4 or less, the patient is generally unable to lift the head or arm. Tidal volume may be normal, but vital capacity and inspiratory force will be reduced. When the ratio is 0.6, most patients are able to lift the head for 3 seconds, open the eyes widely, and stick out the tongue, but vital capacity and inspiratory force are often still reduced. At a TOF ratio of 0.7 to 0.75, the patient can normally cough sufficiently, and lift the head for at least 5 seconds, but the grip strength may still be as low as about 60% of control. [83] When the ratio is 0.8 and more, vital capacity and inspiratory force are normal. [13] [84] [85] [86] The patient may, however, still have diplopia and facial weakness (Table 36-1) . [83]

In clinical anesthesia, a TOF ratio of 0.70 to 0.75 or even 0.50, has been thought to reflect adequate recovery of neuromuscular function. [86] [87] However, recent studies have shown that the TOF ratio, whether recorded mechanically or by EMG, must exceed 0.80 or even 0.90 to exclude clinically important residual neuromuscular blockade. [56] [68] [88] [89] [90] Eriksson et al have shown that moderate degrees of neuromuscular block decrease the chemoreceptor sensitivity to hypoxia, leading to insufficient response to a decrease in oxygen tension in blood. [88] [89] They also showed that residual block (TOF < 0.90) is associated with functional impairment of the muscles of the pharynx and upper esophagus, most probably predisposing to regurgitations and aspiration. [56]

TABLE 36-1 -- Clinical Signs and Symptoms of Residual Paralysis in Awake Volunteers After Mivacurium-Induced Neuromuscular Block [83]

TOF ratio	Diplopia and visual disturbances
0.70-0.75	Decreased hand-grip strength
	Inability to maintain incisor teeth apposition
	"Tongue depressor test" negative
	Inability to sit up without assistance
	Severe facial weakness
	Speaking a major effort
	Overall weakness and tiredness
TOF ratio	Diplopia and visual disturbances

0.85-0.90	Generalized fatigue

In accordance with this, it has recently been documented that residual block (TOF < 0.70) caused by the long-acting muscle relaxant, pancuronium, is a significant risk factor for the development of postoperative pulmonary complications (Table 36-2 and Fig. 36-16) . [90] Available evidence indicates that adequate recovery of neuromuscular function requires return of the TOF ratio to
0.90, which cannot be guaranteed without the use of mechano-, electro, or acceleromyography. [91] [92] [93]

Depolarizing Neuromuscular Blockade (Phase I and II Blocks)

Patients with normal plasma cholinesterase activity who are given a normal dose of succinylcholine (0.5-1.5 mg/kg) undergo a typical depolarizing neuromuscular block (phase I block) (i.e., the response to TOF or tetanic stimulation does not fade, and no post-tetanic facilitation of transmission occurs). By contrast, some patients with genetically determined abnormal plasma cholinesterase activity who are given the same dose of succinylcholine undergo a nondepolarizing-like block characterized by fade in the response to TOF and tetanic stimulation and occurrence of post-tetanic facilitation of transmission (Fig. 36-17) (Figure Not Available) . This type of block is called a phase II block (or dual, mixed, or desensitizing block). Also, phase II blocks sometimes occur in genetically normal patients after prolonged infusion of succinylcholine.

Figure 36-16 Predicted probabilities of postoperative pulmonary complications in different age groups in orthopedic, gynecologic, and major abdominal surgery with a duration of anesthesia of less than 200 minutes. The full lines represent patients having residual neuromuscular block (TOF < 0.70) following the use of pancuronium; the broken lines represent patients with TOF 0.70 following pancuronium and all atracurium and vecuronium patients, independent of the TOF ratio at the end of anesthesia. [90]

TABLE 36-2 -- Relationship Between Train-of-Four Ratio at First Postoperative Recording and Postoperative Pulmonary Complications (POPC) [a]

	PANCURONIUM (n = 226)			ATRACURIUM OR VECURONIUM (N = 450)		
	NO. OF PATIENTS	PATIENTS WITH POPC		*NO. OF PATIENTS*	PATIENTS WITH POPC	
		n	%		*n*	%
TOF 0.70	167	8	4.8	426	23	5.4
TOF < 0.70	59	10	16.9 [b]	24	1	4.2

[a] Results from a prospective, randomized, and blinded study of postoperative POPC in a total of 691 adult patients undergoing abdominal, gynecologic, or orthopedic surgery, receiving either pancuronium, atracurium, or vecuronium. [90] In 4 of the 46 patients with POPC (1 in the pancuronium group and 3 in the atracurium-vecuronium groups) the TOF ratio was not available. Because there were no significant differences in the two groups of patients given the intermediate-acting muscle relaxants, the data from these groups are pooled.
[b] $P < 0.02$ compared with patients in the same group with TOF ratio 0.70.

Figure 36-17 (Figure Not Available) Typical recording of the mechanical response (Myograph 2000) to TOF nerve stimulation of the ulnar nerve after injection of succinylcholine, 1 mg/kg *(arrow)* in a patient with genetically determined abnormal plasma cholinesterase activity. The prolonged duration of action and the pronounced fade in the response indicate a phase II block. *(From Viby-Mogensen J [94])*

From a therapeutic point of view, a phase II block in normal patients must be differentiated from a phase II block in patients with abnormal cholinesterase activity. In normal patients, a phase II block can be antagonized by administering a cholinesterase inhibitor a few minutes after discontinuation of succinylcholine. [94] In patients with abnormal genotypes, the effect of intravenous injection of an acetylcholinesterase inhibitor (e.g., neostigmine) is unpredictable. For example, neostigmine can potentiate the block dramatically, temporarily improve neuromuscular transmission, and then potentiate the block or partially reverse the block, all depending on the time elapsed since administration of succinylcholine and the dose of neostigmine given. [94] Therefore, unless the cholinesterase genotype is known to be normal, antagonism of a phase II block with a cholinesterase inhibitor should be undertaken with extreme caution. Even if the neuromuscular function improves promptly, patient surveillance should continue for at least 1 hour.

USE OF NERVE STIMULATORS WITHOUT RECORDING EQUIPMENT

Although the interest in recording the evoked responses to nerve stimulation during clinical anesthesia is growing, muscle response is usually still evaluated by eye or by feel. Therefore, the anesthesiologist must know how to use a nerve stimulator when recording equipment is unavailable and must be aware of the possible pitfalls of this method. Otherwise, the information obtained from nerve stimulation may not be clinically useful.

First, for supramaximal stimulation, careful cleansing of the skin and proper placement and fixation of electrodes are essential. Second, every effort should be taken to prevent central cooling as well as cooling of the extremity being evaluated. Both central and local surface cooling of the adductor pollicis muscle may reduce the twitch tension and the TOF ratio. [95] [96] Peripheral cooling may affect nerve conduction, decrease the rate of release of acetylcholine [97] and muscle contractility, increase skin impedance, and reduce blood flow to the muscles, thus decreasing the rate of removal of muscle relaxant from the neuromuscular junction. These factors may account for the occasional very pronounced difference in muscle response between a cold extremity and the contralateral warm extremity. [98] Third, when possible, the response to nerve stimulation should be evaluated by feel and not by eye, and the response of the thumb (rather than that of the fifth finger) should be evaluated. Direct stimulation of the muscle often causes subtle movements of the fifth finger when no response is present at the thumb. Finally, the different sensitivities of various muscle groups to neuromuscular blocking agents should always be kept in mind.

Figure 36-18 shows which modes of nerve stimulation can be used at various perioperative times.

Figure 36-18 This diagram shows when the different modes of electrical nerve stimulation can be used during clinical anesthesia. Dark dotted areas indicate appropriate use; light dotted areas, less effective use. Modes of nerve stimulation: TOF = train-of-four stimulation; PTC = post-tetanic count; DBS = double-burst stimulation; and ? = TOF is less useful in the recovery room unless measured using mechano-, electro-, or acceleromyography. (See text for further explanation.)

Use of a Peripheral Nerve Stimulator During Induction of Anesthesia

The nerve stimulator should be attached to the patient before induction of anesthesia but should not be turned on until after the patient is unconscious. Single-twitch stimulation at 1 Hz may be used initially when seeking supramaximal stimulation. However, after supramaximal stimulation has been ensured and before muscle relaxant is injected, the mode of stimulation should be changed to TOF (or 0.1-Hz twitch stimulation). Then, after the response to this stimulation has been observed (the control response), the neuromuscular blocking agent is injected. Although the trachea is often intubated when the response of TOF stimulation disappears, postponement of this procedure for 30 to 90 seconds, depending upon the muscle relaxant used, usually produces better conditions.

Use of a Peripheral Nerve Stimulator During Surgery

If tracheal intubation is facilitated by the administration of succinylcholine (1 mg/kg), no more muscle relaxant should be given until the response to nerve stimulation reappears or until the patient shows other signs of returning neuromuscular function. If the plasma cholinesterase activity is normal, the muscle response to TOF nerve stimulation reappears within 4 to 8 minutes.

When a nondepolarizing neuromuscular drug is used for tracheal intubation, a longer-lasting period of intense blockade usually follows. During this period of no response to TOF and single-twitch stimulation, the time until return of response to TOF stimulation may be evaluated by using post-tetanic count (see Fig. 36-5) (Figure Not Available) .

For most surgical procedures requiring muscle relaxation, a twitch depression of approximately 90 percent will be sufficient, provided the patient is properly anesthetized. If a nondepolarizing relaxant is used, one or two of the responses in TOF can be felt. However, because the respiratory muscles (including the diaphragm) are less sensitive to neuromuscular blocking agents than are the peripheral muscles, the patient may breathe, hiccup, or even cough at this depth of block. To ensure paralysis of the diaphragm, neuromuscular blockade of the peripheral muscles must be so intense that PTC is zero in the thumb.

An added advantage of keeping the neuromuscular blockade at a level of one or two responses to TOF stimulation is that antagonism of the block is facilitated at the end of surgery.

Use of a Peripheral Nerve Stimulator During Reversal of Neuromuscular Blockade

Antagonism of a nondepolarizing neuromuscular block should not be initiated before at least two, and preferably three or four, responses to TOF stimulation can be felt or before obvious clinical signs of returning neuromuscular function are present. If all four responses to TOF stimulation can be felt before injection of the cholinesterase inhibitor, reversal is normally sufficient in less than 10 minutes, even when a long-lasting muscle relaxant has been given.

During recovery of neuromuscular function, when all four responses to TOF stimulation can be felt, an estimation of the TOF ratio may be attempted. However, manual (tactile) evaluation of the response to TOF stimulation (see Fig. 36-9) (Figure Not Available) is not sensitive enough to exclude the possibility of residual neuromuscular blockade. [33] [93] [95] Greater sensitivity is achieved with double-burst stimulation ($DBS_{3,3}$), but even absence of manual fade in the $DBS_{3,3}$ response does not exclude clinically significant residual blockade. [39] Therefore, manual evaluation of responses to nerve stimulation should always be considered in relation to clinical signs and symptoms of residual neuromuscular blockade, such as the ability of the patient to lift the head for 5 seconds, to open the eyes, to stick out the tongue, and to cough sufficiently. [44] [54]

/das/book/view/29494766/875/416.html

CONDITIONS WARRANTING THE USE OF PERIPHERAL NERVE STIMULATORS

At some institutions, nerve stimulators are used routinely whenever a neuromuscular blocking drug is given. In most cases, the response is evaluated by touch, and only in selected cases are the responses recorded. Many anesthesiologists do not agree with this extensive use of nerve stimulators and argue that they manage quite well without these devices. As stated elsewhere, however, [64] the question is not how little an experienced anesthetist can manage with, but rather, how to ensure that all patients receive optimal treatment. In my opinion, a nerve stimulator should be used in at least the following situations [4] : (1) whenever a long-acting muscle relaxant is used, (2) when the pharmacokinetics of a muscle relaxant are abnormal--in severe liver or kidney disease, severe illness, or the extremes of age, (3) during pharmacodynamics change--as in neuromuscular diseases such as myasthenia gravis and myasthenic syndrome, (4) when one wishes to avoid drug-induced reversal (with, for example, neostigmine) of neuromuscular blockade--as in severe heart disease or bronchial asthma, (5) when it is important that postoperative muscle power be maximal--as in severe pulmonary disease and marked obesity, (6) when surgery will be lengthy, and (7) when neuromuscular blockade is produced by continuous infusion of a neuromuscular blocking drug. [60] [91]

In some instances, tactile evaluation of the response to nerve stimulation is sufficient, when considered in relation to clinical signs and symptoms of residual neuromuscular blockade. However, it should be kept in mind that absence of manually and visually detectable fade in TOF and DBS $_{3,3}$ responses does not exclude clinically significant residual neuromuscular blockade. [39] [92] [93] [99] Only by measuring the response to nerve stimulation by more objective methods can this be achieved. [91] Thus every anesthesia department and every recovery room should have at least one apparatus for recording evoked responses. Whether the functioning of such a neuromuscular transmission analyzer is based on electromyography, mechanomyography, or measurement of acceleration is not crucial, as long as the physician knows how to use the apparatus in question.

Chapter 37 - Temperature Monitoring

Daniel I. Sessler

INTRODUCTION

Mammals and birds are homeothermic, requiring a nearly constant internal body temperature. When internal temperature deviates significantly from normal, metabolic functions usually deteriorate, and death may result. The thermoregulatory system usually maintains core body temperature within 0.2°C of "normal," which is about 37°C in humans. Anesthetic-induced inhibition of thermoregulation combines with exposure to a cold operating room environment to make most unwarmed patients hypothermic.

In recent years, major outcome studies have shown that mild hypothermia (
1-2°C) (1) triples the incidence of morbid cardiac outcomes, (2) triples the incidence of surgical wound infections and prolongs hospitalization 20 percent, and (3) significantly increases surgical blood loss and the need for allogeneic transfusions. An understanding of normal and anesthetic-influenced thermoregulation facilitates prevention and management of these and numerous other temperature-related complications.

NORMAL THERMOREGULATION

Thermoregulation is similar to many other physiologic control systems in that the brain uses negative and positive feedback to minimize perturbations from preset, "normal" values. Since 1912, investigators have known that animals regulate body temperature poorly when the hypothalamus is destroyed. The importance of thermal input from the skin surface was recognized in the late 1950s, when it was observed that mice placed in a cold environment shivered *without decreasing* their hypothalamic temperatures.

In the early 1960s, physiologists reported active thermoregulation in response to isolated warming and cooling at sites other than hypothalamus or skin surface, including extrahypothalamic portions of the brain, deep abdominal tissues, and the spinal cord. [1] Thus, thermoregulation is now known to be based on multiple, redundant signals from nearly every type of tissue. The processing of thermoregulatory information occurs in three phases: *afferent thermal sensing, central regulation,* and *efferent responses.*

Afferent Input

Temperature information is obtained from thermally sensitive cells throughout the body. Cold-sensitive cells are anatomically and physiologically distinct from those that detect warmth. Warm receptors increase their firing rates when temperature increases, and cold receptors increase their firing rates when temperature decreases. Cutaneous warm receptors rarely depolarize at normal skin temperatures and probably are important only during heat stress. The hypothalamus, other parts of the brain, the spinal cord, the deep abdominal and thoracic tissues, and the skin surface each contribute roughly 20 percent of the total thermal input to the central regulatory system. [2] [3]

Cold signals travel primarily via Adelta nerve fibers, and warm information travels by unmyelinated C fibers, although there is some overlap. [4] The C fibers also detect and convey pain sensation, which is why intense heat cannot be distinguished from sharp pain. Most ascending thermal information traverses the spinothalamic tracts in the anterior spinal cord, but no single spinal tract is critical for conveying thermal information. Consequently, the entire anterior spinal cord must be destroyed to ablate thermoregulatory responses.

Central Control

Temperature is regulated by central structures (primarily the hypothalamus) that compare integrated thermal inputs from the skin surface, neuroaxis, and deep tissues with *threshold* temperatures for each thermoregulatory response. Although integrated by the hypothalamus, most thermal information is "preprocessed" in the spinal cord and other parts of the central nervous system. This hierarchical arrangement presumably developed when the evolving thermoregulatory control system co-opted previously existing mechanisms (e.g., shivering from muscles previously used for posture and locomotion). [1] It is likely that some thermoregulatory responses can be mounted by the spinal cord alone. [3] For example, animals and patients with high spinal-cord transections regulate temperature better than expected.

The slope of response intensity versus core temperature defines the *gain* of a thermoregulatory response. Response intensity no longer increasing with further deviation in core temperature identifies the *maximum intensity.* This system of thresholds and gains is a model for a thermoregulatory system that is further complicated by interactions between other regulatory responses (i.e., vascular volume control) and time-dependent effects.

How the body determines absolute threshold temperatures is unknown, but the mechanism appears to be mediated by norepinephrine, dopamine, 5-hydroxytryptamine, acetylcholine, prostaglandin E_1, and neuropeptides. The thresholds vary daily in both sexes (circadian rhythm) and monthly in women by 0.5°C. Exercise, food intake, infection, hypothyroidism and hyperthyroidism, anesthetic and other drugs (including alcohol, sedatives, and nicotine), and cold and warm adaptation alter threshold temperatures. Central regulation is intact in infants, but it frequently is impaired in elderly or extremely ill patients.

Figure 37-1 (Figure Not Available) There is a linear relation between mean skin temperature and the core temperature triggering vasoconstriction and shivering. Skin temperature contributes about 20 percent to control of each thermoregulatory defense. *(From Cheng et al [5])*

Control of autonomic responses is approximately 80 percent determined by thermal input from core structures (Fig. 37-1) (Figure Not Available) . [5] [6] In contrast, a large fraction of the input controlling behavioral responses is derived from the skin surface. The *interthreshold range* (core temperatures *not* triggering autonomic thermoregulatory responses) is only 0.2°C. [7] This range is bounded by the sweating threshold at its upper end and by vasoconstriction at the lower end. Because energy cost and nutrients are conserved without excessive autonomic control within this range, some animals, such as camels and desert rats, use this strategy extensively, allowing core temperature changes up to 10°C each day.

Both sweating and vasoconstriction thresholds are 0.3 to 0.5°C higher in women than in men, even during the follicular phase of the monthly cycle (first 10 days). [8] Differences are even greater during the luteal phase. [9] Central thermoregulatory control is apparently intact even in somewhat premature infants. [10] In contrast, thermoregulatory failure is common in the elderly. [11]

Efferent Responses

The body responds to thermal perturbations (body temperatures differing from the appropriate threshold) via effector mechanisms that increase metabolic heat production or alter environmental heat loss. Each thermoregulatory effector has its own threshold and gain, so there is an orderly progression of responses and response intensities in proportion to need. In general, energy-efficient effectors such as vasoconstriction are maximized before metabolically costly responses such as shivering are initiated. The interaction among thermal input, central control, and effector responses

---

Figure 37-2 (Figure Not Available) Schematic illustration of thermoregulatory control mechanisms. Mean body temperature is the integrated thermal input from a variety of tissues including the brain, skin surface, spinal cord, and deep core structures. These are shown entering the hypothalamus (large square) from the left. However, thresholds usually are expressed in terms of core temperature. A core temperature below the thresholds for response to cold provokes vasoconstriction, nonshivering thermogenesis, and shivering. Core temperature exceeding the hyperthermic thresholds produces active vasodilation and sweating. No thermoregulatory responses are initiated when core temperature is between these thresholds; these temperatures identify the interthreshold range. The interthreshold range in humans is usually only about 0.2°C. (Threshold data from Lopez et al [7] ; figure from Sessler DI: Perioperative hypothermia. N Engl J Med 336:1730, 1997.)

is shown in Figure 37-2; this figure also shows the normal values for the major autonomic response thresholds.

Effectors determine the ambient temperature range that the body will tolerate while maintaining core temperature normal. When specific effector mechanisms are inhibited (e.g., shivering prevented by administration of muscle relaxants), the tolerable range is decreased. Still, temperature remains normal unless other effectors cannot compensate for the imposed stress. Quantitatively, *behavioral regulation* (e.g., dressing appropriately, modifying environmental temperature, assuming positions that oppose skin surfaces, and voluntary movement) is the most important effector mechanism.

Infants regulate their temperatures remarkably well. In contrast, advanced age, infirmity, or medications can diminish the efficacy of thermoregulatory responses and can increase the risk of hypothermia. For example, decreased muscle mass, neuromuscular diseases, and muscle relaxants all inhibit shivering and thereby increase the minimum tolerable ambient temperature. Similarly, anticholinergic drugs inhibit sweating, thus decreasing the maximum tolerable temperature.

Cutaneous vasoconstriction is the most consistently used autonomic effector mechanism. Metabolic heat is lost primarily via convection and radiation from the skin surface, and vasoconstriction reduces this loss. Total digital skin blood flow is divided into nutritional (mostly capillary) and thermoregulatory (mostly arteriovenous shunt) components. [12] The arteriovenous shunts are anatomically and functionally distinct from the capillaries supplying nutritional blood to the skin; thus, vasoconstriction does not compromise the needs of peripheral tissues. Shunts are typically 100 mum in diameter, which means that one can convey 10,000-fold as much blood as a comparable length of capillary 10 mum in diameter.

Control of blood flow through the arteriovenous shunts tends to be "on" or "off." In other words, the gain of this response is high. Local alpha-adrenergic sympathetic nerves mediate constriction in the thermoregulatory arteriovenous shunts; flow is minimally affected by *circulating* catecholamines. Systemic hemodynamic changes usually are not observed during thermoregulatory vasoconstriction because only about 10 percent of cardiac output traverses these vessels; larger arterioles that control blood pressure are not influenced.

Nonshivering thermogenesis increases metabolic heat production (measured as whole-body oxygen consumption) without producing mechanical work. It doubles heat production in infants, [13] but it increases it only slightly in adults. [14] The intensity of nonshivering thermogenesis increases in linear proportion to the difference between mean body temperature and its threshold. Skeletal muscle and brown fat are the major sources of nonshivering heat in adults. The metabolic rate in both tissues is controlled primarily by norepinephrine release from adrenergic nerve terminals, and it is further mediated locally by an uncoupling protein. [15]

Sustained shivering increases metabolic heat production only 50 to 100 percent in adults. This augmentation is small compared with that produced by exercise (which can at least briefly increase metabolism 5-fold) and is thus surprisingly ineffective. Shivering does not occur in newborn infants, and probably it is not fully effective until children are several years old. The rapid tremor (
250 Hz) and unsynchronized muscular activity of thermogenic shivering suggest no central oscillator. However, superimposed on the fast activity, there usually is a slow (4-8 cycle/min), synchronous "waxing-and-waning" pattern that presumably is centrally mediated. [16]

Sweating is mediated by postganglionic, cholinergic nerves. [17] It thus is an active process that is prevented by nerve block or atropine administration. [18] Even untrained individuals can sweat up to 1 L/hr, and athletes can sweat at twice that rate. Sweating is the only mechanism by which the body can dissipate heat in an environment exceeding core temperature. Fortunately, the process is remarkably effective, dissipating 0.58 kcal/g of evaporated sweat.

Active vasodilation is mediated by a yet-to-be-identified factor released from sweat glands; the mediator may be a protein because it is not blocked by any standard drugs. [19] Because active vasodilation requires intact sweat gland function, it also is largely inhibited by nerve block. During extreme heat stress, blood flow through the top millimeter of skin can reach 7.5 L/min, equaling the entire resting cardiac output. [20] The threshold for active vasodilation usually is similar to the sweating threshold, but the gain may be less. Consequently, maximum cutaneous vasodilation usually is delayed until core temperature is well above that provoking maximum sweating intensity.

THERMOREGULATION DURING GENERAL ANESTHESIA

Behavioral regulation is not relevant during general anesthesia because patients are unconscious and frequently paralyzed. All general anesthetics so far tested markedly impair

normal autonomic thermoregulatory control. Anestheticinduced impairment has a specific form: warm-response thresholds are elevated slightly, whereas cold-response thresholds are markedly reduced. Consequently, the interthreshold range is increased from its normal values near 0.2°C to 2 to 4°C. [21] [22] [23] [24] [25] The gain and maximum intensity of some responses remain normal, [8] whereas others are reduced by general anesthesia. [26] [27]

Response Thresholds

Propofol, [21] alfentanil, [22] and dexmedetomidine [23] all produce a slight, linear increase in the sweating threshold combined with a marked and linear decrease in the vasoconstriction and shivering thresholds. Isoflurane [25] and desflurane [24] similarly slightly increase the sweating threshold; however, they decrease the cold-response thresholds nonlinearly. Consequently, the volatile anesthetics inhibit vasoconstriction and shivering less than propofol at low concentrations, but more than propofol at typical anesthetic doses. In all cases (except during meperidine administration [28]), vasoconstriction and shivering decrease synchronously, thus maintaining their normal
1°C difference.

The dose-dependent response thresholds for four anesthetic drugs are shown in Figure 37-3. The combination of increased sweating thresholds and reduced vasoconstriction thresholds increases the interthreshold range
20-fold, from its normal value near 0.2°C to
2 to 4°C. Temperatures within this range do *not* trigger thermoregulatory defenses; by definition, patients are thus poikilothermic within this temperature range.

Halothane, [29] enflurane, [30] and the combination of nitrous oxide and fentanyl [31] decrease the vasoconstriction threshold 2 to 4°C from its normal value near 37°C. However, the effects of these drugs on sweating or shivering remain unknown. Clonidine synchronously decreases cold-response thresholds, [32] while slightly increasing the shivering threshold. [33] Nitrous oxide decreases the vasoconstriction threshold less than equipotent concentrations of volatile anesthetics. [34] It also decreases the shivering threshold. [35] The only sedative or anesthetic drug so far tested that minimally influences thermoregulatory control is midazolam. [36]

Thresholds in Infants and the Elderly

Thermoregulatory vasoconstriction is comparably impaired in infants, children, and adults given isoflurane [37] or halothane [38] (Fig. 37-4). In contrast, the vasoconstriction threshold is about 1°C less in patients aged 60 to 80 years than in those between 30 and 50 years old (Fig. 37-5) (Figure Not Available) . [39] [40] Painful stimulation slightly increases vasoconstriction thresholds [30] ; Consequently, thresholds are somewhat lower when surgical pain is prevented by simultaneous local or regional anesthesia.

Nonshivering thermogenesis does not occur in anesthetized adults, [41] a finding that is not surprising because this response is not particularly important in unanesthetized adults. [14] Nonshivering thermogenesis in animals is inhibited peripherally by volatile anesthetics. [42] However, this thermoregulatory defense also fails to increase metabolic rate in infants anesthetized with propofol. [43]

Figure 37-3 The major autonomic thermoregulatory response thresholds in volunteers given desflurane, alfentanil, dexmedetomidine, and propofol. All slightly increase the sweating threshold (triggering core temperature) while markedly and synchronously decreasing the vasoconstriction and shivering thresholds. Standard deviation bars smaller than the data markers have been deleted. *(Data from Annadata et al [24] ; Kurz et al [22] ; Talke et al [25] ; and Matsukawa et al [21])*

Figure 37-4 (Figure Not Available) The core thermoregulatory threshold in 23 healthy children and infants undergoing abdominal surgery with halothane anesthesia. Differences among the groups are not statistically significant. Results are presented as means ± standard deviation. *(From Bissonnette and Sessler [36])*

Gain and Maximum Response Intensity

Both the gain and maximum intensity of sweating remain normal during isoflurane [8] and enflurane anesthesia. [44] The gain of arteriovenous shunt vasoconstriction is reduced 3-fold during desflurane anesthesia (Fig. 37-6) (Figure Not Available) . [26] Maximum vasoconstriction intensity, however, remains normal during general anesthesia. [45]

Shivering is rare during surgical doses of general anesthesia, a finding consistent with its threshold of roughly 1°C less than the vasoconstriction threshold. [21] [22] [23] [24] [25] (Vasoconstriction usually prevents additional hypothermia, [46] so even unwarmed patients rarely become cold enough to shiver.)

Figure 37-5 (Figure Not Available) The vasoconstriction threshold was significantly less in elderly patients (33.9 ± 0.6°C) than in younger patients (35.1 ± 0.3°C) during 60 percent nitrous oxide and isoflurane (0.75% end-tidal concentration). Filled squares indicate the vasoconstriction threshold in each patient; open circles show the mean and standard deviations in each group. *(From Kurz et al [39])*

Figure 37-6 (Figure Not Available) Finger blood flow without (open circles) and with (filled squares) desflurane administration. Values were computed relative to the thresholds (finger flow, 1.0 mL/min) in each subject. Flows of exactly 1.0 mL/min are not shown because flows in each individual were averaged over 0.1 or 0.05°C increments; each data point thus includes both higher and lower flows. The horizontal standard deviation bars indicate variability in the thresholds among the volunteers; although errors bars are shown only at a flow near 1.0 mL/min, the same temperature variability applies to each data point. The slopes of the flow versus core temperature relationships (1.0-
0.15 mL/min) were determined using linear regression. These slopes defined the gain of vasoconstriction with and without desflurane anesthesia. Gain was reduced by a factor of 3, from 2.4 to 0.8 $mL \cdot min^{-1} \cdot °C^{-1}$ ($P < .01$). *(From Kurz et al [26])*

Nonetheless, shivering can be induced by sufficient active cooling.

Gain and maximum shivering intensity remain normal during both meperidine and alfentanil administration. [47] Gain also remains nearly intact during nitrous oxide administration, although maximum intensity is reduced. [35] Isoflurane changes the macroscopic pattern of shivering to such an extent that is no longer possible to determine gain easily. The drug does, however, reduce maximum shivering intensity. [27]

Sweating thus appears to be the thermoregulatory defense that is best preserved during anesthesia. Not only is the threshold only slightly increased, but also the gain and maximum intensity are well preserved. In contrast, the thresholds for vasoconstriction and shivering are markedly reduced. Furthermore, these responses are less effective than normal, even after being activated.

DEVELOPMENT OF HYPOTHERMIA DURING GENERAL ANESTHESIA

Inadvertent hypothermia during anesthesia is by far the most common perioperative thermal disturbance. Hypothermia results from a combination of anesthetic-impaired thermoregulation and exposure to a cold operating room environment.

Heat Transfer

Heat can be transferred from a patient to the environment four ways: (1) radiation, (2) conduction, (3) convection, and (4) evaporation. Among these, radiation and convection contribute most to perioperative heat loss.

All surfaces at temperatures higher than absolute zero radiate heat; similarly, all surfaces absorb radiative heat from surrounding surfaces. Heat transfer via this mechanism is proportional to the difference of the fourth power of the absolute temperature difference between the surfaces. It is likely that radiation is the major type of heat loss in most surgical patients. [48]

Conductive heat loss is proportional to the temperature difference between two adjacent surfaces and the strength of the thermal insulation separating them. In general, conductive losses are negligible during surgery because patients usually only directly contact the foam pad (an excellent thermal insulator) covering most operating room tables.

Conductive loss of heat directly to air molecules is limited by the development of a layer of still air adjacent to the skin that serves as an insulator. When this layer is disturbed by air currents, the insulative properties diminish substantially, and heat loss therefore increases. This increase is termed convection, and it is proportional to the square root of air speed; this is the correction used in the familiar "wind chill" factor. Air speed in operating rooms--even those with fairly high rates of air turnover--typically is only
20 cm/s, a speed that only slightly increases loss compared with that in still air. Nonetheless, convective loss usually is the second most important mechanism by which heat is transferred from patients to the environment. Convective loss presumably increases substantially in operating rooms equipped to provide laminar flow. However, the actual augmentation has not been quantified and may be less than expected from the increase in air speed because surgical draping provides considerable thermal insulation.

Sweating increases cutaneous evaporative loss enormously, but it is rare during anesthesia. In the absence of sweating, evaporative loss from the skin surface is limited to less than 10 percent of metabolic heat production in adults. In contrast, infants lose a higher fraction of their metabolic heat from transpiration of water through thin skin. The problem becomes especially acute in premature infants, who may lose one-fifth of their metabolic heat production via transcutaneous evaporation. [49] [50] Simple thermodynamic calculations and clinical measurements indicate that only trivial amounts of heat are lost from the respiratory system. [51] However, evaporation inside surgical wounds can contribute substantially to total heat loss. [52]

Patterns of Intraoperative Hypothermia

Hypothermia during general anesthesia develops with a characteristic pattern. An initial rapid decrease in core temperature is followed by a slow, linear reduction in core temperature. Finally, core temperature stabilizes and subsequently remains virtually unchanged (Fig. 37-7) . Each component of this typical pattern has a different cause.

Figure 37-7 Hypothermia during general anesthesia develops with a characteristic pattern. An initial rapid decrease in core temperature results from a core-to-peripheral redistribution of body heat. This is followed by a slow, linear reduction in core temperature that results simply from heat loss exceeding heat production. Finally, core temperature stabilizes and subsequently remains virtually unchanged. This plateau phase may be a passive thermal steady state, or it may result when sufficient hypothermia triggers thermoregulatory vasoconstriction. Results are presented as means ± standard deviation.

Volatile anesthetics cause vasodilation via a direct peripheral action. [53] More importantly, they also inhibit tonic thermoregulatory vasoconstriction, resulting in arteriovenous shunt dilation. [21] [22] [23] [24] [25] Nonetheless, anesthetic-induced vasodilation increases cutaneous heat loss only slightly. [54] Anesthetics reduce metabolic rate 20 to 30 percent. [55] However, even the combination of increased heat loss and reduced heat production is insufficient to explain the 0.5 to 1.5°C decrease in core temperature usually observed during the first hour of anesthesia.

The key to understanding the initial decrease in core temperature is to appreciate that body heat is not evenly distributed. Core temperature represents only about half the body mass (mostly the trunk and head); the remaining mass is considerably cooler, typically 2 to 4°C less than core temperature. This core-to-peripheral tissue temperature gradient is normally maintained by tonic thermoregulatory vasoconstriction. Anesthetic-induced vasodilation, however, allows core heat to flow peripherally. This warms the arms and legs, but it does so at the expense of the core (Figs. 37-8, 37-9) . [56]

Following initial redistribution hypothermia, core temperature usually decreases in a slow, linear fashion for 2 to 4 hours. This reduction results simply from heat loss exceeding metabolic heat production. [57] After 3 to 4 hours of anesthesia, core temperature usually reaches a plateau and remains virtually constant for the duration of surgery. [31] The core temperature plateau may simply represent a thermal steady state (heat production equaling heat loss) in patients remaining relatively warm. [58] In others, however, the plateau phase is associated with peripheral thermoregulatory vasoconstriction triggered by core temperatures 33 to 35°C. [59]

Thermoregulatory vasoconstriction during anesthesia significantly decreases cutaneous heat loss, [45] but this decrease alone is usually insufficient to produce a thermal steady state. Furthermore, neither adults [41] nor infants [43] appear able to increase intraoperative heat production in response to hypothermia. An additional mechanism must therefore

Figure 37-8 A cartoon illustrating internal redistribution of body heat following induction of general anesthesia. Hypothermia following induction of spinal or epidural anesthesia results similarly, but

redistribution is restricted to the legs.

contribute to the core temperature plateau. Evidence suggests that a primary factor is constraint of metabolic heat to the core thermal compartment. In this situation, distribution of metabolic heat (which largely is produced centrally) is restricted to the core compartment, thus maintaining its temperature. Peripheral temperature, in contrast, continues to decrease because the tissue is no longer being supplied

Figure 37-9 (Figure Not Available) Changes in body heat content and distribution of heat within the body during induction of general anesthesia (at elapsed time zero). The change in mean body temperature was subtracted from the change in core (tympanic membrane) temperature, leaving the core hypothermia specifically resulting from redistribution. Redistribution hypothermia was thus not a measured value; instead, it is defined by the decrease in core temperature not explained by the relatively small decrease in systemic heat content. After 1 hour of anesthesia, core temperature had decreased 1.6 ± 0.3°C, with redistribution contributing 81 percent to the decrease. Even after 3 hours of anesthesia, redistribution contributed 65 percent to the entire 2.8 ± 0.5°C decrease in core temperature. Results are presented as means ± standard deviation. *(Modified from Matsukawa et al [56])*

Figure 37-10 (Figure Not Available) Changes in body heat content and distribution of heat within the body during the core temperature plateau. Elapsed time zero indicates the onset of arteriovenous shunt vasoconstriction, which causes the plateau. Core temperature decreased 1.3°C in 2 hours before constriction, then remained constant. The difference between core temperature and mean body temperature (which continued to decrease) indicates how much heat was retained in the core thermal compartment by thermoregulatory vasoconstriction. In this case, 22 ± 8 kcal was constrained to the core. Results are presented as means ± standard deviation. *(Modified from Kurz et al [46])*

with sufficient heat from the core (Fig. 37-10) (Figure Not Available) . [46] A core temperature plateau resulting from thermoregulatory vasoconstriction thus is not a thermal steady state, and body heat content continues to decrease even though core temperature remains nearly constant.

NEUROAXIAL ANESTHESIA

Autonomic thermoregulation is impaired during regional anesthesia, and the result typically is intraoperative core hypothermia. Interestingly, this hypothermia often is not consciously perceived by patients, but it nonetheless triggers shivering. The result frequently is a potentially dangerous clinical paradox: a shivering patient who denies feeling cold.

Thermoregulation

Epidural [60] [61] and spinal [61] [62] anesthesia each decreases the thresholds triggering vasoconstriction and shivering (above the level of the block) about 0.6°C (Fig. 37-11) (Figure Not Available) . Presumably, this decrease does not result from recirculation of neuroaxially administered local anesthetic because impairment is similar during epidural and spinal anesthesia, [60] [61] [62] although the amount and location of administered local anesthetic differ substantially. Furthermore, lidocaine administered intravenously (IV) in doses producing plasma

Figure 37-11 (Figure Not Available) Spinal anesthesia increased the sweating threshold but reduced the thresholds for vasoconstriction and shivering. Consequently, the interthreshold range increased substantially. The vasoconstriction-to-shivering range, however, remained normal during spinal anesthesia. Results are presented as means ± standard deviation. *(From Kurz et al [62])*

concentrations similar to those occurring during epidural anesthesia has no thermoregulatory effect. [63] Finally, neuroaxial administration of 2-choloprocaine, which has a plasma half-life near 20 seconds, also impairs thermoregulatory control. [64]

The vasoconstriction and shivering thresholds are comparably decreased during regional anesthesia, [62] suggesting an alteration in central, rather than peripheral, control. Peripheral administration of local anesthesia appears to impair centrally mediated thermoregulation by altering afferent thermal input from the legs. The key factor here is that tonic cold signals dominate thermal input at leg skin temperatures in typical operating room environments. [4] [65] Regional anesthesia blocks all thermal input from blocked regions, but in the typical case this is mostly cold information. The brain then seems to interpret decreased cold information as relative leg warming. Because skin temperature is an important input to the thermoregulatory control system, leg warming proportionately reduces the vasoconstriction and shivering thresholds. Consistent with this theory, a leg skin temperature near 38°C is required to reduce cold-response thresholds as much as regional anesthesia. [66] Furthermore, reduction in the thresholds is proportional to the number of spinal segments blocked (Fig. 37-12) (Figure Not Available) . [67] Major conduction anesthesia thus appears to reduce the vasoconstriction and shivering thresholds by producing an abnormal elevation of *apparent* (as opposed to actual) leg temperature.

Because neuroaxial anesthesia prevents vasoconstriction and shivering in blocked regions, it should not be surprising that epidural anesthesia decreases the maximum intensity of shivering. However, epidural anesthesia also reduces the gain of shivering, which suggests that the regulatory system is unable to compensate for lower body paralysis (Fig. 37-13) (Figure Not Available) . [68] Thermoregulatory defenses, once triggered, are thus less effective than usual during regional anesthesia.

Neuroaxial anesthesia is frequently supplemented with sedative and analgesic medications. With the exception of midazolam, [36] most such agents significantly impair thermoregulatory control. Alfentanil [22] and meperidine, [28] for example, decrease the vasoconstriction and shivering thresholds. Similarly, propofol impairs cold responses during epidural anesthesia. [69] Such inhibition may be severe when combined with the intrinsic impairment produced by regional

Figure 37-12 (Figure Not Available) The number of dermatomes blocked (sacral segments, 5; lumbar segments, 5; thoracic segments, 12) versus reduction in the shivering threshold (difference between the control shivering threshold and spinal shivering threshold). The shivering threshold was reduced more by extensive spinal blocks than by less extensive ones (Delta threshold = 0.74 - 0.06 (dermatomes blocked); r^2 = .58, P < .006). The curved lines indicate the 95 percent confidence intervals for the slope. *(Modified from Leslie and Sessler [67])*

anesthesia and other factors, including advanced age or preexisting illness (Fig. 37-14) (Figure Not Available) . [11]

Interestingly, core hypothermia during regional anesthesia may not trigger a perception of cold. [60] [70] The reason is

Figure 37-13 (Figure Not Available) Systemic oxygen consumption without (circles) and with (squares) epidural anesthesia. The horizontal standard deviation bars indicate variability in the thresholds among the volunteers; although errors bars are shown only once in each series, the same temperature variability applies to each data point. The slopes of the oxygen consumption versus core temperature relationships (solid lines) were determined using linear regression. These slopes defined the gain of shivering with and without epidural anesthesia. Gain was reduced 3.7-fold, from -412 $mL \cdot min^{-1} \cdot °C^{-1}$ (r^2 = .99) to -112 $mL \cdot min^{-1} \cdot °C^{-1}$ (r^2 = .96). *(From Kim et al [66])*

Figure 37-14 (Figure Not Available) Fifteen patients aged less than 80 years (58 ± 10 y) (mean ± SD) shivered at 36.1 ± 0.6°C during spinal anesthesia; in contrast, 8 patients aged 80 years (89 ± 7 y) or more shivered at a significantly lower mean temperature, 35.2 ± 0.8°C. The shivering thresholds in 7 of the 10 patients aged more than 80 years was less than 35.5°C, whereas the threshold equaled or exceeded this value in all the younger patients. *(From Vassilieff et al [11])*

that thermal perception (behavioral regulation) is largely determined by skin rather than by core temperature. During regional anesthesia, core hypothermia is accompanied by real and apparent increases in skin temperature. The result typically is a perception of continued or increased warmth accompanied by autonomic thermoregulatory responses including shivering (Fig. 37-15) (Figure Not Available) . [60] [70]

Taken together, these data indicate that neuroaxial blocks inhibit numerous aspects of thermoregulatory control. The vasoconstriction and shivering thresholds are reduced by regional anesthesia, [60] [61] [62] [66] [67] and they are further reduced by adjuvant drugs [22] [28] [69] and advanced age. [11] Even once triggered, the gain and maximum response intensity of shivering

Figure 37-15 (Figure Not Available) Induction of epidural anesthesia at elapsed time 15 minutes decreased core temperature and increased thermal comfort as determined by a 100-mm visual-analogue scale (VAS). However, maximal thermal comfort coincided with *minimum* core temperature. Results are presented as means ± standard deviation. *(Modified from Sessler and Ponte [60])*

are about half normal. [68] Finally, behavioral thermoregulation is impaired. [70] The result is that cold defenses are triggered at a lower temperature than normal during regional anesthesia, defenses are less effective once triggered, and patients frequently do not recognize that they are hypothermic. Because core temperature monitoring remains rare during regional anesthesia, substantial hypothermia often goes undetected in these patients.

Heat Balance

Hypothermia is common during regional anesthesia and may be nearly as severe as during general anesthesia. [71] [72] [73] Core temperature typically decreases 0.5 to 1.0°C shortly after induction of anesthesia. However, vasodilation induced by regional anesthesia only slightly increases cutaneous heat loss. Furthermore, metabolic heat production remains constant, or it increases because of shivering thermogenesis. This rapid decrease in core temperature, similar to the one that follows induction of general anesthesia, also results from an internal core-to-peripheral redistribution of body heat (Fig. 37-16) (Figure Not Available) . [74] As during general anesthesia, redistri-bution hypothermia during regional anesthesia can be minimized by cutaneous warming before induction. [75]

Subsequent hypothermia results simply from heat loss that exceeds metabolic heat production. Unlike in patients given general anesthesia, however, core temperature does

Figure 37-16 (Figure Not Available) Overall heat balance was only slightly negative (loss exceeding production) before induction of anesthesia, and subsequently changed little. To separate the contributions of decreased overall heat balance and internal redistribution of body heat to the decrease in core temperature, the change in overall heat balance was divided by body weight and the specific heat of humans. The resulting change in mean body temperature ("mean body") was subtracted from the change in core temperature ("core"), leaving the core hypothermia specifically resulting from redistribution ("redistribution"). After 1 hour of anesthesia, core temperature had decreased 0.8 ± 0.3°C, with redistribution contributing 89 percent to the decrease. During the subsequent 2 hours of anesthesia, core temperature decreased an additional 0.4 ± 0.3°C, with redistribution contributing 62 percent. Redistribution thus contributed 80 percent to the entire 1.2 ± 0.3°C decrease in core temperature during the 3 hours of anesthesia. The increase in the "redistribution" curve before induction of anesthesia indicates that thermoregulatory vasoconstriction was constraining metabolic heat to the core thermal compartment. Such constraint is, of course, the only way in which core temperature could increase while body heat content decreased. Induction of epidural anesthesia is identified as elapsed time zero. Results are presented as means ± standard deviation. *(Modified from Matsukawa et al [74])*

not necessary plateau after several hours of surgery. Not only is the vasoconstriction threshold centrally impaired by regional anesthesia, [61] [62] but more importantly, vasoconstriction in the legs is directly prevented by nerve block. [76] [77] Because the legs constitute the bulk of the thermal compartment, an effective plateau cannot develop without vasoconstriction in the legs and the resulting decrease in cutaneous heat loss and constraint of metabolic heat to the core.

The importance of intraoperative leg vasoconstriction is illustrated during combined regional/general anesthesia. Consistent with the impairment of thermoregulatory responses with regional anesthesia alone, [61] [62] vasoconstriction during combined regional/general anesthesia is triggered at a core temperature approximately 1°C less than during general anesthesia alone. Furthermore, vasoconstriction, once triggered, produces a core temperature plateau during general anesthesia alone but not during combined regional/general anesthesia. The result is that core temperature during combined regional/general anesthesia continues to decrease throughout surgery. [78] Consequently, core temperature monitoring and thermal management are particularly important in patients given simultaneous regional and general anesthesia.

Shivering

Shivering-like tremor in volunteers given regional anesthesia always is preceded by core hypothermia and vasoconstriction (above the level of the block). [60] Furthermore, electromyographic analysis indicates that the tremor has the 4- to 8-cycle/min waxing-and-waning pattern characterizing normal shivering. [64] The tremor thus apparently is normal thermoregulatory shivering, triggered when redistribution hypothermia decreases core temperature. It remains probable, however, that tremor during regional anesthesia in pregnant women has a different cause. Similarly, the shivering-like tremor so often observed during labor without regional anesthesia has yet to be adequately characterized. In both cases, there appears to be a significant incidence of shivering-like tremor in normothermic and vasodilated patients. This observation suggests that some tremor is nonthermoregulatory because shivering should always be preceded by hypothermia and arteriovenous shunt vasoconstriction.

Spinal thermal receptors have been detected in every mammal and bird so far tested. Experimental stimulation of these receptors reliably produces shivering in animals. Stimulation in humans of these putative receptors by epidural anesthetic injection theoretically could initiate thermoregulatory responses including shivering. Consistent with this possibility, the incidence of shivering in pregnant women is greater when they are given refrigerated epidural anesthetic than when the anesthetic is warmed before injection. [79] However, epidural administration of large amounts of ice-cold saline does not trigger shivering in nonpregnant volunteers. [80] Furthermore, the incidence of shivering is comparable in volunteers [60] and nonpregnant patients [81] given warm or cold epidural anesthetic injections. These data indicate that, at least in nonpregnant individuals, temperature of injected local anesthetic does not influence the incidence of shivering during major conduction anesthesia.

Most shivering during regional anesthesia can be prevented by maintaining strict normothermia. [60] However, it may be difficult to prevent redistribution from decreasing core temperature the relatively small amount necessary to trigger shivering. Alternatively, shivering can be treated in most cases by warming sentient skin to increase cutaneous thermal input to the central regulatory system, thus increasing the degree of tolerated core hypothermia. [82] Because the entire skin surface contributes 20 percent to thermoregulatory control [5] and the lower body contributes about 10 percent, [66] sentient skin warming is likely only to compensate for small reductions in core temperature. The same drugs that are effective for postanesthetic tremor also are useful for shivering during regional anesthesia: these include meperidine (25 mg IV or epidurally), [83] clonidine (75 mug IV), [84] ketanserin (10 mg IV), [84] and magnesium sulfate (30 mg/kg). [85]

CONSEQUENCES OF MILD INTRAOPERATIVE HYPOTHERMIA

Perianesthetic hypothermia produces potentially severe complications as well as distinct benefits. Thermal management thus deserves the same thoughtful analysis of potential risks and benefits as other therapeutic decisions.

Benefits

Substantial protection against ischemia and hypoxia is provided by just 1 to 3°C of hypothermia. [86] [87] [88] Protection initially was thought to result from the 8 percent/°C reduction in tissue metabolic rate. However, the efficacy of mild hypothermia far exceeds that of treatments, such as high-dose isoflurane or barbiturate coma, that comparably reduce metabolic rate. [89] These data suggest that other actions (e.g., decreased release of excitatory amino acids) explain the protective action of hypothermia.

The protection afforded by mild hypothermia is so great that reduced core temperature (i.e., 34°C) is probably indicated during carotid artery surgery, neurosurgery, and other procedures in which tissue ischemia can be anticipated. However, there are currently no outcome data in humans substantiating this extrapolation from animal data. Mild hypothermia does, however, appear beneficial in patients with traumatic brain injury. [90] It similarly appears beneficial in patients with acute respiratory distress syndrome. [91]

Acute malignant hyperthermia is more difficult to trigger in mildly hypothermic swine than in those kept normothermic. Furthermore, once triggered, the syndrome is less severe. [92] [93] These data suggest that active warming should be avoided in patients known to be susceptible to malignant hyperthermia; instead, they should be allowed to become slightly hypothermic during surgery.

Complications

Coagulation is impaired by mild hypothermia. The most important factor appears to be a cold-induced defect in platelet function. [94] Interestingly, the defect in platelet function

is related to local temperature, not core temperature. [95] Wound temperature, however, is largely determined by core temperature and is distinctly higher in normothermic patients. Perhaps as important, hypothermia directly impairs enzymes of the coagulation cascade. This is not apparent during routine coagulation screening because the tests are performed at 37°C. When these tests are performed at hypothermic temperatures, however, the defect becomes apparent. [96] [97] Consistent with these *in vitro* defects, a prospective, randomized clinical trial indicates that mild hypothermia significantly increases blood loss during hip arthroplasty and increases allogeneic transfusion requirements. [98]

Wound infections are among the most common serious complications of anesthesia and surgery, probably causing more morbidity than all anesthetic complications combined. [99] [100] Hypothermia can contribute to wound infections both by directly impairing immune function [101] and by triggering thermoregulatory vasoconstriction that, in turn, decreases wound oxygen delivery. [102] It is well established that fever is protective and that infections are aggravated when naturally occurring fever is prevented. [103] [104] Similarly, mild hypothermia, maintained only during anesthesia, impairs subsequent resistance to the both *Escherichia coli* and *Staphylococcus aureus* dermal infections in guinea pigs. [105] [106] As may be expected from these *in vitro* and animal data, a prospective, randomized clinical trial indicated that mild intraoperative hypothermia tripled the incidence of surgical wound infection in patients undergoing colon surgery. Furthermore, hypothermia delayed wound healing and prolonged duration of hospitalization 20 percent even in patients without infection. [107] Consistent with poor wound healing, urinary nitrogen excretion remains elevated for several postoperative days in patients allowed to become hypothermic during surgery. [108]

Thermal comfort is markedly impaired by postoperative hypothermia. [109] Patients, asked years after surgery, often identify feeling cold in the immediate postoperative period as the worst part of their hospitalization--sometimes rating it worse than surgical pain. Postoperative thermal discomfort is also physiologically stressful, by elevating blood pressure, heart rates, and plasma catecholamine concentrations. [110] [111] These factors presumably contribute to what may be the most important consequence of mild perioperative hypothermia: morbid myocardial outcomes. [112] Given that myocardial ischemia is among the leading causes of unanticipated perioperative death, the results of this prospective, randomized trial must be taken extremely seriously.

Drug metabolism is markedly decreased by perioperative hypothermia. The duration of action of vecuronium is more than doubled by 2°C of core hypothermia, and the prolongation is a pharmacokinetic effect, not a pharmacodynamic one. [113] Atracurium duration is less dependent on core temperature: a 3°C reduction in core temperature increases the duration of muscle relaxation only by 60 percent. [114] With each drug, the recovery index (time for 25-75% twitch recovery) remains normal during hypothermia. Interestingly, core hypothermia per se decreases twitch strength 10 to 15 percent, even without muscle relaxants. [115]

During a constant infusion of propofol, plasma concentration is 30 percent greater than normal when individuals are 3°C hypothermic. [114] The effects of mild hypothermia on the metabolism and pharmacodynamics of most other drugs have yet to be reported. However, the results for muscle relaxants and propofol suggest that the effects likely are substantial. Hypothermia also alters the pharmacodynamics of the volatile anesthetics, reducing the minimum alveolar concentration (MAC) about 5%/°C. [116] [117] Consequently, no anesthesia whatsoever is required to prevent movement in response to skin incision at core temperatures lower than 20°C. [118] As may be expected from the pharmacokinetic and pharmacodynamic effects of hypothermia, duration of postanesthetic recovery is significantly prolonged, even when temperature is not a discharge criterion. When "fitness for discharge" and a core temperature exceeding 36°C are required (as in many postanesthesia care units), recovery duration is prolonged by several hours. [119] Table 37-1 (Table Not Available) lists proven consequences of mild perioperative hypothermia.

Postanesthetic Shivering

The incidence of postoperative shivering-like tremor reportedly is 40 percent, but it now appears to be less because

TABLE 37-1 -- Major *In Vivo* Consequences of Mild Perioperative Hypothermia in Humans[a]

[a] Only prospective, randomized human trials are included; subjective responses were evaluated by observers blinded to treatment group and core temperature.

more patients are kept normothermic, and opioids are administered more frequently and in larger doses than previously. It is a potentially serious complication, increasing oxygen consumption roughly 100 percent, in proportion to intraoperative heat loss. [120] Interestingly, however, myocardial ischemia is poorly correlated with shivering, a finding suggesting that increased metabolic rate is not the primary cause of this complication. [112] In addition to increasing intraocular and intracranial pressures, postoperative shivering likely aggravates wound pain by stretching incisions.

Over the years, postanesthetic tremor has been attributed to uninhibited spinal reflexes, pain, decreased sympathetic activity, pyrogen release, adrenal suppression, respiratory alkalosis, and, most commonly, simple thermoregulatory shivering in response to intraoperative hypothermia. Unfortunately, the causes of postanesthetic shivering-like tremor remain unclear. Certainly, much postoperative tremor is simply normal shivering. As early as 1972, however, investigators recognized the existence of at least two distinct tremor patterns. [121] That perceptive observation subsequently was confirmed in a study that used electromyography to demonstrate (1) a tonic pattern resembling normal shivering, typically having a 4- to 8-cycle/min waxing-and-waning component, and (2) a phasic, 5- to 7-Hz bursting pattern resembling pathologic clonus. [122] The clonic pattern was consistent with the previous observation that pathologic spinal cord responses, including clonus, nystagmus, and exaggerated deep tendon reflexes, were common during recovery from general anesthesia. [123]

It was not until 1991 that a triple crossover study in volunteers established that the tonic and clonic patterns were both thermoregulatory, that is, always preceded by core hypothermia and arteriovenous shunt vasoconstriction. [124] The tonic pattern consistently demonstrated the 4- to 8-cycle/min waxing-and-waning pattern of normal shivering, [16] and apparently it is a simple thermoregulatory response to intraoperative hypothermia. In contrast, the clonic pattern is not a normal component of thermoregulatory shivering and appears specific to recovery from volatile anesthetics. Although the precise cause of this tremor pattern remains unknown, it may result from anesthetic-induced disinhibition of normal descending control over spinal reflexes. Data in surgical patients, however, belie the simple conclusion from the volunteer study [124] that all postanesthetic tremor is thermoregulatory. Instead, there appears to be a distinct incidence of nonthermoregulatory tremor in normothermic postoperative patients [125] ; similar nonthermoregulatory tremor has been observed in women during labor. The cause of this tremor and the reason that volunteers and patients should respond differently remain unknown; however, preliminary data suggest that pain contributes.

Postanesthetic shivering can be treated by skin surface warming [82] because the regulatory system tolerates more core hypothermia when cutaneous warm input is augmented. [5] The degree to which clinically available skin surface warmers can compensate for core hypothermia remains to be quantified, but the technique probably is effective in most patients with core temperatures exceeding 35°C. Postanesthetic shivering also can be treated using a variety of drugs, including clonidine (75 mug IV), [84] [126] ketanserin (10 mg IV), [84] physostigmine (0.04 mg/kg), [127] and magnesium sulfate (30 mg/kg). [85] The specific mechanisms by which ketanserin, physostigmine, and magnesium sulfate stop shivering remain unknown. Similarly, how clonidine arrests shivering also remains unknown, but the drug comparably reduces the vasoconstriction and shivering thresholds, [32] suggesting it acts on the central thermoregulatory system, rather than by peripherally preventing shivering.

Alfentanil, a pure mu-receptor agonist, significantly impairs thermoregulatory control. [22] However, meperidine reportedly is considerably more effective in treating shivering than equi-analgesic doses of other mu-agonists. [128] Clinically, this efficacy is manifested as a shivering threshold that is reduced twice as much as the vasoconstriction threshold [28] without a decrease in the gain or maximum intensity of shivering. [47] The efficacy of meperidine is largely preserved during administration of moderate doses of naloxone (0.5 mug·kg$^{-[1]}$·min$^{-[1]}$) but it is virtually obliterated by enormous doses (5.0 mug·kg$^{-[1]}$·min$^{-[1]}$). [129] These data suggest that action of this drug is, in part, mediated by non-mu-opioid receptors. The most likely target is the kappa receptor, and meperidine possesses considerable kappa activity. [130]

PERIOPERATIVE THERMAL MANIPULATIONS

Intraoperative thermoregulatory vasoconstriction, once triggered, is remarkably effective in preventing further core hypothermia. [38] [46] Nonetheless, most patients are poikilothermic during surgery because they do not become sufficiently hypothermic to trigger thermoregulatory responses. [21] [22] [24] [25] Therefore, intraoperative hypothermia can be minimized by any technique that limits cutaneous heat loss to the environment resulting from cold operating rooms, evaporation from surgical incisions, and conductive cooling produced by administration of cold IV fluids.

Mean body temperature decreases when heat loss to the environment exceeds metabolic heat production. Heat production during anesthesia is approximately 0.8 $kcal \cdot kg^{-1} \cdot hr^{-1}$ [1] . Because the specific heat of the human body is about 0.83 kcal/kg, [131] body temperature decreases approximately 1°C/h when heat lost to the environment exceeds metabolic production by a factor of 2. Normally, about 90 percent of metabolic heat is lost through the skin surface. During anesthesia, additional heat is lost directly from surgical incisions and by administration of cold IV fluids.

Effects of Vasomotor Tone on Heat Transfer

Thermoregulatory vasodilation causes the initial core-to-peripheral redistribution of body heat [56] ; similarly, reemergence of vasoconstriction in patients becoming sufficiently hypothermic produces a core temperature plateau. [46] It is thus evident that vasomotor tone alters intercompartmental heat transfer. In addition to thermoregulatory arteriovenous shunt status, arteriolar tone is directly modulated by anesthetics per se. [132] Both factors potentially influence the speed with which peripherally applied heat reaches the core thermal compartment.

Thermoregulatory vasoconstriction slightly impairs induction of therapeutic hypothermia during neurosurgery. [133] Similarly, nitroprusside administration facilitates even distribution of heat during rewarming on cardiopulmonary bypass. [134] However, arteriovenous shunt tone has little effect on intraoperative cooling [135] or heating. [136] It thus seems that intraoperative vasoconstriction impedes peripheral-to-core transfer of cutaneous heating and cooling, but the effect is relatively small. Little clinical effect presumably results because intraoperative thermoregulatory vasoconstriction is opposed by direct anesthetic-induced peripheral vasodilation.

During postanesthetic recovery, however, the situation differs markedly. Here, anesthetic-induced peripheral dilation [132] dissipates, leaving unopposed thermoregulatory vasoconstriction. As may be expected, this vasoconstriction then becomes an important factor and significantly impairs transfer of peripherally applied heat to the core thermal compartment. Patients having a residual spinal anesthetic block thus warm considerably faster than those recovering from general anesthesia alone (Fig. 37-17) (Figure Not Available) . [137] Heat balance studies indicate that core warming is slowed because vasoconstriction constrains up to 30 kcal in peripheral tissues. [138]

Because postoperative thermoregulatory vasoconstriction decreases peripheral-to-core transfer of heat, applied warming is most effective during surgery when patients are vasodilated. From a practical point of view, this means that it is easier to maintain intraoperative normothermia (when most patients are vasodilated) than to rewarm them postoperatively (when virtually all hypothermic patients are vasoconstricted). In addition to being more effective, intraoperative warming is more appropriate than postoperative treatment of hypothermia because it prevents the complications resulting from hypothermia. [98] [107] [112] Patients who unavoidably

Figure 37-17 (Figure Not Available) Intraoperative and postoperative core temperatures in patients assigned to general anesthesia (*n* = 20) and spinal anesthesia (*n* = 20). All patients were warmed with forced air during the postoperative period. Core temperature did not differ significantly during surgery, but it increased significantly faster postoperatively in patients given spinal anesthesia (1.2 ± 0.1°C/h versus 0.7 ± 0.2°C/h, means ± standard deviations). *(From Szmuk et al [137])*

become hypothermic during surgery nonetheless should be actively heated postoperatively to increase thermal comfort, to decrease shivering, and to hasten rewarming.

Preventing Redistribution Hypothermia

The initial 0.5 to 1.5°C reduction in core temperature is difficult to prevent because it results from redistribution of heat from the central thermal compartment to cooler peripheral tissues. [56] Consequently, even the most effective clinical warmers do not prevent hypothermia during the first hour of anesthesia. [57] [107] Lack of efficacy during this period results both because the central-to-peripheral flow of heat is massive and because transfer of applied cutaneous heat to the core requires nearly an hour, even in vasodilated patients.

Although redistribution cannot effectively be treat-ed, [57] [107] it can be prevented. Redistribution results when anesthetic-induced vasodilation allows heat to flow peripherally down the normal temperature gradient. Skin surface warming before induction of anesthesia does not significantly alter core temperature (which remains well regulated), but it does increase body heat content. Most of the increase is in the legs, the most important component of the peripheral thermal compartment. When peripheral tissue temperature is sufficiently increased, subsequent inhibition of normal tonic thermoregulatory vasoconstriction produces little redistribution hypothermia because heat only can flow down a temperature gradient (Fig. 37-18) (Figure Not Available) . [139] [140] Although substantial amounts of heat must be transferred across the skin surface, active prewarming for as little as 30 minutes likely prevents considerable redistribution. [141]

Figure 37-18 (Figure Not Available) During the preinduction period (-120-0 min), volunteers were either actively warmed or passively cooled (no warming). At induction of anesthesia (time, 0 minutes), active warming was discontinued and volunteers were exposed to the ambient environment. Initial tympanic membrane temperatures were similar before each preinduction treatment. During the 60 minutes following induction of anesthesia, core temperature decreased less when volunteers were prewarmed. (DeltaT = -1.1 ± 0.3°C) compared with when the same volunteers were not warmed (DeltaT = -1.9 ± 0.3°C). Data presented as means ± standard deviations. *(From Hynson et al [139])*

Airway Heating and Humidification

Simple thermodynamic calculations indicate that less than 10 percent of metabolic heat production is lost via the respiratory tract. The loss results from both heating and humidifying inspiratory gases, but humidification requires two-thirds of the heat. [51] Because little heat is lost via respiration, even active airway heating and humidification minimally influence core temperature. [57] [142] The *apparent* clinical efficacy of these devices probably results from artifactual warming of proximally positioned esophageal stethoscopes. [143]

Because respiratory heat loss remains virtually constant during anesthesia, the fraction of total heat lost via the respiratory tract decreases dramatically during large operations in which substantial heat is lost from evaporation within surgical incisions. [52] Consequently, airway heating and humidification are even less effective than usual in patients most in need of effective warming. Cutaneous warming maintains normothermia so much better than respiratory gas conditioning that intraoperative active airway heating and humidification are rarely, if ever, indicated. Airway heating and humidification are more effective in infants and children than in adults, [144] but cutaneous warming also is more effective in these patients and transfers more than ten times as much heat. Hygroscopic condenser humidifiers and heat-and-moisture exchanging filters ("artificial noses") retain substantial amounts of moisture and heat within the respiratory system. In terms of preventing heat loss, these passive devices are about half as good as active systems [144] ; however, they cost only a fraction as much. Heat retention is comparable in all clinically available heat-and-moisture exchangers. [51]

Intravenous Fluids

It is not possible to warm patients by administering heated fluids because the fluids cannot (much) exceed body temperature. On the other hand, heat loss resulting from cold IV fluids becomes significant when large amounts of crystalloid solution or blood are administered. One unit of refrigerated blood or 1 L of crystalloid solution administered at room temperature decreases mean body temperature
0.25°C. Fluid warmers minimize these losses and should be used when large amounts of IV fluid or blood are administered.

For routine cases, there are no clinically important differences among the available warmers. Although most warmers allow fluid to cool in the tubing between the heater and the patient, this cooling is of little consequence in adults: at high flows, there is little cooling, and at low flows, the amount of fluid given is trivial. [145] Special high-volume systems with powerful heaters and little resistance to flow facilitate care of trauma victims and are useful in other cases in which large amounts of fluid must be administered quickly.

Cutaneous Warming

Operating room temperature is the most critical factor influencing heat loss because it determines the rate at which metabolic heat is lost by radiation and convection from the skin and by evaporation from within surgical incisions. Consequently, increasing room temperature is one way to minimize heat loss. However, room temperatures exceeding 23°C generally are required to maintain normothermia in patients undergoing all but the smallest procedures [146] ; most operating room personnel find such temperatures uncomfortably warm. Infants may require ambient temperatures exceeding 26°C to maintain normothermia. Such temperatures are sufficiently high to impair performance of operating room personnel and to decrease their vigilance.

The easiest method of decreasing cutaneous heat loss is to apply passive insulation to the skin surface. Insulators readily available in most operating rooms include cotton blankets, surgical drapes, plastic sheeting, and reflective composites ("space blankets"). A single layer of each reduces heat loss approximately 30 percent, and there are no clinically important differences among the insulation types (Fig. 37-19) (Figure Not Available) . [147] Insulators, therefore, should be chosen strictly on the basis of cost; paying a premium to purchase reflective composites, for example, is not justified.

The reduction in heat loss from all the commonly used passive insulators is similar because most of the insulation is provided by the layer of still air trapping beneath the covering. Consequently, adding additional layers of insulation further reduces heat loss only slightly. For example, one cotton blanket reduces heat loss about 30 percent, but three cotton blankets reduce heat loss only by 50 percent. Furthermore, warming the cotton blankets provides little benefit, and the benefit is short-lived (Fig. 37-20) (Figure Not Available) . [148] These data indicate that simply adding additional layers of passive insulation or warming the insulation before application usually is insufficient in patients who become hypothermic while covered with a single layer of insulation.

Cutaneous heat loss is roughly proportional to surface area throughout the body. [149] (The popular perception that a large fraction of metabolic heat is lost from the head is false in adults. Loss from the head can be substantial in small infants, [150] [151] but loss is high mostly because the head represents a large fraction of the total surface area.) Consequently, the amount of skin covered is more important than which surfaces are insulated. It does not make sense, for example, to cover the head and to leave the arms exposed: the arms have more surface area than the head and account for more heat loss.

Figure 37-19 (Figure Not Available) Insulators readily available in most operating rooms include cotton blankets, surgical drapes, plastic sheeting, and reflective composites ("space blankets"). A single layer of each reduces total cutaneous heat loss approximately 30 percent, and there are no clinically important differences among the insulation types. Data presented as means ± standard deviations. *(From Sessler et al [147])*

Figure 37-20 (Figure Not Available) Total cutaneous heat loss when the volunteers were covered with a single warmed or unwarmed blanket ("1 warm" or "1 unwarmed") or three warmed or unwarmed blankets ("3 warm" or "3 unwarmed"). These data indicate that warming cotton blankets is of little benefit, and adding additional blankets only slightly decreases cutaneous heat loss. Data presented as means ± standard deviations. *(From Sessler and Schroeder [148])*

Passive insulation alone rarely is sufficient to maintain normothermia in patients undergoing large operations: active warming is required in those cases. Because about 90 percent of metabolic heat is lost via the skin surface, only cutaneous warming transfers sufficient heat to prevent hypothermia. Most infrared systems are little more effective than passive insulation. [147] [152] Consequently, for intraoperative use, circulating-water and forced-air devices are the two major systems requiring consideration.

Studies consistently report that circulating-water mattresses are nearly ineffective. [153] Presumably, they are unable

Figure 37-21 (Figure Not Available) Rectal temperatures increased in adults given forced-air warming and decreased in those warmed with circulating water during maxillofacial surgery. Temperature of the warmer was decreased from "high" to "medium" (
37°C) in all patients assigned to forced-air warming
7 hours after induction of anesthesia when their rectal temperatures exceeded 36.5°C. After 15 hours of anesthesia, core temperatures were 3.4°C higher in the patients given forced-air warming. There was no initial redistribution hypothermia because these patients were maintained in a warm environment before induction of anesthesia. *(From Kurz et al [158])*

to maintain normothermia because little heat is lost from the back into the 5 cm of foam insulation covering most operating room tables. Furthermore, the combination of heat and decreased local perfusion (resulting when the patient's weight reduces capillary blood flow) increases the propensity for pressure/heat necrosis ("burns"). [154] Such tissue injury can occur even when water temperature does not exceed 40°C. [155] Circulating water is more effective, and safer, when placed *over* patients rather than *under* them, and in that position, it can almost completely eliminate metabolic heat loss. [152] Metabolic heat production increases mean body temperature approximately 1°C/h when cutaneous heat loss is eliminated.

The most effective perianesthetic warming system is forced air. The best forced-air systems transfer more than 50 watts across the skin surface, rapidly increasing mean body temperature. [152] [156] Forced air has been shown to maintain normothermia even during the largest operations [57] [107] [157] and is superior to circulating water (Fig. 37-21) (Figure Not Available) . [158] Figure 37-22 shows the relative effect of common patient warming methods and the changes in mean body temperature resulting from infusion of unwarmed crystalloid or blood.

Figure 37-22 Relative effects of warming methods on mean body temperature (DeltaMBT) as a function of time (upper portion) or administered fluid (lower portion). Mean body temperature is the average temperature of body tissues and is usually somewhat less than core temperature. The calculations assume an undressed 70-kg patient with a metabolic rate of 80 kcal/h, in thermal steady state with a typical 21°C operating room environment. Only changes resulting from specific treatments are shown; changes from combined interventions are additive. (A-D) Changes in MBT per liter of administered blood or crystalloid at various fluid temperatures. (E) Inspiring warmed, humidified gas. (F, G) Warmed or unwarmed blankets, with all skin below the neck covered. Savings are similar with a single layer of other passive insulators. (H) Full-length circulating-water mattress. (I) Full-length forced-air warmer. *(From Sessler DI: Consequences and treatment of perioperative hypothermia. Anesthesiol Clin North Am 12:425, 1994.)*

DELIBERATE SEVERE INTRAOPERATIVE HYPOTHERMIA

Severe hypothermia may be induced deliberately to confer protection against tissue ischemia, specifically during cardiac and, occasionally, neurosurgery. Drugs such as barbiturates and volatile anesthetics provide considerably less protection than even mild hypothermia. [89] Because many organs compensate poorly for hypothermia, temperatures as low as those deliberately induced are usually lethal when unintentional. Deliberate hypothermia is safe only because anesthesiologists understand and treat the physiologic changes caused by core temperatures 10 to 15°C lower than normal.

Organ Function

Ischemia damages tissues because oxygen deprivation forces cells to obtain energy anaerobically. Because this mechanism is inefficient, it may not provide adequate energy. Anaerobic metabolism also produces more toxic metabolic waste products (e.g., lactate and superoxide radicals) than does the Krebs cycle, a situation that is particularly serious when these products are not removed by circulating blood.

Hypothermia decreases the whole-body metabolic rate by
8 percent/°C, to approximately half the normal rate at 28°C. Whole-body oxygen demand diminishes, and oxygen consumption in tissues that have higher than normal metabolic rates, such as the brain, is especially reduced. Low metabolic rates allow aerobic metabolism to continue during periods of compromised oxygen supply; toxic waste production declines in proportion to the metabolic rate. Although decreased metabolic rate certainly contributes to the observed protection against tissue ischemia, other specific actions of hypothermia (including "membrane stabilization" and decreased release of toxic metabolites) may be most important.

Cerebral blood flow also decreases in proportion to metabolic rate during hypothermia because of an autoregulatory increase in cerebrovascular resistance. The arteriovenous partial pressure of oxygen (P_{O_2}) difference thus remains constant, and venous lactate concentration does not increase. Cerebral function is well maintained until core temperatures reach
33°C, but consciousness is lost at temperatures lower than 28°C. Primitive reflexes such as gag, pupillary constriction, and monosynaptic spinal reflexes remain intact until
25°C. Nerve conduction decreases, but peripheral muscle tone increases, resulting in rigidity and myoclonus at temperatures near 26°C. Somatosensory- and audio-evoked potentials are temperature-dependent, but they are not significantly modified at core temperatures of 33°C or higher.

Hypothermic effects on the heart include a decrease in heart rate, increased contractility, and well-maintained stroke volume. Cardiac output and blood pressure both decrease. At temperatures lower than 28°C, sinoatrial pacing becomes erratic, and ventricular irritability increases. Fibrillation usually occurs between 25 and 30°C, and electrical defibrillation is usually ineffective at these temperatures. Because coronary artery blood flow decreases in proportion to cardiac work, hypothermia per se does not cause myocardial ischemia.

Hypothermia decreases blood flow to the kidneys by increasing renal vascular resistance. Inhibition of tubular absorption maintains normal urinary volume. As temperature decreases, reabsorption of sodium and potassium is progressively inhibited, causing an antidiuretic hormone-mediated "cold diuresis." Despite increased excretion of these ions, plasma electrolyte concentrations usually remain normal. Kidney functions return to normal when patients are rewarmed. Respiratory strength is diminished at core temperatures less than 33°C, but the ventilatory carbon dioxide response is minimally affected. Hepatic blood flow and function also decrease, significantly inhibiting metabolism of some drugs.

Acid-Base Changes

The pH of neutral water ($[OH^-] = [H^+]$) increases 0.017 units for each 1°C reduction in temperature; pH of blood in a closed system (e.g., test tube or artery) changes similarly (Ch. 38). Cold-blooded animals allow pH to vary with body temperature as it would *in vitro* (i.e., blood becomes more alkalotic as temperature decreases), whereas homeotherms who decrease body temperature during hibernation maintain an arterial pH (pH_a) near 7.4. Interpretation of pH_a in hypothermic humans is difficult because it is unclear which strategy is optimal. [159] To mimic the compensatory mechanisms used by hibernating homeotherms, blood pH (which is measured by electrodes at 37°C) traditionally has been "corrected" to the patient's actual body temperature. Without correction, tissue oxygen availability decreases because hemoglobin's affinity for oxygen increases
1.7 percent/°C. This effect is small compared with the 5.7 percent/°C increase in oxyhemoglobin affinity caused by hypothermia itself. Fortunately, the combined increases in affinity are offset by the 8 percent/°C reduction in metabolic rate caused by hypothermia. Tissue hypoxia is thus unlikely, with or without correction, and it has not been demonstrated experimentally.

Ectothermic strategy also is known as "alphastat" because the dissociation constant of the alpha-imidazole group in histidine changes in parallel with that of water. Maintaining constant imidazole ionization results in optimal enzyme function as temperature changes. In contrast, homeothermic dynamics significantly decrease metabolic function, and animals are essentially anesthetized by cold. Constant relative alkalinity also maintains a stable intracellular to extracellular gradient that promotes removal of acidic products of intracellular metabolism.

There are no convincing studies indicating that ectothermic strategy is better than that adopted by hibernating homeotherms. However, many anesthesiologists now use "uncorrected" values. This technique facilitates comparison among serial blood gas values because "normal" pH_a remains
7.4, and "normal" partial arterial pressure of carbon dioxide (Pa_{CO_2}) remains
40 mm Hg at any temperature. However, both techniques work well, and physiologic differences between them appear to be subtle and have minimal effect on patient outcome.

HYPERTHERMIA AND FEVER

Hypothermia is by far the most common perianesthetic thermal perturbation. However, hyperthermia is more dangerous than a comparable degree of hypothermia. Hyperthermia is a generic term simply indicating a core body temperature exceeding normal values. In contrast, fever is a regulated increase in the core temperature targeted by the thermoregulatory system. Hyperthermia can result from a variety of causes, and it usually indicates a problem of sufficient severity that physician intervention is required.

Passive Hyperthermia and Malignant Hyperthermia

Passive intraoperative hyperthermia results from excessive patient heating and is most common in infants and children (Ch. 27). It is especially frequent when effective active warming is used without adequate core temperature monitoring. Passive hyperthermia, by definition, does not result from thermoregulatory intervention. Consequently, it can easily be treated by discontinuing active warming and removing excessive insulation.

The increase in body temperature during malignant hyperthermia results from an enormous increase in metabolic heat produced by both internal organs and skeletal muscles. Central thermoregulation presumably remains intact during acute crises, but efferent heat loss mechanisms may be compromised by intense peripheral vasoconstriction resulting from circulating catecholamine concentrations 20 times normal. [160]

Fever

Normal body temperature is neither set nor maintained by circulating factors. In contrast, fever results when endogenous pyrogens increase the thermoregulatory target temperature ("set point"). Identified endogenous pyrogens include interleukin-1, tumor necrosis factor, interferon-alpha, and macrophage inflammatory protein-1. [161] Although it was initially believed that these factors acted directly on hypothalamic thermoregulatory centers, [162] there is increasing evidence for a more complicated system involving vagal afferents. [163] Most endogenous pyrogens have peripheral actions (e.g., immune system activation) in addition to their central generating capabilities.

Fever usually results from infection. Such fevers may reflect preexisting infection, or they may result, for example, from urologic manipulations. However, perioperative fever also occurs in response to mismatched blood transfusions, blood in the fourth cerebral ventricle, and allergic reactions. [164] The causes of fever are sufficiently diverse, and potentially serious, that a search for a specific cause usually is warranted.

Fever is relatively rare during general anesthesia, considering how often febrile stimuli are likely to be present. Fever is rare because volatile anesthetics per se inhibit expression of fever (Fig. 37-23) (Figure Not Available) . Clinical management of fever should primarily be directed at identifying and treating the

Figure 37-23 (Figure Not Available) Change in core temperature after administration of 50,000 IU/kg of interleukin-2 (IL-2) followed by a second dose of 100,000 IU/kg 2 hours later. The first dose of IL-2 defined elapsed time zero; anesthesia was started after 3 elapsed hours and was continued for 5 hours. Data are presented as means ± standard deviations. *(From Negishi C, Lenhardt R, Sessler DI et al: Desflurane reduces the febrile response to interleukin-2 administration. Anesthesiology 88:1162, 1998.)*

underlying cause. A secondary approach is to administer antipyretic medications such acetaminophen, centrally reducing the thermoregulatory drive to maintain an abnormally high core temperature. In contrast, simple cooling measures are rarely effective, but they do decrease thermal comfort and increase shivering.

TEMPERATURE MONITORING

Core temperature measurements (e.g., tympanic membrane, pulmonary artery, distal esophagus, and nasopharynx) are used to monitor intraoperative hypothermia, to prevent overheating, and to facilitate detection of malignant hyperthermia. Muscle or skin surface temperatures may be used to evaluate vasomotion [165] and ensure validity of peripheral neuromuscular monitoring. [166] Both core and skin surface temperature measurements are required to determine the thermoregulatory effects of different anesthetic drugs. Temperatures are not uniform within the body; consequently, temperatures measured at each site have different physiologic and practical significance.

Thermometers

Traditionally, the medical community has used mercury-in-glass thermometers. These slow and cumbersome thermometers have largely been replaced by electronic systems. The most common electronic thermometers are thermistors and thermocouples. Both devices are sufficiently accurate for clinical use and are inexpensive enough to be disposable. Also sufficiently accurate for clinical use are "deep tissue" thermometers that are based on actively reducing cutaneous

---

heat flux to zero [167] [168] unfortunately, these monitors are not currently available in Europe or the United States. True infrared tympanic membrane thermometers are another alternative. [169] [170] However, the more common infrared monitors that extrapolate tympanic membrane temperature from outer ear temperature are often unreliable. [171]

When Temperature Monitoring is Required

Local anesthetics (including amides) administered to produce regional blocks and sedatives used during monitored anesthesia care do not trigger malignant hyperthermia. [172] Nonetheless, core hypothermia is as common during epidural and spinal anesthesia as during general anesthesia, and it can be nearly as severe. [71] Core temperature should therefore be measured during regional anesthesia in patients likely to become hypothermic (e.g., those undergoing body cavity surgery).

Core temperature monitoring is appropriate during most cases of general anesthesia, both to facilitate detection of malignant hyperthermia and to quantify hyperthermia and hypothermia. Malignant hyperthermia is best detected by tachycardia and an increase in end-tidal P_{CO_2} out of proportion to minute ventilation. [173] Although increasing core temperature is not the first sign of acute malignant hyperthermia, it certainly helps confirm the diagnosis. More common than malignant hyperthermia is intraoperative hyperthermia, which has other causes including excessive warming, infectious fever, blood in the fourth cerebral ventricle, and mismatched blood transfusions.

By far the most common perioperative thermal disturbance is inadvertent hypothermia. Core temperature usually decreases 0.5 to 1.5°C in the first 30 minutes following induction of anesthesia. Hypothermia results from internal redistribution of heat and a variety of other factors whose importance in individual patients is hard to predict. [56] [74] Core temperature perturbations during the first 30 minutes of anesthesia thus are difficult to interpret, and measurements are not usually required. Body temperature should, however, be monitored in patients undergoing general anesthesia exceeding 30 minutes in duration and in all patients whose surgery lasts longer than 1 hour.

Temperature Monitoring Sites

The core thermal compartment is composed of highly perfused tissues whose temperature is uniform and high compared with the rest of the body. Temperature in this compartment can be evaluated in the pulmonary artery, distal esophagus, tympanic membrane, or nasopharynx. [174] [175] Temperature probes incorporated into esophageal stethoscopes must be positioned at the point of maximal heart sounds, or even more distally, to provide accurate readings. [143] Even during rapid thermal perturbations (e.g., cardiopulmonary bypass), these temperature monitoring sites remain reliable. Core temperature can be estimated with

Figure 37-24 (Figure Not Available) Axillary and esophageal temperatures correlated well during acute malignant hyperthermia in swine, but forehead and neck skin temperatures did not. Rectal temperature also failed to identify onset of malignant hyperthermia promptly. Elapsed time zero indicates an end-tidal P_{CO_2} of 70 mm Hg. These data indicate that forehead and neck skin surface temperatures do not adequately confirm other clinical signs of malignant hyperthermia. Valid core temperature monitoring sites include the distal esophagus, pulmonary artery, nasopharynx, and tympanic membrane. Except during cardiopulmonary bypass, body temperature also can be measured in the mouth, axilla, and bladder. Data presented as means ± standard deviations. *(Modified from Iaizzo PA, Zink RS, Kehler CH et al: Skin and central temperature during malignant hyperthermia in swine. Anesthesiology 77:A569, 1992.)*

reasonable accuracy using oral, axillary, rectal, and bladder temperatures except during extreme thermal perturba-tions. [174] [175]

Skin surface temperatures are considerably lower than core temperature. [176] Skin surface temperatures, even when adjusted with an appropriate offset, sometimes reflect core temperature reasonably well. [177] In other cases, though, they are insufficiently accurate and precise for perioperative use. Skin temperatures fail to confirm the clinical signs of malignant hyperthermia (tachycardia and hypercarbia) reliably in swine [178] and have not been evaluated for this purpose in humans (Fig. 37-24) (Figure Not Available) . Rectal temperatures also normally correlate well with core temperature, [174] [175] but they fail to increase appropriately during malignant hyperthermia crises [178] and under other documented situations. [179] [180] Consequently, rectal and skin surface temperatures must be used with some caution.

Even during cardiopulmonary bypass, the core temperature monitoring sites (e.g., tympanic membrane, nasopharynx, pulmonary artery, and esophagus) remain useful. In contrast, rectal temperatures lag behind those measured in core sites. Consequently, rectal temperature is considered an "intermediate" temperature in deliberately cooled patients. During cardiac surgery, bladder temperature is equal to rectal temperature (and therefore intermediate) when urine flow is low, but it is equal to pulmonary artery temperature (and thus core) when flow is high. [181] Because bladder temperature is strongly influenced by urine flow, it may be difficult to interpret in these patients. The adequacy of rewarming is best evaluated by considering both "core" and "intermediate" temperatures.

Temperature Monitoring and Thermal Management Guidelines

The objective of temperature monitoring and perioperative thermal management is to detect thermal disturbances and to maintain appropriate body temperature during anesthesia. Available data suggest the following guidelines:

1. Core body temperature should be measured in most patients given general anesthesia for more than 30 minutes.
2. Temperature should also be measured during regional anesthesia when changes in body temperature are intended, anticipated, or suspected. This at the very least includes body cavity surgery and other large and long operations.
3. Unless hypothermia is specifically indicated (e.g., for protection against ischemia), efforts should be made to maintain the intraoperative core temperature higher than 36°C.

SUMMARY

Body temperature normally is controlled by a negative feedback system in the hypothalamus that integrates thermal information from most tissues. Approximately 80 percent of this thermal input is derived from core body temperature, which can be measured using distal esophageal, nasopharyngeal, or tympanic membrane thermometer probes. The hypothalamus coordinates increases in heat production (nonshivering thermogenesis and shivering), increases in environmental heat loss (sweating), and/or decreases in heat loss (vasoconstriction) as needed to maintain normothermia.

Thermal steady state requires that heat loss to the environment equal metabolic heat production; hypothermia occurs when heat loss exceeds production. Mild core hypothermia is common during surgery and anesthesia and results initially from redistribution of body heat from the core to peripheral tissues and subsequently from heat loss exceeding metabolic heat production. Clinical doses of all tested general anesthetics decrease the threshold for response to hypothermia from approximately 37°C (normal) to 33 to 35°C. Thus, anesthetized patients with core temperatures exceeding these temperatures usually are poikilothermic and do not actively respond to thermal perturbations. Patients who become sufficiently hypothermic do trigger thermoregulatory vasoconstriction, and the vasoconstriction is remarkably effective in minimizing further core hypothermia.

Mild intraoperative hypothermia provides significant protection against tissue ischemia and hypoxia. It also decreases triggering of malignant hyperthermia and reduces the severity of the syndrome, once triggered. However, most consequences of inadvertent hypothermia are harmful. Major adverse effects include morbid myocardial outcomes, reduced resistance to surgical wound infections, impaired coagulation, prolonged duration of drug action, shivering, and decreased postoperative thermal comfort.

Little metabolic heat is lost via the respiratory tract. Consequently, even active airway heating and humidification are of little benefit and are rarely indicated. Administration of sufficient volumes of cold IV fluid can produce substantial hypothermia. Fluids therefore should be warmed in patients requiring IV administration of more than several liters per hour. Among the clinically available active systems, forced air is the most effective and can usually maintain normo-thermia even during the largest operations.

Regional anesthesia produces both peripheral and central inhibition of thermoregulatory control. Peripheral inhibition results when local anesthetics block nerves that are required for thermoregulatory defenses. In contrast, central impairment apparently results when the regulatory system incorrectly concludes that leg skin temperature has markedly increased. Hypothermia during neuroaxial anesthesia results initially from core-to-peripheral redistribution of body heat and subsequently from heat loss exceeding heat production. Hypothermia during major conduction anesthesia may be as severe as that during general anesthesia.

Increased core temperature can result from augmented thermogenesis (malignant hyperthermia), excessive heating (passive hyperthermia), or a specific increase in the thermoregulatory target temperature (fever). Because the causes of hyperthermia are varied and often serious, the cause of observed increases in core temperature should be sought, and appropriate treatments should be instituted.

A reasonable strategy for detecting and preventing thermal disturbances is to monitor core temperature in patients having general anesthesia lasting longer than 30 minutes and in those undergoing major surgery with regional anesthesia. Unless hypothermia is specifically indicated (i.e., for protection against cerebral ischemia), core temperature should be maintained at more than 36°C.

Chapter 38 - Acid-Base Balance

Robert E. Shangraw

INTRODUCTION

A thorough understanding of acid-base balance is important for the anesthesiologist because changes in acid-base balance can occur quickly in the patient undergoing surgery or otherwise requiring critical care. Further, these rapid changes may exert a profound influence on the body's physiologic functions, including compatibility with life. [1] [2] The purposes of this chapter are to present the dynamics of acid-base homeostasis and to facilitate recognition and treatment of acid-base disturbances encountered in clinical anesthesiology. The principal determinants for assessing acid-base balance are pH and CO_2 partial pressure (P_{CO_2}), from which are derived bicarbonate [HCO_3^-] and base excess (BE). Briefly, the goals are to

1. Use arterial blood P_{CO_2} (Pa_{CO_2}) to quantify a respiratory abnormality.
2. Use arterial [HCO_3^-] and BE to quantify a metabolic abnormality.
3. Diagnose a general acid-base derangement (respiratory acidosis, respiratory alkalosis, metabolic acidosis, or metabolic alkalosis).
4. Make a differential diagnosis of a metabolic disturbance using anion gap (AG), or unidentified anions (UA^-) calculated from the strong ion difference (SID).
5. Determine the extent to which compensatory mechanisms have been activated.
6. Synthesize a treatment plan, based on correcting the proximate cause and mechanism of the disturbance.

The chapter is organized to define clinical terms for acid, base, and buffer, to present the action of the HCO_3^- and other buffers, to discriminate among different causes of acid-base disturbance and their respective consequences, to show physiologic compensatory mechanisms, and to outline mechanisms for and treatment of the four basic types of acid-base disturbance.

OVERVIEW: ACID GENERATION AND ELIMINATION

Acid-base balance is regulation of hydrogen ion activity ($[H^+]$), in solution. Arterial blood $[H^+]$ is normally maintained at 40 ± 4 nmol/L, which is one-millionth of that for other common cations. In the circulation, $[H^+]$ may change by an order of magnitude, which makes it unique among ions. H^+ competes for protein binding space, and by displacing protein-bound hormones and drugs, it affects their bioavailable free concentrations.

Complex mechanisms control H^+ movement across plasma membranes to determine its intracellular versus extracellular concentrations, details of which are only beginning to be elucidated. Intracellular $[H^+]$ varies among tissues and, as a general rule, is slightly higher and less variable than that of the blood. [3] [4] [5] [6] Because of its small size and charge density, it exerts a powerful regulatory action on cellular function. [5] [6] Intracellular $[H^+]$, however, cannot be evaluated with equipment routinely available in the operating room, thus making direct assessment impractical. Fortunately, intracellular acid-base status can be reasonably, if indirectly, evaluated by analysis of blood. Ease of accessibility has made arterial blood the most common sampling source for assessment of acid-base balance, reflecting the extracellular compartment and serving as a window of whole-body acid-base balance. The intracellular compartment, however, contains a large reservoir of H^+ that may not change in lock step with extracellular fluid (ECF), but it can exchange with it.

Either $[H^+]$ or its negative logarithm, pH, is the central indicator of acid-base balance. The relationship between $[H^+]$ and pH is shown in Figure 38-1. (Figure Not Available) Note that pH 7.40 is equivalent to an $[H^+]$ of 40 nmol/L. Most of this chapter is devoted to control of blood acid-base balance *in vivo,* the processes of H^+ production into and removal from the blood that maintain H^+ homeostasis.

Endogenous H^+ is produced intracellularly by turnover of high-energy phosphates (adenosine triphosphate [ATP]), metabolism of sulfur-containing or cationic amino acids, incomplete or nonoxidative metabolism of carbohydrates, and ingested or administered metabolic acids such as salicylate. Oxidative catabolism of protein in general yields 1,000 mmol each of HCO_3^- and ammonium (NH_4^+) daily. The kidney excretes about 80 mmol H^+ per day, mostly as NH_4^+.

Cellular oxidative metabolism produces at least 20,000 mmol of CO_2 per day in adults, which is matched by alveolar ventilation (V_A) such that Pa_{CO_2} is normally maintained at 40 ± 4 mm Hg. The relationship between CO_2 and ventilation is described by the V_A equation:

where V_A (mL/min) is the difference between minute ventilation (V_E) and dead space (V_D); V_{CO_2} is tissue CO_2 pro-duction (mL/min); and K is a patient-specific constant (mm Hg · min/L). Rearrangement of the equation as:

Figure 38-1 (Figure Not Available) Relationship between $[H^+]$ and pH. Note an approximately linear relationship near pH 7.40, but that $[H^+]$ increases more than pH at pH less than 7.20. *(From Narins and Emmett [141])*

demonstrates that Pa_{CO_2} is directly proportional to V_{CO_2} and is inversely proportional to V_A.

V_{CO_2} and H^+ production are linked by carbonic acid (H_2CO_3), which enables H^+ to interconvert with CO_2. This interaction is known as the HCO_3^- buffer system:

The relationship between H^+ and CO_2 is important for three reasons. First, it indicates that the largest single H^+ source under physiologic conditions is tissue CO_2 production. Second, it allows flexibility in $[H^+]$ regulation because H^+ can be more quickly and efficiently removed from the body as CO_2 than as the H^+ with which it equilibrates. Renal excretion alone cannot effectively remove a H^+ challenge. Third, it permits CO_2 removal from the body to keep pace with its tissue production by allowing interconversion of CO_2 and HCO_3^-.

CO_2 produced by oxidative metabolism ultimately leaves the body as CO_2 by alveolar ventilation. However, most CO_2 (~80%) is transported in blood to the lungs in the form of HCO_3^-, because of the poor water solubility of CO_2. Carbamino compounds, including carbaminohemoglobin, account for another 15 percent of blood CO_2 content, and dissolved CO_2 represents only ~5 percent of total blood CO_2 content. CO_2 is converted to HCO_3^- in the nonpulmonary microcirculation and back to CO_2 in the pulmonary circulation. [7] These important relationships illustrate that acid-base regulation is intimately linked to body CO_2 transport.

ACIDS, BASES, AND BUFFERS

An *acid,* as defined by Bronsted and Lowry, is a substance that donates H^+ at a given pH. A *base* accepts H^+ at a given

pH, and a *buffer pair* is a weak acid (HA) in equilibrium with a weak conjugate base (A^-):

The relative strength of the acid and base components of the buffer pair determines the balance of the equation to either the right or left, according to an equililibrium constant (K):

which rearranges to form the Henderson equation:

Acidity of a solution, or $[H^+]$, is determined by the degree of dissociation of an acid into its free H^+ and conjugate base. Mineral acids, such as hydrochloric acid (HCl), dissociate completely in solution and have infinitely high K values.

The Henderson relationship is better recognized when expressed in the logarithmic form of the Henderson-Hasselbalch equation:

where pK is the negative logarithm of K, the dissociation constant. A low pK indicates a strong acid, and a high pK represents a weak acid or strong base. When pH equals pK, an acid is 50 percent dissociated. Common organic acid pK values are shown in Table 38-1 .

A *buffer* minimizes changes in $[H^+]$ from the baseline value, which for arterial blood is 40 nmol/L (pH 7.4). It must be capable of either binding free H^+ during an H^+ challenge or donating free H^+ during an OH^- challenge, to defend the baseline $[H^+]$. A buffer thus acts as a weak base during an H^+ challenge or a weak acid during an OH^- challenge. Because a buffer must be able to either donate or accept H^+, its best buffering capacity occurs at a pH that approximates its pK, where it is 50 percent dissociated. Greater than 90 percent of buffering capacity occurs when the pH is within ±1 units relative to the pK of a buffer.

Let us first consider the buffering capacity of lactic acid, which has a pK of 3.86. Lactic acid (HL) equilibrates with

TABLE 38-1 -- Strength of Common Organic Acids

ORGANIC ACID	pK_a
Acetoacetate	3.58
Formate	3.75
Carbonic acid	3.77
Lactate	3.86
beta-Hydroxybutyrate	4.70
Acetate	4.76
Phosphate	6.80

pK_a , negative logarithm of the acid ionization dissociation constant

lactate (L^-) as HL
$H^+ + L^-$. Substitution of lactic acid values into the Henderson-Hasselbalch equation at pH 7.40 yields:

rearranging:

Lactic acid (or lactate) is a poor buffer at physiologic pH because it exists steadfastly in the dissociated state and cannot bind free H^+ ions. Similarly, most common organic acids are poor buffers in the physiologic pH range for both intracellular and extracellular fluids (see Table 38-1) . These organic acids are overwhelmingly ionized within the relatively small $[H^+]$ range that is compatible with life.

In contrast, phosphate (HPO_4^{2-}), with a pK of 6.80, yields the following values at pH 7.40:

rearranging:

During an H^+ challenge, HPO_4^{2-} readily accepts H^+ to form $H_2PO_4^-$, minimizing free H^+ accumulation in solution and the change in $[H^+]$ from the baseline 40 nmol/L. HPO_4^{2-} is an effective buffer when present at the concentration found in urine and intracellular fluid. Its concentration in extracellular fluid, however, is normally too low for it to play a major role in acid-base balance.

Protein can be an effective buffer, largely dependent on the imidazole ring of its histidine (His) moiety, which has a nominal pK of 6.00. At pH 7.4:

rearranging:

Histidine's imidazole ring buffers within the physiologic pH range, especially in intracellular fluid where the pH is closer to 7.0, and the imidazole ring ionized/unionized ratio becomes 10:1. A high histidine content of hemoglobin (Hb) is important for its buffering capacity. Protein conformation may alter the effective pK of imidazole. For example, at least 13 histidine residues in albumin can buffer, with individual pK values ranging from 5.15 to 7.82. [8] Buffers play an important role in acid-base homeostasis by preventing wide $[H^+]$ oscillations during the course of diurnal H^+ or CO_2 challenges.

COMPONENTS OF BODY ACID-BASE BUFFERING

Carbon Dioxide - Bicarbonate Buffer System

The most important buffer in blood is the CO_2 -HCO_3^- system, where HCO_3^- acts as a weak base:

CO_2 -HCO_3^- is not a true, or closed, buffer because its ability to maintain a pH of 7.4 depends on free movement of CO_2 out of the system, rather than HCO_3^- absorbing H^+ and remaining in solution. Hydration of CO_2 to form carbonic acid (H_2CO_3) is relatively slow unless the reaction is catalyzed by *carbonic anhydrase* (CA). CA is widely distributed in tissues throughout the body in the form of different isoenzymes. [9]

H_2CO_3 is a strong organic acid with a pK of 3.77. H_2CO_3 quickly and almost completely dissociates into H^+ and HCO_3^- at physiologic pH. Therefore, H_2CO_3 represents less than 0.5 percent of the CO_2 -HCO_3^- system mass. Because of rapid overall equilibration in the presence of CA, the reaction between CO_2 and HCO_3^- is considered collectively. Substituting CO_2 -HCO_3^- buffer values in the Henderson equation yields:

where the equilibrium constant for the overall CO_2 -HCO_3^- reaction (K
) is 24 nmol H^+ · mmol HCO_3^- /mm Hg at 37°C. Alternatively, substituting CO_2 -HCO_3^- buffer values into the Henderson-Hasselbalch equation yields:

where pK_a
is the dissociation constant for the overall CO_2 -HCO_3^- reaction, and alpha is the solubility coefficient for CO_2 in plasma. At 37°C, pK_a
is 6.1 and alpha is 0.03 mmol/L/mm Hg, yielding the equation:

Note that by the Henderson or the Henderson-Hasselbalch equation, acidity of a solution is determined by the ratio of P_{CO_2} to [HCO_3^-], not by the absolute value of either. Substituting the normal values Pa_{CO_2} = 40 mm Hg and [HCO_3^-] = 24.0 mmol/L:

Let us first perturb the system by increasing Pa_{CO_2} to 80 mm Hg and assume that the change in [HCO_3^-] (nmol/L) is too small to affect the result:

At pH 7.10, [H^+] is 80 nmol/L, or 40 nmol/L greater than the baseline 40 nmol/L (see Fig. 38-1) (Figure Not Available) . For electroneutrality, [HCO_3^-] must also increase by 40 nmol/L accompanying the H^+ increase, but the change (to 24.000040 mmol/L) is negligible. From a practical standpoint, [HCO_3^-] is insensitive to changes in P_{CO_2} in an isolated system, and the change in [H^+] is directly proportional to the change in P_{CO_2}. Of course, the body is normally an open system that can rapidly eliminate CO_2 via the lungs, and [HCO_3^-] does increase modestly *in vivo* with increases in P_{CO_2}. [10]

Consider next a 5-mmol/L nonvolatile H^+ challenge in the form of HCl. An equal quantity of HCO_3^- will be consumed, decreasing its concentration from 24 to 19 mmol/L. The effect on pH is:

At pH 7.30, [H^+] is 50 nmol/L, or 10 nmol above the baseline 40 nmol/L (see Fig. 38-1). Thus, addition of 5 (Figure Not Available) million nmol H^+ to a solution containing 24 mmol/L HCO_3^- increases free [H^+] by only 10 nmol/L. This relationship is also demonstrated by using the Siggaard-Andersen nomogram (Fig. 38-2) (Figure Not Available) .

Body *total* CO_2 content includes HCO_3^-, carbonate, carbamino compounds, dissolved CO_2, and H_2CO_3. The whole body total CO_2 pool, at 13 to 18 mmol/kg body weight, is very large. From the standpoint of acid-base balance, it is not easily exhausted. However, it is compartmentalized into at least three distinct functional pools, only one of which (central compartment) turns over rapidly (Fig. 38-3) (Figure Not Available) . [11] [12] Body fluid HCO_3^- accounts for about 9 mmol/kg, and most of the

remaining 4 to 9 mmol/kg exists as carbonate in bone. The relative size of the total CO_2 compartments may change with acid-base status, such that the fast turnover central pool can increase 3-fold when [H^+] is increased. [13] Another consequence of the large but compartmentalized total CO_2 pool is some functional separation of CO_2 and HCO_3^- fluxes *in vivo.*[14]

The CO_2 -HCO_3^- buffer system exerts a powerful effect on acid-base balance. Further, when presented in graphic form (Fig. 38-4) (Figure Not Available) , it is used to differentiate the various types of acid-base disturbances. It an ideal buffer for the following reasons:

1. The system is open, allowing volatile CO_2 produced from reaction of H^+ and HCO_3^- to be easily removed from the body by V_A. Ventilatory adjustment can quickly correct acid-base disturbances.
2. It has an extraordinary apparent molar buffer value, roughly four times that of most other buffer species, such as HPO_4^{2-}. (See the discussion on quantitation of buffer content later.)
3. Its other physiologic functions are uncompromised when it is consumed for H^+ homeostasis, although a protracted

H^+ load depleting HCO_3^- will ultimately demineralize and weaken bone over a period of months to years. In contrast, acute dependence on albumin as the principal H^+ buffer system would, by displacing hormones and drugs from their binding sites, lead to endocrine dysfunction or convert an appropriate drug dose into a lethal one. Similarly, excessive dependence on hemoglobin for H^+ buffering would decrease its ability to bind and carry oxygen (O_2) to tissues.

Figure 38-2 (Figure Not Available) Siggaard-Andersen alignment nomogram. This is used for determination of HCO_3^- and base excess (BE) from measured values of pH and P_{CO_2}. See text for details. *(From Astrup and Severinghaus [22])*

Two principal measures of the CO_2 -HCO_3^- system, pH and P_{CO_2}, can be rapidly and directly measured with substrate-specific electrodes. These values are part of the *blood gas analysis* routinely performed in clinical laboratories. The third component, HCO_3^-, is calculated as the difference between total CO_2 and dissolved P_{CO_2} ($0.03 \cdot P_{CO_2}$), or a by using a nomogram (see Fig. 38-2) (Figure Not Available) .

Carbonate and carbamino compounds, although a major fraction of whole body total CO_2 content, are absent from plasma. HCO_3^- accounts for 95 percent of plasma total CO_2, with the remaining 5 percent due to dissolved CO_2. [7] Therefore, venous plasma total CO_2 content is commonly used as a surrogate measure of [HCO_3^-], to approximate acid-base status in patients without a respiratory abnormality.

Weak Acid Plasma Buffers: Proteins and Phosphate

Despite its great importance, the CO_2 -HCO_3^- system is not the only buffer in the body, or even in the intravascular compartment. The next buffers to consider are plasma proteins

Figure 38-3 (Figure Not Available) Distribution of the HCO_3^-/CO_2 pool in humans. Note that most of the pool is located in slow-turnover compartments. *(Modified from Irving et al [11])*

and HPO_4^{2-}. Plasma proteins are heterogenous, with different pK values and buffering capacities. *Albumin* is the only important buffering plasma protein, and its buffering capacity can be modified when other substrates, including Ca^{2+}, bind to it. [8] *Phosphate* (HPO_4^{2-}) can usually be ignored as a buffer unless its plasma concentration becomes pathologically increased, for example, by renal failure. Even in renal failure, the added buffering of hyperphosphatemia plays a relatively minor role in clinical acid-base homeostasis.

Whole Blood: The Importance of Erythrocytes

Although erythrocytes are cells, they are in practice considered part of the ECF when assessing acid-base balance. Erythrocytes supply CA within blood, a process that facilitates the CO_2 -HCO_3^- buffer system by catalyzing rapid interconversion of CO_2 and HCO_3^-. [9] As mentioned earlier, CO_2 -HCO_3^- interconversion is critically important for efficient removal of CO_2 produced by the tissues.

Erythrocytes also contain a Cl^-/HCO_3^- anion-exchange transporter (AE-1), which mediates isoelectric exchange of HCO_3^- for Cl^- across its plasma membrane *(chloride shift).*[7] Tissue CO_2 production increases venous P_{CO_2}, and V_A decreases P_{CO_2} in pulmonary capillaries. AE-1 mediates erythrocyte HCO_3^- release in peripheral tissues (in exchange for Cl^- uptake), maintaining a stable P_{CO_2}/HCO_3^- ratio and minimizing the increase in venous blood acidity. HCO_3^- in venous plasma also reacts with H^+ released by tissues. An opposite Cl^-/HCO_3^- exchange occurs in the pulmonary microcirculation, where AE-1 mediates erythrocyte uptake of HCO_3^- in exchange for intracellular Cl^-. Erythrocyte HCO_3^- uptake from plasma in the lung coincides with CO_2 movement from the blood into the alveoli, again maintaining a constant P_{CO_2}/HCO_3^- ratio and minimizing the alkalinity that would occur in the pulmonary capillary. Furthermore, because the Cl^- shift in peripheral tissues promotes HCO_3^- movement from the erythrocyte into the plasma, it speeds the CA reaction by dispersing intracellular [HCO_3^-] and facilitates CO_2 transport.

Erythrocyte-bound Hb buffers in two ways. First, Hb has a high histidine content (8% of total amino acid content) with an average pK of ~6.8. Several histidine residues participate in each chain of the Hb molecule, increasing its effective buffering. The molecular mechanism of H^+ buffering by Hb depends on the Hb O_2 saturation state. Hb deoxygenation in peripheral tissues increases its H^+ binding according to the equation: $HbO_2 + H^+$ $HHb + O_2$ (the *Bohr effect*). The effect of H^+ binding by Hb on the free [H^+] is mitigated by the HCO_3^- system ($CO_2 + H_2O$ $H^+ + HCO_3^-$), making the overall equation: $HbO_2 + CO_2 + H_2O$ $HHb + HCO_3^- + O_2$ (the *Haldane effect*). The

Figure 38-4 (Figure Not Available) Siggaard-Andersen acid-base chart. This is used to determine the appropriate compensation for a primary acid base disturbance. Chronic metabolic adaptation to respiratory disturbances requires days to weeks. *(From Astrup and Severinghaus [22])*

process reverses in the lung: Hb oxygenation releases CO_2 and H_2O as HCO_3^- is consumed. The Haldane effect represents coordination of Hb with the CA and AE-1 systems. It minimizes the pH decrease in nonpulmonary tissues and the venous system, where Hb is desaturated, maintaining acid-base homeostasis.

The second Hb buffering mechanism is direct Hb binding of CO_2 to form *carbaminohemoglobin,* which accounts for ~10 percent of peripheral CO_2 uptake by the blood. [7] Non-Hb proteins in the erythrocyte also form carbamino compounds to buffer a CO_2 challenge. Both non-Hb proteins and intracellular HPO_4^{2-} serve as direct H^+ buffers.

Extracellular Fluid Buffering

ECF includes plasma, erythrocytes, and interstitial fluid. Total ECF volume is three to five times that of blood because of a large interstitial space that, unfortunately, is

difficult to sample. Interstitial fluid [HCO_3^-] and [HPO_4^{2-}] resemble those of plasma, but [albumin] is normally about onethirtieth of that in plasma and [Hb] is negligible. Further, the relationship between plasma and interstitial albumin and Hb concentrations may change during acute hemodilution.

Despite the distance of interstitial fluid from erythrocytes, its close juxtaposition to tissues containing CA facilitates local HCO_3^- formation from CO_2 diffusing from the tissues. This augments CO_2 transport to the lungs. A side effect of the CA reaction is that H^+ is produced along with the HCO_3^-, thereby decreasing the local pH. Skeletal muscle contains a CA isoenzyme (CA-3) with low catalytic activity, which minimizes local H^+ production in skeletal muscle because of CO_2 hydration. [9]

QUANTITATION OF EXTRACELLULAR FLUID BUFFER CONTENT AND ACID-BASE BALANCE

Buffer power (beta) quantitates the effectiveness of buffers in solution. It is defined as the negative of the slope of the acid titration curve at a given pH, usually 7.40 (Fig. 38-5) . Buffer power is expressed as millimoles of H^+ removed (or

Figure 38-5 Quantitation of buffering capacity (beta) in extracellular or intracellular fluid. This model depicts a hypothetic buffer solution, with point A on the X axis representing the baseline pH. The Y axis is the change in OH^- removed (or H^+ added) and X axis it the consequent change in pH. beta is defined as the slope of -DeltaH^+ added/DeltapH. A better buffer, which requires either more H^+ or OH^- added for a given pH change, would have a larger beta value.

base added) per liter/DeltapH unit. In the presence of CO_2 -HCO_3^-, non-HCO_3^- buffering power is defined in units called *slykes* (Delta[HCO_3^-]/DeltapH unit). [15] *Molar buffer power* is the defined as buffer power/mole buffer. For example, at pH 7.40, the molar buffer power is 2.3 for HCO_3^-, 0.575 for HPO_4^{2-}, ~3 for Hb, and 8 for albumin. [8] [15]

Understanding buffer power requires knowledge of the conditions of analysis. First, a CO_2 challenge should be distinguished from a nonvolatile acid (H^+) challenge. Second, the buffer components present during the challenge must be identified. Third, it is important to determine whether the data were generated *in vitro* or *in vivo.* Most buffer power data have been generated from *in vitro* samples.

For CO_2 titration, the buffer power of plasma separated from blood cells before CO_2 equilibration ("separated" plasma) is proportional to its protein content (Table 38-2) . Much greater buffer power is obtained from plasma that has been equilibrated with CO_2 *before* separation from cells ("true" plasma). The added buffering is due to erythrocyte-contained Hb, which converts CO_2 to plasma HCO_3^- before separation. Erythrocytes and other cells have a buffer power of ~50 slykes. [7] [15] [16] Buffer power of human whole blood is intermediate between that of plasma and red cells, whereas that of overall normal ECF resembles that of dilute "true" plasma.

ECF buffering power *in vivo* is more time-dependent than that determined *in vitro,* because of the influences of cellular buffering mechanisms (discussed later), mobilization of carbonate from bone, and the extent to which [H^+] or [HCO_3^-] is altered by renal function. In dogs breathing CO_2, *in vivo* buffer power almost doubles within 2 hours from that predicted on the basis of ECF buffering capacity, and it further increases to 5-fold by 24 hours. [17] Similar findings have been made in rats. [7] Comparable data in humans are not available, other than to demonstrate that the apparent HCO_3^- volume of distribution *(HCO_3^- space)* increases over time. [11] [14] One implication of this progressive increase in buffer power is that an unexpected overshoot is possible during acute therapy of acid-base disturbances as intrinsic buffer power increases. Conservative initial treatment and frequent reassessments of acid-base status are prudent. There are few nontheoretic descriptions of the effect of changes in the individual factors controlling acid-base balance. [18] [19]

Different clinical methods have been developed to quantify the buffer content, or to assess acid-base status, in body solutions. An important, and widely used, method to assess buffer content is *base excess* (BE) , developed by Siggaard-Andersen and colleagues using blood samples *in vitro.*[20] [21] [22] BE is popular because it is easy to calculate or determine using a nomogram (see Fig. 38-2) (Figure Not Available) . It is also automatically reported by many commercially available blood gas machines. BE is defined as the deviation of the patient's [HCO_3^-] from 24 mmol/L after the pH is corrected to 7.40. This could be determined by adjusting the patient's arterial blood pH to 7.40 by altering minute ventilation (V_E) to change Pa_{CO_2}. At

TABLE 38-2 -- Buffer Power of Body Constituents

BUFFER	BUFFER POWER (beta)	INVESTIGATORS
Phosphate solution		
2.5 mmol/L	1.0	Klocke [7]

Muscle	~50	Woodbury [15]

pH 7.40, all non-HCO_3^- buffers are in their resting distribution; that is, they are neither accepting nor donating H^+ to compensate for a pH deviation from 7.40. All buffering is then produced by the CO_2 -HCO_3^- system.

Alternatively, BE can be calculated by multiplying the pH deviation from 7.40 by the apparent ECF buffer power, then adding this value to the "measured" [HCO_3^-] value, and subtracting these from the expected "normal" [HCO_3^-] value of 24 mmol/L at 7.40. ECF buffer power, assuming normal concentrations of Hb, albumin, and HPO_4^{2-}, is ~10 to 12 slykes (= Delta[HCO_3^-](mmol/L)/DeltapH). [15] An ECF buffer power of 10 slykes is often used to simplify the mathematics. The equation for BE can be written as follows:

where both [HCO_3^-] and Delta[HCO_3^-] are expressed in millimoles per liter and

Substituting blood gas values of pH 7.20, Pa CO_2 32 mm Hg, and [HCO_3^-] 20 mmol/L, the DeltapH is 7.20 - 7.40 = -0.20, and:

Combining this with the [HCO_3^-] determined from the blood gas analysis and subtracting from the normal [HCO_3^-] of 24 mmol/L:

Normal ECF volume is approximately three times that of the intravascular compartment. For this reason, determination of ECF base excess using the Siggaard-Andersen nomogram (see Fig. 38-2) (Figure Not Available) is most accurate using the isobar for a Hb concentration of 5 mg/dL or less. The single charge on HCO_3^- permits BE to be expressed as either millimoles per liter or milliequivalents per liter. A negative BE value is referred to as a "base deficit."

The numeric value for BE has clinical importance. A normal BE is 0 ± 2 mmol/L. If the base deficit, in millimoles per liter, is multiplied by the HCO_3^- space, in liters per kilogram of body weight, an appropriate dose of sodium HCO_3^- ($NaHCO_3$) to reverse the base (HCO_3^-) deficit can be calculated. Alternatively, if a BE has an appreciable value, this can be used to determine the HCO_3^- excess to be neutralized by HCl infusion. HCO_3^- space is often used interchangeably with ECF, although the functional HCO_3^- space is in practice more variable than ECF. Commonly, the HCO_3^- space is taken to be 0.2 to 0.3 L/kg (40-50% total body water), but it can double (to 100% of total body water) when [H^+] is markedly increased. [13] Almost 30 percent of the HCO_3^- space can be accounted for by CO_2 loss in the breath. [23] The space also increases slowly over time (hours) as administered HCO_3^- distributes progressively into slower turnover compartments *in vivo.* [11] [12] [14]

The BE concept, as presented, has three shortcomings. First, it does not elucidate the mechanism for a pH disturbance other than to eliminate the contribution of CO_2. Second, because it assumes "normal" ECF concentrations of Hb, albumin, and HPO_4^{2-}, it is insensitive to the change in buffering power consequent to abnormal concentrations of these factors. Specifically, hypoalbuminemia can mask an acidosis because the BE equivalent of albumin is 3.7 mEq/g. [18] Third, because the Siggaard-Andersen nomogram was generated from blood *in vitro,* it is insensitive to *in vivo* processes that increase buffering power over time. [7] [17] Nevertheless, it provides a useful, if imperfect, assessment of clinical acid-base balance.

An alternative approach to assessing acid-base balance utilizes the terms "acid" and "base" to refer to anions and cations, respectively. Singer and Hastings introduced the term "buffer base" (B_B) using whole blood *in vitro.* [24] They defined B_B as the sum of charges on all strong "bases" (nonbuffering cations) minus the sum of charges on all strong "acids" (nonbuffering anions), according to the equation:

where [SI] is the concentration of a strong ion (e.g., Na^+, Cl^-), and *z*SI is its charge. To satisfy the requirement for electroneutrality, B_B must be balanced by the charge sum of buffer ions such that:

where [BI] is buffer ion concentration and zBI is its charge. The weakness of B_B is that the distinction between strong and buffer ions is arbitrary, and it depends on the prevailing pH. A nomogram has been created using pH, P CO_2, and Hb concentration to determine B_B. [24]

Stewart's "physicochemical" approach to acid-base is a modification of B_B, although it was developed using plasma rather than whole blood. [25] It defines "strong ion difference" (SID) as the net charge sum of strong electrolytes:

It is important to account for the double charge on Ca^{2+}, although magnesium (Mg^{2+}) is typically reported as milliequivalents per liter. As originally developed, acid-base problem solving required simultaneous iterative approximations of six polynomial equations, which limited its appeal to bedside clinicians. Fencl and Leith experimentally simplified the Stewart approach. [26] Actual SID cannot be determined directly because "other strong anions" are not quantified. The "other strong anions" are ignored to calculate an *apparent SID* ($SID_{apparent}$), defined as the charge sum:

An example of normal $SID_{apparent}$ is 140 + 4 + (2 · 2.5) + 2 - 105 = 46 mEq/L.

For electroneutrality, $SID_{apparent}$ is balanced in part by the sum of charges on buffers, that is, HCO_3^- and all weak nonvolatile acids, which Fencl and Leith [26] termed *effective SID* ($SID_{effective}$). Plasma weak nonvolatile acids are proteins (albumin) and inorganic phosphate. Albumin has a net

charge of -2.6 mEq/g at pH 7.4. [8] Phosphate has a net charge of -1.8 at pH 7.4, based on its equilibrium between HPO_4^{2-} and $H_2PO_4^-$. Therefore:

A normal plasma albumin concentration of 3.6 to 5.2 g/dL produces a negative charge range of 9 to 14 mEq/L, whereas phosphate, with a normal plasma concentration of 0.8 to 1.5 mmol/L, yields a negative charge range of 1.5 to 2.2 mEq/L. An example of normal $SID_{effective}$ at pH 7.4 is:

The charge difference between $SID_{apparent}$ and $SID_{effective}$ is accounted for by unidentified anions (UA^-). Thus a normal UA^- value is 46 minus 36 = -10 mEq/L. A UA^- value of substantially greater magnitude than -10 mEq/L indicates an increased plasma content of anions, possibly pathogenic.

The SID physicochemical approach, by accounting for plasma albumin and HPO_4^{2-} concentrations, has the potential to provide insight into the mechanism of an acid-base disturbance. $SID_{effective}$ may become an important adjuvant to evaluate acid-base status during marked hypoalbuminemia or when plasma [HPO_4^{2-}] is pathologically increased. However, the clinical utility of $SID_{effective}$ and UA^- remains to be tested in widespread application. A database of normal population values is lacking.

An analogue of SID used in clinical medicine is the "anion gap" (AG), which is defined as

For simplicity, potassium ([K^+]) is often ignored, and total CO_2 is substituted for [HCO_3^-] because 95 percent of plasma total CO_2 is due to HCO_3^-. [7] [27] AG allows gross assessment of acid-base balance, even using peripheral venous plasma. The AG is due to the presence of unmeasured anions, similar to the UA^- for the SID approach. [25] [26] An altered AG is sometimes the first indication of an acid-base disturbance in a patient, most commonly resulting from a change in [HCO_3^-]. [28]

Calculated as [Na^+] - ([Cl^-] + [total CO_2]), the normal AG has historically been 12 mEq/L (range, 8-16). However, a change in laboratory equipment over the past 15 years to an ion-specific electrode for the [Cl^-] assay has resulted in higher reported [Cl^-] values, without a commensurate decrease in the expected normal AG range. As a result, AG has been criticized as an insensitive gauge for acid-base disturbances. [29] An update (decrease) of institutional AG normal values to reflect the equipment change would allow true AG increases to be better appreciated.

A limitation of the AG, besides the technical matter regarding normal [Cl^-] values, is that it also cannot distinguish plasma concentration changes of negatively charged proteins (albumin) or HPO_4^{2-} from that of other anions. Hypoalbuminemia masks an increased AG caused by pathogenic organic acids. [18] [19] [30] Alternatively, hyperphosphatemia increases AG without being diagnosed specifically because it is not part of the defining equation for AG.

INTRACELLULAR FLUID BUFFERS AND PUMPS

Acid-base balance within cells is very important because many cellular functions are exquisitely sensitive to pH changes. Further, endogenous H^+ or CO_2 production usually originates within the intracellular space. Intracellular pH (pH_i) regulation has recently been reviewed. [5] [6] However, it remains poorly understood in clinical acid-base balance, especially *in vivo.* Tissue cells contain high buffer content in the form of proteins, HPO_4^{2-}, and HCO_3^-. Intracellular concentrations of both protein and HPO_4^{2-} are approximately three times greater than those in plasma. [15] [31] [32] [33] [34] [35] Cells also actively transport H^+ or HCO_3^- across the plasma membrane. [16] [36] Although not true buffering, this transport contributes to maintaining a stable pH_i. Both true buffering and active ion transport are included in the term *cellular buffering power* (beta), also defined as millimoles H^+ added per liter intracellular fluid/DeltapH unit, similar to that for ECF (Fig. 38-6) (Figure Not Available). Intracellular fluid has a buffer power approximately five times greater per liter than the ECF (see Table 38-2).

Although pH_i is generally lower than in the ECF, it is still higher than that predicted by Nernst electrochemical equilibrium, which would be about pH 6.8. Measured pH_i is 7.30 in liver, 7.00 in resting skeletal muscle, and 7.20 to 7.30 in different regions of the kidney. [3] [16] [37] Relatively high pH_i is maintained by active H^+ extrusion and/or importation. Mechanisms involved in cellular acid-base regulation have recently been described. [5] [6] [16]

Liver cells maintain low intracellular $[H^+]$ at plasma pH 7.4 in part by taking up plasma HCO_3^- via the Na^+:HCO_3^- cotransporter (Fig. 38-7) (Figure Not Available). [16] [36] Although not directly energy driven, the Na^+:HCO_3^- cotransporter is linked to membrane Na^+/K^+-ATPase because the Na^+ must be subsequently extruded to prevent intracellular Na^+ accumulation. With extracellular H^+ challenge, HCO_3^- uptake is

Figure 38-6 (Figure Not Available) Intracellular buffering capacity as a function of intracellular pH. Filled circles indicate buffering, which includes active ion pumps, and open circles indicate passive buffering alone. *(From Benedetti et al [16])*

Figure 38-7 (Figure Not Available) Schematic mechanisms of cellular ion pumps that regulate intracellular acid-base homeostasis. *(Modified from Strazzabosco et al [36])*

decreased by diminished availability of extracellular HCO_3^- because the HCO_3^- is consumed directly as it reacts with H^+. There is still a tendency for pH_i to decrease, which activates a normally dormant H^+ extruder, the amiloridesensitive Na^+-H^+ *e*xchanger (NHE-1), which is also linked to the Na^+/K^+ ATPase to maintain constant intracellular $[Na^+]$. The net result is a modest but sustained increase in intracellular $[H^+]$. Extracellular H^+ challenge also activates a separate mechanism involving the plasma membrane, whereby extracellular H^+ is, in effect, exchanged for intracellular K^+. Increased intracellular H^+, in turn, activates the NHE-1:Na^+/K^+-ATPase system to moderate the effect, by passively extruding H^+ and actively importing K^+, but net result is cellular H^+ influx and K^+ efflux.

Increased extracellular $[HCO_3^-]$ has the exact opposite effect on the liver Na^+:HCO_3^- transporter, but intracellular HCO_3^- accumulation is mollified by a Cl^-/HCO_3^- exchanger (AE-2), similar to that in the erythrocyte, which is normally inactive at resting pH_i but increases its activity markedly with alkalization of pH_i. [16] [36] Increased extracellular P_{CO_2} decreases pH_i acutely, with a gradual but incomplete return to baseline. The opposite effect is observed with a decrease in P_{CO_2}. The pH_i moves in the direction of the extracellular pH, reducing but not eliminating the changes in the plasma by availing more passive buffer and redistributing H^+, HCO_3^-, or both. The $DeltapH_i/DeltapH_o$ for liver cells is 0.2 to 0.5 in response to changes in extracellular pH, regardless of whether the primary event is an alteration of $[H^+]$ or P_{CO_2}.

Skeletal muscle has a lower resting pH_i than liver. Muscle contains the NHE-1 transporter ("acid-extruder") and the AE-2 isoform of a Na^+-driven, Cl^-/HCO_3^- exchanger ("acid-loader"). Both transporters resist a change in pH from occurring in the same direction as that produced in plasma. [6] However, skeletal muscle pH_i still decreases in the setting of decreased extracellular pH, with a $DeltapH_i/DeltapH_o$ of 0.2 to 0.5, comparable to liver. [15] The importance of this relationship is that change in pH_i occurs despite the large buffering capacity of the concentrated intracellular HPO_4^{2-} and protein (including myoglobin), and the larger intracellular volume in comparison to the ECF.

Brain tissue has an overall pH_i of 7.2 to 7.5, depending on the region evaluated. It contains the NHE-1 exchanger like liver and skeletal muscle. [6] [38] [39] When studied *in vitro,* brain pH_i changes in response to extracellular $[H^+]$ alterations in a manner comparable to other tissues. *In vivo,* however, brain pH_i is unusually resistant to changes in blood $[H^+]$. [38] [39] Although the brain pH_i *in vivo* is resistant to fixed H^+ challenge compared with other tissues, its sensitivity to P_{CO_2} changes is similar to that for liver and muscle. [38] [39] Resistance of brain pH_i to a blood H^+ challenge may be a function of the blood-brain barrier, which excludes H^+ and/or the accompanying anion.

Overall, the intracellular compartment limits changes in H^+ presented to the ECF by absorbing or releasing H^+. Quantitation of intracellular buffering in various clinical circumstances remains difficult. Nevertheless, half of the total body acid-base buffering capacity to either a CO_2 or exogenous H^+ challenge resides within cells. [40] [41]

RENAL ACID SECRETION AND HCO_3^- KINETICS

In kidney, intracellular "buffering" of ECF pH acquires another dimension because H^+ is secreted by the kidney into the urine and is lost from the body. First, the proximal tubule reabsorbs 90 percent of filtered HCO_3^-, mostly by virtue of a specialized electrogenic 1:3 *Na^+ / bicarbonate cotransporter* (NBC) that is unique to kidney (Fig. 38-8) (Figure Not Available) . [42] NBC differs from most Na^+/HCO_3^- cotransporters by its reverse polarity; that is, it extrudes HCO_3^- into the plasma instead of importing it. The NBC acts in concert with a Na^+/H^+ exchanger (NHE-3) located on the luminal surface, and luminal (CA-4) and cytosolic (CA-2) isoforms of

Figure 38-8 (Figure Not Available) Major mechanism of kidney proximal tubule HCO_3^- reabsorption. See text for details. *(From Boron et al [42])*

carbonic anhydrase. HCO_3^- absorption in the proximal tubule, although large in volume, does not create new HCO_3^- to replace that consumed in neutralizing H^+, and its function is not greatly altered by changes in acid-base balance. A "vacuolar" H^+-AT-Pase located on the urine luminal surface actively secretes H^+ into the urine and accounts for 30 to 40 percent of proximal tubule H^+ secretion. [43]

The distal tubule and collecting duct, in contrast to the proximal tubule, actively synthesize HCO_3^- in addition to secreting H^+. CO_2 produced from substrate oxidation rapidly yields H^+ and HCO_3^-, facilitated by CA. The "vacuolar" H^+-ATPase also secretes H^+ into the urine in the distal tubule (Fig. 38-9A) (Figure Not Available) . [43] Simultaneously, HCO_3^- is exported to plasma by a Cl^-/HCO_3^- exchanger, which takes up plasma Cl^-. In addition, H^+ is actively secreted into urine in exchange for K^+ uptake, against steep [H^+] and [K^+] gradients, by a "colonic" H^+,K^+-ATPase (cHKA). [44] Distal tubule and collecting duct cHKA responds to acid-base disturbances within hours, increasing H^+ secretion in exchange for cellular K^+ uptake in response to a systemic H^+ challenge. [45]

NH_4^+ secretion is the most important mechanism for direct H^+ elimination from the body. (Fig. 38-9B) (Figure Not Available) . [46] [47] The source of the NH_4^+ is glutamine synthesized by the liver and other tissues. Renal glutamine metabolism forms NH_4^+ in the net reaction: glutamine $3CO_2 + 2NH_4^+ + 2HCO_3^-$. Ammonium (pK 9.0) equilibrates as:

Because of the high pK, 99.7 percent of intracellular NH_4^+ is ionized NH_4^+ at a renal pH_i of 7.23. Proximal tubule NH_4^+ is excreted into urine by the NHE-3 exchanger, with NH_4^+ substituting for H^+, as Na^+ moves into the cell. NH_4^+ is subsequently reabsorbed into the interstitial fluid

Figure 38-9 (Figure Not Available) Important mechanisms for kidney distal tubule H^+ secretion. (A) Direct H^+ secretion by H^+-ATPase, which has two types. (B) The role of renal glutamine in H^+ elimination as NH_4^+. See text for details. *(From Halperin and Goldstein [142])*

at the loop of Henle, then resecreted into urine by collecting duct cells. Mechanisms of urinary NH_4^+ elimination in the collecting duct are poorly understood, although an exchange of interstitial NH_4^+ for intracellular K^+ is involved. [48] Imported NH_4^+ then passively moves into the acidic urinary lumen. The role of Na^+/K^+-ATPase in renal NH_4^+ transport is uncertain. NH_3 also diffuses into the urine space, where it is trapped as NH_4^+ because of the lower urinary pH.

HPO_4^{2-} (pK 6.8) excretion in the urine is another mechanism for H^+ elimination. H^+ is trapped in the urine as the acid $H_2PO_4^-$, the major component of the so-called urinary *titratable acid.* Failure of glomerular HPO_4^{2-} filtration and its consequent paucity in urine with accumulation in plasma contribute to the acidosis of renal failure. HPO_4^{2-} excretion is controlled, in part, by the prevailing plasma acid-base status; that is, tubular HPO_4^{2-} reabsorption is increased in the setting of increased plasma or pH_i and decreased by low pH. [49] Renal H^+ secretion and HCO_3^- reabsorption or synthesis are important in long-term acid-base regulation, as evidenced in chronic renal failure.

Renal mechanisms are less important in acute acid-base disturbances because they are either completely insensitive to acute disturbances (i.e., they do not alter), or they respond slowly over a period of several hours to days. Renal

function, unlike pulmonary function controlling Pa CO_2 or the various buffering mechanisms, cannot quickly moderate acid-base derangements that may develop in the operating room.

HEPATIC HCO_3^- "PRODUCTION" AND CONSUMPTION

The liver has a central role in substrate metabolism that may influence acid-base balance. First, the liver is the principal organ that clears lactic acid produced by different tissues of the body. [50] Each mole of lactic acid is accompanied by a mole of H^+ . Lactic acid taken up can be metabolized by two pathways; either oxidation to CO_2 , or gluconeogenesis to form glucose and glycogen (Fig. 38-10) . Regardless of the pathway, lactate disposal is accompanied by a stoichiometric 1:1 consumption of H^+ . Removal of free H^+ during lactate metabolism in effect increases the available HCO_3^- pool by diminishing its consumption. Normally, each pathway accounts for ~50 percent of lactate uptake. During a lactic acid challenge, however, most lactate follows the oxidative pathway, and glucose production remains unchanged. [51] [52] Decreased ECF pH stimulates hepatic lactate uptake unless the liver itself is ischemic or hypoxic.

Countering H^+ consumption during lactate metabolism is HCO_3^- consumption during synthesis of urea from protein and amino acid catabolism. Urea synthesis, which occurs only in the liver, can be written empirically as

where each mole of urea synthesis consumes two moles of HCO_3^- . Urea produced by the liver is excreted in the urine. A normal daily excretion of 30 g urea in the urine translates

Figure 38-10 Schematic representation of hepatic lactate metabolism. Normally 50 percent of lactate uptake traverses the pathway to oxidation via the TCA cycle, and the remaining lactate is converted to glucose by gluconeogenesis. During a lactate challenge, the TCA cycle oxidative pathway is preferentially employed. PDH, pyruvate dehydrogenase, the rate-limiting enzyme for pyruvate and lactate oxidation; DCA, dichloroacetate. See text for details.

to the equivalent of 1,000 mmol of HCO_3^- . [53] In perfused liver, an *in vitro* H^+ challenge markedly decreases urea synthesis and hepatic HCO_3^- consumption. [54]

Hepatic nitrogen disposal also involves synthesis of glutamine from glutamate and NH_4^+ liberated from other amino acid catabolism. Hepatic glutamine synthesis, in contrast to urea synthesis, does not affect HCO_3^- consumption. It does, however, provide glutamine for renal NH_4^+ excretion. Haussinger proposed a model whereby the liver controls acid-base balance by altering the balance of urea or glutamine synthesis rates to dispose of nitrogen at a constant rate (Fig. 38-11) (Figure Not Available) . [55] Accordingly, an H^+ surfeit inhibits urea synthesis and stimulates hepatic glutamine synthesis, whereas the balance is reversed during plasma HCO_3^- excess. [55] However, the extent to which liver function regulates acid-base balance in humans remains to be tested.

HOMEOSTASIS

All the individual components presented separately in the previous discussion coordinate to maintain H^+ homeostasis. A primary disturbance of acid-base balance prompts a response among one or more of the other factors, to minimize the change in pH. These responses are collectively called *compensation.* Acid-base compensation, however vital for life, complicates assessment of acid-base status. Nevertheless, compensation is never complete with a continued primary disturbance. A deviation in arterial pH from 7.4 persists in the direction of the precipitating event. This permits diagnosis of the primary problem, enabling one to distinguish between primary and compensatory mechanisms.

In Vivo Compensation for Ventilatory Derangements

Primary ventilatory disturbances, which either increase or decrease Pa CO_2, prompt certain responses that return pH back toward 7.4. Increased Pa CO_2, along with the consequent decrease in pH, stimulates ventilatory drive in the spontaneously breathing patient. Augmented ventilatory drive occurs via feedback to the brain and the medullary respiratory control center, mediated by central and carotid body chemoreceptors (Ch. 15). The ultimate result is increased V_A, returning Pa CO_2 back toward 40 mm Hg.

Increased Pa CO_2 does not directly alter plasma [HCO_3^-], as demonstrated by the Henderson-Hasselbalch equation. However, decreased plasma pH decreases hepatic HCO_3^- uptake and stimulates HCO_3^- transfer into plasma from erythrocytes. Carbonate (CO_3^{-2}) is mobilized from bone to form free $HCO_3^- \cdot (CO_3^{-2} + H^+ \; HCO_3^-)$. Together, these increase plasma [HCO_3^-]. Further, decreased pH inhibits phosphofructokinase (PFK), an enzyme that controls glycolysis in liver, erythrocytes, and other tissues. PFK inhibition, in turn, decreases tissue lactic acid production with a consequent decrease in plasma HCO_3^- consumption. Urea production, which consumes plasma HCO_3^-, may also be inhibited by the decreased pH. Respiratory acidosis acutely increases arterial [HCO_3^-] by 0.8 mmol/L for each 10 mm

Figure 38-11 (Figure Not Available) Putative role for hepatic urea and glutamine synthesis in whole body acid-base regulation. *(Modified from Haussinger, [55] with permission from Elsevier Science.)*

Hg of CO_2 greater than 40. [10] During respiratory alkalosis, the acute decrease in [HCO_3^-] is 2.5 mmol/L for each 10 mm Hg of CO_2 less than 40. [56] About 50 percent of an acute CO_2 challenge is buffered by intracellular mechanisms, and another 30 percent by the erythrocyte-mediated Cl^- shift. [7] [40] Acute compensatory responses occur within minutes and persist for hours. In general, however, ventilatory derangements prompt a weak acute compensation.

A long-term increase in Pa CO_2 will, over a period of days to weeks, prompt renal compensation in the form of decreased Cl^- and HPO_4^{2-} reabsorption, increased HCO_3^- reabsorption, and increased active H^+ secretion. Chronic adaptation by the kidney can effectively return arterial pH close to normal, by increasing arterial [HCO_3^-] to reestablish a normal plasma Pa CO_2 /HCO_3^- ratio. In chronic respiratory acidosis, arterial [HCO_3^-] increases by 5 mmol/L for each 10 mm Hg of Pa CO_2 greater than 40. [57] [58] Wellcompensated respiratory acidosis is often observed in the patient with significant chronic obstructive lung disease (COPD), in whom a [HCO_3^-] of greater than 30 mmol/L may accompany an arterial pH only slightly less than 7.40. Opposite effects occur in the setting of chronic hypocapnia. Chronic respiratory alkalosis decreases arterial [HCO_3^-] by 5 mmol/L for each 10-mm Hg decrease in Pa CO_2 less than 40. [59]

In Vivo Compensation for Metabolic Derangements

A nonvolatile acid H^+ challenge is first buffered to minimize free H^+ accumulation. Free H^+ is neutralized by reacting with body HCO_3^- to form CO_2, which is removed from the body by alveolar ventilation (V_A). V_A is stimulated by increased Pa CO_2 and also directly by plasma H^+ (Ch. 15). The ventilatory response decreases Pa CO_2 by 1.1 mm Hg less than 40 for each mmol/L HCO_3^- less than 24. [60] Increased ventilation is the most important compensation to a nonvolatile H^+ load, and it occurs over a period of minutes. However, there are also "metabolic" responses that attenuate H^+ accumulation. The actual nature of the metabolic response depends on the underlying cause of the H^+ challenge.

Decreased pH secondary to a nonvolatile H^+ challenge inhibits PFK, decreasing endogenous lactic acid production. Together with stimulated lactic acid uptake by the liver, the result is decrease plasma lactic acid concentration. Urea synthesis is also inhibited, which decreases physiologic HCO_3^- utilization. In addition, CO_3^{-2} is mobilized from bone to form plasma HCO_3^-, according to the reaction: $CO_3^{-2} + H^+ \; HCO_3^-$. [61] These responses increase HCO_3^- availability in the ECF. In addition, cellular H^+ uptake and intracellular buffering account for ~50 percent of an exogenous H^+ challenge. [41] Renal responses to a nonvolatile H^+ challenge require hours to days for full expression, but ultimately they include decreased Cl^- and HPO_4^{2-} reabsorption, increased H^+ and NH_4^+ secretion, and increased HCO_3^- reabsorption.

Opposite compensatory mechanisms, in general, occur in response to decreased ECF [H^+], including deposition of HCO_3^- into bone as Na_2CO_3. [61] HCO_3^- accumulation, by decreasing [H^+], inhibits respiratory drive such that Pa CO_2 increases above 40 mm Hg by 0.4 to 1.2 mm Hg for each mmol/L HCO_3^- greater than 24. [60] [62] [63] However, ECF volume depletion with or without hypochloremia hampers renal compensation for decreased ECF [H^+]. This is partly because hypovolemia increases aldosterone-mediated Na^+ reabsorption. Na^+ must be accompanied by Cl^- or HCO_3^- reabsorption for electroneutrality, and Na^+ uptake outstrips Cl^- supply. In addition, decreased glomerular filtration leads to increased efficiency of proximal tubule HCO_3^- reabsorption. [64] Thus, despite negligible urinary Cl^- excretion, HCO_3^- reabsorption is inappropriately increased, perpetuating the ECF [H^+] depletion. Only Cl^- replacement reverses H^+ deficiency coupled with hypo-volemia.

/das/book/view/29494766/875/442.html

TERMINOLOGY OF ACID-BASE DISTURBANCES

Clinical acid-base disturbances are usually defined on the basis of changes in arterial blood. Arterial blood pH is normally regulated such that the pH is between 7.35 and 7.45, corresponding to a [H^+] of 45 to 36 nmol/L, respectively (see Fig. 38-1) (Figure Not Available) . *Acidemia* is clinically defined as blood pH less than 7.35, and *alkalemia* is defined as blood pH greater than 7.45, although less marked deviations from 7.40 could technically be included. *Acidosis* is a process leading toward acidemia, whereas *alkalosis* is a process leading toward alkalemia.

When arterial pH falls below 7.35, or exceeds 7.45, as a result of an overwhelming primary event or impaired compensation, physiologic tissue consequences begin to appear. There are four fundamental acid-base disturbances: respiratory acidosis, respiratory alkalosis, metabolic alkalosis, and metabolic acidosis. The defining variables (pH, P_{CO_2}, [HCO_3^-], and BE) are all available on, or calculated from, a commercially available blood gas analysis. Alternatively, [HCO_3^-] and BE can also be determined from pH and P_{CO_2} using a Siggaard-Andersen alignment nomogram (see Fig. 38-2) (Figure Not Available) . It is nevertheless important to understand the limitations of these calculations, as outlined earlier.

A single acid-base disturbance can be present, or more than one disturbance may be superimposed. Compensation is a second disturbance that physiologically attenuates the effect of the primary disturbance. Alternatively, a more complex picture occurs when two acid-base disturbances alter the pH in the same direction (mixed disturbance). This chapter limits the presentation to uncomplicated disturbances, listing the definition, pathophysiology, consequences, and fundamental treatment of each.

Respiratory Acidosis

Definition

Respiratory acidosis is concomitant arterial pH less than 7.35 and Pa_{CO_2} greater than 45 mm Hg (see Fig. 38-4; (Figure Not Available) . Ch. 72)

Mechanism and Compensation

Respiratory acidosis results when CO_2 production exceeds V_A (hypoventilation). This is most commonly the result of decreased V_E. Most anesthetic drugs decrease V_E in the spontaneously breathing patient by impairing ventilatory drive (Ch. 12) . Other causes for decreased V_E include airway obstruction, obstructive or restrictive lung disease, obesity, marked ascites, or neuromuscular disease. Pulmonary edema can lead to CO_2 retention by increasing pulmonary dead space, thus compromising V_A even with a well-maintained V_E. Alternatively, tissue and mixed venous (but not arterial) P_{CO_2} is retained during low cardiac output states with normal respiratory function because blood CO_2 transport to the alveoli is impaired. In the paralyzed, mechanically ventilated patient, increased Pa_{CO_2} can result from inappropriately low ventilator settings or interrupted communication between alveoli and fresh gas inflow (e.g., extubation, endotrachial tube obstruction, circuit disconnection, or ventilator failure).

Less frequently, respiratory acidosis can be caused by increased V_{CO_2} . Mechanisms of increased V_{CO_2} include marked fever, extensive burn injury (which increases V_{CO_2} by as much as 80-100%), and malignant hyperthermia. It is noteworthy that malignant hyperthermia is often heralded not by temperature change, but by a failure to contain the end-tidal CO_2 concentration despite a high V_E.

Acute metabolic compensation to respiratory acidosis has very limited effectiveness. Renally mediated metabolic compensation can return arterial pH close to normal, but it requires days to months for a full effect.

Consequences

Acute respiratory acidosis is associated with dysfunction of the central nervous system (CNS) and cardiovascular system. In the patient breathing room air, hypercapnia is commonly accompanied by hypoxemia, sometimes making it difficult to differentiate between the two causes. However, *CNS effects* of acute hypercapnia are anxiety, disorientation, incoherence, confusion, and dyspnea. Very high Pa_{CO_2} (>70 mm Hg) can produce a *CO_2 narcosis* syndrome of drowsiness progressing to stupor or coma. CO_2 -induced cerebrovascular dilation presents a clinical picture consistent with intracranial hypertension (pseudotumor cerebri), with headache and diminished mental status accompanied by papilledema.

Cardiovascular effects of acute hypercarbia are hypertension, tachycardia, and increased cardiac output mediated by increased sympathoadrenal tone. This hyperdynamic cardiovascular response occurs despite a direct negative inotropic effect of increased P_{CO_2} . [65] Increased catecholamine concentration with high Pa_{CO_2} may mediate supraventricular or ventricular dysrhythmias other than tachycardia. Cardiovascular effects may be altered in the presence of hypoxia, drugs, or preexisting cardiac disease, such that hypotension supplants hypertension. Increased P_{CO_2} increases pulmonary vascular tone in patients with preexisting pulmonary hypertension, to induce or exacerbate extrapulmonary shunting of blood flow. Acute cor pulmonale may result. Respiratory acidemia causes hyperkalemia as intracellular K^+ is released in exchange for cellular uptake of H^+ by liver and skeletal muscle. [66] Hyperkalemia can contribute to dysrhythmias, including cardiac arrest. In the patient receiving beta-adrenergic blockade, diaphoresis and peripheral vasodilation with warm, flushed skin may be evident. Respiratory acidosis potentiates the neuromuscular blockade produced by several nondepolarizing muscle relaxants, including pancuronium, vecuronium, pipecuronium, and atracurium. [67] Chronic hypercapnia differs from acute hypercapnia because, given adequate time for renal compensation, it is well tolerated. However, pulmonary hypertension is likely to persist in the patient with COPD and chronic respiratory acidosis.

Treatment

The goal of treatment is to remove the underlying cause and return the Pa_{CO_2} to baseline, usually 40 mm Hg. Decreasing Pa_{CO_2} is accomplished by increasing V_A. Even if increased Pa_{CO_2} is due to increased V_{CO_2} , such as in malig-nant hyperthermia, it is still appropriate to temporize by increasing V_E to return the Pa_{CO_2} to baseline. In the spontaneously breathing patient with respiratory insufficiency, assisted mask ventilation or controlled mechanical ventilation may be required. Residual neuromuscular blockade, or inappropriately high plasma levels of opioids or benzodiazepines, should be reversed. Supplemental O_2 , in addition to ventilatory support, is appropriate therapy for accompanying hypoxemia. Alternatively, cardiac output should be optimized if low cardiac output underlies respiratory acidosis.

Coexisting metabolic acidosis, such as lactic acidosis secondary to hypoxemia, should be treated according to the section on metabolic acidosis. Metabolic alkalosis leading to hypoventilation should be rectified according to the section on metabolic alkalosis.

In the patient with well-compensated CO_2 retention, the goal of therapy is to return Pa $_{CO_2}$ to the patient's baseline, which may exceed 40 mm Hg. Caution should be used in O_2 therapy for patients with well-compensated respiratory acidosis because of their dependence on hypoxic O $_2$ drive for ventilation.

Respiratory Alkalosis

Definition

Respiratory alkalosis is concomitant arterial pH greater than 7.45 and Pa $_{CO_2}$ less than 35 mm Hg.

Mechanism and Compensation

Respiratory alkalosis occurs when alveolar ventilation outstrips V $\cdot$ $_{CO_2}$. The most common cause is frank hyperventilation (increased V $_E$), resulting either from the patient's action or from that of the anesthesiologist. Common patient-related causes are fear, anxiety, and pain, all of which can occur in the perioperative setting. Hypoxemia from a variety of causes (e.g., pulmonary embolism), brain injury, and chronic cirrhosis, also lead to respiratory alkalosis. In the mechanically ventilated patient, inappropriately high ventilator settings may underlie respiratory alkalosis. Hyperventilation may be intentional during craniotomy or in the patient with intracranial hypertension, in an effort to decrease intracranial volume. However, the decrease in cerebral blood flow in response to hyperventilation is transient, lasting less than 24 hours.

Alkalosis can also result from decreased V $_{CO_2}$ if V $_E$ is not decreased to match. Decreased V $_{CO_2}$ during surgery results from an anesthetic drug-induced decrease in metabolic rate, especially in the CNS and skeletal muscle. Second, hypothermia reduces metabolic rate by 9 percent/°C decrease in anesthetized humans. [68] In the patient undergoing general anesthesia, the net result is decreased whole-body V $_{CO_2}$, with relative preservation of splanchnic V $_{CO_2}$. [69] As with respiratory acidosis, there is no clinically significant compen- sation for acute respiratory alkalosis. Effective renal com-pensation for chronic respiratory alkalosis, as HCO_3^- reabsorption decreases to match the decreased Pa $_{CO_2}$, requires days to occur.

Consequences

Respiratory alkalosis produces CNS and cardiovascular dysfunction. Acute hypocapnia causes lightheadedness, impaired judgment, confusion, or coma. Neuromuscular irritability may be due to decreased free Ca^{2+} availability resulting from increased albumin binding. The condition is hallmarked by parasthesias, tetany, or seizures. Although hypocapnia-induced cerebral vasoconstriction is useful to decrease intracranial volume during craniotomy or with intracranial hypertension, it can cause regional cerebral ischemia in patients with a preexisting limitation of cerebral blood flow. Increased brain lactate production during respiratory alkalosis has been interpreted as a sign of cerebral ischemia. However, increased lactic acid production is a widespread physiologic response to alkalemia, which also occurs in well-perfused tissues. [70]

Respiratory alkalosis is associated with a propensity to ventricular dysrhythmias. During anesthesia with positive-pressure ventilation, decreased cardiac output and hypotension can occur. However, it is difficult to determine whether these hemodynamic effects are caused by alkalosis per se or whether they are the mechanical effect of decreased venous return secondary to increased intrathoracic pressure. No hemodynamic effects of respiratory alkalosis have been reported in spontaneously breathing patients.

Hypokalemia is a frequent consequence, especially when mannitol or furosemide is concomitantly administered during neurosurgery. Hypokalemia results from the confluence of increased K^+ uptake by liver and skeletal muscle, and diuretic-induced kaliuresis. [66] Hypokalemia can cause ventricular dysrhythmias, including increased sensitivity to those mediated by digitalis. Finally, alkalemia shifts the hemoglobin O $_2$ dissociation curve to the left, impairing O_2 delivery by compromising off-loading to the tissues.

Treatment

The only effective therapy in the spontaneously breathing patient is to remove the underlying cause, such as O $_2$ therapy for hypoxemia or analgesia for pain. In the mechanically ventilated patient, V $_E$ can be decreased to allow return of Pa $_{CO_2}$ to baseline, usually 40 mm Hg.

Metabolic Alkalosis

Definition

Metabolic alkalosis is arterial pH greater than 7.45, concomitant with [HCO_3^-] greater than 30 mmol/L, or BE greater than 2 mEq/L.

Mechanism and Compensation

Potential mechanisms underlying an increased [HCO_3^-] are, at the most basic level, due to increased H^+ losses, decreased H^+ production, increased HCO_3^- production, or decreased HCO_3^- elimination. In most circumstances, metabolic alkalosis is an iatrogenic disease.

Increased H^+ loss can result from metabolism of an excessive intake of lactate, citrate, or acetate. Lactate administration, such as with lactated Ringer's solution, has been shown to increase arterial pH in volunteers. [71] [72] Packed erythrocytes contain a high lactic acid content that is directly proportional to the age of the blood unit. Alkalemia occurs because H^+ is consumed as the lactate is metabolized (see the discussion of hepatic HCO_3^- "production" and consumption). Citrate is contained in banked blood products, particularly plasma. Massive transfusion, for example during liver transplantation, can increase plasma citrate concentration 10-fold. This citrate challenge is ultimately cleared and metabolized. Three moles of H^+ is consumed with each mole of citrate metabolized. Patients receiving a large intraoperative transfusion generally clear the accumulated lactate and citrate within the first 2 postoperative days. During this time, a characteristic metabolic alkalosis develops. [73] Acetate metabolism results in net consumption of one H^+ for each acetate. Acetate infusion during hemodialysis or hyperalimentation has been reported to produce acetate intoxication and consequent metabolic alkalosis. [74] [75]

Other causes of excessive H^+ loss are nasogastric tube suctioning and diuretic therapy. Nasogastric suctioning depletes H^+ and Cl^- directly. Thiazide and loop diuretics increase urinary H^+ loss because they augment Cl^- excretion more than Na^+ loss and induce hypovolemia. Cl^- loss is an important factor initiating metabolic alkalosis. [76] Hypo-volemia stimulates mineralocorticoid secretion, retaining plasma Na^+ at the expense of plasma K^+ and, as hypokalemia ensues, plasma H^+ . Rarely, excessive H^+ loss is caused by a primary mineralocorticoid excess (primary hyperaldosteronism or Cushing disease).

Metabolic alkalosis is maintained, regardless of the initiating cause, by a hypovolemia-induced decrease in glomerular filtration, with or without hypochloremia, because renal HCO_3^- reabsorption is inappropriately increased. [64] Increased HCO_3^- retention occurs regardless of the precipitating cause of the alkalosis. The major difference between alkalosis resulting from diuretics and that of other metabolic causes is that urinary [Cl^-] is increased by diuretic therapy, but it is markedly decreased in other settings. Decreased hepatic HCO_3^- elimination as a mechanism underlying metabolic alkalosis has been reported in patients with urea synthesis impaired by cirrhosis, but this is very unusual. [77] Excessive $NaHCO_3$ intake in antacid therapy has been reported to cause metabolic alkalosis, with a [HCO_3^-] of 64

mmol/L. [63]

Major compensation for metabolic alkalosis is decreased ventilation leading to increased Pa $_{CO_2}$. Hypoventilation is often the initial sign of underlying metabolic alkalosis. It can cause hypoxemia in the patient with marginal pulmonary function who is breathing room air. Chronic metabolic alkalosis decreases renal NH_4^+ elimination by inhibiting proximal tubule NH_4^+ secretion. [78] Alkalemia stimulates PFK, increasing lactic acid release, with the concomitant H^+ reacting with HCO_3^- to decrease plasma [HCO_3^-]. [70] [79] Metabolic alkalosis may also increase urea synthesis and hepatic HCO_3^- consumption. [54]

Consequences

The most serious consequence of metabolic alkalosis is decreased ventilatory drive, resulting in hypoventilation. In the postoperative patient receiving opioid analgesia, decreased CO_2 ventilatory drive coupled with a pharmacologically ablated O_2 drive can cause frank apnea. Alkalemiamediated hypoventilation complicates weaning of some patients from mechanical ventilation. Compensatory hypercapnia causes confusion, lethargy, and stupor, even with increased arterial pH because CO_2 , unlike HCO_3^- , readily penetrates the blood-brain barrier. [38] [39]

Neuromuscular irritability, marked by agitation, twitching, or seizure activity occurs uncommonly. It is thought to be caused by increased binding of Ca^{2+} by albumin, causing a functional free hypocalcemia. The relationship between metabolic alkalosis and plasma [K^+] is not straightforward. [66] Early studies with a small number of patients indicated that metabolic alkalosis produced by $NaHCO_3$ infusion causes hypokalemia. [66] However, $NaHCO_3$ -induced metabolic alkalosis does not alter plasma [K^+] in patients with renal failure and normal baseline plasma [K^+]. [80] [81] In the unusual case in which metabolic alkalosis occurs without hypo-volemia or Cl^- depletion (for example, with excessive HCO_3^- intake) there is increased urinary HCO_3^- loss. This can lead, eventually, to hypokalemia as the distal tubule secretes K^+ to accompany the urinary HCO_3^- . On the other hand, thiazide diuretic therapy causes both hypokalemia and metabolic alkalosis, with hypokalemia exacerbating metabolic alkalosis. Hypokalemia causes cardiac dysrhythmias, notably those associated with digitalis therapy, and muscle weakness. Hyperlactatemia may be misinterpreted as an indication of tissue disease or hypoperfusion, but it is usually a benign response that disappears with correction of the alkalemia. [70] [82]

Treatment

Two treatment modalities may be appropriate as the underlying cause is identified. The first is to reverse the Cl^- deficit resulting from nasogastric suction or diuretic therapy. The easiest method of Cl^- replacement is intravenous 0.9 percent NaCl infusion, although KCl or $CaCl_2$ can be substituted in the patient in whom aggressive volume replacement is contraindicated. KCl administration also corrects coincident hypokalemia. A more aggressive replacement therapy is HCl infusion, which in addition to Cl^- provided H^+ directly to react with HCO_3^- , forming CO_2 and H_2O. HCl therapy is usually reserved for severe metabolic alkalosis, with [HCO_3^-] greater than 50 mmol/L.

The second approach is to decrease renal proximal tubule HCO_3^- reabsorption by inhibiting CA with acetazolamide. Acetazolamide effectiveness may be limited, however, in part because it also inhibits the hepatic CA that facilitates hepatic HCO_3^- uptake for urea synthesis. [9] Moreover, by increasing proximal tubule HCO_3^- loss, acetazolamide may

exacerbate hypokalemia. Rarely, for example in primary hyperaldosteronism or Cushing disease, metabolic alkalosis is refractory to Cl^- replacement and acetazolamide therapy. In these cases, removing the steroid-secreting neoplasm is the only effective treatment.

Metabolic Acidosis

Definition

Metabolic acidosis is arterial pH less than 7.35, concomitant with [HCO_3^-] less than 20 mmol/L, or BE less than -2 mEq/L.

Mechanism and Compensation

Metabolic acidosis is the most complex and potentially most ominous acid-base disturbance encountered. There are multiple possible causes, unlike respiratory acidosis, which is a pure CO_2 phenomenon. At the simplest level, the initiating event increases [H^+], decreases [HCO_3^-], or both. A host of different diseases could be responsible for metabolic acidosis, each one stimulating a slightly different compensatory response.

Ventilatory compensation is reasonably consistent, because H^+ stimulates carotid body chemoreceptors, a process that, in turn, leads to increased V_E and decreased Pa $_{CO_2}$ (Ch. 10) . Many patients with metabolic acidosis are debilitated by their underlying disease, and the compensatory Pa $_{CO_2}$ decrease could falter as the patient fatigues. The acute "metabolic" response to metabolic acidosis involves tissues not affected by the primary event. For example, lactic acidosis of acute liver failure is not compensated by increased lactic acid uptake by the liver, and acute renal failure is not ameliorated by renal compensation. A renal response to lactic acidosis of acute liver failure occurs, but it has a latency of hours to days. Therefore, the most common causes of metabolic acidosis are presented separately.

Differential Diagnosis

The magnitude of acidosis is first quantitated by the base deficit. To determine the cause, the next step is to calculate the AG (Table 38-3) . An increased AG reflects increased presence of one or more unmeasured anions and is referred to as *increased AG acidosis.* In contrast, acidosis without an increased AG *(non- AG acidosis)* reflects a pathologic failure of Cl^-/HCO_3^- exchange leading to hyperchloremia. Non-AG acidosis is usually due to gastrointestinal or renal tubular dysfunction, although there are other causes (see Table 38-3). In addition, plasma albumin and HPO_4^{2-} concentrations should be evaluated. Hypoalbuminemia masks the severity and alters the AG of metabolic acidosis: A decrease in plasma [albumin] of 1 g/dL increases apparent BE by 3.7 mEq/L and decreases the AG by 2.4 to 3 mEq/L. [18] Rarely, a very elevated HPO_4^{2-} alone can be responsible for an increased AG, but more often it is part of the acidosis of renal failure. A potentially more discriminating index is the UA^- , using the SID (see the earlier discussion of quantitation

TABLE 38-3 -- Anion Gap in Assessment of Metabolic Acidosis

INCREASED ANION GAP (> 16 mEq/L)	
DISEASE	***ANION RESPONSIBLE***
Lactic acidosis (e.g., shock, ischemia)	Lactate
Diabetic ketoacidosis	Acetoacetate, beta-hydroxybutyrate
Starvation	Acetoacetate, beta-hydroxybutyrate
Alcohol intoxication	beta-Hydroxybutyrate, acetoacetate, lactate
Salicylate intoxication	Salicylate
Methanol intoxication	Formate
Rhabdomyolysis	Phosphate, others (?)
Acute renal failure	Sulfate, phosphate, others (?)
Chronic renal failure	Unknown

NORMAL ANION GAP (16 mEq/L)
DISEASE
Protracted diarrhea
Potassium-sparing diuretics
Carbonic anhydrase inhibition
Renal tubular acidosis
Copious sodium chloride fluid administration
Pancreatic fistula
Biliary drainage
Ammonium chloride administration
Hypoaldosteronism

of buffers). UA^- has only recently been introduced into clinical practice, but it may be less prone to the criticism of insensitivity to lactic acidosis that has been directed toward the AG because it corrects for hypoalbuminemia, a common occurrence in the critically ill patient. [30]

Consequences

Metabolic acidosis induces widespread system dysfunction. *CNS effects* are fatigue, somnolence, confusion, and possibly coma. The initial respiratory response is increased ventilation. However, decreased systemic pH impairs muscle strength and endurance. As a result, respiratory function may be compromised, especially in the debilitated patient, and complicating *respiratory failure* can ensue. The *cardiovascular system* is affected at many points. First, H^+ progressively impairs cardiac contractility with decreasing pH below 7.2. [83] H^+ dilates both capacitance and resistance vasculature, decreasing both preload (functional hypovolemia) and afterload. Hypotension commonly occurs. If tissue O_2 delivery is compromised by hypotension, tissues commence anaerobic production of lactic acid, exacerbating the acidemia. To some extent, the negative direct hemodynamic effects are moderated by increased sympathoadrenal activity, which maintains cardiac output and blood pressure. However, concomitantly increased [catecholamines] and $[H^+]$ irritate the myocardium and conduction system, sensitizing them to ventricular fibrillation and other dysrhythmias. [84] Although patients receiving beta-adrenergic blockers are theoretically less susceptible to epinephrine-induced cardiac dysrhythmias, they are at increased risk for hypotension.

Acute hyperkalemia secondary to metabolic acidemia per se is unusual, possibly because organic anions (lactate, acetoacetate,

beta-hydroxybutyrate) may accompany H^+ into cells and may minimize the electrochemical charge effect of the H^+, and the modest K^+ efflux can be offset by increased urinary K^+ excretion. [66] However, massive blood transfusion presents a concomitant lactic acid and K^+ challenge. Under this circumstance, K^+ is poorly tolerated because it does not redistribute normally into acidotic cells, and urinary K^+ excretion alone cannot match its rate of appearance in the plasma. Hyperkalemia is potentially life-threatening because of its arrhythmogenicity, including cardiac arrest. Protracted metabolic acidosis depletes total body K^+ stores, despite normal or slightly increased plasma $[K^+]$. Body K^+ depletion eventually manifests as hypokalemia once the acidemia is corrected and K^+ redistributes into its normal compartments.

Acute acidosis impairs O_2 uptake by Hb, compromising O_2 carrying capacity and delivery. Decreased protein binding of anesthetic drugs, such as thiopental, increases their bioavailability in the acidemic patient. This causes an otherwise appropriate thiopental dose, for example, to become an overdose in the acidemic patient. A direct action of acidemia on local anesthetics, which are weak bases, is to increase their ionization, which decreases their effectiveness. On the other hand, acute acidemia potentiates the action of several nondepolarizing neuromuscular blockers, pancuronium, vecuronium, pipecuronium, and atracurium. [67] Finally, protracted metabolic acidosis eventually depletes bone structural calcium carbonate as CO_3^{-2} is mobilized to replenish free plasma HCO_3^-. [61] Demineralized bone can develop pathologic fractures.

Treatment

The underlying cause should be corrected. General temporizing measures include mechanical ventilation to facilitate respiratory compensation. Additional supportive care measures are O_2 therapy for hypoxemia and pharmacologic reversal of low cardiac output or inappropriate systemic vasodilation. HCO_3^- replacement therapy may be indicated, depending on the severity and nature of the disturbance. [85] [86] Specific therapy depends upon the etiology of the acidosis. [1] [13] [87]

Lactic Acidosis

Lactic acid flux is rapid in healthy persons, on the order of 55 to 66 mmol/h. [50] Tissues (muscle, brain, skin, erythrocytes) produce and release lactic acid into the blood. Erythrocytes lack mitochondria, rendering them completely dependent on glycolysis, which yields lactic acid for energy production. Lactic acid is taken up by the liver (and kidney), where it is converted to glucose to complete the Cori cycle (see Fig. 38-10 mmol/L.). These processes yield a normal arterial [lactate] of ~1

Plasma lactic acid accumulates when production outstrips clearance, and the change occurs quickly because of the rapid turnover. *Lactic acidosis* is concomitantly increased [lactate] and decreased pH. It is generally associated with high mortality. Lactic acidosis is perhaps the most common, and worrisome, cause of metabolic acidosis encountered by the anesthesiologist. It is divided clinically into *type A,* associated with tissue hypoxia, and *type B,* resulting from other causes. [50]

Increased lactic acid production occurs during hypoxia, tissue ischemia, exercise, seizures, sepsis, burn injury, biguanide intoxication, and liver disease. Hypoxia, ischemia, and nitroprusside intoxication inhibit oxidative metabolism, causing tissues to rely on anaerobic glycolysis for ATP production. [88] O_2 metabolism is normal in sepsis, burn injury, or biguanide (metformin) intoxication. However, excessive pyruvate production from stimulated glycolysis overwhelms its oxidative capacity. Pyruvate then "spills over" to produce lactic acid. Patients with liver disease exhibit normal peripheral lactate production, but they have an exaggerated lactate output in response to a glucose challenge. [89] An exogenous source of lactic acid is packed erythrocytes, which have a high lactic acid content directly proportional to the age of banked blood. Plasma lactate clearance is impaired in cirrhosis, even in patients without baseline hyperlactatemia. [90] Hepatic ischemia alters the role of the liver in lactate metabolism such that it will produce, rather than clear, plasma lactic acid.

Treatment is based on correcting the cause and replenishing HCO_3^- to return the pH toward 7.4. $NaHCO_3$, the mainstay of HCO_3^- replacement therapy, has been criticized on four grounds. First, in a closed system in which circulation or ventilation is compromised, $NaHCO_3$ causes paradoxic intracellular acidosis as the increased CO_2 generated by the CA reaction accumulates and crosses into cells. [91] [92] [93] [94] [95] This is especially true in brain, which most effectively excludes HCO_3^- because of the blood-brain barrier. [39] [93] Second, the high Na^+ load of $NaHCO_3$ therapy (1,000 mmol/L) is associated with rapid-onset hypernatremia and brain injury (central pontine myelinolysis). [96] [97] Third, a Na^+ -induced intravascular volume overload may worsen hemodynamics and may cause pulmonary edema in a patient with congestive heart failure. Fourth, $NaHCO_3$ therapy either does not change or occasionally compromises myocardial performance even in the absence of volume overload. [92] [98] [99] [100] [101] Incidentally, $NaHCO_3$ may further increase plasma [lactate] as the PFK inhibition is reversed by the eventually increased pH_i. [79] [82]

Carbicarb, a mixture of $NaHCO_3$ and sodium carbonate (Na_2CO_3) was recently introduced as an experimental alternative to $NaHCO_3$. [102] Carbicarb administration avoids a marked increase in P_{CO_2} because Na_2CO_3 dissociates to form two Na^+ and CO_3^{2-}. CO_3^{2-} reacts with H^+ as:

In effect, one Na_2CO_3 neutralizes two H^+ because the produced HCO_3^- can then react with H^+ to form CO_2. Consumption of 2 mmol H^+ with Na_2CO_3 results in production of only 1 mmol of CO_2, half of that by $NaHCO_3$. Carbicarb is referred to as a "CO_2-consuming" buffer, which is a misnomer because it still generates CO_2, but less than $NaHCO_3$ of equal effectiveness. Carbicarb increases P_{CO_2} less and decreases intracellular pH less than an equimolar treatment with $NaHCO_3$ alone. [93] [94] [103] This could be valuable in a clinical setting of compromised CO_2 elimination. Despite the theoretic advantage, Carbicarb has not been shown to be superior to $NaHCO_3$ in treatment of lactic acidosis.

THAM (*T*ris *h*ydroxymethyl *a*mino *m*ethane) is a less potent alkalinizing agent than $NaHCO_3$. [104] It does not increase Pa_{CO_2} or $[Na^+]$. However its negative side effects, including local vascular irritation, tissue necrosis, and hyperkalemia, have caused its virtual disappearance from clinical practice. [104] An experimental tris buffer combined with $NaHCO_3$ is being evaluated in preclinical trials. [105]

A different experimental approach is to activate pyruvate dehydrogenase (PDH), rather than to alkalinize plasma directly. PDH is a regulatory enzyme that controls pyruvate entry into the Krebs cycle. PDH activity varies among tissues, being high in cardiac tissue (60-80% active), intermediate in skeletal muscle, and low in liver (10-20% active). Dichloroacetate (DCA) stimulates PDH activity, increasing fractional PDH activity to 100 percent of the total enzyme content. [106] As a result, whole-body lactate production decreases and hepatic lactate clearance is stimulated. [107] DCA decreases circulating [lactate] by 50 percent in healthy volunteers, burned patients, septic patients, and in patients undergoing liver transplantation. [106] [108] It remains to be demonstrated whether DCA can affect outcome of lactic acidosis of a specific etiology, although it does not alter the course of profound hypodynamic sepsis. [109] DCA is a specific therapy for lactic acidosis, because its mechanism directly affects lactate metabolism. With a pK of 3, it is neither a buffer nor an alkalinizing agent.

Diabetic Ketoacidosis

Diabetic ketoacidosis (DKA) occurs in the insulindependent, type 1, diabetic patients (Chs. 25 and 55). It results from plasma accumulation of the ketone bodies, acetoacetate and beta-hydroxybutyrate. Ketone bodies are formed by the liver from lipolysis-generated free fatty acid metabolism. If lipolysis is accelerated, because of a lack of insulin, ketone body accumulation occurs because hepatic synthesis outstrips clearance by, mostly, kidney and brain. Ketone bodies are strong acids like lactate (see Table 38-1). Perioperative DKA occurs because of the combination of preoperative fasting, inappropriate withholding of insulin therapy, and the stress response to infection or surgical trauma. These factors all decrease plasma insulin concentration. The plasma insulin concentration required to suppress lipolysis and ketone body formation is less than one-tenth of that necessary for plasma glucose regulation. Patients with type 2 diabetes, with insulin resistance and a generally increased circulating insulin concentration, are therefore not at risk for DKA.

A detailed treatment protocol for DKA can be found elsewhere. [1] [13] [59] [87] In short, the essential treatment is insulin infusion, to inhibit ketone body production, and intravenous fluid resuscitation. Care must be taken to monitor plasma potassium concentration during insulin therapy, because the insulin promotes intracellular uptake of plasma K^+, particularly by the liver. The term "insulin resistance," which applies to glucose regulation, does not extend its hypokalemic effect. Hypokalemia occurs during insulin therapy for DKA unless a prophylactic KCl infusion is begun with the insulin, even if the initial plasma K^+ concentration is normal or modestly elevated. $NaHCO_3$ therapy may be required for marked acidemia to return the arterial pH toward normal, restoring physiologic stability until the ketone bodies excess is cleared.

Renal Failure

Metabolic acidosis resulting from renal failure can have more than one component (Chs. 53 and 55). Glomerular diseases limit filtration of phosphates and sulfates, which normally serve to trap H^+ in the urine. Proximal tubule injury compromises its HCO_3^- reabsorption. Because the distal tubule cannot handle the added urinary HCO_3^- load, HCO_3^- is excreted. Primary distal tubule disease inhibits active H^+ secretory function as well as *de novo* HCO_3^- synthesis. Renal failure thus results in decreased plasma HCO_3^- and increased plasma H^+ concentrations. AG may or may not be increased, depending on the extent of proximal tubule involvement, because proximal tubule dysfunction retains Cl^- and minimizes the increase in AG associated with HCO_3^- depletion. Less well known is the importance of the kidney in handling a HCO_3^- challenge, making the patient with chronic renal dysfunction more prone to alkalemia from aggressive $NaHCO_3$ intake. [63]

Conservative treatment of acute renal failure includes stimulation of diuresis with furosemide, mannitol, or low-dose dopamine infusion. A more aggressive treatment, also utilized in chronic renal failure, is dialysis or continuous arteriovenous hemofiltration (which usually includes HCO_3^- replacement in the dialysate). The definitive treatment is renal transplantation.

SPECIAL CIRCUMSTANCES IN ACID-BASE MANAGEMENT

Hypothermia and Cardiopulmonary Bypass

Acid-base management during hypothermic cardiac surgery is controversial, with two distinct schools of thought regarding the ideal blood pH at low body temperature, during which CO_2 solubility in blood is increased (Chs. 49 and 50) . [110] The traditional strategy, *pH-stat,* holds that Pa $_{CO_2}$ must be maintained to preserve pH. Under pH-stat management, arterial blood gas analysis measured with electrodes at 37°C is corrected to the patient temperature, and blood Pa $_{CO_2}$ maintained constant by addition of CO_2 to the blood during hypothermic cardiopulmonary bypass (CPB).

The rival management concept, alpha *-stat,* proposes that what must be maintained during hypothermia is not Pa $_{CO_2}$ but the ratio of ionized to un-ionized alpha-imidazole ring on the histidine moiety of proteins, as occurs naturally in poi-kilotherms. [111] Imidazole ionization, unlike Pa $_{CO_2}$, does not change with temperature in the setting of constant total CO_2 content. Under alpha-stat management, no correction is made for patient temperature during interpretation of arterial blood gases determined with electrodes at 37°C. A characteristic "corrected" arterial blood gas during CPB at 28°C with pH-stat management is pH 7.34 to 7.38 and Pa $_{CO_2}$ 40 to 41 mm Hg; corresponding values for alpha-stat management are pH 7.51 to 7.55 and Pa $_{CO_2}$ 25 to 27 mm Hg. [112]

Neither management strategy appreciably alters *in vivo* pH_i in animal heart or brain. [113] The alpha-stat method has been reported to limit myocardial damage and better preserve sensitivity to adrenergic stimulation during CPB, but this has not been universally observed. [114] [115] [116] [117] One consistent major difference is greater cerebral blood flow during CPB with pH-stat management. [112] [115] [118] [119] Neuropsychiatric outcome studies reveal little immediate postoperative effect of acid-base management strategy. [116] [120] [121] However, a lower incidence of cognitive dysfunction may be apparent later (7 days or 6 weeks postoperatively) in patients managed by the alpha-stat technique. [112] [122] On the other hand, in the special circumstance of deep hypothermia with cardiac arrest, pH-stat management may be more beneficial, as assessed by recovery of cerebral energy metabolism in animals and attainment of postoperative developmental milestones in children. [123] Currently, slightly over half of cardiac surgery centers in the United States and the United Kingdom utilize alpha-stat acid-base management, and debate continues regarding which strategy is better. [124] [125]

Cardiopulmonary Resuscitation

Ischemia and hypoxemia after cardiac arrest quickly lead to metabolic (lactic) acidosis, and metabolic acidosis is often a precipitating factor for the cardiac arrest (Ch. 75) . [126] During cardiopulmonary resuscitation (CPR), an acid-base environment of arterial respiratory alkalosis, tissue respiratory acidosis, and metabolic acidosis coincides. [127] Although metabolic acidosis sensitizes the myocardium to fibrillation, it does not appear to affect the defibrillation threshold. [84] [128] $NaHCO_3$ has historically been a component of CPR because it increases arterial HCO_3^- and pH. $NaHCO_3$ therapy, however, fails to increase intracellular pH during CPR, and may instead decrease it, at least transiently. [105] [129] $NaHCO_3$ also induces hypernatremia and hyperosmolarity, because it has an Na^+ concentration of 1,000 mEq/L. [96] $NaHCO_3$ -induced metabolic alkalemia is associated with a worse outcome from CPR. [130] Carbicarb causes less transient intramyocardial acidosis than $NaHCO_3$. [105] The Na^+ load of carbicarb, however, does not differ from that of $NaHCO_3$ alone. An experimental mixture of tris and $NaHCO_3$ causes less CO_2 production than $NaHCO_3$, and also it does not increase serum Na^+ concentration. [105] However, despite these theoretic advantages, neither carbicarb nor tris demonstrably improves outcome in animal CPR studies. [105] [131] [132] This may be due, in part, to the failure of buffer agents to reverse intramyocardial acidosis despite alkalinizing the blood. [129] In addition, buffer agents may reduce effective coronary perfusion pressure during CPR. [133] Alkalinizing therapy in general during CPR remains controversial. [127]

Laparoscopic Surgery

Laparoscopy-assisted gynecologic and general surgery can expose the patient to potential acid-base disturbances because of systemic absorption of insufflated CO_2 (Ch. 56) . Insufflated CO_2 diffusing into the circulation increases effective CO_2 "production" and causes respiratory acidosis unless V_E is increased to maintain a normal Pa $_{CO_2}$ and to return

Figure 38-12 (Figure Not Available) Decay curve for $^{13}CO_2$ release after equilibration with body HCO_3^- stores. *(From Irving et al [111])*

pH to 7.40. Depending on the abdominal pressure achieved with CO_2 insufflation, V_E must be increased 35 to 50 percent to restore normal Pa $_{CO_2}$. [134] [135] Steady-state apparent CO_2 "production" during laparoscopy may be delayed by up to 2 hours because the insufflated CO_2 equilibrates with the large reservoir of slow turnover HCO_3^- in extravascular compartments (Fig. 38-12) (Figure Not Available) . Increased Pa $_{CO_2}$ persists during postoperative recovery because the absorbed excess CO_2 must be eliminated by V_A. [134] A patient with poor respiratory mechanics and function is at risk for respiratory acidosis during and after laparoscopic procedures.

There is also a tendency to *metabolic* acidosis during laparoscopy, because of compromised splanchnic blood flow as abdominal pressure is increased. [134] [136] An additional factor underlying intraoperative metabolic acidosis is the impairment of renal function associated with increased abdominal pressure. [134] Whether metabolic acidosis persists into the postoperative setting is unknown.

UTILITY OF VENOUS BLOOD GAS

Peripheral venous blood is more readily available for sampling than arterial blood. However, because venous blood is collected downstream from the microcirculation, it differs from the arterial sample in that P $_{O_2}$ is decreased and P $_{CO_2}$ is increased relative to that of arterial blood. Normally, the peripheral venous P $_{CO_2}$ is only ~5 mm Hg greater than that in arterial blood. Peripheral venous P $_{CO_2}$ can be used to roughly approximate systemic acid-base balance, provided cardiac output is within normal limits and blood flow through the dependent tissue is unimpeded.

Mixed venous P $_{CO_2}$, sampled at the right atrium or pulmonary artery, normally differs from Pa $_{CO_2}$ by less than 6 mm Hg. In the setting of increased muscle V $_{CO_2}$ (e.g., severe exercise) or decreased cardiac output, mixed venous P $_{CO_2}$ may be markedly increased relative to arterial P $_{CO_2}$. Mixed venous P $_{CO_2}$ has special diagnostic value with decreased cardiac output, such as occurs during CPR, because tissue respiratory acidosis may be reflected only in mixed venous

blood, whereas it is not apparent in arterial blood. [137] [138] An increased P $_{CO_2}$ gradient between mixed venous and arterial blood may indicate suboptimal cardiac output in the immediate postoperative environment.

GASTRIC TONOMETRY

Gastric tonometry has been introduced as a technique to assess splanchnic acid-base balance, and splanchnic perfusion (Ch. 71) . [139] A nasogastric probe is used to indirectly measure [H^+] in the gastric mucosa, determining intraluminal pH rather than pH_i . A decrease in mucosal pH without a commensurate change in arterial blood pH is evidence of a local acidosis, usually resulting from lactic acid production, in the splanchnic bed. Gastric tonometry may therefore be especially useful during surgical procedures that potentially compromise splanchnic oxygenation or perfusion. The intraoperative and postoperative potential for gastric tonometry has recently been reviewed. [140]

ACKNOWLEDGMENT

The author thanks Drs. Thomas Hornbein, Vladimir Fenel, Wendell Stevens, and Per-Olaf Jarnberg for their advice and critical review of the manuscript.

Chapter 39 - Airway Management *

David J. Stone
Thomas J. Gal

INTRODUCTION

The major responsibility of the anesthesiologist is to provide adequate respiration for the patient. The most vital element in providing functional respiration is the airway. No anesthetic is safe unless diligent efforts are devoted to maintaining an intact functional airway. Furthermore, the same principles of airway management outlined in this chapter are equally applicable to all clinical situations in which respiratory inadequacy may develop.

STRUCTURE AND FUNCTION OF THE UPPER AIRWAYS

Nose

The normal airway begins functionally at the nares. As air passes through the nose, the important functions of warming and humidification occur. The nose is the primary pathway for normal breathing unless obstruction by polyps or upper respiratory infection is present. During quiet breathing the resistance to air flow through the nasal passages accounts for nearly two-thirds of the total airway resistance. [1] The resistance through the nose is nearly twice that associated with mouth breathing. This explains why mouth breathing is utilized when high flow rates are necessary as with exercise.

The sensory innervation of the nasal mucosa arises from two divisions of the trigeminal nerve. The anterior ethmoidal nerve supplies the anterior septum and lateral wall whereas the posterior areas are innervated by nasopalatine nerves from the sphenopalatine ganglion. Local anesthesia can be produced by blocking anterior ethmoidal and maxillary nerves bilaterally; however, simple topical anesthesia is usually quite effective.

Pharynx

The pharyngeal airway extends from the posterior aspect of the nose down to the cricoid cartilage, where the passage continues as the esophagus. An upper area, the nasopharynx, is separated from the lower oropharynx by the tissue of the soft palate. The principal impediments to air passage through the nasopharynx are the prominent tonsillar lymphoid structures. The tongue is the principal source of oropharyngeal obstruction, usually because of decreased tone of the genioglossus muscle. The latter contracts to move the tongue forward during inspiration and thus acts as a pharyngeal dilator.

Larynx

The larynx, which lies at the level of the third through sixth cervical vertebrae, serves as the organ of phonation and as a valve to protect the lower airways from the contents of the alimentary tract. The structure consists of muscles, ligaments,

* *See Appendix 1, Practice Guidelines for Management of the Difficult Airway*

and a framework of cartilages. These include the thyroid, cricoid, arytenoids, corniculates, and the epiglottis. The latter, a fibrous cartilage, has a mucous membrane covering that reflects as the glossoepiglottic fold onto the pharyngeal surface of the tongue. On either side of this fold are depressions called valleculae. These areas provide the site for placement of the curved MacIntosh laryngoscope blade. The epiglottis projects into the pharynx and overhangs the laryngeal inlet. However, it is not absolutely essential for sealing off the airway during swallowing. [2]

The laryngeal cavity extends from the epiglottis to the lower level of the cricoid cartilage. The inlet is formed by the epiglottis, which joins to the apex of the arytenoid cartilages on each side by the aryepiglottic folds. Inside the laryngeal cavity one first encounters the vestibular folds, which are narrow bands of fibrous tissue on each side. These extend from the anterolateral surface of each arytenoid to the angle of the thyroid where the latter attaches to the epiglottis. These folds are referred to as the false vocal cords and are separated from the true vocal cords by the laryngeal sinus or ventricle. The true vocal cords are pale white ligamentous structures that attach to the angles of the thyroid anteriorly and to the arytenoids posteriorly. The triangular fissure between these vocal cords is termed the glottic opening, which represents the narrowest segment of the laryngeal opening in adults. In young children (<10 years old), the narrowest segment lies just below the cords at the level of the cricoid ring. The mean length of the relaxed open glottis is about 23 mm in males and 17 mm in females. The glottic width is 6 to 9 mm but can be stretched to 12 mm. Thus, the cross-sectional area of the relaxed glottis may be 60 to 100 mm^2 .

The scope of this chapter does not permit a detailed description of the actions of the laryngeal muscles; however, these muscles may be classified into three basic groups relative to their actions on the cords: (1) abductors, (2) adductors, and (3) regulators of tension. The entire motor innervation to these muscles as well as the sensory supply to the larynx is supplied by two branches of the vagus nerve: the superior and recurrent laryngeal nerves. This motor and sensory innervation is summarized in Table 39-1 .

Trachea

The trachea is a tubular structure that begins opposite the sixth cervical vertebra at the level of the thyroid cartilage. It is flattened posteriorly and supported along its 10- to 15-cm length by 16 to 20 horseshoe-shaped cartilaginous rings until bifurcating into right and left main bronchi at the level of the fifth thoracic vertebra. The cross-sectional area of the trachea is considerably larger than that of the glottis and may be more than 150 mm^2 and as high as 300 mm^2 .

There are a number of receptors in the trachea that are sensitive to mechanical and chemical stimuli. Slowly adapting stretch receptors are located in the trachealis muscle of the posterior tracheal wall. These are involved in regulating the rate and depth of breathing, but they also produce dilation of upper airways and the bronchi by decreasing vagal efferent activity. Other rapidly adapting irritant receptors lie all around the tracheal circumference. These are usually considered to be cough receptors, although their other reflex actions consist of bronchoconstriction. Studies of topical anesthesia in dogs suggest that the latter receptors are more readily blocked by local anesthetics than are the slowly adapting stretch receptors. [2]

Upper Airway Obstruction

Airway obstruction may be total or partial. Total obstruction is characterized by the lack of any air movement or breath sounds. Confronted with ineffective breathing efforts, it is important that inexperienced persons not interpret any retractive movements of the rib cage and the diaphragmatic tugging motions as respiration. Actual air movement must be perceived by feeling with the hand or placing the ear over the mouth. Recognition of obstruction depends on close observation and a high index of suspicion.

The patient with partial obstruction exhibits diminished tidal exchange that is associated with retraction of the upper chest and accompanied by a snoring sound if the obstruction is nasopharyngeal or inspiratory stridor if obstruction is near the area of the larynx. If inspiratory efforts are severe, the upper airway may undergo a dynamic inspiratory compression because of the marked pressure gradient in the upper airway.

Treatment of upper airway obstruction depends for the most part on whether it is due to soft tissue obstruction, tumor, foreign body, or laryngospasm. Most often, upper airway obstruction is due to reduction of the space between the pharyngeal wall and the base of the tongue by relaxation of the tongue and jaw. The same

obstruction may occur with foreign bodies or even dentures. In the absence of a foreign body, air flow may be restored by preventing the mandible from falling back. Forward motion is applied by placing the forefinger and second finger behind the angle of the

TABLE 39-1 -- Laryngeal Innervation

NERVE	SENSORY	MOTOR
Superior laryngeal (internal division)	Epiglottis, base of tongue	None
	Supraglottic mucosa

	Cricothyroid joint	
Superior laryngeal (external division)	Anterior subglottic mucosa	Cricothyroid (adductor, tensor)
Recurrent laryngeal	Subglottic mucosa	Thyroarytenoid
	Muscle spindles	Lateral cricoarytenoid
		Interarytenoid (adductors)
		Posterior cricoarytenoid (abductor)

mandible. The patient's neck can also be slightly extended to provide an optimal airway. The resultant changes in head position have been shown to modify upper airway resistance significantly. [3]

Oropharyngeal obstruction can also be overcome to some extent by increased oropharyngeal pressure from manual inflations with a breathing bag. One of the major concerns with such manual inflation of the lungs without tracheal intubation is the potential for gastric insufflation with high inflation pressures. The relationship between pressure and gas entry into the stomach has been examined in unconscious paralyzed patients. [4] The authors reported that gastric inflation rarely occurred when pressures less than 15 to 20 cm H_2O were utilized. In general such pressures were associated with tidal volumes well in excess of 1 L.

One of the primary skills required of anesthesiologists is the ability to correct upper airway obstruction in the unconscious or anesthetized patient. This obstruction is commonly attributed to occlusion of the pharynx by the tongue, which falls back. Correction of such a problem would be expected by insertion of devices termed oropharyngeal or nasopharyngeal airways (insertion is described later in the chapter). The nasopharyngeal airway is a soft rubber tube that is less traumatic and better tolerated in lighter stages of anesthesia or unconsciousness. The airway itself extends sufficiently into the pharynx to pass behind the base of the tongue. In situations in which the nares do not permit passage, bleeding occurs, or obstruction is not received, an oropharyngeal airway may be used. The latter is designed for insertion along the tongue until teeth or gums prevent further passage. The placement of these devices that provide an artificial passage behind the tongue does not in many cases provide unobstructed airflow. This suggests that the tongue is not the principal cause of upper airway obstruction in the anesthetized patient.

This is further borne out by daily experience of the frequent need to utilize head tilt and maintain head extension, even in patients with an oral airway in place. It is difficult to understand how this means of establishing airway patency produces any forward pull on the tongue. Observations in anesthetized patients indicate that this maneuver actually elevates the hyoid bone and epiglottis and appears to relieve the major cause of upper airway obstruction. [5] The angle of the extension or retroflexion required to achieve airway patency was reduced as the occiput was elevated. The latter to some extent pushes the mandible forward. Further support of the mandible may be provided by forward traction or pressing forward at the mandibular angles. When these simple maneuvers and the use of artificial airways do not provide adequate relief of upper airway obstruction, the insertion of an endotracheal tube to bypass the upper airway must be contemplated.

Physiology of Airway Protection

The pharynx, epiglottis, and vocal cords play a role in protecting the lower airway from aspiration of foreign bodies and secretions. Although the epiglottis covers the laryngeal inlet, it is not absolutely essential for airway protection. Most vital in this protective function is the glottic closure reflex, which produces protective laryngeal closure during deglutition. The physiologic exaggeration of this reflex, laryngospasm, is counterproductive to respiration. Laryngospasm consists of prolonged intense glottic closure in response to direct glottic or supraglottic stimulation from inhaled agents, secretions, or foreign bodies. Stimulation from the periosteum or celiac plexus or dilation of the rectum may also precipitate the problem on a reflex basis.

Varying degrees of laryngospasm produce sounds that range from a high-pitched squeaky sound to total absence of sound. The latter indicates complete closure of the cords and must be diagnosed and treated immediately. Treatment of severe spasm may require use of muscle relaxants such as succinylcholine. However, forward displacement of the mandible together with oxygen administered by a mask under pressure is often effective. Strong intermittent pressure applied manually to a bag full of oxygen can force gas effectively through the upper airway and the adducted cords. The traditional concerns about limiting airway pressure to avoid pulmonary barotrauma are not important in this case. However, the stomach contour should be watched closely should an inordinate amount of air be forced into the esophagus. In many cases when laryngospasm is less severe, slight amounts of positive pressure alleviate the difficulty. In any case, one should certainly utilize these simple maneuvers before resorting to tracheal intubation.

An indispensable mechanism for expelling secretions and foreign bodies from the lower respiratory tract is the act of coughing. The major stages of a cough are characterized by three events. First, there is a deep inspiration to attain a high lung volume, which allows attainment of maximum expiratory flow rates. Second, a tight closure of glottis occurs along with contraction of the expiratory muscles. Intrapleural pressure rises to above 100 cm H_2O such that during the third, or expiratory phase, a sudden expulsion of air occurs as the glottis opens. Glottic opening at the onset of the phase is associated with oscillation of tissue and gas that results in the characteristic noise of a cough.

Various physiologic aspects of cough have been observed with radiologic and endoscopic techniques. None is more important than the dramatic narrowing of the airway lumen. The physiologic significance of this reduced airway caliber is the fact that the decreased cross-sectional area increases linear velocity of gas flow and improves cough effectiveness. Various estimates suggest that this dynamic compression decreases the cross-sectional area of the trachea and main bronchi to about 40 percent of their caliber during normal breathing and thus increases linear velocity two and a half times. [6]

Neuromuscular weakness may decrease cough flow rates by limiting the inspired volume prior to cough if inspiratory muscles are weakened. Expiratory weakness, on the other hand, does not appreciably diminish flow rates. [7] The major effect appears to be a reduction in cough-induced dynamic airway compression, which results in decreased linear velocity of flow.

Glottic closure is the one phase of cough that differentiates it from other forced expiratory maneuvers and that allows for greater development of pressures. Closure of the glottis is not crucial, however, to the development of high pressures and flow rates of a normal cough. This is well illustrated in tracheotomized and intubated patients. The presence of the endotracheal tube, for example, does not lessen

the build-up of peak pressure during coughing. However, by preventing normal glottic closure, the tube allows flow to begin as soon as pressure begins to increase, and, in most cases, the tube allows flow to continue between cough bursts. [8] The normal timing of pressure and flow is altered such that cough resembles a normal forced expiration. Also, because the tube is noncollapsible, it does not permit the high velocities through the tracheal segment that it occupies. Secretions therefore are likely to accumulate in the area at the end of the tube unless subsequent coughs are begun from high lung volumes to allow high flow rates to be achieved.

EVALUATION OF THE AIRWAY

History

A documented history of difficulties with general anesthesia or, more specifically, mask ventilation or endotracheal intubation should immediately arouse concern regarding a patient's airway, and the information should not be lightly dismissed. If one encounters a difficult airway, it is important to specifically inform the patient of the problems encountered so that this information can be transmitted to the next anesthesia caregiver. Until a searchable national database is available, the patient can be provided with a form letter providing information on the airway problem. [9] Even a brief note on the back of a business card provides a handy mobile source of information to future caregivers: e.g., "difficult mask ventilation and intubation." The best means of communication may be the use of a MedicAlert bracelet labeled "difficult airway/intubation." [10] The MedicAlert System can be reached at 1-800-344-3226. Previous anesthesia records are extremely useful, especially when the problem is clearly defined. Remember also that some diseases, such as rheumatoid arthritis and morbid obesity, may have progressed in the interim and now may present a more difficult airway than suggested by the previous anesthetic record.

TABLE 39-2 -- Selected Congenital Syndromes Associated With Difficult Endotracheal Intubation

SYNDROME	DESCRIPTION
Down	Large tongue, small mouth make laryngoscopy difficult; small subglottic diameter possible
	Laryngospasm frequent
Goldenhar (oculoauriculovertebral anomalies)	Mandibular hypoplasia and cervical spine abnormality make laryngoscopy difficult
Klippel-Feil	Neck rigidity because of cervical vertebral fusion
Pierre Robin	Small mouth, large tongue, mandibular anomaly; awake intubation essential in neonate
Treacher Collins (mandibulofacial dysostosis)	Laryngoscopy difficult
Turner	High likelihood of difficult intubation

Many congenital syndromes that involve the airway may make mask ventilation or endotracheal intubation difficult. Several excellent sources provide an extensive listing of these. [11] It may be prudent to keep one of these lists in a readily available place. The more common congenital syndromes and their airway implications are listed in Table 39-2 .

Other diseases of infectious, traumatic, neoplastic, or inflammatory cause may also profoundly affect airway management. Table 39-3 lists many that should be considered while eliciting a patient history.

Physical Examination

The patient must be initially subjected to simple inspection from front and side to identify obvious problems such as massive obesity, cervical collars or traction devices, external trauma, or any indications of respiratory difficulty such as stridor. The presence of ear and hand anomalies often suggests the presence of a difficult airway. Nostril size and patency are essential to establish before considering nasal intubation. A large beard may make physical examination, mask ventilation, and direct laryngoscopy more difficult. Consideration to trimming or removing the beard should be made when the airway is judged difficult or when the surgery prevents circumferential securement of the tracheal tube (e.g., cervical or intracranial surgery).

Edentulous patients are seldom difficult to intubate unless other associated problems are severe. Protuberant upper incisors, on the other hand, can make laryngoscopy difficult and expose the teeth to damage. Isolated loose teeth are particularly prone to damage. These should be noted as well as the location of crowns, bridges, braces, and other significant dental work. Bridges and dentures should be removed if possible unless dentures significantly improve mask fit. Very loose teeth are best removed prior to laryngoscopy to avoid aspiration of a tooth. Most important, patients should be warned of likely damage to teeth both in person and in the preoperative note.

Mouth opening, which is largely a function of the temporomandibular joint, is of prime importance to allow the insertion of a laryngoscope blade and subsequent glottic visualization. [12] Adults should be able to open their mouths so that there is a 30- to 40-mm distance between upper and lower incisors (about two large fingerbreadths). [13] A problem with mouth opening should not be underestimated as it can make visualization of any laryngeal structures impossible. It may be risky to assume that limited mouth opening is due to spasm that will reverse after neuromuscular blockade. Conversely, in some patients able to open the mouth widely in the awake state, adequate mouth opening in the anesthetized state was only possible when the mandible was pulled forward. [14] Previous transtemporal neurosurgery may produce severe limitation in mouth opening that was not present during the original anesthetic. [15]

The oral cavity examination is aimed at identifying a long narrow mouth with a high arched palate that is associated with difficult intubation. A large tongue in relation to oral cavity size may make laryngoscopy more difficult. Mallampati et al [16] emphasized the importance of the base of the tongue in determining the difficulty of laryngoscopy. If the faucial pillars (palatoglossal and palatopharyngeal arches)

TABLE 39-3 -- Selected Pathologic States That Influence Airway Management

PATHOLOGIC STATE	DIFFICULTY
Infectious epiglottitis	Laryngoscopy may worsen obstruction
Abscess (submandibular, retropharyngeal, Ludwig's angina)	Distortion of airway renders mask ventilation or intubation extremely difficult
Croup, bronchitis, pneumonia (current or recent)	Airway irritability with tendency for cough, laryngospasm, bronchospasm
Papillomatosis	Airway obstruction
Tetanus	Trismus renders oral intubation impossible

Traumatic foreign body	Airway obstruction
Cervical spine injury	Neck manipulation may traumatize spinal cord
Basilar skull fracture	Nasal intubation attempts may result in intracranial tube placement
Maxillary/mandibular injury	Airway obstruction, difficult mask ventilation, and intubation; cricothyroidotomy may be necessary with combined injuries
Laryngeal fracture	Airway obstruction may worsen during instrumentation
	Endotracheal tube may be misplaced outside larynx and may worsen the injury
Laryngeal edema (postintubation)	Irritable airway, narrowed laryngeal inlet
Soft tissue, neck injury (edema, bleeding, emphysema)	Anatomic distortion of airway
	Airway obstruction
Neoplastic upper airway tumors (pharynx, larynx)	Inspiratory obstruction with spontaneous ventilation
Lower airway tumors (trachea, bronchi, mediastinum)	Airway obstruction may not be relieved by tracheal intubation
	Lower airway distorted
Radiation therapy	Fibrosis may distort airway or make manipulations difficult
Inflammatory rheumatoid arthritis	Mandibular hypoplasia, temporomandibular joint arthritis, immobile cervical spine, laryngeal rotation, cricoarytenoid arthritis all make intubation difficult and hazardous
Ankylosing spondylitis	Fusion of cervical spine may render direct laryngoscopy impossible
Temporomandibular joint syndrome	Severe impairment of mouth opening
True ankylosis	
"False" ankylosis (burn, trauma, radiation, temporal craniotomy)	
Scleroderma	Tight skin and temporomandibular joint involvement make mouth opening difficult
Sarcoidosis	Airway obstruction (lymphoid tissue)
Angioedema	Obstructive swelling renders ventilation and intubation difficult
Endocrine/metabolic acromegaly	Large tongue, bony overgrowths
Diabetes mellitus	May have reduced mobility of atlanto-occipital joint
Hypothyroidism	Large tongue, abnormal soft tissue (myxedema) make ventilation and intubation difficult
Thyromegaly	Goiter may produce extrinsic airway compression or deviation
Obesity	Upper airway obstruction with loss of consciousness
	Tissue mass makes successful mask ventilation unlikely

and uvula cannot be seen in a seated, vocalizing patient with the tongue protruding (Figs. 39-1 (Figure Not Available) , 39-2) (Figure Not Available) , then visualization of the glottis is likely to be more difficult than in patients in whom these structures are readily visible. An increase in Mallampati score may be noted during pregnancy and correlates with the slightly higher rate of difficult laryngoscopy in this population. [17]

The distance from the inner surface of the mandible to the hyoid bone during neck extension should be at least two large fingerbreadths in adults. If the thyromental space is examined, the comparable distance is 50 mm or about three large fingerbreadths. There appears to be no difference in the results of using the hyomental versus thyromental distances, except that the thyroid cartilage may be easier to locate. [18] These areas are important because the laryngoscope displaces the tongue into this space, and exposure of the glottis may be inadequate if the space is narrowed or noncompliant. [19] A receding or hypoplastic mandible results in a situation often referred to as an "anterior larynx" or "high larynx" by clinicians. An inability to bring the lower incisors edge to edge with the upper incisors, i.e., impaired mandibular protrusion, is an important warning that laryngoscopy may be difficult. [20]

The neck is examined for masses, fixation of the trachea, and mobility, particularly with extension. A patient with a short, thick, muscular neck (such as the classic football lineman)

Figure 39-1 (Figure Not Available) Illustration of patient in whom faucial pillars, soft palate, and uvula are visible. *(From Mallampati et al [16])*

with a full set of teeth may pose difficult mask ventilation as well as very difficult laryngoscopy. Exposure of the larynx requires some degree of flexion (
35 degrees) in the lower cervical spine and extension (
80 degrees) in the upper

Figure 39-2 (Figure Not Available) Illustration of patient in whom none of the three pharyngeal structures is visible. *(From Mallampati et al [16])*

cervical spine (especially at the atlanto-occipital joint) (Fig. 39-3) . [21] Consequently, the patient should be asked to flex and extend the neck maximally, provided there are no contraindications such as suspected or known cervical spine fracture, severe cervical spondylosis with cord or vertebral artery symptoms on motion, or rheumatoid arthritis with atlantoaxial subluxation. Extension of the head can be quantitated by determining the angle of head extension, with the lower neck flexed about 30 to 40 degrees in the "sniff position." Normal extension is 80 degrees, with lesser degrees representing increasing limitation and increased potential for difficult laryngoscopy. [22] The presence of a hoarse voice or previous prolonged intubation or tracheostomy should alert the clinician to the possibility of a stenotic airway at some level. Note that the combination of several minor physical anomalies may result in a difficult intubation even when no one single factor is severely abnormal. [22] [23] A number of studies have attempted to combine physical factors to predict difficult intubation with mixed results, but it is not clear to the authors that these indices represent an improvement over the clinical evaluation of a seasoned clinician. [24] [25] Additional problems with preoperative airway assessment tests are that they have only moderate interobserver reliability and depend on the definitions of airway difficulties. [26] [27] Difficult intubations also occur occasionally for reasons that are currently unexplained, and none of the available indices predicts all difficult intubations. The truly life-threatening problem is the inability to ventilate when intubation is difficult or impossible. [28]

Further Evaluation

If there is suspicion of undetected disease, such as an airway tumor or if the impact of such a tumor or an infection on airway management is not clear, consultation should be obtained for indirect or fiberoptic laryngoscopy. [29] These may be the only methods to detect occult but life-threatening

Figure 39-3 Schematic diagram demonstrating head position for endotracheal intubation. (A) Successful direct laryngoscopy for exposure of the glottic opening requires alignment of the oral, pharyngeal, and laryngeal axes. (B) Elevation of the head about 10 cm with pads below to occiput with the shoulders remaining on the table aligns the laryngeal and pharyngeal axes. (C) Subsequent head extension at the atlanto-occipital joint serves to create the shortest distance and most nearly straight line from the incisor teeth to glottic opening.

problems such as lingual tonsillar hyperplasia. [30] Serious doubt about an airway may justify the presence of an otolaryngologist during induction to establish an airway surgically, if necessary.

The chest x-ray may reveal problems undetected by the history and physical examination. Lateral and anteroposterior cervical spine films should be obtained if the bony spine or joints may be a source of difficulty or if there is suspected encroachment on the airway. CT scanning has been employed to evaluate the involvement of the trachea, bronchi, and cardiovascular structures in mediastinal tumors. [31] [32] Other means of airway assessment with magnetic resonance

imaging have been reported. [33] However, flow-volume loops provide detection and assessment of the physiologic importance of such obstructive lesions, be they extra- or intrathoracic.

MASK: VENTILATION EQUIPMENT AND TECHNIQUE

Anesthesia face masks of rubber or plastic are employed to administer oxygen and anesthetic gases as well as to ventilate the nonintubated patient. Masks come in a large variety of shapes, but the anatomic mask is most commonly used in adults. [34] Adult masks come in small, medium, and large sizes (#3, 4, and 5). Most adults can be ventilated with a small or medium mask, but the occasional patient with a long or wide face or large nose will need a large mask. Children's masks come in newborn, infant, and children sizes. In addition to the anatomic mask, the relatively flat Rendell-Baker-Soucek mask is often used as it conforms to the child's flatter face and has minimal dead space. Transparent masks are being used more often for adults as well as for children. They are less frightening than a black opaque mask, and the patient can be better observed for cyanosis and vomiting.

The mask is held with one hand as shown in Figure 39-4 . The fingers should be kept on the bone rather than soft tissues because the latter can cause discomfort in the awake patient and can cause airway obstruction if such pressure sufficiently raises the base of the tongue. Ventilation with a mask requires a tight fit that involves downward displacement of the mask with the thumb and first finger and upward displacement of the mandible with the other three fingers. Mandibular displacement along with upper cervical extension and chin lift all tend to pull the tongue and soft tissues up off the posterior pharyngeal wall and relieve the upper airway obstruction that occurs in the anesthetized or unconscious patient (Fig. 39-5) (Figure Not Available) . This may require holding the mask with two hands and vigorously pulling the mandible upward ("jaw thrust") (Fig. 39-6) . A two-handed mask grip will require an assistant to provide manual ventilation. If no such help is available, the anesthesia ventilator can be used to supply positive-pressure breaths. If necessary, the anesthetist's chin can exert downward pressure on the elbow connector to achieve a tight mask fit. Alternatively, the second person can provide jaw thrust while the first seals the mask and ventilates by anesthesia bag. [35]

As noted in the previous section, mask ventilation may be extremely difficult for patients with problems such as obesity, tumors, infections, and inflammatory disorders. The pediatric patient usually presents less of a problem than the adult as the pediatric airway can usually be managed by mask ventilation unless laryngospasm ensues. Providing a leak-free seal with the mask may be particularly difficult in the older, edentulous patient, and this may be helped by leaving dentures in place, using packing, or employing a mask strap or assistant to pull up the sagging cheeks. In addition to the inability to ventilate, other serious problems with mask ventilation include pulmonary aspiration and pressure damage to the eyes.

When airway integrity cannot be maintained with manipulation of the mask, mandible, or neck, a mechanical airway may restore airway patency. Both oral and nasal airways serve to separate the tongue from the posterior pharyngeal wall (Figs. 39-7 (Figure Not Available) , 39-8) (Figure Not Available) . The rigid oral airway may provoke a gag reflex or be followed by cough, vomiting, laryngospasm, or even bronchospasm if the patient is not adequately anesthetized. The airway may be inserted right side up or upside down and then rotated 180 degrees into the position of function. In either case, trauma to the teeth must be avoided as well as a misplacement in which the airway (especially if too short) pushes the tongue back into the pharynx and actually increases airway obstruction. After intubation, an airway is often inserted to prevent the patient from biting down on the tube. However, it is advisable to avoid the use of oral airways in prone cases that require extensive

Figure 39-4 Technique for holding the mask with one hand. An effort should be made to avoid excessive pressure on the soft tissues of the neck.

Figure 39-5 (Figure Not Available) (A) The normal airway. The tongue and other soft tissue are forward, allowing an unobstructed air passage. (B) Obstructed airway. The tongue and epiglottis fall back to the posterior pharyngeal wall, occluding the airway. *(From Dorsch and Dorsch [34])*

neck flexion as severe swelling of the tongue may result. [36] A 4 × 4-inch piece of gauze can be placed between the teeth to avoid active or passive biting with occlusion of the airway. Oral airways are generally made of plastic and in adults range in size from 80 to 90 to 100 mm (#3, 4, and 5, respectively). Children's airways range from 50 to 60 to 70 mm (#0, 1 and 2, respectively), with special small airways (#00, 000) for premature and newborn babies.

Soft nasal airways are useful in patients who are not deeply anesthetized because such airways tend to provoke less of a gag reflex. Relative contraindications to such airways include coagulopathy, basilar skull fracture, and nasal infections or deformities. If possible, vasoconstriction with phenylephrine nose drops (and topical anesthesia with lidocaine if the patient is awake) should precede any nasal instrumentation. However, in the acute situation, the lubricating qualities of lidocaine ointment may suffice. The tip of the airway should be inserted perpendicularly to the face and not upwards toward the cribriform plate. It has been suggested that the length of the airway should be roughly the distance from the tip of the nose to the meatus of the ear. [34] Adult nasal airways are measured in French numbers, which relate to their outer diameter and hence reflect circumferences that range in size from 28, 30, and 32 to 34. If the nasal airway does not have a sizable flange at the nasal end, the placement of a safety pin (taped to the face) in the airway tip will prevent loss of the nasal airway into the patient's lower airway. Both adequately large oral and nasal airways should be employed together if mask ventilation cannot be otherwise accomplished. [35]

Figure 39-6 Technique for holding the mask with two hands.

LARYNGEAL MASK AIRWAY

The laryngeal mask airway (LMA) is an ingenious supraglottic airway device that is designed to provide and maintain a seal around the laryngeal inlet for spontaneous ventilation and allow controlled ventilation at modest levels (up to 15 cm H_2O) of positive pressure. [37] This device is currently available in seven sizes for neonates, infants, young children, older children, and small, normal, and large adults (Fig. 39-9) (Figure Not Available) . After establishing an adequate depth of anesthesia and lubrication of the cuff, the appropriately sized LMA is inserted into the mouth, with the aperture facing the base of the tongue and the cuff tip pressed against the posterior pharyngeal wall. While the standard method involves total cuff deflation, other clinicians prefer to insert the LMA with the cuff partially inflated. An excellent instruction manual is available from the manufacturer (Gensia Automedics Inc, 9360 Towne Centre Drive, San Diego, Calif 92121). The requirement for adequate anesthesia makes the LMA generally unsuitable for use in the conscious emergency room patient. The index finger of the dominant hand is used to guide the LMA into the hypopharynx until resistance is felt, and the cuff is inflated with the appropriate volume of air (Fig. 39-10) (Figure Not Available) . The resistance indicates that the cuff tip has reached the upper esophageal sphincter (Fig. 39-11) (Figure Not Available) . A bite block, usually a folded 4 × 4- inch gauze, is inserted in the mouth to protect the LMA before both gauze and LMA are secured with tape. It is important to check by capnography as well as by auscultation and visualization of air movement that the cuff is correctly positioned and has not produced obstruction from downward displacement of the epiglottis. Because of the limited ability of the LMA to seal off the laryngeal inlet, the elective use of the device is contraindicated in any of the conditions associated with an increased risk for aspiration. [38] In patients without these predisposing factors, the risk for pharyngeal regurgitation appears to be low. [39]

The LMA may be used as a substitute for the classic mask airway to eliminate the presence of a relatively large mask and practitioner's hand that may interfere with surgical access. [40] A new, flexible LMA (LMA-Flexible, Gensia Medtronics) may allow for easier connection at any angle from the mouth while resisting kinking and displacement. The LMA may be inserted to establish an emergency airway in awkward settings for intubation such as the lateral or prone positions. The device may also be employed to establish an airway in the patient in whom either mask ventilation or tracheal intubation is difficult. [36] This role is discussed in a later section of this chapter. In addition, the LMA may be used to provide a conduit to facilitate fiberoptic, gum bougie-guided or blind oral tracheal intubation (Fig. 39-12) (Figure Not Available) . The size of the LMA dictates the size of endotracheal tubes that can be employed; cuffed 6.0 mm internal diameter (ID) for the size 3 and 4 and 7.0 mm ID for the recently introduced size 5 [42] Problems include inadequate endotracheal tube length as dictated by the presence of the LMA, limitation on endotracheal tube size, and inability to remove the LMA without risking extubation. [43] The use of the fiberoptic scope to assist in placing a gum elastic bougie rather than direct placement of the endotracheal tube is one possible approach to this situation. Benumof [43] has suggested a number of alternative solutions to the LMA/ fiberoptic intubation dilemma. A laryngeal mask specifically designed to facilitate tracheal intubation is now available (LMA-Fastrach, Gensia Automedics, San Diego, Calif.)

With increasing use, problems have been reported with the LMA; they include pulmonary aspiration, laryngospasm, need for neck extension in the patient with cervical spine disorder, and failure to function properly in the presence of local pharyngeal or laryngeal disease. [41] [44] [45] In patients with diminished pulmonary compliance or increased airway resistance,

Figure 39-9 (Figure Not Available) Range of patient laryngeal mask airway sizes. From upper left to lower right: Size 1: neonates/infants up to 5 kg (4); Size 1.5: infants 5-10 kg (7); Size 2: infants/children 10-20 kg (10); Size 2.5: children 20-30 kg (14); Size 3: children/small adults over 30 kg (20); Size 4: normal and large adults (30); Size 5: large adults (40). Maximum cuff inflation volumes in mL are given in parentheses for each size LMA. *(Gensia Automedics, San Diego, Calif)*

Figure 39-10 (Figure Not Available) Insertion of the LMA. (A) The tip of the cuff is pressed upward against the hard palate by the index finger while the middle finger opens the mouth. (B) The LMA is pressed backward in a smooth movement; note that the nondominant hand is used to extend the head. (C) The LMA is advanced until a definite resistance is felt. (D) Before the index finger is removed, the nondominant hand presses down on the LMA to prevent dislodgement during removal of the index finger; the cuff is subsequently inflated; an outward movement of the tube is often noted during this inflation. *(Gensia Automedics, San Diego, Calif)*

Figure 39-11 (Figure Not Available) The laryngeal mask in position. *(From Brain [37])*

adequate ventilation may not be possible because of the high inflation pressures required and the resultant leaks. The overall role of the LMA in clinical anesthesia would appear to lie somewhat between that of the face mask and that of the endotracheal tube as it provides more airway security (when properly positioned) than the former but not the reliable airway protection and maintenance of the latter. The LMA can be used to access the glottis for intubation as described; this is likely to become a more common use as the LMA becomes more generally available and clinicians gain experience with it. More important, it has become a nearly essential back-up airway device to provide emergency ventilation when conventional mask ventilation and intubation attempts fail.

THE COMBITUBE

The Combitube (Sheridan Catheter, Argyle, NY) is another supraglottic airway device that can provide an emergency airway when conventional means are not effective or possible. The Combitube has two lumens so that it can function appropriately whether placed in the trachea or, much more commonly, in the esophagus (Fig. 39-13) (Figure Not Available) . It also possesses an esophageal balloon to provide for protection from aspiration, which may represent an advantage over the LMA in obstetric anesthesia. The Combitube has been used successfully in cardiopulmonary resuscitation and probably presents a lower risk of esophageal rupture than the older esophageal obturator airway. [46] Care must also be taken to avoid excessively deep placement in the esophagus, which obstructs the glottic openings. [47] The Combitube is contraindicated for patients less than 5 feet tall and those with intact gag, esophageal disease, or caustic ingestion. A redesigned Combitube with a larger pharyngeal orifice has been found effective in providing a conduit for tracheal suctioning, fiberoptic bronchoscopy, and the use of a guide wire for tube exchange. [48] The practicing clinician can probably

Figure 39-12 (Figure Not Available) The use of the LMA as a conduit for fiberoptic intubation. (A) After loading an appropriately sized endotracheal tube, the fiberoptic scope is placed through the LMA into the glottis. (B) The endotracheal tube is threaded into the trachea. (C) The fiberoptic scope is removed. *(Gensia Medtronics, San Diego, Calif)*

Figure 39-13 (Figure Not Available) Insertion of the Combitube. (A) The tongue and mandible are lifted with one hand and the Combitube is inserted in the direction of the natural curvature of the pharynx with the other hand. The printed ring is aligned with the teeth. (B) The blue pharyngeal cuff is inflated with 100 mL of air while the white distal cuff is inflated with 15 mL. (C) Ventilation is begun through the longer blue tube as placement is usually in the esophagus. (D) If ventilation is absent and the stomach is being insufflated, begin ventilation through the clear connecting tube *(Sheridan Catheter, Argyle, NY)*

anticipate continued modifications in the present supraglottic devices as well as the introduction of new modalities to maintain and protect the airway without tracheal intubation.

ENDOTRACHEAL INTUBATION

Indications

The basic indications for endotracheal intubation in the operating room and intensive care unit are summarized in Table 39-4 . Before attempting tracheal intubation, the clinician should clearly establish the basis for the decision.

Equipment

In addition to endotracheal tubes and laryngoscopes, other essential items include an oxygen source, bag and

mask, airways, stylet, lubricant, tape, and reliable suction. Other devices that may be utilized in special situations are also discussed.

Endotracheal Tubes

The endotracheal tube that is most commonly utilized in current practice is a polyvinylchloride tube that has a low-pressure,

Figure 39-14 Various types of endotracheal tubes. (A) An armored or anode tube with a built-in spiral wire to minimize the opportunity of collapse or kinking. (B-D) Tubes made of smooth plastic and recommended for single use. Tube B is uncuffed and is a size appropriate for a child. Tubes C and D are appropriate for adult patients. Tube C is equipped with a built-in high-pressure low-residual-volume cuff. Tube D is constructed to incorporate a low-pressure high-residual-volume cuff. Numbers and letters visible on tubes B, C, and D denote tube diameter, length from tracheal end, and confirmation that the tubes have been tested for tissue compatibility (I.T. or Z-79).

high-volume cuff. This type of tube is illustrated in Figure 39-14 . Clinical use of the tube is generally dictated by the internal diameter that limits air flow. The external diameter of the tube depends on the internal diameter and on the thickness of the tube's wall, which varies among manufacturers. In adults, external diameter is limited at the level of the glottic aperture, whereas in children the subglottic (cricoid cartilage) area is the limiting factor in external diameter. Tubes are manufactured in 0.5 mm ID increments from 2.5 to 9.0 mm (Table 39-5) . French size reflects the circumference, the product of external diameter and pi, and is therefore higher for thicker-walled tubes than for thinner-walled tubes with the same ID. The table also gives recommended distance of insertion for the tube tip to be placed in the midtrachea. This distance must be evaluated in each individual patient. A small percentage of patients will require a shorter or longer distance of insertion, depending on the highly variable tracheal length.

TABLE 39-5 -- Endotracheal Tube Size and Position Based on Patient Age

AGE	INTERNAL DIAMETER (mm)	EXTERNAL DIAMETER (mm) (APPROXIMATE, VARYING AMONG MANUFACTURERS)	FRENCH UNIT	DISTANCE INSERTED FROM LIPS FOR TIP PLACEMENT IN MID-TRACHEA[a] (cm)
Premature	2.5	3.3	10	10
Full-term newborn	3.0	4.0-4.2	12	11
1-6 mo	3.5	4.7-4.8	14	11
6-12 mo	4.0	5.3-5.6	16	12
2 y	4.5	6.0-6.3	18	13

	8.0 (males)	10.7-11.3	32-34	

[a] Add 2 to 3 cm for nasal tubes.

The tube material itself is stamped Z-79 (Committee Z-79 on Anesthesia Equipment of the USA Standards Institute) or IT (implantation tested), indicating that the tube is free of toxic or irritant properties so far as testing can indicate. A line of x-ray opaque material is manufactured into the wall of the tube to aid in placement. Most tubes have a hole cut in the wall opposite to the bevel. This hole is known as the Murphy eye and is designed to allow gas passage if the bevel lumen is occluded. The tube is manufactured to be sterile, and most present-day tubes are disposable. It is wise to check the free flow of air through the tube as part of the pre-case checkout. The interface between the plastic tube and 15 mm connector should be tightened snugly.

The cuffs of present-day plastic tubes are so-called high-volume, low-pressure cuffs. These compliant cuffs are designed to accommodate a relatively large volume of inflation before pressure rises. High pressure in the cuff lumen is transmitted to the tracheal mucosa where it can cause ischemic injury. This is generally not an important issue during an anesthetic and is addressed further in the section on complications of intubation. Before the use of the tube, the cuff should be inflated to check for symmetry and leaks. The syringe must be removed from the one-way valve to test the sealing function of the valve. After insertion, the cuff should be inflated so that there is no air leak on positive-pressure inspiration. This will allow for reasonable airway protection from aspiration without excessive lateral wall pressure. Cuff pressures that afford good (but not perfect) protection (20-25 mm Hg) are just below the perfusion pressure of the tracheal mucosa (25-35 mm Hg). [49] [50] During the case, nitrous oxide may diffuse into the cuff and increase its pressure. [51] With high-volume cuffs and cases of reasonable duration (<24 hours), this is probably not an important issue as even high-pressure cuffs are acceptable for such cases. Although the tension of the pilot balloon is not an exact indication of pressure, a small amount of gas can be released from the cuff in this setting if the balloon becomes very tense, and the clinician is concerned about mucosal ischemia. Alternatively, nitrous oxide can be avoided or even used in the clinical concentration to inflate the cuff. Uncuffed endotracheal tubes have generally been used in children younger than age 8 years. The narrow subglottic area is believed to limit the use of cuffed tubes in these young children. An uncuffed tube is shown in Figure 39-14 . Endotracheal tube leak pressure is a clinically useful way to fit to confirm proper selection of uncuffed tube size in children. [52] Leak should occur at 15 to 20 cm H_2O pressure. The use of cuffed tubes in neonates, infants, and children has undergone renewed scrutiny and has the advantages of reducing waste gas exposure, allowing for lower fresh gas flows, and avoiding repeat laryngoscopy without an increased incidence of croup. [53] These authors used a new formula (cuffed endotracheal tube internal diameter = age/4 + 3) to successfully predict the required cuffed tube size in 99 percent of 488 children younger than 8 years of age.

The top tube shown in Figure 39-14 is reinforced with a spiral wire to reduce kinking or collapse. These tubes are known as armored, anode, spiral embedded, or reinforced tubes, among other names. [34] They are useful when an endotracheal tube is placed in a tracheostomy or laryngectomy stoma to provide an airway. They may also be used in head and neck or neurosurgical procedures when kinking of the tube is a strong possibility. However, care must then be taken to avoid an excessive degree of neck flexion by overenthusiastic surgeons as increased peak airway pressures during positioning will not be available as a monitor for excessive flexion or head turning. The RAE tube is made in oral and nasal versions and is bent to keep the tube out of the respective surgical fields (Fig. 39-15) . It may be somewhat difficult to secure the tube tip at an appropriate tracheal level if the patient has an unusually long or short lip to midtracheal distance. The Endotrol tracheal tube (Mallinckrodt Critical Care, Glens Falls, NY) has a mechanism that allows for anterior tip displacement when an operator end loop is pulled. This is particularly useful when a nasally placed tube repeatedly enters the esophagus, and cervical movement is contraindicated. Further information on the equipment employed in airway management can be found in the monograph by Dorsch and Dorsch. [34]

Tube Size Versus Age and Sex

In adult males, an 8.0 mm ID endotracheal tube is appropriate, whereas in adult females a 7.0 mm endotracheal tube is usually suitable. Given the variation between individuals, a tube of 1 mm ID size smaller or larger may be best for an individual patient. In general, the larynx is smaller in women, and it is the glottic aperture that limits the size of endotracheal tubes in adults. As noted, uncuffed tubes have traditionally been used in young children. The sizes of uncuffed endotracheal tubes for use in children is given in Table 39-5 . Tubes of 0.5 mm ID smaller and larger sizes must be immediately available. Tube size on children can be estimated from the formula (16+ age) ÷ 4, but variation between individuals requires the availability of multiple tube sizes. If there is a suspicion of laryngeal or tracheal disease in any age group, smaller tubes should be available. A small tube (such as 6 mm ID in adults) may facilitate an otherwise difficult intubation.

Laryngoscopes

The standard rigid laryngoscope consists of a detachable blade with removable bulb that connects to a battery-containing handle. Each of the standard blades has a flange for displacing the tongue to the side and an open side for visualization of the larynx (Fig. 39-16) . Sizes range from 0 (Miller) to 1 (MacIntosh), which are the smallest blades, to 4 (Miller or MacIntosh), which are the largest. The No. 3 blades are most frequently employed for adult use, with the No. 4 blades reserved for unusual or difficult patients. The smaller blades are used in pediatric patients.

The curved blade introduced by MacIntosh is probably most popular for adult use. [54] The commonly used straight blades are the Miller, which has a curved tip, and the Wisconsin blade (and its modified forms) which has a straight tip. [55] Although straight blades may be advantageous in young children, the choice of blade in older children and adults is really a matter of familiarity and taste. The practitioner should be trained in the use of curved and straight blades, because when laryngoscopy is difficult with one type of blade, use of the other type may permit adequate laryngeal

Figure 39-15 Preformed RAE endotracheal tubes: bottom, oral; top, nasal.

visualization. For example, the straight blade may be advantageous when mouth opening is vertically limited or the larynx is anterior. It has been reported that less force and head extension is required with the Miller blade. [56] The curved blade may be advantageous when mouth opening is horizontally limited or when more room is needed to perform the instrumentation desired (e.g., use of Magill forceps, changing tubes, intubation with esophageal obturator in place). Many other types of blades have been designed but their use is too limited to warrant additional discussion.

Figure 39-16 Examples of the most frequently used detachable laryngoscope blades, which can be used interchangeably on the same handle. The uppermost blade is the straight or Jackson-Wisconsin design. The middle blade incorporates a curved distal tip (Miller). The lowermost blade is the curved or MacIntosh blade. All three blades are available in lengths appropriate for neonates and adults.

Other Equipment for Routine Use

A stylet is a rigid implement usually made of a flexible metal, which is inserted into the endotracheal tube in order to maintain a chosen shape. This will facilitate intubation when the glottis is visualized, but the tube tip cannot be directed through the glottis or when glottic visualization is minimal or absent and a semiblind or blind technique is required. The usual shape used is that of a hockey stick, but more of a curve may be required for blind or difficult intubations. A stylet is used during rapid sequence intubations or whenever the hemodynamically stressful time of laryngoscopy is best minimized (e.g., cardiac anesthesia or neuroanesthesia). The stylet should be lightly lubricated to facilitate removal and advanced into the tube without its tip protruding past the end of the tube. The stylet should be removed as the endotracheal tube tip enters the larynx to avoid undue trauma.

The Eschmann introducer (Connell Neurosurgical, Exton, Pa) is a 60-cm stylet-like device that is 5 mm in external diameter and has a 35-degree bend 2.5 cm from the end that is inserted into the trachea. Its structure is designed to provide a combination of stiffness and flexibility. It is more commonly known as the gum elastic bougie although it is neither gum, elastic, nor bougie. It is an extremely useful instrument when laryngoscopic view is poor or the tube cannot be otherwise guided into the glottis. It is also useful in limiting the degree of necessary neck movement during intubation with potential cervical spine injuries and to lessen the risk of dental damage. [57] The bent tip is directed blindly or under reduced vision into the glottic inlet and passed about 30 cm into the trachea (the "bougie" has distance markings).

Tracheal entry is marked by the sensation of clicking over the tracheal cartilages as well as the hold-up by the reduction in luminal size near the carina. [58] While keeping the laryngoscope in place, the endotracheal tube is slid over the bougie into the trachea--a 90-degree counterclockwise turn facilitates glottic passage by presenting the bevel posteriorly. A smaller tube may also be required for passage. The bougie can also be used as tube changer, although it is a bit short for this purpose. It is reasonable to practice use of the bougie in a simulated difficult laryngoscopy in which a good glottic view is progressively reduced by lessening the force on the laryngoscope. This device is an indispensable part of practice in the United Kingdom and clearly allows for a significant number of direct laryngoscopic intubations that cannot be otherwise accomplished. It is a relatively expensive piece of equipment, and care must be taken that it is not inadvertently thrown out in the course of a difficult airway situation.

Some clinicians lubricate the tip of the endotracheal tube with local anesthetic ointment. This is not necessary, and the ointment may actually increase the incidence of sore throat. [59] Furthermore, the greasy ointment may interfere with handling of the endotracheal tube. The ointment is useful for placing nasal instruments (airways, endotracheal tubes, nasogastric tubes) with oral airways and for lubricating the stylet. Some kind of adhesive tape is necessary for securing the tube after placement. Taping methods that avoid splitting the tape and that include additional reinforcing segments over the tape applied directly to the tube are most effective in preventing dislodgement. [60] Particular care in securing the tracheal tube is indicated for surgical positions in which later access is difficult (e.g., prone neurosurgical patient in head pins with table turned away from the anesthesiologist), when dislodgement is likely (e.g., cleft palate repair), and when intubation is difficult. Cloth (twill) tape is useful in trauma where blood makes adhesive tape less effective and in patients with heavy beards. It cannot be overemphasized that oxygen, bag and mask, and suction should be available for all but the most emergent intubations. An additional oxygen source connected to a manual ventilation bag should be available in the operating room to back-up and supplement the oxygen supply available from the anesthesia machine.

Techniques

In every case, the anesthesiologist must attempt to determine whether mask ventilation and intubation will be possible if the patient is anesthetized and paralyzed. The usual intubation sequence includes the administration of a rapidly acting induction agent (e.g., thiopental), the demonstration of adequate mask ventilation, and the administration of a rapidly acting neuromuscular blocking agent (e.g., succinylcholine). The introduction of sevoflurane has made inhalational induction and intubation a reasonable alternative for selected adults as well as children. [61] Preoxygenation of such routine patients is optional but strongly recommended as it provides an added margin of safety. Preoxygenation is essential when a "rapid-sequence" intubation is chosen because of a "full-stomach" situation or other propensity to aspiration (e.g., esophageal disease). In this situation, the neuromuscular blocker is administered with the induction agent, cricoid pressure (Sellick maneuver) is applied, and mask ventilation is not provided unless unsuccessful intubation necessitates it. [62]

Before routine or rapid-sequence intravenous induction, the clinician must determine whether this is the best and safest way to intubate the patient. This determination is aided by the history and physical examination, as noted previously in this chapter, in conjunction with a knowledge of those factors and syndromes that affect the airway. The critical point in the decision tree is the administration of muscle relaxants: the clinician must decide whether difficulties in ventilation are due to factors that will be improved by the advent of paralysis or if the patient should be awakened and intubated with a conscious technique. If there is sufficient doubt before induction with regard to the patient's airway, a conscious intubation with sedation and topicalization is indicated. Other clinical factors may influence the decision, including hemodynamic instability and severe intestinal obstruction, for example. In children, such an awake intubation is not generally possible except in newborns. However, a mask airway can usually be maintained in most difficult pediatric intubations.

Endotracheal Intubation During Anesthesia

Once the decision has been made that the patient can be safely anesthetized for intubation, a variety of methods can be used to achieve acceptable intubating conditions.

For intravenous induction, a rapidly acting anesthetic is first administered (Ch. 12) . This is usually thiopental or propofol, but induction drugs include other rapidly acting barbiturates (methohexital, thiamylal), ketamine, benzodiazepines, narcotics (large doses if given alone), and etomidate. The details of the pharmacology of these drugs are described in the chapters on narcotics and nonnarcotic intravenous anesthetic agents. The choice of drug depends mainly on the status of the cardiovascular system but is also influenced by central nervous system effects, effects on bronchomotor tone, presence of an allergy, pharmacokinetic differences, side effects, and the experience of the clinician. Intubation may be accomplished with intravenous or inhalational anesthetics without relaxant, but this approach also possesses difficulties such as the potential for laryngospasm and a lesser degree of muscle relaxation to improve laryngoscopic conditions. In practice, the majority of clinicians employ muscle relaxants to facilitate intubation.

The most commonly employed relaxant for intubation is succinylcholine, but the nondepolarizing relaxants in appropriate doses may be used as well. The popularity of succinylcholine has been questioned, mainly in reference to its association with masseter spasm and malignant hyperthermia. Succinylcholine may also produce the severe side effect of hyperkalemia after burns, neurologic injury, and trauma as well as increases in intraocular and intracranial pressure. The great advantage of succinylcholine is that it produces excellent intubating conditions usually within a minute, or slightly longer if pretreatment with a small (about 1/10 intubating dose) amount of nondepolarizing relaxant is employed to diminish fasciculations and postoperative throat and skeletal muscle soreness. [63] However, others believe that with this pretreatment the quality of intubating conditions is worsened. In sensitive individuals, frightening paralysis and even aspiration may occur. The rapid onset of adequate paralysis for intubation can now be duplicated with rocuronium. [64] However, succinylcholine maintains the advantage of rapid offset of action by ester hydrolysis. If the airway cannot be secured, the patient's own ventilation and airway maintenance will return much more quickly than with any of the currently available nondepolarizing relaxants. Succinylcholine is still the only relaxant with a duration of action (assuming normal pseudocholinesterase activity) that may provide for the resumption of spontaneous ventilation within a time sufficiently short that cerebral integrity can be maintained in the properly preoxygenated patient. When a muscle relaxant is to be employed in a difficult or potentially difficult airway, succinylcholine appears to be the relaxant of choice unless there are contradictions to its use, such as a risk of hyperkalemia.

The use of nondepolarizing relaxants for intubation has increased with the availability of short-acting compounds such as rocuronium. Atracurium, vecuronium and cisatracurium are alternatives that are not quite as rapid in onset as is rocuronium. [64] The effects of these agents can generally be reversed in a shorter time than those of the older, nondepolarizing relaxants. Intubating doses of curare, metocurine, and pancuronium may result in histamine release or undesirable autonomic effects. However, the pancuronium-induced tachycardia that is disadvantageous with certain cardiac disorders may be advantageous in children, with bradycardia, or in massive trauma. In addition, an intubating dose of pancuronium may be cost-effective when relaxation will be required for several hours after intubation.

Nasal Versus Oral Route

In the operating room, nasal intubation is performed when surgery in the oral cavity or on the mandible is facilitated by an unobstructed view. If the mouth is to be wired or banded shut after surgery, a nasal tube must be used. Contraindications to nasal intubation include coagulopathy, severe intranasal disorder, basilar skull fracture, and presence of a cerebrospinal fluid leak. There is at least one report of an endotracheal tube entering the cranium through a nasal fracture. [65] If an oral tube is surgically unacceptable, and nasal intubation is contraindicated, the anesthesiologist must discuss the relative risks of tracheostomy and oral and nasal intubation in that patient with the surgeon to arrive at an acceptable compromise.

Nasal intubation is also used in the operating room in difficult airway situations. These include blind or fiberoptic intubation in the topicalized, sedated patient. Nasal intubation may be chosen because direct laryngoscopy is impossible; it may be quicker and more comfortable than oral intubation in the topicalized, sedated patient. Details on nasal intubations follow in the appropriate sections. Nasal intubation (unlike oral intubation) may produce a bacteremia, and appropriate endocarditis prophylaxis should therefore precede it. [66] [67]

Oral Endotracheal Intubation

This is the usual method of intubation in the operating room. In adults, a rapidly acting anesthetic is usually given intravenously, mask ventilation is ensured, and a muscle relaxant is administered to facilitate laryngoscopy. In children, mask, rectal, and intramuscular inductions are frequently employed. Intubation may be performed with anesthesia and no relaxant, but a deep level of anesthesia must be achieved to avoid unforgiving reflexes such as laryngospasm. Unless there is a

contraindication, the head is maintained in the classic "sniffing position" to align the oral, pharyngeal, and laryngeal axes (see Fig. 39-3) . In adults, a small foam pillow or several folded sheets are often employed to maintain flexion in the lower cervical spine. The Popitz "sniffing position" pillow is an excellent way to establish a satisfactory position for both mask ventilation and endotracheal intubation in the adult patient (Fig. 39-17) . It is important to use a head support that, unlike a big, soft pillow, does not allow the head to sink down into it. The laryngoscope is held in the left hand while the fingers of the right hand are used to gently open the mouth. The clinician should wear gloves because of the likely entry of fingers into the patient's mouth. The laryngoscope blade is gently inserted into the right side of the patient's mouth to avoid the incisor teeth and to enable the flange of the blade to keep the tongue to the left. Pressure on the teeth, gums, or lips is avoided. A mouth piece or maxillary teeth protector may be employed to lessen the likelihood of injury to those teeth. A full-fingered grip on the laryngoscope handle rather than a two-fingered hold at the junction of the handle and blade may provide a mechanical advantage that helps in difficult adult exposures.

Figure 39-17 A volunteer positioned on the Popitz pillow demonstrating cervical flexion and a small degree of atlanto-occipital extension (Dermacare, Louisville, Ky). The flexion serves to align the laryngeal and pharyngeal axes. Further extension of the head results in the true "sniffing" position.

After visualization of the epiglottis, the curved blade (e.g., MacIntosh) is inserted into the vallecula (the space between the tongue and epiglottis), and the laryngoscope is pulled forward and upward (Fig. 39-18) to expose the glottis. It is important to recognize structures sequentially as the blade is inserted and not just to insert deeply, pull, and hope for the best. The endotracheal tube is inserted into the right side of the mouth and inserted between the open vocal cords under direct vision (Fig. 39-19) (Figure Not Available) . An assistant may help by pulling the right side of the mouth open to improve vision (especially with the Miller blade). Difficulties in visualization may be due to head position, a blade that is too far advanced or not far enough advanced, or a reluctance on the part of the novice laryngoscopist to apply adequate (but gentle) upward force.

A straight blade is used in somewhat similar fashion except that it is usually advanced beyond the epiglottis, so that

Figure 39-18 Schematic diagram depicting proper position of the laryngoscope blade during direct laryngoscopy for exposure of the glottic opening. (A) The distal end of the curved blade is advanced into the space between the base of the tongue and pharyngeal surface of the epiglottis (vallecula). (B) The distal end of the straight blade (Jackson-Wisconsin or Miller) is advanced beneath the laryngeal surface of the epiglottis. Regardless of blade design, forward and upward movement exerted along the axis of the laryngoscope blade (arrows) serves to elevate the epiglottis and expose the glottic opening.

Figure 39-19 (Figure Not Available) Schematic view of glottic opening during direct laryngoscopy when the epiglottis is elevated with a curved or straight laryngoscope blade. The glottic opening is recognized by its triangular shape and the pale white vocal cords. *(From Stoelting RK and Miller RD: Basics of Anesthesia, 3rd ed. New York, Churchill Livingstone, 1994)*

the epiglottis is included in the structures lifted up by the blade (see Fig. 39-18) . Gentle dorsad pressure on the cricoid or thyroid cartilage may bring a nonvisualized larynx into view. The BURP maneuver, which includes backward, upward, and right lateral displacement of the thyroid cartilage, has been shown to be effective in improving the grade of glottic exposure. [68] As noted, the choice of blade is a matter of the clinician's preference. It is not established that one or the other blade causes less of a stimulus to airway reflexes and cardiovascular response. It is traditional but in no way mandatory for the novice to start with a curved blade. Because the peculiar anatomy of an individual patient may allow successful laryngoscopy with one blade but not the other, skill should be developed in the use of both blade types. Turning the head to the left and inserting a straight blade lateral to the molars may improve visualization on occasion by displacing the tongue and affording a more direct line of sight to the larynx. A common cause of inadequate visualization is insufficient flexion of the lower cervical spine that can be augmented while mask ventilation is continued.

In adult males, the tube is generally inserted to about 23 cm at the lips to position the tube, with the tip an appropriate

Figure 39-20 (Figure Not Available) Diagrammatic representation of key distances relating to endotracheal tube position *(From Stone and Bogdonoff [171])*

4 cm above the carina. For adult females, the distance is about 21 cm. Tubes inserted too far will cause endobronchial (usually right) intubation whereas tubes that are not in far enough may be difficult to seal because of cuff protrusion through the larynx and will be more at risk for accidental extubation (Fig. 39-20) (Figure Not Available) . Exact placement of the tube requires a fiberoptic bronchoscope, but this is not usually necessary. Endobronchial intubation is easier to remedy than accidental extubation. In children, the distance (cm) at the lips can be estimated from the formula: 12 + (age/2). In this age of laparoscopic surgery, be aware that abdominal insufflation can shift the carina cephalad and convert an acceptable location to an endobronchial one. [69]

A rapid-sequence induction is employed when the patient is at particular risk for aspiration and there is reasonable certainty that intubation should not be difficult (Table 39-6) . If there is sufficient doubt about the ability to intubate the patient in this setting, an intubation in the conscious patient with judicious use of topical anesthesia with or without sedation should be strongly considered. Before a rapid-sequence induction, the patient is preoxygenated. Although healthy lungs may be largely denitrogenated with four vital capacity breaths, the longer time constants of diseased or aged lungs require a longer period of preoxygenation to ensure adequate

nitrogen washout. [70] End-tidal nitrogen concentration, if available, can be used to assess nitrogen washout more precisely if a tight mask seal can be established. When time is critical, as in emergency cesarean section, four vital capacity breaths are adequate. [71] After preoxygenation, an intravenous anesthetic and muscle relaxant are administered together. It is the authors' practice to locate the cricoid cartilage in the conscious patient but not apply pressure until the patient is unconscious. This is because the proper amount of cricoid pressure is very uncomfortable in the awake patient, may provoke vomiting and obstruct the airway, is less likely to be effective in the patient before paralysis inhibits active vomiting, and has been shown to lower esophageal sphincter tone. [72] The downward force on the cricoid cartilage required to occlude the esophagus appears to be approximately 30 to 40 N, about the force of an 8- to 9-lb weight. [73] This may prevent regurgitation if applied properly, and because the force of vomiting is blunted by the muscle relaxant, the force should greatly decrease the risk of aspiration. [74] Interestingly, there have been no studies proving that cricoid pressure is truly beneficial. [73] Incorrectly applied pressure will not protect the patient from aspiration because only the

cricoid forms a complete ring that will occlude the esophagus. [75] When intubation is difficult, cephalad (in conjunction with dorsal) cricoid pressure may aid visualization. [76] Laryngoscopy and intubation in this setting are generally performed without any preceding manual ventilation, if possible. If intubation is not possible, mask ventilation should be provided while cricoid pressure continues. It is critical that the cricoid pressure be applied correctly so that it does not actually impede visualization of the glottis or passage of the tube. If glottic visualization or endotracheal tube passage is impaired, pressure may need to be let up or entirely released to see if it is contributing to the problem. In addition to preventing regurgitation, cricoid pressure decreases the flow of gas to the stomach, minimizing gastric distention that can impede ventilation as well as predisposing to regurgitation. Pretreatment with an anticholinergic is recommended to minimize secretions that may impair visualization during a rapid-sequence intubation. Pharmacologic approaches to the patient at risk from aspiration are discussed in Chapters 12 and 57 .

Special Considerations

Laryngoscopy and intubation are powerful noxious stimuli, and the response may have deleterious respiratory, neurologic, or cardiovascular effects. Furthermore, deeper levels of anesthesia are required to blunt the response to laryngoscopy and intubation than the response to surgical incision. [77] [78] When planning the anesthetic induction, these effects must be blunted to whatever degree is possible, especially if the patient falls into a high-risk population (e.g., with coronary artery disease, asthma, elevated intracranial pressure, cerebral aneurysm, and so on).

Nasal Endotracheal Intubation

When nasal intubation is chosen solely for purposes of surgical convenience, anesthesia may be induced before intubation. A vasoconstrictor should be applied before nasal

instrumentation. Cocaine (4% up to 1.5 mg/kg) can be used but phenylephrine (¼-1% nose drops) is more readily available and less toxic. After anesthesia is induced and mask ventilation is established, the endotracheal tube is introduced into the nose in a plane that is roughly perpendicular to the face. The patient may be allowed to breathe spontaneously to facilitate blind intubation. In this case, the tube is inserted until maximum breath sounds are heard (usually about 14-16 cm in adults), implying that the tube tip is just above the glottis. The tube is then inserted into the glottis during inspiration. Some clinicians choose to administer CO_2 or doxapram to induce hyperpnea and facilitate intubation during spontaneous ventilation, but this is not commonly done currently. Because entry into the glottis is not seen directly, it is essential to have capnographic or bronchoscopic confirmation of endotracheal placement because, at times, all the indirect signs of intubation may be misleading. Anesthetized blind nasal intubation may also be attempted in the apneic, paralyzed patient, but in this case there are no spontaneous breath sounds to aid placement, which is guided by external observation for tip location in the neck.

If the tube does not enter the glottis, the patient's head may be extended, flexed, or turned to guide the tip (if not contraindicated by spinal bony disease). If the tube tip is felt anteriorly, flexion may help; if the tip is felt beside the larynx (in the pyriform sinus), turning the tube tip away from that side may help. Most of the time, the tube enters the esophagus, and extension of the head will help. If the trachea cannot be blindly intubated, the patient can be intubated with guidance under direct vision (after appropriate mask ventilation). In this situation, a curved laryngoscope blade appears to provide the greatest amount of space for maneuvering. The tube is inserted into the nose, and direct laryngoscopy is performed in the usual fashion. Under such direct vision, the laryngoscopist may be able to direct the tip into the glottis. If not, Magill forceps may be used to carefully grasp the tube while avoiding trauma to the cuff. The tube can then be directed into the glottis, often with the help of an assistant who can push on the nasal end of the tube. If the glottis cannot be visualized by direct laryngoscopy, the Magill forceps can still be used to attempt to guide the tip blindly into the area of the glottis. Excessive force on the tube should be avoided as delicate laryngeal structures can be damaged or false passages created.

An anterior curve in the endotracheal tube may help in blind nasotracheal intubation. This can be accomplished by putting a stylet in the tube (removed before use) with the desired C-shape or by placing the tube tip in the 15-mm connector to form a circle. The time that the tube holds the curve can be lengthened by placing the curved tube in a refrigerator or freezer for some time before the case. An Endotrol endotracheal tube, which has an operator-end loop that directs the tube tip anteriorly when pulled, may be used. Another technique that utilizes cuff inflation has been described to further aid blind intubation. [79] Breath sounds must be audible, so breathing must be spontaneous. When breath sounds are of maximal intensity, the endotracheal tube cuff is inflated with 15 mL of air, which tends to direct the tip anteriorly. The air is released from the cuff as the tube is passed (2 cm) through the glottis to avoid damage to the cords. The use of a stylet has also been suggested in difficult nasal intubations. [80] After the endotracheal tube is placed so that its tip should be just above the glottis, a stylet in a C-shape is carefully inserted into the endotracheal tube. The tube is then slid off the stylet, which directs it more anteriorly and (ideally) into the glottis.

When Intubation Fails

Every practitioner, no matter how skilled, will encounter patients who are unexpectedly difficult to intubate. The induction of anesthesia should be approached with this possibility in mind so that a clear plan of action can be pursued. The prevalence of difficult laryngoscopy appears to be approximately 1 to 4 percent and is higher in the obstetric than the nonobstetric population. [23] The degree of glottic exposure as described by Cormack and Lehane allows interobserver comparison of the difficulty of laryngoscopy (Fig. 39-21) (Figure Not Available) . Patients of grade 4 difficulty and many patients of grade 3 view are likely to present difficulties and may even be impossible to intubate. In addition to difficult visualization,

Figure 39-21 (Figure Not Available) Grades of difficulty in laryngoscopy ranging from grade 1, no difficulty; grade 2, only posterior extremity of glottis visible; grade 3, only epiglottis seen; grade 4, no recognizable structures. *(From Cormack RS, Lehane J: Difficult tracheal intubation in obstetrics. Anaesthesia 39:1105, 1984)*

Figure 39-22 (Figure Not Available) Difficult airway algorithm developed by ASA Task Force on Guidelines for Difficult Airway Management *(Modified from American Society of Anesthesiologists Task Force on Management of the Difficult Airway: Practice guidelines for the management of the difficult airway. Anesthesiology 78:597, 1993)*

other pathologies, including epiglottitis, laryngeal or tracheal stenosis, and luminal tumors, may make translaryngeal passage of the endotracheal tube difficult.

When an initial attempt at intubation fails, mask ventilation should be resumed while the situation is reassessed. As long as mask ventilation can be maintained, the problem is not emergent. Cricoid pressure should be maintained when a full stomach is suspected. Head position and laryngoscopy technique need to be reexamined. The laryngoscopist may wish to exchange a curved for a straight blade (or vice versa). A longer MacIntosh blade (#4) can be useful in this situation. The Miller No. 4 blade is wider but not much longer than the No. 3 model. This width may help keep the tongue out of the visual field and provide a more effective fulcrum for displacement of the tongue muscle. If repeated laryngoscopy by an experienced practitioner is unsuccessful, a decision-branch point is reached if short-acting drugs (thiopental, inhalational anesthetic, succinylcholine) have been used: the patient may be allowed to awaken for an attempt at intubation with topical anesthesia, or the case may even be postponed if nonemergent. If long-acting drugs have been used (high-dose narcotic, nondepolarizing relaxant), mask ventilation must obviously be maintained until reversal is possible. A task force of the American Society of Anesthesiologists has developed an algorithm for the difficult airway, which is a useful guide in this setting (Fig. 39-22) (Figure Not Available) . Benumof has incorporated previously approved ideas and concepts into one flow diagram that some readers may find preferable (Fig. 39-23) (Figure Not Available) . He has defined a best attempt at laryngoscopy as being performed by a laryngoscopist with at least 3 years' experience, optimal positioning, use of external laryngeal manipulation, and change of blade type and length one time each. [35] As he also points out, a difficult laryngoscopy will likely be readily apparent to a skilled practitioner on the first attempt.

If intubation cannot be accomplished, and the decision has been made to keep the patient anesthetized for intubation (or long-acting drugs have been used), a variety of other techniques can be utilized. First, help should be obtained, if possible. The assistant may provide laryngeal displacement such as a BURP maneuver, which is likely to improve glottic exposure. The assistant also provides a fresh pair of hands for mask ventilation and laryngoscopy and an objective viewpoint in what may be a rapidly deteriorating situation. An anticholinergic should be administered to reduce the secretions that often accumulate in this situation. If the arytenoids or epiglottis

can be visualized, the gum elastic bougie represents an effective approach to intubation. [81] Currently, this is

Figure 39-23 (Figure Not Available) Single-flow diagram version of the ASA Difficult Airway Algorithm. +Always consider calling for help (e.g., technical, medical, surgical) when difficulty with mask ventilation and/or tracheal intubation is encountered. ++Consider the need to preserve spontaneous ventilation. *Nonsurgical tracheal intubation choices consist of laryngoscopy with a rigid laryngoscope blade (many types), blind orotracheal or nasotracheal intubation, fiberoptic/stylet technique, retrograde technique, illuminating stylet, rigid bronchoscope, and percutaneous dilational treacheal entry. See Benumof [38] for a complete discussion of these TI choices. *(Modified from Benumof [43])*

the next approach to this situation at the authors' institution. The elastic gum bougie is less effective in grade 4 views, but an attempt at entering the glottis can still be made. If a skilled bronchoscopist is available and mask ventilation is possible, fiberoptic bronchoscopy is probably best attempted immediately, before the field is obscured with blood and edema. However, this is not an ideal setting for the novice bronchoscopist. Other options include blind nasotracheal intubation or blind orotracheal intubation employing direct laryngoscopy with a curved blade and an endotracheal tube directed anteriorly with a stylet. The use of a lighted stylet or retrograde intubation may be appropriate and are described later. The use of the LMA as a conduit for blind, bougie-guided, or fiberoptic intubation has been discussed. [43] Selected cases can proceed with an LMA or Combitube as airways. An LMA can also be inserted simply to facilitate ventilation until the effects of relaxants and other agents wear off. Other clinicians have suggested the Bullard laryngoscope (Circon ACMI, Stamford, Conn) or the Augustine introducer (Augustine Medical, Eden Prairie, Minn). [82] [83] If multiple attempts fail and the case is not of an emergent nature, it is best to simply ventilate the patient until drugs can be reversed, because edema and blood may produce serious airway obstruction, preventing even mask ventilation. A patient for elective surgery who experiences intermittent laryngospasm and serious dysrhythmias is also a poor candidate for continued attempts at intubation.

When Mask Ventilation and Intubation Are Impossible

The patient who is truly impossible to mask-ventilate (two-handed mask ventilation with oral and nasal airways, complete forward mandibular dislocation, and bag ventilation by an assistant) or intubate presents a brain- and life-threatening emergency that has been estimated to occur 1 in 10,000 anesthetics. [84] As in so many instances in medicine, the best treatment is prevention: the clinician must always carefully evaluate the airway to determine the safest plan for intubation and extubation. [85] In the patient who has been thoroughly denitrogenated, there should be sufficient time to institute one of the following interventions before serious oxygen desaturation and consequent hemodynamic deterioration occur. In reality, one is often dealing with a severely hypoxic patient who has suffered or is near to cardiac arrest. It is critical to institute one of the following interventions *before* irreversible cardiac arrest or brain damage has occurred. If only short-acting drugs have been used (succinylcholine, thiopental, lidocaine, etc.) and the patient has been adequately preoxygenated, adequate spontaneous ventilation may resume before further intervention is required.

The LMA has become the next intervention in this situation; the Combitube is a reasonable alternative, particularly if aspiration is a major concern (Fig. 39-24) (Figure Not Available) . If one of these supraglottic devices does not produce adequate gas exchange quickly, transtracheal jet ventilation (TTJV) should be instituted. In TTJV, a 14- or 16-g cannula is inserted through the cricothyroid membrane and attached to a high-pressure oxygen source via a low-compliance circuit (Fig. 39-25) (Figure Not Available) . The review of Benumof and Scheller [84] demonstrates that TTJV can provide adequate ventilation as well as oxygenation and serves as a valuable source for those planning to assemble an acceptable TTJV system. Perhaps the most readily available (and least expensive) system employs the fresh gas outlet and oxygen flush valve of the anesthesia machine as the high pressure oxygen source. A 5-mm ID endotracheal tube adapter attached to oxygen supply tubing is

Figure 39-24 (Figure Not Available) Role of the LMA in the ASA Difficult Airway Algorithm. *(Modified from Benumof [43])*

Figure 39-25 (Figure Not Available) Anatomy of the cricothyroid membrane *(Courtesy of Cook Critical Care, Bloomington, In.)*

inserted into the fresh gas outlet. A three-way stopcock (of large bore, if possible) is attached to the other end of the tubing and then connected to the translaryngeal cannula (Fig. 39-26) . The three-way stopcock may help in preventing excessive pressure build-up by releasing the aperture to air between jet inspirations. A much less effective but more readily available system includes use of the standard anesthesia circuit or a self-inflating reservoir bag attached to the translaryngeal cannula (via a 3-mm ID endotracheal tube adapter placed directly into the cannula or an 8-mm ID endotracheal tube adapter placed into the wide end of a 3-mL plungerless syringe, then connected to the cannula). [84] Successful TTJV should be followed up with provision of a definitive airway by tracheostomy, endotracheal intubation, or wake-up and resumption of the normal airway. The most serious complications of TTJV involve some form of hyperinflation due to inadequate venting of inspired gases in the presence of complete or nearly complete upper airway obstruction. This may result in barotrauma and/or diminished

Figure 39-26 Transtracheal jet ventilation apparatus assembled from components generally available in the operating room (5.0-mm ID endotracheal tube adapter, oxygen tubing, three-way stopcock). The connections can be banded for further security.

cardiac output in the context of an immediately life-threatening problem.

Although a classic tracheostomy can, in general, not be performed quickly enough in the "cannot ventilate/intubate" situation, cricothyroidotomy can be employed to insert a small endotracheal or tracheostomy tube. A surgical blade (such as #11) on a handle and a Kelly clamp for spreading the incision are required. Kits with all the required materials are commercially available (Melker emergency cricothyrotomy catheter set, Cook Critical Care, Bloomington, Ind). Although an experienced surgeon is the best choice to perform a cricothyroidotomy, the anesthesiologist must be prepared to do so if TTJV is unavailable or unsuccessful. Neither therapy, however, will relieve obstruction that occurs below the first few tracheal rings. Complications of cricothyroidotomy include misplaced tubes early and hoarseness and subglottic stenosis as later problems. [86]

Difficult-Airway Cart

The ASA Task Force on Difficult Airway Management has made the reasonable suggestion that a portable storage unit for a variety of intubation aids be readily available. Suggested equipment for this is listed in Table 39-7 (Table Not Available) . The bronchoscope cart itself is a practical choice for storage of these additional devices, which may be needed urgently on rare occasions.

Conscious ("Awake") Intubation

While emergency nonanesthetized intubations outside the operating room may be performed with minimal topical anesthesia and no sedation, the term "awake" intubation applied to nonanesthetized intubations in the operating room is usually something of a misnomer. After appropriate sedation, topical anesthesia, and nerve blocks, such intubations can be performed with minimal discomfort in the conscious patient. Conscious intubation is performed when the clinician

TABLE 39-7 -- Suggested Contents of the Portable Storage Unit for Difficult Airway Management

(Not Available)

Modified from Caplan RA (Task Force Chairman): Ameriacn society of Anesthesiologists Guidelines for Difficulty Airway Management, 1992

believes that it is the safest way to insert an endotracheal tube. Indications include a history of difficult intubation, findings on history or physical examination that can

make intubation difficult, and severe risk for aspiration or hemodynamic instability. The reasons for conscious intubation should be explained to the patient as time allows and documented in the chart. The primary consideration of safety should be emphasized. At times, surgeons (and other physicians) may be unhappy about their patients being subjected to such procedures because of unwarranted fear of patient discomfort and the time required. If the anesthesiologist has concluded that such intubation is indicated, the demands of such individuals must not take precedence over patient safety. The reasons for conscious intubation should be emphasized to the surgeon as well as to the patient because airway disaster, poor outcome, and litigation may follow airway mismanagement. In the American Society of Anesthesiologists' closed claims study, adverse respiratory events including inadequate ventilation, esophageal intubation, and difficult tracheal intubation form the largest single class of injury. [87] [88]

Drugs for Sedation

Narcotic analgesics are the key to facilitating conscious intubation. They afford mild sedation, analgesia, and reduction of airway reactivity that may result in cough and bronchospasm. Any narcotic may be used, but the overall characteristics of fentanyl have made it the most useful in such procedures. A lag in onset (hysteresis) of about 5 minutes for the full effect of fentanyl should be kept in mind as incremental doses of the drug are administered. [89] Dose requirements also vary greatly between individuals (25-500 mug), and thus the drug should be administered slowly in small increments. The effect (or lack thereof) may not be apparent until the laryngoscope is inserted. Perhaps the greatest advantage of narcotics, especially fentanyl, is the ease of reversibility by naloxone should an undesired degree of respiratory depression result. Such patients may simply need to be reminded to breathe in order to ventilate adequately. If awake intubation is being performed because of a severe risk of aspiration, narcotics (and other intravenous sedatives) must be used sparingly.

In order to afford more sedation than a moderate dose of narcotics provides, a second drug is usually given. Droperidol (Inapsine) is a butyrophenone that supplies adequate sedation without adding to narcotic-induced respiratory depression. [90] The drug is contraindicated in patients with Parkinson's disease because it blocks dopamine receptors and may produce a dystonic reaction. Doses of 1.25-5.0 mg intravenously are usually adequate, although doses up to 10 mg can be used. The latter doses may be associated with bizarre side effects such as akathisia and dysphoria and a prolonged state of sedation (up to 24 hours). To maximize patient comfort, it is best to administer a small dose of fentanyl before droperidol is given.

Other clinicians prefer to add a benzodiazepine to the narcotic effect. Midazolam (Versed), diazepam (Valium), or lorazepam (Ativan) may all be used, but midazolam is probably the most popular at present because of its relatively rapid onset and offset of action as well as the production of anterograde amnesia. The benzodiazepines should be administered slowly in small doses because their effect on consciousness, respiration, and cardiovascular status in individuals is unpredictable. Even 0.5 mg may produce adequate amnesia in some adults. Unlike droperidol, benzodiazepines result in increased respiratory depression in the presence of narcotics, which is usually manifest by apneic spells. [91] Flumazenil, a specific reversal agent, is now available clinically. The principal disadvantage of using benzodiazepines may be the profound decreased level of consciousness that results in loss of verbal contact with the patient, who in such situations must be able to respond to commands, especially to breathe. In the frail elderly patient, intravenous diphenhydramine (Benadryl) in doses of 12.5 mg may provide good supplemental sedation to narcotics without excessive respiratory depression or adverse mental effects.

Anticholinergicsical Anesthesia

Before any anticipated difficult intubation, a dose of anticholinergic, such as glycopyrrolate (Robinul) 0.2 mg intravenously, is strongly advised. If bronchospasm is anticipated, larger doses (0.4-1.0 mg IV) are recommended to blunt the response to airway instrumentation. Besides improving visualization during laryngoscopy by reducing secretions, topical solutions of local anesthetics will be less diluted and less likely to be washed off the desired site of application. The use of anticholinergics is reasonable for general anesthesia in any smoker, for surgical positions in which suctioning will be difficult, for surgical positions in which secretions could loosen securing tape and predispose to tube dislodgement, and for surgery that involves the airway. For patients in whom succinylcholine is contraindicated, the decreased production of secretions occurring after prophylactic anticholinergics may lessen the chance of severe postextubation laryngospasm, which is especially difficult to treat without succinylcholine.

Anesthesia of the nares and nasopharynx should be accompanied by vasoconstriction to widen the available passage and decrease bleeding. Cocaine (4%) may be used up to 1.5 mg/kg. It is far more convenient and reasonably effective to use a lidocaine/phenylephrine combination. The phenylephrine may be applied first as 1/4 to 1 percent nose drops or the solutions may be mixed and applied together (4 percent lidocaine and 1 percent phenylephrine in a 3:1 combination to yield a 3 percent lidocaine/0.25 percent phenylephrine solution). [92] To anesthetize the sensitive nasopharynx, the solution may be instilled through a 16- or 18-gauge plastic catheter inserted deeply into the nose or on long cotton-tipped applicators that are slowly inserted until they reach the posterior wall of the nasopharynx. If three such applicators can be inserted, a 7.0-mm ID endotracheal tube will usually pass through that nostril. The applicators can be gently moved anteriorly and posteriorly to contact the entire mucosa, and additional solution can be dripped in along the wooden sticks as necessary. The total dose of lidocaine should be carefully controlled to avoid toxicity, particularly if additional lidocaine application is planned. Other practitioners topicalize the nares using progressively larger-sized soft nasal airways coated with 2 percent lidocaine ointment. Finally, the nasal endotracheal tube can be coated

with 2 percent lidocaine ointment to facilitate passage and give further analgesia.

The tongue and oropharynx can be anesthetized with 10 percent lidocaine spray, which is placed progressively further into the pharynx using the laryngoscope blade or a tongue depressor to keep the tongue out of the way. The cooperative patient can also gargle and expectorate viscous lidocaine to produce topical anesthesia of the tongue and pharynx. Once there is sufficient topicalization to allow the insertion of an oral airway, the long applicator adaptor for 10 percent lidocaine spray can be blindly placed through the airway to spray local anesthetic directly onto the supraglottic and glottic structures. Nebulization of 5 mL of 4 percent lidocaine can also be employed. [93]

The larynx can be sprayed with additional lidocaine directly onto the visualized glottis. If a laryngotracheal applicator (LTA) kit is to be used, it can be inserted with some holes below the vocal cords and some above. This will anesthetize the supraglottic area (including epiglottis) as well as the trachea when the lidocaine is injected. The LTA kit has also been used as an intubation guide with the applicator inserted through the Murphy eye and the endotracheal tube oriented with the concavity to the left. [94] The trachea can also be anesthetized with a transtracheal (or more correctly, translaryngeal) application of 2 to 3 mL of 2 percent lidocaine. A 23-gauge needle is inserted perpendicularly through the cricothyroid membrane in the midline, air is aspirated to ascertain the location of the needle tip, the lidocaine is quickly injected, and the needle is removed (see Fig. 39-25) (Figure Not Available) . This may cause vigorous coughing in some patients, but coughing provides excellent spread of the anesthetic in the larynx below the vocal cords. Other practitioners insert a 14-gauge or 16-gauge intravenous catheter through the cricoid membrane and remove the metal inner cannula before injecting local anesthesia. The catheter can be left in place to provide TTJV or access for retrograde intubation. The topicalization produced in the larynx and trachea is suitable for the use of the elastic gum bougie as well as a direct attempt at intubation. Contraindications to such injections include coagulopathy and local disorders such as tumor masses.

The use of topical anesthesia of the airway in the presence of a full stomach should be approached with common sense. The nose, tongue, and oropharynx can be safely anesthetized, but similar anesthesia in the larynx and trachea may diminish airway protection to unacceptable levels. When the cords are visualized, some clinicians may choose to spray the laryngotracheal structures with an LTA kit and then immediately follow with insertion of the tube. Others believe that even such a brief period of susceptibility to aspiration is unacceptable.

Nerve Blocks

The glossopharyngeal block blocks the sensory input from the areas of the posterior tongue innervated by that cranial nerve (Ch. 43) . A 22-gauge spinal needle is used to inject 5 mL of 1 percent lidocaine with epinephrine into the area where the base of the tongue apposes the palatoglossal fold (Fig. 39-27) (Figure Not Available) . The needle should be aspirated to avoid intravascular injections. The block is acceptable with a full stomach and does not appear to affect airway integrity when performed bilaterally. The block is intended to provide more comfortable laryngoscopy with lower doses of injective drugs. However, a study reported that viscous lidocaine

Figure 39-27 (Figure Not Available) Area of needle insertion for glossopharyngeal block. *(Courtesy of Andrew Woods, M.D., and Christopher Lander, M.D.)*

swish and gargle folowed by spray application of 10 percent lidocaine is as effective as glossopharyngeal block without producing the prolonged local discomfort seen in some individuals after the block. [95]

The superior laryngeal nerve innervates the epiglottis, aryepiglottic folds, and the laryngeal structures down to the false cords. The superior laryngeal nerve (SLN) may be blocked by an external approach using a 23-gauge needle and 3-mL syringe to inject 2 to 3 mL of 1 percent lidocaine between the greater cornu of the hyoid bone and the thyroid cartilage. This block is contraindicated by coagulopathy, a local pathologic problem, or full stomach. The SLN may also be blocked by the application (for about a minute per side) of lidocaine-soaked gauze pads with Krause forceps held in the pyriform fossa. This latter technique is frequently performed by otolaryngologists prior to laryngoscopy.

Choice of Technique

The choice of technique for conscious intubation depends on preference for oral or nasal tube placement, experience, and availability of equipment. If one technique fails, another is usually tried. All anesthesiologists should develop skill with conscious oral intubation with direct laryngoscopy. Blind nasal intubation that avoids the discomfort of laryngoscopy is equally important to learn. If fiberoptic bronchoscopy is an option, it should be performed reasonably early in the sequence because blood, secretions, and edema can make its use extremely difficult.

Conscious Oral Intubation with Direct Laryngoscopy

Preparation for conscious oral intubation involves use of the drying agents, sedation, topical anesthesia, and/or nerve blocks previously discussed. Topical application of anesthesia to oropharynx and tongue without glossopharyngeal nerve blocks may allow for laryngoscopic visualization and further anesthesia of the glottis and the trachea via an LTA kit or similar device. The laryngoscope must be inserted gently but with firm manipulation when required. The requirement for sedation, topicalization, and nerve blocks varies greatly among patients so that care must be taken to avoid excessive doses while providing acceptable comfort levels. The use of the elastic gum bougie may improve comfort by reducing the force required to produce acceptable glottic exposure. Superior laryngeal blocks and transtracheal anesthesia are not generally used if there is a concern for aspiration of gastric contents.

To supplement the commonly used laryngoscope blades, a variety of ingenious blades have been devised to cope with the difficult intubation. In addition to a variety of shapes, mirrors (Siker blade) and prisms (Huffman, Bellhouse) have been adapted for looking literally "around the corner." [96] [97] The Howland lock fits between the blade and handle, changing the angle of their relationship. In very obese patients, the laryngoscope may need to be inserted by turning the handle to the right, inserting the blade and then attaching the handle, or by using a short laryngoscope handle. [98] While some clinicians take an "awake look" and then anesthetize the patient for intubation, visualization of the glottis in the conscious patient does not guarantee similar visualization after anesthesia and/or paralysis as muscle relaxation causes the larynx to shift anteriorly. [99]

Conscious Oral Intubation with Indirect Laryngoscopy

Unlike the flexible fiberoptics to be discussed, a rigid stylet fiberoptic laryngoscope is available for oral intubation only. The device is used to locate the glottis, but the stylet tip does not actually enter the larynx. [34] The Bullard laryngoscope, an instrument for indirect laryngoscopy, is inserted much like a routine laryngoscope. The handle is then rotated from horizontal to vertical as the blade slides around the tongue. The endotracheal tube may be passed from the intubating attachment of the laryngoscope, or a tube containing a stylet in the shape of the laryngoscope may be used. [83]

Blind Oral Intubation

When there is minimal visualization of laryngeal structures during direct laryngoscopy, a blind or semiblind technique for intubation may be attempted in the conscious or anesthetized patient. A MacIntosh blade is helpful to pull up the tongue and thereby open up and maintain the airway. An endotracheal tube with a curved stylet is then guided in the presumed direction of the glottis where the tube is then slid off, ideally, into the trachea. Spontaneous ventilation is helpful as breath sounds will guide the way to the larynx. After a blind intubation, confirmation of endotracheal intubation with capnometry and/or bronchoscopy is advisable. The use of the elastic gum bougie has already been discussed. [100] In order to change the direction of the tube tip, stylets with a tip-moving device have been designed [101] (Flexguide, Scientific Sales International, Kalamazoo, Mich). The Magill forceps may also be used to guide the tube tip in the desired direction. Even the clinician's fingers may be used in a blind, tactile technique. The first and second fingers of the nondominant hand are placed on either side of the tip of the epiglottis to guide the tube. The patient must be cooperative lest the anesthetist risk getting bitten. The Augustine guide includes a curved positioning blade with a guide channel that fits in the vallecula. The tip is then moved anteriorly to expose the vocal cords, and an endotracheal tube is slid over a flexible stylet that has been passed into the trachea after confirmation of easy air aspiration. [82]

Stylets with lights at the tip ("lightwand" stylet) are advantageous in that the stylet tip can be guided by observation of the light's movement under the skin (Flexilum, Concept Corp., Clearwater Fla; Tubestat, Xomed-treace, Jacksonville, Fla). These are useful when mouth opening or neck movement is limited. The room must usually be quite dark to see the light adequately. When the tube tip is correctly positioned just above the vocal cords in the midline, a distinct glow is seen in the anterior neck, and the tube is slid off into the trachea. [102] [103] To avoid the reported complication of disruption of the light bulb, the stylet should be well lubricated,

---

removed gently, used a single time, and not used nasally (unless manufactured for nasal use). [104] A new lightwand device (Trachlight, Laerdal Medical, Armonk, NY) has been studied and has the potential advantages of a brighter light source and a flexible wand to facilitate tracheal entry. [105]

Nasal Intubation in a Conscious Patient

Conscious nasal intubation is useful for urgent intubations outside the operating room when mouth opening or neck movement is limited or prohibited and whenever a nasal endotracheal tube is required but anesthesia and/or paralysis are thought to be too risky. Topical anesthesia of the nose and oropharynx as described is important as well as an appropriate amount of sedation. The supraglottic area can be anesthetized with superior laryngeal blocks or local anesthetic sprayed through the tube during its passage. Translaryngeal anesthesia is especially useful for blind, conscious nasal intubation. The lubricated, curved endotracheal tube is inserted perpendicularly into the nose and gently passed into the hypopharynx. If breath sounds disappear, the tube has passed into the esophagus or a pyriform sinus and must be withdrawn above the level of the glottis. A variety of devices have been employed to amplify the breath sounds, but the ear over the end of the tube is usually adequate. On occasion, vomiting or bronchial secretions will make this unpleasant. Capnography may be used to assist in the process of placement in addition to confirmation of proper position. [106] The tube is passed into the larynx during inspiration, which tends to be deepest immediately following a cough. Some clinicians ask the patient to "pant" to maintain an open glottis with plenty of air movement. The section on anesthetized nasal intubation describes several techniques for facilitating passage of the recalcitrant endotracheal tube. If the mouth can be opened, direct laryngoscopy and Magill forceps can be used to guide the tube into the glottis. If direct laryngoscopy is necessary, further airway anesthesia, heavier sedation, or glossopharyngeal blocks are likely to be required.

Retrograde Endotracheal Intubation

Retrograde intubation involves passage of a wire or plastic stylet through the cricothyroid membrane that is then coughed out of the larynx and into the oropharynx by the patient. This may be done in the anesthetized or conscious patient. In the conscious patient, it should be preceded by transtracheal topicalization. In adults, this can be done with a "long-arm CVP" catheter or epidural catheter passed through the accompanying needle. In children, a 20-gauge IV catheter with a .021-inch "J" wire is appropriate. [107] A J-wire technique can also be used in adults. [108] A kit with a J-wire is available that can be used to insert endotracheal tubes as small as 4 mm ID (Fig. 39-28 (Figure Not Available) , Cook Critical Care, Bloomington, Ind). If a nasal tube is desired and the wire or catheter comes out of the mouth, the tip can be secured to a nasally passed catheter and then pulled up and out through the nose. The endotracheal tube is then inserted into the larynx over the wire which is held with mild tension. The tip

Figure 39-28 (Figure Not Available) Retrograde intubation with the Cook Retrograde Intubation Set. (A) After placement of an 18-gauge sheath needle into the larynx, the J end of the wire guide is inserted in a cephalad direction until it exits the mouth or nose. (B) An 11.0 French Teflon catheter is threaded down over the guide wire until it contacts the laryngeal access site. The guide wire is removed from above. (C) After advancing the Teflon catheter 2 to 3 cm, the endotracheal tube is advanced into the trachea while maintaining constant control of the catheter. *(Courtesy of Cook Critical Care, Bloomington, Ind.)*

of the tube may catch on the anterior commissure and therefore not pass. Turning the tube, loosening the wire, or threading the tube onto the wire via the Murphy eye (rather than the bevel tip) may facilitate passage. The use of a catheter rather than a wire as a guide (as in the Cook kit) is very helpful in allowing tube passage. The wire can also be threaded up the suction port of a fiberoptic bronchoscope that serves as a stylet with visual capabilities. [28] Details on retrograde intubation technique can be found in Benumof's monograph on airway management. [109]

Fiberoptic Bronchoscopy

Fiberoptic bronchoscopy is a technique that may be utilized for all of the difficult airway situations previously described in this chapter. In addition, the scope may be used to evaluate possible obstruction of the endotracheal tube, to rule out esophageal intubation, check for endobronchial intubation, and ensure the correct placement of double-lumen endobronchial tubes. Much like that of the traditional laryngoscope, skillful use requires practice in situations that are neither urgent nor extremely difficult. This may initially include practice on a teaching mannequin if possible. Even in experienced hands, successful intubation with the fiberoptic scope usually requires several minutes and therefore another technique should be used if an airway must be established rapidly in the face of severe hypoxia. On the other hand, when use of the bronchoscope is anticipated for the more elective management of a difficult airway, the bronchoscope should be employed first before airway visualization is obscured with blood, secretions, and edema. Pathologic processes such as tumors, infection, and edema that diminish the space between the anterior and posterior pharyngeal wall may make passage of the bronchoscope difficult.

The bronchoscope itself contains thin glass fibers that transmit reflected light along their length. The fiber size (5-25mum diameter) is chosen for flexibility, strength, and light transmission. In addition to the image-transmitting bundle of fibers, there is another light fiber bundle that transmits the light from a powerful source. The instruments also include wire controls for changing angulation of the tip and a port for suction or injection of local anesthetics and oxygen. The bronchoscope is a relatively delicate instrument and must always be handled with care. Because replacement or repairs are very expensive, the scope should be turned only as a unit and not twisted upon its shaft. The monograph by Ovassapian [110] supplies details concerning care and cleaning of the instrument and has many photographs and illustrations of great utility to the bronchoscopist.

If oral intubation is planned, an endoscopic oral airway or bite block is best used to protect the bronchoscope. The oral airway also has the advantage of preventing dorsal displacement of the tongue, keeps the instrument in the midline, and guides the bronchoscope past the epiglottis into the larynx. Such devices include the Patil-Syracuse airway, Williams airway intubator, and the Ovassapian intubating airway. [110] [111] If an anesthetized intubation is planned, a mask with a sealing endoscopy port can be used to maintain anesthesia with spontaneous or controlled ventilation during the bronchoscopy.

Before any fiberoptic procedure, a dose of anticholinergic is strongly recommended to prevent secretions from obscuring the view in the upper airway. The light source should be checked and the bronchoscope prefocused on printed material. The tip of the bronchoscope should be defogged with commercial solution or warm soapy water. The bronchoscope is lightly lubricated along its entire length with a water-soluble agent (K-Y jelly or eye lubricant) to facilitate passage through the endotracheal tube. A patent suction port is important and a syringe of 10 mL of 1 percent lidocaine solution can be attached for further topical spray through the bronchoscope. If oxygen insufflation is desired, an appropriate source adaptable to the bronchoscope port should be available, which is useful in keeping secretions off the tip and diminishing fogging as well as providing a source of 100 percent oxygen. However, it also poses the potential for marked gastric insufflation before the trachea is entered and for barotrauma, after tracheal entry.

The bronchoscopist must decide whether the intubation will be nasal or oral and conscious or anesthetized. Nasal intubation has the advantage that the fiberoptic scope is usually positioned to directly visualize the glottis and is therefore technically easier. During conscious, sedated nasal intubation, there is less interference by the tongue. An intubating airway is not required, but a standard airway may be used to keep the tongue off the posterior pharyngeal wall during anesthetized intubations. Some clinicians use a soft nasal airway that has been split lengthwise to introduce the bronchoscope. The previously discussed contraindications to nasal intubation apply. If there is doubt about the ability to maintain the mask airway, intubation should proceed with conscious sedation only. The patient can be anesthetized for fiberoptic intubation if the mask airway can be maintained but intubation is difficult. Such anesthetized intubations are usually more difficult because of the development of upper airway obstruction.

Sedation and topical anesthesia of the airway have been previously addressed in this chapter. In the conscious, sedated patient, superior laryngeal blocks and translaryngeal anesthesia may be applied. Alternatively, the supraglottic, glottic, and tracheal areas may be topicalized with 1 percent lidocaine sprayed through the injection port.

For conscious, sedated nasal insertion, the patient's nares and nasopharynx must be anesthetized and vasoconstricted as previously described. The endotracheal tube or split nasal airway is inserted into the posterior nasopharynx and the fiberoptic bronchoscope passed through it. In the vast majority of cases, the glottis can then be seen with minimal tip manipulation. Note that the appearance of the glottis is quite different during fiberoptic bronchoscopy than the stretched appearance the laryngoscopist expects during classic rigid laryngoscopy. [110] The endotracheal tube can be inserted into the nose under bronchoscopic guidance if there is concern about a foreign body or if the tube will enter the nares but not pass into the oropharynx. A useful alternative method is to blindly insert the endotracheal tube until breath sounds are heard maximally, as in blind nasotracheal intubation. This usually results in an easily-visualized glottis that is quite close to the bronchoscope tip. On occasion, a deviated septum will cause compression of the endotracheal tube and difficult passage of the bronchoscope.

Oral, sedated fiberoptic intubation is somewhat more difficult than nasal intubation because the epiglottis becomes a greater obstacle and the tube tip is not usually directed towards the glottis. An intubating oral airway, or at least a bite block, is inserted after topicalization of the posterior tongue, soft palate, and lateral oropharyngeal areas. This can be accomplished with 10 percent lidocaine spray, nebulization of 4 percent lidocaine, or gargling with about 30 mL of viscous lidocaine. The endotracheal tube is inserted about 8 to 10 cm into the airway and the bronchoscope passed through the tube. If the posterior pharyngeal wall is encountered (usually a pink blur), the tip of the bronchoscope is turned down to visualize the glottis. Otherwise the posterior tongue, epiglottis, and glottis are visualized in proper sequence. If the epiglottis obstructs vision, the bronchoscope must be manipulated under the epiglottis to see the vocal cords. An Endotrol tube may be helpful in guiding the bronchoscope tip to the position required to visualize the glottis. The view may also be improved by having the patient protrude his tongue or gently pulling the tongue anteriorly with a piece of gauze wrapped around the tongue.

Fiberoptic intubation in the anesthetized patient may be performed with spontaneous or controlled ventilation with a standard or Patil endoscopic mask. Other clinicians use some form of insufflation to provide oxygen without a mask. Spontaneous ventilation has the obvious advantage of avoiding apnea while bronchoscopy takes place. However, a diminished anesthetic level may occur resulting in cough, vomiting, laryngospasm, and bronchospasm. The patient must be ventilated by mask with 100 percent O_2 between intubation attempts. During bronchoscopy, O_2 may be administered through the injection port, but insufflation will require an additional source of oxygen. The endoscope mask has a sealing port that allows for the continuous use of a sealed mask airway during bronchoscopy. If a specialized mask is unavailable, a substitute may be constructed by placing the endotracheal tube cuff into the mask inlet to form a seal and then placing a fiberoptic swivel connector on the endotracheal tube to allow simultaneous bronchoscopy and mask ventilation via the anesthesia circuit. [112] For any fiberoptic anesthetized intubation, an assistant is required to hold the endoscopic mask, maintain the airway, deliver equipment and sometimes help stabilize the endotracheal tube while the bronchoscope is inserted.

If nasal, anesthetized intubation is planned, vasoconstriction of the nares and nasopharynx is again necessary. The actual technique of bronchoscopy is as previously described but may be somewhat more difficult due to soft tissue upper airway obstruction caused by anesthesia and/or paralysis. Pulling the tongue anteriorly as previously described may aid visualization of the glottis. Anesthetized, oral intubation is probably the most difficult of the four possible techniques.

The bronchoscopist may choose to stand at the head or the side of the table. If the patient cannot lie flat, standing at the side is essential, but standing on the side of the bed makes the procedure less awkward. The sitting position may facilitate visualization by gravity drainage of secretions and by pulling the scope tip towards the larynx. Keys to successful intubation include control of secretions, bronchoscopic intervention before extensive bleeding and edema have occurred, adequate topical anesthesia and sedation, proper defogging of the lens, and aligning the scope in the midline. Occasionally the bronchoscope will enter the trachea easily, but the endotracheal tube cannot be advanced over it. This is usually due to the bevel catching on the right arytenoid (oral) or epiglottis (nasal) depending on the approach. [113] This may respond to turning the tube 90 degrees counterclockwise, and then 180 degrees if necessary. Careful laryngeal and neck manipulation may also help. If a small (4-mm) bronchoscope has been used, the substitution of a larger (6-mm) instrument may prove helpful. Alternatively, a smaller endotracheal tube may be necessary. The use of an anode or flexible reinforced tube has been reported to be advantageous. [114] Sometimes, sliding the tube in as the bronchoscope is withdrawn will work. Excessive force should be avoided to minimize laryngeal trauma as well as trauma to the delicate fibers at the tip of the scope.

Bronchoscopy is difficult in the presence of bleeding or airway edema. Severe edema or anatomic airway distortion will occasionally necessitate another approach to airway management if surgery must be performed. The presence of a large epiglottis flopping against the posterior pharyngeal wall can occasionally be an insurmountable problem. [115] If the location of the bronchoscope tip is uncertain, the bronchoscope has usually entered a pyriform fossa that may resemble the glottis in this situation. [116] When direct visualization cannot be accomplished, the room lights can be dimmed and the strong light at the bronchoscope tip observed and manipulated into the midline much like a lightwand stylet. [117]

Finally, removal of the bronchoscope may be difficult. At this time it is essential that the tip manipulation lever is in the unlocked, neutral position. The bronchoscope should not be removed with undue force because the fibers may be damaged, the patient injured, or the endotracheal tube displaced. This is most likely to occur with a poorly lubricated bronchoscope used in a relatively small bore tube. It may also be due to pinching of the tube in a tight nasal passage or an errant tip that has gone out through the Murphy eye. In this situation, bronchoscope and tube may have to be removed as a unit and the procedure begun again.

PEDIATRIC AIRWAY MANAGEMENT

This subject is covered in more detail in textbooks on pediatric anesthesia and is discussed only in general terms here (Ch. 59) .

After about age 8 years, airway differences between adults and children mainly reflect size differences. The newborn has the most dramatically different anatomy from the adult that persists during the first year of life and then slowly evolves to the adult form. Differences include a large head that tends to flex the short neck and obstruct the airway and a disproportionately large tongue that may cause airway obstruction and more difficult laryngoscopy. The larynx is more cephalad in infants because the cricoid cartilage is opposite the fourth cervical vertebra (rather than the sixth in adults). The epiglottis is longer, stiffer and lies more horizontally

than in adults. As noted, the cricoid cartilage is the narrowest point of the airway until about age 8. The shorter trachea also leaves less margin for error in placement of the endotracheal tube. Finally, the angles of the main bronchi take-off points make left-sided endobronchial intubation as likely as right-sided.

The sizes and insertion lengths of uncuffed endotracheal tubes for children are shown in Table 39-5 . Tubes should pass easily and allow for leak at inflation pressures of 15 to 20 cm H_2O. As noted, the use of cuffed tubes for children of all ages has become common practice as has the use of appropriately sized LMAs (see Fig. 39-9) (Figure Not Available) . [53] Awake intubation may be performed in newborns up to about 4 weeks of age. Oxygen, atropine, and topicalization of the tongue with lidocaine jelly on a finger are followed by laryngoscopy with a straight blade and thin-handled laryngoscope. Hyoid pressure with the little finger may aid visualization. Older or more vigorous children will require anesthesia for intubation under most circumstances. Sevoflurane has rapidly become the mask induction agent of choice for most circumstances.

COMPLICATIONS OF SHORT-TERM INTUBATION

Laryngoscopy

When the laryngoscope is used improperly, when laryngoscopy is particularly difficult, or when there is dental/periodontal disease, teeth may be injured. If a tooth is chipped or partially broken, the fragment should be located but cannot be re-affixed to the natural tooth. If an entire tooth is dislodged, the tooth should be carefully handled without touching the root. Dental consultation should be obtained to re-affix the tooth in its socket. If such consultation is not available, the tooth can be placed in saline or milk until dental expertise can be obtained. If fragments or whole teeth cannot be located, chest and abdominal x-rays should be done for localization.

The laryngoscope can also injure the soft tissues, usually the lips or gums, but any area of contact can be injured. These injuries are more likely to occur when intubation is difficult and the finer points of technique are sacrificed to expedite intubation. The details of the injury should be well documented in the anesthetic record and chart and the patient informed of the injury.

When laryngoscopy is performed under inadequate anesthesia, coughing, laryngospasm, bronchospasm, and vomiting (with the possibility of aspiration) may occur. Cough should be especially avoided in the settings of an open-eye injury, increased intracranial pressure, or an intracranial vascular anomaly. Laryngospasm should be treated with oxygen, jaw thrust, and gentle mask pressure but may require muscle relaxants to avoid a period of severe desaturation. If cervical spine disease is present due to traumatic, congenital, inflammatory, or neoplastic disease, the spinal cord can be injured during neck movement. [118] Eye trauma may occur due to accidental injury with an instrument or by the laryngoscopist.

Laryngoscopy and Intubation

Hypoxemia and hypercarbia are potential complications of laryngoscopies and intubations that are not successful in a reasonable amount of time. Careful evaluation of the airway will screen out most patients who cannot be adequately ventilated by mask or intubated. The pulse oximeter is essential for detecting desaturation during this time. If neither mask ventilation nor intubation can be accomplished, the insertion of a supraglottic airway device such as the LMA or Combitube should be performed with TTJV or a surgical airway reserved for when less invasive maneuvers are unsuccessful.

There is an increased risk of aspiration in the patient with a full stomach and a difficult airway, but aspiration can also occur in the properly fasting patient who does not present special difficulties. Rapid sequence induction and conscious intubation have been described as means of protecting the patient from aspiration. Aspiration remains a concern but a much lesser one in the patient with a properly placed, cuffed endotracheal tube.

Cardiovascular responses to laryngoscopy include hypertension, tachycardia, and dysrhythmias. In children, bradycardia may occur, but hypoxemia must always be considered as the primary cause. In healthy patients these responses are generally well tolerated; however, in patients with limited coronary or myocardial reserve, myocardial ischemia or failure may follow. The patient with a vascular lesion at risk such as an intracranial vascular anomaly or trauma of the thoracic aorta may also suffer serious sequelae. The clinician must be careful so as not to overtreat these responses and create more difficulties than the responses themselves. Because the MAC for endotracheal intubation is about 30 percent higher than MAC for surgical incision, a relatively deep level of anesthesia must be established. Because deep anesthesia may not be tolerated by many patients, drugs that tend to block the response to airway instrumentation or antihypertensives may be used. Narcotics are one option as an adjunct. Fentanyl has been best studied and requires doses of at least 3 to 4 mug/kg to be effective. [119] Alfentanil has a more rapid onset of action and is effective for this purpose, and remifentanil is also likely to be similarly effective. [120] In addition to its local anesthetic actions, lidocaine reduces anesthetic requirements by 30 percent with a 1.5 mg/kg IV bolus that is minimally depressive to the cardiovascular system. [121] Intravenous lidocaine may be used to supplement the narcotic effect on hemodynamics. [122] Other studies have called the effectiveness of lidocaine in this setting into doubt. [123] Topical anesthesia with lidocaine has been a less effective method for blunting hemodynamic responses because laryngoscopy precedes intratracheal administration of lidocaine. Transtracheal anesthesia avoids laryngoscopy but is stimulating in its own right. Glossopharyngeal and superior laryngeal nerve blocks may also be effective methods to blunt adverse hemodynamic responses. A variety of antihypertensive agents have also been used to diminish the blood pressure and heart rate responses to intubation. These include beta-adrenergic blockers, phentolamine, nitroprusside, clonidine, captopril, nitroglycerin, and hydralazine, [124] [125] [126] [127] [128] but their relative efficacy is not established. However, one study reported that a 150 mg esmolol bolus was superior to

IV high-dose lidocaine or low-dose fentanyl in preventing the tachycardia associated with intubation. [129] All three treatments provided equivalent blunting of blood pressure increases. In treated (with drugs other than beta blockers) hypertensive adult patients, a single 100-mg intravenous bolus of esmolol given before laryngoscopy appears to control heart rate and blood pressure without excessive hypotension. [130] Dysrhythmias during or immediately following laryngoscopy and intubation generally resolve with adequate ventilation, and establishment of adequate anesthetic depth.

The respiratory response of laryngospasm has been described. In predisposed individuals, laryngoscopy alone may also cause bronchospasm. In healthy volunteers, intubation results in an increase in airway resistance that is greater than the resistance of breathing through the tube held externally. This doubling of the expected resistance even in topically anesthetized airways represents reflex bronchoconstriction to the mechanical irritation of the tube. [131] Bronchospasm may be especially severe in the lightly anesthetized patient with reactive airways. Propofol may be the intravenous induction agent of choice in patients prone to bronchospasm. [132] Clinically, it appears that bronchospasm is blunted by the prior administration of anticholinergics, steroid, inhaled beta $_2$ -agonists, lidocaine (topical, nerve block, intravenous), and narcotics. [133] After intubation, deepening anesthesia with intravenous or inhaled agents and the administration of inhaled or IV beta agonists will help treat the bronchospasm. Muscle relaxants may improve ventilation, and in extreme situations, a small amount of positive end-expiratory pressure may improve oxygenation when it is unsatisfactory on 100 percent oxygen. [134] With the tube *in situ,* it is important to ensure that the audible wheezing is not due to some form of mechanical obstruction of the tube: kinking, clot, mucus, active biting or passive mouth closure, foreign body, cuff-overinflation, bevel against tracheal wall, or endobronchial intubation. Other less likely problems such as tension pneumothorax, a nasogastric tube in the trachea, heart failure, or the negative pressure of a descending ventilator bellows must also be eliminated before definitively treating wheezing as bronchospasm. Visual inspection, passage of a suction catheter (or preferably, a fiberoptic bronchoscope) along with cuff deflation and 90 degree rotation of the tube will rule out several of these possibilities.

The patient with elevated intracranial pressure (ICP) who has minimal reserve in intracranial compliance is actually at risk for brain-stem herniation and sudden death during laryngoscopy and intubation. Instrumentation of the airway may result in a sudden increase in cerebral blood flow due to increases in cerebral metabolic activity and systemic cardiovascular effects. The normal autoregulation mechanism may not be effective because of disease or because its upper pressure limit (normally, mean arterial pressure 150 mm Hg) may be exceeded. Coughing or bucking will decrease venous return from the head and may increase ICP as well. Induction drugs that result in cerebral vasoconstriction are most useful. In practice, this has included thiopental and lidocaine, although etomidate and propofol can also be considered. [135] [136] [137] Narcotics are somewhat useful, although they do not have a great direct effect on central brain function. [138] On the other hand,

ketamine is best avoided. Adjunctive measures may include voluntary and/or mask hyperventilation, mannitol, steroids, and establishment of ICP monitoring before laryngoscopy and intubation. [36]

Intubation

In addition to failed intubation, a most feared complication of intubation is esophageal intubation. [139] Although this occurs most frequently in the setting of inexperience, it can happen to experienced practitioners. Unfortunately, except for direct visualization of the tube passing through the cords, fiberoptic confirmation of placement, and presence and persistence of appropriate levels of end-tidal carbon dioxide levels, the usual clinical means for determining endotracheal placement of the tube may not always be reliable. These include presence of bilateral breath sounds, chest movement, exhaled tidal volumes, tube condensation, epigastric auscultation, reservoir bag filling and compliance, and chest radiography. [140] Routine monitoring of end-tidal CO_2 is helpful in the definitive determination of tube placement when visualization is impossible and fiberoptic equipment is not available. A colorimetric single-use carbon dioxide detector (FEF end-tidal carbon dioxide detector, Fenem, New York, NY) may be employed when capnometry is unavailable. [141] The esophageal detector device (EDD) employs a self-inflating bulb that is connected to the endotracheal tube and can be carried in a mobile airway case when capnography is not available. The principle of use is that the esophagus will collapse when the subatmospheric pressure is applied, and therefore, the bulb should stay collapsed if esophageal intubation has occurred. This is in contrast to the more rigid trachea that allows for free aspiration of gas and reinflation of the bulb. The EDD was initially reported to be quite effective, but subsequent studies have noted problems in the obese and in the parturient. [142] [143] This device may have a place in intubations when capnography is not available but independent confirmation is encouraged. A new device that differentiates tracheal from esophageal intubation by recognition of differences in resonating frequency (sonomatic confirmation of tracheal intubation) appears to be no more effective than the simpler, cheaper, bulb device. [144]

The endotracheal tube (and/or stylet) may also cause mechanical damage to the pharynx, esophagus, larynx, and trachea. This may involve blunt injury, dissection, or perforation. The delicate structures of the larynx (vocal cord, arytenoids) are especially susceptible. Infections and/or barotrauma may follow these types of injuries. Acute injury to the trachea is associated with use of a stiff protruding stylet and previous pathology such as trauma. Gentle, careful manipulation of the airway and proper use of a stylet that is removed after the glottis is entered should help avoid most of these types of injury.

Endobronchial intubation is most common when there is the least distance for the tube tip to be placed properly above the carina yet below the vocal cords as in small children. Guidelines for placement distance have been discussed (see Table 39-5) . In patients older than 1 year of age, right-sided endobronchial intubation will be far more common. Hypoxemia, bronchospasm, atelectasis, and coughing may result. Auscultation and observation of the chest may

suggest the diagnosis, but the tube may have to be pulled back a small distance to finalize it. Fiberoptic bronchoscopy is the optimal diagnostic tool. The clinician must be extremely careful when withdrawing the tube in awkward positions or in the difficult airway. Note also that properly placed tubes may change their position during head movement, abdominal insufflation, or repositioning of the patient. [69] [145] [146] Inadvertent extubation may occur during repositioning and surgical manipulation and may even result from head movement and coughing in small children, such that continued vigilance is essential.

In addition to bronchospasm, the endotracheal tube has several other effects on pulmonary mechanics. [147] The tube acts a fixed resistor that substitutes for the normal upper airway resistance. The cross-sectional area of an 8.0-mm ID tube (50 mm^2) is not remarkably less than the mean cross-sectional area of the glottis (narrowest part of the adult airway) during quiet breathing. Thus, the use of 8.0-mm tubes in men or 7.0-mm tubes in women whose glottic aperture is smaller does not impose an undue increase in resistance. Anatomic dead space is reduced by intubation, however. In adults, functional residual capacity is not altered by the presence of an endotracheal tube. [131]

Several complications are peculiar to nasal intubation. Epistaxis may occur even when vasoconstriction, a lubricated tube, and careful manipulation are employed. The inflated cuff may tamponade the hemorrhage if correctly positioned. Patients with pharmacologic or spontaneous coagulopathies judged to be significant by the clinician should not be intubated nasally. Severe hemorrhage may result requiring simple tamponade with devices that include the balloons of Foley catheters and require expert consultation with otolaryngologists. The stream of blood pouring down the pharynx may also make subsequent oral intubation extremely difficult.

The nasal or nasopharyngeal mucosa may be damaged and false passages created. Tracheal or esophageal trauma can lead to the serious complications or pneumothorax and infection, respectively. [148] [149] Adenoids, polyps, and foreign bodies may be displaced, causing bleeding and even airway obstruction. Nasal instrumentation in these situations should be done under direct vision if possible. The problems of bacteremia and basilar skull fracture have been mentioned previously. In the former, endocarditis prophylaxis is indicated. [66] [67] In the latter, intubation is contraindicated for fear of entering the cranium or introducing CNS infection. Nasal necrosis is more likely a complication of chronic intubation but may occur perioperatively, especially with the use of nasal RAE tubes. [150] Ulceration of the inferior turbinate has also been described. [151] Sinusitis and otitis are two more common sequelae of longer-term nasotracheal intubation. [152] [153]

EXTUBATION

Extubation of the trachea may be performed while the patient is deeply anesthetized or is nearly fully awake. "Deep" or more precisely, anesthetized extubation, is performed after muscle relaxants have been fully reversed and the patient is maintaining an acceptable respiratory rate and depth. A difficult mask airway, difficult intubation, risk of aspiration, or surgery that may produce airway edema or maintenance problems are contraindications to such extubation. Adequate recovery of the ability to maintain and protect the airway must be demonstrated after the use of neuromuscular relaxants. [154] It is important to remember that adequate ventilation through an endotracheal tube does not guarantee the muscle strength to maintain the airway. Sustained tetanus using a nerve stimulator is very painful in the conscious patient, but sustained (5 sec) head lift is an excellent way to assess clinically adequate reversal. If head lift is contraindicated or painful, leg lift or sustained tongue protrusion can be similarly assessed. As the anesthetic level diminishes, the patient is suctioned, and the tube is removed after a positive pressure breath has been given with the anesthesia bag to allow subsequent expulsion or secretions out of the glottis. Advantages include reduced coughing on the endotracheal tube that may lessen laryngotracheal trauma and cause less adverse effects. However, the airway must be scrupulously maintained because obstruction and aspiration remain possibilities. Furthermore, as the patient awakens, laryngospasm and cough may occur anyway. Because there is no way to entirely avoid such coughing after an anesthetic, many authors regard "deep" extubations merely as premature extubations. The perspective appears valid because present anesthetic practice seldom utilizes techniques of truly "deep" anesthesia.

When such extubations in the anesthetized state are contraindicated, awake extubation is essential. The patient is not extubated until judged ready to maintain and protect the airway. The patient who is unresponsive to verbal stimuli, has deviation of the eyes, or is breath-holding is not ready for extubation and is prone to laryngospasm, which is most likely to occur when patients are extubated in between awake and anesthetized states. Coughing and bucking probably indicate the ability to protect the airway, but the timing of awake extubation remains a matter of clinical judgment. Lidocaine (1-1.5mg/kg IV) or a small dose of narcotic may help smooth out awake extubation at the cost of prolonging the process of awakening. After extubation, the patient may be maintained in the supine or lateral position. After anesthetized extubation, oral or nasal airways are usually left in place until the patient can no longer tolerate them. Vigilance should not be relaxed at this time.

Difficult removal is usually the result of leaving the endotracheal tube cuff inflated. If the cuff will not deflate because of obstruction in the tubing, it can be punctured by a needle placed through the cricothyroid membrane after the cuff is raised to this level. More serious and somewhat unusual causes of difficult extubation include fixation of the endotracheal tube or pilot tube by a Kirschner (K) wire used in head and neck surgery or a suture placed from the pulmonary artery through the trachea into the endotracheal tube. A tangled nasogastric tube, swollen or tense vocal cords, or a "barb" accidentally cut on the endotracheal tube can all interfere with extubation. [155] The nature of the surgical procedure must be kept in mind when a tube will not come out after cuff deflation or rupture so as to avoid trauma from vigorous extubation attempts. Direct or fiberoptic examination may be required.

Special care must be taken in a variety of potential high-risk extubations when the ability to immediately reestablish

the airway is questionable. [156] The endotracheal tube may be removed while leaving a device such as a tube changer, nasogastric tube, or bronchoscope within the trachea so that the airway can be immediately reestablished if necessary. [157] A variety of tube changer devices are available and may also be employed with jet ventilation (Cook Airway Exchange Catheter, Cook Critical Care, Bloomington, In; Sheridan TTX tracheal tube exchanger, Sheridan Catheter Corp, Argyle, NY; and Endotracheal ventilation catheter, CardioMed Supplies, Gormley, Ontario, Canada). Note that the presence of such a device does *not* guarantee that the tracheal tube can be replaced. Also note that supraglottic devices such as the LMA may or may not be successful in establishing an airway as the pathology may be at the supraglottic level or below. The presence of an individual who can establish a surgical airway (along with the necessary equipment) may be reasonable in selected instances of anticipated difficult extubation, particularly if there is no leak when the endotracheal tube cuff is let down. [158]

Complications of Extubation

Airway obstruction, laryngospasm, and aspiration are complications that have been previously discussed. Note that after intubations lasting 8 hours or more, airway protection may be impaired for 4 to 8 hours. [159] Sore throat is a complication of anesthesia that may have pharyngeal, laryngeal and/or tracheal sources and may occur in the absence of endotracheal intubation. [160] Factors that may affect the incidence of sore throat include area of cuff-trachea contact (tracheitis), use of lidocaine ointment and size of the endotracheal tube (laryngitis), and the use of succinylcholine (pharyngitis). Cuffs with a longer cuff-trachea interface appear to cause a higher incidence of sore throat. [161] The incidence of sore throat may also be related to intracuff pressures. [162] As previously noted, lidocaine ointment has a questionable effect on the incidence of sore throat. The higher incidence of sore throat in women is probably related to the tube size/laryngeal size relationship. One study demonstrated that tube size is related to the incidence and severity of sore throat in both sexes. [163] This study did not find that the use of succinylcholine was related to sore throat but other workers have reported succinylcholine to be a contributing factor and that nondepolarizing pretreatment reduced the incidence somewhat (from 68 to 45%). [63] The mechanism for succinylcholine-related sore throat is postulated to be myalgias due to fasciculation of peripharyngeal muscles. Sore throat is a minor side effect that should resolve within 72 hours and should not be a factor in determining whether endotracheal intubation is required. It may also occur with the use of an LMA. Hoarseness is another minor side effect correlated with endotracheal tube size and should be investigated if persistent.

Laryngeal edema is most commonly symptomatic in children because their small airway size is more severely reduced by edema; i.e. edema producing only hoarseness in an adult may cause a significant reduction in laryngeal cross-sectional area in a small child. Subglottic edema is particularly more common in children as the nonexpandable cricoid cartilage is the narrowest part of the pediatric airway. Edema may also be uvular, supraglottic, retroarytenoid, or at the level of the vocal cords. The precise diagnosis may be made with fiberoptic laryngoscopy, but this is not usually necessary. Stridor is produced by the extrathoracic obstruction that produces mainly inspiratory wheezing. Diminished stridor may represent total airway obstruction, and movement of air must be repeatedly confirmed. The contributing factors to the production of laryngeal edema are somewhat controversial but include too large a tube, trauma from laryngoscopy and/or intubation, excessive neck manipulation during intubation and surgery, excessive coughing or bucking on the tube, and present or recent upper respiratory infection. The prophylactic use of steroids before extubation to reduce edema is an unproven but frequently utilized treatment if the likelihood of postextubation stridor is suspected. Treatment includes warmed, humidified oxygen, nebulized racemic epinephrine (.25-1mL), and IV dexa-methasone (.5 mg/kg up to 10 mg). If obstruction is severe and persistent, reintubation must be considered.

Vocal cord paralysis may be due to surgical injury of the recurrent laryngeal nerve or from the endotracheal tube cuff. [164] Vocal cord edema occurring in the presence of a paralyzed cord may precipitate complete airway obstruction as can bilateral cord paralysis. It may be prudent to pursue preoperative otolaryngologic evaluation of the hoarse patient for elective surgery so that important pathology is detected and so that subsequent vocal problems are not entirely attributed to the anesthesiologist. The arytenoid cartilage may be dislocated by the laryngoscope blade and result in a weak voice after extubation that may require surgical correction. [165] [166] Other complications include ulcerations or granulomas of the vocal cords that may result in persistent hoarseness. [167] More serious complications resulting in laryngeal or tracheal stenosis are extremely rare sequelae of short-term perioperative intubation. [168]

/das/book/view/29494766/875/459.html

THE ANESTHESIOLOGIST AS AIRWAY MANAGEMENT CONSULTANT

In addition to the usual role in providing airway management during the administration of an anesthetic, the anesthesiologist may be consulted as an expert in airway management in settings outside the operating room. These consultations may involve the provision of an acute airway or the management of problems that have arisen in the patient requiring ongoing endotracheal intubation. Considerations in the acute setting include a variety of clinical situations such as trauma, upper airway obstruction, and medical conditions that must be specifically addressed to provide optimal care. [169] These intubations are particularly high-risk because the patients are often hemodynamically unstable. [170] In the patient requiring long-term endotracheal intubation, the issues of site of intubation, leak-free ventilation, tube changes, laryngeal injury, and tracheostomy (among others) may be encountered. [171] Anesthesiologists may also be directly involved in performing percutaneous dilational tracheostomy or anesthetic/airway support for the procedure in the ICU. [172] Both acute and chromic settings require a solid background in airway management principles as well as the ability to deal with unusual and unpredictable problems in a relatively foreign environment. Two recent reviews address these areas in detail. [173] [174]

General Recommendations

1. Preoxygenate all patients (including children) to whatever extent possible. This provides a buffer to tolerate an inability to ventilate or intubate for several additional minutes.
2. Evaluate every airway carefully from the standpoint of history, physical examination, and other indicated investigations. Keep in mind that several small abnormalities may add up to a difficult airway.
3. Approach every patient with the possibility that mask ventilation and/or endotracheal intubation may not be possible. Have a back-up plan formulated before the problem occurs. A transtracheal jet ventilation system cannot be assembled from scratch when the oxygen saturation is falling. Make sure that whatever might be needed is available.
4. Whenever possible, provide mask ventilation before administering any muscle relaxant, especially nondepolarizers. Unless succinylcholine is contraindicated, consider its use when the airway looks potentially difficult and anesthetized intubation is selected. The short-action (as opposed to any currently available nondepolarizing relaxant) of succinylcholine can be life-saving and brain-saving in the "can't mask/can't intubate" situation. However, the duration of a dose of succinylcholine may be longer than the duration of a brain tissue oxygen level compatible with full recovery. [175]
5. Gain confidence and skill with a variety of approaches to conscious intubation so that it can be applied properly when needed. Don't let less cognizant individuals (surgeons, nurses, etc.) unduly influence your decision to employ conscious intubation. The airway is your responsibility, and you, the patient, and the patients' loved ones suffer the consequences of misjudgments.

Chapter 40 - Monitored Anesthesia Care

Monica M. Sa Rego
Paul F. White

INTRODUCTION

Monitored anesthesia care (MAC) has become increasingly important in the practice of anesthesiology. The primary objective in providing MAC is to ensure patient comfort, safety, and satisfaction during surgery. In most instances, the patient is undergoing a procedure under local anesthesia in the operating room (OR). The technologic advances in fiberoptics and lasers have enabled many diagnostic and therapeutic procedures to be performed by use of minimally invasive ("keyhole") techniques. Many of these procedures are being performed outside the operating suite and in the office-based setting. Because anesthesiologists have the greatest expertise in sedation-analgesia, they are often consulted for sedation and monitoring of these patients.

In this chapter, the objectives and techniques used for providing MAC are discussed, along with guidelines and recommendations for intraoperative monitoring. The relevant pharmacology of the commonly used adjuvant drugs, such as sedative-hypnotics, anxiolytics, and analgesics, are also reviewed. [1]

DEFINITION OF MAC

The American Society of Anesthesiologists (ASA) [2] defines MAC as instances in which an anesthesiologist has been called on to provide specific anesthesia services to a particular patient undergoing a planned procedure, in connection with which a patient receives local anesthesia or, in some cases, no anesthesia at all. In such a case, the anesthesiologist is providing specific services to the patient, is in control of his or her vital signs, and is available to administer anesthetics or provide other medical care as appropriate.

The policy of the ASA states that the same standard of care should be provided by an anesthesia practitioner during MAC as for general or regional anesthesia. [3] The provisions of MAC shall include the following:

1. Performance of a preanesthetic examination and evaluation
2. Prescription of the anesthesia care required
3. Personal participation in, or medical direction of, the entire plan of care
4. Continuous physical presence of the anesthesiologist or, in the case of medical direction, of the resident or nurse anesthetist being medically directed
5. Proximate presence or (in the case of medical direction) availability of the anesthesiologist for diagnosis or treatment of emergencies

In addition, all institutional regulations pertaining to anesthesia services shall be observed, and all the usual services performed by the anesthesiologist shall be furnished, including but not limited to the following:

1. Usual noninvasive cardiocirculatory and respiratory monitoring
2. Oxygen administration, when indicated
3. Intravenous administration of sedatives, tranquilizers, antiemetics, narcotics, other analgesics, beta-adrenergic blockers, vasopressors, bronchodilators, antihypertensives, or other pharmacologic therapy as may be required in the judgment of the anesthesiologist

ROLE OF MAC IN THE PRACTICE OF ANESTHESIA

The incidence of MAC as the anesthetic technique of choice varies among institutions. It has been estimated that 6 to 12 percent of all inpatient procedures and 30 to 60 percent of outpatient procedures are performed under MAC. With the technology of minimal invasive surgery and the development of rapid and short-acting sedative and analgesic drugs, the number and the variety of procedures being performed in the outpatient setting continue to increase, and MAC techniques are likely to become even more widely used in the future. [1]

Procedures performed with the patient under local anesthesia with sedation usually have a shorter recovery time than similar procedures performed with the patient under general or regional anesthesia. [4] A decreased use of drugs and disposable anesthetic supplies has also been reported in women undergoing laparoscopic tubal sterilization with a midazolam-alfentanil MAC technique compared with a propofol-alfentanil-atracurium general anesthetic technique ($21 versus $46). The MAC technique was associated with less time in the OR (30±4 versus 34±1 min), a higher "awakeness" score on the evening of the day of surgery (4.3±1.4 versus 3.6±1.4), as well as decreased postoperative pain (33% versus 80%) and sore throats (3% versus 70%), contributing to a significant reduction in perioperative costs. [5] Peterson et al [6] confirmed these findings and added that the incidence of emesis was also lower after MAC. Finally, Patel et al [7] reported that the use of intravenous sedation resulted in a 6- to 7-minute decrease in the OR exit time over that when general anesthesia was used, contributing to a significant cost saving as a result of enhanced turnover of the cases. This is an important consideration in today's practice environment with the emphasis on "fast-tracking" processes.

A wide variety of procedures can be performed under MAC (Table 40-1) . Local infiltration and peripheral nerve block techniques account for at least 40 to 50 percent of the nongeneral anesthetics administered in the United States. The use of local and regional (peripheral block) anesthetic techniques may avoid the common side effects of general anesthesia, minimize the risk of aspiration pneumonitis, decrease the postanesthesia nursing care, and provide residual analgesia in the early postoperative period. Simple surgical procedures can be performed with local wound infiltration, whereas more extensive operation may be undertaken by use of field blocks and intravenous regional anesthetic techniques (Table 40-2) (Table Not Available) . For upper and lower extremity procedures, peripheral nerve block techniques (e.g., axillary, su-praclavicular, interscalene, and ankle blocks) are also useful. However, many patients are reluctant to undergo local or regional anesthesia without supplemental medication because of the discomfort of the local injection and concerns about incisional pain and awareness during surgery (Chs. 43 and 44) . [4] [8] Anxiety regarding these issues can be eliminated by a careful explanation of the anesthesia treatment plan during the preoperative assessment. The patient should be reassured that needed adjuvant therapy is available to control pain and provide sedation, amnesia, and anxiolysis. [9]

The primary goal of MAC is to provide for patient comfort and safety. This objective can be achieved by careful monitoring of vital signs and by provision of anxiolysis, analgesia,

amnesia, and sedation without compromising cardiorespiratory function or delaying recovery. [10]

Drug administration may be preoperative, intraoperative, or postoperative, with anesthetic and analgesic drugs from two or more drug groups often being combined. [11] [12] [13] A wide variety of routes of administration (e.g., oral, nasal, trans-mucosal, parenteral, and rectal) as well as techniques (e.g., intermittent bolus, continuous infusion, and patient-controlled

TABLE 40-2 -- Common Techniques for Administering Local Anesthetics During MAC

(Not Available)

Modified from White [16]

analgesia) have also been used in patients receiving MAC. [14] [15] [16] [17]

There is an ever-present risk of synergistic interactions between sedative and analgesic drugs with respect to respiratory and cardiovascular depression. The respiratory depressant effects can be minimized when sedative drugs are administered by carefully titrated infusions versus large intermittent bolus doses. [11] Unwanted cardiovascular problems (e.g., hypotension, hypertension, drug-induced arrhythmias) can also be prevented by use of careful drug administration techniques. Thus, diligent monitoring is needed in order to assess the efficacy of adjunctive drugs during MAC and to minimize their potentially deleterious side effects.

The single greatest danger associated with MAC is a lack of vigilance because so-called minor surgical procedures are often being performed. Guidelines and recommendations for monitoring sedated patients have been published by the American Society of Anesthesia, the American Academy of Pediatrics, and the American Dental Society of Anesthesiology, as discussed later in the chapter.

USE OF SEDATIVE-ANALGESIC DRUGS DURING MAC

Sedation during local anesthesia is often desirable to diminish anxiety and fear associated with the OR activity and surgical preparation. Studies have shown that patients prefer surgery under local anesthesia with sedation to local anesthesia alone. [18] [19] To help relieve the discomfort associated with the painful injection of the local anesthetic solution, small doses of analgesics (e.g., fentanyl, 25-50 mug/70 kg intravenously [IV] or remifentanil, 12.5-25 mug/70 kg IV) can be administered.

Sedation can be useful for diagnostic tests that require immobilization for a significant period of time or for lengthy examinations in the closed confines of a magnetic resonance imaging (MRI) or computed tomographic scanner (Ch. 66) . This is especially useful both in children (Ch. 59) and in adults with claustrophobia, who have great difficulty cooperating with these procedures.

A wide variety of centrally active drugs are used to provide for sedation, anxiolysis, and analgesia (Table 40-3) . Administration should be individualized to the patient's level of discomfort, as well as to the patient's drug and medical history. Potent, rapid-acting sedative-hypnotics with steep dose-response curves (e.g., midazolam, propofol) should be carefully titrated by use of small bolus doses or a continuous variable-rate infusion. Although intermittent boluses of drugs can result in transient respiratory depression, use of continuous intravenous infusions can minimize cardiorespiratory depression. [20] [21] A stable level of intraoperative sedation can also be achieved by use of a continuous infusion.

The usual end point for titration of sedative-anxiolytic drugs is the patient's verbal acknowledgment of comfort and relaxation, which is usually confirmed by vital signs. The patient should remain cooperative and comfortable with airway reflexes intact. Because the need for sedative and analgesic drugs is highly subjective, patient-controlled sedation and analgesic techniques may offer advantages over physician-controlled drug administration. Studies have shown high patient satisfaction with these techniques. [14] [15] [16] Propofol,

TABLE 40-3 -- Recommended Doses of Commonly Used Sedative and Analgesic Drugs During MAC[a] [b]

DRUG	BOLUS DOSAGE	INFUSION RATE
Sedative-anxiolytics		
Diazepam	5-10 mg	
Midazolam	2.5-7.5 mg (alone)	1-2 mug/kg/min
	1-2 mg (with propofol)	
Propofol	25-100 mg	25-75 mug/kg/min
Thiopental	50-150 mg	
Methohexital	10-20 mg	20-60 mug/kg/min
Sedative-analgesics		
Ketamine	20-40 mg	5-15 mug/kg/min
Analgesics		
Alfentanil	0.25-0.75 mg	0.5-1 mug/kg/min
Fentanyl	25-50 mug	
Nalbuphine	5-15 mg	
Remifentanil	12.5-25 mug	0.025-0.15 mug/kg/min
Ketorolac	15-30 mg	
Benzodiazepine antagonist		
Flumazenil	0.5-1.0 mg	
Opioid antagonists		
Naloxone	0.1-0.4 mg	
Nalmefene	0.1 mg	
Nitrous oxide (inhaled concentration)	30-50%	

From Sa Rego et al [1]

[a] In the elderly population, lower doses of the sedative-analgesic drugs should be administered until their sensitivity has been determined (e.g., midazolam, 0.5-1.0 mg IV).
[b] Chs. 8 - 10

midazolam, and alfentanil have all been successfully administered by use of a patient-controlled device.

The ideal drug for sedation should have a rapid onset of action with a predictable dose-effect relationship with respect to its sedative-hypnotic actions. Excitatory effects should be minimal, as should its respiratory and cardiovascular depressant effects. Anxiolysis and amnesia should be predictable, with rapid recovery following discontinuation of its administration. Parenterally administered drugs are most popular in adults, whereas in children, enteral routes are more readily accepted.

The benzodiazepines remain the most widely used drugs for anxiolysis, amnesia, and sedation. Diazepam produces dose-dependent anxiolysis, sedation, and amnesia (Fig. 40-1) (Figure Not Available) [8] [22] However, large doses of diazepam (0.3 mg/kg IV) impair driving skills for at least 10 hours and may prolong recovery to a greater extent than in patients undergoing general anesthesia, a characteristic that makes it less desirable to outpatients. [23] [24] The original formulation of diazepam (Valium) contains propylene glycol, and its parenteral administration is associated with a higher incidence of pain on injection, as well as venoirritation and

phlebitis. [25] However, the newer lipid-based formulation of diazepam (Dizac) is associated with a lower incidence of venoirritation. [26]

Midazolam is more widely used because it is associated with less pain on injection and venous irritation. [8] Midazolam provides more profound perioperative amnesia, anxiolysis, and sedation than diazepam. [8] [27] [28] Although full recovery from the central nervous system (CNS) effects of midazolam is generally considered to be more rapid than recovery from the effects of diazepam, large doses of midazolam (0.2 mg/kg) can result in prolonged postoperative sedation. [29] Although midazolam provided more effective intraoperative sedation and amnesia than methohexital or propofol, it was associated with a slower recovery of psychomotor function. [4] [30] The time required to achieve a peak CNS effect with midazolam (2-4 minutes) may lead to cumulative effects (oversedation) when repeated bolus doses are administered over a short time interval. When midazolam is administered

Figure 40-1 (Figure Not Available) Dose-response curves for the level of sedation as a function of midazolam or diazepam dose. A score of 2 indicates minimal sedation; a score of 6 equals unconscious (hypnotic) state. Steeper dose-response curve for midazolam is illustrated. *(From White et al [8])*

as an infusion (loading dose of 0.025-0.05 mg/kg followed by a maintenance infusion of 1-2 mug/kg/min), it provides a titratable level of sedation during local anesthesia. [4]

White et al [8] noted a similar spectrum of CNS activity with midazolam (0.05-0.15 mg/kg IV) and diazepam (0.1-0.3 mg/ kg IV). However, the slope of the dose-response curve for sedation was much steeper with midazolam than with diazepam (see Fig. 40-1 (Figure Not Available)), suggesting that midazolam possesses a smaller margin of safety and necessitates more careful titration to achieve the desired clinical end point without untoward side effects. [8] Although clinical recovery characteristics were similar for diazepam and midazolam when they are used as adjuvants to ketamine, the incidence of amnesia and overall patient acceptance was significantly higher with midazolam. [8] Magni et al [31] also found a higher patient preference for midazolam (versus diazepam) during upper gastrointestinal endoscopy.

Midazolam has been administered orally (0.5-0.75 mg/ kg) to children. It produces reliable anxiolysis and sedation before surgery, without prolonging recovery time. [32] [33] In comparative studies, parents of children undergoing bone marrow biopsy procedures preferred midazolam to fentanyl for sedation. [34] Some studies have suggested that the combination of oral midazolam, 0.5 mg/kg, and low concentrations of inhaled nitrous oxide (N_2O) for sedation-analgesia is associated with only mild ventilatory depression in children; however, progression from conscious to deep sedation occurs with N_2O concentrations exceeding 30 percent. [35] In adults, oral temazepam (20-40 mg) is an effective alternative to parenteral benzodiazepines for sedation during endoscopy or oral surgery. [36] [37] Rapid reversal of residual benzodiazepine sedation and amnesia is possible with flumazenil, a specific benzodiazepine antagonist. [38] [39] [40]

Clinical studies involving outpatients undergoing dental surgery, endoscopic procedures, and minor ambulatory surgery have reported that flumazenil facilitates early recovery without producing adverse side effects when given in small incremental doses of 0.2 mg IV. [20] [41] [42] Ghouri et al [43] noted that the administration of flumazenil, 1 mg IV, at the end of surgery decreased the time to ambulation and discharge in patients who received large doses of midazolam (10.9±4.2 mg IV) during local anesthesia. The similar intraoperative conditions and early recovery profiles suggest that the use of a midazolam-flumazenil combination or a propofol infusion is equally acceptable during MAC. [43] Cost-effectiveness analyses would suggest that flumazenil should be used only to treat persistent excessive sedation after the MAC procedure. [44] Although there are only a few reported cases of clinically significant resedation after conscious sedation with midazolam followed by flumazenil, a subsequent increase in the level of sedation after discharge is common. [45]

Propofol has a pharmacodynamic-kinetic profile that is ideally suited to administration by continuous infusion. It has a rapid onset of action, a short duration of effect, and minimal side effects (Ch. 9) . Low-dose propofol infusions (25-75 mug/kg/min) have been used as adjuvants to local infiltration anesthesia in patients undergoing central venous catheter placement, [46] oral surgery, [47] and superficial surgical procedures (e.g., breast biopsy and herniorrhaphy). [4] [48] In comparing propofol and midazolam infusions for sedation during procedures performed with the patient under local

anesthesia, loading doses of 69±23 mg and 4.2±1.4 mg, followed by maintenance infusion rates of 61.7±16.7 mug/kg/ min and 2.0±1.1 mug/kg/min, respectively, were used. [4] Use of propofol was associated with a more rapid recovery of cognitive function and less postoperative sedation, drowsiness, confusion, clumsiness, and amnesia than midazolam (Fig. 40-2) (Figure Not Available) .

Both early and intermediate recovery have been found to be superior after a propofol infusion compared with repeated doses or infusion of midazolam [4] [46] and diazepam, [47] even when the benzodiazepine antagonist flumazenil was administered. [43] Compared to midazolam and methohexital, propofol was associated with the least frequent incidence of awareness during injection of the local anesthetic for retro-bulbar and peribulbar blocks and also resulted in more satisfactory sedation during the remainder of the procedure. [49] Several studies suggest that subhypnotic doses of propofol possess specific antiemetic properties, an important benefit in the outpatient setting. [50] [51] [52] Because subhypnotic doses of propofol are associated with minimal intraoperative amnesia, a small dose of midazolam (2 mg IV) is beneficial in enhancing propofol-induced sedation, amnesia, and anxiolysis without delaying recovery. [13] [53] [54]

In a volunteer study comparing midazolam (0.05 mg/kg) or fentanyl (2.0 mug/kg) to a midazolam-fentanyl combination, the incidence of hypoxemia and apnea was significantly increased when the two drugs were combined. [55] Careful

Figure 40-2 (Figure Not Available) Comparison of preoperative (baseline) and postoperative sedation, anxiety, and digit-symbol substitution test (DSST) scores in patients receiving midazolam (open circles) or propofol (solid circles) during local or regional anesthesia. *(From White and Negus [4])*

titration of these drugs and use of supplemental oxygen (e.g., nasal prongs) can diminish these undesirable respiratory depressant effects. The combination of propofol and alfentanil (50 mL of propofol [10 mg/mL] with 4 mL of alfentanil [0.5 mg/mL] can be administered by continuous infusion at 1-2 mL/kg/h) has been used successfully for sedation and analgesia during MAC. [12]

The objective of the use of opioid and nonopioid analgesics during MAC is to decrease the pain associated with the injection of local anesthetics, as well as the discomfort related to nonincisional factors (e.g., back pain secondary to lying on a hard OR table or pressure and traction on deep tissues that are not rendered insensitive by the local anesthetic solutions). [56] Fentanyl, the most commonly used opioid during MAC, has an onset time of 3 to 5 minutes and a duration of effect of 45 to 60 minutes when administered in doses of 50 to 100 mug IV. However, even small doses of fentanyl (25-50 mug) can cause respiratory depression when combined with large doses of sedative drugs. [57] Fentanyl, 1 mug/kg IV, has been used to sedate children undergoing repair of minor lacerations. [58] [59] Fentanyl is also available in a sucrose base for oral transmucosal administration (Oralet). Although this opioid preparation is readily accepted by children and is effective for procedure-related pain, its use is associated with typical opioid-related side effects, including emesis, pruritus, and respiratory depression. [17] [60]

Alfentanil may be given by intermittent boluses during the injection of local anesthetics or by continuous infusion to provide a stable level of analgesia. [61] White et al [62] reported fewer perioperative side effects when alfentanil was administered as a continuous titrated infusion compared with intermittent bolus injections. An equianalgesic dose of alfentanil is associated with a shorter duration of respiratory depression than fentanyl [62] and similar or shorter recovery times in the outpatient setting. [63] [64] The use of alfentanil and midazolam has been reported to provide highly satisfactory conditions for immersion extracorporeal shock-wave lithotripsy (ESWL). [53] Avramov et al [65] described the combined use of alfentanil (0.3-0.4 mug/kg/min) and propofol (25, 50, or 75 mug/kg/min) infusions for MAC. Concomitant use of propofol significantly reduced the opioid dose requirement (30-50%) and the incidence of postoperative nausea and vomiting (0-17% versus 33%) when compared with alfentanil infusion alone.

Remifentanil (Ch. 10) is unique among the opioid analgesics because of its extremely short context-sensitive half-time (3-5 minutes). [66] [67] [68] An infusion of remifentanil, 0.05 to 0.15 mug/kg/min, can provide adequate sedation and analgesia during minor surgical procedures performed with the patient under local anesthesia in combination with midazolam, 2 to 4 mg. [69] Sa Rego et al [70] compared the use of intermittent remifentanil boluses (25 mug) versus a continuous variable-rate infusion (0.025-0.15 mug/kg/min) when administered to patients undergoing ESWL under a MAC technique involving midazolam (2 mg) and propofol (25-50 mug/kg/min). Patients' comfort was higher during the procedure when remifentanil was administered by a variable-rate infusion. However, these patients also experienced a higher incidence of desaturation (30% versus 0%) compared with those receiving intermittent boluses of remifentanil. In comparison of remifentanil and propofol administered by continuous infusion after premedication with midazolam, there was a decreased

level of sedation and a greater degree of respiratory depression with remifentanil (versus propofol) administration. [71] Therefore, remifentanil infusions must be carefully titrated to avoid excessive respiratory depression. [1] [70] The use of remifentanil in combination with local anesthetics obviates the disadvantages of the minimal residual analgesia when remifentanil is used during painful procedures.

Ketorolac, a potent, parenterally active nonsteroidal anti-inflammatory drug, has been used both as a sole supplement and as an adjunct to propofol sedation during local anesthesia. Use of ketorolac is associated with a lower incidence of pruritus, nausea, and vomiting than fentanyl. [48] [56] [72] However, when used with propofol sedation, ketorolac-treated patients required higher intraoperative doses of propofol and more supplemental opioid analgesia compared with the fentanyl-treated patients. [56] The cost-effectiveness of ketorolac use during MAC techniques needs to be further investigated. [73]

Ketamine (0.25-0.5 mg/kg IV) (Ch. 9) produces sedation and analgesia without respiratory depression in adults. In patients undergoing intercostal nerve block procedures, ketamine produced more optimal clinical conditions and higher patient acceptance than diazepam or a droperidol-fentanyl combination. [74] Low-dose ketamine (0.25-0.75 mg/kg) combined with either diazepam or midazolam has also been administered before injection of local anesthetics in outpatients undergoing cosmetic surgical procedures. [75] Furthermore, the use of a diazepam-ketamine combination was not associated with any more side effects or a greater need for postoperative care than an unpremedicated control group undergoing similar nerve block procedures. [75] Benzodiazepines appear to be the most effective drugs in attenuating the psychomimetic actions of ketamine. However, large doses of benzodiazepines may be required (e.g., midazolam 5-15 mg) and can result in prolonged recovery times after ambulatory procedures. In pediatric patients, Green et al [76] demonstrated acceptable sedation with ketamine doses of 4 mg/kg IM. Ketamine-induced dysphoria was not encountered in these studies.

Methohexital has also been used successfully either by intermittent boluses (10-20 mg) or as a variable-rate infusion (0.1-0.2% solution). [30] [77] Although residual sedation appears to be greater with methohexital than with propofol, one study found no statistical difference in the recovery times when comparing infusions of methohexital (40 mug/kg/min) and propofol (50 mug/kg/min) during a MAC technique. However, there was also a higher incidence of pain on injection in the propofol infusion group. [78] [79] [80] Therefore, methohexital may be a safe and cost-effective alternative to propofol for sedation during MAC.

Subanesthetic concentrations of inhaled anesthetics (N_2O, 30-50% in oxygen or one-third of the minimum alveolar concentration of an inhaled anesthetic) can also be used to supplement regional or local anesthesia. [10] However, caution should be used to avoid excessive sedation or an inadvertent unconscious state.

alpha$_2$ -Agonists reduce central sympathetic outflow and have been shown to produce anxiolysis and sedation. [81] Kumar et al [81] demonstrated that oral clonidine (300 mug) provided effective anxiolysis for elderly patients undergoing ophthalmic surgery under local anesthesia and also decreased the incidence of intraoperative hypertension and tachycardia.

TABLE 40-4 -- Classification of Sedative and Analgesic Drugs Used During MAC (Pediatric Dosages)

DRUG	USUAL PEDIATRIC DOSAGES
Opioid analgesics	
Fentanyl	2-5 mug/kg IV
Morphine sulfate	0.05-0.1 mg/kg IV
Sedative-anxiolytics	
Diazepam	0.05-0.2 mg/kg IV
	0.2-0.5 mg/kg PO
Midazolam	0.035-0.1 mg/kg IV/IM
	0.3-0.7 mg/kg PO
Choral hydrate	25-100 mg/kg PO or PR
Pentobarbital	1-7 mg/kg IV/IM
Sedative-analgesics	
Demerol-phenergan-thorazine	2-1-1 mg/kg IM
Ketamine	4 mg/kg IM
	0.2-1 mg/kg IV

Data from Cook et al [85] and Sa Rego et al [1]

Dexmedetomidine, a more selective and potent alpha$_2$ -agonist, significantly decreased anxiety levels and reduced the requirements for supplemental analgesic medications when given before IV regional anesthesia for hand surgery. [82] When comparing dexmedetomidine with midazolam for sedation, Aho et al [83] described a faster recovery from sedation when dexmedetomidine was followed by reversal with the specific alpha$_2$ -antagonist atipamezole. However, the administration of dexmedetomidine has been associated with bradycardia, which may limit its usefulness during MAC. [82] [84]

For pediatric-aged patients, the dosages of sedative and analgesic drugs are higher on a per kilogram basis (Ch. 59) (Table 40-4) . Although midazolam and propofol have been used to sedate children, three other regimens are commonly used for procedures outside the OR. Chloral hydrate is one of the oldest and safest hypnotic drugs used for sedating children. In a survey conducted by Cook et al, [85] chloral hydrate was found to be the most popular sedative drug for painless diagnostic procedures. Chloral hydrate in doses of 25 to 100 mg/kg (oral and/or rectal administration) was shown to be both safe and effective (Ch. 59) . The second most common pediatric drug regimen is the so-called DPT injection, a combination of parenteral Demerol (meperidine), Phenergan (promethazine), and Thorazine (chlor-promazine) (maximum dose of 2-1-1 mg/kg). Although deaths have been reported following use of DPT, these were in children with congenital heart disease undergoing cardiac catheterization. [85] The third most commonly used sedative drug for pediatric sedation was pentobarbital (5-7 mg/kg).

DEFINING LEVELS OF SEDATION DURING MAC

The American Dental Society of Anesthesiology has defined sedation as follows [86]:

1. Conscious sedation: a minimally depressed level of consciousness that retains the patient's ability to maintain the airway independently and continuously and to respond

appropriately to physical stimulation and verbal command; produced by pharmacologic and nonpharmacologic methods, alone or in combination
2. Deep sedation: a controlled state of depressed consciousness, accompanied by partial loss of protective reflexes, including inability to respond purposefully to verbal command; produced by pharmacologic or nonpharmacologic methods, alone or in combination
3. General anesthesia: a controlled state of unconsciousness accompanied by partial or complete loss of protective reflexes, including inability to maintain an airway independently and to respond purposefully to physical stimulation or verbal command

Conscious sedation lies on a dose-dependent continuum leading from minimal sedation to general anesthesia. Table 40-5 (Table Not Available) illustrates the clinically significant differences between conscious and deep sedation.

The objectives of conscious sedation as outlined by Scamman et al [87] follow:

1. To relieve anxiety and produce amnesia. These goals are accomplished by means of good preoperative communication and instruction, low levels of visual and auditory stimuli in the OR, and maintenance of patient warmth and covering.
2. To provide relief from pain and other noxious stimuli. Opioid analgesics are given in order to supplement local or topical anesthetics and to block pain sensations remote from the operative site.
3. To achieve adequate sedation with minimal risk. Sedative medication should not interfere with the patient's ability to communicate verbally, and the usual monitoring devices and emergency systems must be available.

The marked variation in individual patient responses to a given dose of anesthetic drug has led the ASA to avoid the use of the term "conscious sedation" in their "Practice Guidelines for Sedation and Analgesia by Non-Anesthesiologists." [88] The ASA prefers the term "sedation-analgesia" and has recommended that all patients receiving this technique be monitored by a designated individual who is primarily

TABLE 40-5 -- Differences Between Conscious Sedation Versus Deep Sedation Techniques

(Not Available)

Modified from Kalkar and Dunwiddie [161]

responsible for administering sedative and analgesic drugs and monitoring the patient's vital signs.

COMPLICATIONS

Serious complications associated with local sedation techniques for dental surgery were initially reported in a British study. [89] Although the overall mortality rate was only 1 in 152,000, one-third of the deaths occurred in association with local sedation anesthesia. The majority of the sedation deaths occurred at the hands of operator-administered anesthetics (e.g., oral surgeons), and the most common precipitating causes included respiratory obstruction, hypoxia, and cardiovascular collapse secondary to arrhythmias. [90] Muir et al [91] found only minor differences in postoperative morbidity when comparing local and general anesthesia for young outpatients undergoing oral surgery.

A survey by the Federated Ambulatory Surgery Association (FASA) found higher overall complication rates after ambulatory surgery with combined local anesthesia and IV sedation (1:106) compared with general (1:120), regional (1:277), or local anesthesia alone (1:268). [92] The length of the operative procedure was another important determinant of morbidity after ambulatory surgery. For procedures lasting less than 1 hour, the incidence of perioperative complications was 1 in 155, and this ratio increased to 1:35 for procedures lasting longer than 3 hours. In this survey, outpatients with preexisting cardiovascular diseases were also reported to be at increased risk for postoperative complications. However, an epidemiologic study at the Mayo Clinic by Warner et al [93] revealed that the overall risk of major morbidity and mortality for outpatients undergoing ambulatory surgery did not differ from that of a similar age-matched population not undergoing an ambulatory surgical procedure.

The risk of adverse drug reactions increases when combinations of sedative and analgesic drugs are administered during local anesthesia. The potential for compromising the respiratory system results from depression of esophageal and laryngeal reflexes, upper airway obstruction, and depression of central hypercarbic and hypoxic ventilatory responses. [55] [94] [95] [96] Interestingly, when sedative drugs are administered by carefully titrated infusions (versus intermittent bolus doses), the respiratory depressant effects can be minimized. [38] However, with the rapid, short-acting opioid analgesic remifentanil, Sa Rego et al [70] reported that the infusion group received a higher total dose of remifentanil than the bolus group, contributing to greater depression of central ventilatory drive. Mora et al [20] found that five of 10 patients given an average diazepam dose of 0.97±0.34 mg/ min developed depressed hypoxic responsiveness and that only one of the five patients had complete reversal of ventilatory depression after flumazenil (1 mg IV) administration. Bailey et al [55] reported no significant respiratory depressant effect after midazolam administration (0.05 mg/kg IV). However, fentanyl (2 mug/kg IV) produced transient hypoxemia in 50 percent of the subjects and significantly depressed the ventilatory response to carbon dioxide. Furthermore, a combination of the same dosages of midazolam and fentanyl increased the incidence of both hypoxemia (92%) and apnea (50%). [55] In another clinical investigation, the incidence

of hypoxemia with a propofol-fentanyl combination was found to be significantly lower than that with midazolam and alfentanil. [53]

Because more than 40 percent of patients breathing room air during local anesthesia with sedation-analgesia for oral surgery experienced clinically significant oxygen desaturation, supplemental oxygen is always recommended when IV adjuvants are utilized during local anesthesia and can be delivered through a nasal cannula with an end-tidal carbon dioxide port to assess ventilatory rate. [97] However, the risk of hypoventilation (hypercarbia) exists despite the administration of supplemental oxygen. Pierce [98] reported that most anesthesia accidents resulting in severe brain damage (or death) were preventable by proper use of available monitoring techniques. [1]

MONITORING

Concerns regarding the safety of sedation practices were raised by reports of increased mortality and morbidity in dental offices and reports of misadventures during sedation for diagnostic procedures (e.g., gastrointestinal endoscopy) by nonanesthesiologists (Chs. 28 - 37) . In response to these reports, the American Academy of Pediatrics developed guidelines for monitoring and managing pediatric patients during and after sedation. [99] In these guidelines, an emphasis was placed on accident prevention and human factor issues to prevent situations in which no one was specifically assigned to monitor the patient and in which attention was directed more to performing the procedure than to observing patient response to the sedative-analgesic drugs. [100] [101] The American Academy of Pediatrics guidelines for deep sedation require that an additional health care provider who is not assisting in the performance of the procedure be available to administer drugs and monitor the child. Maxwell and Yaster [102] claimed that some practitioners attempt to circumvent this requirement by referring to all sedation techniques as "conscious sedation." In 1996, the ASA published its guidelines for sedation-analgesia by nonanesthesiologists. [88] These guidelines state that the individual administering the sedative-analgesic medications should have previous experience with the drugs they are using and should be familiar with the patient's medical history.

The ASA Standards for Basic Intraoperative Monitoring have been adopted as the national standard (see Appendix I). [3] The ASA has specified that the standards for basic monitoring during MAC by anesthesiologists are the same as those for general anesthesia. These recommendations stress quantitative rather than qualitative measurements. Standard I makes provisions for "qualified anesthesia personnel" to be present in the room. Standard II addresses objective measurements of patient oxygenation, ventilation, circulation, and body temperature. Although monitoring standards and guidelines may help detect human errors or mishaps, there is no substitute for vigilance and meticulous attention to detail. The Joint Commission on Accreditation of Health Care Organizations has insisted that the same standards of care that apply for general and regional anesthesia be provided during sedation techniques in all areas of an institution. [103] Because anesthesiologists have the most expertise in sedation-analgesia techniques, anesthesia departments are increasingly required to approve institutional policies and procedures for sedation-analgesia.

Specific Monitoring Requirements

The choice of monitoring devices, particularly when the emphasis is on patient safety, requires concomitant attention to quality control, safety procedures, risk recognition, decision-making, and other efforts to reduce human error (Chs. 28 , 29 , 33 - 37) . [104] The essential characteristics of monitoring techniques for outpatient MAC are that they not only be effective but also simple to apply, noninvasive, and economical. [105] The pulse oximeter has become an invaluable monitor because it fulfills all of these criteria. The monitoring guidelines of the American Academy of Pediatrics and the ASA regarding the routine use of pulse oximetry to assess oxygenation during sedation are based on studies establishing the superiority of pulse oximetry over visual inspection of mucous membranes and nail beds in detecting oxygen desaturation. [106] The initial opposition to the routine use of these devices outside the OR has disappeared as nonanesthesiologists have become more familiar with their clinical use. However, desaturation following sedation is a late event, and the inadequacy of ventilation should be detected and corrective measures instituted as the oxygen saturation value decreases below 90 percent. Unfortunately, impedance plethysmography may fail to detect airway obstruction, and the measurement of exhaled carbon dioxide can be difficult in nonintubated patients.

A simple, inexpensive, disposable oxygen delivery system involving the use of nasal prongs and an intranasal cannula connected to a capnograph can provide the anesthesiologist with a useful monitor of the expired carbon dioxide concentrations (Fig. 40-3) . [107] [108] [109] [110] Oxygen administration nasal cannulas with a sample port specifically for the carbon dioxide monitor line are commercially available (Salter Labs One-No. 4706F, patent 5,335,656, Salter Labs, Arvin, CA). A stable, discernible capnogram tracing is achievable in most patients having transcannula carbon dioxide sampling (Fig. 40-4) with an acceptable correlation between end-expiratory and arterial carbon dioxide tension readings. [111] [112] Problems with these devices include displacement and false sampling, false alarms (secondary to mouth breathing), and delays in alarm responses. Although useful in assessing respiratory rate (or airway obstruction), the capnographic tracing should not be relied on for accurate measurement of end-tidal carbon dioxide values.

Thus, the vigilance of the observer responsible for monitoring the patient receiving sedation-analgesia remains the best protection against adverse respiratory events. As with other types of anesthesia, the optimal level of patient care during MAC is achieved by meticulous attention to detail. [113]

Many monitoring devices are merely mechanical extensions of these senses and may create a barrier between the patient and the anesthesiologist. Vandam [114] pointed out that monitoring is an extension of the physical examination and that by keeping in close contact with the patient (e.g., feeling the pulse, observing respiration, watching the operative field, and using other senses to detect unusual events), anesthesiologists can improve the quality of monitoring during all types of MAC techniques.

Figure 40-3 Oxygen delivery via nasal prongs during MAC, with sedation produced by a midazolam infusion, 0.05 to 0.1 mg/min intravenously. (A) 14-Gauge intravenous cannula inserted into one of the nasal prongs, or (B) nasal adapter set (Datex Instrumentarium Corp., Helsinki, Finland) can be used for monitoring end-expiratory carbon dioxide.

Monitoring the Level of Sedation

A wide variety of objective clinical scoring systems have been developed to reduce individual observer bias and to provide a more consistent method for monitoring temporal changes in the level of sedation during MAC. [115] The most commonly used methods for assessing the level of sedation include the following:

1. The Ramsay scale, an objective scoring system that was originally used to quantitate the level of drug-induced sedation and to measure patient responsiveness and drowsiness in the intensive care unit. Unfortunately, it is difficult to quantify the degree of agitation and oversedation with this scale. [116]
2. The observer's assessment of alertness/sedation (OAA/S)scale was developed to quantify the CNS effects of benzodiazepines. [117] The OAA/S score is based on assessments in four separate categories: (1) responsiveness, (2) speech, (3) facial expression, and (4) ocular appearance. To correlate a greater degree of sedation with a higher OAA/S score, the original five-point OAA/S scoring system is usually reversed (with a score of 1 corresponding to an awake and alert state and 5 representing profound sedation). The OAA/S scale provides a higher discriminatory power of the different levels of sedation. The scale has also been validated against the digit symbol substitution test, a sensitive measure of cognitive and psychomotor impairment produced by sedative-hypnotic drugs. [118] The major disadvantages of these methods of CNS assessment are that the patients must be stimulated to perform the testing procedure during the operation, the patients' cooperation is required, and they are subject to testing fatigue.
3. The sedation visual analogue scale has also been used to quantify the level of sedation during MAC. [4] [48] [54] A 100-mm visual analogue scale for sedation is anchored at one end by the adjective "awake and alert" and at the opposite end by "asleep." Although this assessment tool also requires that the patients be

stimulated for the testing procedure, it requires minimal patient cooperation. Smith et al [54] demonstrated a good correlation between visual analogue scale sedation scores assessed simultaneously by the patient and by an independent observer during fixed-rate propofol infusions.

4. The most common neurophysiologic techniques for monitoring the depth of sedation involve the use of the electroencephalogram (EEG), a noninvasive, objective and continuous measure of brain function that has been shown to correlate with the depth of sedation. [119] Because sedative and analgesic drugs alter the EEG in a drug-specific fashion, interpretation of EEG changes can be difficult when drug combinations are used. [119] [120] The interpretation of EEG changes has been simplified by use of computerized EEG analysis (e.g., power bands [a, b, d, and q], frequency variables [95% spectral edge frequency and median frequency], and interfrequency phase-coupling numbers [bispectral {BIS} index]). Studies with the EEG-BIS index suggest that the BIS value correlates best with the "depth of sedation." [121] [122] Liu et al [123] [124] demonstrated that the EEG-BIS index correlates with the depth of both midazolam and propofol-induced sedation as validated by use of the OAA/S rating scale (Fig. 40-5) (Figure Not Available) . With an increasing depth of sedation with either midazolam or propofol, there are consistent and predictable decreases in the EEG-BIS index, with recovery following a similar pattern. These preliminary data suggest that anesthesiologists may be able to improve the titration of sedative-hypnotic drugs during MAC by utilizing the EEG-BIS monitor as an adjunct to the clinical assessment of CNS depression.

Figure 40-4 (A) Ohmeda 600 multiple gas monitor capnograph tracing during MAC in a patient receiving midazolam infusion, 0.05 to 0.1 mg/mL intravenously, for sedation during a urologic procedure. (B) After supplementation with an opioid analgesic (fentanyl, 25 mug intravenously), a marked slowing of the respiratory rate and an increase in end-expiratory carbon dioxide concentration were noted.

Figure 40-5 (Figure Not Available) Electroencephalogram (EEG) bispectral index as a function of the level of propofol (A) and midazolam (B) induced sedation during the onset and recovery phases. Observer assessment of alertness/sedation scale (OAA/S) score: 5=awake/alert to 1=deeply sedated. The values are either mean or individual (scatter plot). *(From Liu et al [123] [124])*

Global Patient Monitoring

Monitored anesthesia care provides a unique opportunity for the anesthesiologist and the patient to discuss the effectiveness of the therapeutic modalities being used (e.g., local anesthesia and adjuvant sedative-analgesic therapy) during surgery. To be effective, the anesthesiologist must remain in close verbal and/or tactile contact with the patient, particularly when centrally active drugs that can produce cardiorespiratory depression are being administered. A closed claims analysis of unexpected cardiac arrests during spinal anesthesia identified a lack of verbal responsiveness, resulting from an excessive depth of sedation, as one of the two recurring patterns. [125] The level of sedation was often reported to have produced a comfortable-appearing sleep-like state with no spontaneous verbalization.

It is useful to explain to patients at the time of the preoperative visit that feedback from them will be encouraged during the procedure (e.g., in preparation for the surgical stimulus) because this will be helpful in achieving the desired level of comfort and safety. Development of good rapport with the patient facilitates both the evaluation process and the intraoperative management of the case.

The age and the physical status of the patient are useful guides in evaluating organ system reserves and in determining their sensitivity to the sedative-analgesic drugs commonly used during MAC. [126] Other important issues include (1) past experiences with general, regional, and local anesthesia; (2) preoperative anxiety level; (3) previous problems with local anesthetics and sedative-analgesic medications; and (4) history of postoperative complications (e.g., nausea and vomiting). Apart from the desirable aim of attaining satisfactory patient acceptance, there are practical issues to be considered, such as delayed discharge from ambulatory surgical facilities because of intractable nausea and vomiting (secondary to opioid analgesics) and excessive drowsiness after benzodiazepine-induced sedation.

Monitoring After MAC

One of the principal aims in recovery room monitoring is to assess the residual effects of drugs administered intraoperatively and to determine when the patient is fit for discharge (Ch. 68) . One important difference between the recovery period and the operative phase is that the patient recovering from MAC with local anesthesia may not be experiencing the same degree of pain or discomfort as the patient emerging from general anesthesia, thereby increasing the potential for delayed side effects related to the use of sedative-analgesic drugs (e.g., excessive sedation, airway obstruction, respiratory depression).

The overall rate of recovery room morbidity varies from 18 to 30 percent and includes airway obstruction, hypoventilation, hypotension or hypertension, arrhythmias, in-adequate analgesia, nausea and vomiting, and postanesthetic shivering. [127] [128] [129] Postanesthesia care unit monitoring after MAC is a natural extension of intraoperative monitoring,

with particular emphasis on respiratory adequacy, cardiovascular stability, and return to baseline levels of cerebral functioning. This requires clinical evaluation as well as use of pulse oximetry, blood pressure, and temperature monitoring. An appropriate level of staffing, good patient supervision, and allowance for adequate recovery time are all essential components for providing for a safe recovery after MAC. [130]

The American Academy of Pediatrics guidelines suggest the same degree of monitoring (vital signs, pulse oximetry, heart rate monitoring) be maintained after the procedure as during the procedure (i.e., until the patient is fully alert and/or appropriate discharge criteria are met). [131] Recommended discharge criteria after intravenous sedation-analgesia include the following:

1. Cardiovascular function and airway patency are satisfactory and stable.
2. The patient is easily arousable, and protective reflexes are intact.
3. The patient can talk (if age-appropriate).
4. The patient can sit up unaided (if age-appropriate).
5. For a very young or handicapped child, incapable of the usually expected responses, the presedation level of responsiveness or a level as close as possible to the normal level for that child should be achieved.
6. The state of hydration is adequate.

USE OF MAC OUTSIDE THE OPERATING ROOM

There has been an increase in the number of diagnostic, radiologic, and minor surgical procedures performed outside the traditional OR setting (Ch. 66) . Although many procedures are painless, some necessitate immobility (e.g., MRI and radiation therapy). Therefore, anesthesiologists are often called on to administer intravenous sedationanalgesia outside the OR environment.

Optimal monitoring conditions rarely exist outside the OR; therefore, the anesthesiologist must often provide a mobile anesthesia machine with monitors and the necessary supplies. In these situations, supplemental oxygen and suction should be available. Because these specialized diagnostic units are not normally designed with anesthesia in mind, the addition of anesthesia equipment and personnel can create a crowded work environment. Advance planning and preparation on the part of both the anesthesiologist and the diagnostic specialist involved in the procedure minimize the possibility of serious complications.

Patients with preexisting medical conditions, such as critically ill patients, mentally handicapped patients, uncooperative children, and patients with psychiatric disorders, are more likely to require anesthesia for diagnostic procedures. These complex patients may be at increased risk for developing complications and, coupled with the difficulties in providing anesthesia care under less than ideal conditions, can make providing anesthesia remote from the OR a challenging experience for anesthesiologists.

Over the past 5 years, a multitude of articles have been published regarding guidelines and techniques for monitoring in locations remote from the OR (e.g., radiologic and angiographic units; cardiology, pulmonary, and gastroenterology procedure suites; lithotripsy; and free-standing MRI facilities). A few of the most pertinent issues related to MAC in areas remote from the OR are summarized in the following sections. [131] [132] [133]

Magnetic Resonance Imaging

Magnetic resonance imaging has become an increasingly popular noninvasive radiologic diagnostic procedure because of the high-quality images provided. MRI requires that the patients be confined for 30 to 60 minutes in a magnetic, closed, noisy space. Therefore, some patients, because of age, altered mental state, or pain, cannot cooperate for this length of time and require either general anesthesia or MAC to accomplish a high-quality image. [133] [134] Patient movement during any part of the examination can degrade the quality of the image. Therefore, anesthesiologists are increasingly involved in patient care for MRI and spectroscopy. There are special anesthetic considerations surrounding MRI because of the high magnetic field and the specialized rooms and buildings for housing the MRI scanners. [134] [135] The problems in monitoring patients undergoing MRI include the following:

1. Ferromagnetic equipment must be removed from the magnetic field, including credit cards, key chains, paper clips, pins, and pens, as well as conventional monitoring devices
2. Limited access to the patient and limited view of the patient while in the scanner
3. Malfunction of monitoring equipment, or interference, produced by the changing magnetic field (e.g., syringe infusion pumps)
4. Degradation of image and special quality arising from stray radiofrequency current produced by monitoring equipment and leads

These issues make it difficult to achieve an adequate balance between meeting the ASA standards for monitoring during anesthesia and acquiring a high-quality image. [133] Newer anesthesia machines and nonferrous monitoring equipment are available. Because the older monitors may have to be located far from the patient (e.g., outside the room), the chances of disconnects and kinks in intravenous tubing, anesthesia circuit tubing, monitoring leads, and cables are increased. The ideal situation is to have two anesthesia personnel: one close to the patient and an assistant outside the room with the monitoring equipment. Unfortunately, the costs of this type of care would be higher.

MAC in the Gastroenterology Suite

For many years, endoscopists have utilized conscious sedation techniques for these patients. Sedation not only improves patient comfort during the examination but also improves patient acceptance of follow-up examinations. [136] Specific monitoring guidelines and sedation techniques for assisting the endoscopist are available. [137] [138] [139] However, many situations arise that can benefit from the services of an anesthesiologist, such as endoscopic procedures that are

performed on patients with complex coexisting medical conditions or in situations in which previous attempts at operator-administered sedation were unsuccessful.

An important consideration in the planning of an anesthetic technique is the position of the patient during the examination. Patients undergoing endoscopic procedures are often positioned lateral or prone to facilitate the examination, and these positions may pose difficulty should resuscitative efforts be required. During upper endoscopic procedures or endoscopic retrograde cholangiopancreatography, the endoscope is inserted orally, which necessitates sharing the patient's airway with the endoscopist. Cooperation and a team approach by the endoscopist, the radiology staff, and the anesthesiologist is essential.

Extracorporeal Shock-Wave Lithotripsy

Extracorporeal shock-wave lithotripsy is the treatment of choice for urinary tract calculi. ESWL has also been used in the treatment of biliary calculi. Although these procedures can be performed with the patient under general and regional anesthesia, these techniques are time consuming, and epidural anesthesia is associated with urinary retention and delayed recovery. [140] [141] MAC techniques reduce the anesthesia and recovery times without compromising patient safety and satisfaction. [53] [132] [142] Monk et al [132] compared alfentanil and ketamine infusions in combination with mid-azolam and described both techniques as effective, although patients receiving alfentanil had a better recovery profile and calculi fragmentation. A MAC technique involving midazolam-alfentanil and fentanyl-propofol has also been utilized for ESWL procedures with a high degree of patient satisfaction. [53] Patient-controlled analgesia with alfentanil has also been described for gallstone and urinary tract calculi lithotripsy. [143] [144] A MAC technique involving midazolam (2 mg), propofol infusion (25-50 mug/kg/min), and a continuous infusion of remifentanil (0.025-0.15 mug/kg/min) has been described. [70]

Office-Based Anesthesia

Office-based surgery and anesthesia are not new concepts. At the beginning of this century, as physicians started to specialize in the practice of anesthesia, one of the pioneering American anesthesiologists, Ralph Waters, opened an office-based anesthetic practice (the Downtown Anesthesia Clinic) in Sioux City, Iowa. In response to an occasional call from a dentist for anesthesia, Dr.Waters set up "a modest office with a waiting room and a small operating room with an adjoining room

containing a cot on which a patient could lie down after his anesthetic before going home." [145]

The role that regulations would play in office-based anesthesia perhaps first became evident in 1968, at the Dudley Street facility in Providence, Rhode Island. In a letter entitled "Surgery in an Office Suite" in the Medical Economics magazine, Charles Hill wrote "In Rhode Island, we have come up with what we hope will be the answer: incorporating in a medical office building an operating suite complete with OR facilities and a recovery room." Unfortunately, the facility was financially insolvent because it was not supported by the state's regulatory agencies (which ruled that the suite was no more than a doctor's office) and also lacked support from Blue Cross and third-party carriers. [146] [147]

For many years, relatively simple, minimally invasive surgical procedures have been performed in physicians' offices. Certified registered nurse anesthetists, dental anesthesiologists, and a small number of anesthesiologists have been active in office-based surgery.

Office-based anesthesia is a rapidly growing practice of ambulatory surgery. Anesthesiologists have begun to assume their position in this shift of surgical procedures to the office facility. A survey by the Society for Ambulatory Anesthesia found that 20 percent of anesthesiologists were devoting an increasing portion of their practice to office anesthesia. Office-based anesthesia has grown from 400,000 procedures in 1984 to 1.2 million in 1990. It is estimated that up to 20 percent of all elective surgery will be performed in an office-based setting by the year 2001. [148]

A number of reasons have been identified for the growth of office-based anesthesia. Not surprisingly, health care reform and economics issues are a major driving force in this growth as the potential exists for office-based surgery to further reduce costs by decreasing facility fees and overhead. The availability of anesthesiologists can ensure the delivery of high-quality patient care in a setting where overhead is lower than in a hospital or free-standing surgical center, thereby decreasing the cost of providing surgical services. A cost comparison of laparoscopic inguinal herniorrhaphy performed by Shultz [149] reported that the total cost for this procedure in their hospital was $5,494, compared with $1,533.84 in the surgical office. The hospital fees for a conventionally performed inguinal herniorrhaphy was $2,237, compared with a fee of $894.79 in the office. [149]

Another reason for the growth in office-based surgery relates to improvements in anesthesia techniques and new surgical technologies. Utilizing these advances in surgical and anesthesia care, the "limits" are continually being pushed as practitioners attempt to determine what procedures can be safely performed in office surgery suites. The office is also likely to provide more convenient and comfortable patient care. Although office-based surgery is likely to continue to grow, the success of providing anesthesia in a surgeon's office will increasingly depend on the ability of the surgery/anesthesia team to perform an astute preoperative assessment of outpatients scheduled for surgical procedures in the office setting. The preoperative work-up should be guided by the same clinical acumen and common sense that drives the decision-making process at free-standing surgery centers. The selection criteria of patients are based on ASA physical status (1-2) and age (7-70 years). In addition, patients with potentially difficult airways are not considered good candidates for office-based anesthesia.

The most popular office-based anesthetic technique involves the use of local anesthesia in combination with rapid and short-acting intravenous (propofol) and inhaled (N_2 O, sevoflurane and/or desflurane) anesthetics. For transient intense discomfort, the potent opioid analgesic fentanyl or one of its newer analogues is recommended. Tang et al [150] described the use of a propofol infusion versus a propofol infusion

---

in combination with N_2 O (60-70%) in patients undergoing superficial surgical procedures in an office-based facility. These investigators reported a decrease in the propofol dosage requirement in the group receiving N_2 O without increasing the incidence of postoperative emesis or prolonging the discharge times. [150] Because most office suites do not have stretchers or recovery beds, patients have to be able to get up from the OR table and transfer themselves to a reclining chair or ambulate to an area where they can rest until they are ready to get dressed and go home.

The major issues in the provision of safe anesthetic care in the office setting are the set-up, maintenance of equipment and supplies, and assessment of the quality of the services provided. A few states (e.g., California and Florida) in the United States have started to address the concerns related to the administration of anesthetics for office-based surgery procedures. The clinical practice guidelines should be consistent with the recommendations and standards established by the ASA, the American Association of Nurse Anesthetists, and the Joint Commission on Accreditation of Healthcare Organizations. These groups have recommended the following office-based practice guidelines [151] :

1. Employment of appropriately trained and credentialed anesthesia personnel
2. Availability of properly maintained anesthesia equipment appropriate to the anesthesia care being provided
3. Documentation of the care provided must be as complete as that required at other surgical sites
4. Use of standard monitoring equipment according to the ASA policies and guidelines
5. Provision of a postanesthesia care unit or recovery area that is staffed by appropriately trained nursing personnel. Specific discharge instructions should be provided
6. Availability of emergency equipment (e.g., airway equipment, cardiac resuscitation)
7. Establishment of a written plan for emergency transport of patients to a site that provides more comprehensive care should an untoward event or a complication occur that requires more extensive monitoring or overnight admission of the patient
8. Maintenance and documentation of a quality assurance program
9. Establishment of a continuing education program for physicians and other facility personnel

Beyond their responsibility to provide safe care in the office, the modern day office anesthesiologist has an opportunity to expand his or her role as a perioperative physician. This practice has the potential to heighten public awareness of the vital role of anesthesiologists in the office setting and can enhance the professional image of our specialty. Patients must be confident that the office setting adheres to the same standards of care required in a hospital-based or a free-standing ambulatory surgery facility. Safety standards can- not be jeopardized for patient convenience or cost savings.

SUMMARY

Monitored anesthesia care has become the anesthetic technique of choice for an increasing number of diagnostic and therapeutic procedures because recovery profiles appear to be improved compared with those of general and regional anesthesia. [1] [5] [6] The administration of sedative and analgesic drugs to enhance patient comfort requires careful titration and adequate monitoring to achieve the desired goal without compromising patient safety. The effective use of a MAC technique can provide highly acceptable patient comfort while optimizing intraoperative conditions. The so-called Iowa satisfaction with anesthesia scale was developed to evaluate patient satisfaction with MAC and may prove to be a useful tool for comparing different MAC techniques. [152] Patient cooperation, effective local anesthesia, and gentle surgical technique are all essential elements for the successful application of a MAC technique. Although local anesthetic-based techniques are generally assumed to be safer than general or regional anesthesia, supplementation with potent sedative-hypnotic and analgesic drugs may result in significant depression of central respiratory drive and/or transient upper airway obstruction. Therefore, the decision to use MAC in place of general or regional anesthesia should be made only after careful assessment of both patient and surgeon preferences, as well as any coexisting medical conditions.

The importance of vigilant monitoring, use of supplemental oxygen when IV sedative-analgesic drugs are administered, and availability of resuscitation equipment are all essential elements for the safe practice of MAC, whether it is administered in a hospital-based unit, an ambulatory surgery center, or an office-based facility. The choice of a regimen of sedative/analgesic drugs for use during MAC should be based on the anticipated degree of pain and the sedation requirements for the successful completion of the operation. Pain and anxiety must be treated with appropriate pharmacologic agents, targeting the intervention at the specific problem and titrating all drugs to the desired effect. [153] If the procedure is relatively pain free and anxiolysis is the main consideration, it may be justified to use only a benzodiazepine (e.g., diazepam, midazolam). For diagnostic procedures that are pain free (e.g., radiation therapy), a low-dose propofol infusion should be utilized. If brief periods of pain are anticipated during the procedure, administration of a rapid short-acting analgesic opioid is indicated (e.g., fentanyl, alfentanil, remifentanil). For procedures in which analgesia is provided by a regional anesthetic technique (e.g., peripheral nerve block), a stable level of sedation can be easily achieved by use of a variable-rate infusion of propofol or methohexital. An effective regimen for MAC might include midazolam, 1 to 3 mg IV, followed by propofol, 25 to 100 mug/kg/min or methohexital 20 to 60 mug/kg/min in combination with intermittent boluses of fentanyl (25 mug), sufentanil (5 mug), alfentanil (250 mug), or remifentanil (12.5 mug). [13] [70] Alternatively, in patients premedicated with midazolam, 1 to 5 mg IV, a basal infusion of alfentanil (0.5-1.0 mug/kg/min) or remifentanil (0.025-0.15 mug/kg/min) can be supplemented with small bolus doses of the same analgesic. Careful titration to ensure adequate cardiorespiratory stability by use of variable-rate infusions of sedative and analgesic drugs minimizes the possibility of adverse side effects during MAC. [1] [154]

In conclusion, concerns regarding the effects of the increasing health-care costs on the medical decision process have led to a reexamination of many anesthetic practices. [155] In general, the overall cost of a MAC technique is less than

that of either general or regional anesthesia. [5] [68] [156] In order to realize the savings resulting from decreased discharge time, reduced postoperative pain, and lower incidence of sore throats and emesis with MAC techniques, recovery procedures and discharge criteria will have to allow the direct transfer of all MAC patients from the OR to a phase II recovery area (i.e., fast tracking). [5] [157] [159] With the growing interest in office-based surgery, the use of MAC techniques will continue to increase in popularity. [1]

Appendix-Standards for Basic Anesthetic Monitoring

These standards apply to all anesthesia care although, in emergency circumstances, appropriate life support measures take precedence. These standards may be exceeded at any time based on the judgment of the responsible anesthesiologist. They are intended to encourage quality patient care, but observing them cannot guarantee any specific patient outcome. They are subject to revision from time to time, as warranted by the evolution of technology and practice. They apply to all general anesthetics, regional anesthetics and monitored anesthesia care. This set of standards addresses only the issue of basic anesthetic monitoring, which is one component of anesthesia care. In certain rare or unusual circumstances, (1) some of these methods of monitoring may be clinically impractical, and (2) appropriate use of described monitoring methods may fail to detect untoward clinical developments. Brief interruptions of continual [a] monitoring may be unavoidable. Under extenuating circumstances, the responsible anesthesiologist may waive the requirements marked with an asterisk ([*]); it is recommended that when this is done, it should be so stated (including the reasons) in a note in the patient's medical record. These standards are not intended for application to the care of the obstetrical patient in labor or in the conduct of pain management.

STANDARD I

Qualified anesthesia personnel shall be present in the room throughout the conduct of all general anesthetics, regional anesthetics, and monitored anesthesia care.

Objective

Because of the rapid changes in patient status during anesthesia, qualified anesthesia personnel shall be continuously present to monitor the patient and provide anesthesia care. In the event there is a direct known hazard, e.g., radiation, to the anesthesia personnel, which might require intermittent remote observation of the patient, some provision for monitoring the patient must be made. In the event that an emergency requires the temporary absence of the person primarily responsible for the anesthetic, the best judgment of the anesthesiologist will be exercised in comparing the emergency with the anesthetized patient's condition and in the selection of the person left responsible for the anesthetic during the temporary absence.

STANDARD II

During all anesthetics, the patient's oxygenation, ventilation, circulation, and temperature shall be continually evaluated.

Oxygenation

Objective

To ensure adequate oxygen concentration in the inspired gas and the blood during all anesthetics.

Methods

1. Inspired gas: During every administration of general anesthesia using an anesthesia machine, the concentration of oxygen in the patient breathing system shall be measured by an oxygen analyzer with a low oxygen concentration limit alarm in use. [*]
2. Blood oxygenation: During all anesthetics, a quantitative method of assessing oxygenation such as pulse oximetry shall be employed. [*] Adequate illumination and exposure of the patient are necessary to assess color. [*]

Ventilation

Objective

To ensure adequate ventilation of the patient during all anesthetics.

Methods

1. Every patient receiving general anesthesia shall have the adequacy of ventilation continually evaluated. While qualitative clinical signs such as chest excursion, observation of the reservoir breathing bag, and auscultation of breath sounds may be useful, quantitative monitoring of the CO_2 content and/or volume of expired gas is strongly encouraged.
2. When an endotracheal tube or laryngeal mask is inserted, its correct positioning must be verified by clinical assessment and by identification of CO_2 in the expired gas. Continual end-tidal CO_2 analysis, in use from the time of endotracheal tube/laryngeal mask placement, until extubation/removal or initiating transfer to a postoperative care location, shall be performed using a quantitative method such as capnography, capnometry, or mass spectroscopy. [*]
3. When ventilation is controlled by a mechanical ventilator, there shall be in continuous use a device that is capable of detecting disconnection of components of the breathing system. The device must give an audible signal when its alarm threshold is exceeded.
4. During regional anesthesia and monitored anesthesia care, the adequacy of ventilation shall be evaluated, at least, by continual observation of qualitative clinical signs.

Circulation

Objective

To ensure the adequacy of the patient's circulatory function during all anesthetics.

Methods

1. Every patient receiving anesthesia shall have the electrocardiogram continuously displayed from the beginning of anesthesia until preparing to leave the anesthetizing location. [*]
2. Every patient receiving anesthesia shall have arterial blood pressure and heart rate determined and evaluated at least every five minutes. [*]
3. Every patient receiving general anesthesia shall have, in addition to the above, circulatory function continually evaluated by at least one of the following: palpation of a pulse, auscultation of heart sounds, monitoring of a tracing of intra-arterial pressure, ultrasound peripheral pulse monitoring, or pulse

plethysmography or oximetry.

Body Temperature

Objective

To aid in the maintenance of appropriate body temperature during all anesthetics.

Methods

There shall be readily available a means to continuously measure the patient's temperature. When changes in body temperature are intended, anticipated, or suspected, the temperature shall be measured.

---

[a] Note that 'continual' is defined as 'repeated regularly and frequently in steady rapid sucession.'whereas 'continuous' means 'prolonged without any interruption at any time.'

Chapter 41 - Deliberate Hypotension

Hugo Van Aken
Edward D. Miller Jr.

INTRODUCTION

The concept of intentionally decreasing arterial blood pressure to hypotensive levels during surgery was first proposed by Cushing [1] in 1917 for intracranial surgery and was introduced into clinical practice by Gardner [2] in 1946. Deliberate hypotension gained popularity in Great Britain after Griffiths and Gillies [3] advocated the "hypotensive spinal technique" in 1948. In 1950 Enderby [4] introduced ganglionic blockade using pentamethonium to decrease arterial blood pressure. Subsequent techniques included decreasing cardiac output with volatile anesthetics such as halothane [5] and administering vasodilators such as sodium nitroprusside; beta-adrenergic receptor blocking drugs, which were initially used with trimethaphan [6] ; or a combination of alpha- and beta-adrenergic receptor blocking drugs. [7] More recently, nitroglycerin, [8] purine derivatives, [9] and isoflurane [10] have also been used.

As early as 1950, Enderby [4] emphasized that bleeding could be controlled not only by decreasing mean arterial blood pressure (MAP) but also by properly positioning the patient (Ch. 52) . Since that time, the decision to induce hypotension has often been controversial, primarily because of an inability to define the lowest safe MAP with confidence. [11] The terms *controlled hypotension, induced hypotension, deliberate hypotension,* and *hypotensive anesthesia* have all been used. This chapter uses *deliberate hypotension.*

Most studies define deliberate hypotension as a reduction in systolic blood pressure to 80 to 90 mm Hg. According to another definition, deliberate hypotension is a decrease in MAP to 50 to 65 mm Hg in normotensive patients.

The main purpose of deliberately inducing hypotension is to decrease blood loss, thereby improving operating conditions or decreasing the need for blood transfusions. Therefore, benefit to the patient should be the single criterion determining the need for deliberate hypotension. The potential for transmitting disease by blood transfusion has made deliberate hypotension an even more important consideration today than ever before (Ch. 46) . The possible benefit to the surgeon of improved visibility of the operative field during delicate procedures (e.g., plastic surgery) is a strong incentive, but it is more difficult to quantitate.

This chapter provides a general overview of deliberate hypotension, leaving the discussion of most specific clinical applications to specialty chapters (e.g., neuroanesthesia in Ch. 52).

THE ABILITY OF DELIBERATE HYPOTENSION TO REDUCE BLOOD LOSS

Enderby's [4] first report demonstrated that of 35 patients, 18 had excellent and 8 had moderate reduction in blood loss during deliberate hypotension, and 9 patients had no reduction. This inconsistency was attributed to differing vascular responsiveness to the hypotensive drugs and, in some cases, inadequate positioning. Enderby emphasized that the absolute MAP may not be as important to bleeding as positioning of the surgical field. He maintained that bleeding at the surgical site would be minimized if the wound were kept uppermost (rather than dependent): arterial vessels would have less pressure, veins would drain more easily, and bleeding at the surgical site would be less.

Deliberate hypotension certainly can decrease blood loss in many surgical procedures. In 1953 Boyan [12] used hexa-methonium (C_6) to lower systolic blood pressure to 65 to 70 mm Hg in 112 patients undergoing radical cancer surgery. Although the impression of the surgical team was that blood

loss was less, no data were provided. Several subsequent reports also claiming a decrease in blood loss noted, however, that some patients continued to bleed during deliberate hypotension and that other patients not undergoing deliberate hypotension had minimal blood loss. Whether these differences can be ascribed to positioning, ventilation, or other factors is unknown.

Assigning importance to the possible influences on blood loss is difficult because few clinicians have actually measured this variable. Also, such studies have had major flaws in experimental design, execution, or data analysis. [13] Usually MAP of 50 to 65 mm Hg is considered a safe range for deliberate hypotension.

Eckenhoff and Rich [14] supplied objective data that deliberate hypotension can indeed decrease blood loss. Blood loss was compared for patients undergoing rhinoplasty, portacaval shunt, or craniotomy for aneurysm or suspected tumor with (*n* = 115) or without (*n* = 116) deliberate hypotension. For each of these procedures, blood loss decreased by 50 percent or more with hypotension. Most of the other studies evaluating different hypotensive agents for a variety of surgical procedures had no control group, and assessment of blood loss was visual. [15] [16] [17] [18]

The best documentation that decreasing arterial blood pressure decreases blood loss applies to patients undergoing major orthopedic procedures. Often blood loss is significant during these procedures, and the effect of deliberate hypotension can be documented more readily. For example, a well-controlled study of 55 patients undergoing total hip arthroplasty found that the 38 patients given pentolinium tartrate, halothane, and *d*-tubocurarine for deliberate hypotension had less blood loss. [19] In another study, 25 patients given sodium nitroprusside to lower arterial blood pressure during total hip arthroplasty had significantly less blood loss than the 25 patients not undergoing deliberate hypotension. [20] Operating room time was also slightly lower for the hypotensive group.

Other studies have also had success reducing blood loss during total hip arthroplasty. Thirty patients undergoing this procedure had MAP reduced to 50 mm Hg by administration of sodium nitroprusside (*n* = 12) or high inspired concentrations of halothane (*n* = 9). [21] Nine control patients were normotensive. Blood loss was 1,200 mL for the normotensive controls but only approximately 400 mL for both hypotensive groups. No complications were seen. Another study had similar results--almost a 50 percent reduction in blood loss--when MAP was decreased to 55 mm Hg by sodium nitroprusside. [22] An interesting aspect of the study was the use of hemodilution to determine whether total blood loss could be reduced by this method. Even with hemodilution, patients given sodium nitroprusside had the lowest blood loss. Table 41-1 shows blood losses for a variety of hypotensive techniques during total hip arthroplasty. [19] [20] [21] [22] [23] [24] Another study on primary total hip arthroplasty (under epidural anesthesia) showed that the degree of hypotension significantly influenced blood loss. [25] Intraoperative blood loss was 179 ± 73 ml when MAP was kept at 50 ± 5 mm Hg and 263 ± 98 mL when MAP was kept at 60 ± 5 mm Hg.

Deliberate hypotension has also been used successfully for a variety of other surgical procedures, including head and neck surgery, [26] procedures on the cranium [18] and middle ear, [17] and radical cancer operations. [27] A retrospective study of 37 patients undergoing radical cystectomy for bladder cancer found that the average blood loss was 50 percent less with deliberate hypotension (versus standard normotensive anesthesia). [28] Elsewhere, the use of sodium nitroprusside-induced hypotension reduced blood loss by 50 percent in patients undergoing lienorenal shunts for portal hypertension. [29] When esmolol was compared with sodium nitroprusside for controlled hypotension during orthognathic surgery, the surgeons generally rated bleeding as mild to moderate and the field as "drier" with esmolol. [26] Furthermore, total measured blood loss with esmolol was 49 percent of that with sodium nitroprusside (436 versus 895 mL, respectively).

Although deliberate hypotension usually decreases surgical blood loss, some exceptions have occurred. For unknown reasons, not all patients respond as predicted. For other patients, the correlation between decrease in arterial blood pressure and blood loss is not linear. [30] Some studies report

TABLE 41-1 -- Reported Blood Losses for Total Hip Arthroplasty

REPORTED INTRAOPERATIVE INVESTIGATORS	HYPOTENSIVE TECHNIQUE	BLOOD PRESSURE (mm Hg)	BLOOD LOSS (mL)
Amaranath et al (1975) [23]	Halothane, N_2O	Normotensive	1,514 ± 273
	Morphine, N_2O, trimethaphan	<30% control	884 ± 89
	Morphine, N_2O, SNP	<30% control	820 ± 96
Thompson et al (1978) [21]	Halothane, N_2O	20% control	1,183
	Halothane, N_2O	50 MAP	407 ± 102
	Halothane, N_2O, SNP	50 MAP	326 ± 42
Eerola et al (1979) [19]	Halothane, N_2O	>80 systolic	2,336 ± 212
	Halothane, N_2O, pentolinium	<80 systolic	730 ± 80
Vazeery and Lunde (1979) [20]	N_2O, fentanyl	94 MAP	1,038 (500-1,750)
	N_2O, fentanyl, SNP	64 MAP	212 (160-350)
Barbier-Bohm et al (1980) [22]	Halothane, N_2O	Normotensive	900 ± 130
	Halothane, N_2O, SNP	55 MAP	320 ± 35
Qvist et al (1982) [24]	N_2O, fentanyl, droperidol	99 MAP	2,093 ± 1,332

	Halothane, N_2 O	73 MAP	718 ± 482
Sharrock et al (1993) [25]	Epidural anesthesia	50 MAP	179 ± 73
	Epidural anesthesia	60 MAP	263 ± 98

Abbreviations: BP, blood pressure; SNP, sodium nitroprusside; MAP, mean arterial blood pressure; N_2 O, nitrous oxide

TABLE 41-2 -- Mean Arterial Blood Pressure Versus Cardiac Output as the Primary Determinant of Blood Loss [a]

(Not Available)

(Adapted from Sivarajan et al [33])

[a] Total blood loss was similar for both trimethaphan (170 ± 102 mL) and SNP (183 ± 92 mL).

that deliberate hypotension did not reduce blood loss significantly and that the incidence of postoperative wound hematoma even increased. [31] It is difficult to evaluate these last two studies because of the scant data presented and the imprecision with which blood losses were measured.

Shortly after the introduction of deliberate hypotension, drug therapy focused on keeping arterial blood pressure at the surgical site at 50 to 65 mm Hg, a level believed to decrease blood loss significantly. Because intraoperative measurement of cardiac output was not done routinely, the specific mechanism by which reduction of arterial blood pressure decreased blood loss could not be defined precisely. Didier et al [32] suggested that depression of cardiac output correlated better with a dry field than did MAP. To determine whether a decrease in arterial blood pressure or cardiac output was the primary cause of decreasing blood loss, Sivarajan et al [33] studied 20 healthy subjects undergoing bilateral sagittal osteotomy of the mandible. Cardiac output decreased 37 percent with trimethaphan but increased 27 percent with sodium nitroprusside. Blood loss was similar for both groups, even though cardiac output was two times greater with sodium nitroprusside (Table 41-2) (Table Not Available) . Sivarajan et al concluded that blood pressure, not cardiac output, determined blood loss.

In summary, most patients will have less blood loss if MAP is decreased to 50 to 65 mm Hg. Patient positioning and attention to ventilation, both of which influence venous return, play important roles in minimizing blood loss. Clinical experience suggests that blood loss can be decreased with less severe degrees of hypotension and that attention to the surgical field may be a better monitor than the absolute value for MAP. Most clinical studies do not support the belief that deliberate hypotension decreases operating room time.

TECHNIQUES TO INDUCE DELIBERATE HYPOTENSION

Physiologic Techniques

Body positioning, the hemodynamic effects of mechanical ventilation, and changes in heart rate and circulatory volume can be used with drugs to lower blood pressure to the desired level. The appropriate use of physiologic maneuvers helps decrease the dose of potentially toxic drugs needed to produce hypotension.

Pharmacologic Techniques

The ideal agent for inducing hypotension would have ease of administration, a predictable and dose-dependent effect, rapid onset and recovery from effects, quick elimination without the production of toxic metabolites, and minimal effects on blood flow to vital organs. In addition, the ideal agent would not increase brain size or affect cerebral autoregulation during neurosurgery. Although such an agent does not yet exist, many anesthetic and vasoactive drugs have been used successfully to produce deliberate hypotension, including (1) spinal and epidural anesthesia, (2) volatile anesthetics (halothane, enflurane, isoflurane, sevoflurane, desflurane), (3) direct-acting vasodilating drugs (sodium nitroprusside, nitroglycerin, hydralazine, purine derivatives), (4) autonomic ganglion-blocking drugs (trimethaphan), (5) alpha-adrenergic receptor blocking drugs (phentolamine, urapidil), (6) beta-adrenergic receptor blocking drugs (propranolol, esmolol), (7) combined alpha- and beta-adrenergic receptor blocking drugs (labetalol), (8) calcium channel entry blocking drugs (nicardipine), and (9) prostaglandin E_1 (PGE_1).

Spinal and Epidural Anesthesia

In 1948 Griffiths and Gillies [3] used subarachnoid block to produce intentional hypotension. In 1952 Greene [34] advocated the use of general anesthesia in which hypotension was induced using a high spinal technique to relieve the distressing symptoms of hypotension. Epidural anesthesia (Ch. 42) was introduced in the early 1950s and is now considered an effective method of inducing hypotension. [35] [36] Pharmacologic sympathectomy with local anesthetics is a very effective way of inducing hypotension. Epidural or spinal anesthesia produces arteriolar and venous dilation and hypotension. These effects are enhanced by a pooling of blood in the venous system that decreases venous return and cardiac output. If the block is extended to the midthoracic region, sympathetic innervation of the heart (T1-T4) is also affected, thereby preventing compensatory tachycardia. [37] The unpredictable degree of hypotension and the necessity for large infusions of fluids are the principal drawbacks of this technique. It was recently demonstrated, however, that if hemodynamic stability is maintained by intravenous infusion of low-dose epinephrine (1-5 mug/min), this technique

can be used safely. [25] [35] An epidural anesthetic technique is most commonly used to minimize blood loss during lower abdominal or pelvic surgery.

Volatile Anesthetic Drugs

Clearly one can decrease MAP by increasing the inspired concentration of inhaled anesthetic (Ch. 5).

Cardiovascular Effects

Hypotension after halothane results primarily from myo-cardial depression that produces a dose-dependent decrease in arterial blood pressure, cardiac output, and stroke volume, plus a dose-dependent increase in right heart filling pressure (Fig. 41-1) (Figure Not Available) . Although halothane also dilates vessels in the skin, brain, and viscera, systemic vascular resistance (SVR) does not decrease significantly because skeletal muscle tone increases; in addition, renal vascular resistance increases. [38]

In studies on patients and animals, isoflurane decreased blood pressure by decreasing SVR, whereas cardiac output was maintained constantly at clinically relevant concentrations of the anesthetic. [10] [39] In another study of 10 patients given isoflurane to reduce MAP to 40 mm Hg, cardiac index showed a small but significant decrease. [40] The two studies on patients [10] [40] may have different results because the latter study used the awake value as control.

The intravascular volume status of the patient before induction of hypotension affects the degree of reduction in cardiac output during isoflurane anesthesia. In healthy young people, 2 to 3 percent isoflurane decreases MAP by decreasing SVR. In older or chronically hypertensive patients, similar concentrations of isoflurane may also decrease cardiac output. For these individuals, combining a moderate concentration of isoflurane with agents that tend to maintain cardiac output would be more appropriate than using high concentrations of isoflurane alone.

Cerebrovascular Effects

Halothane decreases cerebrovascular resistance and increases cerebral blood flow (CBF) in a concentration-related manner, provided autoregulatory limits are not exceeded. As a result, intracranial pressure (ICP) may increase. Cerebral autoregulation is lost when the concentration of halothane increases. [41]

By increasing the normal production of cerebrospinal fluid, enflurane is also capable of increasing ICP. [42] In addition, enflurane has induced seizure activity in some patients, especially during hypocapnia.

The administration of low concentrations of isoflurane (
1 MAC) produces controllable decreases in MAP and a concentration-related depression of cerebral metabolism while preserving the physiologic relationships between flow and pressure, and flow and metabolism. With higher concentrations of isoflurane, the direct vasodilatory effects predominate: CBF increases, and autoregulation is impaired. [39] [43] However, even low concentrations of isoflurane may increase ICP in patients who have reduced intracranial compliance. [44] In the presence of cerebral vasodilation, cerebral edema is more likely to occur if systemic blood

Figure 41-1 (Figure Not Available) Effect of increasing concentrations of halothane anesthesia on mean arterial blood pressure (MAP), stroke volume (SV), and systemic vascular resistance (SVR) during the awake state, spontaneous ventilation (SpV), and controlled ventilation (intermittent positive-pressure ventilation, IPPV). Elevation in right arterial pressure (RAP) is evidence of myocardial depression. *(From Prys-Roberts et al [38])*

pressure is allowed to increase. Therefore, the possibility of secondary neurologic injury exists. A recent study on dogs with cryogenic brain lesions showed that brain edema was greater when hypotension was induced with isoflurane than with labetalol. [45] Adenylate kinase, a marker of brain cell injury, was found in the cerebrospinal fluid of patients undergoing isoflurane-induced hypotension for corrective surgery of dentofacial deformities. [46] However, this study did not include a control group. In a subsequent investigation the same authors found that adenylate kinase occurred also in patients after isoflurane anesthesia under normotensive conditions for orthognathic surgery. [47] In conclusion, adverse effects on the brain were found, using a sensitive biochemical method and a battery of psychometric examinations. Arterial hypotension, however, was not shown to have a direct causal relationship to the adverse effects found.

Volatile anesthetics should not be used as the sole agent to induce hypotension in patients who have intracranial disease because the high concentrations that may be required can worsen brain edema. Such a technique may also increase ICP before opening of the dura and may affect autoregulation. The combination of increased ICP and decreased MAP can reduce cerebral perfusion pressure to less than 40 mm Hg, a circumstance that can produce brain ischemia. Recent studies in animals and patients showed that combining isoflurane with either an alpha-adrenergic receptor blocking drug or a combined alpha- and beta-adrenergic receptor blocking drug attenuated the negative effects of using isoflurane as the sole hypotensive agent. [48] [49] In summary, isoflurane should only be used as an adjuvant drug (and in low concentrations) during induced hypotension. This method has the advantages of decreased cerebral metabolism and preserved pulmonary gas exchange. [50] The profile of hemodynamic changes induced by sevoflurane and desflurane is very similar to that of isoflurane. However, due to the pharmacokinetic properties of these volatile agents, including a low blood/gas solubility, these hemodynamic effects can be better controlled with them as compared with isoflurane. Therefore, sevoflurane and desflurane appear to be superior to isoflurane when used as an agent to facilitate deliberate hypotension. Surprisingly, these drugs have not been investigated yet with respect to their suitability in deliberate hypotension.

Information on the cerebral effects of the newer anesthetic agents is limited. Hypotensive anesthesia with desflurane reduces CBF by 36 percent and reduces $CMRO_2$ by a similar amount, [51] and 4 MAC of sevoflurane has no adverse effects on brain energy metabolism. [52]

Intravenous Drugs

Many intravenous drugs have been used to decrease arterial blood pressure acutely. Certainly, drugs that permit moment-to-moment control of blood pressure are the most popular. Most of these drugs are titrated to obtain the desired surgical field or predetermined MAP, or both. The differences in pharmacologic properties among agents suggest that combinations of these drugs may provide a better pharmacologic profile than could be provided by any agent used alone.

Sodium Nitroprusside

Sodium nitroprusside is a vasodilating drug most commonly used to induce hypotension during surgery. Its onset of action is rapid, of short duration, and readily controllable. Sodium nitroprusside acts primarily on arteriolar tone; only 65 to 70 percent of arterial sodium nitroprusside is recovered in venous plasma. [53]

Studies on the cardiovascular effects of sodium nitroprusside have yielded contradictory results. Some studies report an increase in heart rate and cardiac output with no change in stroke volume. [54] [55] Yet others report either no change in cardiac output [57] [58] [59] or a decrease. [60] [61] However, sodium nitroprusside clearly has no adverse effect on myocardial contractility. [57] [58]

The different results concerning cardiac output and stroke volume probably relate to differences in circulatory volume and cardiac filling pressures before hypotension. Patients with subarachnoid hemorrhage have low circulatory volume, [62] a condition that can decrease preload and cardiac output. [61] Lawson et al [63] found that stroke volume and cardiac output increased during sodium nitroprusside-induced hypotension in deliberately overhydrated patients undergoing orthopedic surgery. The importance of circulatory volume was demonstrated by experiments in dogs in which fluid balance was shown to be an important determinant of the cardiovascular response to sodium nitroprusside. [64] When sodium nitroprusside was given, cardiac output decreased during hypovolemia but not normovolemia.

Because the intact sodium nitroprusside contains five cyanide groups, toxicity is a concern [65] (Fig. 41-2) (Figure Not Available) . The breakdown of sodium nitroprusside in the blood produces free cyanide, the concentration of which depends on the quantity of sodium nitroprusside infused. [66] Cyanide diffuses rapidly into the tissue, where it binds with high affinity to cytochrome oxidase. Such binding causes interference with electron transport and produces tissue hypoxia. Some of the cyanide ions diffuse out of the erythrocytes and are metabolized in the liver and kidney to thiocyanate, which is excreted in the urine. Bisset et al [67] challenged the concept that cyanide is released *in vivo,* arguing that any cyanide found in the blood of patients given sodium nitroprusside is caused by photodegradation of the drug *in vitro,* either before infusion or during assay of the samples. These investigators also stated that "it may well be safe to infuse quantities larger than those currently recommended."

Experiments examining the question of photodegradation concluded that cyanide measured in the blood of patients given sodium nitroprusside did not appear to be an artifact of assay methods. [68] Furthermore, degraded nitroprusside remains biologically active and may be more toxic than intact nitroprusside, as free cyanide is a product of degradation.

Shortly after the widespread use of sodium nitroprusside, reports of toxicity began to appear. [69] [70] In some of the initial reports, large concentrations of sodium nitroprusside had been infused. However, in some individual cases, younger patients appeared to show resistance to the effects of nitroprusside, and the mechanisms were sought. Studies designed to investigate the complex physiologic changes that occur whenever arterial blood pressure is decreased focused, for example, on resetting of baroreflex sensitivity in

---

Figure 41-2 (Figure Not Available) Schematic representation of the breakdown of sodium nitroprusside *in vivo.* The high affinity of cytochrome oxidase for cyanide leads to tissue hypoxia. *(Modified from Tinker and Michenfelder [65])*

control of heart rate. [71] The sympathetic nervous system and the renin-angiotensin system are activated. Also, the release of vasopressin increases. [72] Although these increases in vasopressin were greater than the increases in plasma catecholamines or plasma-renin activity during sodium nitroprusside-induced hypotension, the significance of this result remains speculative and will not be resolved until a specific antagonist of the vascular properties of vasopressin is found.

The question of resistance or tachyphylaxis to sodium nitroprusside is complex, and each of the previous possibilities needs further discussion. In one study, normal patients had significant increases in plasma levels of norepinephrine and epinephrine during sodium nitroprusside-induced hypotension. [73] This response does not occur in patients with subarachnoid hemorrhage, possibly because the adrenergic system is already maximally activated before induction of hypotension. Such activation of the adrenergic system could also contribute to the low circulatory volume found in subarachnoid hemorrhage. [62] Consequently, the hemodynamic effects of sodium nitroprusside in patients with subarachnoid hemorrhage will differ from that in normal subjects because of differences in circulatory volume and activity of the sympathetic nervous system. This increase in the plasma catecholamine level may produce resistance to the effects of sodium nitroprusside.

One study on the effect of pretreatment with propranolol 1 day before cerebral aneurysm surgery found that plasma catecholamine levels were significantly lower during surgery (including the time of deliberate hypotension) with propranolol. [74] Similarly, the intraoperative intravenous administration of incremental doses of propranolol reduced heart rate and the amount of sodium nitroprusside necessary to maintain hypotension. [75]

The renin-angiotensin system is also activated when hypotension is induced with sodium nitroprusside. Infusion of sodium nitroprusside increased plasma-renin activity in rats 4-fold. [76] When the production of angiotensin II was inhibited by saralasin, arterial blood pressure decreased further. Subsequently, Khambatta et al [77] reported a 5-fold increase in plasma renin activity in patients made hypotensive with sodium nitroprusside. Because the renin-angiotensin system plays an important role in tachyphylaxis to sodium nitroprusside-induced hypotension, two approaches use this system to circumvent the problem.

The first approach is based on the fact that the renin response was attenuated (but not abolished) when patients were pretreated with propranolol for 1 day before surgery. [78] Furthermore, the dose of sodium nitroprusside necessary to produce hypotension was reduced, and rebound hypertension did not occur on

discontinuation of the drug. The second approach tries to inhibit the renin-angiotensin system directly by pretreating patients with a single oral dose of captopril, a drug that prevents conversion of angiotensin I to angiotensin II. [79] The dose of sodium nitroprusside needed to produce the same degree of hypotension was one-fifth that needed for untreated patients. In addition, the desired level of hypotension was easier to maintain, and rebound hypertension did not occur on discontinuation of sodium nitroprusside.

Because of the decreased requirement for sodium nitroprusside, pretreatment with captopril resulted in significantly lower plasma levels of cyanide. Converting-enzyme inhibition can also be done by IV administration of enalaprilat (2.5 mg) 60 minutes before hypotension is started. [80]

Investigators have sought other causes of resistance to the effects of sodium nitroprusside. Grayling et al [81] found that free cyanide can cause contraction of an aortic ring after the ring has been contracted by norepinephrine and then relaxed by sodium nitroprusside. If this phenomenon occurs in humans, then as the plasma level of cyanide increases, an increasing dose of sodium nitroprusside would be necessary to produce a comparable degree of relaxation. A potentially lethal cycle could thus begin.

Aging also plays an important role in the response to sodium nitroprusside. Early reports of resistance to sodium nitroprusside involved younger patients. Wood et al [82] studied 16 patients 18 to 76 years of age. The vasodepressor effect of sodium nitroprusside was enhanced in the elderly (Fig. 41-3) (Figure Not Available) . Plasma norepinephrine and epinephrine concentrations were similar for both groups. This increased sensitivity to sodium nitroprusside may be owing in part to resistance of cardiac adrenergic receptors to catecholamine stimulation as a consequence of reduced affinity to beta-adrenergic receptors.

Because the question of resistance to tachyphylaxis to sodium nitroprusside is so complex, guidelines for the administration of this agent should be followed to prevent toxicity. Simply titrating sodium nitroprusside against arterial blood pressure alone cannot be justified. Accurate knowledge of dose, rate of administration, and total dose given is prerequisite to the use of sodium nitroprusside. The recommended maximum dosages of 1.5 mg/kg for acute administration and 0.5 mg/kg/h (8 mug/kg/min) for chronic administration appear to be safe. [83]

Data on the effects of sodium nitroprusside on CBF during controlled hypotension are inconsistent. Some studies reported no change in CBF from baseline. [84] [85] [86] Other studies reported that CBF decreased [87] [88] [89] or, along with ICP, increased (in animals and neurosurgical patients). [90] [91] The reasons for these conflicting results are not easy to determine; differences in species, anesthetic technique, and baseline conditions may play a role. Delayed measurement

Figure 41-3 (Figure Not Available) Plotting the age of 16 patients against change in mean arterial pressure (BP) per mug/kg/min dose of sodium nitroprusside (SNP) shows that the elderly need less SNP than the young to produce the same degree of deliberate hypotension. *(From Wood et al [82])*

of CBF after the start of sodium nitroprusside may be the reason that early changes in flow are not observed.

One study showed the importance of the degree of hypotension induced by sodium nitroprusside on cerebral blood flow. [92] Initially, when sodium nitroprusside was given to decrease MAP moderately, CBF also increased. However, as larger doses of sodium nitroprusside were administered to decrease MAP further, CBF remained near its baseline value until MAP reached 65 mm Hg. When MAP fell below this level, the pressure-flow relationship was linear.

In rats the effects of profound hypotension (MAP of 30 mm Hg for 30 minutes), using trimethaphan or sodium nitroprusside CBF on basal cerebral blood flow was investigated. [93] Hypotension induced with nitroprusside caused a smaller reduction in CBF. EEG activity, which indicates continuing neuronal function, was maintained for longer in the nitroprusside group.

Impairment or loss of autoregulation of CBF is a primary concern when hypotensive agents are used in neurosurgical anesthesia. Clearly, sodium nitroprusside impairs autoregulation in normal animals. [92] Impairment of autoregulation by sodium nitroprusside precludes any modulation of CBF in response to acute alterations in systemic arterial blood pressure. Under these circumstances, the intracranial contents not only are subjected to the specific pharmacologic activity of these drugs but will also closely reflect changes in the systemic circulation.

Nitroglycerin

Nitroglycerin directly dilates venous capacitance vessels. [94] It has a short half-life and no clinically significant toxic metabolites. The effect of nitroglycerin on cardiac output is variable. Although most studies suggest that cardiac output does not change, this result may depend on the volume status of the patient. Although both resistance and capacitance vessels are dilated, nitroglycerin has its major effect on the latter. Because capacitance of the venous circulation increases markedly with nitroglycerin, cardiac output may decrease if preload is compromised. [95] However, the effect of reduced preload would be offset by an increase in nervous sympathetic activity, elicited through baroreceptor activity and resulting in increased heart rate and myocardial contractility. [96] The baroreceptor reflex mechanism would also counteract the decrease in SVR, resulting in a biphasic response (initial arteriolar vasodilation followed by vasoconstriction in the mesenteric, iliac, coronary, and systemic beds). [97]

Because the adrenergic response will be partially blocked by anesthesia, the cardiovascular effects of nitroglycerin will be different in anesthetized subjects. [96] Recent research indicates that cardiac index is lower when MAP is decreased to 40 mm Hg with nitroglycerin rather than sodium nitroprusside. [40] Yaster et al [98] studied 14 patients 9 to 14 years of age. Mean arterial blood pressure was reduced to 55 mm Hg or less by infusion of sodium nitroprusside or nitroglycerin. At infusion rates as high as 40 mug/kg/min, nitroglycerin was not able to produce rapid, predictable, and sustained decreases in arterial blood pressure during general anesthesia. Nitroglycerin did not decrease MAP below 60 mm Hg in six of the eight patients studied.

The decrease in blood pressure with sodium nitroprusside is more rapid. Significant differences also seem to exist on discontinuation of the two drugs. Significant rebound hypertension frequently occurs after acute termination of sodium nitroprusside, [77] whereas acute termination of nitroglycerin has produced a prolonged period of vasodilation in animals. [99] As with sodium nitroprusside, low intracranial compliance contraindicates the use of nitroglycerin prior to opening of the dura mater. [100] Even when the dura has been opened, both nitrates incur some risk of increased cerebral blood volume and significant brain swelling. [101] Differences between sodium nitroprusside and nitroglycerin clearly exist. Although both drugs are able to decrease arterial blood pressure, the effect of sodium nitroprusside is more rapid and consistent.

Hydralazine

Hydralazine, a smooth muscle relaxant, effectively induces hypotension when low concentrations of enflurane are administered. [102] Hydralazine significantly reduces SVR without changing cardiac output, pH, or venous admixture. Rebound hypertension does not occur, and ICP increases significantly. [102]

Purine Derivatives

A natural substance that produces hypotension would be an attractive alternative to the previously discussed drugs. Both adenosine triphosphate (ATP) and adenosine meet these criteria. [103] Adenosine triphosphate rapidly degrades into adenosine and phosphate, adenosine being the component producing vasodilation. Adenosine is metabolized to uric acid; the amount is in dispute. [104] Hypotension occurs rapidly, owing to marked dilation of resistance vessels, the subsequent hyperkinetic circulation, and an increase in cardiac output. Plasma-renin activity and plasma catecholamines do not increase. [105] [106] Similar degrees of hypotension can be achieved as with sodium nitroprusside, but recovery is more rapid, and no rebound hypertension occurs. [8] [104] Unfortunately, ATP and adenosine dilate cerebral vessels, increase CBF, increase ICP when intracranial compliance is low, and impair cerebral autoregulation [104] [107] [108] (Fig. 41-4) (Figure Not Available) .

Adenosine is a potent coronary vasodilator that can produce an unfavorable redistribution of coronary blood flow, leading to ischemia. Some patients with coronary artery disease have shown signs of ischemia during administration of adenosine. [109] Administration through a central venous catheter is advocated to increase

efficacy of the drug. With peripheral administration, partial breakdown of the drug occurs before it can reach the arteriolar vascular smooth muscle. As a result, drug requirements are 40 percent higher. The dose requirement can be reduced by concomitant administration of dipyridamole, which inhibits adenosine uptake, primarily by blocking carrier-mediated diffusion into cells. [105] Another potential disadvantage of adenosine and ATP is their ability to cause heart block. [110]

Figure 41-4 (Figure Not Available) Changes in cerebral blood flow (DeltaCBF) after acute increases in mean arterial pressure (MAP) before, during, and after adenosine triphosphate (ATP)-induced hypotension demonstrate that cerebrovascular reactivity is normal before hypotension but impaired during and after hypotension. Specifically, five anesthetized baboons had acute increases in MAP of approximately 20 mm Hg (by means of intravenous administration of angiotensin II amide) at three times: before ATP-induced hypotension; during infusion of ATP, once MAP had decreased to approximately 40 percent of control; and after infusion of ATP, once CBF had returned to control. Mean values ±SD. * $P < .05$; ** $P < .01$. *(Modified from Van Aken et al [104])*

Trimethaphan

Ganglionic blockade has long been the mainstay of deliberate hypotension. Hypotension results from occupation of the receptor sites and stabilization of the postsynaptic membrane, both of which block neural transmission through the autonomic ganglia. Because autonomic ganglion-blocking drugs such as trimethaphan lack selectivity, both parasympathetic and sympathetic activity are depressed. Parasympathetic depression produces unwanted effects like tachycardia, mydriasis, cycloplegia, reduced gastrointestinal tone and motility, and urinary retention.

Trimethaphan has maintained some popularity because of its short half-life (1-2 minutes), owing to rapid inactivation by plasma cholinesterase with subsequent renal excretion. This characteristic makes it easy to control blood pressure. Potential problems include histamine release (related to the rate of infusion), bronchospasm, tachyphylaxis, and potentiation of succinylcholine-induced myoneural blockade. [111] Trimethaphan seldom increases ICP, as ganglionic blockade generally does not affect the cerebral circulation. However, trimethaphan may increase ICP when rapidly infused during low intracranial compliance (possibly because of histamine release). In addition, cerebral ischemia has occurred in dogs given trimethaphan to induce hypotension to a MAP of 55 mm Hg. [112] These results contrast with the safety of comparable levels of hypotension produced by sodium nitroprusside, nitroglycerin, adenosine, and isoflurane, presumably because these drugs are cerebral vasodilators. It should be noted that dilation of the pupils is a pharmacologic

property of trimethaphan caused by blockade of the ciliary ganglion. This effect might erroneously be attributed to cerebral ischemia by those unfamiliar with the drug.

Combined Therapy (Sodium Nitroprusside and Trimethaphan)

Large doses of sodium nitroprusside can produce cyanide toxicity. Large doses of trimethaphan may result in prolonged hypotension. To avoid these problems, the use of a 10:1 mixture of trimethaphan and sodium nitroprusside has been advocated. This ratio was proposed because of the relative potencies of the two agents. The mixture proved to be an efficient and rapid hypotensive agent with the potential for rapid recovery; also, the total dose of sodium nitroprusside could be reduced substantially. [113]

Miller et al [114] compared sodium nitroprusside with a 10:1 trimethaphan-sodium nitroprusside mixture in 20 patients undergoing neurosurgical procedures. Controlled ventilation kept arterial carbon dioxide partial pressure (Pa_{CO_2}) at 25 to 30 mm Hg. Cardiac output was significantly lower with the mixture than with sodium nitroprusside alone. However, the total dose of sodium nitroprusside needed to produce a similar degree of reduction in blood pressure was five times lower with the mixture. This type of combined therapy might be beneficial for prolonged periods of hypotension.

Phentolamine

Phentolamine decreases MAP by blockade of alpha-adrenergic receptors within 2 minutes of intravenous administration. Blood pressure returns to control values within 15 minutes. Intracranial pressure does not change significantly, but cerebral perfusion pressure is lower for 10 minutes after drug administration. [115]

Urapidil

Urapidil, an antihypertensive drug not available in the United States, has two mechanisms of action: antagonism of peripheral alpha-adrenergic receptors and interaction with 5-hydroxytriptamine$_{1A}$ receptors in the brain. This pharmacologic profile explains the vasodilation and lack of significant sympathetic activation observed during administration of urapidil. [116] Intracranial pressure and compliance have not been affected in animals or patients given urapidil. [117] [118] Cerebral blood flow of baboons did not change when MAP was decreased from 107 ± 13 to 70 ± 13 mm Hg with urapidil. [119] A greater degree of hypotension could not be achieved by increasing the dose. Rebound hypertension did not occur. Urapidil seems to be a suitable agent for the induction of moderate degrees of hypotension (MAP of 70 mm Hg). Administration of urapidil with isoflurane in animals has attenuated the undesirable effects and diminished the required concentration of the volatile anesthetic. [48] This technique is often used in clinical practice in Europe.

Esmolol

Esmolol is a short-acting cardioselective intravenous beta-adrenergic receptor-blocking drug having a very rapid onset of action (Ch. 14). [120] It has been used by itself to decrease blood pressure [26] [121] [122] or in combination with other drugs. [123] In contrast to sodium nitroprusside-induced hypotension, plasma renin activity decreased slightly during esmolol-induced hypotension. This absence of renin release improved the stability of hypotension. [123]

One study on 30 patients undergoing resection of arterio-venous malformations with deliberate hypotension showed the potential of esmolol to produce marked myocardial depression. [122] Patients were randomly assigned to receive isoflurane (
4%), sodium nitroprusside (
8 mug/kg/min), or esmolol (
24 mg/min) for a 20 percent reduction in MAP to 60 to 65 mm Hg. Esmolol was associated with a 39 percent decrease in cardiac output, which, because of a 22 percent increase in SVR, far exceeded the reduction in MAP. The increase in SVR occurred despite a 32 percent decrease in plasma-renin activity. In contrast, with sodium nitroprusside or isoflurane, the decrease in MAP was accompanied by a decrease in SVR of similar magnitude but no change in cardiac output (Fig. 41-5). (Figure Not Available) Plasma-renin activity increased 48 percent with sodium nitroprusside and 126 percent with isoflurane. Heart rate increased 13 percent with sodium nitroprusside, did not change with isoflurane, and decreased 23 percent with esmolol. Because of its potential for marked myocardial depression, it seems prudent to combine esmolol with other drugs or to use it when only modest reductions in blood pressure are required.

Labetalol

Labetalol produces hypotension by blocking both alpha$_1$- and beta$_1$-receptors (Ch. 14). Labetalol also blocks beta$_2$-receptors. As a result of decreases in cardiac output and peripheral vascular resistance, blood pressure decreases promptly after intravenous administration of labetalol. Although the peak effect of intravenous labetalol occurs within 5 minutes, its half-life is relatively long (4 hours) compared with that of sodium nitroprusside or nitroglycerin. [124]

Hypotension induced with labetalol produces only minimal increase in intrapulmonary shunting and no increase in heart rate, whereas both variables increase significantly with sodium nitroprusside. [124] Combining labetalol with inhalation agents such as halothane and isoflurane produces a remarkable hypotensive synergism; labetalol is less potent in this regard when combined with intravenous anesthetics. [125] An important advantage of labetalol is the absence of any increase in ICP, even when intracranial compliance is reduced. [126] Experiments in rats showed that blood flow to vital organs was significantly better when the hypotensive agent was isoflurane combined with labetalol rather than isoflurane alone. [127] A study on patients also confirmed that preservation of renal blood flow was superior with labetalol. [49] The same investigators also showed that hypotension induced by labetalol with isoflurane anesthesia did not cause more impairment of mental functions than normotensive general anesthesia. [128] However, clinicians should be

Figure 41-5 (Figure Not Available) Percentage change from baseline for hemodynamic variables and plasma-renin activity (PRA) during hypotension induced by esmolol, sodium nitroprusside, or high-dose isoflurane in 30 patients undergoing resection of intracranial arteriovenous malformations. For mean arterial blood pressure (MAP) and heart rate (HR), *n* = 10 for esmolol and nitroprusside and *n* = 9 for isoflurane. For cardiac output (CO), central venous pressure (CVP), pulmonary capillary wedge pressure (PCWP), and systemic vascular resistance (SVR), *n* = 9 for esmolol and isoflurane and *n* = 7 for nitroprusside. For plasma renin activity, *n* = 8 for all groups. *Significantly (*P* < .05) different from the other two groups. *(From Ornstein et al [122])*

aware that labetalol masks the adrenergic response to acute blood loss. Because of the relatively long half-life of labetalol, this effect lasts through the early postoperative period.

Nicardipine

Nicardipine is a calcium channel blocking drug that dilates peripheral, coronary, and cerebral vessels while maintaining myocardial contractility and cardiac output without tachycardia. [129] Careful titration of nicardipine infusions (10-250 mug/kg/h) is mandatory because nicardipine-induced hypotension resists conventional treatment such as phenylephrine. [130] [131]

Prostaglandin E_1

Prostaglandin E_1 (PGE_1) is another naturally occurring substance that has been evaluated as a possible hypotensive drug. One study of 14 mastectomy patients given PGE_1 reported that all but two had a decrease of approximately 40 mm Hg in arterial blood pressure, which returned to control values on termination of the drug. [132] None of these patients complained of abdominal pain, diarrhea, or other known side effects of prostaglandin infusion after recovery from general anesthesia. Renal blood flow increased, and no arrhythmias were noted. Other studies reported that local CBF and carbon dioxide reactivity were well maintained during PGE_1-induced hypotension for cerebral aneurysm surgery. [133] [134] PGE_1 appears to be a mildly hypotensive agent that may not be able to produce profound hypotension in all patients.

EFFECT OF HYPOTENSION ON ORGAN FUNCTION

Deliberate hypotension decreases arterial blood pressure by decreasing cardiac output or SVR, or both. However, a reduction in cardiac output may not be the most appropriate method because keeping cardiac output stable is crucial for maintaining blood flow to the tissues. Cardiac output should remain sufficiently high not only to provide adequate oxygen and energy substrates but also to remove metabolic waste products before their accumulation causes tissue damage. The final effect of hypotensive anesthesia on cardiac output depends on the balance of its effects on afterload, preload, myocardial contractility, and heart rate. These effects interact with homeostatic mechanisms. Other important factors include the physical state of the patient, the administration of additional drugs, and the pattern of ventilation used intraoperatively. Because deliberate hypotension is clearly designed to decrease arterial blood pressure but still preserve organ blood flow and function, it must be emphasized that decreasing blood pressure by hemorrhage also decreases organ blood flow. The use of deliberate

---

hypotension requires constant assessment of intravascular fluid volume throughout surgery, to ensure optimal organ function.

The effects of hypotension on various organ beds are complex, depending on the drugs used and the magnitude and length of hypotension. Differences in species may also be important when evaluating the many animal studies on organ function during deliberate hypotension.

Central Nervous System

Because ischemia of the brain and myocardium are the principal hazards of deliberate hypotension, the effects of arterial hypotension on the cerebral circulation (Chs. 19 and 52) are particularly important. The adequacy of cerebral perfusion during induced hypotension has been studied using clearance of radioactive xenon, electroencephalographic monitoring, and measurement of jugular venous oxygen content. [135] [136] [137] Although these tools are relatively crude measurements of cerebral function, all have shown that deliberate hypotension does not produce permanent changes in cerebral hemodynamics. Furthermore, the performance of elderly patients on psychologic tests given several days after total hip arthroplasty with deliberate hypotension did not differ from their performance before surgery. [21] The current rationale for setting the "safe" lower limit for MAP at 50 to 55 mm Hg in normothermic patients is based on the belief that this range represents the lowest MAP at which autoregulation of CBF is still in force. [136] Once MAP falls below this limit, CBF decreases in parallel with pressure. For chronically hypertensive patients, the curve for autoregulation (CBF versus MAP) shifts to the right, that is, the lowest blood pressure at which autoregulation of CBF is still in force is higher for these patients than for normotensive patients [138] (Fig. 41-6) . With effective antihypertensive therapy, however, the curve for autoregulation moves back to its normal position. [139] Sharrock et al [35] showed that induced hypotension is a safe technique for patients with medically controlled hypertension.

The factor most important to cerebral autoregulation is cerebral perfusion pressure and not blood pressure as such. Perfusion pressure is the difference between arterial input and venous outflow pressures. Because pressure in the cerebral venous system approximates ICP, cerebral perfusion pressure is usually calculated as MAP - ICP. An important consequence is that patients with increased ICP should never undergo deliberate hypotension before the dura is opened unless measurement of ICP is available before the surgical procedure. According to several investigators, normal cerebral oxygen metabolism can continue with a reduction in CBF to a value as low as 18 mL/100 g/min. A "normal" man has CBF this low when cerebral perfusion pressure decreases to 30 to 40 mm Hg. Children are able to tolerate even lower levels. When the skull is opened, cerebral perfusion pressure corresponds to MAP of approximately 30 to 40 mm Hg, measured at the level of the internal carotid artery. When such extreme hypotension is applied, the use of brain retractors should be avoided, blood oxygenation should be optimal, and the margin for error is zero. In our opinion, this situation creates an unjustifiably high risk for the patient. We believe that deliberate hypotension should not be pushed to this limit. Higher cerebral perfusion pressure is required for patients with chronic hypertension and altered cerebral autoregulation. Autoregulation may be absent in the tissue surrounding brain tumors, [140] in the acute phase of a subarachnoid hemorrhage, [141] and after brain trauma. [142]

Pinaud et al [143] studied the consequences of this very low level of hypotension in nine adults undergoing repair of cerebral aneurysms. MAP was decreased to 40 mm Hg with sodium nitroprusside. Intraoperative CBF and the cerebral metabolic rate for oxygen were measured before, during, and after hypotension. This reduction in MAP seemed to be safe for the area of the brain studied. In poorly perfused regions, however, the occurrence of local brain and cerebrospinal fluid lactic acidosis, especially in the retracted areas, might increase risk at such low pressures. Unfortunately, the study technique did not allow such a determination.

Figure 41-6 The curve for autoregulation of cerebral blood flow (CBF); that is, CBF versus mean arterial blood pressure (MAP) shifts to the right for chronically hypertensive patients. The lowest MAP at which autoregulation of CBF is still in force is higher for these patients than for normotensive patients. "Breakthrough" refers to the upper limit, in normotensive and hypertensive individuals, of autoregulation of CBF beyond which CBF suddenly increases, this upper limit being displaced toward higher pressures in hypertensive patients. [138]

Figure 41-7 (Figure Not Available) The relationship between cerebral blood flow (CBF) and arterial carbon dioxide partial pressure (Pa CO_2) at normal blood pressure and during extreme hypotension (mean arterial blood pressure of 35 mm Hg). The complete relationship between CO_2 and CBF at normotension is sigmoid in shape, but the relationship between CBF and Pa CO_2 values in the range of 20 to 70 mm Hg is virtually linear. *(Modified from Harper et al [144])*

Pa CO_2 is an important consideration during deliberate hypotension. During normotension, CBF changes linearly with Pa CO_2 when Pa CO_2 is 20 to 70 mm Hg. An increase of 1 mm Hg in Pa CO_2 produces a 2.65 percent increase in CBF. However, when a progressive degree of hypotension is induced, this relationship becomes progressively flatter, so that when the MAP falls below 50 mm Hg, CBF no longer responds to changes in Pa CO_2 [144] (Fig. 41-7) (Figure Not Available) . A partial exception may be sodium nitroprusside-induced hypotension: in one study, hypocapnia did not further reduce CBF during trimethaphan hypotension but did so with sodium nitroprusside. [145] It must be emphasized that hypocapnia reduces CBF only at moderate levels of hypotension, and that at very

Figure 41-8 (Figure Not Available) Change in cerebral blood flow (DeltaCBF) in dogs subjected to varying degrees of hypotension induced by trimethaphan or sodium nitroprusside. When cerebral perfusion pressure (CPP, which is systemic arterial blood pressure minus cerebrospinal fluid pressure) was decreased incrementally from 80 to 30 mm Hg, CBF decreased with trimethaphan but not SNP. *(Modified from Stoyka and Schutz [84])*

low blood pressures (deep hypotension) Pa CO_2 no longer influences CBF.

Whether one drug is better than another in preserving CBF is often debated. Stoyka and Schutz [84] examined the effects of sodium nitroprusside and trimethaphan in dogs subjected to a cerebral perfusion pressure of 80 to 30 mm Hg. With trimethaphan, autoregulation was lost below 60 mm Hg and CBF decreased as cerebral

perfusion pressure decreased. However, with sodium nitroprusside, CBF remained at a stable level despite the decrease in cerebral perfusion pressure (Fig. 41-8) (Figure Not Available) . Similarly, another study demonstrated that the normal ionic gradients established across cell membranes were depressed by hypotension, more so with trimethaphan than with nitroprusside. [146] Ishikawa et al [147] used Evans blue dye to examine the blood-brain barrier in dogs. Dysfunction of the blood-brain barrier was more pronounced with sodium nitroprusside than with trimethaphan. Because each of these studies used extreme degrees of hypotension, their results cannot be applied automatically to the usual clinical practice of decreasing MAP to 50 to 65 mm Hg. This level of MAP appears to keep CBF at rates adequate for the needs of the brain. For the moderate degrees of hypotension used routinely, both sodium nitroprusside and trimethaphan are equally effective. At deeper levels of hypotension, sodium nitroprusside may be preferable.

The use of isoflurane alone to induce hypotension has gained popularity. For normocapnic dogs, isoflurane appeared to offer certain advantages over other techniques commonly used to induce hypotension. [148] At low cerebral perfusion pressures (<30 mm Hg), the cerebral metabolic rate for oxygen was better preserved, suggesting cerebral protection. Isoflurane also favorably influenced the global cerebral oxygen supply/demand ratio in humans having a MAP of 50 mm Hg [149] (Fig. 41-9) (Figure Not Available) .

The data of Seyde and Longnecker [150] in rats indicate that isoflurane is not harmful to the central nervous system during hypotension. When MAP was decreased to 40 mm Hg with sodium nitroprusside, adenosine, or deep levels of isoflurane anesthesia and tissue oxygen pressures were measured, the lowest incidence of low values for tissue oxygen

Figure 41-9 (Figure Not Available) The changes in cerebral blood flow and cerebral metabolic rate for oxygen ($CMRO_2$) in 12 patients before, during, and after decrease in mean arterial blood pressure induced by isoflurane. * $P < .25$ compared with prehypotension value. *(From Newman et al [149])*

occurred with deep isoflurane. Again, current data suggest that either isoflurane or sodium nitroprusside is safe to use for deliberate hypotension.

Heart

Clinical and experimental studies demonstrate that cardiac function is better preserved with isoflurane than with equihypotensive doses of halothane or enflurane (Ch. 16) . [10] [38] [151] [152] Investigators believe that isoflurane is the volatile anesthetic most suitable for healthy patients undergoing deliberate hypotension. Experimental data indicate that the cardiovascular effects of the newly developed volatile anesthetics sevoflurane and desflurane are comparable to those of isoflurane. [153] [154] Although the low blood solubility of these drugs would allow even more rapid control of blood pressure, [155] further clinical experience and studies on potential side effects are required.

Recent clinical reports describe the successful use of continuous infusion of propofol to produce deliberate hypotension. [156] The cardiovascular effects of anesthetic doses of propofol are very similar to those of isoflurane: arterial blood pressure decreases primarily because of venodilation and a reduction of SVR. [157] However, using the cardiovascular side effects of anesthetic drugs to produce arterial hypotension may entail excessive doses that increase the risk of cardiac depression [152] [158] [159] and toxic side effects. For this reason, a technique combining anesthetic drugs with specific vasodilating drugs has recently gained popularity.

During deliberate hypotension, maintenance of an oxygen supply sufficient for the metabolic needs of the myo-cardium is of primary importance. The intact coronary circulation undergoes a high degree of pressure-flow autoregulation that is mildly disrupted by volatile anesthetic agents. [160] However, progressive systemic hypotension gradually depletes coronary vasodilatory reserve and diminishes the ability of the heart to cope with stresses that increase myocardial oxygen demand. [161] Arterial hypotension obtained with direct vasodilating drugs such as sodium nitroprusside and with the calcium channel blocker nicardipine frequently incurs reflex tachycardia. [60] [162] In addition to increasing myocardial metabolism, tachycardia shortens diastole and may thus reduce myocardial perfusion. [161]

Many drugs have been used to suppress tachycardia. The cardioselective beta$_1$-receptor antagonist esmolol decreases heart rate but has profound negative inotropic properties. [122] In combination with vasodilating drugs, however, esmolol can be used at lower doses to block reflex tachycardia, thus avoiding excessive cardiac depression. [123] A similar approach using ganglionic blocking drugs to suppress reflex tachycardia induced by nitroprusside has been effective in humans and animals. [114]

Some drugs having a unique pharmacologic profile do not induce reflex tachycardia despite their predominantly vasodilatory action. With labetalol and urapidil, reflex tachycardia in response to alpha$_1$-mediated vasodilation is counterbalanced by the drug's concomitant beta$_1$-antagonistic and central serotoninergic properties, respectively. [116] [124] Adenosine, a powerful vasodilator, directly depresses the sinus node and may also cause less tachycardia. [163]

As a compensatory mechanism to preserve myocardial perfusion at rest, the vasodilatory reserve of patients with coronary artery lesions is diminished even at normal coronary perfusion pressure. Under these circumstances, systemic hypotension will directly decrease myocardial perfusion. [164] Whether myocardial ischemia will develop as a result of hypotension depends on the concomitant changes in myocardial metabolic requirements. [165] Drugs that reduce metabolic requirements (e.g., anesthetic agents and beta$_1$-antagonists) may protect the heart from ischemia. [166] [167] Nitroglycerin can also be advantageous, as it improves perfusion to jeopardized myocardium. [168] In contrast, potent arteriolar coronary vasodilators, such as adenosine and sodium nitroprusside should be avoided unless appropriate monitoring is used because they may redistribute coronary blood flow away from ischemic myocardium, that is, cause coronary steal. [169] [170]

Controversy still exists over the ability of isoflurane, also an arteriolar vasodilator, to cause coronary steal. Clinical and experimental studies indicate that hypotension induced by isoflurane causes more regional myocardial ischemia than

halothane. [171] [172] [173] Other experimental studies, however, provide evidence against this hypothesis. [169] [174] That is, the vasodilating properties of isoflurane are weak and probably offset by the concomitant reduction in metabolic requirements. Isoflurane may even favor collateral myocardial perfusion. [175] [176]

As a general rule, however, patients with known or suspected ischemic heart disease should not undergo deliberate hypotension unless appropriate monitoring is used. For these patients, other techniques that can partially replace the use of systemic hypotension for a given indication (e.g., reduction of blood loss) must be considered.

Finally, considerable interest has developed in the combined use of deliberate hypotension and normovolemic hemodilution to reduce the requirements for perioperative autologous blood transfusion. Preliminary data from animals, however, indicate that hemodilution reduces coronary vasodilatory reserve and the tolerance to myocardial ischemia during hypotension, even in the intact coronary circulation. [177]

Lungs

Eckenhoff et al [178] noted a higher than normal carbon dioxide tension in the blood during hypotension induced with either pentolinium or trimethaphan. Measuring physiologic dead space in 25 patients, they concluded that hypotension combined with increased mean airway pressure, head-up tilt, and surgery may all lead to increased dead space. Khambatta et al [179] measured dead space in patients undergoing hypotensive anesthesia with sodium nitroprusside. They concluded that if cardiac output were maintained by replacement of intravascular fluids during induced hypotension, physiologic dead space would not increase. This conclusion is supported by Suwa et al [180] who earlier demonstrated that a decrease in cardiac output would increase dead space; this result may explain the findings of Eckenhoff et al. [178]

Oxygenation may also change during deliberate hypotension (Ch. 15) . In one study, arterial oxygenation decreased markedly with infusion of sodium nitroprusside. [181] In another study, normal subjects had a similar decrease in oxygenation and an increase in shunt fraction when sodium nitroprusside was infused. [182] For patients with chronic obstructive pulmonary disease whose shunt fractions were already increased, no change in shunt fraction could be demonstrated. The response to

infusion of nitroglycerin in both normal patients and those with chronic obstructive pulmonary disease was similar to the response to sodium nitroprusside. A third study compared hypotension induced with sodium nitroprusside versus isoflurane in 16 patients undergoing total hip arthroplasty. [183] Pulmonary shunt fraction increased with sodium nitroprusside but not isoflurane. Animal data support this clinical observation. [184]

Other effects of hypotensive agents on pulmonary function have been minimal. Trimethaphan caused a slight increase in respiratory rate and a mild degree of alveolar hyperventilation. [185] Lung mechanics did not change. Because of changes in oxygenation and possibly carbon dioxide elimination, controlled ventilation is preferable for patients undergoing deliberate hypotension.

Kidneys

Renal blood flow normally equals 20 to 25 percent of cardiac output (Ch. 18) . The renal circulation is characterized by a well-functioning autoregulatory mechanism. Renal arterioles have low resting vascular tone and therefore limited ability to dilate further in response to hypotensive drugs. The glomerular filtration rate is maintained until MAP falls below 75 mm Hg. [186] At this level, perfusion is still sufficient to meet the metabolic needs of the kidney cells, although oliguria may ensue. Because most clinical studies have demonstrated that normovolemic patients have rapid recovery of urine production on discontinuation of induced hypotension, strict maintenance of urine production during deliberate hypotension is unnecessary. [187] [188] [189]

Thompson et al [21] could find no significant changes in serum creatinine, blood urea nitrogen, or serum or urinary electrolytes for 30 patients having deliberate hypotension. Because renal dysfunction is not a frequent complication of deliberate hypotension, short periods of decreased renal flow are apparently not detrimental.

Recently Toivonen et al [49] demonstrated that kidney function is better preserved during hypotension induced with a combination of labetalol and isoflurane than with deep levels of isoflurane anesthesia alone (Table 41-3) (Table Not Available) .

TABLE 41-3 -- Effect of Induced Hypotension on Kidney Function [a]

(Not Available)

(From Toivonen at al [49])

[a] Mean values (±SEM) for urinary flow rate (UF), creatinine clearance (C_{Creat}), urine osmolality (U_{Osm}), and fractional excretion of sodium (FE_{Na}) for 10 patients in two hypotensive groups. Variables were determined during anesthesia, before the start of hypotension (before); during hypotension (during); and after anesthesia (after).

Splanchnic Circulation

Because pressure-flow autoregulation is limited in the hepatic arterial bed and probably absent in the portal venous circulation, profound changes in liver perfusion may occur during deliberate hypotension. [190] Consequently, preference should be given to drugs that preserve cardiac output during systemic hypotension. Extrinsic control of hepatic blood flow occurs primarily through alpha $_1$ -mediated vasoconstriction. [191] Baroreflex activation, surgical stress, or exogenous vasopressors will therefore decrease hepatic blood flow. [191] Autoregulation in the intestine is less pronounced than in the kidney or brain, and the circulatory control of splanchnic perfusion is poorly understood. Again, increased sympathetic nervous outflow following baroreflex stimulation induces splanchnic vasoconstriction. [192]

Clinical monitoring of the splanchnic circulation is extremely difficult. In addition, only a few animal studies provide data on splanchnic perfusion during systemic hypotension. Chronically instrumented dogs had better preservation of hepatic oxygen supply with isoflurane than with halothane or enflurane. [193] [194] Also, using a combination of intravenous adjuvants with isoflurane to induce hypotension was better at preserving hepatic blood flow than using isoflurane alone. [48] Whether some hypotensive adjuvant drugs offer advantages over others regarding homeostasis of splanchnic circulation is unknown. Finally, the combination of hemodilution and isoflurane-induced hypotension adversely affected hepatic perfusion, oxygenation, and function in acutely instrumented laparotomized pigs. [195]

Eye

Intraocular pressure consists of the combined pressure of blood and aqueous humor within the eye (Ch. 63) . When arterial blood pressure decreases, intraocular pressure also decreases. The eye has two separate systems of blood vessels: the retinal and the uveal. The uveal vessels are peculiar in possessing both precapillary sphincters and, hence, having a steady blood flow. Because the uveal system carries most of the blood supplying the eye, sudden decreases in MAP are transmitted to the eye as decreases in intraocular pressure. [196] The effect of hypotension on blood flow to the eye accounts for some of the complications of deliberate hypotension, including blurring of vision and, on rare occasion, blindness. Therefore, proper positioning with special attention to local pressure on the eyes is extremely important.

Skin and Muscle

Measurement of blood flow to skin and muscle has relied on microsphere studies in animals. As relative blood flow to skin and muscle is small, this method is suspect. Hoffman et al [197] found that blood flow to the skin of rats decreased with sodium nitroprusside, nitroglycerin, and 2 percent enflurane, whereas blood flow to skeletal muscle increased. In another study, 20 patients given sodium nitroprusside or trimethaphan to induce hypotension for middle-ear surgery had no change in lactate, pyruvate, or standard bicarbonate with either drug. [198] Extensive clinical experience with a variety of hypotensive drugs seems to support the claim that deliberate hypotension is not injurious to these tissues, as myoglobinuria, skin necrosis, and muscle weakness do not occur.

However, experimental studies report differences between sodium nitroprusside and nitroglycerin regarding oxygen pressure in muscle. Hauss et al [199] found that the oxygen pressure in canine skeletal muscle decreased markedly with sodium nitroprusside but not nitroglycerin. These investigators suggested that sodium nitroprusside but not nitroglycerin severely impairs autoregulation of the microcirculation. This study used a surface technique and generation of a histogram to assess oxygen pressure in tissue. Some investigators believed this method is too crude and, because of the size of the electrode used, does not give an accurate estimate of tissue oxygenation.

When Endrich et al [200] used more complex methods to compare the effects of sodium nitroprusside versus nitroglycerin on striated hamster muscle, they also found significant differences. Endrich and coworkers not only examined tissue oxygenation but also measured microvascular pressures, vascular diameters and density, and blood cell velocity, in addition to visualizing the microvasculature directly. Although both sodium nitroprusside and nitroglycerin affected resistance vessels similarly, venous capillaries dilated only in response to nitroglycerin. Accordingly, the pressure difference between the arterioles and the venules, which determines capillary perfusion, did not change with nitroglycerin but decreased significantly with sodium nitroprusside (Fig. 41-10) (Figure Not Available) . Furthermore, a significant amount of blood was diverted through arteriovenous shunts during sodium nitroprusside-induced hypotension. This mechanism probably explains why tissue oxygenation decreased with sodium nitroprusside but not with nitroglycerin. Endrich et al [200] concluded that nitroglycerin has a distinct advantage over sodium nitroprusside. Unfortunately, the desired degree of hypotension cannot always be achieved with nitroglycerin.

CLINICAL CONSIDERATIONS

When considering the many facets of deliberate hypotension, the concern of the anesthesiologist should be directed toward not only selection of the most appropriate hypotensive drug but also the type of surgery, length of procedure, need to decrease blood loss, and patient suitability.

Indications and Contraindications

Many circumstances and conditions indicate the possible need for deliberate hypotension: neurosurgery, large orthopedic procedures such as total hip arthroplasty or complicated back surgery, surgery on large tumors, surgery of the head and neck, and a variety of plastic surgical procedures. Deliberate hypotension has also been used when religious beliefs preclude blood transfusion. [201] As mentioned, positioning the patient may be as important in controlling bleeding as decreasing arterial blood pressure. Before beginning a surgical procedure, the logistics of patient positioning should be discussed by the anesthesiologist and surgeon.

Figure 41-10 (Figure Not Available) The pressure in arterioles and collecting venules of hamsters before, during, and after hypotension was induced with either sodium nitroprusside (SNP) or nitroglycerin (NTG). Numbers in parentheses indicate the diameters of the vessels studied. h70 and h40, mean arterial blood pressure of 70 and 40 mm Hg, respectively; 10 ph, 10 minutes after hypotension. *(From Endrich et al [200])*

The contraindications to deliberate hypotension have relaxed over the years. Better drugs and monitoring and more experience with the technique have permitted more patients to benefit from deliberate hypotension during surgery. Even when a clear indication for deliberate hypotension exists, several relative contraindications must be considered. For example, a history of cerebrovascular disease, renal dysfunction, liver dysfunction, or severe peripheral claudication suggests that the patient is less likely to have good organ perfusion during hypotension. Similarly, patients with hypovolemia or severe anemia would not be suitable candidates, as their reserves for adequate organ perfusion are markedly diminished.

The decision to use deliberate hypotension in a patient with long-standing hypertension is more difficult. Strandgaard [202] studied 13 untreated or ineffectively treated hypertensive patients (MAP of 145 mm Hg). Blood pressure was decreased by trimethaphan and head-up tilt. The lower limit of CBF autoregulation was higher for these patients (113 ± 17 mm Hg) than for similarly treated normotensive patients (73 ± 9 mm Hg). The shift in the autoregulatory curve to the right for hypertensive patients puts these patients at higher risk of death and morbidity during deliberate hypotension. Treatment of hypertension returns cerebral autoregulation toward normal. [139] [202] Furthermore, deliberate hypotension seems to be safe for patients with medically controlled hypertension. [35]

The usefulness of deliberate hypotension during clip ligation of cerebral aneurysms is controversial. [203] [204] Because wall stress at any given pressure depends on the thinness of the aneurysm sac, decreasing transmural pressure in the aneurysm during manipulation theoretically decreases the potential for rupture. Therefore, either an increase in MAP or a decrease in ICP prior to opening of the skull will increase transmural pressure (which is equal to MAP - ICP), thereby increasing wall stress and the risk of rupture.

Unfortunately, review of the literature does not produce any firm conclusions regarding the usefulness of deliberate hypotension for preventing rupture of cerebral aneurysms. [203] Furthermore, there is an acceptable alternative that facilitates clipping of a cerebral aneurysm: temporary occlusion of the proximal vessel. [205] In addition, Farrar et al [206] argue that deliberate hypotension increases the incidence of vasospasm, seriously compromises borderline ischemic brain tissue, and impairs cerebral autoregulation. Thus, controlled hypotension may place focal areas and the entire brain at risk of ischemia.

It is also controversial whether patients with myocardial infarction or a history of angina should undergo deliberate hypotension. Our growing knowledge of coronary artery disease and increased ability to monitor these patients more effectively have enabled many more patients with coronary artery disease to undergo induction of deliberate hypotension.

Monitoring During Induced Hypotension

Beat-to-beat measurement of arterial blood pressure is mandatory for patients undergoing clinically significant, deliberate decreases in blood pressure. The usual practice is to insert an arterial catheter for continuous monitoring of

---

blood pressure. The catheter also allows for intermittent sampling of arterial blood for blood gas analysis. The pressure transducer should be referenced to zero and positioned at the level of the head. Electrocardiographic monitoring is essential for detecting the signs of inadequate myocardial perfusion that indicate excessive hypotension--ectopic beats and changes in the ST segment (Chs. 30 - 32) .

The correlation between end-respiratory and Pa CO_2 is unreliable during hypotension. The changes in physiologic dead space, cardiac output, and body metabolism produced by hypotensive anesthesia obscure the interpretation of end-respiratory CO_2 monitoring. Nevertheless, capnography still provides useful information during hypotensive anesthesia. For example, a sudden decrease in end-expiratory P CO_2 may be caused by a sudden decrease in cardiac output (pulmonary embolism) or by disconnection of the breathing system. Capnography may help avoid hyperventilation, which could be harmful, as the decrease in Pa CO_2 would further reduce CBF during moderate hypotension.

Pulse oximetry and temperature monitoring (especially important because body heat is lost more rapidly from dilated skin vessels) should be used routinely. If large blood loss is anticipated, a central venous line should be inserted. For long procedures, measurement of urinary output is also mandatory. Serum electrolytes, blood gases, and hematocrit level should be measured routinely.

Other monitors that could be used include evoked potentials, the EEG, and tissue pH. [207] These need further evaluation before they are used routinely. Because of the potential problems with deliberate hypotension, monitoring should be optimized for the type and length of surgery performed (Chs. 28 and 35) .

/das/book/view/29494766/875/479.html

COMPLICATIONS

The precise incidence of complications with deliberate hypotension is difficult to determine. In response to a questionnaire circulated during the early 1950s by Hampton and Little, [208] 96 deaths were reported for 27,930 responses, for an incidence of 0.34 percent. Of these deaths, 0.24 percent were attributed to anesthesia and hypotension. This initial report almost caused the abolition of deliberate hypotension in the United States. [209] However, in 1961 Enderby [210] reported 9 deaths among 9,107 cases, but only 0.055 percent of the deaths were attributed to anesthesia and hypotension. Table 41-4 summarizes the published mortality rates for various forms of deliberate hypotension. [208] [210] [211] [212] [213] [214] Mortality appears not to differ from that for all anesthetics (0.01 to 0.007%) (Ch. 22) .

Nonfatal complications, which are more common, were described several decades ago. Hampton and Little [208] reported 908 major and minor complications, for an incidence of 3.3 percent. Complications usually related to the nervous system, such as dizziness, prolonged awakening, and cerebral thrombosis. [215] For Prys-Roberts et al [38] there were two cases of cerebral damage among 15 patients. One 27-year-old patient had hemiplegia after surgery, and a 56-year-old patient who failed to regain consciousness was found to have extensive cerebral and cerebellar infarction. Way and Clarke [216] reported 1 death (cerebral artery thrombosis) among 50 patients undergoing deliberate hypotension. For Linacre, [217] no cerebral complications occurred among 1,000 patients. In another series, retinal thrombosis occurred in 3 of 27,930 patients. [218] Comparable series of patients undergoing present-day techniques to induce hypotension have not been reported. Other potential complications include anuria and oliguria. The more recent literature does not contain reports of these complications, with the exception of postoperative bleeding into the operative site. [31]

Current data indicate that hypotension of 50 to 65 mm Hg is safe for young healthy patients. Unfortunately, many of the most appropriate candidates for deliberate hypotension have underlying organ dysfunction that cannot be appreciated easily by routine examination. Certainly these patients are at risk of complications related to hypotension. Thus all candidates for deliberate hypotension should undergo thorough and complete examination before surgery. The decision to use deliberate hypotension should not be made in the operating room without careful consideration of the potential complications.

SUMMARY

Deliberate hypotension is effective in decreasing blood loss and providing better visibility in the surgical field. Many drugs and techniques have been successful in lowering arterial blood pressure. The mechanisms of action of these drugs differ and produce complex changes in reflexes and, subsequently, blood flow to various organs. Because deliberate hypotension is not without risk, the advantages and disadvantages must be considered.

For the healthy young patient, complications are rare. The elderly and those with underlying organ dysfunction are probably at higher risk. Therefore, the anesthesiologist must assess each patient carefully so that the decision to use deliberate hypotension is based on reason. The intelligent use of deliberate hypotension has distinct advantages for certain procedures and may promote surgical success.

TABLE 41-4 -- Mortality in Deliberate Hypotension

INVESTIGATORS	YEARS	DELIBERATE HYPOTENSION (NO. OF PATIENTS)	DEATHS (NO. [%])
Hampton and Little (1953) [208]	1950-1953	27,930	96 (0.34)
Enderby (1961) [210]	1950-1960	9,107	9 (0.10)
Larson (1964) [211]	1958-1964	13,264	113 (0.10)
Enderby (1980) [212]	1960-1976	9,256	2 (0.02)
Pasch and Huk (1986) [213]	1977-1984	1,802	1 (0.06)
Enderby (1985) [214]	1950-1979	20,558	10 (0.04)

Chapter 42 - Spinal, Epidural, and Caudal Anesthesia*

David L. Brown

INTRODUCTION

Neuraxial blocks (spinal, epidural, and caudal) result in sympathetic block, sensory analgesia, and motor block (depending on dose, concentration, or volume of local anesthetic) after insertion of a needle in the plane of the centroneuraxis. Despite these similarities, there are significant physiologic and pharmacologic differences. Spinal anesthesia requires a small mass (i.e., volume) of drug, virtually devoid of systemic pharmacologic effect, to produce profound, reproducible sensory analgesia. In contrast, epidural anesthesia necessitates use of a mass (i.e., large volume) of local anesthetic that produces pharmacologically active systemic blood levels, which may be associated with side effects and complications unknown with spinal anesthesia. The introduction of combined spinal and epidural techniques blurs some of these differences but also adds flexibility to clinical care.

The blurring of differences between spinal and epidural anesthesia began early, when Corning reported on spinal anesthesia and local medications of the cord (Ch. 1) [1] . It remains unclear whether his injection of cocaine "between spinous processes" produced spinal or epidural anesthesia. It was clear that Bier understood he was producing spinal anesthesia in 1898, and through self-investigation of spinal anesthesia he had personal knowledge of the symptoms of postdural puncture headache. These early years were principally involved with the advancement of spinal rather than epidural anesthesia for at least three reasons. First, the only practical local anesthetic available until 1904 (when procaine was synthesized) was cocaine, which was more suited to spinal than epidural anesthesia because of systemic side effects at doses required for each. Second, the equipment available for neuraxial blocks favored spinal anesthesia because the end point of cerebrospinal fluid (CSF) return was well defined and did not demand sophisticated glass syringes and needles required for epidural anesthesia. Third, muscle relaxants had not been introduced, and spinal anesthesia produced superb skeletal muscle relaxation facilitating surgical exposure.

These advantages of spinal anesthesia historically created many enthusiastic clinicians. Morton promoted high spinal anesthesia for surgical procedures carried out on the head and neck, whereas Koster used total spinal blockade for thoracic and intracranial procedures. [2] [3] Spinal anesthesia was not limited to surgical conditions but was touted for the treatment of medical conditions (e.g., pulmonary edema) by taking advantage of its venodilatory effect. Still, a number of impediments have prevented more widespread use of spinal and epidural blocks.

Despite the many advantages and safety of spinal anesthesia, Kennedy et al in 1950 described "grave spinal cord paralysis" accompanying the use of spinal anesthesia; this report was followed by one in 1954 detailing the well-publicized Woolley and Roe trial in England. [4] [5] In the latter instance, two patients, Woolley and Roe, had neurologic injury after receiving their spinal anesthetics, which were administered in the same hospital, on the same day, by the same anesthetist in 1947. The exact cause of their neurologic dysfunction remains cloudy: was it contaminated ampules or a toxic substance administered into the subarachnoid space by mistake? [6]

Anesthesiologists continue to face confusion about balancing the risks and benefits of spinal anesthesia, specifically those involving continuous spinal anesthesia or the use of 5 percent lidocaine. The U.S. Food and Drug Administration (FDA) withdrew some spinal catheters in 1992 owing to concerns over a perceived association between the small-bore catheters and development of cauda equina syndrome. [7] This decision appears to have been made with as many political implications as scientific ones. Since that time, attention turned to the question of what are safe variables for the use of intrathecal 5 percent lidocaine. [8] [9]

** See Appendix 1, practice Guidelines for Active Pain Management in the Perioperative Setting, Practice Guidelines for Chronic for Chronic Pain Management, and Practice Guidelines for Obstetrical Anesthesia*

Other impediments to the effective use of neuraxial blocks are the predictable decreases in arterial blood pressure and heart rate through the accompanying sympathectomy with its attendant vasodilation and blockade of cardioaccelerator fibers. Maintaining arterial blood pressure and heart rate at normal values during these blocks often requires administration of vasoactive drugs and intravenous fluids. The extent to which these steps are necessary are discussed later.

Another clinically important impediment to successful use of these blocks is the idea that the "blocks should do it all." It seems unreasonable to expect a single injection of local anesthetic into either the subarachnoid or epidural space to provide ideal conditions for all patients undergoing varied surgical procedures, even in the face of an adequate block. It seems likely that far more spinal and epidural anesthetics have failed due to inadequate intravenous sedation and anxiolysis than due to technically flawed blocks.

Evidence is accumulating that the use of neuraxial blocks, principally continuous epidural techniques to provide postoperative analgesia, may be able to decrease perioperative morbidity (Ch. 69) . These techniques may also decrease length of hospital stay and allow more efficient use of our ever-increasingly stretched health-care monies. [10] [11] [12] To gain maximum benefit and minimize complications from these blocks, attention to technique and anatomy is essential, and of course, the blocks should be utilized when the risk-benefit equation for the block is favorable. [13] [14] [15]

Indications and Contraindications

At the most basic level, neuraxial block is indicated whenever the surgical procedure can be accomplished with a sensory level of anesthesia that does not produce adverse patient outcome. The surgical procedure must include the amount and type of supplemental medications and even capacity for administering "light general anesthesia" to ensure effective sedation and anxiolysis. The level of sensory analgesia required is of prime importance. It is clear that low spinal anesthesia (i.e., a T10 or lower sensory level) carries different physiologic impact than does a block performed to produce high (T5) spinal anesthesia. [16]

There are few strong contraindications to neuraxial block. Some of the most important ones include patient refusal; patient inability to maintain stillness during the needle puncture, thus exposing the neural structures to unacceptable risk of injury; and raised intracranial pressure, which theoretically may predispose to brain stem herniation. Relative contraindications that must be weighed against the potential benefits include coagulopathy, both intrinsic and idiopathic, such as that occurring with administration of coumadin or heparin; skin or soft tissue infection at the proposed site of needle insertion; severe hypovolemia; and lack of anesthesiologist experience. The often cited relative contraindication of preexisting neurologic disease (e.g., lower-extremity peripheral neuropathy) is not usually based on medical criteria but rather on legal considerations.

When deciding between epidural and spinal anesthesia, a number of variables should be considered. Is the procedure (or surgeon's typical time) of predictable length, minimizing the need to consider a continuous catheter technique? Is the surgical procedure so short that waiting for the epidural to take effect makes spinal anesthesia more practical? Is the patient a candidate for prolonged postoperative analgesia, making a continuous epidural or combined spinal-epidural technique preferred? Can the procedure be equally well handled with either spinal or epidural anesthesia, thus allowing consideration of patient variables affecting headache incidence (e.g., age and gender)? Are there concurrent patient diseases, such as hypertrophic cardiomyopathy, that might be of concern with either technique? Will the patient be traveling a significant distance immediately after the procedure, making epidural blood patch therapy for a postdural puncture headache problematic?

These are a sampling of many questions that should be considered when contemplating the risk and benefit of neuraxial blocks.

Anatomy

Once a decision is made to utilize one of these blocks, the key feature of performing the block is combining appropriate technique with a three-dimensional understanding and tactile appreciation of anatomy.

Subarachnoid local anesthetics affect their sensory block at the spinal cord, which is continuously cephalad with the brain stem via the foramen magnum and terminates distally in the conus medullaris. This distal termination, because of differential growth rates between the bony vertebral canal and central nervous system, varies from L3 in the infant to the lower border of L1 in the adult. Most of us develop the impression that the spinal nerve roots are uniform in size and structure, yet Hogan has shown that there is a large interindividual variability of nerve root sizes. [17] These differences may help in explaining the interpatient differences in neuraxial block quality when equivalent techniques are used on seemingly similar patients. Furthermore, CSF volume is variable from patient to patient, in part due to differences in body habitus and weight. [18]

Surrounding the spinal cord in the bony vertebral column are three membranes (from within to the periphery): the pia mater, arachnoid mater, and dura mater (Fig. 42-1 and Plate 6 [see Color Atlas following Chapter 43]). The pia mater is a highly vascular membrane that closely invests the spinal cord (and brain). The arachnoid mater is a delicate nonvascular membrane closely attached to the outermost layer, the dura. Between these two innermost membranes is the space of interest in spinal anesthesia, the subarachnoid space. In this space are the CSF, spinal nerves, a trabecular network between the two membranes, and blood vessels that supply the spinal cord and the lateral extensions of the pia mater and the dentate ligaments, which supply lateral support from the spinal cord to the dura mater (Fig. 42-2 and Plate 6). [19] Although the spinal cord ends at the lower border of L1 in adults, the subarachnoid space continues to S2. The third and outermost membrane in the spinal canal is the longitudinally organized fibroelastic membrane, the dura mater (or theca). This layer is the direct extension of the cranial dura mater and extends as spinal dura mater from the foramen magnum to S2, where the filum terminale (an extension of the pia mater beginning at the conus medullaris) blends with the periostium on the coccyx (see Fig. 42-1 and Plate 9). There is a potential space between the dura mater

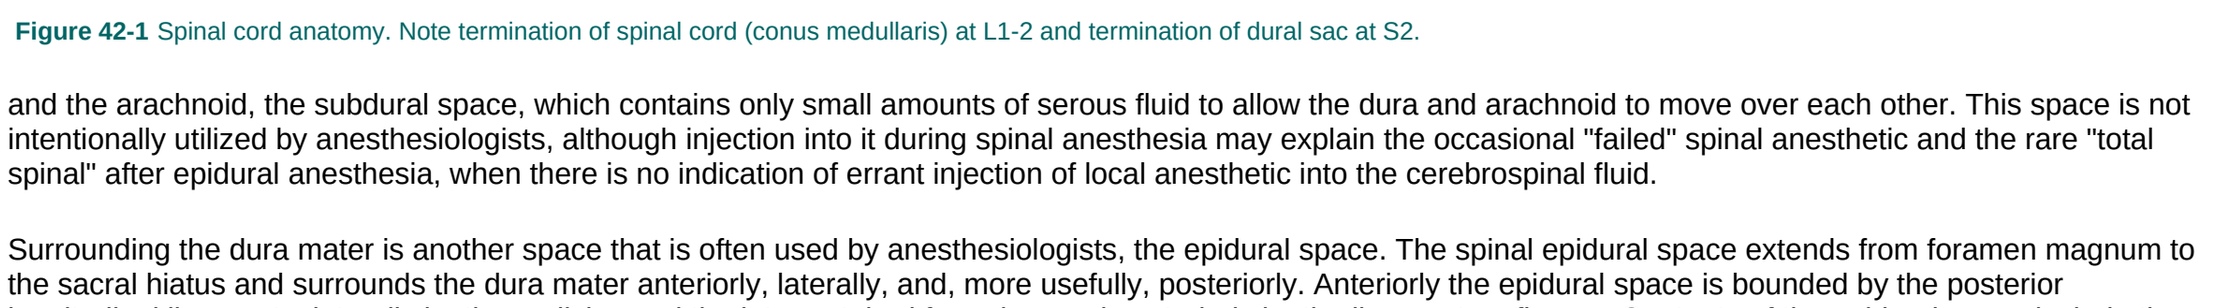

Figure 42-1 Spinal cord anatomy. Note termination of spinal cord (conus medullaris) at L1-2 and termination of dural sac at S2.

and the arachnoid, the subdural space, which contains only small amounts of serous fluid to allow the dura and arachnoid to move over each other. This space is not intentionally utilized by anesthesiologists, although injection into it during spinal anesthesia may explain the occasional "failed" spinal anesthetic and the rare "total spinal" after epidural anesthesia, when there is no indication of errant injection of local anesthetic into the cerebrospinal fluid.

Surrounding the dura mater is another space that is often used by anesthesiologists, the epidural space. The spinal epidural space extends from foramen magnum to the sacral hiatus and surrounds the dura mater anteriorly, laterally, and, more usefully, posteriorly. Anteriorly the epidural space is bounded by the posterior longitudinal ligaments, laterally by the pedicles and the intervertebral foramina, and posteriorly by the ligamentum flavum. Contents of the epidural space include the nerve roots that traverse it from foramina to peripheral locations, as well as fat, areolar tissue, lymphatics, and blood vessels, which include the well-organized Batson venous plexus. Hogan [20] suggests from frozen cryomicrotome cadaver sections that the epidural space is more

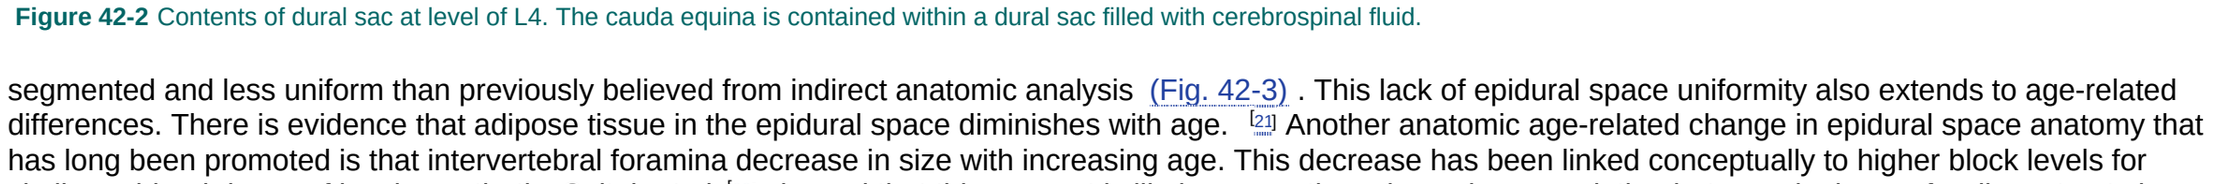

Figure 42-2 Contents of dural sac at level of L4. The cauda equina is contained within a dural sac filled with cerebrospinal fluid.

segmented and less uniform than previously believed from indirect anatomic analysis (Fig. 42-3) . This lack of epidural space uniformity also extends to age-related differences. There is evidence that adipose tissue in the epidural space diminishes with age. [21] Another anatomic age-related change in epidural space anatomy that has long been promoted is that intervertebral foramina decrease in size with increasing age. This decrease has been linked conceptually to higher block levels for similar epidural doses of local anesthetic. Saitoh et al [22] showed that this concept is likely wrong; they showed no correlation between leakage of radiocontrast via intervertebral foramina and age. When Igarashi et al and Saitoh et al data are considered together, it may be that the decrease in epidural space adipose tissue with age may dominate the age-related changes in epidural dose requirements.

Posterior to the epidural space is the ligamentum flavum (the "yellow ligament"), which also extends from the foramen magnum to the sacral hiatus. Although classically portrayed as a single ligament, it is really composed of two ligamenta flava, the right and the left, which join in the middle, forming an acute angle with a ventral opening (Fig. 42-4) and Plate 8). [20] [23] The ligamentum flavum is not uniform from skull to sacrum, nor even within an intervertebral space. The ligament thickness, distance to dura, and skin to dura distance vary with the area of vertebral canal (Table 42-1) . Additionally, the two ligamenta flava are variably joined (fused) in the midline, and this fusion, or lack of fusion of the ligamenta flava, even occurs at different vertebral levels in individual patients. [20] Immediately posterior to the ligamentum flavum are either lamina and spinous processes of vertebral bodies or the interspinous ligaments. Extending from the external occipital protuberance to the coccyx posterior to these structures is the supraspinous ligament, which joins the vertebral spines (see Fig. 42-4).

One anatomic clarification that has been made through epiduroscopy and epidurography confirms prior clinical observations

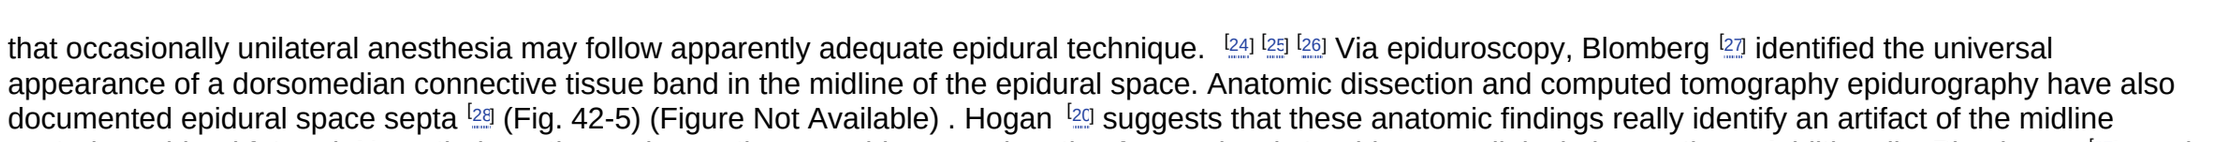

Figure 42-3 (A) Sagittal section of epidural space demonstrates that the contents of the epidural space depend on level of section. (B) Three-dimensional drawing of the epidural space shows the discontinuity of the epidural contents, but this potential space can be dilated by injection of fluid into the epidural space.

that occasionally unilateral anesthesia may follow apparently adequate epidural technique. [24] [25] [26] Via epiduroscopy, Blomberg [27] identified the universal appearance of a dorsomedian connective tissue band in the midline of the epidural space. Anatomic dissection and computed tomography epidurography have also documented epidural space septa [28] (Fig. 42-5) (Figure Not Available) . Hogan [20] suggests that these anatomic findings really identify an artifact of the midline posterior epidural fat pad. Nevertheless, these observations provide an explanation for previously troublesome clinical observations. Additionally, Blomberg [27] used fiberoptic technique to demonstrate that the subdural extra-arachnoid space is easily entered in 66 percent of autopsy attempts in humans. In spite of this being an infrequent clinical problem with epidural anesthesia, it does allow a visual understanding of subdural complications of epidural anesthesia. [29] Blomberg [27] continued his endoscopic approach to understanding neuraxial anatomy with a subarachnoid study. [30] He identified in the autopsy subjects that a distinct posterior midline membranous structure was present in lower thoracic and upper lumbar regions. He also found that fibrous attachments were present between nerve roots and other subarachnoid structures in many subjects. He postulated that these fibrous structures and attachments may help explain some variation in spinal anesthesia.

Figure 42-4 Vertebral anatomy. (A) Sagittal view. (B) Oblique view of lumbar vertebra showing ligamentum flavum thickening in the caudad extent of intervertebral space and in the midline. (C) Oblique view of single lumbar vertebra.

TABLE 42-1 -- Characteristics of Ligamentum Flavum at Different Vertebral Levels

SITE	SKIN TO LIGAMENT (cm)	THICKNESS OF LIGAMENT (mm)
Cervical	--	1.5-3.0
Thoracic	--	3.0-5.0
Lumbar	3.0-8.0 [a]	5.0-6.0 [b]
Caudal	Variable	2.0-6.0

Data from Cousins and Bromage [173] and other sources

[a] Distance is 4 cm for 50 percent of patients and 4 to 6 cm for 80 percent of patients.
[b] Within each interlaminal space the ligamentum flavum varies in thickness from cephalad to caudad: near the rostral lamina 1.3 to 1.6 mm, near the caudad lamina 6.9 to 9.1 mm.

The performance of caudal anesthesia calls for an expanded understanding of epidural anatomy and especially of the frequent variations in sacral anatomy. [31] The sacrum results from the fusion of the five sacral vertebrae. The sacral

Figure 42-5 (Figure Not Available) Anteroposterior view of lumbosacral epidural space after contrast injection. Arrow indicates a median dorsal band in the epidural space. *(From Savolaine and Pandya [26])*

hiatus, which is the failure of the laminae of S5 and usually part of S4 to fuse in the midline, is the detail of interest. This results in a variably shaped and sized inverted V-shaped bony defect, covered by the posterior sacrococcygeal ligament (a functional counterpart to the ligamentum flava). This sacral hiatus may be identified by locating the sacral cornua (the remnants of the S5 articular processes) (Fig. 42-6) . This bony defect allows access to the sacral canal, although needle insertion through this defect may be difficult because of the frequency of anatomic variation. For example, the shape of the space may vary from slit-like to a wide-based, inverted V, and in 1 of 20 patients the bony defect may be absent, precluding the caudal approach (Fig. 42-7) (Figure Not Available) . [32] [33]

The sacral canal contains the terminal portion of the dural sac, which typically ends cephalad to a line joining the posterior superior iliac spines, or S2. Variation is found in this feature as well, with the termination of the dural sac being lower in children, although the ease of palpating the sacral hiatus in children may make pediatric caudal technique easier overall. In addition to the dural sac, the sacral canal also contains a venous plexus, which is part of the valveless internal vertebral venous plexus. It is estimated from magnetic resonance (MR) imaging that in adults the volume of the caudal canal, excluding the foraminae and dural sac, ranges from about 10 mL to 27 mL. Perhaps this wide variability in volume accounts for some the variation in block height with caudal anesthesia. [31]

Once the anatomy pertinent to neuraxial blocks is understood, it is tempting to administer the blocks immediately. Nevertheless, safe conduct of spinal, epidural, and caudal anesthesia requires an appreciation for the physiologic effects of these blocks if they are to be used appropriately.

Figure 42-6 Sacral surface anatomy. An equilateral triangle can be drawn to connect the posterior superior iliac spines and the sacral hiatus. This can be useful in confirming palpation of the sacral hiatus.

Figure 42-7 (Figure Not Available) Anatomic variants of sacrum and sacral hiatus. Sacral hiatus variants. (A) Normal. (B) Longitudinal slit-like hiatus. (C) Second midline hiatus. (D) Transverse hiatus. (E) Large hiatus with absent cornua. (F) Transverse hiatus with absent coccyx and two prominent cornua and two proximal "decoy hiatuses lateral to the cornua." (G-I) Large midline defects contiguous with sacral hiatus. (J-L) Enlarged longitudinal hiatuses, each with an overlying "decoy" hiatus. *(From Willis [186])*

Physiologic Effects

The physiologic effects of neuraxial blocks are often misinterpreted as complications, which are highlighted by observers who list hypotension under complications of the techniques. [34] A clear distinction should be made between physiologic effects of an anesthetic technique and complications that imply some harm to the patient. [35] This distinction is important to determine the risk-benefit equation of the technique in question.

Cardiovascular Effects

The cardiovascular effects of neuraxial blocks are similar in some ways to the combined use of intravenous alpha $_1$ - and beta-adrenergic blockers: heart rate and arterial blood pressure decrease (Ch. 16) . The sympathectomy that accompanies the techniques is dependent upon height of the block, with the sympathectomy typically described as extending for two to six dermatomes above the sensory level with spinal anesthesia and at the same level with epidural anesthesia. [36] This result causes both venous and arterial vasodilation, but because of the large amount of blood in the venous system (approximately 75% of total blood volume), the venodilation effect predominates because of the limited amount of smooth muscle in venules, whereas the vascular smooth muscle on the arterial side of the circulation retains a considerable degree of autonomous tone. After neuraxial block-induced sympathectomy, if normal cardiac output is maintained, total peripheral resistance should decrease only 15 to 18 percent in normovolemic healthy patients, even with near total sympathectomy. In elderly patients with cardiac disease, systemic vascular resistance may decrease almost 25 percent following spinal anesthesia, whereas cardiac output decreases only 10 percent. Heart rate during high neuraxial block typically decreases as a result of blockade of the cardioaccelerator fibers arising from T1 to T4. Additionally, the heart rate may decrease as a result of a fall in right atrial filling, which decreases outflow from intrinsic chronotropic stretch receptors located in the right atrium and great veins. [36]

The clinical question of what level of arterial blood pressure decrease after neuraxial block is acceptable remains to be answered. This likely will remain speculative because conducting ethical human investigations designed to define a dose-response curve of decreased arterial blood pressure accompanying neuraxial block will be difficult.

There are some data available to help determine the extent to which arterial blood pressure should be allowed to decrease. Although there are methodologic problems with the study, * Kety et al [37] demonstrated that producing spinal anesthesia to midthoracic levels with procaine, even in patients with essential hypertension, resulted in a decrease in mean arterial pressure of 26 percent (155-115 mm Hg) accompanied by only a 12 percent (52-46 mL/100 g/min) decrease in cerebral blood flow. When the level of spinal anesthesia was purposely increased to produce higher levels of block (T4) in normotensive and hypertensive patients, the mean arterial pressure decreased by 32 percent (93-63 mm Hg) and 50 percent (158-79 mm Hg), respectively. Although cerebral blood flow was unchanged in the normotensive group (45-46 mL/100 g/min), a 19 percent decrease occurred in the apparently untreated hypertensive patients (46.5-37.5 mL/100 g/min). [38] When coronary artery blood flow and myocardial metabolism were determined in humans during spinal anesthesia to T4 in both hypertensive and normotensive patients, decreases in coronary blood flow (153-74 mL/100 g/min) paralleled the decrease in mean arterial blood pressure (119 to 62 mm Hg) and the percentage extraction of myocardial oxygen was unchanged (75-72%). The extraction of oxygen was unchanged because myocardial work, as expressed by myocardial utilization of oxygen, paralleled the decrease in mean arterial pressure and coronary blood flow (16-7.5 mL/100 g/min). [39]

These human studies are limited by cerebral and myocardial blood flow methodologies that were not limiting factors when Sivarajan et al [39A] investigated organ blood flow via microspheres in rhesus monkeys during spinal anesthesia at both T10 and T1 levels. During T10 block there was no significant change in organ blood flow; during the T1 block, with a 22 percent decrease in mean arterial pressure, cerebral and myocardial blood flows were insignificantly altered. Thus, prevention of decreases in mean arterial pressure of more than 30 percent has some basis, but these data were collected in severely hypertensive, presumably untreated patients.

For normotensive and treated hypertensive patients, a wider undocumented margin of safety probably exists.

Once arterial blood pressure decreases to a level for which treatment is believed necessary, ephedrine (a mixed adrenergic agonist) provides more appropriate therapy for the noncardiac circulatory sequelae of neuraxial block than either a pure or pure-adrenergic agonist (Ch. 16) . [40] It has long been taught that the decrease in blood pressure following neuraxial block can be minimized by administration of crystalloids intravenously prior to the block; however this logic may need rethinking. Buggy et al showed that withholding prehydration before spinal anesthesia in elderly patients undergoing elective procedures is not associated with any greater degree of hypotension or need for vasopressor therapy compared with crystalloid or colloid prehydration.

Is there any indication that epidural and spinal anesthesia differ in the effect on arterial blood pressure? A common concept is that the decrease in arterial blood pressure is more gradual and of less magnitude with epidural than spinal anesthesia of comparable levels. In spite of this belief, there is evidence that when tetracaine (10 mg) spinal anesthesia was compared with lidocaine (20-25 mL of 1.5%) epidural anesthesia, there was a larger decrease in arterial blood pressure, approximately 10 percent, with the epidural technique than with the spinal. [41] Furthermore, the proposed advantage of slower onset of epidural blockade is often mitigated by anesthesiologists administering a decreased volume of local anesthetic with the initial epidural therapeutic dose; then, when the block height does not rise as rapidly as desired, additional epidural local anesthetic is administered and a higher block than necessary may result. The extent to which arterial blood pressure decreases with either technique is obviously dependent on multiple factors, including patient age and intravascular volume status.

Respiratory Effects

Alterations in pulmonary variables in healthy patients during neuraxial block are usually of little clinical consequence. Tidal volume remains unchanged during high spinal anesthesia, and vital capacity decreases a small amount from 4.05 to 3.73 L. [42] This decrease in vital capacity is a result of a decrease in expiratory reserve volume related to paralysis of abdominal muscles necessary for forced exhalation, rather than a decrease in phrenic or diaphragmatic function. [16] This minimal impact on pulmonary function also holds for elderly patients undergoing lumbar and thoracic epidural anesthesia. [43] Pulmonary function testing in cesarean section patients undergoing epidural anesthesia shows that using lidocaine provides larger decrements in peak expiratory pressure (abdominal musculature dependent maneuver) than using bupivacaine. [44]

The rare respiratory arrest associated with spinal anesthesia is also unrelated to phrenic or inspiratory dysfunction, but rather, is related to hypoperfusion of the respiratory centers in the brain stem. Supportive evidence for this concept is observed after resuscitation, when apnea almost always disappears as soon as pharmacologic and fluid therapies have restored cardiac output and blood pressure. This would not be the case if phrenic paralysis due to high levels of local anesthetic were the cause of apnea. [16] There is experimental evidence in rabbits that during epidural anesthesia their response to hypoxia results in apnea, which is different than the response without neuraxial anesthesia. [45] This finding may have implications for understanding some episodes of cardiovascular depression during neuraxial blocks in humans, although confirmation is needed. Conversely, in a canine model of hypoxia epidural anesthesia and hypoxic challenge results in the same outcome but with more normal acid-base function, compared to animals receiving general anesthesia alone. [46]

Neuraxial block should be used cautiously in respiratory cripples because of paralysis of respiratory muscles. Except for the severely compromised patient with respiratory failure, inspiratory muscle function during neuraxial blocks

*Cerebral blood flow (CBF) studied with nitrous oxide; only global CBF measured; patients studied were severely hypertensive (i.e., average mean arterial blood pressure was 155 mm Hg).

should be adequate to maintain ventilatory function. The physiologic consideration related to muscle paralysis with neuraxial block should focus on the expiratory muscles in these severely compromised patients because these muscles are important for effective coughing and clearing of intrapulmonary secretions. [36] [42]

Gastrointestinal Function

Another organ system affected during neuraxial block is the gastrointestinal (GI) tract. Nausea and vomiting may be associated with neuraxial block in up to 20 percent of patients and is primarily related to GI hyperperistalsis due to unopposed parasympathetic (vagal) activity. [47] Accordingly, atropine is effective in treating nausea associated with high (T5) subarachnoid anesthesia. [48] [49] This GI hyperperistalsis has the advantage of providing excellent surgical conditions because of a contracted gut. [50] An often cited advantage of regional anesthesia in patients with compromised GI function (e.g., hepatic dysfunction) is that less physiologic impairment is possible as compared with general anesthesia. Nevertheless, it appears that if intra-abdominal surgery is performed, the magnitude of decrease in hepatic blood flow parallels the site of operation, rather than anesthetic technique chosen. Additionally, the decrease in hepatic blood flow during spinal anesthesia parallels the decrease in mean arterial blood pressure. [51] When epidural analgesia is continued into the postoperative period, there may be a protective effect on the gastric mucosa because intramucosal pH is higher during postoperative epidural analgesia than with systemic analgesia. [52]

Renal Function

Renal function has a wide physiologic reserve. Despite predictable decreases in renal blood flow accompanying neuraxial block, the decrease is of little physiologic importance. [53] One aspect of genitourinary function that is of clinical importance is the belief that neuraxial blocks are a frequent cause of urinary retention, which either delays discharge of outpatients or necessitates bladder catheterization in inpatients. It is clear that lower concentrations of local anesthetic are necessary for paralysis of bladder function than for motor nerves to lower extremities. Still, some studies do not support this belief. For example, in orthopedic patients undergoing hip replacement, it was demonstrated that bladder catheterization was no more frequent after neuraxial (spinal or epidural) block than after general anesthesia and narcotic analgesics. [54] Still, it is prudent to avoid administration of excessive volumes of crystalloid solutions intravenously to patients undergoing spinal anesthesia.

Physiologic Effects Specific to Epidural Anesthesia

The physiologic effects of epidural anesthesia are similar to those of spinal anesthesia, with the exception that local anesthetic blood levels reach concentrations sufficient

Figure 42-8 (Figure Not Available) Meperidine requirements during the first and second postoperative days in patients receiving intravenous lidocaine (shaded bars) and in control patients (open bars). Data expressed as mean ± SEM. *, $P < 0.02$; **, $P < 0.01$ compared to control data. *(Modified from Cassuto et al [55])*

enough to produce systemic effects on their own. Even intravenously administered lidocaine (resulting in blood levels similar to those following continuous epidural analgesia) can decrease postoperative narcotic requirements (Fig. 42-8) (Figure Not Available) . [55] When blood levels are excessive, adverse central nervous system and cardiovascular effects occur (Ch. 13) .

SPINAL ANESTHESIA

Technique

To perform spinal anesthesia, pertinent anatomy must be constantly kept in mind as one is inserting the spinal needle. It is often helpful for the technique to be broken down into a series of steps (the four "Ps"): preparation, position, projection, and puncture.

Preparation

Preparation of the equipment and drugs is essential for subarachnoid injection. When choosing a drug for subarachnoid injection the duration of block should be matched not only to the surgical procedure but also to patient variables. It may be more time-efficient to use a hypobaric solution in a patient in the prone-jackknife position, rather than turning the patient after a hyperbaric solution has been allowed time to take effect. Is the patient planning to go home after an outpatient procedure, thus dictating a shorter-acting drug? Will a prolonged period of lower extremity analgesia, such as that obtained from adding an opioid to the spinal drugs, be advantageous to a patient undergoing knee reconstruction and immediate postoperative use of a range-of-motion machine? These are only a few of the many clinical permutations that dictate familiarity with the combinations of drugs available for subarachnoid use.

When choosing equipment for spinal anesthesia, the initial choice involves reusable or disposable equipment. Most

Figure 42-9 Spinal needle assortment, including disposable (A) 25-gauge Whitacre, (B) 24-gauge Sprotte, and (C) 25-gauge Quincke. The first two have conical tips, and the Quincke has a cutting-tip design.

anesthesiologists are forced to accept disposable spinal trays, which may seem limiting. Still, most suppliers are willing to customize trays to meet one's preferences. Despite the emphasis on disposable trays, there is no indication that these trays shift the spinal anesthesia risk-benefit equation in the patient's favor. [56]

Spinal needles fall into two main categories: those that cut the dura and those designed to spread dural fibers. The former include the "traditional" disposable spinal needle, the Quincke-Babcock needle, and the latter contain the Greene, Whitacre, and Sprotte needles (Fig. 42-9) . If a continuous spinal technique is chosen, the use of a Tuohy or other thin-walled needle will facilitate passage of the catheter. The use of small needles reduces the incidence of postdural puncture headache, whereas the use of larger needles improves the tactile "sense" of needle placement. Also, multiple punctures probably increase the incidence of headaches. If use of a smaller needle increases the number of punctures, the difference between small and large needles in producing headaches may be reduced. There is also a decrease in postdural puncture headache incidences when a conical-tipped needle is used, even when needle sizes are comparable. [57] [58] Nevertheless, as facility with spinal anesthesia increases, the use of a smaller, similarly "tipped" needle will decrease headache incidence, if the number of dural punctures does not increase.

Position

Positioning (Ch. 26) is frequently the most poorly managed part of spinal technique for at least two reasons. First, the assistant often does not understand the rationale for positioning a patient, and second, patients are often inadequately or excessively sedated, making cooperation poor. The three primary methods of patient positioning include lateral decubitus, sitting, and prone, each with advantages in specific situations.

The lateral decubitus position is the most commonly used because it allows safe administration of more sedation and is less dependent on a well-trained assistant than with the sitting position. Patients are placed with the back parallel to the edge of the operating table nearest the anesthesiologist, with thighs flexed upon the abdomen, and the neck flexed to allow the forehead to be as close as possible to the knees. The assistant may be invaluable during this positioning, by encouraging and assisting a patient in assuming the ideal lateral decubitus position (Fig. 42-10) . The patient should be positioned so that spread of hypo-, iso-, or hyperbaric solution to the operative site is optimized.

Choose the sitting position when low lumbar and sacral levels of sensory anesthesia are adequate for the surgical procedure, such as perineal and urologic operations, or when obesity or scoliosis makes identification of midline anatomy difficult in the lateral position. When placing patients in this position, a stool can be provided as a footrest, and a pillow is placed in their lap. The assistant then maintains the patient in a vertical plane while flexing the patient's neck and arms over the pillow to open up the lumbar vertebral space (Fig. 42-11) . If the reason for choosing the sitting position is to keep the sensory level low, the patient should be maintained sitting for 5 minutes; if the choice was made because of obesity or scoliosis and a higher sensory level is needed, the patient should be put supine immediately after

Figure 42-10 Lateral decubitus positioning for centroneuraxis block. The assistant can help the patient assume the ideal position of "forehead-to-knees."

Figure 42-11 Sitting position for centroneuraxis block. The assistant provides the patient with a foot rest (stool) and a pillow and prevents the patient from slumping to either side.

subarachnoid injection, with the table manipulated appropriately. The most common error made in placing patients in this position is allowing the patient to slump, with the advantage of improved midline identification lost.

The prone position should be chosen when the patient is to be maintained in that position (often with jackknife modification) during the surgical procedure. This position is often appropriate for rectal, perineal, or lumbar procedures. An advantage of hypobaric technique is that patients can help in positioning themselves, thus minimizing the opportunity for positioning injuries. Once the patient is in position, lumbar lordosis should be minimized and, most often, the paramedian approach should be used. Also, one may have to aspirate for CSF because CSF pressures are minimized when lumbar needle insertion is carried out in this position.

Projection and Puncture

Once the equipment, local anesthetics and additives, and the patient have been properly prepared, the spinal puncture, either midline or paramedian, can be performed. The midline approach relies on the ability of patients and assistants to minimize lumbar lordosis and allow access to the subarachnoid space between adjacent spinous processes, usually at the L2-L3, L3-L4, or sometimes the L4-L5 spaces. The palpating fingers (usually index and third fingers) should identify the interspinous area by identifying the caudad extent of the more cephalad spine and the midline by rolling the fingers medial to lateral (Fig. 42-12) . A subcutaneous skin wheal is developed overlying this space and the introducer is inserted into the substance of the interspinous ligament. The introducer is grasped with the palpating fingers and steadied, while the other hand is used to hold the spinal needle like a dart, with the fifth finger used as a tripod against the patient's back to prevent patient movement producing unintentional insertion to a level deeper than intended. The needle, with bevel parallel to longitudinal dural fibers, is advanced slowly both to heighten the sense of tissue planes traversed and to prevent skewing of nerve roots until the characteristic change in resistance is noted as the needle passes through ligamentum flavum and dura. The stylet is then removed, and CSF should appear at the needle hub. If it does not, the needle is rotated in 90-degree increments until CSF appears. If CSF does not appear in any quadrant, the needle should be advanced a few millimeters and rechecked in all four quadrants. If CSF still has not appeared, and the needle is at a depth appropriate for the patient, the needle and introducer should be withdrawn and insertion steps repeated, recognizing that the most common reason for lack of CSF return is that the needle is being inserted off the midline. Another common error preventing subarachnoid placement is too large a cephalad angulation on the initial needle insertion.

Once CSF is freely obtained, the dorsum of the anesthesiologist's nondominant hand steadies the spinal needle against the patient's back while the syringe containing the therapeutic dose is attached to the needle. CSF is again freely aspirated into the syringe and the dose injected at a rate of approximately 0.2 mL/s. After completion of the injection, 0.2 mL of CSF is again aspirated into the syringe and reinjected subarachnoid, both to reconfirm location and to clear the needle of the remaining local anesthetic. The patient and operating table should then be placed in the position appropriate for the surgical procedure and drugs chosen.

The midline approach is the technique of first choice because it requires anatomic projection in only two planes (Fig. 42-13) (Figure Not Available) and provides a relatively avascular plane. When difficulties with needle insertion are encountered with the midline approach, one option is to use the paramedian route, which does not require the same level of patient cooperation or reversal of lumbar lordosis for success.

The paramedian approach exploits the larger "subarachnoid target" that exists if a needle is inserted slightly lateral to the midline (see Fig. 42-13) (Figure Not Available) . The most common error made in utilizing the paramedian technique is that the needle entry site is placed too far off the midline, making the vertebral lamina barriers to needle insertion. In the paramedian approach, the palpating fingers again identify the caudad edge of the cephalad spinous process, and a skin wheal is raised 1 cm lateral and 1 cm caudad to this point. A longer needle (e.g., 12-inch) is then used to infiltrate deeper tissues

Figure 42-12 Spinal needle insertion. (A) The palpating fingers are "rolled" in both a side-to-side and cephalad-to-caudad direction to identify interspinous space. (B) During needle insertion, the needle should be stabilized in a tripod fashion while placed in the hand, similar to a dart being thrown.

Figure 42-13 (Figure Not Available) Vertebral anatomy of midline and paramedian approaches to centroneuraxis blocks. The midline approach highlighted in the inset requires anatomic projection in only two planes: sagittal and horizontal. The paramedian approach shown in both the inset and the posterior view requires an additional oblique plane to be considered, although the technique may be easier in patients who are unable to cooperate in minimizing their lumbar lordosis. The paramedian needle insertion is made 1 cm lateral and 1 cm caudad to the caudad edge of the more superior vertebral spinous process. The paramedian needle is inserted approximately 15 degrees off the sagittal plane, as shown in the inset. *(Modified by permission of the Mayo Foundation)*

Figure 42-14 (Figure Not Available) Centroneuraxis anatomy of the Taylor approach to spinal anesthesia. This is really a paramedian approach at the L5-S1 vertebral level. A skin mark is made 1 cm caudad and 1 cm medial to one of the posterior superior iliac spines. Through this skin mark, the needle is inserted cephalad and medial. The needle is walked off the sacrum and into the largest interspinous space, the L5-S1 intervertebral space. The posterior superior iliac spines are located immediately anterior to the often present "skin dimples" found overlying the superior aspect of the sacrum. *(By permission of the Mayo Foundation)*

in a cephalomedial plane. The spinal introducer and needle are then inserted 10 to 15 degrees off the sagittal plane in a cephalomedial plane (see Fig. 42-13 (Figure Not Available)). Similar to the midline approach, the most common error is to angle the needle too far cephalad on initial insertion. Nevertheless, if the needle contacts bone, it is redirected slightly in a cephalad direction. If bone is again contacted, but at a deeper level, the slight cephalad angulation is continued because it is likely that the needle is being "walked up" the lamina. As in the midline approach, the characteristic feel of the ligaments and dura is possible, although needle angulation will require more of the needle to be inserted. Once CSF is obtained, the block is carried out in a manner similar to that described for the midline approach.

Figure 42-15 Continuous spinal needle examples, including disposable (A) 18-gauge Hustead, and (B) 17-gauge Tuohy. Both have distal tips designed to direct the catheters inserted through the needles along the course of the bevel opening; 20-gauge epidural catheters are used with these particular needle sizes.

A variation on the paramedian approach is the lumbosacral approach described by Taylor. [59] This technique is carried out at the L5-S1 interspace, the largest interlaminal interspace of the vertebral column. A 5-inch spinal needle is inserted in a cephalomedial direction through a skin wheal raised 1 cm medial and 1 cm caudad to the lowermost prominence of the posterosuperior iliac spine. If bone is encountered on first needle insertion, the needle is walked off the sacrum into subarachnoid space. Once CSF is obtained, the steps are similar to those previously outlined (Fig. 42-14) (Figure Not Available) .

If a continuous spinal anesthetic is prescribed, a needle with a lateral-faced opening is used to perform the lumbar puncture (Fig. 42-15) . Either a midline or paramedian approach may be used, with some suggesting that use of the paramedian approach facilitates catheter insertion. [60] The catheter should be threaded 2 to 3 cm into the subarachnoid space, and then the needle is withdrawn over the catheter. Care must be taken to ensure that the catheter is not inserted more deeply into the subarachnoid space when the needle is withdrawn over the catheter.

Pharmacology

Useful Drugs

There are three drugs (Ch. 12) commonly used in the United States to produce spinal anesthesia: lidocaine (Xylocaine), tetracaine (Pontocaine), and bupivacaine (Marcaine or Sensorcaine) (Fig. 42-16) . Lidocaine provides a short- to intermediate-acting spinal drug; tetracaine and bupivacaine provide intermediate- to long-duration block (Table 42-2) .

Figure 42-16 Ampules of drugs commonly used in the United States for spinal anesthesia. (A) Lidocaine 5 percent, with glucose 7.5 percent. (B) Bupivacaine 0.75 percent, in glucose 8.25 percent. (C) Tetracaine 1 percent. (D) Tetracaine niphanoid crystals, 20 mg.

TABLE 42-2 -- Drug Selection for Hyperbaric Spinal Anesthesia

LOCAL ANESTHETIC MIXTURE	DOSE (mg)[a]		DURATION (min)	
	TO T10	TO T4	PLAIN	0.2 mg EPINEPHRINE
Lidocaine (5% in 7.5% dextrose)	50-60	75-100	60	75-100
Tetracaine (0.5% in 5% dextrose)	6-8	10-16	70-90	100-150
Bupivacaine (0.75% in 8.5% dextrose)	8-10	12-20	90-110	100-150

[a] Doses are for use in a 70-kg adult male of average height.

Lidocaine is often chosen for procedures, such as inguinal herniorrhaphy, that can be completed in 1 hour or less. It has measurable effect in less than 5 minutes and is most commonly used as the 5 percent solution in 7.5 percent dextrose; however, many are exploring reducing the concentration of the drug during spinal anesthesia. [61] [62] It is not clear that reducing the concentration of lidocaine affects the incidence of what is being termed "transient radicular irritation." [63] It is important to caution against abandoning the use of our most useful short-acting spinal anesthetic drug, lidocaine, until the infrequent back pain associated with lidocaine spinal anesthetics is better defined. At present, my use of lidocaine for spinal anesthesia is directed by the following suggestions: limit dose to 60 to 70 mg; inject the dose at a rate exceeding 0.2 mL/s; keep needle apature directed cephalad; and limit use of the drug for continuous spinal techniques as much as is practical.

Previously, it was thought that epinephrine did not prolong the length of spinal anesthesia with lidocaine because duration was most often defined by two-segment regression in the thoracic dermatomes. In spite of that, the duration of lidocaine spinal anesthesia was found to be prolonged at the operative site by 0.2 mg of epinephrine. [64] Additionally, the use of epinephrine with spinal drugs may do more than simply prolong the duration of the block at the operative site. An improvement in the quality of block probably occurs as well. [65] [66] In dogs, subarachnoid lidocaine (plain) increases spinal cord blood flow (21-35 mL/100 g/min), whereas when epinephrine is added to lidocaine no statistically significant change (30-24 mL/100 g/min) in spinal cord blood flow results. [67] Two-segment regression is a measure of duration of neuraxial blocks. The time from injection of local anesthetic mixture until the maximum level of the spinal or epidural anesthetic (usually thoracic) has decreased by two dermatome levels.

Tetracaine has been used in spinal anesthesia for years and is packaged as both niphanoid crystals (20 mg) and a 1 percent solution (20 mg). This drug has an onset of 5 to 10 minutes and is selected for procedures lasting up to 2 to 3 hours when epinephrine is added, and up to 5 hours for lower extremity procedures when phenylephrine (0.5 mg) is added as the vasoconstrictor. When niphanoid crystals are used, a 1 percent solution is mixed by adding 2 mL of sterile water (without preservatives) to the crystals. Then the appropriate milligram dose of 1 percent solution is mixed in equal volumes of 10 percent dextrose to produce a 0.5 percent tetracaine solution weighted with 5 percent dextrose. Subsequently, the vasoconstrictor may be added. Once again, epinephrine and phenylephrine both prolong spinal anesthesia with tetracaine (Table 42-3) (Table Not Available) . [68] In dogs, subarachnoid tetracaine increases spinal cord blood flow (21-47 mL/100 g/min); addition of epinephrine to tetracaine leaves blood flow unaltered (24-24 mL/100 g/min). [69]

Bupivacaine spinal anesthesia is commonly carried out with 0.75 percent and 0.5 percent solutions in dextrose. Increasingly though, the clinical isobaric forms of the drug, the 0.5 percent and the 0.75 percent plain solutions, are also used. The clinical difference between tetracaine 0.5 percent and bupivacaine 0.75 percent as hyperbaric solutions is minimal. It appears that when "isobaric" 0.5 and 0.75 percent bupivacaine are compared, the mass of drug (mg dose) injected is more important in determining the eventual block height than the volume of isobaric drug administered. [70] [71] Bupivacaine is appropriate for procedures lasting up to 2 to 2.5 hours. [72] Subarachnoid bupivacaine in dogs decreases lumbosacral spinal cord blood flow with (35 to 20 mL/100 g/min) or without (31-22 mL/100 g/min) added epinephrine. [73] In spite of this laboratory finding, the clinical significance seems minimal.

Spinal Anesthetic Additives

Some physicians have been concerned that the use of additives, particularly vasoconstrictors, may be risky. The concept

TABLE 42-3 -- Effect of Adding Epinephrine or Phenylephrine to Tetracaine Spinal Anesthesia

(Not Available)

Modified from Caldwell et al [68]

is that epinephrine and phenylephrine have such potent vasoconstrictive action as to put the blood supply of the spinal cord at risk. There are no human data supporting this theory. Kozody et al [74] have shown that administering subarachnoid epinephrine (0.2 mg) or phenylephrine (5 mg) does not decrease spinal cord blood flow in dogs. These traditional vasoconstrictors are not the only adrenergomimetic agents being studied. Clonidine, an alpha $_2$ -agonist, prolonged motor block associated with tetracaine spinal anesthesia in dogs as much as epinephrine while prolonging sensory blockade for an even longer interval. [75] The mechanism for this prolongation may involve both vasoconstriction and anti-nociception from alpha-stimulation. [76] Another drug being investigated for spinal use as an additive is neostigmine. [77] It may prolong and intensify analgesia through release of nitric oxide in the spinal cord.

The interaction of various vasoconstrictors and local anesthetics is better understood. Traditionally, epinephrine was thought to prolong only tetracaine spinal anesthesia but not bupivacaine or lidocaine spinal anesthesia. [78] This theory was postulated because of differences in vasodilatory actions of the local anesthetic drugs: plain lidocaine and bupivacaine cause vasodilation, whereas plain tetracaine does not. Additionally, the original investigations of spinal anesthetic duration used two-dermatome regression in the thoracic dermatomes to establish duration. [79] [80] [81] Since that time, it has become clearer that two-dermatome regression in the mid- to high-thoracic dermatomes may be misleading when measuring spinal anesthetic duration in the lower thoracic and lumbar dermatomes. There are data that lidocaine spinal anesthesia is prolonged by epinephrine when measured by two-dermatome regression in the lower thoracic dermatomes and by occurrence of pain at the operative site for procedures carried out at the level of lumbosacral dermatomes. [64] [82]

When epinephrine has been compared to phenylephrine as a means of prolonging spinal anesthesia, conflicting information again appears to exist. Concepcion et al [83] compared epinephrine (0.2 and 0.3 mg) and phenylephrine (1 and 2 mg) added to tetracaine and did not find a difference in increased duration with the two vasoconstrictors. Caldwell et al [68] used higher doses of vasoconstrictors, epinephrine at 0.5 mg and phenylephrine at 5 mg, and showed that phenylephrine

prolonged tetracaine spinal anesthesia significantly more than epinephrine (see Table 42-3 (Table Not Available)). Additionally, phenylephrine has been shown to prolong lidocaine spinal anesthesia, but it appears that the length of prolongation is more similar to that produced with epinephrine than significantly longer. [82] [84] Duration of bupivacaine spinal anesthesia does not appear to be prolonged by phenylephrine. [80] [85] Whichever local anesthetic solution and additives are selected for subarachnoid injection, special care should be taken to assure that one knows what substance is being injected and that all procedures have been carried out aseptically.

Hypobaric and Isobaric Spinal Anesthesia

The density of any solution is the weight in grams of 1 mL of the solution at a standard temperature. Specific gravity is the density of a solution compared in a ratio to the density of water. In contrast, baricity is a ratio comparing the density of one solution to another. If the other solution happens to be water, the baricity will be the same as the specific gravity. In order to make a drug hypobaric to CSF, it must be less dense than CSF, having a baricity appreciably less than 1.0000 or a specific gravity appreciably less than 1.0069 (the mean value of CSF specific gravity).

In the United States, the most common method of formulating a hypobaric solution is to mix tetracaine in a 0.1 to 0.33 percent solution with sterile water. This makes the baricity of the solution less than 0.9977 and allows clinically useful anesthesia to be produced. In the prone position for anorectal procedures or in the lateral position for hip repairs, 4 to 6 mg of selected hypobaric dilution is often adequate. There is evidence that rate of injection (0.02 mL/s versus 0.5 mL/s) of hypobaric (0.2 percent) tetracaine influences spread of the drug. [86]

Another method of formulating a hypobaric-like solution is to use warmed 0.5 percent bupivacaine. [87] [88] These data show that 0.5 percent bupivacaine warmed to 37°C, compared with 4°C, demonstrates hypobaric characteristics when the block is administered to sitting patients. Additionally, these investigators suggest that warmed bupivacaine provides more predictable cephalad spread of sensory level, in contrast to a cold or room temperature drug.

Another drug that has been investigated as a "clinically" hypobaric spinal drug is 2 percent lidocaine. Its physiochemical characteristics make it more similar to an isobaric than hypobaric drug; however, some clinicians have found it useful in situations generally reserved for hypobaric techniques. [89]

When isobaric spinal anesthesia is planned, the drugs most often chosen today are 0.5 or 0.75 percent bupivacaine. Another drug that can be used is tetracaine. It is formulated into an isobaric solution by diluting the niphanoid tetracaine crystals (20 mg) with CSF and then injecting the selected mass of drug in an isobaric fashion.

Factors Affecting Block Height

More than 20 factors may alter spinal anesthetic block height (Table 42-4) . [90] Table 42-5 lists the most important documented factors. Age has a statistically significant effect on block height, yet, when examined, the difference in block height using isobaric bupivacaine and comparing the 3rd to 9th decades is small (i.e., T9 for those 20-28 years and T6 for those older than 80 years of age). [91] [92] Unlike epidural dose requirements, weight is not related to block height during spinal anesthesia. Patient height is related, although again the contribution is minor compared to more important factors (Table 42-6) . Similarly, injection rate and barbotage of isobaric and hyperbaric solutions have not been shown to affect block height, although injection rates in these studies have been above 0.1 to 0.2 mL/s. [93] [94] It is becoming clear that the direction of spinal needle lateral-facing openings impact block height levels, even with isobaric spinal solutions. [95] [96] Other maneuvers that do not appear to affect block height are coughing and straining after local anesthetic injection. This is related to the physics of injecting drugs into a closed column of CSF, which instantaneously transmits pressure changes throughout the CSF column, such as those that occur with coughing or straining. [90]

Vasoconstrictors

When more global factors affecting block quality are examined, at least in some teaching programs, the spinal "failure rate" may be as high as one in six blocks. [97] To understand "failure rate" fully, the definition must be examined. These investigators considered need to supplement the block with any inhaled anesthetic as failure. This is a key point because to provide comprehensive regional anesthesia supplementation of the block must be considered appropriate rather than a de facto failure. [98] These data do emphasize an important contributor to failed blocks, that is, the lack of free flow of CSF after needle placement. There is obviously some level of experience necessary to carry out spinal anesthesia successfully, but even in a teaching program, this should not prohibit the successful use of spinal anesthesia because the failure rate can be as low as 1 percent. [47] [72]

TABLE 42-5 -- Factors Documented to Be Related to the Height of a Spinal Anesthetic Block

	EFFECT	
	MAJOR	*MINOR*
Patient characteristics		
Age		0

Complications

Complications include neurologic changes, headache after dural puncture, backache that accompanies 25 percent of procedures performed with spinal anesthesia, and unexpected cardiac arrests. [99]

As outlined earlier, neurologic injury after spinal anesthesia has received considerable media attention through the years, including the Wooley and Roe case in England, the "investigation" published by Kennedy [4] in 1950 in the United States, and the cases of cauda equina syndrome associated with small-bore continuous spinal anesthesia. [100] Overlooked by many is information from Marinacci, [101] whose investigation was performed after Kennedy's publication. Marinacci, a neurologist, evaluated 542 patients who were thought to have neurologic complications related to a previous spinal anesthetic. After neurologic evaluation, in only 4 of the 542 patients was there any indication that the prior spinal anesthetic was the cause of the postoperative neurologic change. It should be emphasized that the total number of patients undergoing spinal anesthesia that resulted in the four cases of neurologic symptoms related to spinal anesthesia is unknown.

There are reports that outline both the numerator and denominator of neurologic change after spinal anesthesia. Vandam and Dripps [102] documented 10,098 patients who underwent spinal anesthesia and reported no severe neurologic sequelae related to spinal anesthesia. Likewise, Moore and Bridenbaugh [57] failed to find a single permanent neuropathy after spinal anesthesia in 11,574 patients undergoing spinal anesthesia. A review of neurologic complications associated with neuraxial blocks, prompted by the chloroprocaine epidural controversy in the early 1980s (Ch. 13) , tabulated [86] 304 patients undergoing spinal anesthesia with only one permanent lesion potentially related to spinal anesthesia (a lumbar plexus injury). [103] Rigler et al reported four patients developing cauda equina syndrome following continuous spinal anesthesia. [100] The pool of patients from which the four patients were drawn is unknown. This research team has continued to highlight perceived difficulties with the use of spinal use of lidocaine (Drasner, unpublished study) and has added significant data to the question. The ultimate decision about using lidocaine for spinal anesthesia still needs consideration of alternatives as well as consideration of the suggestions outlined in the earlier section of this chapter on pharmacology of spinal drugs.

The large series and case reports documenting only rare neurologic lesions after spinal anesthesia should not provide one with a false sense of security. [104] Neurologic changes can occur; the important point is that severe neurologic change

can also occur after general anesthesia. The risk-benefit equation of anesthesia and neurologic injury must include those cases of neurologic injury (e.g., hypoxic central nervous system lesions), that are possible during general anesthesia if a logical and well-informed decision based on neurologic outcome is to be made.

A more common complication of spinal anesthesia is postoperative headache. This postdural puncture headache is not exclusively related to spinal anesthesia but occurs after myelography and diagnostic lumbar puncture as well. Lybecker et al have popularized a postdural puncture headache rating scale that may make comparison between future studies of postoperative headache more meaningful. [105] Factors increasing the incidence of postdural puncture headache or unrelated to its development are listed in Table 42-7 . [106]

Mihic's investigation of bevel "direction" during insertion of a spinal needle clearly demonstrated that splitting, rather than cutting the longitudinally directed dural fibers, resulted in a lower incidence of postdural puncture headache [107] (Fig. 42-17) (Figure Not Available) . Although needle type was unspecified in Mihic's report, it is likely that a Quincke-type needle was used. This clinical observation has been supported by the laboratory investigation by Ready et al showing that simulated dural puncture by cone-shaped spinal needle tips produces a slower transdural loss of fluid than similar puncture with cutting-tipped needles. [58] Perhaps more importantly, meta-analysis has shown that noncutting needle tip designs have a lower frequency of postspinal dural puncture headaches than cutting needle tip designs. [108]

Also to be emphasized is that an arbitrary period of recumbancy after spinal anesthesia has not been found to decrease the incidence of postdural puncture headache, [109] and some data indicate that early ambulation may actually decrease the incidence of postdural puncture headache. [110] [111]

Possibly more important than knowing all the variables resulting in an increased incidence of postdural puncture headache is understanding how and when to carry out the definitive therapy--epidural blood patch--for this complication. The successful use of spinal anesthesia necessitates the early use of epidural blood patching when indicated. This therapy was introduced by Gormley, [112] although its safety and efficacy (more than 90 percent effective in relieving headache per epidural patch) have been well documented. [113] [114] [115]

TABLE 42-7 -- The Relationship Among Variables and Postdural Puncture Headache

Factors *related* to increased incidence of postdural puncture headache	
Age:	Younger more frequent
Gender:	Females > males

Needle size:	Larger > smaller
Needle bevel:	More when dural fibers cut transversely
Pregnancy:	More when pregnant
No. dural punctures:	More with multiple punctures
Factors *not increasing* postdural puncture headache incidence	
Continuous spinals	
Timing of ambulation	

Figure 42-17 (Figure Not Available) Types of needle insertion in Mihic report. In the vertical versus parallel insertion, the bevel of the spinal needle is inserted through the dura mater interna perpendicular to, instead of parallel to, the long axis of the vertebral column. *(Modified from Mihic [107])*

A question that has been debated since its introduction concerns the volume of blood that is most effective in balancing blood patch efficacy and risks. Szeinfeld et al [116] have shown, via radionucleotide-labeled red blood cells injected epidurally, that approximately 15 mL of blood provides efficacy and allows spread over a mean distance of nine spinal segments, thus providing some latitude for blood patch needle placement. They demonstrated that the blood was spread over more segments in the cephalad direction than the caudad direction. As a result, they recommend inserting the blood patch needle in a more cau-dad site if it is impossible to insert the needle at the same level as that of the prior dural puncture. Their data about primarily cephalad spread of an epidural blood patch has been validated by MR imaging of epidural blood patch spread. [117]

Data from Brown and Elman [118] demonstrate that approximately 25 percent of all our surgical patients undergoing anesthesia, regardless of anesthetic technique, experience backache. Thus backache after neuraxial block should not immediately be attributed to "needling" of the back or to use of 5 percent lidocaine.

When properly conducted, spinal anesthesia has proved to be extremely safe. Caplan et al [99] identified 14 cases of sudden cardiac arrest in healthy patients receiving spinal anesthesia. Because these cases seemed to appear suddenly after stable hemodynamic status, they concluded that a poorly understood potential exists for sudden cardiac arrest in healthy patients. It can be debated whether this represented a lack of vigilant monitoring and treatment as opposed to some mysterious physiologic explanation. [119] It is clear that hypoxemia and oversedation are not required for severe bradycardia and asystole to develop during well-conducted spinal anesthesia. [45] [120] Likewise, it is clear that the development of severe bradycardia following spinal anesthesia is not a new phenomenon and has been recognized for many years. [121] [122] In any case, it should be emphasized that cardiovascular changes can occur rather suddenly following spinal anesthesia.

Clinical Pearls

Often the "little things" necessary to carry out effective spinal anesthesia are unstated because they somehow seem less important than the broader issues, such as the incidence of neurologic complications after spinal anesthesia. Nevertheless, the little things often spell the difference between successful use of the technique and failure.

The successful integration of neuraxial blocks into an anesthesia practice requires that anesthesiologists be willing to supplement their blocks with CNS depressants. [98] A concept has developed that a regional anesthetic should need no supplementation and, if it does, it should be considered a failed block. This reasoning needs rethinking. For example, an anesthesiologist would not be expected to pick an arbitrary concentration of isoflurane before a general anesthetic and, on discovering that the concentration needs to be altered during the anesthetic, consider the technique a failure! Likewise, supplementation of a spinal or epidural anesthetic contributes to its comprehensive use and should not be a marker of failed blocks. Once this concept is accepted, neuraxial blocks can be adapted to many more situations, thus allowing an anesthesiologist's experience and confidence with the techniques to grow.

Additionally, to prevent prolongation of a patient's recovery room stay, and thus unnecessarily introduce institutional inefficiency, inpatients should be allowed to leave the recovery room after spinal anesthesia once it can be demonstrated their block is receding appropriately (at least four dermatomes' regression or *a spinal level < T10*), they are hemodynamically stable, and they are comfortable. After spinal anesthesia, outpatients should be able to ambulate without orthostatic changes and void prior to their discharge (Ch. 65) .

Intraoperatively, during high spinal anesthesia, patients occasionally complain excessively about dyspnea. This is not a result of significantly decreased inspiratory capacity but most often seems related to loss of chest-wall sensation. This does not allow patients to experience the reassurance of a deep breath. This impediment to patient acceptance can often be overcome by instructing the patients to raise a hand near the mouth and exhale forcefully. The tactile appreciation of the deep breath seems to provide reassurance.

If a neurologic complication is noted after an operation performed with spinal anesthesia, it is useful to obtain neurologic consultation early, so that ideally an unbiased consultant can examine the patient and determine whether the "new" neurologic finding was preexistent, related to a peripheral neuropathy, or, more rarely, potentially related to the spinal anesthetic. The latency in electromyographic alterations associated with denervation due to neurologic injury takes time to develop in the lower extremities (14-21 days). Therefore, one should obtain electromyography studies early and serially after a potential spinal-related lesion. In this manner it is possible to document whether the lesion was preexisting or give evidence that it is a peripheral rather than central lesion.

Probably more important than any single factor for the success of spinal anesthesia in the day-to-day use of anesthesia is that it must be time-efficient. It cannot add measurably to the surgical day if nurses and surgeons are to be coadvocates of the technique. Thus, one should plan ahead to maximize time efficiency. Often overlooked is that the patient preparation for surgery can begin almost as soon as the block is administered if patient sedation is at an appropriate level.

EPIDURAL AND CAUDAL ANESTHESIA

Epidural Technique

The technique of epidural anesthesia relies on the same four "Ps" as does spinal anesthesia, with minor modifications.

Preparation

In addition to patient preparation, selection of epidural equipment is essential. One must decide on a continuous or single-shot technique. This is the principal determinant of needle selection. If a single-shot epidural technique is chosen, a Crawford needle is appropriate; if a continuous catheter technique is indicated, either a Tuohy or another needle with a lateral facing opening is chosen (Fig. 42-18) . A method of identifying the epidural space also must be chosen, with most using a loss-of-resistance technique. If a loss-of-resistance technique is utilized, an additional decision on type of syringe (glass versus plastic, Luer-lok versus friction hub) is required. The theoretic ideal is the Luer-lok, finely ground glass syringe because it minimizes the chance of misidentification of the epidural space. Once again, most disposable equipment can be customized to an individual's needs if the advantages of reusable equipment are not available.

Position

The patient positions necessary for epidural puncture are the same as those for spinal anesthesia, with the exception of the prone position for the caudal approach. Once again, inadequate positioning of the patient will negate otherwise meticulous technique and should be prevented. Limitation of block spread (height) is not clinically predictable with position alterations during epidural anesthesia because gravity and solution baricity are not intimately related to block spread. In spite of this, Seow et al [122A] have demonstrated slightly faster block onset times in patients' dependent body regions when the lateral decubitus position was utilized for epidural block.

Three positions are available for caudal anesthesia, with the prone position most often chosen in adults, the lateral decubitus position in children, and the knee-chest position infrequently used. The lateral decubitus position is utilized in children because it is easier to maintain a patent airway in this position than in the prone position, and the landmarks are more easily palpable than in adults (Ch. 44) . This consideration is valuable because caudal anesthesia is often combined with general anesthesia in pediatric patients either to decrease the amount of volatile agent intraoperatively

or to provide postoperative analgesia. In contrast, a caudal block is often administered during preoperative sedation in adults and when the prone position is applicable. When placing a patient in the prone position, a pillow should be inserted beneath the iliac crests to rotate the pelvis and make cannulation of the caudal canal easier. An additional help is to spread the lower extremities about 20 degrees with the heels rotated laterally, which minimizes gluteal muscle contraction and eases needle insertion (Fig. 42-19) .

Projection and Puncture

Epidural technique requires placement of the needle tip into the ligamentum flavum for both loss-of-resistance and hanging drop methods. Placing the needle (with stylet) into the ligamentum flavum before attaching the syringe or placing solution into the needle hub allows an improved appreciation of epidural anatomy for the operator. If the needle is merely inserted into the supraspinous ligament and then either loss-of-resistance or hanging drop insertion is begun, an increased chance of false release seems likely.

When a lumbar approach is used, the depth from skin to ligamentum flavum commonly approaches 4 cm, with most (80%) patients between 3.5 and 6 cm. In this region the ligamentum flavum is 5 to 6 mm thick in the midline, thus requiring needle control if unintentional dural puncture is to be prevented. When a thoracic approach is chosen, control is of equal or greater importance because injury to the spinal cord is possible if the needle is advanced too far. Theoretically, the increased angle of needle insertion in the thoracic region may provide an element of safety because the more acute angle necessary to gain epidural cannulation provides some margin of safety (Fig. 42-20) . Clinically, thoracic epidural anesthetics do not appear associated with an increased

Figure 42-18 Epidural needle with catheter assortment. (A) A 19-gauge reusable Crawford epidural needle. (B) A 19-gauge disposable Tuohy needle. (C) Single-end-hole epidural catheter. (D) Closedtip, multiple-side-hole catheter. (E) Spring-wire reinforced polymer-coated epidural catheter.

incidence of neurologic injury because those choosing to use the technique are most often anesthesiologists with considerable experience with lumbar epidural anesthesia. [123] In any event, significant caution about performing thoracic epidural techniques in adult patients receiving general anesthesia is warranted because these patients are unable to provide feedback to the operator about neural stimulation during needle insertion.

Figure 42-19 Prone position for caudal technique. Pillow used under anterior iliac crests to rotate pelvis, legs spread 20 degrees to ease identification of sacral hiatus and heels rotated laterally to relax gluteal musculature.

The preferred method of carrying out the loss-of-resistance technique involves inserting the needle to the ligamentum flavum and then attaching a 3- to 5-mL glass syringe filled with 2 mL saline and a small (0.25-mL) air bubble. The needle is grasped with the nondominant hand

Figure 42-20 (A) Lumbar and thoracic epidural technique. The increased angle of needle insertion during thoracic epidural cannulation may provide a slightly longer distance of "needle travel" prior to entering the subarachnoid space (B), in contrast to lumbar epidural cannulation (C), where the distance traveled is modified by more perpendicular angle of needle insertion.

and pulled toward the epidural space, while the dominant hand (thumb) applies constant steady pressure on the syringe plunger, compressing the air bubble. When the epidural space is entered, the pressure applied to the syringe plunger will allow the solution to flow without resistance into the epidural space (Plate 7A).

An alternative, although with a less precise end point, is the technique of hanging-drop identification of entry into the epidural space. Once the needle is placed into the ligamentum flavum, a drop of solution is placed within the hub of the needle. When the needle is advanced into the epidural space the solution should be "sucked in" (Plate 7B). The theory behind this maneuver has been attributed to a subatmospheric pressure in the epidural space. The subatmospheric pressure has been related to the expansion of the epidural space as the needle pushes the dura away from ligamentum flavum. [124] The negative intrathoracic pressure may influence the pressure in the epidural space in the thoracic region.

Regardless of the method selected for needle insertion, when one chooses to cannulate the epidural space with a catheter success may be increased by advancing the needle 1 to 2 mm once the space is identified. Additionally, the incidence of unintentional intravenous cannulation with an epidural catheter may be lessened by injecting air or solution prior to threading the catheter. [125] [126] Unless radiographic guidance is used for some special reason, epidural catheters should be inserted only 2 to 3 cm into the epidural space for surgical patients or obstetric patients needing rapid onset of analgesia. [127] Threading more catheter may increase the likelihood of catheter malposition. If malposition does occur, data suggest that one of the more common sites of misposition is entry of the catheter into the anterior epidural space. [128] Additionally, in obstetric patients it appears that catheters should be inserted between 4 and 6 cm to optimize efficacy and prevent unintentional movement of the catheters during prolonged labor analgesia. [129] [130] When choosing a catheter either multiport (three lateral ports) or single-end-hole (uniport or distal port) catheters are available. Choice is practically up to individual clinicians, although it has been shown in laboring patients that multiport catheters reduce the incidence of inadequate analgesia compared to uniport catheters. [131]

In spite of an adequately positioned catheter during first use of local anesthetic, each subsequent injection should be preceded by aspiration and an epidural test dose because catheter migration into vessels and subarachnoid or subdural spaces does occur. In the event that the epidural catheter hub becomes disconnected from the epidural catheter, many in the past have considered the catheter unusable. It appears that the catheter can be reused if strict reconnection criteria are followed. [133]

Caudal Technique

Caudal anesthesia requires identification of the sacral hiatus. The sacrococcygeal ligament (an extension of ligamentum flavum) overlying the sacral hiatus lies between the sacral cornu. To facilitate locating the cornu, the posterior superior iliac spines should be located and, by using the line between them as one side of an equilateral triangle, the location of the sacral hiatus approximated (Fig. 42-21) . Once

Figure 42-21 Caudal technique. (A) Palpating fingers locate the sacral cornua by using equilateral triangle (shown in Fig. 42-6). (B) Needle insertion is carried out by insertion and withdrawal in stepwise fashion ("1-2-3-insertion"), until needle can be advanced into the caudal canal and solution can be injected easily (without creation of a subcutaneous "lump" of fluid).

the sacral hiatus is identified, the index and middle finger of the palpating hand are placed on the sacral cornu and the caudal needle is inserted at an angle of approximately 45 degrees to the sacrum. While advancing the needle, a decrease in resistance to needle insertion should be appreciated as the needle enters the caudal canal. The needle is advanced until bone (the dorsal aspect of the ventral plate of the sacrum) is contacted, and then slightly withdrawn, and the needle redirected so that the angle of insertion relative to the skin surface is decreased. In males this angle is almost parallel to the coronal plane; in females a slightly steeper angle (15 degrees) is necessary. During redirection of the needle and once loss of resistance is again encountered, the needle is advanced approximately 1 to 2 cm into the caudal canal. Further advance is not attempted because dural puncture and unintentional intravascular cannulation become more likely. One method of increasing the likelihood of correct caudal needle placement is to inject 5 mL of saline rapidly through the caudal needle while palpating the skin overlying the sacrum. If no midline "bulge" is detected, the needle is probably correctly positioned. In contrast, if a midline bulge is detected during saline injection, the needle is incorrectly positioned.

After ensuring correct needle position and prior to injection of the therapeutic dose of caudal anesthetic, aspiration and a test dose should be administered because as in lumbar epidural anesthesia, a vein or the subarachnoid space can be entered unintentionally.

Pharmacology

Useful Drugs

Successful choice of drug for epidural anesthesia (Ch. 13) requires an understanding of the local anesthetic potency and duration as well as estimation of surgical requirements and duration and postoperative analgesia requirements. As with any regional anesthetic the surgeon, anesthesiologist, procedure, and anesthetic technique must all be included in the drug choice equation.

Drugs available for epidural use can be categorized into short-, intermediate-, and long-acting local anesthetics, and with the addition of epinephrine to these agents surgical anesthesia ranging from 45 to 240 minutes is possible (Table 42-8) . Chloroprocaine, an ester local anesthetic, is a short-acting agent that was associated with neurotoxicity (adhesive arachnoiditis) when unintentionally injected in large volumes subarachnoid prior to a formulation change. [133] [134] Since 1985, reduced bisulfate concentrations have been available; since 1987 bisulfate-free 2-chloroprocaine has been available; and since 1996 preservative-free 2-chloroprocaine has been available. Since these formulation changes there have not been reports of neurotoxicity attributable to 2-chloroprocaine. In the era of ever-increasing numbers of surgical outpatients, combining 2-chloroprocaine and a catheter technique allows an efficient matching of surgical procedure and duration of epidural analgesia and enables patients to spend a minimal recovery time in the facility. It is available in 2 and 3 percent concentrations, with the latter preferable for surgical anesthesia and the former for techniques not requiring muscle relaxation.

There is evidence that back pain developing after larger volumes (>25 mL) of 2-chloroprocaine was related to the EDTA used as a preservative in the chloroprocaine. [135] It remains to be seen whether the preservative-free chloroprocaine will be associated with back pain in larger doses.

Lidocaine is the prototypical amide local anesthetic and is used in 1.5 to 2 percent concentrations epidurally. Mepivacaine is similar to lidocaine in the concentrations necessary for epidural anesthesia and lasts 15 to 30 minutes longer. Epinephrine significantly prolongs the duration of surgical anesthesia, approximately 50 percent, with both lidocaine and mepivacaine. [101] Another additive to these drugs that may influence clinical use is fentanyl in the intermediate-acting amide epidural drug. When fentanyl was added to mepivacaine, it accelerated the onset of analgesia and enhanced the analgesic effect during epidural anesthesia. [136] One technique receiving more attention to minimize length of an epidural motor block once surgery is completed is the use of saline in 15 to 30 mL volumes through the epidural catheter before it is removed. [137]

Bupivacaine is the most widely used long-acting local anesthetic; it is used in 0.5 and 0.75 percent concentrations for surgical anesthesia. Analgesic techniques can be performed with concentrations from 0.125 to 0.25 percent. Its duration of action is less consistently prolonged by addition of epinephrine, although up to 240 minutes of surgical anesthesia can be obtained when epinephrine is added. In 1983, the FDA stated that 0.75 percent bupivacaine was no longer recommended in obstetric anesthesia, as a result of a perception that systemic toxicity with that concentration resulted in more difficult resuscitations than occurred with the lower concentrations. The evidence for this action remains

TABLE 42-8 -- Comparative Onset Times and Analgesic Durations of Local Anesthetics Administered Epidurally in 20- to 30-ml Volumes

DRUG	CONCN.(%)	ONSET (MIN)	DURATION (MIN)	
			PLAIN	1: 200,000 EPINEPHRINE
2-Chloroprocaine	3	10-15	45-60	60-90
Lidocaine	2	15	80-120	120-180
Mepivacaine	2	15	90-140	140-200
Bupivacaine	0.5-0.75	20	165-225	180-240
Etidocaine	1	15	120-200	150-225

Data from Cousins and Bromage [173] and other sources

controversial, although it does appear that bupivacaine and etidocaine are more likely to impair myocardial performance and conduction than other local anesthetics when systemic toxicity occurs. [138] [139]

Etidocaine is an infrequently used epidural anesthetic principally because of the perception, and some data, that motor block is more profound than sensory block with the drug. [140] The reason for this may be that etidocaine is less effective than bupivacaine in producing small fiber blockade. [141]

Another amide, ropivacaine, is likely to become another useful agent for epidural anesthesia. It has an anesthetic effect quite similar to that of bupivacaine, although its central nervous system-cardiovascular toxicity profile may provide an increased safety margin. [142] It appears to produce less motor block and has a slightly shorter duration of action than bupivacaine. [143] Its place in regional anesthesia is believed by many to be best suited to obstetric anesthesia and postoperative infusion techniques.

Additives

As for spinal anesthetic drugs, some advocate combining agents with local anesthetics either to make epidural anesthesia last longer, to improve the quality of blockade, or to accelerate onset of block. Epinephrine will increase the duration of useful anesthesia with all the agents, though the proportional effect is greatest with lidocaine, mepivacaine, and 2-chloroprocaine and shows a lesser effect with bupivacaine and etidocaine (see Table 42-8). Phenylephrine has been used in epidural anesthesia less widely than in spinal anesthesia, perhaps because it does not reduce peak blood levels of local anesthetic as effectively as epinephrine during epidural use. [144]

Carbonation of the local anesthetic solution has been suggested as a means of increasing both speed of onset and quality of block by producing more rapid intraneural diffusion and more rapid penetration of connective tissue surrounding the nerve trunk. [145] [146] There are data suggesting that there are no clinical advantages of the carbonated solutions, [147] and some disadvantages may occur more rapidly because peak blood levels of the drug are higher after carbonation of the local anesthetic and blood pressures decreases (Ch. 13) . [148] [149]

The addition of bicarbonate has also been suggested as a means of increasing the pH of local anesthetic solution, thus increasing the concentration of nonionized free base, which will theoretically increase the rate of diffusion of the drug and speed onset of block. Clinically, the addition of 1 mEq of sodium bicarbonate to each 10 mL of commercially prepared 1.5 percent lidocaine solution produces a significantly faster onset of anesthesia and more rapid spread of sensory block. [150] The clinical applicability of this modification should be considered individually on its merits by each institutions' anesthesia group.

One other alteration of drugs for epidural use involves combining long- and short-acting drugs, theoretically to gain the benefits of each. This practice does not seem necessary or prudent because familiarity with the local anesthetics and additives available allows a spectrum of block lengths to be produced. Further, the purported advantage of faster onset with the combinations of local anesthetics seems clinically inconsequential.

Complications

Intravascular Injection

Epidural anesthesia has the potential to produce local anesthetic systemic toxicity (Ch. 13) , primarily through the unintentional administration of drug into an epidural vein. Considerable research has been undertaken to define the ideal test dose for continuous epidural catheter use. The use of test doses should minimize unintentional intravascular injections, although there are concepts in treating a local anesthetic-induced systemic toxicity reaction that all anesthesiologists should understand.

The toxic effects of local anesthetics primarily affect the central nervous and cardiovascular systems, with the central nervous system (CNS) affected at lower blood levels. For example, four to seven times the dose of local anesthetic necessary to produce convulsions in dogs is required to produce cardiovascular collapse. [151] The CNS stimulation is a result of local anesthetic-induced inhibition of the CNS. The initial excitatory phase of a reaction is due to selective inhibition of inhibitory neurons in the cerebral cortex, thus allowing facilitatory neurons to discharge in an unopposed fashion. [152] Once blood levels increase high enough, both inhibitory and facilitatory pathways are inhibited, leading to CNS depression.

Initially, potential for local anesthetic-induced toxicity, both CNS and cardiovascular, was thought to parallel anesthetic potency. [153] [154] Information suggests that bupivacaine and etidocaine may be proportionally more cardiotoxic than their anesthetic potency predicts. [155] [156] This relative increase in cardiotoxicity appears to result from more potent electrophysiologic effects of the long-acting amides due to their fast-in-slow-out sodium channel blockade. Ropivacaine, another long-acting amide local anesthetic, has a CNS-to-cardiotoxicity ratio intermediate between lidocaine and buipivacaine. [157] The clinical importance of these observations about toxicity must be balanced against clinical studies showing limited cardiovascular depression in patients undergoing bupivacaine-induced seizures during regional anesthetics. [158]

If signs of CNS toxicity or frank convulsions occur, a number of steps must be followed if adverse outcomes are to be prevented (Ch. 13) . Early in local anesthetic-induced seizures hypoxemia, hypercarbia, and acidosis develop rapidly, and symptomatic treatment of the toxicity must involve treatment of these factors. Oxygen should be given by bag and mask, and tracheal intubation is not mandated unless ventilation is ineffective. [159] The next step in therapy remains controversial, with either succinylcholine or anticonvulsant administered. Succinylcholine is often recommended because the local anesthetic-induced seizures are usually short-lived, and the muscle relaxation obtained facilitates ventilation and decreases the magnitude of metabolic acidosis. [159] Nevertheless, it does not decrease cerebral metabolism; thus CNS oxygen requirements remain increased. Others suggest that diazepam is effective in controlling local anesthetic-induced seizures, although 2 to 3 minutes is required to control seizures once administered. [160] [161]

The most effective method of treating toxic reactions is prevention. Administration of excessive doses of local anesthetics should be prevented, and test doses of local anesthetics should be used prior to the injection of therapeutic

doses. If a toxic reaction does occur, it is imperative that oxygen, a method of administering it, succinylcholine, and anticonvulsant drugs are immediately available.

Subarachnoid Injection

The adverse effects of unintentionally administering an epidural dose of local anesthetic into the spinal fluid are highlighted by the neurologic changes that followed subarachnoid injection of 2-chloroprocaine. However, most subarachnoid injections of epidural local anesthetics are less dramatic; rather, the issue is how one should treat the cardiopulmonary effects resulting from such an injection. As in any neuraxial block that reaches high levels, arterial blood pressure and heart rate should be supported. The Trendelenberg position should be instituted to maximize venous return. Intravenous atropine and ephedrine are often effective and will provide the time to administer a more potent catecholamine, if needed. Additionally, ventilation should be supported, and if the entire dose (20-25 mL) of local anesthetic has been administered into the CSF, tracheal intubation and mechanical ventilation are indicated because patients may require approximately 1 to 2 hours to maintain adequate spontaneous ventilation consistently. After a large dose of local anesthetic into the CSF, patients will also develop dilated pupils, which may seem to indicate CNS injury if this phenomenon is not recognized for what it is. The pupils will return to baseline state as the high block recedes. Fortuitously, the necessity for sedation during the period of tracheal intubation and mechanical ventilation is minimal. These patients generally do not recall such events. [162]

When an epidural is performed and the higher-than-expected block develops only after a delay of 15 to 30 minutes, subdural placement of local anesthetic must be considered. Treatment is once again symptomatic; the most difficult aspect is recognizing the possibility of a subdural injection.

Neurologic Injury

With the exception of the publicity surrounding the 2-chloroprocaine-induced adhesive arachnoiditis, epidural anesthesia has not been linked with neurologic injury more frequently than other anesthetics, regional or general. [102] [104] No particular local anesthetic, needle versus catheter technique, addition or omission of epinephrine, or location of epidural puncture seems to be associated with an increased incidence of neurologic injury. In spite of this information, neurologic injury is often feared and epidural anesthesia avoided in patients in whom antiplatelet drugs or other anticoagulants have been used preoperatively. Is this justified? There are no data in patients taking antiplatelet drugs, such as aspirin, that there is an increased incidence of neurologic injury secondary to epidural bleeding (hematoma) when epidural anesthesia is utilized. [163] It is doubtful that a perceived lack of data indicates that the problem has been overlooked, because epidural anesthesia is frequently used in patients undergoing orthopedic procedures, in whom aspirin use is widespread. Nevertheless, there are isolated case reports of neurologic injury after both epidural and spinal anesthesia in patients in whom antiplatelet drugs were used. It may be significant that in these case reports the initial neuraxial technique was abandoned after technical difficulties with needle placement. [164] [165]

The use of epidural anesthesia for patients receiving anticoagulants is less clear-cut because epidural anesthesia is often avoided in these patients. There are data from Odoom and Sih, [167] who used continuous epidural anesthesia in 1,000 vascular operations, in patients receiving preoperative oral anticoagulants without problem. The acceptable magnitude of preoperative anticoagulation and risk-benefit ratio of performing epidural anesthesia must remain undetermined at this time. Once again, despite lacking data, the use of epidural techniques in patients receiving subcutaneous hep-arin therapy is probably acceptable if the block can be performed atraumatically, although the risk-benefit ratio must be determined for each patient. Some speculate that proof of minimal systemic effect from the subcutaneous heparin (normal PTT) is necessary prior to neuraxial block. [167]

There is growing consensus that when low-molecular-weight heparin--enoxaparin (Lovenox)--is used perioperatively, neuraxial block techniques need to be managed differently. It is clear that there is an increased risk of neuraxial bleeding when enoxaparin and neuraxial techniques are combined if the following recommendations are not followed [168] : (1) neuraxial block should be delayed for at least 10 to 12 hours after the last dose of enoxaparin for patients receiving the drug preoperatively; (2) postoperative treatment with enoxaparin should be delayed at least 12 hours after completion of the surgical procedure; and (3) removal of epidural and spinal catheters used for postoperative analgesia should occur 10 to 12 hours after the last dose, with subsequent dosing delayed for at least 2 hours. [169] [170]

It does seem that the issue of intraoperative anticoagulation after epidural catheter insertion is as settled as clinical data allow. There are now approximately 5,000 patients who have undergone epidural anesthesia for vascular surgery, with intraoperative heparinization, without a neurologic injury attributable to epidural bleeding. [166] [171] [172] In spite of minimal problems with epidural anesthesia and neurologic dysfunction related to anticoagulation, if a patient has neurologic symptoms consistent with neuraxial mass after regional block, immediate neurosurgical consultation is indicated because time is of the essence if permanent sequelae are to be prevented. Furthermore, if the patient appears to be at increased risk for neuraxial bleeding and yet the neuraxial technique remains indicated, it may be prudent to use a shorter-acting epidural local anesthetic even if it means reinjecting more frequently so that the block will resolve as rapidly as possible following the surgical procedure.

Clinical Pearls

The adage, "Success covers a multitude of blunders"
is certainly appropriate for use of epidural anesthesia. To be successful one must perform the technique often enough to be technically facile. To increase the use of the technique, a number of practical observations may be helpful.

George Bernard Shaw (1856-1950).

If catheters can be avoided during epidural anesthesia (e.g., by selecting the appropriate local anesthetic), a potential source of difficulties with the technique can be made moot. It is important to allow the block enough "soak time" prior to the surgical procedure; this can be facilitated if the block is carried out in an induction room separate from the operating room. One must recognize that there appears to be a plateau effect in dosing epidural local anesthetics. That is, once some quantity of the local anesthetic has been injected, additional local anesthetic does not significantly increase the block height but rather may make the block more dense (i.e., improve quality). [173] To be successful with the technique, one should be prepared at all times to treat complications associated with epidural anesthesia: airway equipment and drugs, especially oxygen and resuscitation, must be immediately available.

CLINICAL CONTROVERSY AND NEURAXIAL BLOCKS

In spite of the many years neuraxial blocks have been used, there remain a number of controversies about the appropriate use of these blocks. Some continue to suggest that spinal anesthesia is inappropriate for outpatients because of the occurrence of postdural puncture headache, yet there are data that the occasional headache can be successfully treated even in the outpatient [174] and considerable other data supporting the use of the technique in outpatients. [175] Similarly, spinal anesthesia seems well suited to use for cesarean section because of the short interval from injection to surgical anesthesia. Once again, if epidural blood patch therapy is utilized in a timely fashion, the increased incidence of headache in this patient population should not necessarily limit the technique's use for cesarean section. An outgrowth of the management of postdural puncture headache was the development of the "micro" or small-bore spinal catheter. [176] This technique's appropriate place in anesthesia practice has not been established because there must be a point at which the risk-benefit ratio of a decreased incidence of spinal headache versus difficulties in technique with the "micro" catheter becomes unacceptable. These catheters (i.e., 27-gauge or smaller) are not available because the FDA withdrew the 510k approval in 1992 following concerns over possible association with development of cauda equina syndrome. [7]

One reason that epidural anesthesia is not used as widely as may be indicated is that controversies surrounding its use create indecision. One of the most controversial adjuncts to epidural anesthesia has been the use of the epinephrine-containing test dose. [177] The original description used 15 mug of epinephrine in 3 mL of local anesthetic to indicate intravascular placement of an epidural catheter or needle. Most controversy surrounds the use of epinephrine in obstetric patients, in whom uterine blood flow may be decreased by the intravascular injection, thereby putting the fetus at risk. Some experimental data suggest that epinephrine may place the fetus at risk [178] ; nevertheless, no clinical data suggest that any fetus has been harmed by a test-dose use, and many anesthesiologists believe epinephrine-containing epidural test doses are useful in obstetric anesthesia. [179] Patients receiving beta-adrenergic blockers also confound the use of a test dose. In these patients, heart rate may not change after intravascular injection of 15 mug of epinephrine; rather, heart rate may decrease as blood pressure increases. [180] The use of epidural anesthesia during general anesthesia may also confound interpretation of the epinephrine test dose. [181] Because there is no fail-safe method of guaranteeing an extravascular location of an epidural local anesthetic, prevention of systemic toxicity should also involve aspiration of the catheter and incremental dosing of the local anesthetic. It has been shown that onset of block, quality of block, and block height are unaffected by administration of the epidural drug in 5-mL fractions. [182]

Related to systemic toxicity with neuraxial blocks is information about benzodiazepines. In spite of a widely held belief that benzodiazepines should be used with regional anesthesia to minimize systemic toxicity by elevating seizure threshold, available data indicate that this concept requires rethinking. [183] It has been shown that resuscitation may be more difficult after cardiovascular collapse due to bupivacaine when diazepam is used as a premedication. It has also been demonstrated that animals premedicated with benzodiazepines may not evidence seizures prior to cardiovascular collapse. [183] Thus, it may be that the benzodiazepines cover up one of the early signs of systemic toxicity, thus potentially delaying definitive therapy.

The clinical arena has not been immune from controversy about epidural anesthesia. Yeager et al demonstrated a significant decrease in morbidity and mortality in high-risk patients undergoing epidural anesthesia and postoperative analgesia, compared to patients receiving high-dose narcotic anesthesia and parenteral narcotic analgesia. [11] This information provided impetus to many investigators to design studies to answer whether the anesthetic technique, especially postoperative analgesic technique, may be able to modify patient outcome. In the case of Yeager et al, it remains unclear whether their data support the benefits of the epidural techniques or condemn the use of high-dose narcotics and postoperative mechanical ventilation. Tuman et al [12] addressed many of the criticisms directed at Yeager et al's work and documented fewer complications in vascular surgery patients when epidural analgesia was used in an integrated perioperative regimen. Christopherson and Rose et al have begun to link the analgesic regimens with possi-ble mechanisms of improved patient outcomes. They iden-tified that using epidural anesthesia and analgesia into the postoperative period limit the adverse effects of surgery on the fibrinolytic system. [13] Further investigations into the appropriate place of neuraxial blocks in anesthetic practice will have to be as concerned with the issue of cost in relation to outcome as with risk in relation to benefit to the patient.

Another development in neuraxial block technique that demands our attention is the development of effective methods of combining epidural and spinal anesthesia via a single-needle system). [184] [185] [186] [187] These methods use epidural needle placement, followed by insertion of the spinal needle through either a side lumen on the epidural needle, or directly via the epidural needle lumen (Fig. 42-22) (Figure Not Available) . The combined technique allows flexibility in a number of clinical settings; some of the possible combinations and advantages are listed in Table 42-9 .

Figure 42-22 (Figure Not Available) An illustration highlighting the concept used in the Coombs epidural-spinal needle combination, which allows placement of a 20-gauge epidural catheter via a modified Hustead-Tuohy needle, as well as placement of a 27-gauge spinal needle (short-cutting or pencil point [conical] bevel), via an additional lumen. *(With permission of Neurodelivery Technology, Inc., Lebanon, NH)*

TABLE 42-9 -- Possible Clinical Advantages of Using Combined Spinal-Epidural Anesthesia

Initial epidural needle placement allows the spinal needle to be guided near the dura, minimizing the number of times the spinal needle tip impacts bone and potentially becomes dulled.
Lower local anesthetic blood levels are possible when an initial spinal anesthetic is used for operation, and the epidural catheter is used for analgesia.
More rapid onset of spinal block allows the operative procedure to begin earlier, while the epidural catheter allows effective analgesia to be provided.
During labor, an opioid may be injected via a small spinal needle and then epidural analgesia added if needed.
Lower initial mass of drug may be used during spinal anesthesia, thereby minimizing the physiologic perturbations, while the epidural catheter is available to provide a higher level if needed.

Chapter 43 - Nerve Blocks *

Denise J. Wedel

INTRODUCTION

The techniques of peripheral neural blockade were developed early in the history of anesthesia (Ch. 1) . The American surgeons Halsted and Hall [1] [2] described the injection of cocaine into peripheral sites, including the ulnar, musculocutaneous, supratrochlear, and infraorbital nerves, for minor surgical procedures in the 1880s. James Leonard Corning [3] recommended the use of an Esmarch bandage in 1885 to arrest local circulation, thus prolonging the cocaine-induced block and decreasing the uptake of that local anesthetic from the tissues. This concept was furthered by Heinrich F. W. Braun, [4] who substituted epinephrine, a "chemical tourniquet," in 1903. Braun [5] also introduced the term "conduction anesthesia" in his 1905 textbook on local anesthesia, which described techniques for every region of the body.

Whereas early discoveries in regional anesthesia involved surgeons and basic scientists, the developing specialty of anesthesiology gradually dominated the use of regional anesthetic techniques. During this period, Sydney Ormond Goldan, credited with publication of the first anesthesia chart, a record designed to record the course of "intraspinal cocainization," [6] and Gaston Labat, the French regional anesthesiologist invited to lecture at the Mayo Clinic by surgeon William Mayo, provided the basis on which regional anesthesia grew.

Peripheral neural blockade is now a well-accepted component of comprehensive anesthetic care. Its role has expanded from the operating suite into the arena of postoperative and chronic pain management (Chs. 69 and 70) . With appropriate selection and sedation, these techniques can be used in all age groups. Skillful application of peripheral neural blockade broadens the anesthesiologist's range of options in providing optimal anesthetic care.

UPPER EXTREMITY BLOCKS

Successful regional anesthesia of the upper extremity requires knowledge of brachial plexus anatomy from its origin as the nerves emerge from the intervertebral foramina to its termination in the peripheral nerves. Detailed anatomic knowledge enables the anesthesiologist to choose the appropriate technique for the intended surgical procedure and to salvage "inadequate" blocks with local anesthetic supplementation. Without mastery of the anatomy, luck rather than skill will be the primary determinant of successful neural blockade. Also important is a knowledge of the side effects and complications of peripheral nerve blocks in the upper extremity as well as the clinical application of available local anesthetics for these blocks. Finally, one must not underestimate the role of appropriate sedation during placement of the block as well as during the surgical procedure. Many a "perfect" regional anesthetic technique has been undone by inadequate management of sedation.

*See Appendix 1, Practice Guidelines for Chronic Pain Management

Figure 43-1 Roots, trunks, divisions, cords, and branches of the brachial plexus.

Anatomy

The brachial plexus is derived from the anterior primary rami of the fifth, sixth, seventh, and eighth cervical nerves and the first thoracic nerve, with variable contributions from the fourth cervical and second thoracic nerves. After leaving their intervertebral foramina, these nerves course anterolaterally and inferiorly to lie between the anterior and middle scalene muscles, which arise from the anterior and posterior tubercles of the cervical vertebra, respectively. The anterior scalene muscle passes caudad and laterally to insert into the scalene tubercle of the first rib; the middle scalene muscle inserts on the first rib posterior to the subclavian artery, which passes between these two scalene muscles along the subclavian groove. The prevertebral fascia invests both the anterior and middle scalene muscles, fusing laterally to enclose the brachial plexus in a fascial sheath.

Between the scalene muscles, these nerve roots unite to form three trunks, which emerge from the interscalene space to lie cephaloposterior to the subclavian artery as it courses along the upper surface of the first rib. Therefore, the "superior" (C5 and C6), "middle" (C7), and "inferior" (C8 and T1) trunks are arranged accordingly and are not in a strict horizontal formation, as often depicted. At the lateral edge of the first rib, each trunk forms anterior and posterior divisions that pass posterior to the midportion of the clavicle to enter the axilla. Within the axilla, these divisions form the lateral, posterior, and medial cords, named for their relationship with the second part of the axillary artery. The superior divisions from the superior and middle trunks form the lateral cord, the inferior divisions from all three trunks form the posterior cord, and the anterior division of the inferior trunk continues as the medial cord.

At the lateral border of the pectoralis minor, the three cords divide into the peripheral nerves of the upper extremity. The lateral cord gives rise to the lateral head of the median nerve and the musculocutaneous nerve; the medial cord gives rise to the medial head of the median nerve, as well as the ulnar, the medial antebrachial, and the medial brachial cutaneous nerves; and the posterior cord divides into the axillary and radial nerves (Fig. 43-1) .

Aside from the branches from the cords that form the peripheral nerves as described, several branches arise from the roots of the brachial plexus providing motor innervation to the rhomboid muscles (C5), the subclavian muscles (C5 and C6), and the serratus anterior muscle (C5, C6, and C7). The suprascapular nerve arises from C5 and C6 and supplies the muscles of the dorsal aspect of the scapula as well as making a significant contribution to the sensory supply of the shoulder joint.

Branches arising from the cervical roots are usually blocked only with the interscalene approach to the brachial plexus. Sensory distributions of the cervical roots and the peripheral nerves are shown in Figure 43-2 .

The brachial plexus shares a close physical relationship with several structures, some serving as important landmarks for the performance of neural blockade. In its course between the anterior and middle scalene muscles, the plexus is superior and posterior to the second and third parts of the subclavian artery. The dome of the pleura lies anteromedial to the inferior trunk.

Interscalene Block

Clinical Applications

The interscalene approach to the brachial plexus is well suited to procedures in which a cervical plexus block is also desired (i.e., shoulder surgery). This technique can be performed with the patient's arm in any position and is technically simple because of easy palpation of necessary landmarks. [7] Although this approach can be used for forearm and hand surgery, blockade of the inferior trunk (C8 through

Figure 43-2 (A) Cutaneous distribution of the cervical roots. (B) Cutaneous distribution of the peripheral nerves.

T1) is often incomplete and requires supplementation at the ulnar nerve for adequate surgical anesthesia in that distribution. [8] The use of a nerve stimulator or elicitation of paresthesias is recommended with this technique in order to place the local anesthetic solution accurately. The risk of pneumothorax is low when the needle is correctly placed at the C5 or C6 level because of the distance from the dome of the pleura.

Side Effects/Complications

Ipsilateral phrenic nerve block resulting in diaphragmatic paresis occurs in 100 percent of patients undergoing interscalene blockade, [9] even with dilute solutions of local anesthetics, and is associated with a 25 percent reduction in pulmonary function. [10] [11] This effect is probably due to anterior spread of the solution over the

anterior scalene muscle and may cause subjective symptoms of dyspnea. Although rare, respiratory compromise can occur in patients with severe respiratory disease. Involvement of the vagus, recurrent laryngeal, and cervical sympathetic nerves is rarely significant, but the patient experiencing symptoms related to these side effects may require reassurance. Nerve damage or neuritis can occur in any peripheral nerve block, but it is uncommon and usually is self-limited. Some surgical approaches to the shoulder are associated with neurologic risk to the brachial plexus, for example, total shoulder replacements. In such cases, interscalene block should be placed postoperatively for pain relief after the surgical service has ascertained and documented that no neurologic damage has occurred. Epidural and intrathecal injections have been reported with this block, a finding emphasizing the importance of inserting the needle in a caudad direction. Several vascular structures are in close proximity to a correctly placed needle. Local anesthetic toxicity as a result of intravascular injection should be guarded against by careful aspiration and incremental injection. Seizure activity secondary to this complication is particularly undesirable following rotator cuff surgery, because the repair can be compromised by the associated muscular activity.

Technique

The patient should be in the supine position with the head turned away from the side to be blocked. The posterior border of the sternocleidomastoid muscle is readily palpated by having the patient briefly lift the head. The interscalene groove may be palpated by rolling the fingers posterolaterally from this border over the belly of the anterior scalene muscle into the groove. A line is extended laterally from the cricoid cartilage to intersect the interscalene groove indicating the level of the transverse process of C6. Although the external jugular vein often overlies this point of intersection, it is not a constant or reliable landmark.

Figure 43-3 Interscalene block. The fingers palpate the interscalene groove, and the needle is inserted with a caudad and slightly posterior angle.

After ordinary sterile precautions and injection of a skin wheal, a 22-gauge, 4-cm short-bevel needle is inserted perpendicular to the skin with a 45-degree caudad and slightly posterior angle (Fig. 43-3) . The needle is then advanced until a paresthesia (usually C5 and C6 dermatomes) is elicited. This will usually occur at a very superficial level. If a blunt needle bevel is used, a "click" may be detected as the needle passes through the prevertebral fascia. If bone is encountered within 2 cm of the skin, it is likely to be a transverse process, and the needle may be "walked" across this structure in order to locate the nerve. The use of a nerve stimulator may be helpful in confirming the correct needle position.

Once a paresthesia is obtained, the needle is stabilized. The use of flexible extension tubing facilitates the maintenance of the needle position while aspiration and injection occur. After negative aspiration, 10 to 40 mL of solution is injected incrementally, depending on the desired extent of blockade. Radiographic studies suggest a volume-to-anesthesia relationship with 40 mL of solution associated with complete cervical and brachial plexus block. [7] Clinical studies, however, indicate variable blockade of the lower trunk (i.e., ulnar nerve) even with large volumes of solution. [8] Digital pressure above the injection site and downward massage along with a 45-degree head-up position may facilitate caudad spread and blockade of the lower trunk.

Supraclavicular Block

Clinical Applications

The supraclavicular approach to the brachial plexus is anesthetically efficient; a small volume of solution can be delivered at a point in which the three trunks are compactly arranged, resulting in rapid onset of reliable blockade of the brachial plexus. The block can also be performed with the patient's arm in any position, to provide excellent anesthesia for elbow, forearm, and hand surgery.

Reliable supraclavicular blockade requires elicitation of a paresthesia. The classic block may be somewhat difficult to describe and to teach. Observation of an experienced anesthesiologist is perhaps the best way to learn the technique. A proposed modification of the technique, the so-called "plumb-bob" approach, may decrease complications and may simplify the concept of this block. [12]

Side Effects/Complications

The prevalence of pneumothorax following supraclavicular block ranges from 0.5 to 6 percent and diminishes with experience. The onset of symptoms is usually delayed and may take up to 24 hours. Routine chest radiography after the block is, therefore, not justified. The supraclavicular approach is best avoided when the patient is uncooperative or cannot tolerate any degree of respiratory compromise because of underlying disease. Other complications include frequent phrenic nerve block (40-60%), Horner syndrome, and neuropathy. The presence of phrenic or cervical sympathetic nerve block usually requires only reassurance. Although nerve damage can occur, it is uncommon and usually is self-limited.

Technique

Several anatomic points are important in the performance of the supraclavicular approach. The three trunks are clustered vertically over the first rib cephaloposterior to the subclavian artery, which can often be palpated in a slender, relaxed patient. The neurovascular bundle lies inferior to the clavicle at about its midpoint. The first rib acts as a medial barrier to the needle's reaching the pleural dome and is short, broad, and flat with an anteroposterior orientation at the site of the plexus.

The patient is placed in a supine position, with the head turned away from the side to be blocked. The arm to be

Figure 43-4 (A) Supraclavicular block. The needle is systematically walked anteriorly and posteriorly along the rib until the plexus is located. (B) The three trunks are compactly arranged at the level of the first rib.

anesthetized should be adducted and the hand should be extended along the side toward the ipsilateral knee as far as possible. In the classic technique, the midpoint of the clavicle should be identified and marked. The posterior border of the sternocleidomastoid can be easily palpated when the patient raises the head slightly. The palpating fingers can then roll over the belly of the anterior scalene muscle into the interscalene groove, where a mark should be made approximately 1.5 to 2.0 cm posterior to the midpoint of the clavicle. Palpation of the subclavian artery at this site confirms the landmark.

After appropriate preparation and injection of a skin wheal, the anesthesiologist stands at the side of the patient facing the patient's head. A 22-gauge, 4-cm short-bevel needle is directed in a caudad, slightly medial and posterior direction until either a paresthesia is elicited or the first rib is encountered. If a syringe is attached, this orientation causes the needle shaft and syringe to lie almost parallel to a line joining the skin entry and the patient's ear. If the first rib is encountered without elicitation of a paresthesia, the needle can be systematically walked anteriorly and posteriorly along the rib until the plexus or the subclavian artery is located (Fig. 43-4 and Plate 3 [color plate Atlas of Regional Anesthesia Procedures follows this chapter]). Location of the artery provides a useful landmark; the needle can be withdrawn and reinserted in a more posterolateral direction that will usually result in a paresthesia. When a paresthesia has been obtained, aspiration for blood should be performed prior to incremental injections of a total volume of 20 to 30 mL of solution. A nerve stimulator can also be used to identify the brachial plexus.

Usually, the rib is contacted at a needle depth of 3 to 4 cm; however, in an obese patient or in the presence of tissue distortion resulting from hematoma or injection of solution, the depth may exceed the needle length. Nonetheless, gentle probing in the anterior and posterior directions should be done at the 2- to 3-cm depth if paresthesias are not obtained before the needle is advanced farther. Multiple injections may improve the quality or may shorten the onset of blockade.

The modified, plumb-bob approach uses similar patient positioning, although the needle entry site is at the point at which the lateral border of the sternocleidomastoid

muscle inserts into the clavicle. After preparation and injection of a skin wheal, a 22-gauge, 4-cm short-bevel needle is inserted while mimicking a plumb bob suspended over the needle entry site. Often, a paresthesia is elicited prior to contacting the first rib or artery. If no paresthesia is elicited, the needle is reinserted while angling the tip of the needle cephalad. If still no paresthesias are obtained, the needle tip is angled caudad in small steps until the first rib is contacted (Fig. 43-5) .

Axillary Block

Clinical Applications

The axillary approach to the brachial plexus is the most popular because of ease of block, reliability of hand and forearm anesthesia, and safety. [13] Furthermore, central neural blockade and pneumothorax are not complications, as in other approaches to the brachial plexus. This block is ideally suited for outpatients and is easily adapted to the pediatric population. [14] [15] Paresthesias are not necessary, although

Figure 43-5 Supraclavicular block. Plumb-bob approach.

multiple injections may shorten the onset and may improve the reliability of blockade.

Axillary block is unsuitable for surgical procedures on the upper arm or shoulder. Anesthesia of the musculocutaneous nerve is not always produced with this approach, but it can be supplemented at the level of the axilla or at the elbow. The patient must be able to abduct the arm to perform the block.

Side Effects/Complications

If large volumes are injected through an "immobile" needle, particularly if a transarterial approach is used, there is an increased risk of intravascular injection resulting in systemic local anesthetic toxicity. The assertion that neuropathies are more common if paresthesias are sought may be valid, but it is not supported by the available data. [16] Hematoma and infection are rare complications.

Technique

Anatomic concepts that should be considered prior to performing an axillary block include the following:

1. The neurovascular bundle is multicompartmental [17] (Fig. 43-6) .
2. The axillary artery is the most important landmark; the nerves maintain a predictable orientation to the artery.
3. The median nerve is found superior to the artery, the ulnar nerve is inferior, and the radial nerve is posterior and somewhat lateral (Fig. 43-7 .and Plate 5)
4. At this level, the musculocutaneous nerve has already left the sheath and lies in the substance of the coracobrachialis muscle.
5. The intercostobrachial nerve, a branch of the T2 intercostal nerve, is usually blocked by the skin wheal overlying the artery; however, adequate anesthesia for the tourniquet can be ensured by extending the wheal 1 to 2 cm caudad and cephalad.

The patient should be in the supine position with the arm to be blocked placed at a right angle to the body, with the elbow flexed to 90 degrees. The dorsum of the hand rests on the bed or pillow; hyperabduction of the arm with placement of the hand beneath the patient's head is not recommended because this position frequently obliterates the pulse.

The axillary artery is palpated, and a line is drawn tracing its course from the lower axilla as far proximally as possible. The artery is then fixed against the patient's humerus by the index and middle fingers of the left hand, and a skin wheal is raised directly over the artery at a point in the axilla approximating the skin crease. Proximal needle placement and maintenance of distal pressure facilitate proximal spread of the solution.

Figure 43-6 Axillary block. Computed tomogram after axillary block with bupivacaine 0.5 percent and iodothalamate. Separate injections of 10-mL solution were made after obtaining median and radial nerve paresthesias and transarterially. Contrast medium appears to remain in three separate compartments.

Figure 43-7 Axillary block. The arm is abducted at right angles to the body. Distal digital pressure is maintained during needle placement and injection of local anesthetic.

At this stage, several methods have been described, with reportedly good results:

1. Paresthesias can be sought with a 25-gauge, 2-cm needle, beginning either deep (radial nerve) or with the nerves supplying the surgical site. Needles longer than 2 cm are rarely needed to reach the neurovascular bundle; smaller needles may be associated with a lower risk of nerve damage. [14] Ten milliliters of local anesthetic is injected at each paresthesia.
2. A nerve stimulator can also be employed with an insulated needle to locate the nerves. This technique obviates the need for paresthesias, and, although unproven, it may lower the risk of nerve damage. [18]
3. A short-bevel needle can be advanced until the "axillary sheath" is entered, as evidenced by a "fascial click," whereupon 40 to 50 mL of solution is injected after negative aspiration. [13] [19]
4. A transarterial technique can be employed, whereby the needle pierces the artery and 40 to 50 mL solution is injected posterior to the artery; or, alternatively, half the solution is injected posterior and half anterior to the artery. Great care must be taken to avoid intravascular injection with this technique, particularly because the pressure of injection within the compartments of the axillary sheath may move anatomic structures in relation to the immobile needle. Some practitioners avoid intentional arterial puncture in the belief that it is unnecessarily traumatic.
5. Field block of the brachial plexus with a fanwise injection of 10 to 15 mL of local anesthetic solution on each side of the artery is a variation of the sheath technique. Paresthesias, although not sought, are often encountered in this technique and provide evidence of correct placement.

The elicitation of paresthesias is controversial because of a reportedly higher risk of nerve damage, although actual data are limited. [16] [20] However, even when intentional paresthesias are not sought, they are often impossible to avoid with any of the proposed techniques. Furthermore, success rates with single-injection techniques can be variable. [21] [22] Thompson and Rorie [17] concluded that the presence of multiple compartments limits diffusion of the solution (i.e., necessary for single-shot technique). More recently, Partridge et al [23] confirmed the presence of these compartments, but these investigators concluded that the "septa" dividing them were incomplete on the basis of injections of methylene blue and latex solutions into cadavers. The controversy surrounding single- versus multiple-injection techniques remains unresolved. Familiarity with a variety of techniques for axillary block of the brachial plexus allows the anesthesiologist maximal flexibility in tailoring the anesthetic approach to the clinical situation.

When the injection is completed, the arm should be adducted and returned to the patient's side. This prevents the humeral head from obstructing proximal flow of the

solution; distal pressure and massage may also help. Vester-Andersen

et al [24] were unable to block the musculocutaneous nerve reliably with volumes up to 80 mL. Thus, if the musculocutaneous nerve is not blocked by the axillary approach, it can be blocked by injection within the body of the coraco-brachialis muscle or at the elbow superficially at the lateral aspect of the antecubital fossa just above the interepicondylar line.

Infraclavicular Block

Clinical Applications

This block offers the theoretic advantages of avoiding pneumothorax while injecting at a level affording block of the musculocutaneous and axillary nerves. No special arm positioning is required. A nerve stimulator is required because there are no palpable vascular landmarks to aid in directing the needle.

Side Effects/Complications

Because of the necessarily blind approach to the plexus, the risk of intravascular injection may be increased. Exaggerated medial needle direction may result in pneumothorax. Other rare complications such as infection and hematoma are theoretically possible.

Technique

The needle is inserted 2 cm below the midpoint of the inferior clavicular border and is advanced laterally, using a nerve stimulator to identify the plexus. [25] Marking a line between the C6 tubercle and the axillary artery with the arm abducted is helpful in visualizing the course of the plexus. An incremental injection of 20 to 30 mL of solution is sufficient once the needle is correctly placed. Modifications of this technique suggesting more lateral insertion sites may result in the absence of blockade of the musculocutaneous nerve, thus removing the major advantage of this approach over the simpler axillary block.

Brachial Plexus Catheters

Methods of providing continuous brachial plexus anesthesia have been described since at least the 1940s, [26] and they frequently offer ingenious solutions for the placement and securing of the needle or catheter. The advantages cited for these techniques are prolongation of surgical anesthesia, decreased risk of toxicity because of lower incremental doses, and postoperative pain relief and sympathectomy.

Risks of infection, difficulty in securing the catheter, and inadequate surgical anesthesia are the major disadvantages. Catheter migration, catheter kinking or coiling, and nerve damage are theoretic complications.

Techniques using both over- and through-needle methods have been described. Longer catheters may be easier to secure and provide superior blockade if the tip lies more proximal in the plexus. [27] Commercial kits offering catheter, needle, and stimulating electrodes are now available.

This technique is especially applicable to patients with upper extremity or digit replantation, total elbow arthroplasty, or reflex sympathetic dystrophies, for which prolonged pain relief and sympathectomy are advantageous.

Peripheral Blocks at the Elbow and Wrist

Clinical Applications

As techniques for brachial plexus blockade have gained popularity, indications for peripheral nerve blockade at the wrist and elbow have diminished. However, these techniques can be useful when limited anesthesia is required, when contraindications to brachial plexus block (e.g., infection, bilateral surgery, coagulation abnormalities, bleeding diasthesis, difficult anatomy) exist, or when brachial plexus blockade is incomplete.

Peripheral nerve blocks do not provide anesthesia for the use of a tourniquet. Most patients tolerate an inflated tourniquet for only a brief period.

A midhumeral approach to the brachial plexus has been described. This novel approach involves blocking each nerve separately in the humeral canal. Blockade of the four major nerves of the upper extremity at the midhumeral level using a peripheral nerve stimulator has been reported to have a higher success rate than traditional (defined as stimulation of two nerves) axillary brachial plexus block. [28] In this study, time to complete the block did not differ between the two techniques; however, onset of complete sensory block was shorter in the axillary approach, whereas the success rate of blockade of all four major nerves was higher in the midhumeral group. This technique may have applications when anatomic difficulties preclude a traditional approach or when the surgical procedure requires a dense block of all four major nerves. The safety and clinical practicality of the midhumeral approach remain to be proven.

Side Effects/Complications

In general, distal peripheral blocks are associated with a lower risk of complications. However, intravascular injection can occur, and the usual precautions of incremental injection after aspiration are recommended. The risk of nerve injury is theorized to be higher when more distal peripheral blocks are performed. This may be due to superficial nerve placement between bony and ligamentous structures, thereby offering ready access to the probing needle point.

Elbow Versus Wrist

The forearm cutaneous nerves arise in the upper arm and are not anesthetized by block of the peripheral nerves at the elbow. Hence, there is no advantage of block of the peripheral nerves of the upper extremity when comparing elbow with wrist techniques; both provide sensory anesthesia of the hand.

Figure 43-8 Anatomic landmarks for median and radial nerve block at the elbow.

Median Nerve

Block of the median nerve provides anesthesia of the palmar aspects of the thumb and index finger, middle finger and radial half of the ring finger, and the nail beds of the same digits. Motor block includes the muscles of the thenar eminence, lumbric muscles of the first and second digits, and, in the case of the block at the elbow, median-innervated wrist flexor muscles of the forearm.

Technique at the Elbow

With the patient's arm placed in the anatomic position (palm up), a line is drawn connecting the medial and lateral epicondyles of the humerus. The major landmark for this technique is the brachial artery, which is found medial to the biceps tendon at the intercondylar line. The median nerve lies medial to the artery (Fig. 43-8) and

can be blocked with 3 to 5 mL of solution after eliciting a paresthesia. If no paresthesia is obtained, the solution can be injected fanwise medial to the palpated artery.

Technique at the Wrist

The median nerve is located between the flexor carpi radialis and palmaris longus tendons and can be blocked at a point 2 to 3 cm proximal to the wrist crease (Fig. 43-9) . (The palmaris longus tendon is congenitally or postsurgically absent from some patients.) A loss of resistance is felt as the

Figure 43-9 Anatomic landmarks for median and ulnar nerve block at the wrist. An alternative method for ulnar nerve block, from the ulnar side of the wrist, is shown.

needle passes through the flexor retinaculum, at which point 2 to 4 mL of solution should be injected. A superficial palmar branch supplying the skin of the thenar eminence can be blocked by injecting 0.5 to 1 mL of solution subcutaneously above the retinaculum. Paresthesias should not be sought because of the confinement of this nerve within the carpal tunnel.

Radial Nerve

Block of the radial nerve provides anesthesia to the lateral aspect of the dorsum of the hand (thumb side) and the proximal portion of the thumb, index, middle, and lateral half of the ring fingers.

Technique at the Elbow

The radial nerve can be blocked at the elbow as it passes over the anterior aspect of the lateral epicondyle. The intercondylar line and lateral edge of the biceps tendon are marked. A 22-gauge, 3- to 4-cm needle is inserted at a point 2 cm lateral to the biceps tendon and is advanced until bone is encountered (see Fig. 43-8) . A fanwise injection is made using 3 to 5 mL of solution.

Technique at the Wrist

The radial nerve block at the wrist is a field block of the multiple peripheral branches descending along the dorsum and radial side of the wrist. The extensor pollicis longus tendon can be identified when the patient extends the thumb. The needle insertion is over this tendon at the base of the first metacarpal; the injection is superficial to the tendon. Two milliliters of local anesthetic is injected proximally along the tendon, and an additional 1 mL is injected as the needle passes at a right angle across the "anatomic snuffbox" (Fig. 43-10) .

Ulnar Nerve

Blockade of the ulnar nerve provides anesthesia of the ulnar side of the hand, the little finger, and the ring finger and all the small muscles of the hand, except those of the thenar eminence and the first and second lumbric muscles.

Technique at the Elbow

Although the ulnar nerve is easily accessible at its subcutaneous position posterior to the medial epicondyle, blockade at this site is associated with a high incidence of neuritis. The nerve is surrounded by fibrous tissue at this point, requiring an intraneural injection for successful blockade. Use of a very fine needle along with a small volume of solution (1 mL) diminishes the risk; however, the nerve can be satisfactorily blocked with 5 to 10 mL of solution at a site 3 to 5 cm proximal to the elbow. The local anesthetic should be injected in a fanwise fashion without elicitation of a paresthesia.

Figure 43-10 Anatomic landmarks and method of needle insertion for radial nerve block at the wrist.

Technique at the Wrist

At the wrist, the ulnar nerve lies beneath the flexor carpi ulnaris tendon between the ulnar artery and the pisiform bone. At this point, it has already given off its palmar cutaneous and dorsal branches. The nerve can be approached by directing the needle medially from the radial side of the tendon or, alternatively, by directing the needle radially from the ulnar side of the tendon (see Fig. 43-9) . After eliciting a paresthesia, 3 to 5 mL of solution is injected or spread in a fanwise fashion.

Musculocutaneous Nerve

The musculocutaneous nerve terminates as the lateral cutaneous nerve of the forearm. This nerve provides sensory innervation to the skin on the radial side of the forearm up to the radiocarpal joint. This block is usually performed to supplement the axillary approach to brachial plexus anesthesia.

Technique at the Elbow

The lateral cutaneous nerve of the forearm can be blocked 1 cm proximal to the intercondylar line immediately lateral to the biceps tendon. Fanwise infiltration of 3 to 5 mL of solution subcutaneously at this site provides excellent anesthesia of this nerve.

Intravenous Regional Blocks

Intravenous regional blocks were first described by a German surgeon, August Bier, in 1908. [29] Early methods involved two tourniquets and the first synthetic local anesthetic, procaine. The technique lost popularity as reliable methods of blocking the brachial plexus evolved.

Clinical Applications

The Bier block has multiple advantages, including ease of administration, rapidity of recovery, rapid onset, muscular relaxation, and controllable extent of anesthesia. It is an excellent technique for short (<90 min) open surgical procedures and for closed reductions of bony fractures.

Side Effects/Complications

Technical problems with this block include tourniquet discomfort, rapidity of recovery leading to postoperative pain, difficulty in providing a bloodless field, and the necessity of exsanguination in the case of a painful injury. Accidental or early deflation of the tourniquet or use of excessive doses of local anesthetics can result in toxic reactions. Injection of the drug as distally as possible at a slow rate has been shown to decrease blood levels and theoretically to increase safety. [30] The use of bupivacaine for intravenous regional anesthesia has been associated with local anesthetic toxicity and death [31] and is not recommended. Cyclic deflation of the tourniquet at 10-second intervals has been shown to increase the time to peak arterial lidocaine levels that may decrease potential toxicity. [32] Other rare

complications associated with this technique include development of compartment syndrome and loss of limb.

Technique

An intravenous cannula is placed in the upper extremity to be blocked as distally as possible (the patient should also have an intravenous cannula in the nonoperative upper extremity for administration of fluids and other drugs). Traditionally, a double tourniquet is placed on the operative side; both cuffs should have secure closures and reliable pressure gauges. After exsanguination of the arm, the proximal cuff is inflated to approximately 150 mm Hg more than the systolic pressure (absence of a radial pulse confirms adequate tourniquet pressure). Total dose of local anesthetic is based on the patient's weight and is injected slowly (4-6 mg/kg of 0.5% prilocaine or lidocaine, without epinephrine). The onset of anesthesia is usually within 5 minutes. When the patient complains of tourniquet pain, the distal tourniquet, which overlies anesthetized skin, is inflated, and the proximal tourniquet is released. There are data suggesting that the use of a single wide cuff allows use of lower inflation pressures during intravenous regional anesthesia. The postulated advantage is that the lower pressures will decrease the incidence of neurologic complications related to high inflation pressures with the narrow double cuffs. [33] The tourniquet may be safely released after 25 minutes, but the patient should be closely observed for local anesthetic toxicity for several minutes after the tourniquet release. Slow injection of local anesthetic solutions at a distal site has been shown to lower the risk of toxicity. [30]

LOWER EXTREMITY BLOCKS

Blocks of the lower extremity are less popular than those routinely employed for surgical procedures of the upper extremity. In part, this is due to the widespread acceptance and safety of spinal and epidural anesthesia. Furthermore, unlike the brachial plexus, the nerves supplying the lower extremity are not anatomically clustered where they can be easily blocked with a relatively superficial injection of local anesthetic. Because of the anatomic considerations, these blocks are technically more difficult and require more training and practice before expertise is acquired. Finally, persistent block of any of the major nerves of the lower extremity leaves the patient unable to ambulate, an unacceptable side effect in the outpatient population. Nonetheless, knowledge of the anatomy of the lumbosacral plexus and peripheral nerves of the lower extremity enables anesthesiologists to provide more comprehensive anesthetic care. These blocks are safe and have certain advantages, such as postoperative pain relief and lack of complete sympathectomy, which make them ideal for selected patients.

Anatomy

The nerve supply to the lower extremity is derived from the lumbar and sacral plexuses. The lumbar plexus is formed by the anterior rami of the first four lumbar nerves, frequently including a branch from T12 and occasionally from L5 (Fig. 43-11 and Plate 11). The plexus lies between the psoas major and quadratus lumborum muscles, in the so-called psoas compartment.

The lower components of the plexus, L2, L3, and L4, primarily innervate the anterior and medial thigh. The anterior divisions of L2, L3, and L4 form the obturator nerve; the posterior divisions of the same components form the femoral nerve; and the lateral femoral cutaneous nerve is formed from posterior divisions of L2 and L3.

The posterior cutaneous nerve of the thigh and the sciatic nerve are derived from the first, second, and third sacral nerves plus branches from the anterior rami of L4 and L5, respectively. These nerves pass together through the pelvis and the greater sciatic foramen and are blocked by the same technique. The sciatic nerve is actually a combination of two major nerve trunks, the tibial (ventral branches of the anterior rami of L4, L5, S1, S2, and S3) and the common peroneal (dorsal branches of the anterior rami of L4, L5, S1, S2, and S3), which form the sciatic nerve. At or above the popliteal fossa they separate, the tibial nerve passing medially and the common peroneal laterally. The cutaneous distributions of the lumbosacral and peripheral nerves are shown in Figure 43-12 .

Psoas Compartment Block

The psoas compartment block utilizes a technique in which a needle is placed into the space between the psoas major and quadratus lumborum muscles. A large volume of injected solution anesthetizes the hip and anterolateral thigh. [34]

Clinical Applications

This technique offers a single injection rather than three separate needle insertions for anesthesia of the lumbar plexus. The technique must be combined with a sciatic block for anesthesia of the entire lower extremity.

Side Effects/Complications

The deep needle placement increases the risk of possible epidural, subarachnoid, or intravascular injection. Peripheral

Figure 43-11 The lumbar plexus lies in the psoas compartment between the psoas major and quadratus lumborum muscles.

nerve damage is also a potential risk with this technique. A side effect of the paravertebral approach to the lumbar plexus is the development of a sympathetic block secondary to extravasation of local anesthetic. This unilateral sympathectomy is usually of little consequence. However, because one of the reasons for choosing a lower extremity block over spinal or epidural blockade is prevention of sympathectomy, the advantage of a psoas compartment block is diminished should this effect occur.

Technique: Posterior Approach

The patient is placed in the lateral position, hips flexed and operative leg uppermost. A line is drawn to connect the iliac crests (intercristal line) identifying the fourth lumbar spine. After skin preparation, a skin wheal is raised 3 cm caudad and 5 cm lateral to the midline on the side to be blocked. A 22-gauge, 15-cm needle is then advanced perpendicular to the skin entry site until it contacts the fifth lumbar transverse process. The needle is redirected cephalad until it slides off the transverse process. At this point, a 20-mL syringe filled with air is attached, and the needle is slowly advanced until a loss of resistance is detected. The depth of the psoas compartment is about 12 cm. When the needle is in place, the compartment can be dilated with 20 mL of air prior to injecting 30 mL of solution. A nerve stimulator can be useful for locating and verifying correct needle position.

Technique: Perivascular Approach ("3-in-1 Block")

The perivascular approach to the psoas compartment is based on the premise that injection of a large volume of local anesthetic within the femoral canal while maintaining distal pressure will result in proximal spread of the solution into the psoas compartment and consequent lumbar plexus block. [35] The key anatomic assumption is that the fascial sheath surrounding the lumbar roots extends into the femoral canal and acts as an enclosed conduit for the spread of local anesthetic solutions. The patient lies in the supine position. The inguinal ligament is marked as a line connecting the pubic tubercle and the anterior superior iliac spine. The femoral artery is marked. A short-beveled 22-gauge, 5- cm needle is advanced lateral to the artery in a cephalad direction until a paresthesia is obtained. The needle is held immobile while distal pressure is applied digitally to the femoral sheath. A total of 20 to 40 mL of solution is injected incrementally after negative aspiration. Reliable anesthesia of the femoral and lateral femoral cutaneous nerves can be predicted with 20 mL; however, obturator nerve block may require volumes greater than 30 mL.

Femoral Nerve Block

The femoral nerve is formed within the psoas major muscle by posterior divisions of the second, third, and fourth

Figure 43-12 (A) Cutaneous distribution of the lumbosacral nerves. (B) Cutaneous distribution of the peripheral nerves of the lower extremity.

lumbar nerves. It emerges from the lateral border of the psoas muscle to descend in the groove between the psoas and iliacus muscles and enters the thigh by passing beneath the inguinal ligament lateral to the femoral artery. At this point, the nerve divides into multiple terminal branches, which have been classified as anterior and posterior. The anterior branches are primarily cutaneous, the deep branches chiefly motor.

The femoral nerve supplies the anterior compartment muscles of the thigh (quadriceps, sartorius) and the skin of the anterior thigh from the inguinal ligament to the knee. Its terminal branch is the saphenous nerve, which supplies an area of skin along the medial side of the leg from the knee to the big toe.

Clinical Applications

The femoral block is primarily used in concert with other peripheral blocks. However, it can be used alone for muscle biopsies of the quadriceps muscle or other surgical procedures limited to the anterior thigh, and it has been reported effective for anesthetic management of knee arthroscopy and surgical repair of midfemoral shaft fractures. [36] [37]

Side Effects/Complications

Intravascular injection and hematoma are possible because of the close proximity of the femoral artery. However, anatomically, the nerve and artery are located in separate sheaths approximately 1 cm apart. In most patients with normal anatomy, the femoral artery can be easily palpated, allowing correct, safe needle positioning lateral to the pulsation. The presence of femoral vascular grafts is a relative contraindication to this block. Nerve damage is rare with this technique.

Technique

The patient is placed in the supine position. A line is drawn between the anterior superior iliac spine and the pubic tubercle, identifying the inguinal ligament. The femoral artery is marked. A 22-gauge, 4-cm short-bevel needle is advanced lateral to this line (Fig. 43-13A and Plate 13A). When the needle reaches the depth of the artery, a pulsation of the hub is visible. Elicitation of a paresthesia or use of a nerve stimulator is also helpful in verifying correct needle position. Local anesthetic, 20 mL, is injected fanwise lateral to the artery. If a paresthesia is obtained, 7 to 10 mL of solution should be injected at that site.

Figure 43-13 (A) Anatomic landmarks for lateral femoral cutaneous, femoral, and obturator nerve blocks. (B) Obturator nerve block. The needle is walked off the inferior pubic ramus in a medial and cephalad direction until it passes into the obturator canal.

Lateral Femoral Cutaneous Nerve Block

The lateral femoral cutaneous nerve (L2 and L3) emerges at the lateral border of the psoas muscle immediately caudad to the ilioinguinal nerve. It descends under the iliac fascia to enter the thigh deep to the inguinal ligament 1 to 2 cm medial to the anterior superior iliac spine. The nerve emerges from the fascia lata 7 to 10 cm below the spine and divides into anterior and posterior branches. The skin of the lateral portion of the thigh from the hip to midthigh is supplied by the posterior branch; the anterior branch supplies the anterolateral thigh to the knee.

Clinical Applications

This block is useful for skin graft harvesting and can be used in concert with other peripheral nerve blocks for complete anesthesia of the lower extremity.

Side Effects/Complications

The extent of anesthesia is quite limited with this block, but there is a low risk of associated complications. Neuritis of this nerve secondary to needle trauma or drug toxicity is a potential but unlikely complication. There are no large blood vessels in the vicinity of this nerve; therefore, the likelihood of rapid uptake or intravascular injection is very small.

Technique

A point is marked 2 cm medial and 2 cm caudad to the anterior superior iliac spine. A short-bevel 22-gauge, 4-cm needle is advanced perpendicular to the skin entry site until a sudden release indicates passage through the fascia lata. As the needle is moved fanwise laterally and medially, 10 to 15 mL of solution is injected, depositing local anesthetic above and below the fascia (see Fig. 43-13 .A and Plate 13A)

The nerve can also be blocked just medial and posterior to the anterior superior iliac crest with 10 mL of solution. Combining the two techniques (belt-and-suspenders method) increases the success rate, but the total volume of solution used may be limiting. Because this is a pure sensory nerve, a nerve stimulator is not helpful in performing this block.

Obturator Nerve Block

The obturator nerve is derived primarily from the third and fourth lumbar nerves with an occasional minor contribution from L2. The nerve lies deep in the obturator canal, having descended from the medial border of the psoas muscle. As the nerve leaves the obturator canal, it divides into anterior and posterior branches. The anterior branch supplies an articular branch to the hip and the anterior adductor muscles and a variable cutaneous branch to the lower medial thigh. The posterior branch innervates the deep adductor muscles and may send an articular branch to the knee.

Clinical Applications

Usually, the obturator nerve is blocked as part of regional anesthesia for knee surgery. Because it is primarily a motor nerve, it is rarely blocked on its own; however, obturator nerve block can be useful in treating or diagnosing the extent of adductor spasm in patients with cerebral palsy and other muscle or neurologic diseases affecting the lower extremities prior to surgical intervention (adductor tenotomy).

Side Effects/Complications

Complications are rare; however, this block is technically more difficult than other lower extremity blocks. The obturator canal contains vascular and neural structures; thus, there is a theoretic risk of intravascular injection, hematoma, and nerve damage. Absence of anesthesia in the obturator nerve distribution can render an otherwise perfect lower extremity block inadequate for surgical procedures on the knee.

Technique

The patient is placed in the supine position, and a mark is made 1 to 2 cm lateral and 1 to 2 cm caudad to the pubic tubercle. A skin wheal is raised, and a short-bevel 22-gauge, 8- to 10-cm needle is advanced perpendicular to the skin entry site with a slight medial direction. The inferior pubic ramus is encountered at a depth of 2 to 4 cm, and the needle is walked in a lateral and caudad direction, until it passes into the obturator canal. The obturator nerve is located 2 to 3 cm past the initial point of contact with the pubic ramus (see Fig. 43-13 and Plate 13B). After negative aspiration, 10 to 15 mL of local anesthetic is injected. A nerve stimulator is helpful in locating the obturator nerve; correct needle position is evidenced by contraction of the adductor muscles of the medial thigh.

The classic approach to obturator nerve block involves painful periosteal contact and multiple needle redirectioning. An alternate interadductor approach was described by Wasseff. [38] In this technique, the needle is inserted behind the adductor tendon, near its pubic insertion, and is directed laterally toward a mark on the skin 1 to 2 cm medial to the femoral artery and immediately below the inguinal ligament representing the obturator canal. The nerve is identified by a motor response to peripheral nerve stimulation in the adductor muscle.

Sciatic Nerve Block

The sciatic nerve (L4 and L5, S1 through S3) is the largest of the four peripheral nerves of the lower extremity, with a width of 2 cm as it leaves the pelvis with the posterior cutaneous nerve of the thigh. After passing through the sacrosciatic foramen beneath the piriformis muscle, it lies between the greater trochanter of the femur and the ischial tuberosity. The nerve becomes superficial at the lower border of the gluteus maximus muscle, where it begins its descent down the posterior aspect of the thigh to the popliteal fossa. It supplies cutaneous innervation to the posterior thigh and all of the leg and foot below the knee, except a thin medial strip supplied by the saphenous nerve.

Clinical Applications

Because of its wide sensory distribution, the sciatic nerve block can be used, together with a saphenous or femoral nerve block, for any surgical procedure below the knee that does not require a thigh tourniquet. It can also be combined with other peripheral nerve blocks to provide anesthesia for surgical procedures involving the thigh and knee. This form of anesthesia avoids the sympathectomy associated with centroneuraxis blocks, and therefore, its use may be advantageous when any shift in hemodynamics could be deleterious, such as in patients with significant aortic stenosis.

Side Effects/Complications

The block is technically difficult to perform and can be quite painful. Hematoma formation is possible; the risk of nerve damage is also reported, although persistent paresthesias are usually self-limited. A minimal degree of vasodilation may occur with sciatic nerve block.

Technique: Classic Approach of Labat (Posterior)

The patient is positioned laterally, with the leg to be blocked rolled forward onto the flexed knee as the heel rests on the knee of the dependent (nonoperative) leg [39] (Fig. 43-14 and Plate 12A). A line is drawn to connect the posterior superior iliac spine to the greater trochanter of the femur. A perpendicular line is drawn bisecting this line and extending 5 cm caudad. A second line is drawn from the greater trochanter to the sacral hiatus. The intersection of

Figure 43-14 Posterior approach to the sciatic nerve: patient positioning.

Figure 43-15 Anatomic landmarks for the posterior approach to sciatic nerve block.

this line with the perpendicular line indicates the point of needle entry and falls 3 to 5 cm along the line. A 22-gauge, 10- to 12-cm needle is advanced until a paresthesia is elicited or bone is contacted (Fig. 43-15 and Plate 12B). If bone is encountered, the needle is redirected systematically in a lateral or medial direction. A nerve stimulator can be useful in locating the nerve. Once the needle is properly placed, a total of 20 to 30 mL of solution should be injected.

Technique: Anterior Approach

This technique is useful when the patient cannot be positioned for the classic posterior approach because of pain or lack of cooperation. [40] Initial blockade of the femoral nerve decreases the pain associated with this approach.

With the patient in the supine position, a line drawn along the inguinal ligament from the anterior superior iliac crest to the pubic tubercle is trisected. A second line parallel to the inguinal ligament is drawn, beginning at the tuberosity of the greater trochanter. A 22-gauge, 10.5- to 12-cm needle is inserted perpendicularly with a slightly lateral angulation at the point where the line representing the juncture of the middle and medial thirds crosses the second line. This needle is advanced until it contacts bone, the lesser trochanter of the femur (Fig. 43-16) . The needle is redirected medially past the femur, and a paresthesia is sought at a depth of about 5 cm past bone. A total of 20 to 25 mL of solution is injected incrementally after careful aspiration.

Technique: Other Approaches

The sciatic nerve can also be blocked with the patient in the lateral [41] and lithotomy positions, [42] although these are rarely employed clinically.

Nerve Blocks at the Ankle

Four of the five individual nerves that can be blocked at the ankle to provide anesthesia of the foot are terminal branches of the sciatic nerve: the posterior tibial, sural, superficial peroneal, and deep peroneal branches. The sciatic nerve divides at or above the apex of the popliteal fossa to form the common peroneal and tibial nerves. The common

Figure 43-16 Anatomic landmarks for the anterior to sciatic nerve block.

peroneal nerve descends laterally around the head of the fibula, where it divides into the superficial and deep peroneal nerves.

The tibial nerve divides into the posterior tibial and sural nerves in the lower leg. The posterior tibial nerve becomes superficial at the medial border of the Achilles tendon near the artery of the same name, and the sural nerve emerges lateral to the Achilles tendon.

Clinical Applications

Ankle blocks are simple to perform and offer adequate anesthesia for surgical procedures of the foot not requiring a tourniquet above the ankle.

Side Effects/Complications

Multiple needlesticks are required for some techniques, resulting in discomfort for the patient. Persisting paresthesias may occur, but they are self-limited. The presence of edema or induration in the area of the ankle block can make palpation of landmarks difficult. Intravascular injection is possible but unlikely if aspiration for blood is negative. The volume of local anesthetic used is small, thereby decreasing the risk of local anesthetic toxicity.

Technique: Posterior Tibial Nerve

The posterior tibial nerve can be blocked with the patient in either the prone or the supine position. The posterior tibial artery is palpated, and a 22-gauge, 3-cm needle is inserted posterolateral to the artery at the level of the medial malleolus (Fig. 43-17A and B and Plate 15A and B). A paresthesia is often elicited; however, it is not necessary for a successful block. If a paresthesia is obtained, 3 to 5 mL of local anesthetic should be injected. Otherwise, 7 to 10 mL of solution should be injected as the needle is slowly withdrawn back from the posterior aspect of the tibia. Blockade of the posterior tibial nerve provides anesthesia of the heel, plantar portion of the toes, and the sole of the foot as well as some motor branches in the same area.

Technique: Sural Nerve

The sural nerve is located superficially between the lateral malleolus and the Achilles tendon. A 25-gauge, 3-cm needle is inserted lateral to the tendon and is directed toward the malleolus as 5 to 10 mL of solution is injected subcutaneously (see Fig. 43-17A and C and Plate 15A and C). This block provides anesthesia of the lateral foot and the lateral aspects of the proximal sole of the foot.
